Preface

This volume of the Computer-Aided Chemical Engineering series puts together a selection of the contributions presented at the 29th European Symposium on Computer-Aided Process Engineering (ESCAPE), held in Eindhoven, The Netherlands, from June 16th to 19th, 2019.

This 29th event of the ESCAPE series is a continuation of the conferences under the auspices of the CAPE Working Party of the European Federation of Chemical Engineering (EFCE), Nederland Procestechnologie (NPT), and Process Systems Engineering NL (PSE-NL).

The conference has been organised since 1992, starting with two meetings in 1992 in Denmark and France, and since then having one event annually. Hosting countries to the conference have been Austria (1993, 2018), Ireland (1994), Slovenia (1995, 2016), Greece (1996, 2011), Norway (1997), Belgium (1998), Hungary (1999, 2014), Italy (2000, 2010), Denmark (1992, 2001, 2015), The Netherlands (2002), Finland (2003, 2013), Portugal (2004), Spain (2005, 2017), Germany (2006), Romania (2007), France (1992, 2008), Poland (2009), and the United Kingdom (2012). Having organised the event in 2002, The Netherlands takes on the torch of research and knowledge exchange with organising ESCAPE-29.

ESCAPE-29 is jointly organized by a team of skilled professionals from Eindhoven University of Technology, Delft University of Technology, University of Twente, and Upfield (The Netherlands), University of Bremen (Germany), The University of Manchester (UK), and The Hong Kong University of Science and Technology (Hong Kong). The main vision was to collaborate in organizing the event and coordinating the scientific program, such that besides traditional themes it offers a platform for additional topics covering a wide range of topics: *from molecule to enterprise*.

The themes of ESCAPE-29 have been selected after a comprehensive discussion with the CAPE Working Party members and the scientific community. The particular topics within these overarching themes have been formulated to allow researchers from CAPE-related sciences to present their results and exchange valuable knowledge and experience. The themes and topics include:

1. **Process-product synthesis, design and integration**: structured products, process integration, single- and multi-objective synthesis and design of processes, modular plants, integration of intensified process units, product-process design: property-prediction- based synthesis and design, synthesis of different supply-chains.
2. **Methods, models and computational tools for PSE**: generation and development of concepts for CAPE/PSE, advances in multi-scale modelling, modelling in different CAPE/PSE applications, numerical methods and tools, numerical analysis, process simulation, large-scale and multi-level optimization, process plant data analysis, agent based modelling.
3. **Process control and operations**: scheduling, operability, flexibility and optimization under uncertainty, supply-chains optimization and logistics,

    cyber-physical structures, interaction and information infrastructure, off-line and on-line control, smart sensors, analysis of dynamic plant data, plant-wide control, remote plant control, operational excellence, real-time optimization, operator training.

4. **CAPE/PSE in sustainable development and food industry**: food & water issues, biorefineries, solar refineries, life cycle analysis, industrial infrastructures, infrastructures for sustainable production, sustainability indicators and footprints, risk assessment, safety, waste reduction and management, waste valorisation, waste-water treatment, conversions of fossil-free energy and materials.

5. **CAPE/PSE in energy transition**: heat and power integration, waste-to-energy applications, renewable resources in total-site integration, novel approaches to address the complex system integration challenges, electrification of chemical industry, integration of energy sources and sinks, reliable dynamic supply and demand.

6. **CAPE/PSE in hi-tech micro/nano-devices and processes**: frontiers at tiny scales: micro-, nano scale products & systems, micro- and nano-scale engineering, semi-conductors, solid state, advanced materials, self-assembly, energy storage.

7. **Education in CAPE/PSE & knowledge transfer**: best practices in academia, continued training in a changing professional practice, effective selling of top quality PSE solutions to industry, knowledge transfer hurdles and lessons, effective exploitation of CAPE/PSE tools.

ESCAPE-29 attracted over 300 contributions from five continents (Europe, Americas, Africa, Asia and Australia), and the International Scientific Committee (ISC) selected 120 oral presentations out of these contributions, the rest of them being presented as posters. The scientific program is rounded up by five plenary lectures given by renowned experts from academia and industry, as well as 20 keynotes given by academic and industrial leaders in their field. Putting together all this would have been impossible without the help of 8 topic coordinators, as well as the 86 members of the ISC. We are deeply thankful for timely and careful reviews by these committees, as well as their invaluable help in suggesting plenary and keynote speakers.

As editors of this special volume, we hope that the contributions in this edition of Computer Aided Process Engineering are excellent illustrations of the current state of the art in their respective field.

Abstract

Throughout the past century, numerous frameworks have been presented to address different types of uncertainty in model-based (dynamic) optimization. One of the most successful and promising frameworks to address uncertainty in dynamic optimization is generalized polynomial chaos (gPC). This framework is applicable to uncertainties modeled as random variables with generic (e.g., correlated and bimodal) probability distributions. An accurate and efficient approximation of the mean and variances of the model responses can then be readily computed from the coefficients of the gPC expansion. Two types of formulations exist to compute the gPC coefficients: intrusive and non-intrusive. In this paper, a tutorial and critical comparison are presented on the implementation of gPC. More specifically, an intrusive Galerkin approach and two non-intrusive approaches (probabilistic collocation and least-squares regression) have been implemented on a continuously stirred tank reactor case study.

Keywords: probabilistic uncertainty, generalized polynomial chaos, dynamic optimization

1. Introduction

Mathematical models are indispensable tools for the analysis, control and optimization of a wide range of complex technical systems. As models are only an approximate representation of reality, uncertainty is inherently present. This uncertainty can be structural, parametric or initial condition uncertainty as well as the impact of external disturbances and process variability which are typically present in the control and optimization of dynamic processes. In order to account for these sources of uncertainty systematically, two approaches can be followed, i.e., *stochastic* and *robust* optimization. In the former approach, the uncertainty is considered to be of a stochastic nature for which the probability distribution information is available. The latter assumes that the uncertainty is known to be fully contained within a given set and usually leads to the formulation where all constraints must be satisfied in the *worst case* scenario (Diehl et al., 2008). In this paper, stochastic uncertainty is considered in the model parameters and/or initial conditions. A key requirement to account for uncertainty in nonlinear optimization is accurate uncer-

tainty propagation while maintaining a computationally tractable formulation.

This paper focuses on generalized polynomial chaos (Wiener, 1938) which exploits information on the distribution to approximate both mean and variance. To this extent a polynomial expansion is derived for which the coefficients need to be determined. A recent historical perspective on the use of polynomial chaos for optimization of dynamic systems has been presented by Kim et al. (2013) and a recent summary of the known theoretical results is provided in Paulson and Mesbah (2017). Two different approaches exist to determine the PCE coefficients: intrusive and non-intrusive formulations. The main contributions of this article, are a tutorial and critical comparison on the implementation of gPC formulations. In addition, an intrusive Galerkin formulation and two non-intrusive formulations (probabilistic collocation and least-squares regression) have been implemented on a continuously stirred tank reactor case study.

2. Dynamic optimization under stochastic uncertainty with gPC

2.1. Dynamic optimization under stochastic uncertainty

Consider the dynamic optimization problem under stochastic uncertainty in the interval $t \in [0, t_f]$:

$$\min_{u(\cdot)} \quad \mathbb{E}\{J(x, u, \theta)\} + \alpha_0 \text{Var}\{J(x, u, \theta)\},$$

$$\text{subject to:} \quad \dot{x} = f(x, u, \theta),$$
$$x(0) = x_0(\theta), \tag{1}$$
$$\mathbb{E}\{g_i(x, u, \theta)\} + \alpha_i \text{Var}\{g_i(x, u, \theta)\} \leq 0, \quad i = 1, \dots, n_c,$$
$$\theta \sim p_\theta,$$

with $x \in \mathbb{R}^{n_x}$ the state vector, $u \in \mathbb{R}^{n_u}$ the control vector, $\theta \in \mathbb{R}^n$ the uncertain parameters, $x_0(\theta)$ is the initial condition, f the model equations, p_θ the parameter probability density function and $J(x, u, \theta)$ and $\{g_i(x, u, \theta)\}_{i=1}^{n_c}$ the optimization objective and constraints, respectively. The parameters $\boldsymbol{\alpha} = (\alpha_0, \alpha_1, \dots, \alpha_{n_c})$ directly control the tradeoff between the mean and variance.

The main difficulty in solving (1), lies in the evaluation of the multidimensional integrals related to the expectation and variance operators $\mathbb{E}\{\cdot\}$ and $\text{Var}\{\cdot\}$ in the above formulation, since $\mathbb{E}\{R_k(\theta)\} = \int_{\theta \in \Theta} R_k(\theta) p_\theta(\theta) d\theta$ and $\text{Var}\{(R_k(\theta)\} = \mathbb{E}\{(R_k(\theta) - \mathbb{E}\{R_k(\theta)\})^2\}\}$ are generally defined in terms of a multidimensional integral for any function $R_k(\theta)$. Unless these integrals can be evaluated analytically as a function of the decision variables, these need to be approximated using a sampling-based method that can either be *deterministic* (e.g., Gauss quadrature) or *random* (e.g., Monte Carlo sampling) (Debusschere et al., 2004). Deterministic sampling methods result in $N = 100^n$, in case 100 points are spaced equally throughout the n uncertainty dimensions. Random sampling methods require less samples, but can still require a very large N to practically converge as e.g. in Monte Carlo where the convergence rate is quite low $O\left(1/\sqrt{N}\right)$.

2.2. Generalized polynomial chaos (gPC)

The gPC method approximates a model response y as a sum of orthogonal polynomials which are a function of the uncertain parameters for which stochastic information is avail-

able. The d-th order polynomial chaos expansion (PCE) of a model response y is defined as follows:

$$y_{\text{PCE}}(\boldsymbol{\theta}) = \sum_{j=0}^{L} \hat{y}_j \Phi_j(\boldsymbol{\theta}), \tag{2}$$

with $\hat{y}_j$ the unknown PCE coefficients and $\Phi_j(\boldsymbol{\theta})$ the multivariate orthogonal polynomials and j a term based index $(j = 0, \ldots, L)$ and $L+1 = (n_\theta + d)!/(n_\theta! d!)$.

These multivariate orthogonal polynomials can be written as a function of univariate orthogonal polynomials as it is typically assumed in polynomial chaos that the uncertain parameters are independent. In gPC, the uncertain parameters are written as a function of a standard distributed uncertain variable ξ. The Wiener-Askey can then be used to define generalized orthogonal polynomials as a function of ξ (Wiener, 1938; Xiu and Karniadakis, 2002). Recently, Paulson et al. (2017) proposed a further generalization, termed arbitrary polynomial chaos (aPC), to define the basis directly in terms of the *moments* of the uncertain variables.

The expected value and variance of R_y can be approximated with PCE as:

$$\mathbb{E}[y] \approx \hat{y}_0 \tag{3}$$

$$\mathbb{V}\text{ar}[y] \approx \sum_{j=1}^{L} (\hat{y}_j)^2 \, \mathbb{E}\left[\Phi_j^2(\boldsymbol{\theta})\right]. \tag{4}$$

Note that $\mathbb{E}\left[\Phi_j^2(\boldsymbol{\theta})\right]$ can be computed upfront and equals 1 for standard normalized polynomials.

3. Computing the PCE coefficients

Remark that up till now, it is not yet mentioned how the unknown PCE coefficients $\hat{y}_j$ can be computed. Two classes of methods exist to compute these unknown coefficients: *intrusive* and *non-intrusive* methods. The dynamic optimization problem formulations are presented in Table 1. In *intrusive methods* a deterministic set of equations is developed for the coefficients $\hat{y}$ based on a Galerkin projection of the approximation error between the model response function and its polynomial chaos expansion. For *intrusive* methods the model response needs to be explicitly known and preferably the explicit model response function is a polynomial function. More details on intrusive methods can be found in e.g., Ghanem and Spanos (1991), Debusschere et al. (2004). In *non-intrusive methods* the model is considered as a black box and exact expressions for the model response are not required. All *non-intrusive* methods can be considered as a weighted sum of model response evaluations in n_s sampling points. The non-intrusive Galerkin, probabilistic collocation and least squares regression differ in the number of sampling points n_s that are selected and the weighting matrices as indicated in Table 1.

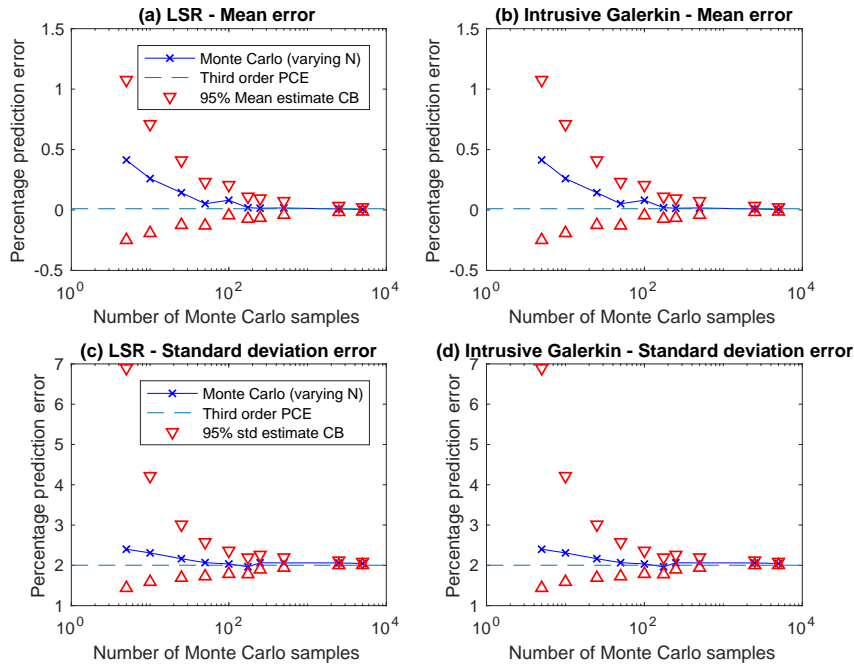
Note that the intrusive gPC problem formulation no longer has any random variables appearing so that it can be solved using standard dynamic optimization methods. However, the complexity of evaluating the right-hand side inner products of the equations above


Figure 1: Prediction errors for mean and standard deviation for LSR (a,c) and intrusive Galerkin (b,d).

(which may not even have closed-form expressions) and the fact that there is no clear exploitable structure due to the strong correlation between all the variables. The fact that the number of terms in the right-hand side grows exponentially with order of the polynomial also implies gradient calculations will be very expensive, which is a key bottleneck in many optimization algorithms including interior point and active set methods.

4. Results for a CSTR case study

4.1. Case study

The continuously stirred tank reactor (CSTR) case study from Lucia et al. (2017) has been implemented to compare three different gPC implementations: intrusive Galerkin with non-intrusive probabilistic collocation (PCM) and least squares regression (LSR). In this CSTR the reactants A and B react to form a product C. The objective of the problem is to maximize the amount of C. The model consists of 7 differential equations, describing the change of the reactor volume with respect to time, the concentration mass balances of A, B and C, the dynamics of the reactor temperature and jacket temperature and the dynamics of the inlet jacket temperature. The controls are the reactor inflow and the setpoint of the thermostat. Two uncertain parameters have been considered to be uniformly distributed within the interval $[0.7\theta_{nom}, 1.3\theta_{nom}]$: the molar reaction enthalpy ΔH_R and the reaction constant k. The dynamic optimization problems have been discretized using an orthogonal collocation scheme.

On the implementation of generalized polynomial chaos in dynamic
optimization under stochastic uncertainty: a user perspective

5

4.2. Prediction error as function of order and method

As a measure the final temperature has been chosen and 10000 Monte Carlo (MC) samples have been taken as a benchmark for comparison with the prediction of mean and variance. Figure 1 indicates a minor effect on mean approximation while variance approximation improves with increasing order. The prediction error between MC and PCE has been plotted as a function of the number of parameter samples for both LSR as intrusive Galerkin.

Table 1: Dynamic optimization problem formulations for intrusive and non-intrusive gPC.

Intrusive Galerkin formulation

$$\min_{u(\cdot)} \hat{J}_0 + \alpha_0 \sum_{i=1}^{L} \hat{J}_i^2 \langle \Phi_i^2 \rangle$$
$$\text{subject to: } \hat{g}_{i,0} + \alpha_i \sum_{j=1}^{L} \hat{g}_{i,j}^2 \langle \Phi_j^2 \rangle \leq 0$$

$$\frac{d\hat{x}_k(t)}{dt} = \frac{1}{\langle \Phi_k^2 \rangle} \left\langle f\left(\sum_{i=0}^{L} \hat{x}_i \Phi_i(\xi), u(t), \sum_{i=0}^{L} \hat{\theta}_i \Phi_i(\xi)\right), \Phi_k \right\rangle,$$
$$\hat{x}_k(0) = \frac{\langle x_0, \Phi_k \rangle}{\langle \Phi_k^2 \rangle},$$
$$\hat{J}_k = \frac{1}{\langle \Phi_k^2 \rangle} \left\langle J\left(\sum_{i=0}^{L} \hat{x}_i \Phi_i(\xi), u(t), \sum_{i=0}^{L} \hat{\theta}_i \Phi_i(\xi)\right), \Phi_k \right\rangle,$$
$$\hat{g}_{i,k} = \frac{1}{\langle \Phi_k^2 \rangle} \left\langle g\left(\sum_{i=0}^{L} \hat{x}_i \Phi_i(\xi), u(t), \sum_{i=0}^{L} \hat{\theta}_i \Phi_i(\xi)\right), \Phi_k \right\rangle,$$
$$\forall k = 0, \ldots, L, \forall i = 1, \ldots, n_c.$$

Non-intrusive formulations

$$\min_{u(\cdot)} \hat{J}_0 + \alpha_0 \sum_{i=1}^{L} \hat{J}_i^2 \langle \Phi_i^2 \rangle$$
$$\text{subject to: } \dot{x}^j = f(x^j, u, \theta^j), j = 1, \ldots, N,$$

$$x^j(0) = x_0(\theta^j), j = 1, \ldots, N,$$
$$\hat{J}_k = \sum_{j=1}^{N} w_{k,j} J(x^j, u, \theta^j), k = 0, \ldots, L,$$
$$\hat{g}_{i,k} = \sum_{j=1}^{N} w_{k,j} g_i(x^j, u, \theta^j), i = 1, \ldots, n_c, k = 0, \ldots, L,$$
$$0 \geq \hat{g}_{i,0} + \alpha_i \sum_{j=1}^{L} \hat{g}_{i,j}^2 \langle \Phi_j^2 \rangle, i = 1, \ldots, n_c,$$
$$\hat{\mathbf{y}} = \mathbf{W}\mathbf{y} \text{ with } \mathbf{y} = \left[y\left(\theta^1\right), \ldots, y\left(\theta^N\right)\right]$$

Non-intrusive Galerkin	Probabilistic collocation	Least squares regression
$\begin{bmatrix} \frac{q^1 \Phi_0(\theta^0)}{\langle \Phi_0^2 \rangle} & \cdots & \frac{q^N \Phi_0(\theta^{n_s-1})}{\langle \Phi_0^2 \rangle} \\ \vdots & \vdots & \cdots \\ \frac{q^1 \Phi_L(\theta^0)}{\langle \Phi_L^2 \rangle} & \cdots & \frac{q^N \Phi_L(\theta^{n_s-1})}{\langle \Phi_L^2 \rangle} \end{bmatrix}$	$\left(\left(\mathbf{\Lambda}^{(d)}\right)^{\mathsf{T}}\right)^{-1}$	$\left(\mathbf{\Lambda}^{(d)}\left(\mathbf{\Lambda}^{(d)}\right)^{\mathsf{T}}\right)^{-1}\mathbf{\Lambda}^{(d)}.$
with weights q^i from the quadrature rule	with $\mathbf{\Lambda}^{(d)} = \begin{bmatrix} \Phi_0(\theta^0) & \cdots & \Phi_0(\theta^{n_s-1}) \\ \vdots & \ddots & \vdots \\ \Phi_L(\theta^0) & \cdots & \Phi_L(\theta^{n_s-1}) \end{bmatrix}.$	with $\mathbf{\Lambda}^{(d)} = \begin{bmatrix} \Phi_0(\theta^0) & \cdots & \Phi_0(\theta^{n_s-1}) \\ \vdots & \ddots & \vdots \\ \Phi_L(\theta^0) & \cdots & \Phi_L(\theta^{n_s-1}) \end{bmatrix}.$

For the mean MC never seems to outperform the PCE accuracy. More than 1000 MC samples are required to outperform PCE.

4.3. CPU time

The IPOPT main loop times for the three different methods are displayed in Table 2 for different PCE orders. All states are initialized at a fixed value, not exploiting the advantage of non-intrusive approaches which can use the nominal state profiles as initialization. PCM outperforms LSR and intrusive Galerkin in all cases except for the first order PCE, where performance is similar. LSR and intrusive Galerkin have a similar performance, although intrusive Galerkin requires $\frac{(n+d)!}{n!d!} n_x$ states and LSR $n^{d+1} n_x$ states.

Table 2: CPU times in seconds for different orders obtained with LSR, PCM and intrusive Galerkin.

First order			Second order			Third order		
LSR	PCM	Galerkin	LSR	PCM	Galerkin	LSR	PCM	Galerkin
0.936	0.713	1.058	3.696	2.317	9.805	17.711	1.817	12.426

5. Conclusions

In this article a comparison between the different gPC formulations has been presented and an intrusive Galerkin, PCM and LSR have been implemented on a CSTR case study. Results indicate that non-intrusive formulations are preferred over intrusive due to the generally lower CPU time and potential further decrease in CPU time due to the parallelizable sampling-based structure of the dynamic optimization problem (Jiang et al., 2017).

Abstract

Mixed integer linear programming (MILP) is the state-of-the-art mathematical framework for optimization of energy systems. The capability of solving rather large problems that include time and space discretization is particularly relevant for planning the transition to a system where non-dispatchable energy sources are key. Here, one of the main challenges is to realistically describe the technologies and the system boundaries: on the one hand the linear modeling, and on the other the number of variables that can be handled by the system call for a trade-off between level of details and computational time. With this work, we investigate how modeling wind turbines, H₂ generation via electrolysis, and storage in salt cavern affect the system description and findings. We do this by implementing methodological developments to an existing MILP tool, and by testing them in an exemplary case study, i.e. decarbonization of the Dutch energy system. It is found that modeling of wind turbines curtailment and of existing turbines are key. The deployment of H₂ generation and storage is driven by the interplay between area availability, system costs, and desired level of autarky.

Keywords: MILP, wind turbines, energy storage, technology modeling, energy transition

1. Introduction

A high penetration of non dispatchable renewable energy sources (NDRES) comes with the necessity for energy storage capacity. While batteries show a very high round-trip efficiency and suitability for intra-day storage, they are not suited for long-term storage, especially seasonal, due to their energy losses over time. (Gabrielli et al. (2018a)) The production of hydrogen via power-to-gas (PtG) is a more promising candidate for such long-term storage. Nevertheless, the large volumes required on a national or even international scale require alternatives to conventional gas tanks. Hydrogen storage in salt caverns is a proven technology (Lord et al. (2014)) that features large point storage capacity, especially in the Netherlands and in Germany. Previous studies focusing on Germany (Welder et al. (2018)) have already shown the potential of the described system. Understanding the trade-offs between offshore vs. onshore wind farms, and planning the replacement of old wind installations is a challenging task that benefits from the adaption of rigorous MILP frameworks. Therefore, this work aims at grasping the aforementioned trade-offs by analyzing a hypothetical Dutch energy system consisting of onshore and offshore wind turbines, and PtG systems with hydrogen storage in salt caverns. Furthermore,

the extent of autarky achievable with such a system will be quantified.

2. Methodology

The model discussed in this work builds upon the MILP modeling framework reported by Gabrielli et al. (2018b). Following, we focus on new developments within this framework.

2.1. Wind turbine modeling

Various approaches to model wind turbines showing different levels of detail can be found in literature, ranging from detailed wind power plant modeling as reported by Gebraad et al. (2017) to simplified models for the use in MILP energy system optimization (Weber and Shah (2011)). In this work, we model the wind turbines using power curves as a function of cut-in, rated, and cut-out windspeed (v_{in}, v_r and v_{out}, respectively) as described by Jerez et al. (2015).

Implementation into the MILP framework: Using wind profiles for the full analyzed time horizon allows to tackle the non linearity arising from the power curve in a pre-processing step. The maximum power output P_{max} for a wind turbine is calculated for every hour of the year and passed on to the optimization as a constant vector. Note that P_{max}, being the uncurtailed output for a given windspeed, is different from P_r, the rated power correlating to v_r. The actual output P_{out} is then calculated as

$$P_{out,i,t} \leq P_{max,i,t} \cdot S_i$$
$$0 \leq S_i \text{ for all } i \in \{1,I\} \text{ and } t \in \{1,T\} \tag{1}$$

where the integer decision variable S is the number of turbines, I the number of types of turbines and T the length of the time horizon. The optimization can choose to build new turbines from a discrete set (offshore: 3.5 MW and 6 MW, onshore: 0.9 MW, 2.5 MW and 4.5 MW). The treatment of existing turbines is more complicated owing to the limited amount of information open databases provide.

Existing turbines: Detailed modeling of existing turbines is required to decide upon replacement and continuous operation. While it is easy to model a certain turbine in detail, the vast variety of existing turbines calls for a more generalized approach, which is described in this section. A data set consisting of 43 turbines, accounting for about 78 % of Dutch turbines, was used. The only clear correlation was found between the P_r and the total integral of the power curve. Based on this observation and the aforementioned set of turbines, an algorithm to calculate estimates of v_{in}, v_r and v_{out} for arbitrary turbines was developed. The algorithm takes P_r and the manufacturer of the wind turbine to be analyzed as an input as well as the 43 turbines data set. Knowing that the maximum hourly windspeeds are usually around 10-20 m s^{-1}, v_{out} usually ranging from 20-25 m s^{-1} is of minor importance and hence neglected here. If a match for the manufacturer is found, the set is reduced to that manufacturer. Otherwise, the full set is used. The resulting data set is compared for P_r. Depending on how many matches are found, 3 cases are distinguished.

- *Case 1: 1 match for P_r found:* The algorithm uses the match from the dataset to simulate the turbine of interest.

- *Case 2: >1 match for P_r found:* A target power curve integral I_t is determined as

$$I_t = \frac{\sum_{i=1}^{N_m} \int_0^{v_{r,max}} P_i(v_{in}, v_r, v) \mathrm{d}v}{N_m} \tag{2}$$

where $v_{r,max}$ is the maximum rated windspeed found in the data set and N_m is the total number of P_r-matches found. v_{in} and v_r are then calculated solving eq. (3)

$$
\begin{aligned}
\min_{v_{in}, v_r} g &= \left| \int_0^{v_{r,max}} P(v_{in}, v_r, v) \mathrm{d}v - I_t \right| \\
\text{s.t. } & v_{in,min} \leq v_{in} \leq v_{in,max} \\
& v_{r,min} \leq v_r \leq v_{r,max}
\end{aligned}
\tag{3}
$$

v_{out} is returned as the average of the values in the considered data subset.

- *Case 3: No turbines found* In this particular case, the turbines with the next higher and next lower P_r are chosen. If more than one turbine each is found, their integrals are averaged as seen in eq. (2) to end up with one upper and one lower value. I_t is then obtained by interpolation. If P_r of the turbine of interest is higher or lower than all turbines in the considered subset, the whole subset forms the basis for a linear fit that allows to calculate I_t by means of extrapolation. Once I_t is obtained, the remaining procedure is identical to Case 2, i.e. solving eq. (3) for v_{in} and v_r and averaging v_{out}.

Curtailment: While the inequality in eq. (1) already allows for curtailment, this formulation is imprecise from a physical point of view since wind turbines are curtailed in a discrete manner. They are either curtailed, i.e. turned off, or operated following their power curves. To account for this effect, the curtailment C was introduced as an additional integer decision variable, describing how many turbines are turned off. The power output can then be formulated as

$$
\begin{aligned}
P_{out,i,t} &= P_{max,i,t} \cdot (S_i - C_{i,t}) \\
0 &\leq C_{i,t} \leq S_i \\
0 &\leq S_i \\
r^2 \pi \cdot \sum_i S_i &\leq A_{max}
\end{aligned}
\tag{4}
$$

Note that the strict equality in eq. (4), as compared to eq. (1), is reducing the flexibility of the system. This formulation allows for a physical-based description of curtailment, but it also increases significantly the complexity of the problem as discussed in the results. The total number of turbines is constraint by the maximum available land A_{max}. It is assumed that the distance between two wind turbines has to be at least 500 m, giving each turbine a radius r of 0.25 km.

2.2. Power-to-gas and hydrogen storage

The power-to-gas system consists of a polymer electrolyte membrane (PEM) electrolyzer and fuel cell, operating with water and air, respectively. Their modeling is reported in detail by Gabrielli et al. (2018b). Hydrogen is considered to be stored in cylindrical salt caverns as described in Gabrielli et al. (2018c).

3. Results

The problem was formulated in MATLAB R2018b using YALMIP (Löfberg (2004)) and solved with Gurobi v8.1 on an Intel Xeon E5-1620 3.60 GHz machine with 16 GB RAM.

Case study 1:   To quantify the effect of discrete compared to continuous curtailment, a hypothetical offshore-island - aimed at providing the whole Dutch electricity demand - was analyzed. The set of technologies encompasses a 3.5 MW wind turbine ($v_{in} = 3\,\mathrm{m\,s^{-1}}$, $v_r = 14\,\mathrm{m\,s^{-1}}$), a 6 MW wind turbine ($v_{in} = 4\,\mathrm{m\,s^{-1}}$, $v_r = 13\,\mathrm{m\,s^{-1}}$) and a PtG system. Due to the absence of salt caverns off-shore, traditional tank storage was assumed. In addition, the currently existing Dutch offshore turbines are considered but can be replaced through new turbines. The analysis was conducted with and without PtG system, both with discrete and continuous curtailment, ultimately resulting in 4 scenarios whose results are summarized in Table 1. As opposed to case study 2, no spatial constraints are assumed. As expected, dissipation of electricity occurs with discrete curtailment only and results from the fact that the costs for dissipation and import are equal at 10^5 euro per kWh. Hence, building an additional turbine and dissipating energy can be more favorable than importing. The application of PtG systems reduces the dissipation by an order of magnitude and the import by a quarter. Surprisingly, the PtG system is not utilized with continuous curtailment. Given the assumptions used, it is most likely that this is a result of the missing cost benefit of avoiding dissipation by using storage. Using discrete curtailment, the computational time is increased by about 80 % without PtG and by 1000 % with PtG. This indicates that the computational effects of discrete curtailment scale with the complexity of the system as a whole. This can easily lead to unsolvable systems due to a lack of memory, as experienced in case study 2. The preference of the 3.5 MW turbines over the 6.0 MW turbines can be explained by comparing their v_{in} with the wind profile, showing that the 3.5 MW turbine operates for 6366 hours per year while the 6.0 MW turbine only operates for 4674 hours per year. This significant downtime for both also explains the high amount of imported electricity despite the high amount of installed turbines. Furthermore, this also shows the need of large scale energy storage; the storage installed in scenario 4 is at its maximum of $4.9290 \cdot 10^7$ kWh.

Case study 2:   The system under investigation consists of 3 nodes, hereafter called onshore-node (ONN), offshore-node (OFFN), and cavern-node (CN). All data refers to the Netherlands and is hourly resolved for 2017. Wind turbines can be installed in ONN and OFF, and PtG systems with storage in CN and without storage in ONN. The country's electricity demand is an input profile for ONN and wind profiles are considered as input for ONN and OFFN. Full connectivity between the nodes is assumed for the electricity network while the hydrogen network needs to be built if required, i.e. investment costs occur. The optimization decides upon selection, sizing, and scheduling of the technologies as well as the flows between the nodes with the levelized costs of the total system as objective. While there is no export of electricity allowed, electricity can be imported at a

Table 1: Effect of discrete curtailment on technology selection. Scenarios: (1) no PtG, continuous curtailment (2) PtG, continuous curtailment (3) no PtG, discrete curtailment (4) PtG, discrete curtailment. For simplicity, only the storage of the PtG system is shown. Import, Dissipation and Storage are given in kWh.

Scenario	WTex	WT-3.5	WT-6.0	Import	Dissipation	Storage
1	79	13356752	0	1.08 E10	0	-
2	79	13356753	0	1.08 E10	0	0
3	79	13356753	0	1.08 E10	1.07 E06	-
4	79	13356752	0	8.27 E09	1.04 E05	4.93 E07

Table 2: Sensitivity of technology implementation towards level of autarky. The sizes for electrolyzer (PEMEC) and fuel cell (PEMFC) are in kW capacity, and for the wind-turbines (WT) in built units. The number next to *WT* refers to its maximum capacity in MW

Autarky	PEMEC	PEMFC	WT-0.9	WT-2.5	WT-4.5	WT-3.5	WT-6.0
0.625	42586	423.8	0	26944	4792	1077	24
0.475	0	0	0	15223	0	0	0
0.325	0	0	0	7520	0	0	0
0.175	0	0	0	3687	0	0	0
0.025	0	0	0	531	0	0	0
0	0	0	0	0	0	0	0

price of 0.032 euro per kWh and an emission factor of 0.676 kg$_{CO_2}$ per kWh. A CO$_2$-tax of 20 euro per tonne was applied, corresponding to the current ETS prices. The available land for ONN was assumed to be 15 % of the total land (WorldBank (2018),McKenna et al. (2015)). For OFFN, a total available area of 2900 km^2 (Dutch Government (2014)) was assumed. Although being spatially reduced to only 3 nodes, the study is based on realistic assumptions and constraints in terms of electricity demand, wind speed, available area and existing turbines. Putting the focus on achievable autarky using PtG, and considering the issues found in case study 1, continuous curtailment is used and existing turbines are neglected. Since imported electricity is the only source of emissions, the maximum achievable autarky was determined by applying a CO$_2$-tax of 10^6 euro per tonne giving an autarky of 62.5 % (defined as the fraction of the produced electricity over the total demand). Following, the autarky was implemented as a constraint and the sensitivity of the technology selection towards this constraint was investigated using the real CO$_2$-tax (see Table 2). It can be observed that in order to achieve the upper limit of autarky, oversizing of production technologies and installation of PtG is necessary. As soon as the constraint on autarky is relaxed, undersizing of production technologies and compensation with import is the preferred combination. Note that this result is also sensitive to the import price, the CO$_2$-tax, and the emission factor of imported electricity. The difference in size between PEMEC and PEMFC indicates that the amplitudes in overproduction are greater than in overdemand. Nevertheless, it does not necessarily follow that the total production for a year is higher than the demand.

4. Conclusions

In this work, the implementation of wind turbines with its various aspects into an MILP framework, and in particular the consideration of existing turbines, was discussed. A first analysis of the Dutch case study shows how the level of targeted autarky affects the selection of technologies. For the considered assumptions and constraints in this study, an upper limit to autarky is given by the available land, and PtG is required to approach this limit. From a computational point of view, the description of the wind turbine curtailment strongly affects the problem complexity and can cause an up to 10-fold increase of computation time for discrete curtailment. The exact impact depends on the overall system complexity. This becomes especially crucial when existing turbines are considered, because each type of turbine is treated as separate technology. Hence, existing turbines intrinsically lead to a vast increase in system complexity.

Abstract

In the sugarcane industry, boilers are widely used for cogeneration. This industry uses mainly sugarcane bagasse as the primary fuel source, followed by other types of biomass. Fuel price has a major impact on the industry results, due to the scenario of the energy market. Therefore, optimizing the combustion is an important lever to reduce this cost. Real-time measurement of oxygen content in the boilers flue gas is one of the requirements for this optimization. Due to the capital cost and the requirements for personnel qualification for maintenance and calibration, sugarcane mills rarely apply such analyzers in closed loop. In this work, a fuzzy control was implemented in the combustion air flowrate of a large boiler in the Tereos group, to maintain the oxygen content in the combustion products within the optimum range. A tool was used to identify the process dynamics and to tune the control loop in real time. After downloading the new strategy in the factory control system and tuning the controller, the oxygen control loop started operation in automatic mode. After twenty-four hours of continuous operation, regulatory and servo controls were able to keep the desired setpoint with low variability (± 1.2% variation in excess air coefficient) and respond to setpoint changes with good response speed (1.5-20 minutes) and overshoot (8-56%). No previous references were found in the literature on the use of fuzzy logic for the combustion control of sugarcane bagasse-fired boilers, especially high pressure and high steam throughput boilers. Results reached so far demonstrate the applicability of fuzzy control for combustion in boilers on sugarcane bagasse, with 40% less variability than a PID controller, and 69% less variability compared to operation in manual mode.

Keywords: sugarcane bagasse boiler, oxygen control, fuzzy logic.

1. Introduction

In the sugarcane industry, boilers are widely used for cogeneration (i.e., simultaneous generation of thermal and electrical energy from the same fuel source). The main fuel used is sugarcane bagasse, followed by other types of biomass, such as cane straw, woodchips and corn stover. According to the Brazilian Sugarcane Industry Union (UNICA), and the National Electric Energy Agency (ANEEL), the granted capacity of electricity supply from biomass represents 9% of the Brazilian energy matrix. The cane harvest period, which occurs between the months of April and November in the southeast of Brazil, is an advantage for electricity generation from bagasse, since it

matches the drier seasons of the year. During this period, the generation demand from thermoelectric power plants is increased. In this scenario, the price of sugarcane biomass (bagasse and straw) has a significant impact on the financial results of sugarcane mills. Since the process of manufacturing sugar and ethanol consumes large amounts of steam, the production of electricity from the very steam consumed at the mills is an inexpensive way of generating electricity. Therefore, it is essential that plants with a focus on bioelectricity generation invest in energy efficiency, to maximize the biomass surplus and its conversion into electricity, which reduces the risk exposure to the biomass market. Excess air is an impact factor on combustion efficiency: boilers use an air/fuel curve to maintain excess air as predicted by the manufacturer. However, variations in fuel quality, mainly humidity, require corrections on this curve. The main mechanism to correct the air/fuel curve is the oxygen control in the outlet duct of the effluent gases. This type of control is still little used in sugarcane bagasse boilers. Advanced control may have advantages over PID in this type of application. Thus, this work presents a fuzzy logic approach for the combustion control.

2. Literature Review

Fuel composition defines the combustion's stoichiometry, which in turn defines the theoretical air for the fuel's complete combustion. However, due to furnace mixing deficiencies, an excess amount of air is required to maintain a sufficient amount of oxygen until the end of the burning. One way of expressing the air/fuel ratio is the excess air coefficient, which is the ratio of the total amount of air used in the combustion to the amount of stoichiometric air. The excess air controls the volume and the enthalpy of the flue gases, which are determinant for the boiler's efficiency. A large excess of air is undesirable because it lowers the flame temperature and increases heat losses by enthalpy of the dry gas. On the other hand, a low excess of air can result in incomplete combustion and the formation of CO, soot and smoke, in addition to an accumulation of unburnt fuel, causing risk of explosion. Therefore, an optimum excess air coefficient is required to minimize both losses. In a boiler's design, manufacturers define a curve known as the air/fuel curve. This curve relates the air inlet as a function of the fuel throughput, and aims to maintain the excess air coefficient within the targeted range for each type of boiler. However, variations in fuel composition cause deviations from this curve, and the boiler no longer operates with the best combustion efficiency. Humidity is the main factor of variation in fuel composition throughout the crop. This is mainly due to limitations in the control of imbibition water in the sugar extraction process, cane throughput variability, wear of the drying/dewatering mills. An oxygen level control in the flue gas can correct the air/fuel curve in real time.

Zadeh (1965) introduced the concept of fuzzy sets, which, as the name suggests, is a theory of sets (or classes) whose boundaries are indefinite. He established that a fuzzy set would be a class with varying membership degrees. That is, each element would be allowed a certain degree of membership to the set. Fuzzy logic provides a means of quantifying states and overlapping between them (eg, High and Low), assigning degrees of membership (truth) to each of them (Akisue et al., 2018). Bhandari et al. (2016) simulated the combustion control of a low pressure (20 kgf/cm²) and low capacity (30 t/h) coal boiler using fuzzy logic, and applied this strategy to the equipment's PLC for testing during load variations. In another work, Li and Chang (1999) combined fuzzy logic control with neural networks in the combustion in coal-fired boilers. This approach aimed to adapt a base of membership functions and rules through a neural

network, from previous system responses, until the desired control performance was achieved. As mentioned, the works referenced in this document are based on the operation of coal boilers. No references were found in the literature on the use of fuzzy logic for the combustion control of sugarcane bagasse-fired boilers, especially high pressure (above 65 bar) and high steam throughput (from 200 t/h) boilers. The present work aims to fill this gap, with the implementation of a fuzzy logic controller in the combustion control loop of a bagasse-fired boiler with 67 bar pressure and 200 t/h of steam throughput.

3. Methodology

The implementation of the closed loop oxygen control, controller tuning and data collection was performed in a high-pressure boiler with an oxygen analyzer at the flue gas outlet. The boiler used in this work, model ZS-2T-200/67-525, is a ZANINI-SERMATEC steam generator with a pin hole grate. It has water wall panels, single pass convection beam, two drums supported by the top of the metal structure, with natural circulation and a bagasse burning system in suspension.

Among the boiler's main control loops is the combustion control: variable frequency drives on primary and secondary air fans adjust the airflow based on the air/bagasse curve, in order to guarantee the required excess air under different operating regimes. The air/bagasse curve operates according to a curve determined by the manufacturer. This curve is corrected by an oxygen control loop by fuzzy logic, which was implanted as object of the present work.

The gas analyzer installed in the boiler is the EL3040 model, manufactured by ABB. It consists of two probes, one infrared probe Uras26 for CO analysis, and the other an electrochemical probe Endura AZ20 for O_2 analysis. The O_2 sensor, object of this work, is based on a zirconium oxide cell. This cell is mounted on the tip of the probe that is inserted into the gas duct. The oxygen concentration in the effluent gases is measured using an in situ wet analysis method. The output signal generated by the zirconium cell is processed in the transmitter, providing a local O_2 reading and a 4-20 mA retransmission signal covering the 0-100% O_2 range.

The plant's main control system is Emerson's DeltaV®. It has development tools that allowed the addition of fuzzy logic blocks to the oxygen control loop, and a tuning application (DeltaV Insight®) adjust the scaling factors. All data was stored using OSIsoft's PI System®.

The controller uses, as input signals, the error and change in error of the O_2 concentration, and the change of the control action for correcting the air/bagasse curve as the output signal (input and output linguistic variables). The relationships between these three variables represent a nonlinear controller. The two linguistic values for error and change in error are Negative and Positive. For the output change, a third linguistic value, Zero, is added. The values of error and change in error, along with the membership scaling, respectively, Se and SΔe, determine the degree of membership (memberships to Negative linguistic values are maximum for –Se and –SΔe; memberships to Positive linguistic values are maximum for +Se and +SΔe). The membership functions of the output change are singletons. A singleton represents a fuzzy set whose support is a single point with a membership function equal to 1. Singletons are usually employed in the industry for output changer in order to simplify the computational demand for defuzzification, since they eliminate the need for numerical integration. The membership scaling (SΔu) determines the magnitude of the output change, positive or negative, for a given error and change in error. There are four

fuzzy logic rules that the controller uses for a reverse control action. These rules are described in Table 1, with N, P and ZO being Negative, Positive and Zero, respectively.

Table 1. Fuzzy logic rules in DeltaV.

Rule 1	If error is N and change in error is N, make change in output P.
Rule 2	If error is N and change in error is P, make change in output ZO.
Rule 3	If error is P and change in error is N, make change in output ZO.
Rule 4	If error is P and change in error is P, make change in output N.

Tuning can be used to establish the scaling factors (Se, SΔe and SΔu). For small control errors and setpoint changes smaller than a nominal value (ΔYsp), the scaling factors of the fuzzy controller are related to the proportional gain (Kp) and the integral time (Ti) that would be used in a PI block being executed with a scan time (Δt) of 1 second to control the same process. Those relationships are expressed in Eq. (1), (2) and (3).

$$S\Delta e = \beta \Delta Y_{SP} \tag{1}$$

$$S\Delta u = 2S\Delta e K_p \tag{2}$$

$$Se = Se_0 = TiS\Delta e \tag{3}$$

Where:

SΔe	=	change in error scaling factor
Se	=	error scaling factor
SΔu	=	change in output scaling factor
Se$_0$	=	error scaling factor for a 1 second scan time

Beta is a function of the process dead time and time constant, and ranges between 0.2 and 0.5. The nominal setpoint change value for ΔYsp is 1%. When the change in setpoint is higher than the nominal setpoint change value (ΔYsp), scaling factors are internally augmented by the FLC block.

Once a control loop is set up to govern a process, it needs to be tuned. The tuning application used in this work applies an on-demand process test to provide tuning recommendations automatically. This on-demand tuning is based on Aström-Hägglund's patented algorithm to calculate the tuning parameters of a closed loop (Aström and Hägglund, 1988). Emerson enhanced this algorithm with the incorporation of a patented technique to identify the process' dead time. During tuning, the output of the controller is determined by a known function that acts as a relay with hysteresis. This relay provides a two-state control and causes a process oscillation with a small, controlled amplitude. From the amplitude and frequency of this oscillation, the tuning software calculates the process' critical gain and critical time. The controller parameters are then computed based on the classical Ziegler-Nichols' rules.

To follow the process variable, manipulated variable and setpoint of the boiler's combustion control loop, OSIsoft's PI System® was used. It is a Plant Information Management System (PIMS), used for plant information management, which collects process data residing in distinct sources and stores it in a single database.

4. Results

After the construction of the oxygen control loop with the FLC block (fuzzy logic controller) and the implementation in the DCS (distributed control system), the combustion control loop was switched to automatic. After starting the operation with this new strategy, the tuner was used to obtain the controller's scaling factors. This step resulted in the following recommendation of scaling factors of the membership functions for the linguistic variables error, change in error and change in output:

• Se (error) = 28.74%; SΔe (change in error) = 0.4%; SΔu (change in output) = 0.68

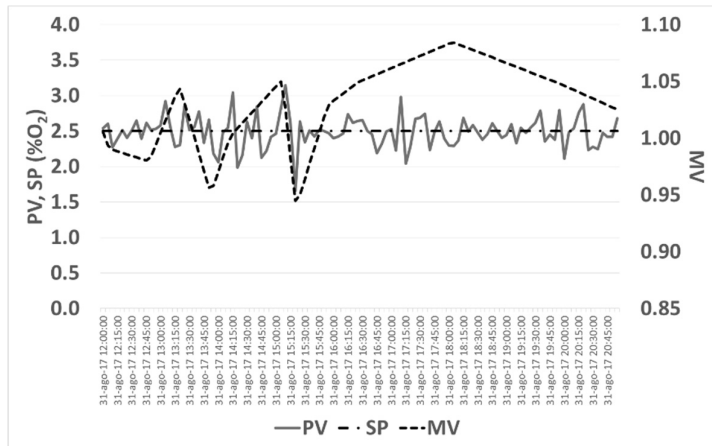
The controller's parameters recommended by the tuning were updated in the DCS, and the controller returned its operating mode to automatic. A specialized company carried out a combustion regulation of the ZS-2T-200 boiler, measuring gas concentration (O_2, CO and CO_2) at various points in the circuit with portable analyzers, as well as an evaluation of the inlet and exhaust fans. A 2.5% setpoint for the O_2 concentration in the boiler effluent was recommended due to an offset of 2 percentage points caused by the probe's position. This corresponds to a 4.5% O_2 content in the center of the gas duct.


Figure 1. History data from eight operating hours with flue gas' oxygen control loop in automatic mode with the fuzzy controller. PV, SP data on left axis, and MV on the right axis. Source: PI System.

Figure 1 shows the historical data of setpoint (SP), process variable (PV) and manipulated variable (MV) during eight hours of operation of the boiler with the control loop in automatic. During this period, the setpoint was set at 2.5% and the variability of the PV (regulatory control) was evaluated. The mean value of PV in this period was 2.49%, with a standard deviation of 0.22. This deviation represents a variation of ± 1.2% in the excess air coefficient. One can also observe, in Figure 1, that the MV acted without saturation during the entire period.

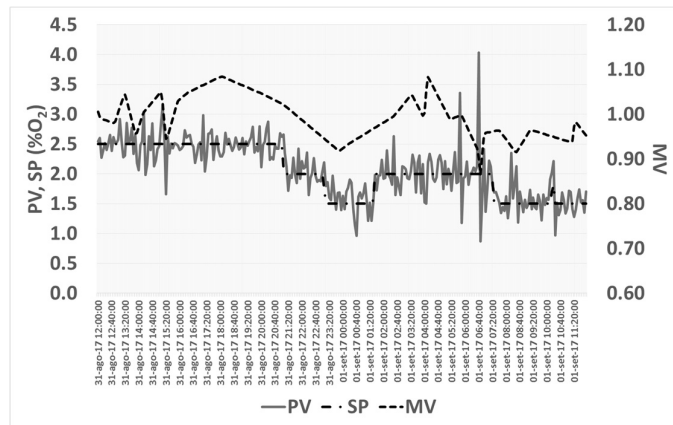
After eight hours of automatic operation with fixed setpoint, tests were performed to evaluate the controller's performance to setpoint changes (servo control), and to maintain the new setpoint values. Figure 2 shows the total interval of 24 hours of testing between servo and regulatory controls. After twenty-four hours of continuous operation, regulatory and servo controls were able to keep the desired setpoint with low variability (± 1.2% variation in excess air coefficient) and respond to setpoint changes with good response speed (1.5-20 minutes) and overshoot (8-56%).


Figure 2. Controller's performance test in servo and regulatory modes over 24 hours. PV, SP data on left axis, and MV on the right axis. Source: PI System.

Compared to previous PID and manual control results (de Mello, 2018) from Tereos, it was observed 40% less variability than the PID controller, and 69% less variability than operation in manual mode.

5. Conclusions

The implementation of a closed loop oxygen control, controller tuning and data collection was performed in a high-pressure boiler with an oxygen analyzer at the flue gas outlet. Results presented here demonstrate the applicability of fuzzy control for combustion in boilers on sugarcane bagasse.

Dynamics and Control of a Fully Heat-Integrated Complex Distillation Column

Manuel Rodríguez [a*], Ignacio P. Fernández Arranz [a]

[a] *Universidad Politécnica de Madrid, José Gutiérrez Abascal 2, 28006 Madrid, Spain*

Abstract

Distillation is the most widely used in the separation section of a process. It consumes an important amount of energy (close to 40 % of the energy of chemical process). Many different configurations to increase its thermodynamic efficiency have been proposed. In this paper a new distillation column configuration developed by Toyo Engineering Corporation called SuperHIDiC is analysed. This new column is simulated and compared with a conventional distillation column. Its dynamic performance and control structure performance are also analysed. Results show that SuperHIDiC achieves an important reduction in energy consumption and that a conventional control configuration can be used in order to have a stable operation.

Keywords: Heat integration, complex distillation, process control

1. Introduction

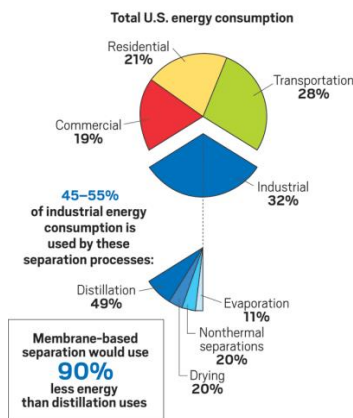
Energy consumption is one of the problems that our world faces in this century. In 2017 energy consumption increased 2.3 % versus 1.1 % increase in 2016 according to the Global Energy Statistical Yearbook 2018, and it is expected to expand by 30 % between today and 2040 as indicated by the International Energy Agency. United Stated energy consumption by use is depicted in Fig 1. industrial consumption amounts to more than 30 % of the total being almost half of it consumed in separation process being distillation the consumer of half of the energy of the separation processes (i.e. around 8 % of the total energy consumption in the U.S.).


Figure 1. United States energy consumption (Ritter, 2017)

Conventional distillation is a very inefficient process in terms of energy, being its efficiency below 10 %. The idea of more efficient distillation columns is not new, in 1977 (Mah et al. 1977) proposed the first method to save energy through heat integration. In the following years based on Mah's idea, different researchers proposed and patented heat integrated distillation configurations like Seader (1980), Aso (1996), Nakaiwa (2000), etc. These types of columns called HIDiC (*Heat Integrated Distillation Column*) have been studied and its feasibility and profitability demonstrated for low relative volatility separations and tight product specifications (Leon Pulido et al., 2010). Although HIDiCs can achieve (theoretically) almost 60 % energy reduction, their use in industry is far from being high, mainly due to complex (and costly) construction and high maintenance costs. In this paper we explore a new HIDiC developed by Toyo Corp. denominated SuperHIDiC. Next section this new type of column is described, then a simulation of its performance and energy savings is presented, section four shows a dynamic model and a valid control structure and finally in the last section comments on the obtained conclusions.

2. SuperHIDiC column concept

SUPERHIDiC® is HIDiC configuration developed by Toyo Inc. In this setup the stripping and rectifying columns switch positions, being the stripping section at the top and the rectifying section at the bottom, side heat exchange is accomplished by thermo-siphon and/or gravity without pumping. The operating pressure in rectifying section is higher, this makes a transfer of the excess heat duty in the rectifying section to the stripping one possible. Fig 2. shows the configuration of the SuperHIDiC column.

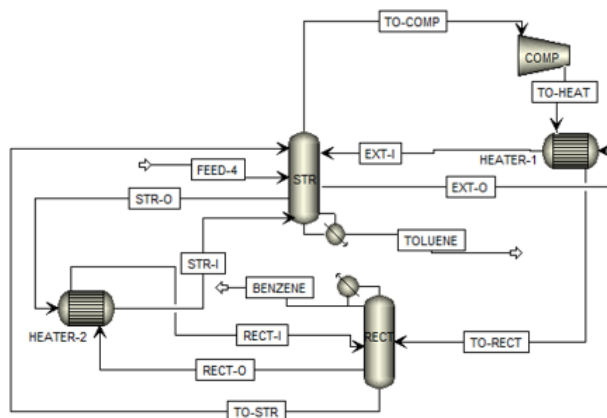
Feed goes into the stripping section. This section operates only with the reboiler, and it has (at least) one side heat exchanger to take advantage of heat integration. The stream at the top of the column goes to a compressor and then exchanges heat before going to the rectifying column. This, high pressure, column operates only with the condenser and it has (at least) one side heat exchanger. The number of side heat exchangers, which can be up to five, depends on the type of separation and operating conditions. Reboiler and condenser duty are significantly reduced due to the heat integration achieved with the side heat exchangers. There is no need of special equipment, so maintenance can be conducted
Figure 2. SuperHIDiC distillation column concept (Toyo Engineering, 2017)


Figure 3. SuperHIDiC simulation configuration using Aspen Plus

by conventional means. Toyo engineers (Toyo Engineering Corporation, 2018) claim to achieve up to a 50 % energy reduction. Main applications are in installations where:

- Temperature difference between the overhead and the bottom is lower than 80 °C.
- Utilities are expensive.
- Condenser and/or reboiler duties are large.

3. SuperHIDiC Simulation

The system to separate using this technology is a stream composed of benzene and toluene. Feed composition is equimolar and its temperature and pressure are 94 °C and 100 kPa respectively. Total flow is 100 kmol/h. Molar purity of both products is 99.5 % molar. The fully heat integrated distillation column has been simulated using Aspen Plus as shown in Fig 3. and the physical properties packages used is RK-SOAVE. The configuration is equivalent to the SuperHIDiC column, it has two columns (stripping and rectifying) with side extractions to the heat exchangers.

The stripping column has 15 stages with side extractions in stages 4 and 13. The rectifying column has also 15 stages with a side stream in stage 4, it operates with a reflux ratio of 2.2. The compressor discharge pressure is 350 kPa.

Table 1. Energy consumption comparison between conventional distillation and SuperHIDiC

	CONVENTIONAL	SUPERHIDIC	REDUCTION (%)
CONDENSER	1.395 MW	0.951 MW	**31.87**
REBOILER	1.240 MW	0.619 MW	**50.10**
COMPRESSOR	-	0.275 MW	-
TOTAL	2.635 MW	1.844 MW	**30.01**

The separation has also been implemented using a conventional distillation column. The conventional column has 30 stages and it operates at a reflux ratio of 2. The obtained results show a significant reduction in energy consumption, see Table 1.

Around 32 % reduction in the condenser and a 50 % reduction in the reboiler. Adding the power needed for the compressor the overall reduction is 30 %, it appears that even considering the extra capital expenses of this new type of column, it can be a better option than the conventional approach. Besides other aspects should be considered as the environmental impact which is much lesser.

The energy savings are 0.791 MW, taking 8760 h/y the resulting annual energy savings are 6929.2 MWh. Considering an emission factor of 0.39 kg CO_2/kWh (Ministry of agriculture, 2018) the greenhouse gas emission reduction is 2702.4 t CO_2/y. The OPEX savings obtained considering an energy price of 52.24 €/MW (OMIE, 2018) are 3.6M €/y.

4. SuperHIDiC Control

According to Toyo Inc. a conventional control structure allows for a stable operation of the distillation column. Pressure control in the stripping column is obtained manipulating compressor speed, and composition control is achieved through inference with temperature. In the rectifying column pressure is control with the condenser duty and distillate flow is also controlled. Inventories in both columns are controlled. This conventional control scheme shown in Fig 4.

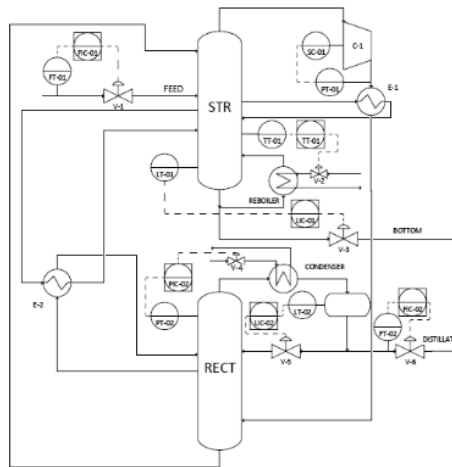
It has been implemented in a dynamic simulation in order to check its validity. The simulation has been done with Aspen Dynamics (Fig 5.) using the steady state model developed previously and adding the dynamic information needed. Feed composition and feed flow disturbances have been applied to the process.


Figure 4. Control scheme to operate the heat integrated column
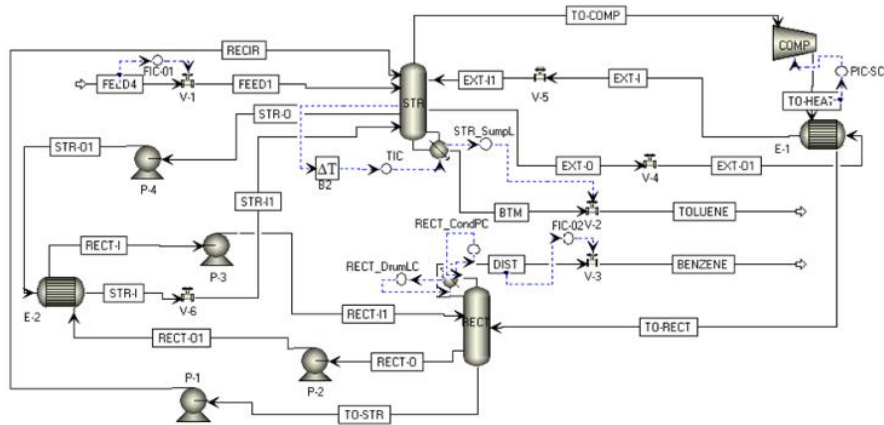

Figure 5. Dynamic simulation of the SuperHIDiC and its control structure

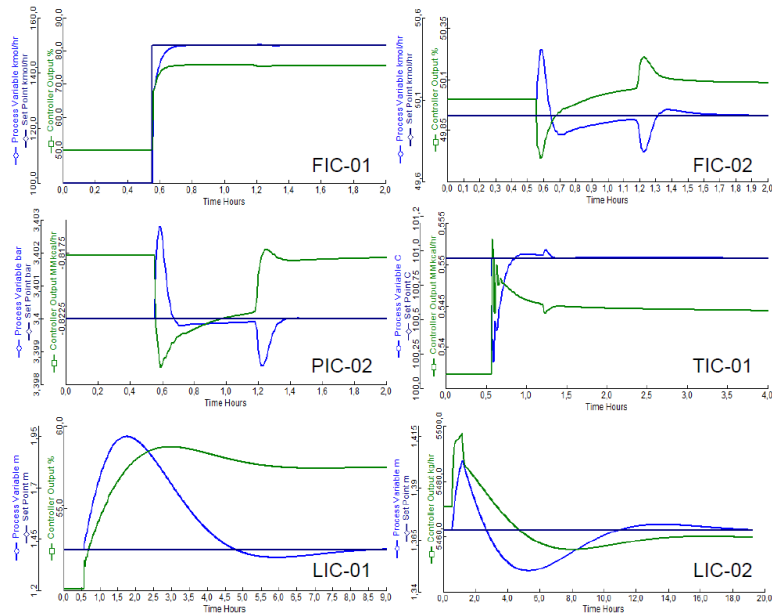
Fig 6. and 7 show the behaviour of the control system flow disturbance (changed from 100 kmol/h to 150 kmol/h which is higher than expected in a real plant as these columns are design for a turndown between 70-100%) and composition disturbance (change of 10% in benzene composition). Both are rejected and the control system exhibits good performance.


Figure 6. SuperHIDiC control performance under feed flow disturbance
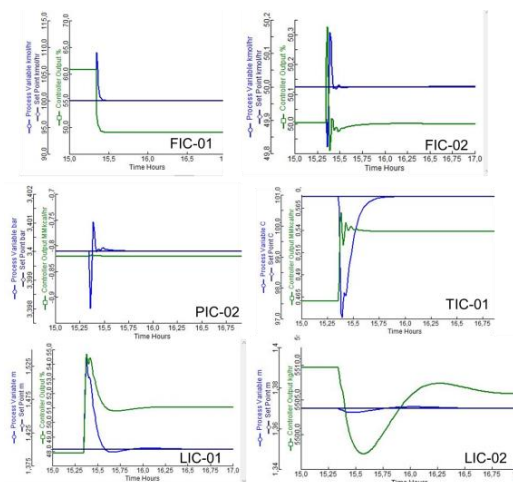

Figure 7. SuperHIDiC control performance under composition disturbance

5. Conclusions and further work

In this work a new distillation configuration to save energy consumption called SuperHIDiC has been tested. A comparison with a conventional distillation column results in significant energy savings (although not so high as claimed by the designers Toyo Inc.) and an important reduction in greenhouse gas emission. A dynamic simulation has also been implemented with its associated control structure. The conclusion is that a conventional control configuration allows good operation of the column. Further work will compare the capital expenses of this configuration with the conventional approach to have a complete economic comparison and will implement advanced control to the column to compare it with the conventional control scheme applied in this work.

Abstract

The paper presents and discusses a basic pharmacokinetic model for vancomycin, an antibiotic that is principally excreted by kidneys. The model accounts for the degree of renal function by employing the CKD-EPI equation. Only one parameter of the model is identified by a nonlinear regression of experimental data, while the other parameters are evaluated *a priori* via correlations from the scientific literature.
We simulate the pharmacokinetic time-curves of vancomycin by accounting for different values of the glomerular filtration rate and show the strong influence of the degree of renal function on the drug pharmacokinetics. In addition, the model can be used to determine the optimal dose for patients featuring varying degrees of renal function. Results underline the importance of individualized treatment.
Keywords: pharmacokinetics, optimal dose, renal function, GFR, vancomycin.

1. Introduction

The assessment of the optimal dose for drug administration is a critical choice for clinical doctors and calls for considering the individual characteristics of patients. Since drugs are typically tested on healthy subjects, dosage guidelines and PK studies are often available for average healthy individuals. Conversely, in clinical practice, drugs are administered to ill and/or elderly patients, who often suffer from varying degrees of renal impairment. About 31% of administered drugs are mainly cleared by the kidneys (Varma et al., 2009). For these drugs, the patient's degree of renal function strongly affects the concentration profile of the drug and the administered dose is critical. The glomerular filtration rate (GFR) represents the volumetric flow of plasma that is filtered by the kidneys and is a useful measure to estimate the degree of renal function.

Renal function declines with age and may be further affected by renal diseases. Renal impairment is extremely common, even though a large fraction of people who suffer from it are unaware of their status (Girndt et al., 2016). Chronic kidney disease (CKD) at stages 3-5 is defined as a condition when GFR < 60 mL/min/1.73 m^2 for 3 months. This corresponds to the loss of more than half of the normal kidney function. According to Hill et al. (2016), 10.6% of the general world population suffers from CKD at stages 3-5. For patients with renal impairment, drug dosage is often suboptimal and drug dosing errors are common (Kim et al., 2016), which trigger adverse effects and reduce life quality and life expectancy.

We developed a pharmacokinetic (PK) model that can be applied as a tool to determine the optimal dose of a drug that is mainly cleared via renal filtration. The optimal dose is personalized according to the individual characteristics of the patients, *i.e.* age, sex, height, weight, and serum creatinine levels. These parameters, in particular, allow

estimating GFR, and therefore the renal function, according to the CKD-EPI equation (Levey et al., 2009).

The PK model is applied to vancomycin, an antibiotic that is almost completely cleared by renal filtration and whose metabolism is negligible. Vancomycin is routinely administered in clinical settings especially to critically ill patients, who typically display heterogeneous characteristics and, in particular, an extremely wide range of degrees of renal function.

2. Methods

A rather simple PK model comprising only three compartments was developed to explicitly focus on renal function. The compartments (Figure 1) are (i) the global circulatory system, (ii) the renal circulatory system, and (iii) the other tissues.
Figure 1 – Compartments of the PK model.

The global circulatory system (CS) involves the plasma contained in the whole circulatory system but the fraction that passes through the kidneys, which is described by the renal circulatory system (RCS) compartment. The third compartment lumps the other tissues and organs (OT) where the drug diffuses through the exchange between plasma and interstitial fluid at the capillaries.

The model consists of three ordinary differential equations (Eqs. 1-3) that quantify the material balances of vancomycin in each of the three compartments, including the exchange between them and the excretion due to renal filtration.

$$\frac{dm_{CS}}{dt} = \dot{m}_{IV} - \frac{Q_{CS \leftrightarrow RCS}}{V_{CS}} m_{CS} + \frac{Q_{CS \leftrightarrow RCS}}{V_{RCS}} m_{RCS} + \\ -\frac{K_{CS \leftrightarrow OT}}{V_{CS}} m_{CS} (1-R) + \frac{K_{CS \leftrightarrow OT}}{V_{OT}} m_{OT} \tag{1}$$

$$\frac{dm_{RCS}}{dt} = \frac{Q_{CS \leftrightarrow RCS}}{V_{CS}} m_{CS} - \frac{Q_{CS \leftrightarrow RCS}}{V_{RCS}} m_{RCS} - \frac{Q_{GFR}}{V_{RCS}} m_{RCS} (1-R) \tag{2}$$

$$\frac{dm_{OT}}{dt} = \frac{K_{CS \leftrightarrow OT}}{V_{CS}} m_{CS} (1-R) - \frac{K_{CS \leftrightarrow OT}}{V_{OT}} m_{OT} \tag{3}$$

m_{CS}, m_{RCS} and m_{OT} are the mass of drug (in mg) in the CS, RCS and OT compartments. $\dot{m}_{IV}$ is the intravenous (IV) infusion rate of vancomycin (in mg/h) administered to the patient, R is the fraction of vancomycin bound to blood proteins, $Q_{CS \leftrightarrow RCS}$ is the volumetric flow (mL/h) of plasma that reaches the kidneys, and $K_{CS \leftrightarrow OT}$ is a mass transfer

coefficient (mL/h) related to capillary exchange. Finally, V_{CS}, V_{RCS}, and V_{OT} are the volumes (mL) of plasma or interstitial fluid in the corresponding compartments.

Q_{GFR} is the volumetric GFR and is estimated via the CKD-EPI equation (Levey et al., 2009) as a function of sex, age, serum creatinine, and body surface area (BSA), which in turn depends on the height and weight of the patient. The plasma flow to the kidneys $Q_{CS \leftrightarrow RCS}$ is calculated as 19% of the overall cardiac output, which is estimated as $3.5\,BSA$ (Cowles et al., 1971) multiplied by the average volumetric fraction of plasma in the blood, *i.e.* 0.53 for men and 0.58 for women.

The plasma volumes of CS and RCS are evaluated from the total mass of blood as a function of weight (Brown et al., 1997), its density (Vitello et al., 2014), and the fraction of blood that is contained in the RCS (Leggett et al., 1995). According to Butterfield et al. (2011), the average factor for vancomycin protein binding R is 0.415.

Since vancomycin poorly diffuses into bones, CNS, and lungs (Giuliano et al., 2010), these elements were excluded from the OT compartment. Following the approach of Abbiati et al. (2016), both mass and density of the overall OT compartment were estimated from Brown et al. (1997) as 70.3% of the total mass and 1.005 g/mL respectively. The OT compartment volume is estimated as their ratio.

The total flow exchanged at the capillaries is proportional to the global capillary exchange area and therefore to the number of capillaries in the body. Therefore, $K_{CS \leftrightarrow OT}$ is assumed to be proportional to the estimated OT compartment mass (Eq. 4).

$$K_{CS \leftrightarrow OT} = m_{OT} \cdot k_{CS \leftrightarrow OT}^{m} \tag{4}$$

For the sake of simplicity, we assume that $k_{CS \leftrightarrow OT}^{m}$ is constant for all the individuals and its value is identified via a nonlinear regression of clinical data. To minimize the distance between the simulated PK profiles and the measured values of vancomycin plasma concentration, the weighted sum of squared errors (SSE) between each experimental and simulated value j (over the N_i^{exp} values), for each patient i (over the N_P patients), is minimized (Eq. 5).

$$\min_{k_{CS \leftrightarrow OT}^{m}} SSE = \frac{1}{N_P} \min_{k_{CS \leftrightarrow OT}^{m}} \sum_{i=1}^{N_P} \left(\frac{1}{N_i^{exp}} \sum_{j=1}^{N_i^{exp}} \left(\frac{c_{CS,ij}^{sim} - c_{CS,ij}^{exp}}{c_{CS,ij}^{exp}} \right)^2 \right) \tag{5}$$

The proposed model is not a physiologically-based pharmacokinetic (PBPK) model, as it features a basic 3-compartment structure and lumps all the organs and tissues of the human body other than the kidneys in just one compartment. However, its description is consistent with the physiological processes in the human body and this allows determining quantitatively the whole set of model parameters but one, *i.e.* $k_{CS \leftrightarrow OT}^{m}$.

The experimental data were extracted from Turner et al. (2018), who published rich pharmacokinetic data of experimental vancomycin profiles for a heterogeneous population of critically ill patients in an intensive care unit (ICU). Vancomycin was administered with periodic infusions at a maximum rate of 1000 mg/h. Each patient received a different dose intravenously (in the range 500-1750 mg) over 0.7-2 h intervals. After a specific period (8, 12 or 24 h), a new cycle was repeated. The desired therapeutic target was to maintain vancomycin concentration above the 15-20 mg/L threshold for the whole time interval. This target, called trough concentration, can be achieved with periodic infusions (*e.g.*, 0.7-2 h) over long time intervals (*e.g.*, 8-24 h) as the elimination

half-life of vancomycin is about 6-12 h (Rybak, 2006).

The initial values of CS concentration were linearly extrapolated from the two initial experimental points in Turner et al. (2018), and the initial RCS concentration was approximated with the CS one (due to the lack of further details in the experimental data). As far as the initial OT concentration values are concerned, the experimental points were collected from patients that had already received at least three successive vancomycin doses. To estimate the accumulation of vancomycin in the OT compartment, three consecutive cycles were simulated, each time using the final OT concentration as the next OT initial condition for the following simulation to achieve a plausible initial value.

3. Results

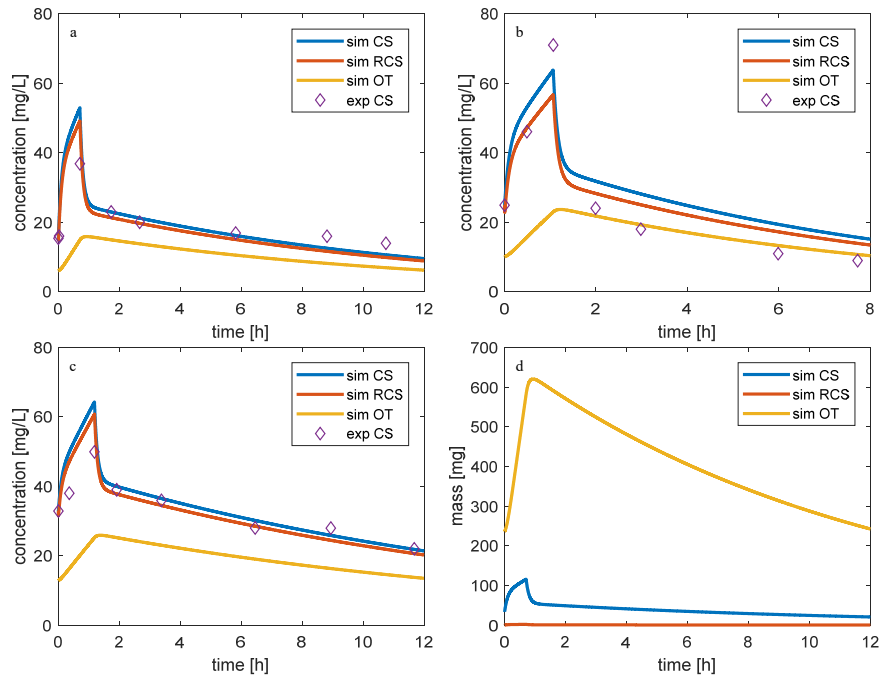
The regression was performed using the data of five patients from Turner et al. (2018) and yielded a value of 843.68 mL/h/kg for $k_{CS \leftrightarrow OT}^m$. For the sake of space, Figures 2 (a-c) show the simulated concentration profiles in CS, RCS, and OT and the experimental CS measures of three of the patients. As SSE (the average squared relative error for each experimental point, see also Eq. 5) is pretty low (0.1440), the regression is considered successful. Accordingly, Figures 2 (a-c) show a good fit of the experimental data. Figure 2 (d) shows the simulated time-profiles of drug mass over the three compartments for just one patient.


Figure 2 – (a-c) Simulated and experimental vancomycin concentration for patients #1-3. (d) Simulated mass profiles in the three compartments of the PK model for patient #1.

Once successfully identified, the model was employed to investigate the effect of the degree of renal function. Thus, we simulated the CS concentration dynamics of a specific

virtual patient for a fixed vancomycin dose at different GFR degrees. The simulated individual was determined from the average characteristics of the abovementioned 5 patients: male, 57.8 years old, 85 kg, and 174 cm. This virtual patient received an infusion of 1000 mg over 1 h. The initial values of CS and RCS were assumed equal to 20 mg/L, whereas the initial OT concentration was estimated by simulating three previous cycles. The simulated GFR range (29-199 mL/min) is the same of patients from Turner et al. (2018), estimated according to the CKD-EPI equation. The results highlight simulated curves which vary widely for different values of GFR, as shown in Figure 3. In case of the highest GFR considered, for example, the peak and trough concentrations are 46.72 and 10.40 mg/L respectively, whereas in case of the lowest GFR they are 88.58 and 55.98 mg/L. It is worth observing that the simulated dose does not allow respecting the target trough concentration in case of the two highest GFR values, whereas it would lead to excessive vancomycin levels for the two patients with the lowest GFR. Horey et al. (2012) report a significant occurrence of nephrotoxicity (81.8%) when trough levels are higher than 35 mg/L.
Figure 3 – Simulated plasma concentration of vancomycin for a virtual averaged patient as a function of their GFR (mL/min). The horizontal dashed line is the target trough concentration.

Finally, the PK model is used to find the optimal dose for the averaged individual, as a function of their GFR. A fixed infusion rate of 1000 mg/h is administered *in silico* for a varying time interval, with a period of 8 h between consecutive infusions. As in previous cases, we assume that the patient has already undergone three cycles and starts with an initial CS concentration of 20 mg/L. The dose is optimized individually so that the CS concentration at the end of the simulated interval is equal to 20 mg/L, which guarantees the target trough concentration. Table 1 reports the optimal doses, which display a marked difference (a ratio higher than 6) between the highest and lowest quantities of vancomycin to be administered. Over 24 h, the simulated doses cover the 924-5667 mg range, which is comparable with the 1000-5250 mg range reported in Turner et al. (2018).

Table 1 – Optimal vancomycin doses for a virtual averaged patient as a function of their renal function (estimated via GFR).

GFR [mL/min]	29	72	114	157	199
Optimal dose [mg]	308.0	593.9	964.6	1403.8	1889.0

4. Conclusions

Whenever renally-excreted drugs are concerned, the degree of renal function must be taken into account to determine the optimal dose for individual administration. In fact, as

shown in Figure 3, the degree of renal function dramatically influences the drug concentration profile. The administered drug dosages can be optimized for each patient according to their bodily characteristics (*i.e.* sex, age, weight, and height) and serum creatinine, by employing suitable PK models, which can lead to improved compliance with therapeutic targets and reduced side effects by avoiding excessive drug concentrations. The proposed PK model allows medical doctors improving the design of personalized clinical treatments.

Automating HAZOP studies using D-higraphs

Borja Martínez, [a] Manuel Rodríguez, [a*] Ismael Díaz, [a]

[a] Universidad Politécnica de Madrid, José Gutiérrez Abascal 2, 28006 Madrid, Spain

Abstract

In this paper we present a methodology to perform guided HAZOP studies using a functional modelling framework: D-higraphs. It is a formalism that gathers in a single model the functional as well as the structural information about the process considered of any given system. This tool uses an expert system to predict the behaviour of the modelled process in order to achieve a semi-automatic and systematic HAZOP analysis. In this paper it is applied to an industrial case showing the easy understanding of the proposed methodology and comparing the obtained results to those obtained conducting the HAZOP study in the conventional way.

Keywords: Functional modelling; HAZOP; Risk assessment.

1. Introduction

Throughout the history of the process industry there have been a lot of important aspects to be considered in the consequences of accidents: environmental impact, pollution, operators' occupational health and economy. This situation can involve lots of losses associated to shutdowns, reparations, compensations or fines, so avoiding accidents is not only a direct way to save money on losses, but also the incomes are increased because productivity does (De la Mata and Rodríguez, 2010).

According to the design stage of the process plant, Process Hazard Analyses (PHA) are carried out to identify the potential safety problems in order to provide possible solutions that enhance the safety of the plant, such as process changes, new control strategies or the use of safety instrumentation. There are a broad variety of methods but the most widely used is the Hazard and Operability Study (HAZOP) (Zhao et al., 2005). However, this technique consumes a lot of time an effort, so in the last decades a lot of work and resources have been put to develop tools and methodologies that automate this process.

Some of these tools are HAZOPExpert (Venkatasubramanian et al., 2000), PHASuite (Zhao et al., 2005), Functional HAZOP assistant (Rossing et al., 2010a, 2010b), Layered Digraph Model (Cui et al., 2008) and PetroHAZOP (Zhao et al., 2009).

In order to do this automation, expert systems (or production rule systems) are used to perform calculations functions of the causes and consequences due to a possible deviation that happened in the process, with a view to understand the severity of the situation.

In this work a new HAZOP assistant is developed based on a modelling technique called D-higraphs, which considers structural and functional information of the system under analysis. This methodology has been implemented using a production rule system called CLIPS (CLIPS, 2018). It has been applied to a standard scenario and its results are compared to those obtained doing the HAZOP study as usual.

2. D-higraphs: merging function and structure

2.1. Dualization: from Higraphs to D-higraphs

Higraphs are a general kind of diagramming objects well suited to specify the behavior of complex concurrent systems but not process system (Harel, 1987).

On the other hand, D-higraphs are an adaptation of Higraphs that consist of blobs, representing transitions, and edges, representing states. This adaptation of Higraphs was first presented in Rodríguez and Sanz (2009) as a modeling technique that merges functional and structural information of the system modeled.

It has to be noted that a D-higraphs is not a dual higraphs, obtained from changing blobs by edges and edges by blobs. The duality lies in their interpretation and properties.

2.2. Elements of a D-higraphs: Blobs and Edges

The two main elements of a D-higraphs are depicted in Figure 1, where the basic blob is represented in the left-hand-side, and the different types of edges are shown in the center. Blobs represent functions that are performed by an ACTOR producing state 2 if state 1 is enabled. Edges represent flows of mass, energy, or information, which are responsible of the interactions in a process system (Lind, 1994). The main properties of blobs and edges are described in De la Mata and Rodríguez (2010).
Figure 1. Basic blob and different types of edges.

2.3. Causal and qualitative reasoning

D-higraphs integrate a series of causation rules relating two events that allow us to track the evolution of failures across the system. These rules combined with sensor data of the plant enables the performance of Fault Detection and Isolation analysis using D-higraphs. However, certain analyses require the use of deviations and not only failures, like HAZOP studies. In a certain way, we need to simulate qualitatively the system in order to propagate these deviations. The description of a system is made in three different layers (Kuipers, 1984):

1. *Structural description*: described by variables, such as flow (F), pressure (P), temperature (T), composition (x), energy (E), information (I), level (L), valve opening (A), etc.

2. *Behavioral description*: potential behavior of the system as a network. The M^+ and M^- constraints (Kuipers, 1986) provide this information, but in some behaviors they need to be modified according to: M^{++}, M^{0+}, M^{-+}, M^{+0}, M^{00}, M^{-0}, M^{+-}, M^{0-} y M^{--}. The first sign shows the monotonicity for values under the expected one, and the other sign does for values above it. In Figure 2 some examples are shown.

3. *Functional description*: describes the purpose of a structural component and its connections provided by the D-higraphs layout.

The three layers of this representation are shown in the right-hand-side of Figure 1, where there is a physical device (DECANTER) whose main purpose is to *store liquid*. The decanter has two characteristic variables: level (Ld) and temperature (Td). Ld is affected by the inflow F3 with variations of the same sign (an increment of F3 increases Ld) and by the outflow F4 in the opposite way. In the same way, the flow F4 is affected by the level of the decanter in the same direction.
Figure 2. Some examples of the M constraints (De la Mata and Rodríguez, 2010).

3. D-higraphs and the CLIPS environment

The D-higraphs models are implemented using a graphic tool that has as input the P&ID of the process and it uses a D-higraphs built using a template (Álvarez, 2010). Once the model has been developed, it is loaded into the expert system that obtains the report of the deviation thanks to the rule database. The HAZOP study is performed feeding the deviations to the reasoning engine. The result of the analysis is provided to the user and it can be fed back in order to make changes into the process or D-higraphs.

CLIPS is the expert system that performs the analysis by entering the command "Assert" followed by the desired deviation, which is formed with a HAZOP guide word, and the process variable.

4. Case study

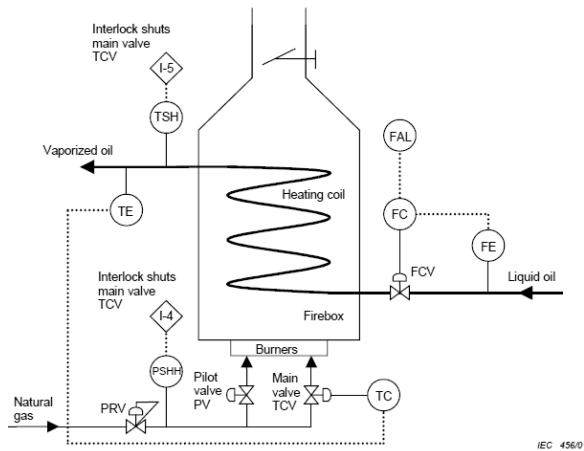
In this section, we present the oil vaporizer unit, which is designed to achieve superheated oil vapor from oil liquid, due to a furnace containing a heating coil and burners, where the natural gas combines with air to burn (BS IEC 61882:2001). To that end, this process uses two control loops: the first one has the goal to regulate the incoming oil flow, besides a low flow alarm of liquid oil, and the second one deals with the temperature of the outgoing vaporized oil flow manipulating the flow of natural gas to the burners. In addition to these control loops, there is an auto regulated valve that controls the pressure of the natural gas flow. A simplified P&ID of the unit is shown in Figure 3.


Figure 3. Oil vaporizer unit (BS IEC 61882:2001).

4.1. Functional decomposition

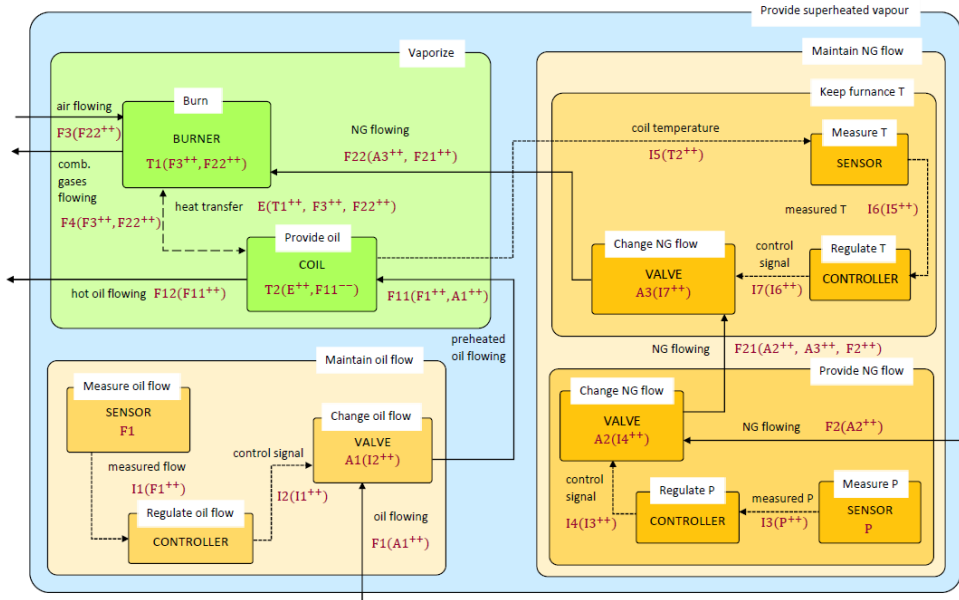
The main goal of the overall unit is to obtain oil vapor from the combustion between natural gas and external air, as said in the process description. To that end, the system can be decomposed into two subsystems that perform the necessary subgoals, in the following way: (1) Oil flow section: provide a constant feed of liquid oil and emerges vapor flow under operation conditions; (2) Burners section: provide through combustion the needed heat to vaporize the oil. This functional decomposition can be continued until the desired level of detail is obtained. Thanks to that and the P&ID, the D-higraphs can be developed. It is shown in Figure 4.


Figure 4. D-higraphs.

5. Hazop and D-higraphs results

In this section the results obtained for "No oil flow" deviation are shown. This deviation consists of the variable "oil flow" that passes through the heating coil and the HAZOP guide word "no". It should be noted that due to space constraints, only this deviation is shown, but the complete study has been conducted, applying all the HAZOP deviations.

5.1. HAZOP analysis

A modified table of the HAZOP report obtained for the case study is featured below in Table 1. It shows relevant details, such as the HAZOP team, the considered part of the process, the design intent and the deviation, which is where we focus on this paper. The HAZOP team points out that the main reasons for the lack of flow are due to a failure of the supply line, the flow control valve FCV or a failure of the vaporizer.

At the same time, the possible consequences of this deviation are reflected, where the overheating of the vaporizer is highlighted, as well as the safeguards and the actions required as preventive measures.

Table 1. Example HAZOP worksheet. No oil flow deviation (BS IEC 61882:2001).

STUDY TITLE: OIL VAPORIZER									
Drawing No. :					REVISION No.:			DATE:	
TEAM COMPOSITION: MG, NE, DH, EK, LB								MEETING DATE:	
PART CONSIDERED: Vaporizer coil from oil inlet (before flow measurement), to vapour exit to process (after temperature control)					DESIGN INTENT:	Inputs: Activities:	Oil flow from the feed line, heat from the furnace Vaporize, superheat and transfer oil vapour to the process		
No.	Guide word	Element	Deviation	Possible causes	Consequences	Safeguards	Comments	Actions required	Action by
1	No	Oil flow	No oil flow	– Supply failure – Flow control valve PCV closed	Vaporizer coil overheats and may fail	Low flow alarm FAL High temperature trip TSH	Safeguard depends on quick operator response	Consider low flow element FE to close main burner valve TCV	LB
				– Plugging of coil – Blockage down-stream of vaporizer	Oil in vaporizer will boil: Possible overheating and coking of heating coil	Low flow alarm FAL High temperature trip TSH		Check whether these safeguards are adequate and the ease with which the coil could be cleaned	NE

5.2. D-higraphs - CLIPS analysis

As it has been said before, once the topology and the rules of causes or consequences have been loaded, the analysis begins. For this, the "Assert" command is used, followed by the guide Word "No" ("Fail", in CLIPS) and the parameter "oil flow" ("hot_oil_flowing"). It is necessary to specify whether this variable belongs to an edge or blob. The CLIPS report is featured below.

```
CAUSES

CLIPS> (assert (Report))
<Fact-1>

[MEASURE_T]
[REGULATE_T]
[KEEP_FURNACE_T]
[CHANGE_NG_FLOW]
[BURN]

There have been double fail in:
[PROVIDE_OIL]

There have been triple fail in:
[hot_oil_flowing]
[coil_temperature]
[MEASURE _T]
[PROVIDE_OIL]

There have been quadruple fail in:
[measured_T]
[hot_oil_flowing]
[coil_temperature]

The Hazard Level of this fail is: 14
```

5.3. Comparing the results

According to the results, CLIPS is useful to show all those edges and blobs that are involved in the contingency created and it also lists a series of devices that are not present in the HAZOP report. However, CLIPS does not go into much detail of the type of failure. That is why this methodology is only helpful to find possible sources, such as [BURN], where it warns that the cause can be due to a failure in the device that provides the energy to oil. In the same way it happens with the consequences, where it also highlights multiple failures in edges and blobs, implying that those devices have a high importance. This guided HAZOP can save a lot of time to the HAZOP team and avoid missing some causes or consequences as it follow every possible path in the process.

6. Conclusions and further work

In this paper we have presented a methodology to perform systematic guided HAZOP studies based on D-higraphs. It has been applied to an industrial process in order to show its applicability and compare a traditional HAZOP study with CLIPS. The results are easy to understand and helpful in order to broaden the field of analysis of the process, to make it more complete and deeper, increasing thus the security of the analysis. On the other hand, future work will be devoted to the implementation of a "translator", which will transform P&IDs models to D-higraphs, avoiding the text template that can be a human error source, hindering its quick implementation. In addition, the rules of causes and consequences should be analysed to give more depth in the analysis of each HAZOP guide word and to increase the level of detail in the CLIPS report.

A Novel Optimizable Inherent Safety Index Based on Fuzzy Logic

Daniel Vázquez[a*], Rubén Ruiz-Femenia[a], José A. Caballero[a]

[a]Institute of Chemical Process Engineering, University of Alicante, PO 99, E-3080 Alicante, Spain

vazquez.vazquez@ua.es

Abstract

In our days, the concept of inherent safety is gaining popularity thanks to its ability to assess the safety level of a plant at an early design stage. Hence, safety can be considered one of the core design principles, instead of a post-design add-on. In this work, we propose a novel index to assess the inherent safety level of a design. This index is based on the principles of fuzzy logic, which allow the user to shift the importance in the safety criteria easily, and its main objectives is to provide an optimizable framework. In order to achieve an optimizable fuzzy index, some concessions must be made in its methodology. As such, the presented index is not as quantitative as other safety indexes. However, this shortcoming is compensated with the comparative ability and modifiability that this index provides the decision maker with. As a conclusion, we showcase the ability of this novel index in assessing the inherent safety level of an example case.

Keywords: Inherent Safety, Fuzzy Logic, Optimization.

1. Introduction

In order to consider the design of a chemical process from a holistic point of view, it is necessary to have a method able to assess the safety level of a plant at an early design stage. The concept of inherent safety, coined by Kletz (Kletz & Amyotte, 2010), presents itself useful for this objective. The four main principles of inherent safety are: intensification, substitution, attenuation and limitation. The consideration of these principles allows the designer to give safety aspects the same importance as economic and environmental issues. Therefore, safety is considered a key design variable, instead of an afterthought once the main variables are fixed.

Safety analysis tend to be performed with the aid of safety indexes, such as Dow's (AICHE, 1994) and Safety Weighted Hazard Index (Khan et al., 2001). Some techniques, like the Hazard and Operability (HAZOP) method, consist in a committee of experts discussing the weak and hazardous points of a design. They use keywords, such as "high" and "low", which cannot be immediately quantified. This methodology resembles spoken language, and the use of fuzzy logic allows the designer to assemble spoken language with mathematical quantifiable rules (Zadeh, 1999). In this work, we use Mamdani's method (Mamdani & Assilian, 1975) in order to extract mathematical information from keywords. Mamdani's method comprises four steps: fuzzification of the inputs, establishment of the relationships among the inputs and outputs, aggregation of the conclusions and defuzzification of the output.

A problem that many safety indexes exhibit is that the mathematical expressions to compute them are nonconvex. Since they work with multiple variables at the same level,

such as flows, temperatures, enthalpies and pressures, they must use nonlinear operators. More complex indexes that use dispersion models are highly nonlinear and nonconvex. Since this work has the objective of providing an optimizable index, the calculations must be maintained the most linear possible. The defuzzification step includes a nonlinear equation which is unavoidable, but the fuzzification and the relationships among fuzzy sets can be made completely linear with the inclusion of Generalized Disjunctive Programming (GDP).

Therefore, this work presents a novel optimizable (in the sense that it can be systematically optimized) inherent safety (in that it is calculated according to the principles of inherent safety) index based on fuzzy logic (which allows the user to connect keywords and establish relationships input-output maintaining a mostly linear model). The index is divided into sub-indices that account for each inherent safety principle. In this paper we present the sub-indices for intensification and attenuation. These are then part of a multi-objective optimization (MOO) problem.

2. Intensification sub-index

The intensification principle, also named minimization principle, is based on the core idea of diminishing the inventory inside a process unit. The inventory refers to both the amount of chemical in the unit (or exiting the unit in a period of time) and the amount of energy that these chemicals carry. The index is obtained as shown in Eq. (1).

$$II = (II_{energy} \wedge II_{inventory})$$ (1)

Where II stands for Intensification Index, II_{energy} stands for the part of the sub-index that takes into account the energy in the unit, and $II_{inventory}$ stands for the part of the sub-index that takes into account the amount of mass in the unit, as well as the streams that go out of the unit.
Each of these parts is calculated by an equation, shown in Eq. (2).

$$II_{energy} = \sum_{i=1}^{C} \Delta Hc_i x_i + \Delta Hr$$

$$II_{inventory} = FE \, V \cdot \rho + \dot{m}_{t=10min}$$

(2)

Where:

-   ΔHc_i stands for the combustion enthalpy of the chemical i of C components in the unit, in kJ/kg.

-   ΔHr stands for the reaction enthalpy in the unit, if a reaction is happening, in kJ/kg

-   x_i stands for the mass fraction of the chemical $i \in C$ inside the process unit.

-   FE, V, ρ stand for the equipment factor, volume and density respectively. The equipment factor is a parameter that relates the volume of the unit with the amount of chemical inside. An example is 0.8 for reactors and tanks. If you are

using the volume of chemical directly, its value is 1. The units of the volume and density are m^3 and kg/m^3 respectively.

- $\dot{m}_{t=10min}$ stands for the mass of chemical that leaves the process unit in a time interval of ten minutes, in kg.

In order to continue Mamdani's method, we have to fuzzify the input values for both parts of the index. As such, an interval must be fixed by the designer. Then, a fuzzification function is used to assign a membership value to each crisp input. It is recommended to use linear functions, such as the triangular or trapezoid functions. An example of fuzzification for both parts of the sub-index is shown in Table 1.

Table 1. Fuzzification of the input. Intensification index.

Semantic pointer	Range	Fuzzification function
Low (L)	0 – 60 % of the interval	Gaussian
Medium (M)	5 – 95 % of the interval	Triangular
High (H)	40 – 100 % of the interval	Gaussian

While the Gaussian function is nonlinear, it is chosen in this work as an example of how, the index is still able to provide a satisfactory result even when dealing with more nonlinearities than the one strictly needed. These intervals are examples. The safety experts of the plant must decide how many intervals are necessary and how wide they are in order to correctly classify the safety level of the design.

The experts must define as well the relationships between the two parts of the sub-index (Eq. (1)). Some decision making techniques, such as Analytical Hierarchy Process, can be useful to ensure that the relationships remain coherent. Each relationship has to be assigned to an output fuzzy set. For example, in order to illustrate this, in this work the relationships are shown in Table 2.

Table 2. Relationships among inputs

Output fuzzy set / Risk level	Implications ($II_{energy} \wedge II_{inventory}$)
Minimal	$(L \wedge L)$
Low	$(L \wedge M) \vee (M \wedge L)$
Medium	$(M \wedge M) \vee (L \wedge H) \vee (H \wedge L)$
Moderate	$(H \wedge M) \vee (M \wedge H)$
High	$(H \wedge H)$

In order to defuzzify the output, we need to know how these output fuzzy sets are created. The chosen outputs of the intensification index are fuzzified as shown in Table 3.

Table 3. Fuzzification of the output

Semantic Pointer	Value of the index	Fuzzification function
Minimal Risk	0 – ~10	Gaussian
Low Risk	4 – 15	Triangular
Medium Risk	15-35	Triangular
Moderate Risk	35-45	Triangular
High Risk	~40-50	Gaussian

After the step of aggregation, we obtain an aggregated output that can be defuzzified using a centroid.

3. Attenuation sub-index

The attenuation principle is based on the idea of diminishing the hazardous conditions during operation. As such, the main variables considered for its calculation are the operating temperature and the operating pressure, although these are not the only parameters that the index takes into account.

The methodology is analogous to the intensification sub-index one. As such, we present only the equations and example fuzzification intervals and relationships.

The equations are as shown in Eq. (3) and Eq. (4)

$$AI = (AI_T \wedge AI_P) \tag{3}$$

Where AI_T stands for the part of the index that depends on the temperature parameters

and AI_P stands for the part of the index that depends on the pressure parameters.

$$
\begin{aligned}
AI_T &= T_{op} + Pen_T \cdot \max(0, T_{op} - T_b) - Rw_T \cdot \max(0, T_b - T_{op}) \\
AI_P &= P_{op} + Pen_P \cdot \max(0, P_{vap} - P_{op})
\end{aligned} \tag{4}
$$

Where T_{op}, T_b stand for the operating temperature and the boiling temperature in ºC and

P_{op}, P_{vap} stand for the operating pressure and vapour pressure in bar. Pen_T , Rw_T and

Pen_P are penalization and reward parameters that reward the unit when working with subcooled liquids and penalize it when it works with overheated vapours. In this work, their values are set to 0.5, 0.1 and 0.5 respectively.

A possible fuzzification is shown in Table 4.

Table 4. Fuzzification of the input. Attenuation index.

Semantic Pointer	Range in temperature (ºC)	Range in pressure (bar)	Fuzzification function
Atmospheric (A)	~30	~1.5	Gaussian
Low (L)	10 – 50	1 – 6	Triangular
Medium (M)	40 – 80	4 – 10	Triangular
High (H)	70 - > 100	8 -> 12	Gaussian

A possible set of relationships is shown in Table 5.

Table 5. Relationships among inputs. Attenuation index

Output fuzzy set/ Risk level	Implications ($AI_T \wedge AI_P$)
Minimal	$(A \wedge A) \vee (A \wedge L)$
Low	$(L \wedge L) \vee (L \wedge A) \vee (A \wedge M) \vee (L \wedge M)$
Medium	$(M \wedge M) \vee (A \wedge H) \vee (M \wedge L) \vee (L \wedge H) \vee (M \wedge A)$
Moderate	$(H \wedge A) \vee (H \wedge L) \vee (M \wedge H)$
High	$(H \wedge H) \vee (H \wedge M)$

The fuzzification of the output is analogous to the one shown in Table 3.

4. Example and Results

We consider a number of units that work with certain operating conditions. No reaction is occurring inside these units. The properties of the chemicals inside the units are shown in Table 6.

Table 6. Data of the example case

Properties	Unit #01	Unit #02	Unit #03	Unit #04	Unit #05	Units
$\sum_{i=1}^{C} \Delta Hc_i x_i$	14.25	17.20	10.43	8.29	5.34	MJ/kg
$FEV \cdot \rho$	20000	15000	34000	10000	5000	kg
$\dot{m}_{t=10min}$	3000	2000	2000	1000	3000	kg
T_{op}, T_b	50, 50	30, 60	50, 30	40, 70	80, 40	ºC
P_{op}, P_{vap}	1, 1	3, 2	4, 6	8, 7	8, 12	bar
Inventory range			$0-40$			t
Energy range			$0-20$			MJ/kg
Temperature range			$0-100$			ºC
Pressure range			$0-12$			Bar

We consider the global index as the aggregation of both the intensification and attenuation sub-indices. The resultant optimization model, based on Generalized Disjunctive Programming (GDP), is a Mixed Integer Non-Linear Programming (MINLP) problem. The nonlinearities are found in the defuzzification of the output step, which is performed using the centroid, and in the Gaussian fuzzification functions of the inputs. The rest of the calculations are linear. The results are shown in Table 7.

Table 7. Results of the optimization

Order from best to worst	Global Index	II	AI
Unit #02	39.86	29.98	9.88
Unit #04	43.40	20.22	23.18
Unit #03	52.74	32.74	20.00
Unit #01	53.10	28.11	24.99
Unit #05	66.26	16.27	49.99

It can be observed that the index is able to rank the different process units regarding its inherent safety level. In this example, an aggregation of both the intensification sub-index and the attenuation sub-index is performed. This is not the only option, since there are multiple possibilities to treat MOO problems. Another alternative is a weighted sum, giving more importance to one sub-index over the other. It is the duty of the decision maker to assign the correct importance to each sub-index.

An important remark is the case of Unit #05. Its attenuation sub-index has a value of practically 50, which is the highest value that the index achieves. If we look at the definition of the fuzzy sets for the input, Table 4, we can see that the high semantic pointer (H) starts at around 70 ºC and 8 bar. If we apply Eq. (4), we obtain the values of $AI_T = 100$ ºC and $AI_P = 10$ bar. While the temperature part of the attenuation index is indeed at its maximum allowed by the chosen range, the pressure part stills has room for an increment. However, any higher pressure, e.g., 11, 12 bar, will still result in an index of 50. This nuance shows that the decision maker must choose carefully the range of the intervals and the fuzzification functions of the inputs, as well as its ranges.

5. Conclusions

In this work we present the initial step in creating a novel inherent safety index based on fuzzy logic. The index is divided in sub-indices that refer to each main principle of inherent safety. The use of fuzzy logic allows the user to maintain a mostly linear model, which can be made strictly linear except for the objective function. It also allows the user to easily and quickly change parameters in order to fit the index to different problems. This is both an advantage and a disadvantage. While the modifiability of the index increases its versatility, it also forces the user to know the system of possibilities beforehand. Ranges must be chosen regarding the corresponding problem at hand, and so must be the relationships. The user has to know where to put more emphasis in the safety analysis. In some units, it may be better to give more importance to the pressure than to the temperature, and this must be reflected in the chosen relationships among input fuzzy sets.

The index proves its efficiency as an optimizable inherent safety index able to rank alternatives depending on their safety level. While its main use is comparative, due to the fact that each sub-index depends on a series of user-chosen parameters and ranges, with the appropriate considerations, i.e., relationships and ranges, it could be used as a global index for a process, with the advantage of being systematically optimizable and modifiable. For future works, it is intended to implement an analogous methodology to obtain an index for the substitution index, using the NFPA(2012) standard as the main variable.

Abstract

Computer-aided modelling and simulation are effective tools to provide guidance in the design of clinical experiments and treatments. Simulations with physiologically-based pharmacokinetic (PBPK) models combine the drug material balances within the body to its real physiological and anatomical features and can be used to optimize drugs dosing and administration timing. We focus on melatonin administration to critically ill patients, a challenging population because of their high inter-individual variability in the pharmacokinetics (due to their heterogeneous and severe conditions). We show how the optimization problem can be suitably formulated to tackle this uncertainty, and compare the results obtained for critically ill patients and healthy individuals. The approach can be easily transferred to any other drug routinely administered in intensive care units whenever a desired pharmacokinetic profile is available.
Keywords: optimization, modelling, simulation, uncertainty, pharmacokinetics.

1. Introduction

Recent years have seen an increasing interest in melatonin. Although it is particularly well-known as a cure for sleep disturbances and restoration of circadian rhythms, researchers are investigating additional physiological and pathophysiological functions. Indeed, there is evidence of anti-cancer, anti-oxidative, anti-inflammatory, and analgesic properties (Brzezinski, 1997). Healthy individuals produce melatonin endogenously by means of the pineal gland according to the day-night rhythm. Melatonin production onsets with darkness (around 9-10 PM) and peaks at 2-4 AM. Healthy plasma peak levels are in between 60-100 pg/mL. After the peak, melatonin levels settle to the low daily baseline (5-10 pg/mL). Collaboration with Intensive Care Unit (ICU) of Ospedale San Paolo di Milano (Italy) allowed focusing on critically ill patients. Such patients exhibit disorders in melatonin secretion rhythm and/or lower levels compared to healthy individuals. This phenomenon is correlated to the lack of sleep, which likely increases both patients' morbidity and probability of mortality. There is evidence that exogenous melatonin has beneficial effects on these patients, mainly for treatment of sleep disorder, delirium, and oxidative stress (Bourne and Mills, 2006; Mistraletti et al., 2010). Several studies investigated the optimal dose with the purpose of reproducing the desired physiological levels of melatonin and proposed different doses (regimens) to restore the healthy endogenous rhythm. While physiological levels are desirable to restore circadian rhythms, pharmacological levels (*i.e.* supraphysiological levels, for instance about 3 orders of magnitude higher) are more suitable for anti-oxidant or anti-cancer purposes (Reiter et al., 2014). We show that computer simulation is an efficient tool to design and/or integrate such pharmacokinetic (PK) studies, with the advantage of reducing times

and costs of the experiments. In addition, simulations using physiologically-based pharmacokinetic (PBPK) models allow comparing and evaluating the pharmacokinetics from not only different doses but also routes of administration. In fact, our first goal is to select the administration route that best mimics human physiological levels. Subsequently, we focus on that route and optimize dosing, also by comparing results for healthy individuals (by neglecting the endogenous contribution for the sake of clarity) and critically ill patients. The main issue with critically ill patients is that they are intrinsically rather heterogeneous, because of their different conditions (*e.g.,* age, dysfunctions, organs failure) (Mistraletti et al., 2010). This feature enhances inter-individual variability of melatonin pharmacokinetics. To deal with this problem, we propose a prospective approach to drug dosing optimization.

2. Methods

Figure 1 shows the structure of a multi-route compartmental PBPK model. The reference model for this work is Abbiati et al. (2016), where organs and tissues of the human body are represented by homogenous compartments. We complemented those compartments number and model structure to melatonin features and administration routes, by adding (i) the pineal gland, which is the source of endogenous melatonin, and (ii) the salivary glands (Savoca et al., 2018). A further equation accounts for the dynamics of main melatonin metabolite: 6-sulfatoxymelatonin (aMT6s) both in plasma and in urine. In case of oral administration (PO, *per os,* see also Figure 1), the model consists of material balances on either single or lumped homogenous compartments.

$$\begin{cases} \dfrac{\partial C_i(t,x)}{\partial t} = D_i \dfrac{\partial^2 C_i(t,x)}{\partial x^2} & 0 \le x < h_i \\ C \\ C_i\,(x = h_i) = k_i C_{i+1} \end{cases}$$

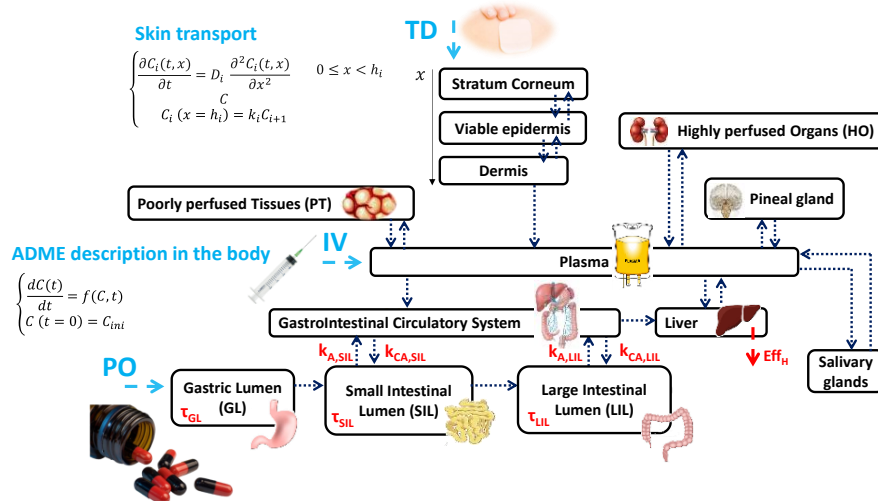
$$\begin{cases} \dfrac{dC(t)}{dt} = f(C,t) \\ C\,(t = 0) = C_{ini} \end{cases}$$


Figure 1 - Scheme of the PBPK model for description of melatonin ADME processes. Parameters in red are associated to the main processes responsible for inter-patient variability. While skin transport is described via PDEs discretized with respect to skin depth *x*, the other body compartments feature melatonin material balances in the form of ODEs.

These are the gastric lumen (GL), the small and large intestinal lumina (SIL and LIL), the gastrointestinal circulatory system (GICS), the plasma, the liver, the poorly perfused tissues (PT, lumping adipose tissue, skin, and muscles), and the highly perfused organs

(HO, lumping brain, lungs, and spleen). In case of intravenous (IV) route, the gastrointestinal compartments are neglected. Finally, in case of transdermal (TD) administration, skin is assumed as a separate compartment from PT and described by a set of partial differential equations (PDEs) with proper boundary conditions for skin TD absorption. The model features three skin layers: (i) stratum corneum, (ii) viable epidermis (also a metabolism site), and (iii) dermis, from which the drug is supposed to reach the systemic circulation. These PDEs are discretized with respect to the spatial coordinate (*i.e.* skin depth) and converted to ODEs and merged to those of the other compartments (Savoca et al., 2018). Model parameters include (i) individualized and assigned parameters that are either calculated as a function of patient's characteristics or found in the literature, and (ii) adaptive parameters (*e.g.,* diffusivities, transfer coefficients, metabolic constants) that are obtained via a non-linear regression of experimental data from the literature. Firstly, we use the multi-route PBPK simulations to compare levels resulting from PO, IV, and TD administration routes. Secondly, we perform an optimization based only on PO controlled release (CR), as it resulted the most suitable to mimic endogenous pharmacokinetics. Based on experimental release curves from the scientific literature, the optimal melatonin amount and time of administration are identified for three *in silico* individuals, (i) a healthy male, (ii) a healthy female, and (iii) an ICU patient. The PBPK model parameters for healthy individuals are identified with melatonin PK experimental data of healthy volunteers. Equally, the parameters that describe the PK of ICU patients are identified via regression with experimental data of the critically ill.

To account for considerable inter-individual variability, the optimization problem considers the uncertainty related to the (patho)physiological differences of such patients. The processes that most likely produce inter-subject variability are (i) absorption from the intestinal walls into gastrointestinal circulation (characterized by absorption constants $k_{A,SIL}$, $k_{A,LIL}$, $k_{CA,SIL}$, and $k_{CA,LIL}$ and residence times in gastrointestinal region τ_{GL}, τ_{SIL}, and τ_{LIL}) and (ii) hepatic metabolism (described by hepatic efficiency Eff_H). These model parameters are randomized within a proper range, which is chosen referring to physiology for the transit times, and model uncertainty for the others, to produce different PK profiles for the ICU virtual patient, VP. These additional NS "scenarios" embody the structure of the optimization problem in Eq. (1), where NM is the number of experimental data C_i^{ideal} that describe the healthy endogenous plasma concentration profile (Voultsios et al., 1997). The degrees of freedom are: *dose* and t_{adm} (*i.e.* timing of administration).

$$\min_{dose, t_{adm}} \sum_{k=1}^{NS} \left(\frac{\sum_{i=1}^{NM} \left(C_i^{ideal} - C_i^{VP,k} \right)^2}{NM} \right) \tag{1}$$

3. Results

3.1. Comparison of administration routes

The physiochemical properties of melatonin (*e.g.,* lipophilicity and low molecular weight) make it suitable for at least three administration routes, *i.e.* PO, IV, and TD. As far as the PO route is concerned, we consider both immediate and controlled release (CR) formulations. Figure 2 allows comparing the pharmacokinetics of these different routes under the same melatonin dose (1.5 mg in the left panel, 12 mg in the right panel). The characteristic slowness of TD absorption is particularly appropriate to mimic the sustained endogenous levels produced by the pineal gland. Equally, the PO (CR)

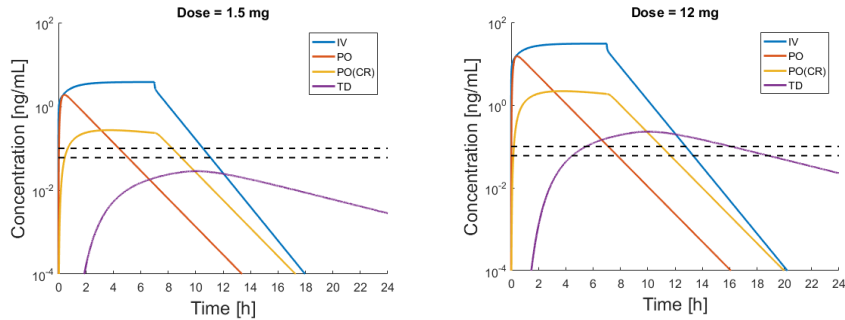
formulation provides continued levels (T_{max} about 4 h), coupled with a steeper absorption.


Figure 2 – PK simulations of a healthy individual with IV, PO (immediate release and controlled release (CR) formulations), and TD administrations of melatonin. Black dashed horizontal lines show the range of concentration peak after healthy endogenous production (60-100 pg/mL).

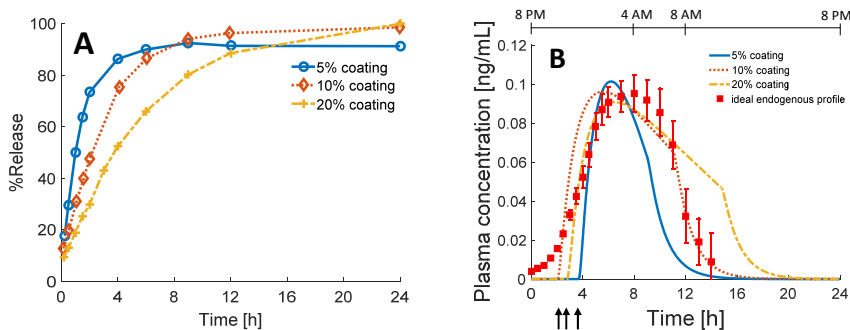
The difference in the velocity of early absorption affects the selection of the optimal administration timing as it affects the onset time of the pharmacological and physiological effects. Predictably, even low doses of continuous IV infusion produce the highest levels, thus it is probably the most appropriate to achieve prompt pharmacological (*i.e.* supraphysiological) levels. On the contrary, TD administration should be excluded for that purpose, even in case of higher doses. In case of PO immediate-release formulation, the melatonin concentration decreases rapidly after administration. However, even for low doses, this administration formulation allows reaching pharmacological levels, alternatively to IV infusion. This conclusion is in line with experimental studies where oral doses higher than 0.3 mg produce supra-physiological levels.


Figure 3 – (A) Experimental release curves for different formulations, as in Lee et al. (1995). (B) Optimized PK levels (continuous, dashed, and dotted lines) in ICU and ideal (experimental) healthy endogenous data (red squares). Black arrows indicate optimal timing of administration.

3.2. Optimization for PO CR route

Panel A of Figure 3 compares three PO (CR) formulations with different percentages of polymer coating (5-10-20%) that generate three different release curves as in Lee et al. (1995). Panel B of Figure 3 shows experimental data of the endogenous profile of an healthy individual (red squares, from Voultsios et al. (1997)), while continuous, dotted, and dashed lines are the optimized pharmacokinetics of an ICU patient who receives tablets featuring the three different release curves. The most suitable release curve

corresponds to the 10%-coating tablet that best approaches the PK endogenous profile.
Figure 4 – Optimal melatonin dose (left panel) and timing of administration (right panel) for HM and HF (healthy male and female individuals) and ICU (critically ill patient). Dashed horizontal line (right panel) indicates the desired time of onset of melatonin effects.

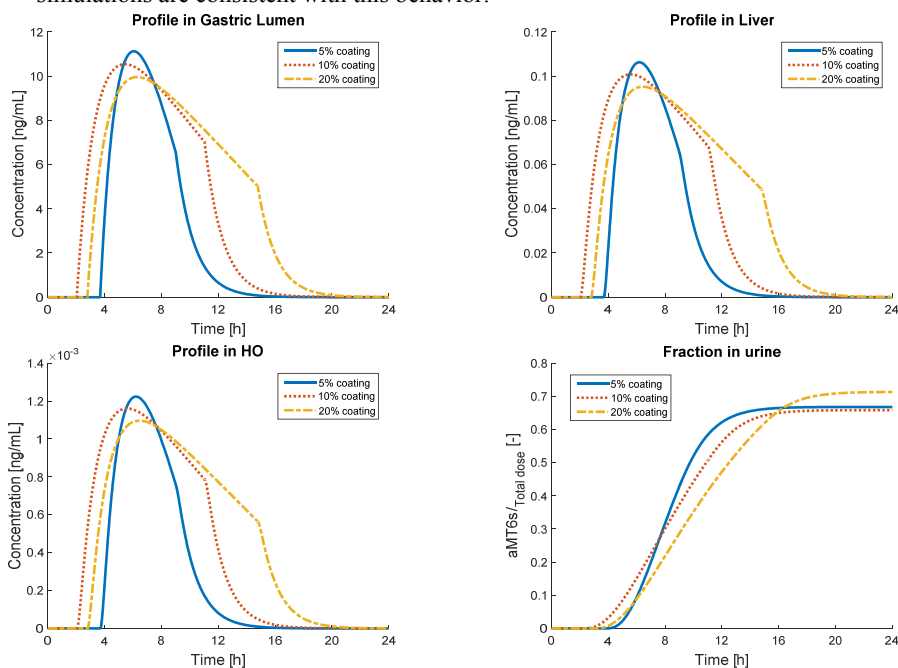
Figure 4 shows the melatonin optimal doses and timing of administration. On the x-axis, HM and HF stand for the male and female healthy individuals, while ICU stands for the critically ill patient. It is worth noticing that the lowest dose is associated to the ICU patient. Indeed, for the same dose, PK studies show higher melatonin concentrations in critically ill patients, compared to healthy individuals. Probably, the continuous enteral nutrition of ICU patients facilitates melatonin absorption. Notably, PBPK model simulations are consistent with this behavior.


Figure 5 - PBPK model simulations for the critically ill patient in Gastric Lumen, Liver, HO (Highly perfused Organs), and aMT6s fraction in urine.

In addition, optimal dose values for the healthy individuals are in line with the results of experimental studies (as already mentioned, oral doses higher than 0.3 mg produce

supraphysiological levels). Our results are not so far from this approximate value. Figure 4 (right panel) shows the optimal timing of administration in relation to the desired onset time for melatonin effects (see the horizontal dashed line at 0). In case of 10%-coating, the optimal administration timing for the ICU patient is about 30 min before the desired onset, while it is shorter for healthy individuals. This is consistent with the fact that critically ill patients exhibit higher levels of melatonin after exogenous administration. In all the other cases, to mimic the endogenous profile optimally, the administration timing should occur *after* the desired onset time, which evidently makes no sense. This confirms that the 10%-coating formulation is the most optimal to deliver physiological levels of melatonin. Finally, Figure 5 shows melatonin PK simulations in different compartments (*i.e.* Gastric Lumen, Liver, and HO, Highly perfused Organs) and the eliminated amount of melatonin metabolite, aMT6s, after the optimal administration of PO (CR) formulation to the ICU patient. Low levels in HO are consistent with the typical tissue hypoperfusion of critically ill patients. Experimentally, the eliminated melatonin is usually higher than 85%, while this threshold is not reached in our simulations. This may be related to two different reasons: (i) from the modeling point of view, our model underestimates aMT6s metabolic production as we consider (for simplicity) the liver contribution only, (ii) from the physical point of view, ICU patients may exhibit lower metabolism compared to healthy patients.

4. Conclusions

PBPK model simulations are an effective tool in melatonin optimal pharmacotherapy. We optimized melatonin dosing by comparing healthy individuals and critically ill patients. As the latter ones represent an extremely heterogeneous population, we proposed an approach that allows accounting for inter-subject variability generated by the gastrointestinal absorption and metabolic processes. Results are in line with conclusions from past experimental PK studies and can provide aid in future study for the challenging identification of melatonin optimal dose regimens in critically ill patients.

Abstract

In this work is presented the simultaneous optimization of design parameters and control properties, using a stochastic method named Differential Evolution with Tabu List Algorithm, as study case the reaction zone in the production process of furfural from biomass. In the objective function, the Total Annual Cost, eco-indicator 99 and condition number are combined as economic, environmental and control criteria respectively. From the multi-objective optimization, results show the direct influence that design parameters have over the control properties having an antagonist behaviour. As consequence, it is possible to see that to have the best control properties there is an increase in TAC and eco-indicator. Based on results, operating conditions founded allows having an acceptable furfural production of 2014.4 $^{kg}/_h$ by reducing costs in a 39% and environmental impact in a 42% in a system with good control properties in dynamic state.

Keywords: Furfural, Optimization, Total Annual Cost, Eco-Indicator99, Control Properties.

1. Introduction

Furfural is a chemical compound produced by biomass rich in pentoses content in the hemicellulose as raw material, in a reaction catalysed in presence of strong acids. Is used as a potential platform to produce biofuels. In recent years, furfural has received special attention as a potential platform to produce biofuels and biochemicals. In a study conducted by the Department of Renewable Energy of the United States, furfural was selected as one of the 30 main chemicals that can be manufactured from biomass (Cai et al., 2014). Industrially, it is a very versatile chemical because of its multiple applications: utilized as a raw material to produce phenol-furfural-resins (Brown, 1959), or can be converted furfuryl alcohol, tetrahydrofurfuryl alcohol, furan, tetrahydrofuran and diols (Bhogeswararao, 2015). The Quaker Oats process is the oldest commercial form of producing furfural industrially. This process was created by the Quaker Oat company using oat cereal waste as raw material, which is mixed with sulfuric acid. The process consists in two steps, first the reaction zone in which the biomass reacted with a solution of sulfuric acid to convert the xylan fraction into furfural, then high vapour

stream is introducing to the reactor to remove the furfural as fast as possible in order to avoid furfural polimerization (Marcotullio, 2011). The vapor stream from the reactor is condensed to feed the azeotropic distillation sequences in order to remove the excess of water and some by-products such as methanol and acetic acid (Marcotullio, 2011).

Under the economy circle concept, the study of the reaction zone in the production of furfural is important because it allows to reduce the excessive use of water, high energy consumption and the formation of decomposition products by reducing the separation costs. In this work aims to present a novel proposal for the simultaneous optimization having as objective function TAC as economic criteria, Condition Number as a control indicator and EI99 as environmental conditions in order to improve reactor productivity in the reaction zone in the furfural production process. So far, there are no publications reported in the literature where the multi-objective optimization methodology for the furfural reaction zone is solved.

2. Methodology

In this work it is consider as raw material, stem of date-palm tree with a composition of: cellulose (glucan) 66.6 wt%, hemicellulose (xylan)14.52 wt%, lignin 13.72 wt% lignin. Experimental data are taken from Bamufleh et.al (2013) to propose a kinetic model and parameters. The model proposed, is analogous to the proposed by Saeman, (1945) on the hydrolysis of cellulose catalyzed by dilute sulfuric acid. In the proposed reaction, furfural is obtained from xylan and the furfural reacts to form the corresponding decomposition products such as methanol and acetic acid (Marcotullio, 2011). For simplicity, decomposition products are condensed in a unique expression as is shown in Eq. (1).

$$\text{Xylan} \xrightarrow{\ r_1\ } \text{Furfural} \xrightarrow{\ r_2\ } \text{Decomposition Product} \tag{1}$$

The r_i value it is expressed as Eq. (2). Kinetic parameters k_o, b and E were estimated with experimental data reported by Bamufleh using the Curve fitting tool from the software Matlab. From Eq. (1), it is reported two reaction rates, which kinetic parameters estimated are: k_{o1}=6.24x10^8 ± 2.28x10^9 (min^{-1}), b_1=1.20 ± 0.21, E_1=93.44 ± 11.16 (kJ/mol), k_{o2}=1.74 ± 7.33 (min^{-1}), b_2=2.06 ± 0.56 and E_2=33.63 ± 11.72 (kJ/mol). The adjustment has a correlation coefficient of 0.96447, indicating a good parameter fitting.

$$r = k_o Ch^b \exp\left(\frac{-E}{RT}\right) \tag{2}$$

To produce furfural, a continuous CSTR reactor with continuous agitation is proposed. From a generalized balance the equations that describe the dynamic of the system are shown in Eq. (3), Eq. (4) and Eq. (5).

$$\frac{dC_{xylan}}{dt} = \frac{F_{in}}{V}\left(C_{in-xylan} - C_{xylan}\right) + r_{xylan} \tag{3}$$

$$\frac{dC_{Furfural}}{dt} = r_{Furfural} - C_{Furfural}\frac{F_{in}}{V} \tag{4}$$

$$\frac{dC_{D.P}}{dt} = r_{D.P} - C_{D.P}\frac{F_{in}}{V} \tag{5}$$

From Eq. (3), Eq. (4) and Eq. (5): the feed flow is represented by Fin [kg / h], the fraction of xylan at the entrance of the reactor $C_{in-xylan}$ [kg/L]. For this system, two other variables to consider are: temperature T [°K] and the concentration of the sulfuric acid Ch [% w], it is reported that the manipulation of acidic conditions and temperature play an important role in the reaction kinetics to produce furfural (Marcotullio, 2011). Within the reactor, it is of interest to study the behaviour that will have during the reaction time: first the degradation of the raw material C_{xylan} [kg/L], as well, the formation of furfural $C_{Furfural}$ [kg/L] and Decomposition Products $C_{D.P}$ [kg/L].

The reaction system presented, has significant number of variables to be optimized order to have an optimal design and operation conditions, by aiming a maximum production of furfural, the best control criteria, lowest environmental impact and lowest cost possible. In this context, the reaction system described as case study is a good model to be optimized simultaneous control and design parameters. Additional factors: the model proposed shows the dynamic behaviour of the system and there is no work in literature where the optimization of design parameters and simultaneous control for furfural reactor are reported. The design variables for the study case are shown in Table 1.

Table 1. Design variables for the multi-objective optimization

Variables	Type Variable	Symbol	Range	Units
Relation of solid (raw material) and water	Continue	LSR	1-15	ml/gr
Feed Flow	Continue	F_{in}	1×1010^3 - 6×10^6	kg/h
Temperature	Continue	T	373 - 413	K
Acid Concentration	Continue	Ch	5 - 15	% w
Volume	Continue	V_o	300 – 520000	L

A multi-objective optimization technique referred to as Differential Evolution with Tabu List (DETL) proposed by Srinivas and Rangaiah (2007) is employed. This technique works as a combined system between the biological evolution from Differential Evolution technique and the random search method from the Tabu search technique. The objective function involves three important axises to analyse: Total Annual Cost (TAC) as an indicator of the economy of the process by calculating the annualized cost of the process equipment and the operating cost, Condition Number (γ*) as an indicator of the dynamic behaviour of the process considering low condition number for systems with good controllability and Eco-indicator 99 (EI99) to quantify the environmental impact. Similar works have been reported by Sánchez-Ramírez et. al. (2017) applying this index for distillation columns. The objective function is expressed as Eq. (6).

$$min[TAC, \gamma^*, EI99] = f(LSR, F_{in}, T, Ch, Vo) \tag{6}$$

Subject to:
$$y_{i,F} \geq x_{i,F}$$
$$w_{i,F} \geq u_{i,F} \tag{7}$$

The objective functions are restricted to satisfy the mass flowrate ($u_{i,PC}$.) espeficfications of furfrual. The minimmum mass flowrate for furfural were fixed to 2000kg/ hr. The values of parameters required by DETL method are: Population size: 120 individuals, Generation number: 710, Tabu list size: 60, Tabu radius: 0.01, Crossover fractions: 0.8, Mutation fractions: 0.3.

3. Results

To represent the main results of the simultaneous optimization of the reactor for furfural bioproduction, Pareto charts are used to identify the best option to produce furfural satisficing in the multi-objective function. Pareto fronts of reactor for furfural bioproduction are presented: a) Condition Number vs Total Annual Cost, b) Total Annual Cost vs Eco-indicator 99 and c) Condition Number vs Eco-indicator 99, all of them comparing with the respective furfural yield %. (See Figure 1).

In Figure 1, each point represents a different design. The best design selected is marked as red square. It was selected according to utopian point methodology where two objectives cannot improve more, both are in equilibrium (Wang and Rangaiah, 2017). The red square corresponds to solutions closer to utopic point. Figure1.a, shows antagonist behaviour between condition number and total annual cost. To explain this trend variable such as temperature and volume, are related both to the costs and to the control properties. When temperature increase, energy consumption will increase having a direct increase in TAC. Referring to the volume, a bigger volume will require more building material and increment the feed flow having an increment in TAC, moreover, for control properties, having an increase in volume the disturbances have less influence on the system thus improving control properties.

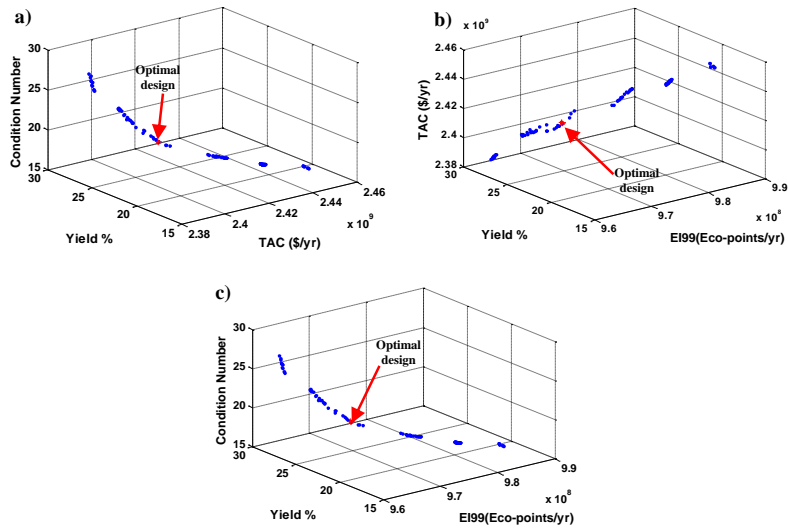
Figure 1.b shows a relation between total annual cost vs eco-indicator 99, in this case both objectives presents the same behaviour strongly influenced by energy supply and cost of energy. To have a reactor of this magnitude it is necessary to increase the heat supply (this represent a direct increase in TAC) and to increase the steel used for the equipment, it is demonstrated that steel has a strong influence in EI99 (Sanchez-Ramirez et al., 2016). In this case is shown a unique minimum but it is not possible to choose it as the optimum because that minimum is an extreme when is evaluated in other index. Figure1.c shows also an antagonist behaviour between control properties and eco-indicator 99, such as the presented in Figure 1.a, when volume is increased eco-points will increase because of the increment of steel used for equipment as well; and simultaneously when volume is increased perturbations has less influence in the system improving controllability. For all the designs the yield % is around 15-30% for an industrial production similar to the reported experimentally by Bamufleh, et al. (2013). The optimal design parameters are presented in Table 2.


Figure 1. Pareto fronts from the reactor of furfural bioproduction.

Table 2. Optimal design parameters for the reactor.

Design Variables	Symbol	Value	Units
Reactor Volume	V_o	518880.77	L
Diameter	D	7.61	M
Height	H	11.41	M
Temperature	T	411.26	°K
Acid concentration	C_h	12.31	% w
Feed flow	F_{in}	728422.31	kg/h
Solid and water relation	LSR	10.497	ml/gr
Total energy Consumed (kJ/hr)	Q	5608969.50	kW
Furfural	Furf	2014.4	kg/h
Decomposition Product	D.P	1731.6	kg/h
Furfural yield	---	25.43	%
Utilities cost	---	2411.46	(millon\$/yr)
Equipment cost	---	0.322	(millon\$/yr)
TAC	TAC	2411.786	(millon\$/yr)
EI99	EI99	970.162	(millonEco-points/yr)
Condition Number	γ^*	18.55	------

4. Conclusions

In this work the reactor zone to produce furfural from palm-date has been optimized. Based on results, is possible to find many possible designs in which furfural yield is

maximized as well cost and eco-points are minimizing in a controllable system. Optimal operation conditions found for the system, like temperature 411.26 °K and acid concentration 12.31%w have strong influence in reaction rate, this conditions allows to maximize furfural yield to 25.43% with a production of 2014.4 kg/h, this represents an improvement compering with the reported by Bamufleh et. al. (2013), with a furfural yield between 11-22% in non-optimal conditions of cost, environmental effects and control properties. As well, dimensions found for the reactor (volume of 518880.77 L) allows to minimize the TAC, eco-points and this size of reactor allows the system to have good control properties.

Abstract

In this work have been designed and optimized simultaneously three different process separations for purify furfural, using Differential Evolution with Tabu List Algorithm. The study cases are a conventional Quaker Oats process, a thermally coupled process and liquid-liquid extraction process. The objective of this work is select the best alternative to purify furfural taken into consideration economic, environmental and safety issues. The results show which the thermally coupled process has several improvements and reductions on the risk, similar cost and environmental impact compared with Quaker Oats process. While the liquid-liquid extraction process does not have any improvement in the objective function, these results are associated with the use of entrainer in this sequence with respect to Quaker Oats Process. Therefore, due to the important improvements in safety issues the TCP process is choosing as the best alternative.

Keywords: Furfural, Process Bio-Refinery, Safety, Optimization Processes.

1. Introduction

In the last years the furfural has aroused a special interest due to it is a chemical produced form biomass, which can compete with the petrochemicals. The US National Renewable Energy Laboratory (NREL) has listed the furfural as one of the 30 most important chemicals produced from biomass, due to their wide applications such as precursor in the production furfural-acetone polymers, extract agents, lubricant oils, nematocide and in the production of furfuryl alcohol which is used in the production of thermoset polymers (Niehn et al. 2016).

The furfural is produced from five carbon sugars as xylose and arabinose which are contained in the hemicellulose fraction of biomass. In an industrial scale the furfural is produced through Quaker Oats process, which is used since 1922. This process is based in two zones: a reaction and separation zones. In the reaction zone, the biomass is treated with sulphuric acid in order to release xylose and convert it into furfural, then a high pressure vapour stream is introduced to reactor in order to remove the furfural and avoid their resinification. During the purification stage, the vapour from the reactor which is

rich in water, methanol, acetic acid and furfural is condensed and then it is feeding to a distillation sequence where the furfural is purified. This process has several disadvantages, one of the most important is the high separation cost due to large amount of water contained in the stream that is introduced to the purification zone. The presences of water imply the formation of azeotropes and therefore, is necessary the use of complex and expensive separation alternatives. However, despite the high separation costs of the Quaker Oats process has been used until now, because their easy implementation and lower cost compared with other alternatives (Zeitsch; 2000). Therefore, in this work are studied three different process separation alternatives for purify furfural. The total annual cost (TAC), eco-indicator (EI99) and the individual risk (IR) as economic, environmental and safety indexes respectively are used to evaluate. The novelty of this work since the point of view of circular economy is that, the optimization and identification of best process parameters allow for get a sustainable and profitable process for purify furfural with the less emissions and residues (Geissdoerfer et al. 2017). In the same time, the determination of best optimal parameters allows for the identification of safest process and operating conditions. In other hand the optimization of these 3 objective functions provide the generation of green and friendly process with the environment according with the reported by Jiménez-González and Constable, (2011).

2. Methodology

In this work three different processes distillation to purify furfural have been studied; the Quaker Oats process (QO), a thermally coupled process (TCP) and extractive distillation process (ED). The QO process consist in three distillation columns, the first equipment is an azeotropic distillation column (C1), wherein the mixture is concentrated until the heterogeneous azeotrope concentration. In the column C2 the methanol is recovered by the top if this equipment, and the column C3 where the furfural is purified in the bottoms column and the bottoms and the top products of columns C2 and C3 are sent to decanter. A side stream is withdrawn between the top and bottom of C1, this stream contains a mixture rich in water and furfural, which is sent to a decanter where the organic phase rich in furfural is purified in a third column (C3) (Zeitsch; 2000). In the case of TCP process is generated from the Quaker Oats process by the replacement of condenser associated to the first column, which was substituted by vapour and liquid streams that are linked in the last and penultimate stages of the rectification zone. The last scheme is the liquid-liquid extraction coupled with a distillation process (ED), which consist a liquid-liquid extractive column (E1) where the butyl-chloride is used as entrainer for separate the furfural from the water mixture according to reported by Nhien et al. 2016. Stream rich in solvent and furfural is obtained by the top of extractive column and subsequently the butyl-chloride and furfural are separated in a conventional distillation column (C1) whereas the C2 is used as a prefractionator and C3 is used for purify the methanol. This scheme was studied previously by Nhien et al. 2016. The Figure 1 shows the schemes of the study cases.

In order to perform this study, the most general and extendible possible to the majority of furfural plants, the average composition reported by Zeitsch has been considered. This composition consists in water 90 %wt, furfural 6 %wt, methanol 2 %wt, and acetic acid 2 %wt. The mass flow rate considered in this work is 105,000 kg/hr that corresponds to the estimated global furfural demand reported by Nhien et al 2016. The thermodynamic property model used to simulate the liquid-liquid-vapour equilibrium is Non-random Two-Liquids with Hayden-O'Connell equation of state (NRTL-HOC), which takes into

account the two liquid phases and the dimerization and solvation characteristics of mixtures with carboxylic acids. All processes separations were simulated rigorously using the software Aspen Plus. The Total Annual Cost (TAC), Eco-Indicator 99 (EI99) and the individual risk (IR) as objective functions to be minimized.

The total annual cost has been computed using the Guthrie methodology, wherein the cost is calculated as the sum annualized of capital cost (cost of all equipments process) and the operating cost, which are associated with the use of steam, cooling water and electricity. All parameters used for calculated the TAC were taken from Turton et al. 2008. Ten years were assumed as payback period, whereas carbon steel is considered as construction material for the process equiments. The operating costs included cooling utilities, heating utilities and 8500 hours per year of operation for each alternative have been considered. Mathematically, the TAC can be defined according with Eq. (1).

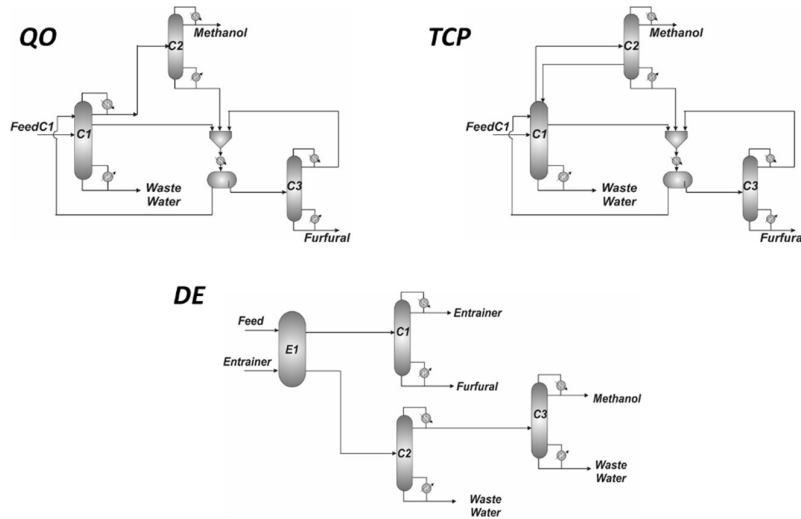
$$TAC = \frac{Capital\,cost}{Payback\,period} + Operating\,cost \tag{1}$$


Figure 1. Processes separation schemes.

The EI99 is used to calculate the environmental impact that provokes of each case of study. This approach is based in the evaluation of three impact categories: human health, ecosystem quality, and resources depletion. This method has been successfully implemented in some previous works as the showed by Quiroz-Ramirez et al 2017. According to importance of three major impact categories the weighting for eco-indicator 99 was considered as follows: damages to human health and damage to ecosystem quality are of equal importance, thus these were equally weighted while the damage to the resources was considered to be half of importance weight. The EI99 can be expressed mathematically as:

$$EI99 = \sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k} \tag{2}$$

where β_b represents the total amount of chemical b released per unit of reference flow due to direct emissions, $\alpha_{b,k}$ is the damage caused in category k per unit of chemical b released to the environment, ω_d is a weighting factor for damage in category d, and δ_d is a normalization factor for damage of category d, respectively. the weights and the valus for the impact categories were taken from Quiroz-Ramirez et al 2017.

Finally, the individual risk is an index used to quantify the security of a process, it is calculated thought a quantitative risk analysis wherein the damage caused by accident is identified and quantified. For all the cases of study have been identified seven possible accidents divided in two categories. Instantaneous incidents: Boiling liquid expanding vapour explosion (BLEVE), unconfined vapour cloud explosion (UVCE), flash fire and toxic release, and whereas the continuous release incidents are: jet fire, flash fire and toxic release. For Calculate the individual risk a reference distance of 50m were chosen. The complete set equations for calculate the IR is showed by Medina-Herrera et al. 2014. The mathematical equation that describes the individual risk is the following:

$$IR = \sum f_i P_{x,y} \tag{3}$$

where f_i is the occurrence frequency of incident i, whereas $P_{x,y}$ is the probability of injury or decease caused by the incident i.

The multi-objective optimization problem was solved using the mathematic technique called differential evolution with tabu list (DETL.). The values of parameters requiered by DETL method are: Population size: 120 individuals, Generations Number: 710, Tabu List size: 60 individuals, Tabu Radius: 0.01, Crossover fractions: 0.8, Mutation fractions: 0.3. The DETL method and the objective functions were implemented in a hybrid platform, which link Aspen Plus™ and Microsoft Excel™ through Visual Basic. The design variables for the different study cases are showed in the Table 1.

Finally, the overall optimization problem can be mathematically expresed as in Eq. (4) and Eq. (5):

$$\min Z = \{TAC; Eco99; IR\} =$$
$$\left\{ \frac{\text{Capital cost}}{\text{Payback period}} + \text{Operating cost} \; ; \sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k} ; \sum f_i P_{x,y} \right\} \tag{4}$$

Subject to: $\quad y_{i,F} \geq x_{i,F}$
$$\qquad\qquad w_{i,F} \geq u_{i,F} \tag{5}$$

The objective functions are restricted to satisfy the purity ($x_{i,PC}$) and mass flowrate ($u_{i,PC}$.) espeficfications of furfural. The minimmum purity of mass flowrate for furfural were fixed to 99.2%tw and 6200kg/ hr respectevely.

3. Results

In this section is showed the results obtained during the simultaneous design and optimization for the three alternatives. In order to simplify the results analysis, the Pareto graphs are studied. The Figure 2 shows a representative Pareto front for TCP scheme,

wherein the QO and DE processes shows exactly the same behaviour. In the Figure 2, can be observed that Pareto front of total annual cost versus eco-indicator 99 have a linear dependency with an only one minimum to both objectives, while the other two charts show an opposite behaviour where the minimum TAC and EI corresponds to a design with highest risk and vice versa. The points selected as the best designs corresponds to black point, these were chosen, because are the points that provides an equilibrium between the three objectives. In the same way the designs for QO were chosen. The Table 1 shows the optimal design specifications for all separation schemes.

Table 1. Values of design variables for all process.

Design specifications	QO	TCP	DWC
Stages, C1	55	91	53
Stages, C2	12	40	50

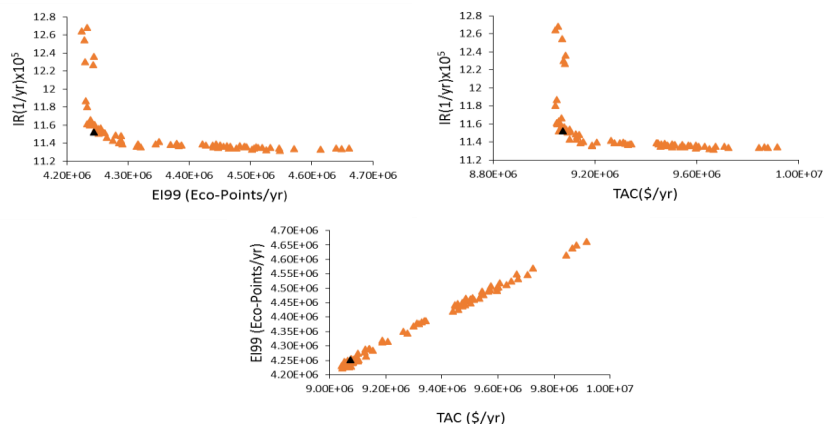
Values of objective functions			
TAC ($/yr)x10^6	9.334	9.301	13.91
Eco99 (Eco-points) x10^6	4.335	4.3623	6.534
IR (1/yr) x10^5	18.674	13.548	36.00

Due to the large amount of water in the feed stream, the column C1 in the process QO and TCP has the greater contribution for energy, thus is the biggest equipment and it has more impact in the economic and environmental indexes. In the case of DE process, it does not have important reductions in the TAC and EI99 because the large amount of water is removed in the liquid-liquid extraction column, which need be purify in order to purify the methanol. In other hand, the DE process has not any saving or improves on TAC, EI99 and IR, which makes it the worst option. The results obtained in the DE process can be explained due to the addition of the solvent. The entrainer need be recovered in a distillation column, increasing the separation cost and the environmental impact caused by the use of energy. In the case of IR, an increment in the risk is observed because the C1 column contains mainly large amounts of solvent increasing the likelihood of releases and fires, and damage caused by a probable accident. TCP process is choosing as the best option of the three alternatives studied. The TCP process has similar EI99 and

TAC respect to Quaker Oats process, however the replacing of condenser in C1 column results in a shorter resident times and lower inventory inside of C1 reducing the risk.


4. Conclusions

In this work three different process separation of furfural have been designed and optimized simultaneously, considering economic, environmental and safety issues, in order to find the most sustainable and safest process. The results indicate that ED process has not improvements with respect to any objective due to the addition of important amounts of solvent which need be separate. The entrainer used in ED process is an organic component, which is flammable and toxic and therefore its use affects the safety index. In other hand, the TCP do not have important savings in TAC and EI99 with respect to Quaker Oats process, but the interconnection flows between the top of C1 and the C2 promotes that the concentration of water inside of C2 be greater which causes a dilution of methanol and reduce the risk. The TCP process is chosen as the best alternative due to it has important improvements in security aspects.

Abstract

Acetic acid is a bulk chemical with many applications in the manufacture of several important products. The carbon footprint of its classic synthesis process (methanol carbonylation) is around 1.3921 - 1.8746 kg CO_2-eq/kg, which adds up as the commodity is used in further syntheses. Hence, a reduction in the acetic acid synthesis Global Warming Potential (GWP) would impact in many end products GWP. We propose an acetic acid synthesis superstructure, including different syngas synthesis processes, gas separation technologies and methanol synthesis, which is aimed at reducing both the cost and GWP of the process. Results show that, integrating the methanol synthesis process provides the best results in both objectives. When minimizing the cost (classic synthesis) is best to use an Auto-thermal Reforming (ATR) and CO absorption configuration (0.388 $/kg, 1.832 kg$CO_2$-eq/kg). Adding a fuel cell and a Reverse Water Gas Shift (RWGS) reactor overall reduces both cost and emission (0.280 $/kg, 1.590 kg$CO_2$-eq/kg) of the synthesis and changes the configuration to Partial Oxidation (POX) and cryogenic distillation. Minimum emission (0.102 kgCO_2-eq/kg) can also be achieved with the fuel cell plus RWGS combo, POX and Pressure Swing Adsorption (PSA), although the cost is almost tripled (0.978 $/kg).

Keywords: CO_2 utilization, methane reforming, carbon monoxide separation, reverse water gas shift, acetic acid synthesis

1. Introduction

Acetic acid, with a high and ever-increasing annual production of more than 14 Mt (2017), is an important chemical used to synthesize vinyl acetate (vinyl acetate monomer, VAM), terephthalic acid (polyethylene terephthalate, PET) and acetate anhydride (cellulose flake) among others ("IHS Markit: Acetic Acid," 2018). However, the most extended process for acetic acid production, methanol carbonylation, whose two main raw materials are carbon monoxide and methanol, provokes an appreciable carbon footprint of 1.3921 - 1.8746 kg CO_2-eq/kg ("Ecoinvent Database 3.4," 2017). On the other hand, it is well-known that in methanol synthesis it is possible to consume CO_2. Furthermore, the main source of CO is syngas separation, hence CO_2 can also be used in syngas synthesis (Medrano-García et al., 2017) allowing for further consumption of the gas. Therefore, consuming CO_2 and decreasing the overall Global Warming Potential (GWP) in acetic acid synthesis would accomplish a significant reduction in global CO_2 emissions due to the relevance and high production of this commodity.

We propose a process superstructure in which carbon monoxide and methanol synthesis are integrated with the production of acetic acid. Seven different syngas synthesis processes, both classic and CO_2-consuming (Table 1) along with several gas separation technologies (adsorption, absorption and cryogenic distillation) for each gas component are considered. In addition, the hydrogen byproduct in the CO separation step can be used as fuel elsewhere in the process, as a methanol raw material or as reactant in the reverse water gas shift reactor (RWGS) to increase CO production while consuming additional CO_2. Additionally, heat integration is included across the whole model. We address the existence or non-existence of the units using the Generalized Disjunctive Programming (GDP) and then transforming the disjunctions into algebraic equations using the Hull reformulation (Lee and Grossmann, 2000). We perform multi-objective optimizations of the resulting MINLP model using the epsilon constraint method, minimizing the cost ($/kg) (1) as our economic indicator and the Global Warming Potential (GWP) (kg CO_2-eq/kg) (2) as our environmental indicator:

$$cost = \frac{Annualized\ Capital\ Cost + Raw\ material\ Cost + Utility\ Cost}{Acetic\ acid\ production} \quad (1)$$

$$emission = \frac{Raw\ material\ GWP + Utility\ GWP + Outlet\ CO_2 - Inlet\ CO_2}{Acetic\ acid\ production} \quad (2)$$

Results show that the RWGS reactor acts as an important sink of CO_2 while reducing the raw materials needed in the syngas synthesis step, and therefore reducing the overall cost and emission of the process. Emissions can be reduced, approximately, 1 kg CO_2-eq per kg of acetic acid.

SMR: Steam Methane Reforming; POX: Partial Oxidation; ATR: Auto-thermal Reforming; CR: Combined Reforming; DMR: Dry Methane Reforming; BR: Bi-Reforming; TR: Tri-Reforming.

2. Methodology

2.1. Superstructure overview

The aim of this work is the reduction of the GWP in the production of acetic acid using the methanol carbonylation classic process. This technology requires both a methanol and carbon monoxide feed. In the proposed superstructure, carbon monoxide is produced by separation of syngas. On the other hand, methanol is manufactured using a mixture of this syngas, H_2 separated as the result of purifying the CO, and a fraction of the CO itself, in addition to possibly being bought from an external source. Furthermore, removed H_2 can be used as fuel or as feedstock in a Reverse Water Gas Shift (RWGS) reactor that, while consuming CO_2, produces additional CO. In addition, depending on its purity, it can be used in a fuel cell that supplies the system electricity. The off-gas produced by the gas separation can also burn as fuel or be partially recycled in order to further remove valuable gases from it. The proposed superstructure is shown in Figure 1.

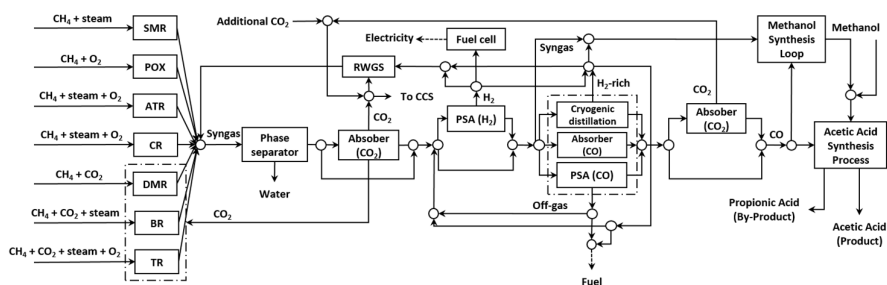
First, the raw materials, which include methane and a reforming agent (steam, oxygen, carbon dioxide or a combination), enter the syngas synthesis section of the superstructure. Here, the feedstock is compressed and heated up to the reaction pressure and temperature. Then, the mixture enters the reformer reactor where syngas is the product. Each syngas process operates at different feed ratios, pressures and temperatures, in addition to producing syngas with different compositions. These process variables are fixed to the most common values found in the bibliography for industrial operation. These values and employed models for the syngas synthesis section can be found in Medrano-García et al. (2017). The syngas stream is then headed to the gas separation section, where it first encounters a phase separator (40 ºC) that removes all the water contained in the gas. The option of capturing CO_2 is given next in a diglycolamine (DGA) absorber. This CO_2 can be used as feedstock in the syngas synthesis step and RWGS reactor, or just be assigned for storage. The RWGS reactor works using an H_2/CO_2 inlet ratio fixed at seven, operating temperature of 300, 350, 400 or 450 ºC and according CO_2 conversion of 11.6, 45.0, 77.6 or 85.9 % (Wolf et al., 2016). Next, a Pressure Swing Adsorption (PSA) unit targeting H_2 can be used to remove this gas from the syngas. This H_2, due to the purity a PSA separation can achieve, is a valid option for fuelling the fuel cell, in addition to be used as fuel or as feedstock in the methanol synthesis loop and/or RWGS reactor. After the H_2 removal option, a fraction of the syngas can be diverted in order to feed the methanol synthesis loop. The remaining syngas then arrives to the CO separation section of the superstructure, where cryogenic distillation, chemical absorption or a CO-targeting PSA can be chosen for the task. These technologies provide an off-gas in addition to the CO-rich product stream and, in the case of cryogenic distillation, also an H_2-rich stream. The off-gas can burn as fuel or be partially recycled back just before the H_2 PSA in order to further remove valuable gases from it. The H_2-rich stream can also be used as fuel or as a raw material for the RWGS reactor or the methanol synthesis loop. Note that the H_2-rich steam purity is insufficient for its use in the fuel cell, and hence this option is not considered. Finally, the CO-rich stream is given the possibility of removing any remaining CO_2 contained in it with a second ammine absorber. After this step, it can be split so that it can feed both the acetic acid synthesis process and the methanol synthesis loop if needed.


Figure 1. Proposed process superstructure for the integration, synthesis and separation of syngas, methanol and acetic acid.

2.2. Methanol synthesis loop

The methanol synthesis loop can be seen in Figure 2. The loop is modelled using linear equations derived from simulations studies in Aspen HYSYS v9.0 with the aim of achieving minimum cost and emission in the synthesis (Medrano et al., 2017). Syngas at 40 ºC and 30 bar, with an $(H_2-CO_2)/(CO+CO_2)$ ratio of 2.00 (2.04 in the reactor inlet) and

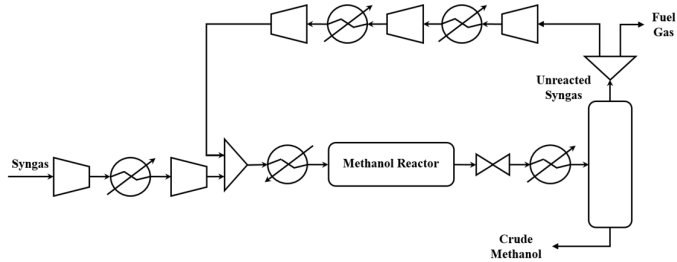
5 % CO_2 content enters the loop and is compressed to 76.5 bar and heated up to 284.2 ºC. The reaction takes place in a plug flow reactor modelled after (Bussche and Froment, 1996) kinetics. The resulting stream then gets depressurized and cooled down to 10 bar and 40 ºC. In a phase separator, crude methanol (96.4 % wt. methanol content) is obtained and sent to the acetic acid synthesis process. The unreacted syngas stream is partially purged (5 %, to burn as fuel), recompressed and recycled back to the heating stage.


Figure 2. Proposed methanol synthesis loop embedded in the superstructure.

2.3. Acetic acid synthesis

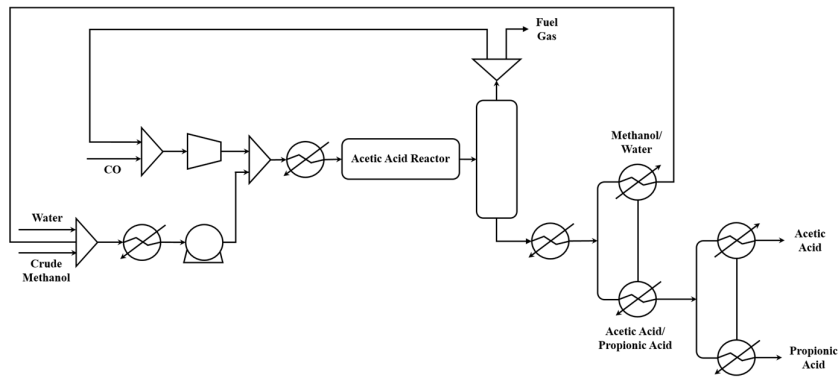
The acetic acid synthesis process is shown in Figure 3 (Cheung et al., 2000):


Figure 3. Proposed acetic acid synthesis process embedded in the superstructure.

Methanol, CO (40 ºC, 1 and 30 bar respectively, 1:1 molar ratio) and water (40 ºC, 1 bar), enter the process and are compressed and heated up to 30 bar and 175 ºC. The catalyst needs water (4.0 - 4.5 % wt.) in order activate the carbonylation reaction, which allows the use of crude methanol as a feedstock for the process, hence resulting in the omission of the methanol purification column. Inside the reactor, the following reactions take place:

$$CH_3OH + CO \longrightarrow CH_3COOH \tag{3}$$

$$CH_3OH + CH_3COOH \longrightarrow CH_3CH_2COOH + H_2O \tag{4}$$

$$CO + H_2O \rightleftharpoons H_2 + CO_2 \tag{5}$$
For the main reaction, the synthesis of acetic acid (3), a CO conversion of 60 % is considered. The parallel reaction of the formation of propionic acid (4) as a byproduct transforms 1 % of the produced acetic acid in reaction (3). Lastly, the Water Gas Shift

(WGS) equilibrium reaction (5), is assumed to have a CO conversion of 10 %. After the reaction, the gaseous phase is recycled (50 % purged, to fuel gas) and the liquid phase is separated (86.25 ºC, 1 bar, 62 stages) into a methanol-water stream, which is recycled, and an acetic acid-propionic acid stream which is further separated (116.97 ºC, 1 bar, 62 stages) into the product (99.87 % wt. acetic acid) and byproduct (99.13 % wt. propionic acid).

3. Results and discussion

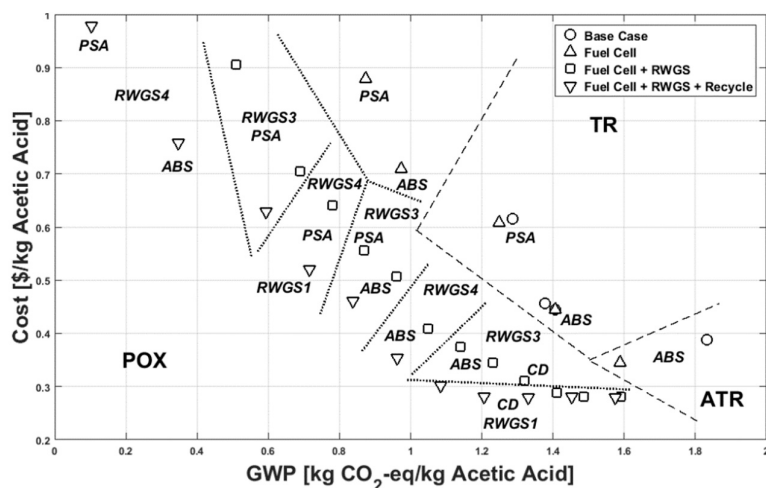
The resulting MINLP model consists of 2,029 equations and 1,587 variables, 25 of which are binary variables. The solving time was 1,667 s per case in an Intel Core 2 Quad with an 8GB RAM. The multi-objective optimization is performed applying the epsilon constraint method and using the solver ANTIGONE (Misener and Floudas, 2014) within GAMS (GAMS, 2018). The main results are shown in Figure 4. The use of specific syngas synthesis processes is separated into areas by dashed lines, while dotted lines split RWGS operating conditions and CO separation units. In addition, all solutions include the integrated methanol synthesis process.


Figure 4. Results of the multi-objective optimization for the synthesis of acetic acid.

Results show that, minimizing the cost in classic (base case) acetic acid synthesis (0.388 $/kg, 1.832 kgCO$_2$-eq/kg) requires ATR as the syngas synthesis process and absorption of CO (ABS) as the CO separation technology. Including a fuel cell reduces overall cost and emission (0.345 $/kg, 1.587 kgCO$_2$-eq/kg) without changing the main configuration units. Adding the RWGS reactor provides a significant decrease in cost (0.280 $/kg, 1.590 kgCO$_2$-eq/kg) and changes the configuration into using POX and cryogenic distillation (CD). Allowing the partial recycle of off-gas streams (0.280 $/kg, 1.575 kgCO$_2$-eq/kg) barely reduces the emission maintaining cost invariable. On the other hand, when minimizing the emission, the addition of the fuel cell (0.873 $/kg, 0.879 kgCO$_2$-eq/kg) more than doubles the synthesis cost of the base case while reducing GWP value almost by1 kgCO$_2$-eq/kg. The RWGS reactor inclusion (0.906 $/kg, 0.510 kgCO$_2$-eq/kg) further reduces emission and increases the cost. Finally, when off-gas streams are free to recycle (0.978 $/kg, 0.102 kgCO$_2$-eq/kg) the cost of the synthesis peaks, almost tripling the base case, while the emission reaches its minimum, reducing the base case emission by more than 1.7 kgCO$_2$-eq/kg; almost achieving carbon neutrality.

4. Conclusions

In this work, we propose an acetic acid synthesis superstructure in order to minimize both the cost and the emission of the production of this commodity. Integrating several methane reforming processes, gas separation technologies and methanol synthesis, we perform multi-objective optimizations of the resulting MINLP model in order to achieve the optimal configurations. Results show that for all cases, methanol should be produced simultaneously with acetic acid to minimize both cost and emissions.

Comparison with the minimum cost configuration (0.388 \$/kg, 1.832 kgCO$_2$-eq/kg) states that the cost of the synthesis can be further reduced using a fuel cell and a RWGS reactor with POX and cryogenic distillation (0.280 \$/kg, 1.590 kgCO$_2$-eq/kg), while recycling the process off-gases barely has an effect. On the other hand, emissions can be significantly decreased with the same configuration but using a PSA instead (0.906 \$/kg, 0.510 kgCO$_2$-eq/kg), however, off-gas recycling does have an effect in further reducing the emission (0.978 \$/kg, 0.102 kgCO$_2$-eq/kg), where the decrease surpasses 1.7 kgCO$_2$-eq/kg.

Abstract

In this research, a model for the physical absorption of CO_2 from flue gas with [hmim][Tf2N] ionic liquid, an innovative solvent used in the last CO_2 absorption processes, is developed in Aspen Plus and optimized through a central composite design by using Minitab. Then a unique combination of simulation and statistical analysis is carried out for the process. The aim is to find the optimal operating conditions that can maximize the amount of captured CO_2 while minimizing the total costs. The study shows the percentage of CO_2 removal is 93.7%, operating costs are 0.279 trillion euro/a and capital costs are 21.9 million euro/year. The obtained results are in agreement with other works reported in literature, considering the high cost for ionic liquid.

Keywords: CO_2 capture, ionic liquid, process simulation, statistical analysis, optimization.

1. Introduction

From the combustion of natural gas, oil, fuels-coal, globally 30 gigatons (Gt) per year of carbon dioxide are emitted impacting the environment dramatically (Wilcox et al., 2014; Tlili et al., 2014). Reducing emissions is critical, but at this time it is also important to capture carbon dioxide efficiently from emission sources. Chemical absorption by with amines is a common technology to capture carbon dioxide from flue gases (Nittaya et al., 2014; Lin et al., 2011). High reactivity, low cost, good absorption capacity, high affinity to carbon dioxide are some positive aspects of this technology. However, there are also serious disadvantages such as tendency for corrosion, high energy demand for regeneration and loss of solvent. Ionic liquids (ILs) are a promising and green alternative due to their low volatility, good dissolution, high decomposition temperature and stability, excellent chemical tunabilities, that allow to reduce the losses of solvent and energy for regeneration (Luo and Wang, 2017; Ma et al., 2018). Using ionic liquids as a solvent for CO2 absorption is still a rather new carbon capture process. As an example: Valencia-Marquez et al. (2017) developed a mixed-integer nonlinear programming (MINLP) problem for absorption process to design the best ionic liquid that can ensure a recovery of CO_2 higher than 90% with a simultaneous optimal product and process design. Currently no study that employs ANOVA analysis, response surface methodology (RSM) by using central composite design has been used for optimizing the absorption

process of CO_2 by using ionic liquid. In particular, a process for the physical absorption of carbon dioxide from flue gas (coming from power plant) with 1-n-hexyl-3-methylimidazolium bis(trifluoromethylsulfonyl)amide ([hmim][Tf2N]) ionic liquid is developed in Aspen Plus. A similar work is not present in literature. The model is used to carry out a face centered central composite design (FCCCD) according to the response surface methodology (RSM) by using Minitab software with the aim to find the optimal operating conditions. In this way c the factors (geometric and operating) and combination of factors that are significant can be identified. The aim is to improve the efficiency of the process reducing the costs. The inlet temperature of flue gas, absorption column pressure, the carbon dioxide composition of flue gas, the height of absorption column are the considered factors, while the percentage of carbon dioxide removal, operating costs (OPEX) and capital costs (CAPEX) are the analyzed responses.

2. Materials and methods

2.1 Description of the absorption process

A process for the absorption of CO_2 by flue gas of power plant is developed in Aspen Plus as in figure 1. In this process flue gas is composed by Ar, CH4, H2, N2, CO, CO2, H2O, NH3, H2S. Absorber (RADFRAC model) is a packed bed with plastic pall rings of 0.025 m and packing surface area of 205 m^2/m^3. The eight of each stage is 3 m. Compressed flue gas is fed at the bottom of the absorber, where IL contacts the flue gas, remove CO2 and discharges the clean gas to the air. The stream existing at the bottom of absorber is rich in IL so it is sent to a flash to recover it and to recirculate to the absorber. The stream gas existing at the top of flash is mainly composed by CO2 and water. Then it is cooled to 288 K in order to separate any water present, so that captured CO2 can be compressed up to 150 bar in the following refrigerated compressors.
Figure 1 Process scheme of CO2 absorption process from flue gas with IL in Aspen Plus environmental

The IL [hmim][Tf2N] is characterized in Aspen Plus as new component by defining density, viscosity, surface tension, vapor pressure, heat capacity and critical properties as reported in Basha et al. (2013). The Peng Robinson Equation of State is chosen as thermodynamic model, by setting binary interaction parameter between each component

via regression analysis (Basha et al., 2013). The amount of flue gas entering the column is 25.63 kg/s, while the amount of fed IL is 280 kg/s.

2.2 Response surface methodology

A face centered central composite design is setup for the absorption process using the response surface methodology principle (Montgomery, 2005). From this design, the surface plots of considered responses with respective second order polynomial models can be obtained. The flue gas inlet temperature, column pressure, CO_2 composition in flue gas and the height of absorber are the selected factors. It is evident as operating and design factors are selected for the optimization of the process. The percent of CO_2 removal from flue gas, operating (costs of raw material and utilities) and capital costs are the analyzed responses. These costs are evaluated by using Aspen Process Economic Analyzer (APEA), considering a price for IL of 20 €/kg over a period of 20 year (Ramdin et al., 2012). Table 1 shows the values set for each level of factor. As shown, three levels are considered for each factor. For the statistical analysis, 31 simulation tests are carried out including 16 cube points, 7 axial points, 7 central points and 1 replication. Star points are set on the centers of each factorial face: the value of α is 1. The significance of each term in the obtained model is validated by analysis of variance.

Table 1 Values of level for each factor in FCCCD analysis

Code	Factor	Level		
		(-1)	**0**	**(+1)**
A	Flue gas inlet temperature (K)	323	411.5	500
B	Column pressure (bar)	15	22.5	30
C	CO_2 composition in flue gas (mol%)	3	13.5	24
D	Height of absorber (m)	2	26	50

3. Results and discussions

The process scheme developed in Aspen Plus is used to carry out different simulations according to the face centered central composite design. From the parameters obtained from the simulation, a mathematical model is obtained for each analyzed response, as the capital costs, the operating costs, the percent of CO_2 removal from flue gas, respectively, as the following equations (Eqs 1-3):

$$CAPEX \ (euro) = 22370478 - 427029 \cdot A + 1076170 \cdot B + 1288803 \cdot D \qquad (1)$$

$$OPEX \left(\frac{euro}{year}\right) = 2.85 \cdot 10^{11} + 3.76 \cdot 10^9 \cdot DD \qquad (2)$$

$$CO_2 \ removal \ (\%)$$
$$= 72.42 + 23.59 \cdot B + 1.13 \cdot BC + 1.02 \cdot BD + 1.02 \cdot CD - 0.91$$
$$\cdot D - 3.36 \cdot BB \qquad (3)$$

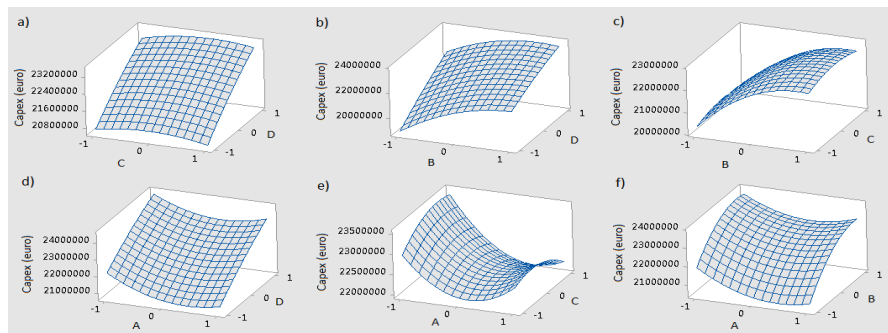
where factor A is the flue gas inlet temperature, factor B is the column absorber pressure, factor C is the CO_2 composition in flue gas and factor D is the height of column absorber. Results show that factor B, interaction BC, BD, CD have a positive effect on the percentage of carbon dioxide removal, while factor D and interaction BB have a negative effect on this response. For the operating costs the interaction DD has a positive effect. In addition, for the capital costs factor D and B have a positive effect, while factor A has a negative effect. It is evident that factors B, C and D have an overall stronger influence on the process while factor A only influences the capital costs. Figures 2, 3, and 4 show the surface plots for CAPEX, OPEX and CO_2 removal respectively obtained by Minitlab as function of two factors, while the others are set to a value of 0 level. It is possible to see especially for the surface plots of CAPEX and OPEX, that even if interactions between factors are not significative, they are present.


Figure 2 Response surface plots for CAPEX (euro): a) CAPEX (euro) as function of factor C and D; b) CAPEX (euro) as function of B and D; c) CAPEX (euro) as function of B and C; d) CAPEX (euro) as function of factor A and D; e) CAPEX (euro) as function of factor A and C; f) CAPEX (euro) as function of factor A and B. (Hold values: A=B=C=D=0).
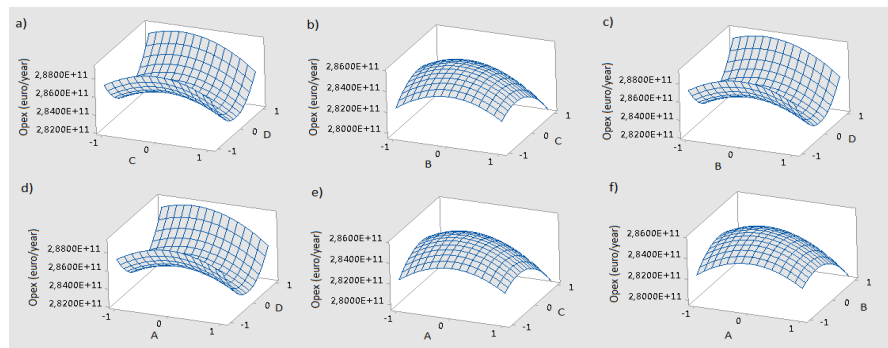

Figure 3 Response surface plots for OPEX (euro/year): a) OPEX (euro/year) as function of factor C and D; b) OPEX (euro/year) as function of factor B and C; c) OPEX (euro/year) as function of factor B and D; d) OPEX (euro/year) as function of factor A and D; e) OPEX (euro/year) as function of factor A and C; f) OPEX (euro/year) and function of factor A and B. (Hold values: A=B=C=D=0).
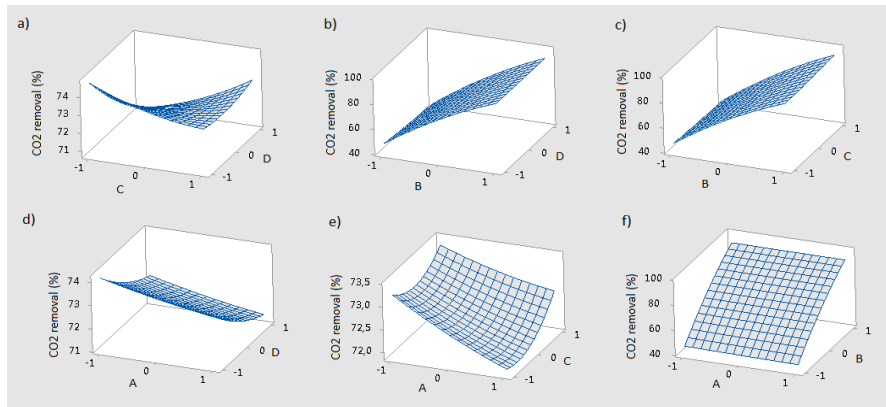

Figure 4 Response surface plots for CO2 removal (%): a) CO2 removal as function of factor C and D; b) CO2 removal as function of facto B and D; c) CO2 removal as function of factor C and B; d) CO2 removal as function of factor A and D; e) CO2 removal as function of factor A and C; f) CO2 removal as function of factor A and B. (Hold values: A=B=C=D=0).

The operating conditions that maximize the capture of carbon dioxide and minimize the costs using a desirability function are found: factor A, B, C and D should be respectively equal to 500 K, 30 bar, 24 mol% and 1.36 m. The percentage of carbon dioxide removal is equal to 93.7%, the operating costs are 0.279 trillion euro/year and the capital costs are 21.9 million euro. The obtained values rare supported by other studies. Significant reductions are made as compared to for example (Nguyen and Zondervan, 2018; de Riva et al., 2017). Capital and operating costs have not been reported for [himm][Tf2N] and comparison is not that easy. For other ionic liquids such as [Bmim][Ac], [bmim][BF4] and [bmim][PF6] economic data has been reported (Ma et al., 2017; Shiflett et al., 2010) but a straight comparison cannot be made. In the current study, the relation suggested by Nguyen and Zondervan (2018) for calculation of operating and capital costs in the case of [bmim][Ac] ionic liquid as function of flue gas flow rate and carbon dioxide composition is used. Results show that capital costs are in the same order, while a higher value for operating cost is obtained may be due to the high flow rate required and the cost of used IL.

4. Conclusions

In this research, an innovative optimization of physical absorption process to capture CO_2 from flue gas through ionic liquid ([hmim][Tf2N]) is developed and a similar work can not be found in literature. A new solution, as ionic liquid is considered due to its better properties compared to traditional ones. However, the high cost of this ionic liquid suggested to find the optimal operating conditions in order to maximize the amount of captured CO_2 and to reduce costs. A face centered central composite design is developed considering as factors flue gas inlet temperature, column absorber pressure, CO_2 composition in flue gas and the height of column absorber. Operating and capital costs and the amount of reduced CO_2 are considered as responses. Results show that to have an optimized process, flue gas inlet temperature, column absorber pressure, CO_2 composition in flue gas and the height of column absorber should be respectively equal

to 500 K, 30 bar, 24 mol% and 1.36 m. In this way, operating costs, capital costs and the percent of CO_2 removal are respectively 0.279 trillion euro/year, 21.9 million euro and 93.7%.

Abstract

Most chemical processes require heat exchangers to modify the temperatures of the streams involved in the production steps. Due to their many applications, the rigorous design of such exchangers is of interest, aiming to determine the physical characteristics required to obtain the desired variation in temperature. The mathematical models representing such devices have several degrees of freedom and non-lineal equations, thus robust optimization algorithms are required to obtain the optimal solution in a short time. In this work, the use of the grey wolf algorithm is proposed for the optimization of a shell-and-tube heat exchanger, modeled by the Bell-Delaware equations. With the proposed method, a minimum total annual cost of 3,978.2 USD was obtained, in a mean time of 0.7976 seconds.

Keywords: meta-heuristic optimization, shell-and-tube heat exchanger, grey wolf algorithm.

1. Introduction

Heat exchangers are among the most used auxiliary equipment in chemical industry, since cooling and heating are common operations which allow modifying the temperature, or even the phase, of process streams, according to the operational requirements. This implies that heat exchangers are necessary for almost any chemical process. Shell-and-tube exchangers are widely used in industry to obtain wide ranges of temperature variations for streams from low to high flow rates, with high heat transfer efficiency due to the turbulence occurring on the shell. The design of a shell-and-tube heat exchanger involves several variables, which are usually related through energy balances and empirical correlations. One of the most common strategies to design heat exchangers in the industry is the Bell-Delaware method, which considers the variations of the convective heat transfer coefficient with the baffle configuration and phenomena occurring in the baffles, as leakage, pass partition bypass, among others. Nevertheless, the equations which model the heat exchanger are highly non-lineal and non-convex, mainly due to the presence of fractional and logarithmic terms in the mathematical model. Moreover, some of the variables are integer, as the number of tubes, and other variables can be taken as continuous, but in practice they take discrete values, as the internal and external diameter of the tubes, which are constrained by the standard dimensions for commercial tubes. Thus, a robust method is necessary to obtain proper solutions to the optimal design problem of the heat exchanger. The use of meta-heuristic optimization strategies offers a viable alternative to the solution of such problem. In this work, a recently reported stochastic optimization method, namely, the grey wolf optimization algorithm, is proposed to solve the optimization problem for a shell-and-tube heat exchanger, represented by the Bell-Delaware model, aiming to the minimization of the total annual cost. The grey wolf optimization algorithm emulates the hunting mechanisms of grey wolves, and it has been reported that it possesses a superior

exploitation capacity than other meta-heuristic algorithms, together with a high capacity to avoid local optima (Mirjalili et al., 2014)

2. Grey Wolf Optimizer

Grey Wolf Optimizer (GWO) emulates the hunting technic of wolves. It was modeled by Mirjalili et al. (2014). This optimization algorithm considers the wolves hierarchy; alpha (α), is not necessarily the strongest but is the one who makes important decisions that affect the whole group; beta (β) wolves help the alpha in decision making activity, these wolves respect the alpha but command the other lower level wolves; omega (ω) are the lowest ranked wolves in the hierarchy, although they are the least important, they help to maintain the structure of the pack; delta (δ) wolves are those that are not in any of the previous categories, they have a lower hierarchy than alpha and betas but higher than the omega.

The GWO algorithm takes into account different actions within the hunting process:

- Tracking, chasing, and approaching the prey.

- Pursuing, encircling, and harassing the prey until it stops moving.

- Attack towards the prey.

2.1. Mathematical model

The GWO algorithm defines the fitness solution as alpha α, the second and third best solutions are beta β and gamma γ, respectively. Other solutions are named omega ω. The optimization process is guided by α, β and γ. As mentioned before, wolves tend to encircle its prey. This behaviour is modeled with the equations 1 and 2.

$$\vec{D} = |\vec{C} \cdot \vec{X}_p(t) - \vec{X}(t)| \tag{1}$$
$$\vec{X}(t+1) = \vec{X}_p(t) - \vec{A} \cdot \vec{D} \tag{2}$$

$\vec{X}_p$ is the position vector of the prey, $\vec{X}$ is the position vector of a grey wolf, $\vec{A}$ and $\vec{C}$ are coefficient vectors, and t is the current iteration. The vectors $\vec{A}$ and $\vec{C}$ are calculated according to the equations 3 and 4

$$\vec{A} = 2\vec{a} \cdot \vec{r}_1 - \vec{a} \tag{3}$$
$$\vec{C} = 2 \cdot \vec{r}_2 \tag{4}$$

where components of the vector $\vec{a}$ are linearly decreased form 2 to 0 as the iterations pass, r_1 and r_2 are random vector with elements between 0 and 1.

In nature, grey wolves know where the prey is, however, in the mathematical framework we don't know where the optimum is (prey). To overcome this problem, it's supposed that the alpha, beta and delta wolves have a better idea about the position of the prey. Assumed this, the best three results are saved and oblige the other search agents to update their position. To simulate this, the equations 5-7 are used.

$$\vec{D}_\alpha = |\vec{C}_1 \cdot \vec{X}_\alpha - \vec{X}|, \; \vec{D}_\beta = |\vec{C}_2 \cdot \vec{X}_\beta - \vec{X}|, \; \vec{D}_\delta = |\vec{C}_3 \cdot \vec{X}_\delta - \vec{X}| \tag{5}$$
$$\vec{X}_1 = \vec{X}_\alpha - \vec{A}_1 \cdot \left(\vec{D}_\alpha\right), \; \vec{X}_2 = \vec{X}_\beta - \vec{A}_2 \cdot \left(\vec{D}_\beta\right), \; \vec{X}_3 = \vec{X}_\delta - \vec{A}_3 \cdot \left(\vec{D}_\delta\right) \tag{6}$$
$$\vec{X}(t+1) = \frac{\vec{X}_1 + \vec{X}_2 + \vec{X}_3}{3} \tag{7}$$

In summary, the population of wolves begins randomly within the search space. Each position of the wolves is a possible solution. The parameter $\vec{a}$ decreases in each iteration from 2 to 0, this parameter indicates the exploration and exploitation capacity of the GWO. If the value of $|A \geq 1|$, the wolf diverges from the prey, if $|A \leq 1|$ the wolf converges towards the prey.

3. Heat Exchanger Mathematical Model

3.1. Heat transfer of shell side

The Bell-Delaware mathematical model is used to predict the shell-side convective heat transfer coefficient h_s. This model considers different parameters and geometrical variables (Shah and Sekulic, 2003). An ideal convective heat transfer coefficient h_i is calculated and corrected using five parameters j according to the equation 8.

$$h_s = h_i j_c j_l j_b j_s j_t \tag{8}$$

h_i is evaluated as

$$h_i = j \frac{C_{ps} Pr_s^{-2/3}}{A_{o,cr}} \tag{9}$$

where C_{ps} is the fluid heat capacity, Pr_s is the Prandlt number, and j_c, j_l, j_b, j_s, j_t are correction factors for baffle configuration, shell to baffle and tube to baffle leakage effects, bundle pass and partition bypass, baffle spacing, and temperature gradient, respectively. $A_{o,cr}$ is the flow area near the shell center-line for one cross-flow section and j is the Colburn factor, it is calculated with the equation 10 (Wildi-Tremblay and Gosselin, 2007). The variable a is determined with 11. The parameters a_1, a_2, a_3 and a_4 are reported in Wildi-Tremblay and Gosselin (2007).

$$j = a_1 \left(\frac{1.33}{Pt/d_o} \right)^a (Re_s)^{a_2} \tag{10}$$

$$a = \frac{a_3}{1 + 0.14 Re_s^{a_4}} \tag{11}$$

$$\tag{12}$$

The Reynolds number Re_s is evaluated with equation 13, μ_s is fluid viscosity, m_s is the mass flow rate in shell-side and d_o is the tube external diameter.

$$Re_s = \frac{m_s d_o}{\mu_s A_{o,cr}} \tag{13}$$

The area of the heat exchanger area is calculated with the Equation 14.

$$A = \frac{Q}{U \Delta T_{ml} F_t} \tag{14}$$

where Q is the heat transfer rate, U is the global heat transfer coefficient, T_{LMDT} is the logarithmic mean temperature difference and F_t is a correction factor. The U coefficient depends of the convective heat transfer of shell and tube side as well as fouling resistance of both sides, it is calculated with the Equation 15

$$U = \frac{1}{\frac{1}{h_s} + R_{fs} + \frac{d_o \ln\left(\frac{d_o}{d_i}\right)}{2k_w} + R_{ft}\frac{d_o}{d_i} + \frac{1}{h_t}\frac{d_o}{d_i}} \tag{15}$$

h_t is convective heat transfer coefficients for tube side, k_w is the material thermal conductivity, R_{fs} and R_{ft} are the fouling factors for shell and tubes. The tube internal diameter, d_i, is calculates as $d_i = 0.8d_o$.

3.2. Heat transfer in tube side

To calculate h_t, the equation 16 is used, this equation only works when the fluid in tubes is water (Sinnott and Towler, 2009). T_{Cm} is the medium fluid temperature and v_t is the fluid velocity in tubes that is calculated with the equation 17. Where ρ_t fluid density, m_t is the mass flow rate and N_t is the total number of tubes, is is calculated according the equation

$$h_t = \frac{4200\left(1.35 + 0.02 T_{Cm}\right) v_t^{0.8}}{d_i^{0.8}} \tag{16}$$

$$v_t = \frac{s}{N_t} \frac{m_t}{\pi \frac{di_i^2}{4} \rho_t} \tag{17}$$

3.3. Pressure drop calculations

The pressure drop in the tubes side is calculated with the equation 18, the friction factor, f, is evaluated as $f = 0.046 Re_t^{-0.2}$, s is the the pass number and L the length of tubes that is calculated using 19.

$$\Delta P_t = s \left(\frac{4fL}{d_i} + 2.5\right) \frac{\rho_t v_t}{2} \tag{18}$$

$$L = \frac{A}{\pi d_o N_t} \tag{19}$$

The expression 20 is used to calculate the pressure drop in shell-side

$$\Delta P_s = \left[(N_b - 1)\Delta P_{b,id}\zeta_b + N_b\Delta P_{w,id}\right]\zeta_l + 2\Delta P_{b,id}\left(1 + \frac{N_{r,cw}}{N_{r,cc}}\right)\zeta_b\zeta_s \tag{20}$$

where N_b is the number of baffles, $\Delta P_{b,id}$ is the ideal pressure drop in the central section, $N_{r,cw}$ is the effective tubes en the cross flow, $N_{r,cc}$ is the effective number of tubes rows crossed, ζ is a correction factor.

3.4. Cost estimation

In this study, the total annual cost (TAC) is used, this is the sum of fixed, C_f and operation cost C_{op}. To calculate the fixed cost the equation 22 is used (Smith, 2005). The purchase price C_p is corrected using the factors f_m, f_p and f_c for construction material, operating pressure and operation temperature, respectively. While the C_{op} is evaluated with equation 23.

$$C_p = 32800 \left(\frac{A}{80}\right)^{0.68} \tag{21}$$

$$C_f = C_p f_m f_p f_c \tag{22}$$

$$C_{op} = \frac{(E_s + E_t) Ec H_r}{1000} \tag{23}$$

$$TAC = C_f \frac{r(1+r)^n)}{(1+r)^n) - 1} + C_f \tag{24}$$

where E_s and E_t is the pump power (Watts) used in shell and tube side, respectively. Ec is the energy cost (\$/kWh), Hr is the operational hours per year, n is the projected life time and r the interest rate per year. The optimization is performed using eleven parameters that can have a value between a given range, those are:

- Diameter of shell (D_s): 300mm -1000mm.

- Outer diameter of tube (d_o): 15.87mm 63.5mm.

- Tube pitch P_t: $[1.25do, 1.5do]$.

- Tube layout angle (TL): $[30°, 45°, 90°]$

- Baffle spacing at center (L_{bc}): $0.2D_s - 0.55D_s$

- Baffle spacing at the inlet and outlet ($L_{bo} = L_{bi}$): $L_{bc} - 1.6L_{bc}$

- Baffle cut (B_c): $[25\%, 30\%, 40\%, 45\%]$

- Number of tube passes (s): $[1, 2, 4]$

- Tube-to-baffle diametrical clearance (δ_{tb}): $0.01d_o - 0.1d_o$

- Diametrical clearance of shell-to-baffle (δ_{sb}): $0.01D_s - 0.1D_s$

- Outer diameter of tube bundle (D_otl): $0.8(D_s - d_{sb})$ - $0.95(D_s - d_{sb})$

The optimization process is subject to constrains for maximum allowed pressure drop in tube-side and shell-side, fluid velocity, and length to shell-diameter ratio, as follows:

$$\Delta P_s, \Delta P_t \le \Delta P_a \tag{25}$$
$$1\text{m/s} \le v_t \le 3\text{m/s} \tag{26}$$
$$L/D_s < 15 \tag{27}$$

The equation 28 is the fitness function. The constants r_1, r_2, r_3 and r_4 are penalty values, if a constrain is violated a penalty value is activated.

$$FF = TAC + r_1 \, max\left[(\Delta P_s - \Delta P_a), \, 0\right] + r_2 \, max\left[(\Delta P_t - \Delta P_a), \, 0\right] +$$
$$r_3\left[max\left\{(1 - v_t)\right\} + max\left\{(3 - v_t)\right\}, \, 0\right] + r_4 \, max\left[(L/D_s - 15), \, 0\right] \tag{28}$$

4. Case study

The case study is taken from Wildi-Tremblay and Gosselin (2007). It is required to design a heat exchanger with a flow rate of 18.8 kg/s of cooling water, the inlet temperature is 33 °C and the outlet temperature is 37.2 °C. The hot fluid is nafta, the inlet temperature is 114 °C and the outlet temperature is 40 °C. Water is placed in tube-side and nafta in shell-side. The construction material for tube and shell side is stainless steel and carbon steel, respectively.

Calculations are performed using a 5 % interest rate, 20 years life time period, 5000 operation hours per year, a pump efficiency of 0.85 and an electricity cost of 0.1 $/kWh. The maximum allowed pressure drop is 70,000 Pa. The factors to modify the purchase cost are $f_m = 1.7$, $f_t = 1.0$ and $f_p = 1.0$.

5. Results

MATLAB was used as codification environment for the heat exchanger mathematical model and GWO model. A population of 50 individuals was used with 50 iterations. To generate statistical information 30 runs where made. An average cost of 4,095.36 USD was found with a standard deviation of 103.57 USD. The minimum value was 3,977.76 USD. Particle swarm optimization (PSO) algorithm was also used to solve the problem as a comparison. With PSO an average cost of 4,197.56 USD with a standard deviation of 220.07 USD, the minimum value was 3,976.38 USD. The Table 1 shows the parameters value for both optimization methods. It can be seen that both method reached a similar solution. The computing time was 1.0161s for GWO and 2.1881s for PSO.

Table 1: Parameters for optimal heat exchanger configuration.

Parameter	D_s	d_o	N_t	A	L	P_t	TL	s	L_{bc}	L_{bo}	B_c
Unit	*mm*	*mm*		*m²*	*m*	*mm*	*°*		*mm*	*mm*	*%*

6. Conclusion

The Grey Wolf Optimizer has been proposed as a technique to solve the design and optimization of a shell-and-tube heat exchanger, modeled through the Bell-Delaware method. The optimization model is a MINLP, which is codified and solved in a MATLAB routine. The method has been proved to be efficient, reaching the optimal solution in a relatively low computing time. Moreover, the standard deviation between the obtained solutions in different tests is low, implying that the method tends to reach very similar optimal points for a number of runs.

Abstract

Data-driven models are increasingly used to model chemical processes with the long-term goal of using them for real-time optimization. At the moment, the uncertainty contained in these models is scarcely modeled or mostly assumed to adhere to a multivariate normal distribution. In this contribution, we model both the input-output relation of a rigorous model as well as the uncertainty. During the training process of surrogate models, both accuracy as well as smoothness of the resulting models are ensured. For the case study of a Chloralkali electrolyzer cell, snapshots are generated based on a rigorous model. Surrogate models for input-output relationships and uncertainty are trained and compared regarding their fit, smoothness, and their applicability in chance-constrained optimization. Based on this methodology, a Gaussian process was developed for the input-output modeling and a functional covariance matrix with separate models for the entries using both artificial neural networks and linear regression for separate entries. The models were tested in a chance-constrained optimization framework showing excellent performance regarding speed of the computation and validity of the results.

Keywords: Data-driven modeling, surrogate, models, optimization under uncertainty

1. Introduction and Motivation

Data-driven models are increasingly used in chemical engineering applications for the support of optimal process operation. Examples of data-driven models recently used are linear regressions, artificial neural networks, support vector regression, gaussian process regression (also known as kriging), etc. Data to train and validate these models can stem from different sources, either experimental data or simulation snapshots from existing first principle models.

These sets of training data, of course, contain uncertainty: on the one hand through experimental measurement error or on the other hand through known uncertain parameters of an original model. This uncertainty information should be considered in the actual description of the data-driven model's output uncertainty.

Given the way how data-driven models are derived, it is well understood that their applicability is limited to the domain of the original data they are trained and validated upon. Beyond that, extrapolation and sometimes even interpolation between sparsely scattered data points becomes highly unreliable. There are a couple of techniques available to make sure that optimization solvers operating on data-driven models stay within the area of applicability, e.g. the implementation of inequality constraints regarding the domain of the model or the introduction of uncertainty maps as model elements.

In this contribution, we investigate possibilities to extend typical data-driven surrogate models by uncertainty models for the description of the uncertainty of each output variable, while standard data-driven techniques only provide static descriptions of the model's uncertainty. Furthermore, we evaluate these models regarding their performance in a framework for optimization under uncertainty.

2. Modeling of Input-Output Relationships and Uncertainty

To derive models for both input-output relationships as well as the uncertainty, we pursue a two-stage procedure. In the first stage, the input-output relationship is modeled, in the second stage the uncertainty of the outputs is then described. This is in contrast to most modeling strategies typically followed in machine-learning, wherein the assumptions for the input-output model often also contain the description of the uncertainty. However, this is then mostly limited to multivariate normal distributions or discontinuous probability density models and only describes the uncertainty of the data-driven model.

For all further discussions here, a set of input and output data points is already given, which could stem from either experiments or sampling on a simulation model. Henceforth, a rigorous model will be taken as the basis.

2.1. Modeling of Input-Output Relationships

For modeling the input-output relationships, we assume that the input and output data have already been clustered, i.e. points in input space close to one another have been aggregated. Hence, clustering techniques will not be discussed here. Building upon existing implementations of various data-driven models in scikit-learn (Pedregosa et al., 2011), our python framework generates linear regression (LR), Gaussian process regression (GPR), and artifical neural networks (ANN) based on a wide selection of options for kernels, model parameters, optimization settings, and of course the ratio between the number of training data and test data.

After training the various models, they are evaluated with different statistical metrics describing their deviation to the testing data and the smoothness of the resulting surface functions for outputs plotted over inputs. The finally selected model is henceforth denoted as g with input variables u and output variables y, see Eq. (3).

2.2. Modeling of Uncertainty

Based on the chosen model for the input-output relationships, the deviations of all data points compared to that model are then computed and taken as the basis for modeling the uncertainty. For this purpose, we take two different approaches, which are sketched in Fig. 1. In the first approach, modeling the uncertainty is solely based on the deviations of the outputs and is independent of any input values. In the second approach, the input values are also considered, so that influences of the inputs on the uncertainty of the outputs may be incorporated.

As ansatz models for the uncertainty, multivariate normal distribution, Dirichlet distribution (multivariate beta distribution), and kernel density estimation are considered. Yet again, these models are trained/fitted to the present data and compared regarding their capabilities to describe the uncertainty. As above, the eventually selected uncertainty model is denoted as $\widetilde{g}$, which describes the uncertain outputs $\widetilde{y}$ depending on the outputs y generated by model g, some model parameters $\hat{p}$, and optionally the inputs u, see Eq. (4).

For the model generation, relevant uncertainty data for the respective ansatz is created at every input point. For a multivariate normal distribution, this would be the covariance of the outputs and for the Dirichlet distribution the model parameters α. Based on this data, the uncertainty model is trained and tested using the same python framework as for the input-output model generation.
Figure 1: Two different modeling strategies pursued herein to accurately model the uncertainty contained in original data and induced by input-output model.

3. Framework for Optimization Under Uncertainty

The framework for optimization under uncertainty is fully implemented in python and builds upon the department's existing framework for chance-constrained optimization - the DoCCE (dynamically optimized chance constraint evaluator (Werk et al., 2012)). The extended framework developed for this contribution now supports systems as characterized by the following nonlinear programming problem (NLP) with objective function f, data-driven model g, uncertainty model $\widetilde{g}$, and the desired probability level α:

$$\min_{x} \quad f(x) \tag{1}$$

$$\text{s.t.} \quad \Pr\{h(x) \geq 0\} \geq \alpha \tag{2}$$

$$y = g(u) \tag{3}$$

$$y, u \subset x \quad \wedge \quad y \cap u = \emptyset$$

$$\widetilde{y} = \widetilde{g}(y, p) \quad \vee \quad \widetilde{y} = \widetilde{g}(y, u, \hat{p}) \tag{4}$$

$$\widetilde{y} \subseteq y$$

For additional information on DoCCE's capabilities for mixed-integer nonlinear programming problems refer to (Esche et al., 2016).

4. Case Study - Chloralkali Electrolyzer Cell

To test the performance of input-output and uncertainty models inside the framework for optimization under uncertainty, a rigorous, steady-state model of the anolyte half cell of a Chloralkali electrolyzer cell (CEC) is used as a small-scale example.

The anolyte cell is modeled as a CSTR for a five component mixture (Na^+, Cl^-, OH^-, H_3O^+, H_2O). The model consists of 32 equations including descriptions for the chlorine production by the anode reaction, the autoprotolysis of water, the migration based sodium ion flux, and descriptions for water leaving by electroosmosis and with the chlorine gas stream.

4.1. Generation of Snapshots

The rigorous model is implemented in MOSAICmodeling (Esche et al., 2017) and from there exported to AMPL (Fourer et al., 2003) and solved as a simulation problem with IPOPT (Wächter and Biegler, 2005). For the case study, the input variables (feed volume flow and current density of CEC) are varied between a given set of bounds and the model parameters (feed temperature and electroosmosis factor) are assumed to follow a multivariate normal distribution. Samples for

the output variables (outgoing liquid volume flow, mass fractions of all components) are generated by sampling 1 000 times from the input variables with a Latin Hypercube sampling and 20 times from the parameters following the normal distribution. Hence, 20 000 output samples are present, which can easily be clustered along the input samples. The output samples obtained from AMPL are then filtered to eliminate randomly appearing, non-converged solutions and the remainder is stored for subsequent training and testing.

4.2. Input-output Model

Based on the aforementioned number of samples, Gaussian process regression shows the best performance regarding match and smoothness of the resulting surface functions compared to the other tested model types. Randomly, 70 % of the generated snapshots are taken for training the Gaussian process with a squared exponential covariance function as kernel. The remaining data is used for testing and shows a mean squared error of 10^{-5}, an R^2 value of around 0.96, and a mean percentual deviation of around 2.7 %. The input-output model describes two inputs (feed volume flow, current density of CEC) and six outputs (outgoing liquid volume flow, mass fractions of all components). For the first two outputs (outgoing liquid volume flow, mass fraction of Na^+), the resulting surface functions are shown in Fig. 2 (plots (a) and (b)).

4.3. Uncertainty Model

For modeling the difference between data-driven model and original snapshot data, a number of different probability density functions were tested. The best fit was achieved with a functional covariance matrix describing all outputs of the data-driven model as follows:

$$\widetilde{y} = \widetilde{g}(y, Cov(u))) = y + \mathcal{N}(0, Cov(u)) \tag{5}$$

Every entry of the covariance matrix Cov is a function of the input variables u, which corresponds to the second approach sketched in Fig. 1. Depending on the form of variance and covariance of the respective output variables, either linear regression or gaussian process regression are used to describe the functional relationship between input and output uncertainty distribution. For the application here, all six output variables are taken as uncertain, resulting in a six-by-six covariance matrix. The surface function describing the relationship between the two inputs and the variance of output no. 2 and the covariance between outputs 1 and 2 are plotted in Fig. 2 (plots (c) and (d)). Of the 36 entries of the covariance matrix, eight entries are described with linear regression models, the remaining ones are described by individual ANNs.

To ensure that the reliability of the input-output model tends to zero outside of its training region, the models for the variance/diagonal entries in Cov are there set to the magnitude of the respective output y. This allows for an indirect hull formulation, which does not need to be added as an additional constraint and is adaptive to further training with new data.

4.4. Chance-constrained Optimization

To test the usability of the derived input-output and uncertainty models, a simple chance-constrained optimization problem is formulated based on the CEC example. As objective function, the outlet flow of sodium ions is minimized while a chance constraint is implemented to enforce an upper bound on the pH value of 2.88 (mass fraction of H_3O^+ equal to $2.5 \cdot 10^{-5}$) inside the cell. Always starting from the same initial point, the enforced probability level α of the chance constraint is steadily increased. The resulting increase in the objective function value is plotted over the probability level in Fig. 3. The objective function value shows the expected increase with the steadily increased constraint probability. The CPU seconds necessary for the computation appear independent of the enforced probability and are in a very reasonable range at below 25 seconds.

(a) Output 1 over Inputs

(b) Output 2 over Inputs

(c) Variance of Output 2 over Inputs

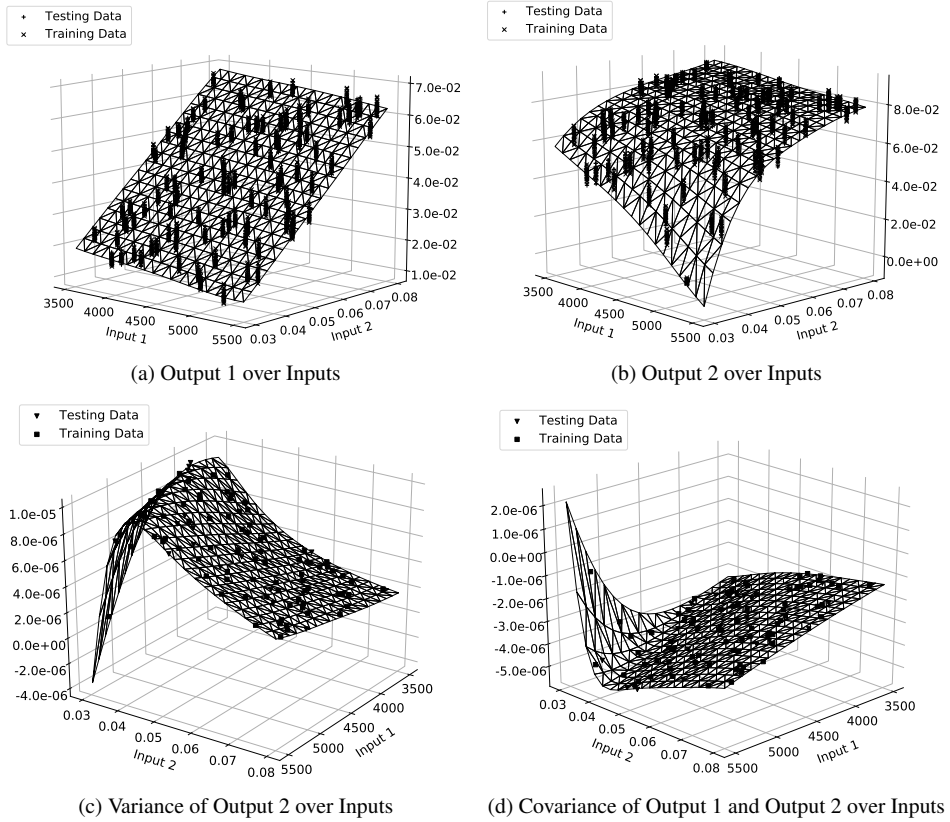
(d) Covariance of Output 1 and Output 2 over Inputs


Figure 2: Figures (a) and (b) showing outputs 1 and 2 plotted over the two input variables. Figures (c) and (d) showing variance of output 2 and covariance between output 1 and output 2 plotted over both inputs. x/square: training data, +/triangle: testing data; surface functions: predicted data and uncertainty models respectively.
Figure 3: Objective function plotted over the enforced probability level. CPU seconds given on the secondary axis.

For the computation of the chance constraint's probability a five-dimensional sparse grid is used (first five outputs). For every single grid point the position is computed, at which the sixth output variable ensures the equality of the inner constraint ($h(x) = 0$; mass fraction of H_3O^+ equal to $2.5 \cdot 10^{-5}$). Given the variation of the covariance matrix over the input space, the sparse grid is adapted to the covariance matrix at every single iteration, i.e. at a probability computation.

The computation of the inner constraint is done by the secant method. The DoCCE framework by default uses Newton's or Haley's method in case first or even second derivatives are available. However, on using the data-driven input-output models, the framework falls back to the derivative-free approach. This is naturally highly inefficient, but given the speed of the input-output models the many function calls necessary for the secant method can be easily handled.

5. Conclusions & Outlook

Up to now, offline or even online application of optimization under uncertainty is still a major challenge with the time required for computing uncertain scenarios or integrating over the uncertainty space being the main hurdles. Using surrogate models to describe both input-output relations and uncertainty of an existing rigorous model or of plant data can be a building block to allow for the wide-spread fast application of optimization under uncertainty.

By initially comparing several different types of surrogate models for the input-output relationship, both a good match and sufficient smoothness can be ensured. Based on the hence obtained model, the uncertainty is then described with an additional model. Here, good results were obtained using a functional description of a covariance matrix of all the outputs of the input-output surrogate model. Using these two models together for optimization under uncertainty ensures both speed and reliability of the optimization results given their high accuracy in modeling the original data and their explicit model structures.

In future work, the derivatives will be added to both input-output as well as uncertainty models to further speed up the optimization run. In addition, the continuous retraining of both models will be exercised in online applications to continuously reduce the model uncertainty and extend the range of validity of these models while optimally running a plant. Furthermore, the minimally required training effort based on rigorous simulation snapshots will need to be discussed and hence also the design of computer experiments to limit the number of potentially expensive simulation runs.

Abstract

Parameter estimation problems are solved on a regular basis to fit thermodynamic models to experiments. However, conducting these experiments with a high accuracy is time-consuming. Hence, methods to identify parameters as fast as possible have to be used. In this contribution, subset selection is applied to parameter estimation problems with different datasets, such as VLE and excess enthalpy data. It is demonstrated that performing a subset selection with sensitivity analysis leads to an efficiently reduced set of estimated parameters. The results of the subset selection could additionally be used for an optimal design of experiments as the information gain of the different experimental datasets (VLE data, excess enthalpy) is different.

Keywords: Parameter estimation, Subset selection, Thermodynamic models

1. Introduction

Thermodynamics are a fundamental aspect of process design, modeling, simulation, and optimal operation in process engineering as evidenced by many publications on this subject in the past decades, e.g. (Hendriks et al., 2010). Many models have been suggested to describe the various phase equilibria appearing in multicomponent mixtures, such as activity models, (semi-)empirical cubic equations of state, and advanced equations of state (SAFT family, CPA, etc.).

Most thermodynamic models are highly nonlinear and hold several parameters, which are fitted to experimental data. At the same time, there is often little measurement data available and obtaining additional high-quality experimental data is time-consuming. By consequence, a number of issues can arise when performing parameter estimation on complex thermodynamic models: Noisy measurement data can be overfitted, identifiability of parameters cannot be ensured, and this in turn may lead to ill-conditioned parameter estimation problems, which show poor convergence and yield large variances of the estimated parameters. In addition, little can be found regarding parameter identifiability or their sensitivity with respect to the objective for thermodynamic applications, although there have been studies on parameter identifiability in general in the past few years, e.g. (Nogueira and Pontes, 2017).

Due to these shortcomings, this contribution investigates the identifiability of parameters in thermodynamic models in further detail. For this purpose, two parameter estimation problems were selected: the binary VLE of methanol and water and the dilution of sodium chloride in water. Both are described with appropriate activity models, which are briefly outlined in the next section. Activity models were selected because of their wide use in practical applications in the process industry. On top of that, they are preferred for low pressure applications for which the fugacity coefficient can usually be neglected. However, the approach is not limited to them and will certainly be extended to other property models in the future, especially equations of state.

2. Theoretical Fundamentals

In this section, the theoretical fundamentals of thermodynamic phase equilibria, the applied activity models and the parameter estimation framework are briefly discussed.

2.1. Thermodynamics

Thermodynamic equilibria can be described using the γ-φ-approach for the isofugacity criterion. Under low pressure assumptions, this yields Raoult's Law, extended by the activity coefficient in the liquid phase:

$$x_i \gamma_i P_{0,i}^{VL} = y_i P, \tag{1}$$

where x_i and y_i are the liquid and vapor mole fraction of component i, γ_i is the activity coefficient, $P_{0,i}^{VL}$ is the vapor pressure of the pure component and P is the pressure of the mixture. The activity coefficient is computed with the Wilson and the NRTL equation (Wilson, 1964; Renon and Prausnitz, 1968) for the methanol/water system and eNRTL (Chen and Evans, 1986) for the NaCl/water system.

Wilson: The expression for the activity coefficient is

$$\ln \gamma_i = 1 - \ln \left(\sum_{j=1} A_{ij} x_j \right) - \sum_{j=1} \frac{A_{ji} x_j}{\sum_k A_{jk} x_k}; \quad A_{ij} = \frac{v_j}{v_i} \exp\left(-\lambda_{ij}\right), A_{ii} = 1, \tag{2}$$

where v_i is the molar volume of component i. The binary interaction parameters λ_{ij} are the two parameters to be estimated. However, λ is often assumed to be temperature-dependent. This leads to a parameter estimation problem of up to ten parameters:

$$\lambda_{ij} = a_{ij} + \frac{b_{ij}}{T} + c_{ij} \ln T + d_{ij} T + e_{ij} T^2. \tag{3}$$

NRTL and eNRTL: The activity coefficient of the solvent is given by the product of the long-range contribution (LR) from the Debye-Hückel equation and the short-range contribution (SR) from the eNRTL equations. The equations for the LR term are not shown here because they do not hold any parameters for this estimation. The reader is referred to the literature (Chen and Evans, 1986). The equation for the SR term is (Chen and Evans, 1986):

$$\begin{aligned}
\ln \gamma_{i=m}^{eNRTL} &= \frac{\sum_j X_j G_{jm} \tau_{jm}}{\sum_k X_k G_{km}} + \sum_{m'} \frac{X_{m'} G_{mm'}}{\sum_k X_k G_{km'}} \left(\tau_{mm'} - \frac{\sum_k X_k G_{km'} \tau_{km'}}{\sum_k X_k G_{km'}} \right) \\
&+ \sum_c \sum_{a'} \frac{X_{a'}}{\sum_{a''} X_{a''}} \frac{X_c G_{mc,a'c}}{\sum_{k \neq c} X_k G_{kc,a'c}} \left(\tau_{mc,a'c} - \frac{\sum_{k \neq c} X_k G_{kc,a'c} \tau_{kc,a'c}}{\sum_{k \neq c} X_k G_{kc,a'c}} \right) \\
&+ \sum_a \sum_{c'} \frac{X_{c'}}{\sum_{c''} X_{c''}} \frac{X_a G_{ma,c'a}}{\sum_{k \neq a} X_k G_{ka,c'a}} \left(\tau_{ma,c'a} - \frac{\sum_{k \neq a} X_k G_{ka,c'a} \tau_{ka,c'a}}{\sum_{k \neq a} X_k G_{ka,c'a}} \right),
\end{aligned} \tag{4}$$

where m, c, and a stand for molecule, cation, and anion. The equations for the cations and anions are not shown here due to space limitations. In addition, $G_{ji,ki}$ is given by:

$$G_{ji,ki} = \exp\left(-\alpha_{ji,ki} \tau_{ji,ki}\right). \tag{5}$$

The binary interaction parameters $\tau_{ji,ki}$ and the non-randomness parameter $\alpha_{ji,ki}$ are the three parameters subject to the estimation. Again, τ and also α are however often assumed to be temperature-dependent. Here, we limit ourselves to the temperature dependence of τ. This leads to a parameter estimation problem of up to seven (eNRTL) or eleven (NRTL) parameters:

$$\tau_{ji,ki}^{eNRTL} = a_{ji,ki} + \frac{b_{ji,ki}}{T} + c_{ji,ki} \left[\frac{T^{ref} - T}{T} + \ln\left(\frac{T}{T^{ref}}\right) \right]; \quad \tau_{ji}^{NRTL} = a_{ji} + \frac{b_{ji}}{T} + c_{ji} \ln(T) + d_{ji} T^{e_{ji}}. \tag{6}$$

2.2. Parameter Estimation Framework with Subset Selection

The parameter estimation and identifiability analysis is carried out using the algorithm presented in (Müller et al., 2014). Its two main features are the regularization of the estimation problem via subset selection and an estimate of the covariance matrix of the parameters. First of all, data must be sampled, i.e. thermodynamic equilibrium data must be collected. Secondly, lower and upper bounds as well as initial guesses must be supplied. More details on this step are given below. Afterwards, a first parameter estimation is performed using the complete parameter set. Based on the results, the Fisher Information matrix (FIM) is approximated by

$$FIM \approx S^T \Sigma^{-1} S, \tag{7}$$

where S is the sensitivity matrix containing all derivatives of the model responses (temperatures, pressures, and vapor mole fractions) with respect to the parameters, and Σ is a matrix holding all variances of the measurements on its diagonal. In the following, the parameters are ranked according to their identifiability based on a singular value decomposition of the FIM. Parameters that cannot be identified are fixed to their current values and the parameter estimation is repeated until no changes in the active set take place. The lower bound of the standard deviation of the estimated parameters is estimated with the Cramér-Rao inequality. Hence, the standard deviations are the roots of the diagonal elements of the inverted FIM (Müller et al., 2014). The objective function f of the parameter estimation problem is

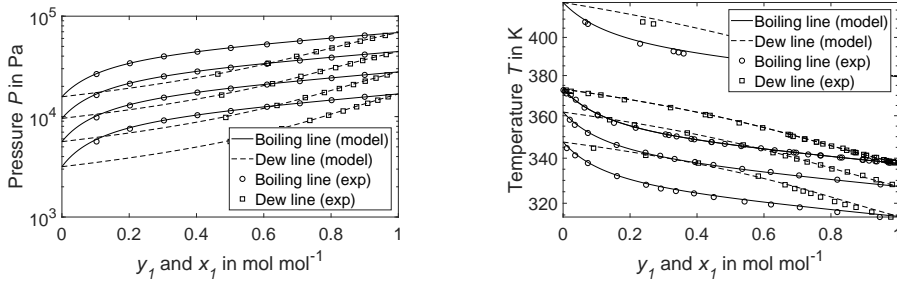
$$\min_p f = \sum_{DP} \sum_{DType} \left(\frac{DType_{DP}^{exp} - DType_{DP}^{calc}}{\sigma_{DType,DP}} \right)^2 \tag{8}$$

where the first sum ranges over all experimental isothermal and isobaric data points DP, the inner sum iterates all data types $DType$ (e.g. temperature, pressure, or mole fraction), and σ is the standard deviation of the measurement error. However, these are not always stated in the original datasets. In these cases, σ_P, σ_T, and σ_{y_i} were assumed to be 100 Pa, 0.1 K, and 0.01, respectively, which are typical values in the literature.

Table 1: Results of parameter estimation for methanol/water in step 1 (Wilson), experimental data at 328 K, taken from (Fu et al., 1989). Full-scale problem did not converge for 8 and 10 parameters.

Estimated parameters	Identifiable parameters	$\frac{\sigma_{a_{12}}^{PE,Full}}{|a_{12}|}$	$\frac{\sigma_{a_{21}}^{PE,Full}}{|a_{21}|}$	$\frac{\sigma_{b_{12}}^{PE,Full}}{|b_{12}|}$	$\frac{\sigma_{b_{21}}^{PE,Full}}{|b_{21}|}$	$\frac{\sigma_{c_{12}}^{PE,Full}}{|c_{12}|}$	$\frac{\sigma_{c_{21}}^{PE,Full}}{|c_{21}|}$
2	2	4.7E-7	1.5E-8	-	-	-	-
4	2	4.4E-1	1.1E-1	3.8E-1	9.9E-2	-	-
6	2	1.7E+0	1.1E+1	4.8E+2	8.4E+2	2.91E-1	1.78E+0

3. Results and Discussion

To analyze the behavior of the subset selection, the results are presented in three parts: In the first step, the parameter estimation is performed on equilibrium data only at a single constant temperature. In a second step, the number of different experimental temperatures is increased and typical temperature-dependent expressions for the parameters are introduced. Finally, additional data, such as excess enthalpies, are added to the parameter estimation problem. For all cases, the number of identifiable parameters and their variances are analyzed to demonstrate the merit of applying subset selection. Initial guesses for the parameters are always set to the arbitrary vectors $p_{init}^{NRTL} = [\alpha, a_{12}, a_{21}]^T = [0.2, 1, 2]^T$, $p_{init}^{Wilson} = [a_{12}, a_{21}]^T = [1, 2]^T$, and $p_{init}^{eNRTL} = [\alpha, a_{12}, a_{21}]^T = [0.2, 4, -8]^T$. Other parameters are initially set to zero. The algorithm has been implemented in Matlab 2017a using lsqnonlin.


(a) Experimental data taken from (Fu et al., 1989) at 298, 308, 318, and 328 K.

(b) Experimental data taken from (Swami et al., 1956; Álvarez et al., 2011; Yang et al., 2011, 2012) at 0.4, 0.67, 1, and 4.3 bar.

Figure 1: P-x-y (a) and T-x-y (b) diagramm for methanol (1) and water, calculated with the NRTL equation; $a_{12} = -0.01$, $a_{21} = 0.79$, and $\alpha = 0.5$.

3.1. Step 1: One dataset

In this first section, only one dataset at constant temperature is used. The results are shown in Tab. 1 for the methanol/water system and the Wilson equation. The algorithm determines that only two of up to ten parameters are identifiable. This is no surprise as the λ values are constants for a given temperature. These results can hence be seen as a plausibility check. Moreover, Tab. 1 shows the estimated standard deviation of the estimation divided by their expected value for the full-scale set (all parameters are active, first iteration of the algorithm) for 2, 4, and 6 estimated parameters. These values increase, the more parameters are added to the problem, until the standard deviation becomes larger than the expected value itself (last line in Tab. 1). Hence, the estimated parameters become more and more uncertain.

3.2. Step 2: Several datasets

In the next step, more experimental data are added to identify additional parameters in the temperature dependence of the interaction energies. The results of the parameter estimation are shown in Fig. 1 for the NRTL equation. The results for the Wilson equation are not shown here. Both activity models can accurately describe the VLE of methanol and water. However, only up to 4 parameters are identifiable for both models. The results for the parameter estimation of the full set (all parameters active, no subset selection) are given in Tab. 2 for NRTL. They show that adding additional data does not necessarily reduce the uncertainty of the parameters. For NRTL, the non-randomness factor α remains unidentifiable for all datasets. Secondly, it is observed that the number of identifiable parameters can decrease when more parameters are added to the problem. In addition to the larger dimensionality of the problem, this further complicates the parameter estimation as it leads to small gradients of the objective function hyperplane. Typically, the standard deviation of the parameter subset SsS0 is at least two orders of magnitude smaller than for the full set (see first line in Tab. 1 and 2). Thirdly, it must be noted that the excess enthalpy is poorly described if it is not considered in the parameter estimation problem (not shown here).

A second parameter estimation was performed for the water/NaCl system, for which total dissociation was assumed. The results are shown in Fig. 2a. Although the parameters are estimated over a temperature range from 298 to 423 K, only three parameters of seven (1 in 3) can be identified. All those three parameters describe the temperature dependence of the same binary interaction energy, meaning that the system can well be described by estimating only one binary interaction and set the other to an arbitrary value.

Table 2: Results of parameter estimation for methanol/water in step 2 (NRTL), experimental data as stated in Fig. 1.

Estimated parameters	Identifiable parameters	$\dfrac{\sigma_{a_{12}}^{PE,Full}}{|a_{12}|}$	$\dfrac{\sigma_{a_{21}}^{PE,Full}}{|a_{21}|}$	$\dfrac{\sigma_{b_{12}}^{PE,Full}}{|b_{12}|}$	$\dfrac{\sigma_{b_{21}}^{PE,Full}}{|b_{21}|}$	$\dfrac{\sigma_{c_{12}}^{PE,Full}}{|c_{12}|}$	$\dfrac{\sigma_{c_{21}}^{PE,Full}}{|c_{21}|}$
3	2	5.0E-6	9.5E-8	-	-	-	-
5	4	2.8E-6	2.7E-6	2.7E-6	5.8E-6	-	-

11	2	8.4E-2	4.1E-6	3.8E-2	7.4E-6	1.6E-3

3.3. Step 3: Additional information

In this last step, additional information for the parameter estimation is given by including data of the excess enthalpy, which is correlated to the activity model by the Gibbs-Helmholtz equation. The results for the calculation of the excess enthalpy are displayed in Fig. 2b. Contrary to previous estimations, the excess enthalpy can now be well described without losing accuracy in the phase equilibria. Adding excess enthalpy data has a decisive effect on the parameter estimation problem as just one set of excess enthalpy data makes four of five parameters identifiable for the NRTL equation. This was not possible by using four different isothermal sets of VLE data in the parameter estimation and leads to an important message with respect to experimental investigations: If one excess enthalpy dataset yields more information gain than three additional VLE sets, significant costs and time can be saved by performing a subset selection with sensitivity analysis on a regular basis to plan the next experiments. As the measurement of thermodynamic equilibria is
(a) calculated with the eNRTL equation, $a_{12} = 955.61$, $a_{21} = -1.12$, and $\alpha = 0.5$, experimental data at temperatures between 298 and 423 K from (Pepela and Dunlop, 1972; Mashovets et al., 1973; Berling et al., 1999; Nasirzadeh et al., 2004).

(b) calculated with the NRTL equation, $a_{12} = 0.98$, $a_{21} = 0.43$, $b_{12} = -321.95$ K, $b_{21} = 95.12$ K, and $\alpha = 0.5$, experimental data at 278.15, 298.15, and 323.15 K from (Tomaszkiewicz et al., 1986).

Figure 2: P-x-y diagramm for water and dissociated NaCl (a) and h^E-x diagramm for methanol and water (b). Only one parameter remains identifiable for the NaCl/water system.

quite time-consuming if done correctly, subset selection will be a valuable asset for optimal design of experiments in thermodynamic application.

4. Conclusion and Outlook

This contribution demonstrated the application of parameter estimation with subset selection for methanol/water and NaCl/water using different activity models. It was shown that thermodynamic models can contain unidentifiable parameters, e.g. the non-randomness parameter α in the NRTL model. This justifies the conventional suggestion to fix α in parameter estimations. The second major result concerns complex parameter estimation problem, for example in electrolyte chemistry. For these applications, the number of parameters could be drastically reduced by using a subset selection to simplify the parameter estimation problem. This may lead to more reliable thermodynamic models for gas treatment or electrolysis. The third important aspect is the improved parameter identifiabiliy of activity models by using excess enthalpy data instead of additional VLE data. This could be related to the additional derivative information on the activity model that is introduced when using excess enthalpy data. In future work, the algorithm will be used for more complex phenomena, such as Vapor-Liquid-Liquid Equilibria, and more complex models, such as equations of state, to investigate its performance.

Abstract

A chloralkali membrane cell process is modeled based on a macro-homogeneous approach. The Poisson-Nernst-Planck (PNP) equation is applied to model the multi-ion transport in the system. A steep gradient problem arises at the membrane's interfaces. The finite differences method, Hermite collocation on finite elements, and the Galerkin finite elements method are compared to determine the most efficient method to tackle the problem. A logarithmic reformulation is also investigated to evaluate its compatibility to solve the problem. The finite differences method and the Hermite collocation method turn out the best results, respectively in terms of the compuational time and accuracy. Afterwards, the finite differences method is applied to model a solution-membrane system based on the 1D PNP equation, whose results are discussed further regarding their subsequent applicability for extensive simulation studies.

Keywords: Hermite Collocation, Galerkin Finite Elements, The Poisson Nernst Planck equation, Chloralkali electrolysis

1. Introduction

The chloralkali membrane process is a potential energy buffer for demand-side management in the electricity market. Although this is an economically promising solution, the resulting dynamic operation is highly challenging. The chloralkali membrane electrolyzer is one among many critical apparatuses, which are fragile to dynamic load changes and also devalue considerably during dynamic operation. The total reaction in the electrolyzer is formulated as:

$$2\,NaCl + 2\,H_2O \longrightarrow Cl_2 + H_2 + 2\,NaOH$$

A model of a chloralkali membrane process is developed to enable further investigation of the dynamic characteristics of this equipment during flexible operation. The macro-homogeneous modeling approach introduced by Verbrugge and Hill (1990) and also validated by Verbrugge and Hill (1992) is considered to model the chloralkali process. It is already widely used to model electrochemical systems due to its reasonable accuracy and low computational cost, while it is adequately able to predict necessary phenomena for practical applications. This approach assumes that the modeled components are continuously distributed over the modeled spatial domain and can be represented by macroscopic variables, such as concentrations. Some authors (Moshtarikhah et al. (2017), Fíla and Bouzek (2003), Kodým et al. (2016)) have modeled the chloralkali membrane cell using this approach for a high current density regime. A numerical challenge in modeling such a system usually comes from the steep gradient at phase boundaries. Zheng and Wei (2011) successfully reduced the boundary layer complexity by incorporating the Boltzmann equation into

the PNP system despite of the narrowed model validity under the overlimiting current regime. Various discretization methods have been applied in modeling the problem. However, the most suitable one remains a question. In the present contribution, a logarithmic reformulation and three well-known discretization methods: the finite differences method, the finite elements method with Hermite collocation, and the Galerkin finite elements method are benchmarked to justify the suitability in solving such problems.

2. Model Description

The modeled system depicted in Fig. 1 considers three main components in the chloralkali membrane cell, i.e. $Na^+(i = 1)$, Cl^- $(i = 2)$ and $OH^-(i = 3)$, which are assumed to have a continuous distributions in space. The domain is divided into three different parts: an anolyte diffusion layer (ADL), the cation exchange membrane (CM), and a catholyte diffusion layer (CDL).
Figure 1: Schematic of the solution-membrane system

2.1. The Poisson Nernst Planck equation

The Poisson Nernst Planck (PNP) model considers the concentration of the three ionic components c_i and the electric potential φ in the modeled spatial domain. The 1D steady-state Poisson-Nernst-Planck system consists of:

$$D_i\left(\frac{d^2 c_i}{dx^2} + \frac{z_i F}{RT}\left(\frac{dc_i}{dx}\frac{d\varphi}{dx} + c_i\frac{d^2\varphi}{dx^2}\right)\right) = 0 \tag{1}$$

$$\frac{d^2\varphi}{dx^2} = -\frac{F}{\varepsilon}\left(z_m c_m + \sum_i^{Ni} z_i c_i\right) \tag{2}$$

D_i is the diffusion coefficient of component i. z_i, R, and T in Eq. (1) are the charge number of component i, the ideal gas constant ($8.314\,\mathrm{J\,K^{-1}\,mol^{-1}}$), and the temperature (K) of the modeled system, respectively. ε and F are the permittivity of the medium (assumed $\varepsilon \approx 3.9825 \times 10^{-10}\,\mathrm{F\,m^{-1}}$) and the Faraday constant ($96485\,\mathrm{C\,mol^{-1}}$). z_m and c_m denote the charge number of the fixed charges in the ion exchange membrane and their concentration.

2.2. The 1D linear model

To be able to benchmark the discretization methods, an analytical solution of a 1D linear model is derived and considered as a reference function. The linear differential system models an ionic liquid system in 1D space between two Dirichlet boundary conditions: $c_i(x = 0) = C_0$ and $c_i(x = L) = C_L$, wherein L is the length of the 1D space. The linear model assumes a linear electric potential distribution over the spatial domain. This assumption reduces the PNP equation into a second order homogeneous linear differential equation:

$$D_i\left(\frac{d^2 c_i}{dx^2} + \frac{z_i F}{RT}\beta\frac{dc_i}{dx}\right) = 0, \tag{3}$$

wherein β is the constant value of the electric potential gradient $\frac{d\varphi}{dx}$. An analytical solution has been derived for the linear model and leads to the following general solution: $c_i(x) = A_1 + A_2 e^{-k_i \beta x}$ with $k_i = \frac{z_i F}{RT}$. The coefficients A_1 and A_2 are determined by the spatial boundary conditions C_0 and C_L. These boundary conditions lead to a particular solution of the linear model:

$$c_i(x) = c_0 + \frac{C_0 - C_L}{1 - e^{-k_i\beta L}}\left(e^{-k_i\beta x} - 1\right) \tag{4}$$

3. The Discretization Methods

We benchmarked the linear model using the three mentioned discretization techniques in comparison to the analytic solution. Space is discretized into $Nn - 1$ equidistant partitions, $0 = x_{n=1} < x_{n=2} < ... < x_{n=Nn} = L$. In the subsequent sections, the evaluated methods will only be briefly reviewed. Further details and fundamental background on these methods can be found in literature (Finlayson (1980)).

3.1. The finite differences method

For the first method, central finite differences are applied. The 1D space is divided into $Nn - 1$ partitions with an equal length of Δx. Eq. (5) shows the discretized form of Eq. (3). The equation system of the finite differences method holds $Nn - 2$ balance equations (Eq. (5)) and two boundary conditions C_0 and C_L.

$$D_i \left(\frac{c_{i,n+1} - 2c_{i,n} + c_{i,n-1}}{\Delta X^2} + \frac{z_i F}{RT} \beta \frac{c_{i,n+1} - c_{i,n-1}}{\Delta X} \right) = 0 \tag{5}$$

3.2. The finite elements method

In this contribution, Hermite collocation and Galerkin are applied on finite elements to approximate the solution. The approximation is carried out on $Nn - 1$ elements by a linear combination of basis functions. To simplify the discretization, the global variable x is transformed into local variable u by $u = \frac{x - x_n}{h_n}$. h_n is the length of the n-th element, given by $h_n = x_{n+1} - x_n$. Within each element, the solution is approximated by a linear combination of some basis function $N_j(u)$ shown in Eq. (6). The coefficients $a_{i,j,n}$ are then solved numerically to provide the approximated solution.

$$c_{i,n}(u) = \sum_{j=1}^{Nj} a_{i,j,n} N_{j,n}(u) \tag{6}$$

For Hermite collocation, four cubic Hermite polynomials are used as basis functions, which are $N_{j=1,n}(u) = (1-u)^2(1+2u)$, $N_{j=2,n}(u) = u(1-u)^2 h_n$, $N_{j=3,n}(u) = (u)^2(3-2u)$, and $N_{j=4,n}(u) = u^2(u-1)h_n$. As shown by Finlayson (1980) and Arora et al. (2006), it is convenient to choose the roots of shifted orthogonal Legendre polynomial ($P_2^{0.0}(u)$) as collocation points: $u_1 = 0$, $u_2 = \frac{1}{2}(1 + \frac{1}{\sqrt{3}})$, $u_3 = \frac{1}{2}(1 - \frac{1}{\sqrt{3}})$, $u_4 = 1$.

Eq. (6) is substituted into Eq. (3) resulting in the discretized form in Eq. (7). Eq. (7) is then evaluated at the inner collocation points, u_2 and u_3. The Hermite polynomials guarantee C^1 continuity at the element boundaries. Hence, only the two global boundary conditions $a_{i,n=1,j=1} = C_0$ at $x = 0$ and $a_{i,n=Nn-1,j=3} = C_L$ at $x = L$ need to be described. The equation system to be solved consists of $2(Nn - 1)$ balance equations (Eq. (7)) and the two overall boundary conditions.

$$D_{i,n} \left(\frac{1}{h_n^2} \sum_{j=1}^{Nj=4} a_{i,n,j} \frac{d^2 N_{j,n}(u)}{du^2} + \frac{z_i F}{RT} \frac{\beta}{h_n} \sum_{j=1}^{Nj=4} a_{i,n,j} \frac{dN_{j,n}(u)}{du} \right) = 0 \tag{7}$$

For the Galerkin method, three second order Lagrange polynomials are applied as basis functions ($N_j(u)$) of Eq. (6). Those polynomials are $N_{j=1} = 2(u-1)(u-1/2)$, $N_{j=2} = 4u(1-u)$, and $N_{j=3} = 2u(u-1/2)$. By substituting Eq. (6) into Eq. (3) and applying Galerkin'S method, the linear model turns into Eq. (8). Two additional boundary conditions in every element, $\frac{dc_{i,n}}{du} - \frac{dc_{i,n-1}}{du} = 0$ and $c_{i,n} - c_{i,n-1} = 0$ are added to the equation system to guarantee C^1 continuity at the element boundaries. C_0 and C_L are also added to the equation system as the outer boundary conditions of the spatial domain.

$$\int_0^L D_i \left(\frac{1}{h_n} \sum_{j=1}^{Nj=3} a_{i,n,j} \frac{d^2 N_{j,n}(u)}{du^2} + \frac{z_i F}{RT} \beta \sum_{j=1}^{Nj=3} a_{i,n,j} \frac{dN_{j,n}(u)}{du} \right) N_{j=2,n}(u) du = 0 \tag{8}$$

3.3. Logarithmic reformulation

In addition to the discretization, a logarithmic reformulation is applied to influence the scaling of the model. For this purpose, all concentrations are replaced by $c_i(x) = e^{\ln((c_i(x))} = e^{\bar{c}_i(x)}$ and the model is then solved in terms of $\bar{c}_i$. The assumption is that this scales better and also guarantees positivity of all concentration values. The reformulated model shown in Eq. (9) is then discretized with the central finite differences method to solve it numerically.

$$D_i e^{\bar{c}_i(x)} \left(\frac{d^2\bar{c}(x)}{dx^2} + \left(\frac{d\bar{c}(x)}{dx} \right)^2 + \frac{z_i F}{RT} \beta \frac{d\bar{c}(x)}{dx} \right) = 0 \tag{9}$$

4. Comparison of the Methods

To benchmark the methods introduced in Section 3, a simulation study on the linear model is set up to determine concentrations of anions ($z_{i=1} = -1$) and cations ($z_{i=2} = +1$) in a solution system. The spatial domain L has a length of $10^{-3}m$ bounded by two Dirichlet boundary conditions for both ions, namely $C_0 = 12$ and $C_L = 10^{-7}$ mol m^{-3}, which represent the maximum concentration difference in the simulation of the electrolyzer model. The diffusion coefficients are $D_{i=1} = 10^{-11}$ and $D_{i=9} = 10^{-9}$ m^2 s^{-1}, which represent the maximum and minimum values of diffusion coefficients in the electrolyzer model. The temperature is set to be 363 K, which is the typical operation temperature of the process. And the β is -500 V m^{-1}, determined by the electric potential difference of 0.5 V devided by L. The condition number of the Jacobian matrix, the

Figure 2: The comparison of the absolute error resulted by three discretization methods. The left side and the right side graphs show respectively the error profile of the negative component ($z_{i=1} = -1$) and the positive component ($z_{i=2} = +1$). The small graphs show the analytic solution of the corresponding model.

computation time and the maximum absolute error or deviation from the analytic solution are also presented in Table 1. The termination tolerance of 10^{-14} is set to end the computation. All equation systems are solved using fsolve of MATLAB with the Trust-Region-Dogleg algorithm.

4.1. The finite differences and the finite elements methods

As initial guesses, the concentrations of all components are set to 1 mol/L. The equation systems are discretized using the finite differences (FD) and both finite elements methods (FE). All simulation problems successfully converged with the absolute value of the function residuals smaller than the required termination tolerance. The simulation results plotted in Figure 2 show that the accuracies of the evaluated methods differ in regions of higher gradient values. The Hermite collocation method overall shows a higher accuracy compared to the other two. Tab. 1 shows that

Table 1: Numerical performance: Hermite collocation, finite differences, and Galerkin method

Parameters	Hermite Coll.(HC)	Finite Differences (FD)		Galerkin Method (GM)	
Nn	24	24	260	24	260
Condition number	$8.59 \cdot 10^7$	$7.38 \cdot 10^3$	$9.31 \cdot 10^5$	$4.68 \cdot 10^{13}$	$5.55 \cdot 10^{15}$
Computation time (s)	0.9958	0.2218	0.9974	0.4347	10.2488
Max.absolute error	0.0014	0.1781	0.0014	0.1781	0.0014

by increasing the number of discrete points/elements (*Nn*) to 260, the finite difference and the Galerkin method can achieve a similar accuracy resulted by the Hermite collocation method with 24 discrete elements. To achieve this accuracy, the finite differences method needs approximately similar computation time to that of the Hermite collocation.

4.2. The logartihmic reformulation

The logarithmically reformulated model is evaluated by comparing its performance to the non-reformulated model. The central finite differences is applied to discretize both models. *Nn* is set to 36, which is reasonably accurate for the finite differences method based on the previous results. The analytic solution is used as an initial guess. To investigate the convergence range of the reformulation method, four variations of boundary conditions (C_0 and C_L in $mol\,L^{-1}$) are simulated: 24 and 2×10^{-1}, 12 and 2, 12×10^4 and 2, 12×10^{-4} and 2×10^{-9}. The other model parameters remain unchanged. The variation of the boundary conditions yields four different condition numbers for the reformulated model, which are 9.49×10^5, 9.06×10^3, 2.20×10^9

Figure 3: The comparison of the absolute error resulted by the log-reformulated model and the non-reformulated model. The left side and the right side graphs show respectively the error profile of the negative component ($z_{i=1} = -1$) and the positive component ($z_{i=2} = +1$). The small graphs show the analytic solution of the non-reformulated model for both components.

and 4.12×10^{12}, respectively. While the condition number of the non-reformulated model remains constant at 1.70×10^4 in all variations of the boundary conditions. Only for the second case of the logarithmic problem, the reformulated model successfully converged. The convergence of the reformulated method starts to breakdown as the solution value approaches one, because of the singularity of the log function as its value approaches zero. The reformulated model obtains higher accuracy only in the region with a concave upward profile as shown in Fig. 3. Since the aim of the current investigation is a selection of the discretization method, necessary further investigations to improve the reformulation method is not done here.

5. Modeling the Solution-Membrane System of the Chloralkali Electrolyzer

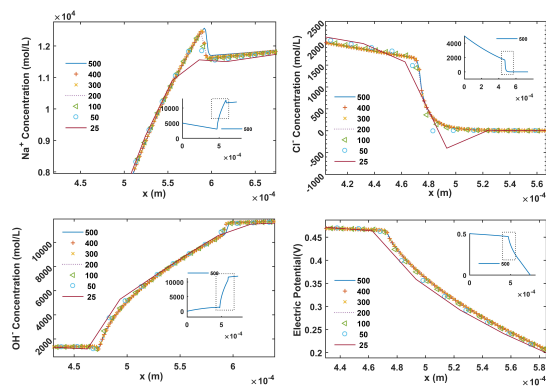
In this section, the application of the Poisson-Nernst-Planck equation to model a system of three ions in a membrane and two diffusion layers (shown by Figure 1) is presented. The model is an approximation of a chloralkali process in a segment of the membrane reactor. D_i and the size of the spatial domain are adopted from Kodým et al. (2016) and Fíla and Bouzek (2003). Continuity of the dependent variables and ion fluxes are applied at both solution-membrane interfaces (x_2 and x_3). Eq. (1) and Eq. (2) are discretized using the central finite differences method due to


Figure 4: Profiles of the ions concentration and the electric-potential in the 1D PNP system (Fig. 1) resulted from simulations with various numbers of discrete points.

its relative simple initialization and low computational cost while preserving reasonable accuracy. The number of the discrete elements (Nn) was varied from 25 to 500 elements to justify the minimum number of elements necessary to obtain adequate accuracy. The simulations were converged with a tolerance of 10^{-14}. Fig. 4 shows the obtained profiles of the ion concentration and the electric-potential. Almost all of the discretization variants provide a similar overall profile. They only differ at the solution-membrane interface ($x = 474\mu m$ and $x = 594\mu m$), where the steepest gradient appears. Increasing the number of elements to more than 300 does not improve the accuracy significantly.

6. Conclusions and Outlook

Three discretization methods: the central finite differences, Hermite collocation on finite elements, and the Galerkin finite elements method have been evaluated using a 1D linear differential model. In comparison with its analytic solution, the Hermite collocation on finite elements method shows the highest accuracy, particularly in regions of steep gradients. However, with extra number of the discrete points the central finite differences method can also achieve the similar accuracy in an approxmiately similar computation time. A logarithmic reformulation was evaluated while using the central finite differences as the discretization method. The results show that this method makes the condition number of the Jacobian matrix more dependent on the actual solution range. Further investigation and modification of this method for tackling the dependency are necessary to make this method more applicable. The 1D Poisson-Nernst-Planck model has been adopted to model a solution-membrane system, approximating a chloralkali membrane process. The presented results show that the method is capable of being implemented in such a case by considering an appropriate number of elements to achieve a desired accuracy.

In future work, we will investigate non-equidistant discretizations. In regions of smaller gradient values, lower numbers of discrete points or finite elements could be applied and consequently the computational cost of the discretization techniques can be further reduced.

Abstract

2, 3-Butanediol is a very promising chemical due to its several applications and may be produced by microbial production. The recovery of 2, 3-Butanediol from the fermentation broth is yet a challenge due to its low concentration. Moreover, a broader point of view is also necessary since current needs require a process with low environmental impact and high inherent safety. In this work, the inherent risk will be approached at early-stages at the same time that economic and environmental issues. The aim of this paper is to synthesis, design and optimize some alternatives to purify 2,3-Butanediol based on distillation, those alternatives are synthesized in such way that is obtained as results thermally coupled, thermodynamically equivalent and intensified sequences. The alternatives were designed and optimized considering three objective functions: the total annual cost as an economic index, the eco-indicator 99 as an environmental index, and the inherent risk of the process (analyzed as individual risk). In general terms, the intensified alternative presented 15 % reduction of the TAC and 14% of the environmental impact. Moreover, the same alternative presented the lowest inherent risk with a reduction of about 50% in comparison with the reference alternative.

Keywords: 2,3-Butanediol, Multi-Objective Optimization, Downstream Process, Individual Risk.

1. Introduction

2,3-Butanediol (2,3-BD) is a renewable chemical if its production is based on biomass. Several reports pointed out 2,3-BD as a quite interesting bio-based compound since its application covers several industrial sectors. Currently, 2, 3-BD has shown its potential for being used in the manufacturing of printing inks, perfumes, explosives, etc. Moreover, an interesting consideration of this bio-based chemical is its use as potential liquid fuel with a heating value of 27.19 kJ/g; additionally, 2,3-BD is an intermediate to produce methyl-ethyl-ketone (MEK) a quire promising biofuel, using a dehydrogenation process. 2,3-Butanediol coming from fermentation comes with a high content of water, making its purification a challenge (Koutinas et al. 2016).

On the other hand, since the boiling point of 2,3-BD is about 180 ℃ at atmospheric pressure and it does not form an azeotrope with water, the use of conventional

distillation seems a natural alternative. While this unit operation has many advantages, one drawback is its significant energy requirement. Therefore, energy consumption plays a major role in the operational costs of a process. Despite at first sight the use of distillation it might be not profitable, it is possible to implement several synthesis alternatives to reduce both capital and energy cost. Regarding the synthesis and design of separation process Errico et al. (2016) have presented an ordered and sequential methodology to generate subspaces of separation alternatives. This kind of methodologies jointly with optimization strategies have shown important improvements. Despite the usefulness of many synthesis and optimization approaches, they have focused mostly on the economic issue which is indeed a critical point. On the other hand, an important issue like inherent safety has been disregarded or considered as an afterthought following the design. So, do not include the risk involved in the downstream process can lead to misleading risk assessment. An effective alternative would be, to include inherent safety, economic and environmental issues on early design stages, guaranteeing in this way a process with low economic and environmental impact and also accounts the risk assessment on each alternative. In this manner, with all background mentioned, this work aims to synthesize, design and optimize some new alternatives to separate and purify an effluent of 2,3-Butanediol coming from fermentation. This approach proposes to produce purification alternatives which consider the balance among several targets, in other words, the optimization procedure will find separation alternatives which considers economic, environmental, and safety issues in order to accomplish the current industrial necessities.

2. Problem statement and methodology

Although 2,3-butanediol is a very useful chemical bio bulk, its microbial production involves a dilute broth which requires further purification. However, according to the state of the art of 2,3- butanediol, this downstream process is not well explored so far. Recently, Penner et al. (2017) proposed a conventional alternative for this task (see Figure 1a). However, it is clear the necessity for new alternatives which improve performance indexes. With this in mind, the schemes in Figure 1a)-b) will be considered as the references cases for further synthesis and design methodology. The complete methodology is described below.

Step 1: Identification of conventional distillation column: The schemes presented in Figure 1a)-b) were considered as reference cases. Initially, (Penner et al. 2017) proposed the direct sequence presented in Figure 1a), the natural complement for Figure 1a is the indirect sequence in Figure 1b).

Step 2: Generation of thermally coupled alternatives: having both cases of Figure 1 as a reference, it is possible to generate the subspace of the modified thermally coupled sequences by the substitution of heat exchangers (reboiler and condenser as appropriate) associated to no-product stream with a liquid/vapor interconnection (See Figure 2). In other words, where the streams of no-product are located, it is possible to set a thermally coupling if either a reboiler or condenser is eliminated, and a stream of steam and liquid is considered instead.

Step 3: Generation of thermodynamically equivalent alternatives. Now, with the thermal couplings already introduced, there are column sections where the condenser/reboiler provides a common reflux ratio/vapor boil-up between two consecutive columns. With

this in mind, it is possible to move this section to generate thermodynamically equivalent alternatives in Figure 3. i. e. Figure 3a) is obtained if section 4 of Figure 2a) is moved below section 2 in Figure 3a).

Step 4 Generation of intensified alternatives: the following methodology is simple and consists of the elimination of the side columns which have only one column section (See Figure 4). i.e. Figure 4a) is obtained if section 3 in Figure 3a) is eliminated.
Fig. 1 Pure distillation schemes   Fig. 2 Thermally Coupled schemes
Fig. 3 Thermodynamic Equivalent schemes   Fig. 4 Intensified schemes
According to their result in fermentation, the Diol concentration is 150 g/L and 10 g/L of 2,3-Butanediol and Acetoin, respectively. In this work, we considered the same mass fractions and a mass flow of 73,170 kg h^{-1}. All alternatives were modeled using Aspen Plus modeler using the NRTL thermodynamic model, which according to Penner et al. (2017), it describes better the interactions among all components. The minimum purities were fixed on a mass base as 99.5% for 2,3-BD and water, and 99.0% for acetoin. The objective function and the optimization method are described below.

2.1 Multi-objective Optimization and Objective Functions

The objective function included the simultaneous minimization of the total annual cost (TAC), the eco-indicator 99 (EI99) and the Inherent Risk (IR) measured as individual risk. The minimization of these objectives was subject to the required recoveries and purities in each product stream (see Eq. 1).

$$Min(TAC, EI99, IR) = f(N_{tn}, N_{fn}, R_{rn}, F_{rn}, F_{vn}, D_{cn}, P_{cn}, FC_{cn}) \qquad (1)$$

Where N_{tn} are total number of column stages, N_{fn} is the feed stage in column, R_{rn} is the reflux ratio, F_{rn} is the distillate/bottoms flux, F_{rn} and F_{vn} are the interconnection liquid/vapor flow, D_{cn} is the column diameter, P_{cn} and F_{cn} are phisicochemical properties for IR calculation such as molecular weight, heat of combustion, LC50 and so on. This multi-objective minimization considered 25 continuous and discrete variables. TAC was calculated through the Guthrie method according to the equation TAC = (Capital Costs/Payback Period) + Operating Costs , all the parameters for the equipment were taken from (Turton R. 2001). The Eco-Indicator 99 (EI99) was used to

evaluate the sustainability of the processes by means of the equation EI99 = $\sum\sum\sum$ (Amount of chemical x damage caused x weighting factor x normalization factor), this methodology is based on lifecycle analysis of different categories where individual scores are assigned depending on the category, three impact categories (steel, electricity, and vapor) were considered according to work presented by Errico et al. (2016) where this indicator has been utilized to quantify the environmental impact in some chemical processes. In the case of the safety, the individual risk was calculated through quantitative risk analysis technique, which is a methodology of inherent safety where the main objective is to evaluate the frequency and probability of decease or injury due to accidents like explosions or toxic release. The inherent risk is evaluated by the equation IR = $\sum$f*P, being f the frequency of accident and P the probability of affection. This methodology has been successfully used to evaluate the risk on the chemical process (Medina-Herrera, et al. 2014), the equations and procedure were realized to a distance of 50m from the equipment according to reported by American Institute of Chemical Engineers, 2000.

To optimize the process route for biobutanol production, a stochastic optimization method, Differential Evolution with Tabu List (DETL) was used, which have shown being robust to optimize intensified separation systems. Srinivas & Rangaiah, (2007) showed that the use of some concepts of the metaheuristic tabu could improve the performance of DE algorithm. The implementation of this optimization approach was made using a hybrid platform where the DETL method was coded using Microsoft Excel (ME). Initially, the method proposes a vector which is sent to Aspen Plus by means of dynamic data exchange (DDE). In there the separation process was rigorously simulated. For the optimization of process routes analyzed in this study, the following parameters for DETL method were used: 200 individuals, 500 generations, a tabu list of 50% of total individuals, a tabu radius of 0.0000025, 0.80 and 0.6 for crossover and mutation fractions, respectively.

3. Results

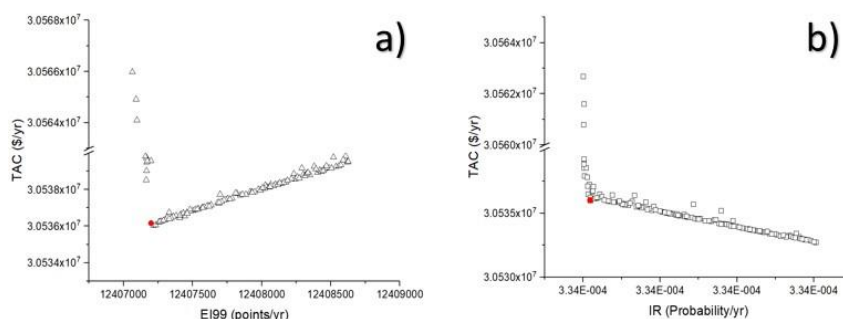
Although the three objective functions are evaluated, the obtained results are shown in Table 1. All Pareto fronts were obtained after 100,000 evaluations, as afterward, the vector of decision variables did not produce any meaningful improvement. Initially, note the pure distillation schemes present a difference of 32%. The high difference in TAC is high enough to select as the best option the direct sequence between both conventional alternatives. For such reason, since the direct alternative has been identified, only the schemes derived for that configuration are considered for optimization procedure. After the optimization process, some trends among objective function were observed. Note, in Figure 5, when the TAC is evaluated jointly IR, it is clear the competitive connection between both targets, as long as the TAC increase, the individual risk decreases and vice versa. Figure 5 also shows the antagonist behavior between the environmental impact and the individual risk associated with the conventional downstream process. It is possible to obtain process with low environmental impact, however, the probability of individual accident increase and vice versa.


Fig. 5 Pareto fronts between EI99/TAC and TAC/IR for the intensified scheme

Table 1. Objective function values   **Table 2**. Intensified scheme 4a) parameters

Objective Function	TAC [$ y^{-1}]	EI99 [points y^{-1}]	IR [P Y^{-1}]
Direct	35,032,419	14,328,558	0.0006686
Indirect	51,155,609	22,627,903	0.0006663
T Coupled	31,360,313	12,559,191	0.0006795
T Equivalent	31,055,124	12,557,857	0.0006684
Intensified	30,536,031	12,407,199	0.0003341

	C1
Number of stages	87
Reflux ratio	0.333
Feed-stage	42
Column diameter (m)	0.675
Distillate (kg h^{-1})	3,416.07
Side stage	49
Side flow (kmol h^{-1})	8.155
Condenser duty (kW)	51,507
Reboiler duty (kW)	61,457

Regarding the evaluation of TAC and IR, it is pretty interesting the reason for such reduction on this incident probability. Since IR calculation considers continuous and instantaneous chemical releases, it is clear that as long as internal flows increase, IR will increase because of the quantity of inventory inside the column increase, which it will provoke that if an accident happens the affectation and duration of the events or probability of death will be greater due to there is more mass that is source to fires, explosion, and toxic releases. This is the general tendency, however, note that for IR calculations several physicochemical properties are involved, such as heat of combustion, flammability limits and so on. With this in mind, note that the feed stream to be separated is mainly composed of water, which obviously for its physicochemical properties generates a contrary behavior. In other words, the IR increases with high internal flows (caused by high reflux o high diameters), however in this case of study for almost all sequences, the first columns separate mainly water, consequently, the internal flows are enriched with water. This amount of water solubilizes the other component to separates and its flammability and toxicity decrease.

Furthermore, at second column acetoin and 2,3-BD are separated, but at this instance, the internal flows follow the common IR behavior, because the quantity of water is fewer in comparison with the first column. In this manner, the IR calculation does not generate a proportional behavior with TAC because of this associated conflict. Finally, when is observed the tendency of EI99 evaluated jointly IR in Pareto front of Figure 5, similar behavior is observed. The internal flows play an interesting role already mentioned. However, those flows must be heated. So, in almost all alternatives, the first column separates the water and implies a significant amount of steam, impacting directly on EI99 value. However, the concentration of flammable compounds decreases. On the other hand, the last column to reduce both IR and TAC values is composed mainly by small columns, which indeed needs fewer services than the first column. Table 2 shows the main parameters of the intensified scheme.

4. Conclusions

This approach has been performed using a multi-objective optimization problem, finding through Pareto fronts the most balanced solution among all objective function, in other words, it was possible to find a solution where all objective functions reach its minimum values. Once the optimization test was applied to the proposed alternatives by a synthesis procedure, the initial results showed that between the two conventional alternatives the direct sequence is better than the indirect scheme. Derived from the direct sequence, the intensified alternatives, which separate and purify the feed stream in a single column, showed the best performance index (economic, environmental and safety) in comparison with all alternatives. It was possible to reach economic savings of about 15% in comparison with the direct sequences, a reduction of about 14% on the environmental impact and a reduction of about 50% regarding the IR. Regarding IR evaluation, it was clear the high dependence of this index with the size of the equipment, the amount of internal flows and the kind of chemical to be separated.

Abstract

Organic Rankine Cycles (ORC) convert low temperature heat into power. To maximize conversion efficiency, both ORC process and working fluid have to be tailored to the specific application. Common solution approaches for the resulting integrated design of ORC process and working fluid are limited to steady-state applications. However, for applications in dynamic settings, steady-state design approaches can lead to suboptimal solutions due to the neglect of the dynamic behavior. In this work, we present an approach for the integrated design of ORC process and working fluid considering the dynamics. The approach is based on the Continuous-Molecular Targeting−Computer-aided Molecular Design (CoMT-CAMD) framework. Herein, the physically based Perturbed-Chain Statistical Associating Fluid Theory (PC-SAFT) is used as thermodynamic model. To capture the ORC behavior under dynamic conditions, dynamic models for the ORC equipment are integrated into the process model. The result is an optimal control problem (OCP) yielding an optimal working fluid and the corresponding optimal process control for a given dynamic input. This so-called dynamic CoMT-CAMD approach is applied to an ORC for waste-heat recovery on a heavy-duty vehicle. Whereas steady-state design approaches fail, the presented approach identifies the optimal working fluid and the corresponding optimal control of the ORC process.

Keywords: CoMT-CAMD, integrated design, dynamic, PC-SAFT, Modelica

1. Introduction

Nearly 30 % of the on-road CO_2 emissions in 2014 were emitted by heavy-duty vehicles (HDV) in the European Union (Muncrief and Sharpe, 2015). CO_2 emissions of HDVs can be decreased by reducing their fuel consumption. To reduce the fuel consumption of HDVs, the exhaust gas waste heat of the engine can be transformed into mechanical power by an Organic Rankine Cycle (ORC). An ORC improves the compliance with future CO_2-regulations and the total cost of ownership (TCO) (Eichler et al., 2015). However, ORCs on HDVs have high investment costs and low power output due to low conversion efficiencies. To maximize conversion efficiency and thus render ORCs profitable, a tailor-made ORC is needed. To tailor an ORC, working fluid design has to be integrated into process optimization (Gani, 2004). To solve the resulting large-

scale mixed-integer nonlinear program (MINLP), many solution approaches have been developed as recently reviewed by Papadopoulos et al. (2018). In our previous work, we developed the Continuous-Molecular Targeting − Computer-Aided Molecular Design (CoMT-CAMD) approach for the integrated design of processes and molecules (Bardow et al., 2010; Lampe et al., 2015). In CoMT-CAMD, the physically-based Perturbed-Chain Statistical Associating Fluid Theory (PC-SAFT) is used as thermodynamic model (Gross and Sadowski, 2001). In the first stage of CoMT-CAMD (CoMT stage), the discrete pure component parameters representing a working fluid in PC-SAFT are relaxed to identify a hypothetical optimal working fluid, the so-called target. In the second stage (Structure-Mapping stage), a second-order Taylor approximation around the target and a CAMD formulation are used to identify real working fluids in a mixed-integer quadratic program (MIQP).

So far, CoMT-CAMD and other integrated design approaches are limited to steady-state input. However, for ORCs on HDVs, the exhaust gas waste heat shows dynamic behavior resulting in transient temperature and mass flow rates of the ORC heat source. The design of ORC processes with dynamic heat sources leads to large-scale dynamic optimization problems (Huster et al., 2018). However, the optimal working fluid also depends on temperature and mass flow of the heat source (Colonna et al., 2015) as well as the control strategy for the ORC (Zarogiannis et al., 2017). Thus, a steady-state design point is not sufficient for working fluid design, and the process dynamics has to be considered within the integrated design to capture all process-related trade-offs.

In this work, we present the dynamic CoMT-CAMD approach for the integrated design of dynamic processes and fluids. For this purpose, dynamic models for the equipment are integrated into the process model of CoMT-CAMD leading to an optimal control problem (OCP). The solution of dynamic CoMT-CAMD is an optimal working fluid and the corresponding optimal process for a given dynamic input.

2. Dynamic CoMT-CAMD

The CoMT-CAMD approach was developed for the integrated design of steady-state applications (Bardow et al., 2010; Lampe et al., 2015). In this work, we extend the CoMT-CAMD approach to applications with dynamic inputs. For this purpose, dynamic models for the equipment are integrated into the process model to capture the dynamic behavior. Thereby, the original MINLP of the integrated design is transformed into a large-scale mixed–integer optimal control programming (MIOCP) problem. To efficiently solve this problem, we split the MIOCP into an optimal control problem (OCP) (CoMT stage, see section 2.1) and an MIQP (Structure-Mapping stage, see section 2.2) according to the idea of the original CoMT-CAMD approach (Figure 1). Finally, the identified working fluids are assessed by individual dynamic process optimizations (see section 2.3).
Figure 1: Workflow of the dynamic CoMT-CAMD approach

ORC on the move: An integrated design approach for ORC process and
working fluid for dynamic truck waste heat
105

2.1. Continuous-molecular targeting (CoMT)

A working fluid is described by a set of pure component parameters in PC-SAFT. In the first stage, the CoMT stage, these discrete pure component parameters representing the working fluid are relaxed to transform the MIOCP into an OCP given by:

$$
\max_{x(t),u(t),p_{\mathrm{pr}},p_{\mathrm{wf}}} \tilde{f} = \int_{t_0}^{t_1} f\big(x(t),u(t),p_{\mathrm{pr}},\theta(t)\big)dt \qquad \text{objective}
$$

$$
\begin{aligned}
s.t. \quad & \dot{x}(t) = k(x(t),u(t),p_{\mathrm{pr}},\theta(t)) \\
& g_1\big(x(t),u(t),p_{\mathrm{pr}},\theta(t)\big) = 0 \\
& g_2\big(x(t),u(t),p_{\mathrm{pr}},\theta(t)\big) \le 0
\end{aligned} \left.\vphantom{\begin{aligned}\\\\\\\end{aligned}}\right\} \quad \text{DAE process model}
$$

$$
\begin{aligned}
& \theta(t) = h\big(x(t),u(t),p_{\mathrm{pr}},p_{\mathrm{wf}}\big) && \text{PC-SAFT} \\
& x_{\min} \le x(t) \le x_{\max} && \text{dynamic states} \\
& u_{\min} \le u(t) \le u_{\max} && \text{input signals} \\
& p_{\mathrm{pr,min}} \le p_{\mathrm{pr}}(t) \le p_{\mathrm{pr,max}} && \text{process parameters} \\
& p_{\mathrm{wf,min}} \le p_{\mathrm{wf}}(t) \le p_{\mathrm{wf,max}} && \text{working fluid}
\end{aligned}
\tag{1}
$$

Herein, the objective function $\tilde{f}$ (e.g., the mean net power output) depends on dynamic states $x(t)$ (e.g., time-dependent temperatures), input signals $u(t)$ (e.g., time-dependent control of the pump), process parameters p_{Pr} (e.g., nominal pressure levels) and equilibrium properties of the working fluid $\theta(t)$ (e.g., enthalpies). The process model consists of a system of differential equations for the dynamic states $\dot{x}(t)$ (e.g. energy balances), equality constraints g_1 (e.g. isentropic efficiencies) and inequality constraints g_2 (e.g., pressure limits). The equilibrium properties of the working fluid $\theta(t)$ are calculated using the PC-SAFT equation of state h.

The result of the CoMT stage in problem 1 is a hypothetical optimal working fluid, the so-called target, and the corresponding optimal control of the process. The target is characterized by its optimal pure component parameters p_{wf}^{*}, the optimal objective function value $\tilde{f}^{*}$ and the derivatives of $\tilde{f}$ at the target.

To reduce the programming effort for the development of new processes, the process model is implemented in Modelica enabling easy drag-and-drop flowsheeting and the use of existing model libraries. The OCP in problem 1 is typically solved within hours using the multiple shooting algorithm MUSCOD-II (Leineweber et al., 2003).

2.2. Structure-Mapping using Computer-aided molecular design (CAMD)

In the second stage, the Structure-Mapping stage, a second-order Taylor-approximation around the target $\hat{f}$ is used to estimate the objective function value $\tilde{f}$ of real working fluids. To design molecular structures with a performance closest to the target in the resulting MIQP, a computer-aided molecular design (CAMD) formulation is used:

$$
\max_{n} \hat{f}(p_{\mathrm{wf}}) = \tilde{f}(p_{\mathrm{wf}}^{*}) + \frac{\partial \tilde{f}}{\partial p_{\mathrm{wf}}}\Big|_{p_{\mathrm{wf}}=p_{\mathrm{wf}}^{*}} (p_{\mathrm{wf}} - p_{\mathrm{wf}}^{*}) + \frac{1}{2}(p_{\mathrm{wf}} - p_{\mathrm{wf}}^{*})^{\mathrm{T}} \frac{\partial^2 \tilde{f}}{\partial p_{\mathrm{wf}}^2}\Big|_{p_{\mathrm{wf}}=p_{\mathrm{wf}}^{*}} (p_{\mathrm{wf}} - p_{\mathrm{wf}}^{*})
$$

$$
\begin{aligned}
s.t. \quad & k(n) = p_{\mathrm{wf}} && \text{group contribution method} \\
& n \in \mathbb{Z} && \text{molecular structure}
\end{aligned}
\tag{2}
$$

Herein, the objective function $\hat{f}$ is the second-order Taylor approximation around the target $\hat{f}^{*} = \tilde{f}(p_{\mathrm{wf}}^{*})$. The homosegmented group-contribution (GC) method for PC-SAFT (Sauer et al., 2014) is used to predict the pure component parameters of PC-SAFT p_{wf} from the molecular structure of the working fluid n. Here, the vector n contains the number of functional groups constituting the molecular structure of the working fluid. In this work, we consider the following non-polar, non-associating functional groups: $-CH_3$, $-CH_2-$, $>CH-$, $>C<$ for alkanes, $=CH_2$, $=CH-$, $>C=$ for alkenes, $-C\equiv CH$ for 1-alkynes,

-CH^{Arom}=, >C^{Arom}= for aromatic compounds, -CH$_2^{Hex}$-, >CH^{Hex}- for branched cyclohexanes and -CH$_2^{Pent}$-, >CH^{Pent}- for branched cyclopentanes.

To overcome shortcomings of the Taylor approximation, a ranking of working fluids is calculated. For this purpose, the MIQP in problem 2 is solved repeatedly using integer cuts (Grossmann and Kravanja, 1995) to exclude previous solutions from the design space. The result of the Structure-Mapping stage is a ranking of optimal working fluids based on the Taylor approximation. The MIQP in problem 2 is typically solved within a few seconds using the software GAMS.

2.3. Final process optimization

Finally, to overcome shortcomings of the Taylor approximation, the working fluids identified in the Structure-Mapping stage are individually optimized using the dynamic process model of the CoMT stage. Thereby, we obtain a more accurate objective function value $\tilde{f}$ for the promising working fluids and the corresponding optimal control of the ORC process. The final optimal control problems are also solved with MUSCOD-II as for the CoMT stage.

3. Case study

3.1. Specifications

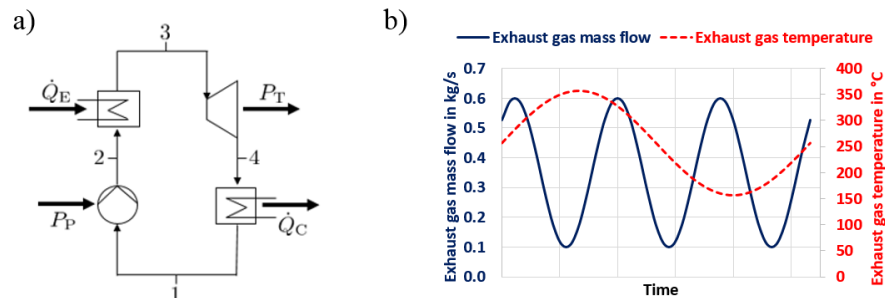
The presented dynamic CoMT-CAMD approach is applied to the integrated design of an ORC for waste heat recovery from heavy-duty vehicles based on Eichler et al. (2015) (see figure 2). The dynamic heat input of the ORC is characterized by time series for the temperature and mass flow of the exhaust gas after the exhaust gas after-treatment. We approximate these time series by sine waves with mean values and amplitudes based on time series from Dünnebeil et al. (2015). We assume cyclic steady-state constraints and thus only one sine wave of the slowest oscillating profile is needed to represent the full time series.


Figure 2: ORC process in (a) flowsheet and (b) temperature and mass flow of the exhaust gas after exhaust gas after-treatment.

The mean net power output of the ORC $\overline{P}$ is considered as objective $\tilde{f} = \overline{P} = \frac{1}{t_f - t_0} \int_{t_0}^{t_f} P(x(t), u(t), p_{Pr}, \theta(t)) \, dt$ in problem 1.

To react to the dynamic input of the ORC, the pump can be used to control the ORC process. For this purpose, the pump is modelled using affinity laws (Calise et al., 2015). The inertia of the pump is captured by a first-order lag element with a time constant $\tau_P = 1$ s (Esposito et al., 2015; Quoilin, 2011). An isentropic pump efficiency of $\eta_{P,s} = 0.5$ is

assumed. For the evaporator, we use a 0-D model based on Peralez et al. (2015) that assumes a homogeneous temperature of the heat exchanger wall T_W. The mass of the heat exchanger wall mass is $m_W = 13$ kg. The expander is modelled by assuming a constant isentropic efficiency of $\eta_{E,s} = 0.7$. In the condenser, we assume a minimal approach temperature of $\Delta T_{min} = 20$ K and for the cooling water, an inlet temperature of $T_{CW,in} = 75\,°C$ and an outlet temperature of $T_{CW,out} = 80\,°C$. For this case study, the dynamic states $x(t) = (T_W, n_{rel})^T$ are the temperature of the evaporator heat exchanger wall T_W and the relative rotational speed of the pump n_{rel} calculated as the ratio of the rotational speed n and the nominal rotational speed n_N. The input signal $u(t)$ is the control variable of the nominal speed of the pump. The process parameters $p_{Pr} = (p_{l,N}^{red}, p_{u,N}^{red}, \dot{m}_N)^T$ are the nominal mass flow rate of the working fluid $\dot{m}_N$, the nominal lower reduced pressure level $p_{l,N}^{red}$ and the nominal upper reduced pressure level $p_{u,N}^{red}$. Additionally, limits on the absolute pressure levels $p_{min} = 1$ bar and $p_{max} = 35$ bar are assumed. Furthermore, a maximal number of functional groups per working fluid of $n_{max} = 25$ is considered in the CAMD problem.

3.2. Results

Dynamic CoMT-CAMD is applied to the integrated design of the described ORC. In this case study, the target has a mean net power output $\bar{P} = 3.20$ kW (see table 1).
All working fluids of the top 5 working fluids identified in the Structure-Mapping stage are short-chained alkanes, alkenes or alkynes. The best 2 working fluids consist of 5 carbon atoms and have an unstable triple bond. Thus, these working fluids would probably not be used in ORC applications. The following 3 working fluids consist of 4 carbon atoms and have just single or double bonds, which are more stable than triple bonds. The best identified working fluid without triple bond is isobutane with $\bar{P} = 1.77$ kW, which is 45 % lower than the mean net power output of the target and 37 % lower than the best working fluid with triple bond, 3-methyl-1-butyne. For isobutane, the net power varies between $P_{min} = 0.44$ kW and $P_{max} = 3.49$ kW during one cycle.

Table 1: The mean net power output of the target and top 5 identified working fluids.

Rank	Name	$\bar{P}$ / kW
Target	-	3.20
1	3-Methyl-1-butyne	2.79
2	1-Pentyne	2.66
3	Isobutane	1.77
4	1-Butene	1.66
5	Isobutene	1.54

The results are compared to the integrated design based on a steady-state input calculated as the mean value of the temperature and mass flow of the dynamic heat source (cf. figure 2b). The steady-state design overestimates the mean net power output of isobutane by 20 %. For 1-butene and isobutene the net power output is overestimated by 23 % and 30 %, respectively. Thus, a steady-state design point is not sufficient for the selection of the optimal working fluid for dynamic ORC applications. Instead, the integrated design based on a dynamic process model is required, which is enabled by the presented dynamic CoMT-CAMD approach.

4. Conclusions

The dynamic CoMT-CAMD approach is presented for the integrated design of molecules and processes with dynamic input such as ORCs for waste heat recovery on HDVs. The underlying CoMT-CAMD approach was limited to steady-state applications. This limitation is overcome in the presented dynamic CoMT-CAMD approach by using

dynamic models for the ORC equipment in Modelica. MUSCOD-II is used in the CoMT stage to identify a hypothetical optimal working fluid in the resulting optimal control problem. Subsequently, a CAMD algorithm is used to identify real working fluids with a performance closest to the hypothetical optimum.

The resulting dynamic CoMT-CAMD approach is successfully applied to the design of an ORC for waste heat recovery on an HDV. Here, isobutane is identified as optimal stable working fluid for the dynamic application. In comparison, the integrated design based on a steady-state input calculated as the mean value of the temperature and mass flow of the dynamic heat source overestimates the mean net power output of the top 5 identified working fluids by up to 30 %. Therefore, the integrated design based on a dynamic process model is required, which is enabled by the presented dynamic CoMT-CAMD approach.

Abstract

This paper addresses the optimal planning of an integrated supply chain (SC) network for waste-to-energy (WtE) systems. A mixed integer linear programming (MILP) model is presented, which simultaneously considers the tactical and operational decisions related to transportation, inventory, production, and distribution. The objective of the proposed model is to find a balance between SC costs, waste reduction, and using the generated waste efficiently. It also ensures environmental sustainability in the operations of WtE systems and continuous feedstock supply. The considered waste type is combustible non-biodegradable municipal solid waste (MSW) with low moisture content, and the employed technologies are pyrolysis, gasification, and combined heat and power (CHP) to produce electricity and heat. The proposed MILP model is formulated and solved using GAMS/CPLEX.

Keywords: municipal solid waste, waste-to-energy, supply chain, sustainability, mixed integer linear programming.

1. Introduction

WtE is an energy recovery process that utilizes waste conversion technologies to generate heat and electricity from non-reusable and non-recyclable waste materials. WtE excels the other waste management (WM) strategies (e.g., reusing and recycling) as it can be used to meet the increasing energy demands and to reduce the dependency on energy imports and natural resources, in addition to reducing the waste amount for disposal. WtE also provides superior economic and environmental benefits because of the produced products through the WtE processes (e.g., transportation fuels, synthetic natural gas, chemicals, ferrous and non-ferrous metals, energy), emitting less carbon dioxide (CO_2) compared to power plants using non-renewable resources, and producing less greenhouse gas emissions (such as methane) compared to landfilling. It can also supply base-load power throughout the year to the community. Hence, WtE has become a promising alternative for many countries as an effective WM solution in a sustainable way and as the superior method of waste disposal. The three main thermochemical technologies for extracting energy from waste include conventional incineration, pyrolysis, and gasification. Moreover, CHP, used for simultaneous electricity and heat generation, can significantly increase operational efficiency of the plant, more than the facilities only generating electricity, and thereby decrease the energy costs.

WM can be considered as an SC problem since it involves determining the number, location, and size of production facilities, stocking and sourcing points, capacity allocation, inventory control, distribution and transportation planning, and order fulfilment. Therefore, to optimize the waste flows and decrease the negative impacts of involved processes, as well as ensuring the sustainability of the system, it is crucial to integrate the SC strategies into energy system planning and management. The literature study shows that many models exist, where the production and logistics problems in WtE practices are separately considered (Ahn et al., 2015; Balaman et al., 2018; Mohammadi et al., 2018; Quddus et al., 2018), but not the integrated WtE SC problem for sustainable heat and electricity production. A well-designed WtE SC results in a smooth flow of waste to treatment plants, balancing the waste supply lots and vehicle loads, reducing inventory levels and the stock-out risks, and better re-use of waste for cost-effective renewable energy production. It also contributes to a significant reduction in the total cost of the SC network and environmental emissions. Accordingly, this paper presents an integrated SC model that aims to maximize the total system profit by producing sustainable energy from waste materials while satisfying existing capacity and environmental constraints.

2. Mathematical Model Formulation

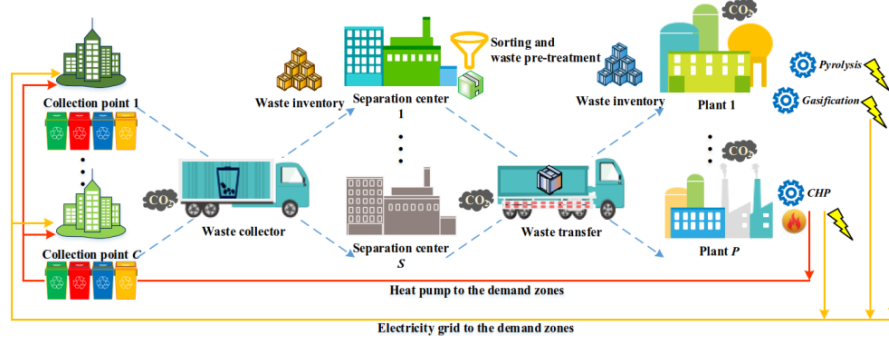
The proposed model covers waste collection at cities, separation and pre-treatment of waste in separation centers, processing for energy recovery in WtE plants, and selling the energy products to the markets, as shown in Figure 1.


Figure 1. The addressed WtE SC network

The integrated WtE SC problem is formulated as an MILP model. The indices used in the formulation are: w (waste), $\tilde{w}$ (treated waste), c (city), s (separation center), p (plant), j^s, j^{int}, j^e (technologies for waste pre-treatment, intermediate production, and energy production), n^{int} (intermediate product), n^{el} (electricity), n^h (heat), and t (time period). Equation (1) shows the objective function of the proposed model, where the revenue from the selling of heat and electricity is maximized, from which the total cost of the entire SC network is deducted. The selling price of electricity and heat is shown by P_{nct}. The total cost includes waste collection (C_{ct}^{col}), waste separation (C_{wst}^{sep}), waste pre-treatment (C_{wst}^{treat}), waste storage in separation centers (C_{wst}^{stor}, $C_{\tilde{w}st}^{stor}$), waste storage in

plants ($C_{\tilde{w}pt}^{stor}$), waste processing for intermediates production in plants ($C_{\tilde{w}pj^{int}_t}^{oper}$), intermediates processing for energy production in plants ($C_{n^{int}pj^{e}_t}^{oper}$), fixed and variable transportation (C^{fix}, C^{var}), and heat and electricity distribution costs (C_{npct}^{dist}).

$$
Max\,f = \sum_{n \in \{n^{el} \cup n^{h}\}} \sum_c \sum_t P_{nct} \cdot q_{nct} - \left(\sum_w \sum_c \sum_t C_{ct}^{col} \cdot A_{wct} + \sum_w \sum_c \sum_s \sum_t C_{wst}^{sep} \cdot q_{wcst} \right.
$$
$$
+ \sum_w \sum_s \sum_t C_{wst}^{treat} \cdot q_{wst}^{sep} + \sum_w \sum_s \sum_t C_{wst}^{stor} \cdot i_{wst} + \sum_{\tilde{w}} \sum_s \sum_t C_{\tilde{w}st}^{stor} \cdot i_{\tilde{w}st} + \sum_{\tilde{w}} \sum_p \sum_t C_{\tilde{w}pt}^{stor} \cdot i_{\tilde{w}pt}
$$
$$
+ \sum_{\tilde{w}} \sum_p \sum_{j^{int}} \sum_t C_{\tilde{w}pj^{int}_t}^{oper} \cdot q_{\tilde{w}pj^{int}_t} + \sum_{n^{int}} \sum_p \sum_{j^e} \sum_t C_{n^{int}pj^{e}_t}^{oper} \cdot q_{n^{int}pj^{e}_t} + \sum_c \sum_s \sum_t (C^{fix} + C^{var} \cdot d_{cs}) \cdot v_{cst}
$$
$$
+ \sum_s \sum_p \sum_t (C^{fix} + C^{var} \cdot d_{sp}) \cdot v_{spt} + \sum_{n \in \{n^{el} \cup n^{h}\}} \sum_p \sum_c \sum_t C_{npct}^{dist} \cdot q_{npct} \left. \right) \qquad (1)
$$

The produced MSW in a city (A_{wct}) is distributed to different separation centers (q_{wcst}) as given in Eq. (2). Equation (3) shows that the total amount of waste inlet to a separation center should not exceed its maximum input capacity (SC_{wst}^{max}). Equation (4) shows the amount of separated waste (q_{wst}^{sep}) using a separation rate for each waste type (R_{ws}^{sep}). Equation (6) shows the amount of waste shipped to the pre-treatment technologies in separation center ($q_{wsj^s t}^{sep}$), which is limited by the technology capacity ($SC_{wsj^s}^{low}$, $SC_{wsj^s}^{up}$) as given in Eq. (7). The binary variable $z_{wsj^s t}^{treat}$ indicates whether the waste is sent for pre-treatment to a technology or not. Equation (8) shows the amount of treated waste ($q_{\tilde{w}st}^{treat}$) using a pre-treatment rate for each waste type ($R_{w\tilde{w}sj^s}^{treat}$). Equations (5) and (9) define the inventory levels of initial waste and treated waste in a separation center ($i_{wst}, i_{\tilde{w}st}$), which cannot exceed its storage capacity ($S_{ws}, S_{\tilde{w}s}$).

$$ A_{wct} = \sum_s q_{wcst} \qquad \forall w \in W, c \in C, t \in T \qquad (2) $$

$$ \sum_c q_{wcst} \le SC_{wst}^{max} \qquad \forall w \in W, s \in S, t \in T \qquad (3) $$

$$ q_{wst}^{sep} = \sum_c q_{wcst} \cdot R_{ws}^{sep} \qquad \forall w \in W, s \in S, t \in T \qquad (4) $$

$$ i_{wst} = i_{ws(t-1)} + q_{wst}^{sep} - \sum_{j^s} q_{wsj^s t}^{sep} \text{ and } i_{wst} \le S_{ws} \qquad \forall w \in W, s \in S, t \in T \qquad (5) $$

$$ \sum_{j^s} q_{wsj^s t}^{sep} \le i_{ws(t-1)} + q_{wst}^{sep} \qquad \forall w \in W, s \in S, t \in T \qquad (6) $$

$$ SC_{wsj^s}^{low} \cdot z_{wsj^s t}^{treat} \le q_{wsj^s t}^{sep} \le SC_{wsj^s}^{up} \cdot z_{wsj^s t}^{treat} \qquad \forall w \in W, s \in S, j^s \in J^s, t \in T \qquad (7) $$

$$ q_{\tilde{w}st}^{treat} = \sum_w \sum_{j^s} q_{wsj^s t}^{sep} \cdot R_{w\tilde{w}sj^s}^{treat} \qquad \forall \tilde{w} \in \tilde{W}, s \in S, t \in T \qquad (8) $$

$$ i_{\tilde{w}st} = i_{\tilde{w}s(t-1)} + q_{\tilde{w}st}^{treat} - \sum_p q_{\tilde{w}spt} \text{ and } i_{\tilde{w}st} \le S_{\tilde{w}s} \qquad \forall \tilde{w} \in \tilde{W}, s \in S, t \in T \qquad (9) $$

Equation (10) shows the amount of treated waste that can be shipped from separation centers to plants ($q_{\tilde{w}spt}$). Equation (11) calculates the number of vehicles used for the

transportation of waste from cities to separation centers (v_{cst}) and from separation centers to plants (v_{spt}) considering the vehicle capacity respecting the waste volume ($VC_w, VC_{\tilde{w}}$). Equation (12) limits the CO_2 emissions emitted from transportation by $TE_{st}^{CO_2}$ considering the distance (D_{cs}, D_{sp}), fuel consumption (F), and emission emitted from per liter of fuel (E^{CO_2}). Equation (13) shows that the total waste inlet to a plant is limited by the input capacity of the plant ($PC_{\tilde{w}pt}^{max}$). Equation (14) presents the waste inventory level in a plant ($i_{\tilde{w}pt}$), which cannot exceed the storage capacity ($S_{\tilde{w}p}$) of the plant. Equation (15) limits the amount of waste that can be transferred to processing technologies ($q_{\tilde{w}pj^{int}{}_t}$), which cannot exceed the capacity limits of the technology ($PC_{\tilde{w}pj^{int}}^{low}$, $PC_{\tilde{w}pj^{int}}^{up}$) as shown in Eq. (16). $z_{\tilde{w}pj^{int}{}_t}^{conv}$ is a binary variable that equals 1 if the waste is sent to conversion technologies for the production of intermediate products.

$$\sum_p q_{\tilde{w}spt} \le i_{\tilde{w}s(t-1)} + q_{\tilde{w}st}^{treat} \qquad \forall \tilde{w} \in \tilde{W}, s \in S, t \in T \tag{10}$$

$$v_{cst} - 1 \le \sum_w \frac{q_{wcst}}{VC_w} \le v_{cst} \text{ and } v_{spt} - 1 \le \sum_{\tilde{w}} \frac{q_{\tilde{w}spt}}{VC_{\tilde{w}}} \le v_{spt} \qquad \forall c \in C, s \in S, p \in P, t \in T \tag{11}$$

$$\left(\sum_c D_{cs} \cdot v_{cst} + \sum_p D_{sp} \cdot v_{spt}\right) \cdot F \cdot E^{CO_2} \le TE_{st}^{CO_2} \qquad \forall s \in S, t \in T \tag{12}$$

$$\sum_s q_{\tilde{w}spt} \le PC_{\tilde{w}pt}^{max} \qquad \forall \tilde{w} \in \tilde{W}, p \in P, t \in T \tag{13}$$

$$i_{\tilde{w}pt} = i_{\tilde{w}p(t-1)} + \sum_s q_{\tilde{w}spt} - \sum_{j^{int}} q_{\tilde{w}pj^{int}{}_t} \text{ and } i_{\tilde{w}pt} \le S_{\tilde{w}p} \qquad \forall \tilde{w} \in \tilde{W}, p \in P, t \in T \tag{14}$$

$$\sum_{j^{int}} q_{\tilde{w}pj^{int}{}_t} \le i_{\tilde{w}p(t-1)} + \sum_s q_{\tilde{w}spt} \qquad \forall \tilde{w} \in \tilde{W}, p \in P, t \in T \tag{15}$$

$$PC_{\tilde{w}pj^{int}}^{low} \cdot z_{\tilde{w}pj^{int}{}_t}^{conv} \le q_{\tilde{w}pj^{int}{}_t} \le PC_{\tilde{w}pj^{int}}^{up} \cdot z_{\tilde{w}pj^{int}{}_t}^{conv} \qquad \forall \tilde{w} \in \tilde{W}, p \in P, j^{int} \in J^{int}, t \in T \tag{16}$$

Equation (17) calculates the amount of produced intermediates ($q_{n^{int}{}_{pt}}$) using the conversion rate of $R_{\tilde{w}n^{int}{}_{pj^{int}}}^{conv}$. Equation (18) shows that the total amount of intermediate product is transferred to energy conversion technologies ($q_{n^{int}{}_{pj^e{}_t}}$), which is restricted to the capacity limits of the technology ($PC_{n^{int}{}_{pj^e}}^{low}$, $PC_{n^{int}{}_{pj^e}}^{up}$) as shown in Eq. (19). The binary variable $z_{n^{int}{}_{pj^e{}_t}}^{energy}$ indicates whether the intermediate product is sent to energy production technologies or not.

$$q_{n^{int}{}_{pt}} = \sum_{\tilde{w}} \sum_{j^{int}} q_{\tilde{w}pj^{int}{}_t} \cdot R_{\tilde{w}n^{int}{}_{pj^{int}}}^{conv} \qquad \forall n^{int} \in N^{int}, p \in P, t \in T \tag{17}$$

$$\sum_{j^e} q_{n^{int}{}_{pj^e{}_t}} = q_{n^{int}{}_{pt}} \qquad \forall n^{int} \in N^{int}, p \in P, t \in T \tag{18}$$

$$PC_{n^{int}{}_{pj^e}}^{low} \cdot z_{n^{int}{}_{pj^e{}_t}}^{energy} \le q_{n^{int}{}_{pj^e{}_t}} \le PC_{n^{int}{}_{pj^e}}^{up} \cdot z_{n^{int}{}_{pj^e{}_t}}^{energy} \qquad \forall n^{int} \in N^{int}, p \in P, j^e \in J^e, t \in T \tag{19}$$

Equation (20) shows the conversion of intermediate products to electricity ($q_{n^{el}pt}$) considering the conversion rate of $\tau_{n^{int}n^{el}pje}$ and efficiency of $\varphi_{n^{int}n^{el}pje}$. Since an intermediate can be converted to both heat and electricity, the coefficient $\lambda^{el}_{n^{int}pt}$ is used, which is the percentage of intermediate product conversion to electricity, and the rest can be converted to heat. Equation (21) shows the heat production considering the conversion rate of $\tau_{n^{int}n^{h}pje}$ and efficiency of $\varphi_{n^{int}n^{h}pje}$. Equation (22) indicates the amount of CO_2 emissions from operating waste ($E^{CO_2}_{\tilde{w}pj^{int}}$) and intermediates ($E^{CO_2}_{n^{int}pje}$), which is limited to the pre-determined emission level ($OE^{CO_2}_{pt}$). Equation (23) limits the electricity and heat generation to the production capacity of plant (PC^{max}_{npt}), and the binary variable z^{prod}_{npt} is to check if energy products are produced by the plant or not. Equation (24) shows the total energy transmitted from a plant to cities (q_{npct}), and Eq. (25) shows the energy products received by cities (q_{nct}), which cannot exceed the product demand (D_{nct}).

$$q_{n^{el}pt} = \sum_{n^{int}}\sum_{je} \lambda^{el}_{n^{int}pt} \cdot q_{n^{int}pje_t} \cdot \tau_{n^{int}n^{el}pje} \cdot \varphi_{n^{int}n^{el}pje} \qquad \forall n^{el}, p \in P, t \in T \tag{20}$$

$$q_{n^{h}pt} = \sum_{n^{int}}\sum_{je} (1-\lambda^{el}_{n^{int}pt}) \cdot q_{n^{int}pje_t} \cdot \tau_{n^{int}n^{h}pje} \cdot \varphi_{n^{int}n^{h}pje} \qquad \forall n^{h}, p \in P, t \in T \tag{21}$$

$$\sum_{\tilde{w}}\sum_{j^{int}} q_{\tilde{w}pj^{int}_t} \cdot E^{CO_2}_{\tilde{w}pj^{int}} + \sum_{n^{int}}\sum_{je} q_{n^{int}pje_t} \cdot E^{CO_2}_{n^{int}pje} \le OE^{CO_2}_{pt} \quad \forall p \in P, t \in T \tag{22}$$

$$q_{npt} \le PC^{max}_{npt} \cdot z^{prod}_{npt} \qquad \forall n \in \{n^{el} \cup n^{h}\}, p \in P, t \in T \tag{23}$$

$$q_{npt} = \sum_{c} q_{npct} \qquad \forall n \in \{n^{el} \cup n^{h}\}, p \in P, t \in T \tag{24}$$

$$q_{nct} = \sum_{p} q_{npct} \text{ and } q_{nct} \le D_{nct} \qquad \forall n \in \{n^{el} \cup n^{h}\}, c \in C, t \in T \tag{25}$$

3. Results and Discussions

The considered multi-echelon SC problem consists of two cities as waste sources and consumer locations, two separation centers for waste separation and pre-treatment operations with two pre-treatment technologies, and three WtE plants to generate electricity and heat. The total MSW generation is 1,164 kt during a year. The presented MILP model is solved efficiently in a reasonable computational time (0.22 CPU-s) using GAMS/CPLEX. Considering the pyrolysis and gasification with the energy potential of 660 kWh/ton waste and the CHP plant with the capacity of 585 kWh/ton waste, 383 GWh of electricity and 171 GWh of heat are produced in a year. Figure 2 (a) presents the generated electricity and heat by the considered WtE plants. As demonstrated, pyrolysis produced the smallest amount of electricity, meeting 21 % of electricity demand, and the gasification plant met 49 % of electricity demand. Operation of CHP plant depends on the heat demand, and afterward, the range of electricity generation is determined; i.e., the more heat is produced the less energy is available for electricity production. The CHP generated 113.85 GWh of electricity during a year and satisfied 100 % of the heat demand. Therefore, CHP is a more profitable conversion technology than the other two WtE alternatives. However, it is most cost-effective when

there is a constant heat demand, e.g., from adjacent industrial plants or district heating systems. The feedstock in pyrolysis was mostly plastic waste with lower calorific value compared to the considered mixed waste, which justifies the lower electricity generation by pyrolysis compared to the other two technologies. As shown in Figure 2 (b), the SC performance is greatly affected by the changes in electricity demand. Regarding the environmental aspects, pyrolysis and gasification are promising technologies in terms of clean energy production and having lower negative environmental impacts, whereas CHP led to the production of higher CO_2 emissions.
Figure 2 (a): Energy generation by WtE plants; 2 (b): Effect of fluctuations in electricity demand on the SC performance

4. Conclusions

The purpose of this study is to measure the environmental impacts and economic costs of the WtE SC network in order to check the economic and ecological feasibility of the entire system. In such systems, the production process, waste availability, energy demand, plant capacity, and level of energy efficiency affect the performance of WtE plants. Moreover, the coordination between SC entities has a substantial impact on the system performance by minimizing the overall costs, satisfying capacity restrictions at each level of the SC network, and fulfilling the demand requirements. The proposed model provides quantifiable information to make effective and optimum decisions regarding the treatment of waste while ensuring the most feasible (sustainable and cost-efficient) operations.

Abstract

We describe the application of an online dynamic and discrete scheduling optimization, also known as real-time hybrid model predictive control, applied to a shuttle-conveyor / tripper car intermittently delivering crushed-ore containing copper, iron, etc., to several stockpiles. Each stockpile continuously feeds an apron feeder located in a tunnel underneath the stockpile where multiple of these are combined to a belt feeder to charge a grinding mill which ultimately produces concentrates of minerals. Crushed-ore from a mine several kilometres upstream is transported by both conveyor belt and automatic trains. The shuttle-conveyor is the discrete actuation or manipulated variable depositing the solids onto each stockpile where we vary the time over each stockpile to automatically control to a setpoint or target their levels sensed by industrial radar. In the field, the motion of the shuttle-conveyor is known as sweeping as it moves from one stockpile (or tunnel) to the next in a fixed sequence. The purpose of our application is to improve the stockpile level control performance by automatically adjusting the up-time, fill-time or run-length of the shuttle-conveyor tripper car over each stockpile based on real-time level measurement feedback and the application which is referred to as *smart sweeping*.

Keywords: Mixed-integer linear programming (MILP), Hybrid dynamic control, Stockpile live inventory, Smart sweeping.

1. Introduction

Advances in manufacturing toward the Industry 4.0 (I4) age push the re-examination of industrial systems to identify opportunities to (re) execute them into an improved production state. For such, the information and communication technologies (ICT), high-performance computing (HPC) and mechatronics (MEC) are evolving together with the advances in modelling and solving algorithms (MSA). Considering this I4 era in manufacturing, we explore the MSA aspects in an application found in the mining field (see the Future of Mining in the 21st Century in Lottermoser, 2017). In the system, shuttle-conveyors are modeled in terms of their sequencing and timing as they travel from one position or location to the next on the shuttle-carriage, whereby stockpile levels are used as setpoints to influence the movements of the shuttle-conveyors. Automated belt conveyor systems integrated with intelligent decision-making core is a successful application of I4 in the mining value chain (Braun et al., 2017).

In the proposed work, the design basis of the advanced control system for managing simultaneously multiple stockpile levels for each feeder in the ore land field, warehouse,

bunker or barn uses the mixed-integer linear programming (MILP) optimization for the positioning, placement, movement or manipulation of the shuttle-conveyors / tripper cars, the discrete (integer), whereas the stockpile levels are continuous. In addition, the supply (filling) and demand (drawing) of crushed-ore in the ore barn is semi-continuous or intermittent especially considering the nature of how crushed-ore travels from the mine to the barn and how crushed-ore is feed to autogenous mills via the feeders.

The proposed problem is known in the control literature as hybrid model predictive control (HMPC) as there is a mix of discrete and continuous variables with a receding or moving prediction time-horizon. The MILP solution defines the shuttle positions which will collectively manage the stockpile levels over each feeder given the supply and demand of crushed-ore. MILP is a search-based algorithm known as branch-and-bound (B&B) which will evaluate quickly many possible scenarios, samples or situations to find the best solution that optimizes the objective function also taking into consideration both the continuous and discrete nature of the controlled and manipulated variables subject to hard constraints (i.e., lower and upper bounds) and soft constraints (target).

Supported by the I4 fundaments, a high-end radar sensing system (for virtual reality) measures the mineral stockpile level (opening inventory) in real-time for the determination of discrete positions and time-slots of the reversing shuttle-conveyor that creates the stockpiles (ST1 to ST8) for feeding multiple fixed discharge points. A reversing shuttle-conveyor in Figure 1 is a belt conveyor sweeping onto a rail system in both directions which manipulates, belt direction and shuttle movement, and can be automated or controlled manually by an operator.
Figure 1. Tripper car shuttle-conveyor schematics.

2. Problem statement

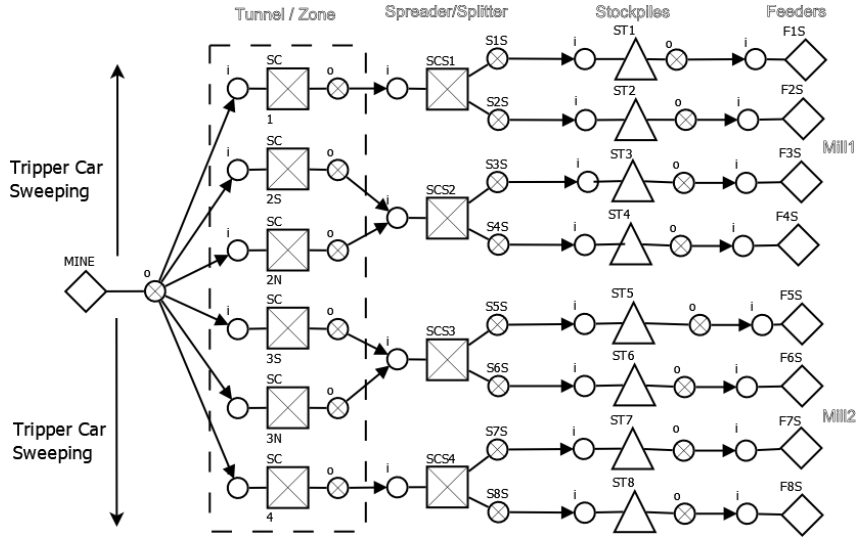
The objective function will minimize the absolute deviations (1-norm performance) of the stockpile estimated *live* inventories (controlled variables) as well as minimizing the absolute excursions or penalties from its lower and upper holdup bounds should any infeasibilities be detected both in the present and in the future. The decision or manipulated variables are the shuttle-conveyor positions (in time-steps) subject to their sequence and timing constraints. In the problem, the shuttle-conveyor (SC) supplies crushed-ore to the ore barn which contains the wet-mills Mill1 and Mill2 as seen in Figure 2. To these mills are fed crushed-ore by eight (8) feeders with corresponding stockpiles (ST1, ST2, …, ST8) connected to them by tunnels or zones below the stockpiles where apron-feeders gravity load crushed-ore onto belt-conveyors on an incline to be sent to the wet-mills for grinding.


Figure 2. Stockpile control system.

The shuttle-conveyor position sequencing policies are based on the notion of whether the placement sequence from one tunnel to the next and the amount of time the shuttle-conveyor spends over each tunnel are fixed or variable. Sweeping is the name given to a fixed-sequence / variable-time policy with SC traveling forward and backward between tunnels 1 to 4. Figure 2 above depicts a flowsheet for how crushed-ore material from the mine can be moved from SC (tunnels) to the stockpiles (ST1, …, ST8) and ultimately to the wet-mill feeders via the spreader / splitter objects shown. These separation structures or shapes are required to model the non-ideal flow of how crushed-ore flow distributes or spreads over to both stockpiles at each tunnel. It should be emphasized that since SC is a unary or single-use resource only one of the six operations configured (1, 2S, 2N, 4, 3S, 3N) can be setup, active, on, open, etc., within any given time-period. Sweeping is similar to the notion of *phasing* found in project scheduling (Menezes et al., 2015) as there is a fixed-sequence of how each shuttle-conveyor traverses its area of the ore warehouse or barn, i.e., from one phase, task or operation to the next and so on.

3. Mathematical formulation

The network in Figure 2 uses the unit-operation-port-state superstructure (UOPSS) formulation (Kelly, 2005). The objects are: a) unit-operations m for sources and sinks ($\diamond$), stockpiles ($\triangle$) and continuous-processes ($\boxtimes$) and b) the connectivity involving arrows ($\rightarrow$), in-port-states i ($\bigcirc$) and out-port-states j ($\otimes$). Unit-operations and arrows have binary and continuous variables (y and x, respectively). In the mixed-integer linear (MILP) problem (P), the objective function (1) minimizes the absolute deviation of the stockpile inventories, levels or holdups $xh_{m,t}$. The performance constraint (2) defines the lower and upper deviation variables ($xh_{m,t}^{LD}$ and $xh_{m,t}^{UD}$, respectively) around the stockpile holdup target ($\overline{xh}_{m,t}$) with w^D as weight. The semi-continuous constraint (3) limits the stockpile holdup by its lower and upper bounds ($\overline{xh}_{m,t}^{L}$ and $\overline{xh}_{m,t}^{U}$), whereby the excursion variables or penalties $xh_{m,t}^{LE}$ and $xh_{m,t}^{UE}$ are included to avoid infeasibilities (with w^E as weight). Similarly, there are semi-continuous constraints for flows of process-units $x_{m,t}$ and arrows $x_{j,i,t}$, although without excursion variables as for the stockpile holdups. Unit-

operations m for the mine, shuttle-conveyor, spreader, stockpile, and feeder belong, respectively, to the sets M_{MN}, M_{SC}, M_{SD}, M_{ST}, and M_{FD}. For $x \in \mathbb{R}^+$, $y, yg \in \{0,1\}$ and $zsu_{m,t}, zsd_{m,t}, zsw_{m,t} \in [0,1]$:

$$(P) \; Max \; Z = \sum_{t} \sum_{m \in M_{ST}} \left[w^D \left(xh_{m,t}^{LD} + xh_{m,t}^{UD} \right) + w^E \left(xh_{m,t}^{LE} + xh_{m,t}^{UE} \right) \right] \quad s.t. \tag{1}$$

$$xh_{m,t} - \overline{xh}_{m,t} + xh_{m,t}^{LD} - xh_{m,t}^{UD} = 0 \;\; \forall \, m \in M_{ST}, t \tag{2}$$

$$\overline{xh}_{m,t}^{L} \, y_{m,t} - xh_{m,t}^{LE} \leq xh_{m,t} \leq \overline{xh}_{m,t}^{U} \, y_{m,t} + xh_{m,t}^{UE} \;\; \forall \, m \in M_{ST} \; t \tag{3}$$

$$\frac{1}{\bar{x}_{m,t}^{U}} \sum_{j \in M_{MN}} x_{j,i,t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^{L}} \sum_{j \in M_{MN}} x_{j,i,t} \quad \forall \, (i,m) \in M_{SC}, t \tag{4}$$

$$\frac{1}{\bar{x}_{m,t}^{U}} \sum_{i} x_{j,i,t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^{L}} \sum_{i} x_{j,i,t} \quad \forall \, (m,j) \in (M_{MN}, M_{SC}, M_{SD}) \, , t \tag{5}$$

$$\frac{1}{r_{i,t}^{U}} \sum_{j} x_{j,i,t} \leq x_{m,t} \leq \frac{1}{r_{i,t}^{L}} \sum_{j} x_{j,i,t} \quad \forall \, (i,m) \in (M_{SC}, M_{SD}) \, , t \tag{6}$$

$$\frac{1}{r_{j,t}^{U}} \sum_{i} x_{j,i,t} \leq x_{m,t} \leq \frac{1}{r_{j,t}^{L}} \sum_{i} x_{j,i,t} \quad \forall \, (m,j) \in (M_{SC}, M_{SD}), t \tag{7}$$

$$xh_{m,t} = xh_{m,t-1} + \sum_{j_{up}} x_{j_{up},i,t} - \sum_{i_{do}} x_{j,i_{do},t} \; \forall \, (i,m,j) \in M_{ST}, t \tag{8}$$

$$\sum_{m \in M_{SC}} y_{m,t} \leq 1 \; \forall \; t \tag{9}$$

$$\sum_{m \in M_{SC}} y_{m,t} \geq 1 \; \forall \; t \tag{10}$$

$$y_{m_{up},t} + y_{m,t} \geq 2 y_{j_{up},i,t} \; \forall \left(m_{up}, j_{up}, i, m \right), t \tag{11}$$

$$y_{m,t} - y_{m,t-1} - zsu_{m,t} + zsd_{m,t} = 0 \; \forall \, m \in M_{SC}, t \tag{12}$$

$$y_{m,t} + y_{m,t-1} - zsu_{m,t} - zsd_{m,t} - 2zsw_{m,t} = 0 \quad \forall \, m \in M_{SC}, t \tag{13}$$

$$zsu_{m,t} + zsd_{m,t} + zsw_{m,t} \leq 1 \; \forall \, m \in M_{SC}, t \tag{14}$$

$$\sum_{g \in G_{SC}} yg_{u,g,t} = 1 \; \forall \; u \in U_{SC}, t \tag{15}$$

$$\sum_{(m \in M_{SC}) \subset G_{SC}} y_{m,t} \leq yg_{u,g,t} \; \forall \, u \in U_{SC}, g \in G_{SC}, t \tag{16}$$

$$yg_{u,g,t} - yg_{u,g,t-1} \leq zsu_{m \subset g,t} \; \forall \, u \in U_{SC}, g \in G_{SC}, t \tag{17}$$

$$yg_{u,g,t-1} - yg_{u,g,t} \leq zsu_{m \subset g',t} \; \forall \, u \in U_{SC}, g \in G_{SC}, g' \in G_{SC}, t \tag{18}$$

Equations (4) and (5) represent, respectively, the sum of the arrows arriving in the in-port-states i (or mixers) or leaving from the out-port-states j (or splitters) and their summation must be between the bounds of the unit-operation m connected to them. Equations (6) and (7) consider bounds on yields, both inverse ($r_{i,t}^L$ and $r_{i,t}^U$) and direct ($r_{j,t}^L$ and $r_{j,t}^U$), since the unit-operations m can have more than one stream arriving in or leaving from their connected ports. The quantity balance of inventory or holdup for unit-operations of tanks ($m \in M_{ST}$) in Eq. (8) considering initial inventories $xh_{m,t-1}$ and inlet and outlet streams of the tanks, whereby the port-states j_{up} and i_{do} represent upstream and downstream ports connected, respectively, to the in-port-states i and out-port-states j of the stockpile unit-operations m as represented in Figure 2. In Eq. (9), for all physical units, at most one unit-operation m (as $y_{m,t}$ for procedures, modes or tasks) is permitted in U_{SC} at a time t. Equation (10) is the zero-downtime constraint to activate SC in all time t. Equation (11) is the structural transition logic valid cut of 4 objects (m', j, i, m) to reduce the tree search in branch-and-bound methods.

The sequencing operation of the multiple SC is controlled by the temporal transition constraints (12) to (14) from Kelly and Zyngier (2007). The setup or binary variable $y_{m,t}$ manages the dependent start-up, switch-over-to-itself and shut-down variables ($zsu_{m,t}$, $zsw_{m,t}$ and $zsd_{m,t}$, respectively) are relaxed in the interval [0,1] instead of considering them as logic variables. Equation 12 is necessary to guarantee the integrality of the relaxed variables. By fixing the sequence (neighbor to neighbor) of the SC modes of operation (time-slots of the positions), the grouping constraints (15) to (18) coordinate the grouping setup variable $yg_{u,g,t}$ to update the shuttle-conveyor operation-group to operation-group sequence-dependent *phasing* (or fixed transition between neighbor modes of the SC, e.g., 1→2S→3S→4→3N→2N→1). Other constraints related to uptime of the SC and the shutting-when-full relationship are found in Zyngier and Kelly (2009).

4. Example

The example in Figure 2 uses the structural-based UOPSS framework found in the semantic-oriented modelling and solving platform IMPL (Industrial Modeling & Programming Language) from Industrial Algorithms Limited using Intel Core i7 machine at 3.4 GHz (in 8 threads) with 64 GB of RAM. The optimization for the proposed MILP for a 2 hours time-horizon with 2 minute time-steps (30 time-periods) is solved in 4.07 seconds (with GUROBI 8.1.0). There are 5,472 constraints (1,593 equality) for 2,823 continuous variables and 900 binary variables with 2,130 degrees-of-freedom. Figure 3 shows the Gantt chart for the shuttle-conveyor and spreader time-slot positions (in min).
Figure 3. Gantt chart for shuttle-conveyor (SC) and spreader (SCS) time-slot positions.

5. Conclusions

By automating a shuttle-conveyor position in variable time-slots of minutes, a hybrid dynamic control problem coordinates the stockpile *live* inventory of crushed-ore of minerals in the mining field. With advanced automation of mining sub-systems, it may be possible to replace human operators in the field in certain areas and functions. One place to start can be the integration of the synchronization of the sensing, calculating and actuating cycle (within minutes) as in the mining system proposed in this paper. The position of the tripper car reached the level of sensing and calculating technologies to be integrated to automatically program the time-slot of positions of the shuttle conveyor system.

Integrated to the decision-making core proposed in this paper (the hybrid dynamic control), for the advances in the infrastructure of cyber-physical systems (CPS) for a digital twin of the reality in the mining system there are needs of other three smart manufacturing foundations. They are: a) information and communication technologies (ICT), with the ecosystem match of the internet of the things and computing edges as the cloud and fog (Bittencourt, 2018), to capture the *live* inventory using the radar apparatus; b) the high-performance computing (HPC), to solve extremely fast the discrete and continuous problems in distributed machine cores; and c) the mechatronics (MEC) to actuate automatically considering an integrated envelop of the main I4 attributes around the sensing, calculation and actuation cycle of an I4-age manufacturing system.

Abstract

High-quality process system engineering (PSE) solutions for production scheduling evolve to a wider scope and scale when moving from simulation- to optimization-based approaches, generally by using mixed-integer programming (MIP) in discrete-time formulations. To reach as we state in this paper as the spotting level of service, into the scheduling operational details and time-step within a time-horizon of planning, the novel aspect of these types of PSE solutions is to integrate automated logistics or blend logistics decisions regarding: (1) sizing the future blend volumes for blending (or throughputs of unit-operations for processing); (2) selecting a product tank for the blends (or modes of operation for the process units); (3) sequencing the blended product grades (i.e., regular before premium, etc.) in multi-product blender (or the sequence of modes of operation for units/tanks); (4) slotting the start-times of the blends (or processing-time of units) into time-periods; and (5) spotting the future product shipments to steward to the plan. Examples of scheduling optimization effectively implemented are: (1) the production of lubes and asphalts with sequence-dependent switchovers between modes of operation; and (2) the gasoline blend scheduling operations using decomposition strategies and cuts based on nominal qualities. Faster results are obtained by tailored solutions of decomposing these industrial problems.

Keywords: Effective knowledge transfer, Industrial PSE applications, Spot markets.

1. Introduction

Integration of planning and scheduling in the processing industries can be achieved by solving a scheduling problem (in terms of time-step, level of details, etc.) within a planning time-horizon (in general for a month or longer). In such a way, the proposed planning-scheduling solution can be considered (in a product point of view) what we name in the paper as spotting, since there are potentials to increase the profit by exploring the higher gains from spot market opportunities when compared with its concurrent and complementary contract market dividends. In this case, for the producer, there is a reasonable degree of confidence in the day-by-day (optimized or prescribed) production by extending a schedule from a week to a month time-horizon. By addressing such high-quality PSE solutions into the spotting state, sellers are still in time to negotiate products in the spot market, which requires by half to one month in advance for the time-restricted contract to be made.

However, major considerations to reach the spotting stage (in a process point of view) must consider the following challenges for such integrated decision-making systems. What is the necessary time-grid of the scheduling solutions for a specific process, varying from online solutions ($\leq$ 1-hour) to 1-day discrete time-step? What planning and scheduling integration strategies exist? What degree of process details is demanded in the modelling? Which advanced manufacturing attribute can be explored and integrated in the optimization core, such as information and communication technologies (ICT) and auxiliary mechatronics (MEC) to automatically sample, analyse and communicate?

Franzoi et al. (2018a) proposed a refinery-wide scheduling approach to investigate the limits or capabilities of an enterprise-wide optimization (EWO) by solving simultaneously the supply, production, and demand chains using MILP. This solution fixes time-varying setups of unit-operations and connections that construct the flowsheet operations for further NLPs (Kelly et al., 2017a). Such EWO scope and scale may use additional detailed calculations within other edges such as in the depooling of aggregated tanks by considering their actual topology and operations (Menezes et al., 2018). Furthermore, Kelly et al. (2018a) introduce the concept of planuling that is a portmanteau of planning and scheduling where we schedule slow processes and plan fast processes together inside the slower process time-horizon, which demands an extra calculation for the fast processes, but henceforth as a scheduling problem.

To achieve the spotting solution in the matters of operational and economical standpoints may be accomplished by reducing the problem complexity when we exclude, relax and fixate part of it. These procedures must be coupled with high-performance computing (HPC) for faster calculations in parallel cores. Additionally, model and plant differences can be reduced by using closed-loop parameter feedback (Franzoi et al., 2018b) with the support of ICT and MEC capabilities. For the integrated planning and scheduling approach toward the spotting service level, we present solutions with 1-week to 2-months as time-horizon varying from 2-hours to 1-day as time-step. The effective implementation of the industrial examples uses the best technologies of modelling and solving algorithms (MSA) to optimize the problem.

2. From planning and scheduling to spotting

Benefit areas from this moving to optimization-based decisions using MILP as a prescriptive analytics application for sizing, selecting, sequencing, slotting and spotting (blend volumes and throughputs) in the processing industries are as follows:

a) optimized (vs. simulated) schedules which maximize profit and performance given pricing and discretizing on a sub-day or sub-hour basis;

b) better coordination with sales and marketing by providing optimized and achievable blend production schedules for all future product (and saleable component) shipments;

c) improved stewardship to the monthly feedstock selection and operations plan which coordinates the supply and demand of all the refinery site production;

d) increased ability to capture spot market opportunities after contract sales have been fulfilled respecting bottlenecks, in-progress blends, planned recipes, etc.;

e) blend schedules matching product quality specifications to reduce key property giveaway and to decrease the chances of off-specification blends to product tanks.

3. Effective knowledge transfer: high-quality PSE solution for spotting

Recently, state-of-the-art technology on modelling and solving algorithms (MSA), one of the ground bases of the *Industry 4.0* mandate, was implemented in an oil and gas company in Southern Asia. The company's call of technology winner has beaten the dominant petroleum scheduling technology sellers since they still deliver simulation-based scheduling solutions with limited optimization capabilities. The potentials of the cutting-edge MSA technologies are used in the examples.

Similar scope and scale to those implemented in crude-oil refineries, the examples are configured in the modelling platform named Industrial Modeling & Programming Language (IMPL) seamlessly coupled with GUROBI's superior simplex and barrier LP algorithms as one of today's most efficient solvers. These technologies optimize the production considering time-horizons for (a) 1-month with 1 day as time-step and (b) 7-days to 30-days with 2h as time-step. They are robustly and reliably solved within minutes combined for both the logistics and the quality sub-problems or any sort of decomposition. The object constructs of the examples (Figures 1 and 2) consider the unit-operation-port-state superstructure (UOPSS) formulation (Kelly, 2005) built-in with IMPL (see IMPL manual in Kelly, 2018). The unit-operation and arrow objects have binary and continuous variables (y and x, respectively) such as: a) unit-operations m for sources and sinks ($\diamond$), tanks ($\triangle$) and continuous-processes ($\boxtimes$) and b) the connectivity involving arrows ($\rightarrow$), in-port-states i ($\bigcirc$) and out-port-states j ($\otimes$).

4. Examples

4.1. Scheduling for production of lubes and asphalts

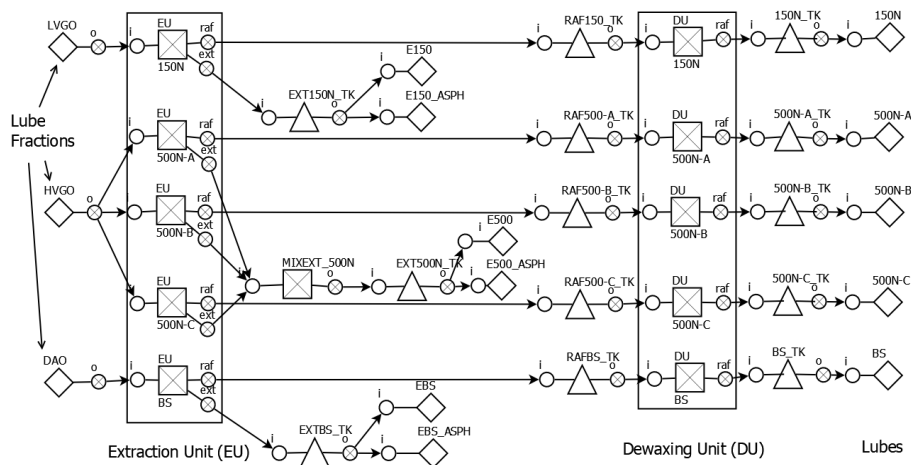
Reduced crude-oil distilled streams or atmospheric residue from crude-oil distillation units are fed to vacuum distillation units to produce fractions of lubes and asphalts (Kyungseok et al., 2017). To schedule the blocks, campaigns or conjugated modes of operation (or grades of lube base oils) in further steps of processing in solvent extraction (EU), dewaxing (DU) and hydrotreating units as in Figure 1, the MILP optimization uses the sequence-dependent switchovers introduced by Kelly and Zyngier (2007).


Figure 1. Production flowsheet for Lubes.

The proposed solution of the flowsheet in Figure 1 solves a 60-day horizon with 1-day time-steps, allowing opportunities of exploring the dynamics of the contract and spot markets. The MILP for a 60-day time-horizon with 1-day time-steps (60 time-periods) is solved in 30.7 seconds (with GUROBI 8.1.0) and 40.9 seconds (with CPLEX 12.8.0) at 0.0% of MILP relaxation gap using an Intel Core i7 machine at 3.4 GHz (in 8 threads) with 64 GB of RAM. There are 10,247 constraints (2,942 equality) for 5,102 continuous variables and 3,120 binary variables with 5,280 degrees-of-freedom. Figure 2 shows the Gantt chart for the dewaxing (DU) operations in time-slot positions.
Figure 2. Dewaxing (DU) modes of operation and the holdup in their feed tanks (TK).

4.2. Gasoline blend scheduling

The gasoline blend scheduling is solved for the logistics (MILP) problem including nominal quality balances (Kelly et al., 2018b) in the MILP solution instead of neglecting the quality relationships completely. In the problem, without preferred recipes initialization as in Mendez et al. (2006), slack or surplus variables are calculated to balance the amounts of quality around the blender unit-operations and a successive MILP can be iterated to meet the quality specifications by using the slack or surplus variables and their distances from their lower and upper respective specifications. In such a way, cuts based on nominal qualities may avoid impending quality NLP infeasibilities if the NLP is needed after the MILP setup variables fixation. In this case, successive linear programming (SLP) technology can be used for these industrially-sized nonlinear dynamic optimizations since any infeasibilities or inconsistencies due to poor opening quantities and qualities, as example, are quickly detected and identified by the user in terms of the offending variable and/or constraint.

The proposed solution solves a 7- to 30-day horizon (time-step of 2 hours) for the problem in Figure 3. Table 1 shows the MILP solution (using nominal quality cuts) at 2% of MILP relaxation gap in an Intel Core i7 machine at 3.4 GHz (in 8 threads) with 64 GB of RAM. Although all cases converged, to reduce the CPU time in the full space MILP when > 60 minutes, we use a temporal decomposition heuristic known as rolling-horizon with crossover (RHC) in the time windows of the neighbouring time-horizon splits (Kelly, 2002) as shown in the additional CPU (in minutes).

Table 1. Statistics for 7, 14, 21 and 30 days (2 h time-step).

CPU (min) GUROBI (8.1.0)				CPU (min) CPLEX (12.8.0)				Equations (for 14d)	Continuous/ Binary Variables (for 14d)
7d	14d	21d	30d	7d	14d	21d	30d		
2.4	6.1	> 60	> 60	25.9	> 60	> 60	> 60	99,300	47,091/ 13,992
RHC		+ 11.1	+8.5	RHC	+ 37.3	> 60	> 60		
Figure 3. Gasoline blend scheduling with regular, medium and premium grade modes.

As an example of a result in the gasoline blend scheduling problem, Figure 4 shows the Gantt chart of the blender unit-operations (R, M and P) for 14 days as time-horizon solved using MILP with cuts on nominal qualities or factors for qualities (Kelly et al., 2018) in octane number (Road) and Reid vapor pressure (RVP) as shown in the flowsheet in Figure 3. The sequence of modes of operation (R, M and P in the blender BL unit) attend the supply of detailed and specific demands of the different grades of gasoline. The gasoline premium grade (P) has a reduced demand and production with punctual deliveries as seen in the holdups of the PT10 and PT11 tanks of the P grade.
Figure 4. Blender (BL) modes of operation and tanks (PT10 and PT11) holdups (14 d).

5. Conclusions

We have exposed the knowledge around PSE solutions transferred to the processing industries. They are configured into a process industry specific domain programming language (IMPL) and solved using one of the best commercial solvers GUROBI. By solving the problems in a planning horizon with a scheduling level of detail (i.e., in time-step and operational relationships), any company's profit and performance may be improved by exploring their spot markets in a timely fashion. It may reduce management gaps between production and market segments inside the plant and teams in headquarters. The dynamics of both contracted and spot market require decisions within quarters and months in advance. For that, in the examples of PSE solutions in this paper, the planning and scheduling merge in the necessary spotting level of service.

Abstract

This paper presents an extension to a gravity separator model that has been previously introduced by some of the authors. It expands the existing model by adding differential states for emulsion layer thickness between the oil- and the water-continuous phases in addition to the gas pressure, the overall liquid level and the water-continuous layers. These differential states can ultimately be used for controller design in order to regulate the layer thickness by adding demulsifiers to the inflow. Due to the fact that demulsifiers are a primary factor to promote coalescence of complex petroemulsions, the demulsifier inflow is a critical variable to incorporate into a control model for gravity separation of petroemulsions.

Keywords: Gravity separator, oil and gas, emulsion layer, modeling, control

1. Introduction

The inflows of dispersed droplets into the new emulsion layers are obtained from a simplified interfacial coalescence relationship presented by Grimes (2012). In this formulation, the product Γ of the interfacial tension σ and retarded Hamaker constant Ha are directly related to the influence of the demulsifier. Realistic combinations of the interfacial tension and Hamaker constant that provide increasing and decreasing emulsion layer thicknesses were determined and a feedback control model was formulated to adjust the demulsifier inflow based on measurement of the thickness of the emulsion layers through the parameter σ. The controllers of simple PI-type were tuned according to the SIMC rule, see e.g. Skogestad (2003), and the theoretical developments of this work are demonstrated in a simulation case study.

2. Mathematical model

The basic principles for the gravity separator model without emulsion layers have been introduced in Backi and Skogestad (2017) and Backi et al. (2018). Three dynamic state variables were defined, where the first describes the dynamics of the overall liquid level (oil plus water), h_L,

$$\frac{dh_L}{dt} = \frac{dV_L}{dt} \frac{1}{2L\sqrt{h_L(2r - h_L)}} \tag{1}$$

where r is the separator's radius and L is the length of the active separation zone. Furthermore, $\frac{dV_L}{dt} = q_{L,in} - q_{L,out}$ is the volumetric change in overall liquid, where $q_{L,out} = q_{W,out} + q_{O,out}$. The manipulated variables are the outflows of water $q_{W,out}$ and oil $q_{O,out}$, respectively.
Figure 1: Schematic over the different variables in a cross-sectional view of the gravity separator

The second variable introduces the change in the water-continuous level, h_W,

$$\frac{dh_W}{dt} = \frac{dV_W}{dt} \frac{1}{2L\sqrt{h_W(2r-h_W)}} \tag{2}$$

with $\frac{dV_W}{dt} = q_{W,in} - q_{W,out}$, where $q_{W,in} = \gamma q_{L,in}$ is a fraction γ of the total liquid inflow $q_{L,in}$ entering the water-continuous phase. Thereby, $\gamma = \alpha\phi_{ww} + (1-\alpha)(1-\phi_{oo})$, where α is the water cut of the inflow, ϕ_{ww} describes the fraction of inflowing water entering the water-continuous phase, and ϕ_{oo} is the fraction of inflowing oil entering the oil-continuous phase.

The third variable describes the pressure dynamics derived from the ideal gas law with temperature T constant

$$\frac{dp}{dt} = \frac{RT\frac{\rho_G}{M_G}(q_{G,in} - q_{G,out}) + p(q_{L,in} - q_{L,out})}{V_{Sep} - A_L L}, \tag{3}$$

where R denotes the universal gas constant, M_G is the molar mass of the gas, ρ_G describes the gas density, and $q_{G,in}$ and $q_{G,out}$ give the in- and outflows of gas, where latter is a manipulated variable.

In addition to the dynamic part of the original model, an algebraic part is introduced. In short, the algebraic part compares horizontal to vertical residence times of different droplet size classes. Based on this calculation, a droplet size class is either separated, not separated, or partially separated. Thereby, several assumptions hold, for example that Stokes' law is the main driving force for separation and that no coalescence or breakage are considered. For further details, the authors refer to Backi and Skogestad (2017) and Backi et al. (2018).

As an extension to the model, two new state variables are introduced in order to represent the emulsion layer between the oil- and the water-continuous layers in a gravity separator. In Figure 1, a schematic of the cross-sectional areas and the variables in such a separator are given.

2.1. Oil interface layer h_{IO}

We derive a differential equation for the oil interface layer, which builds up on top of the water-continuous layer. We write the cross-sectional area of the oil interface layer (index *IO*) as

$$A_{IO} = A_W - A_{W-IO}, \tag{4}$$

with the two cross-sectional areas A_W (index W for water layer) and A_{W-IO} (index $W-IO$ for water-continuous layer minus oil interface layer) defined as

$$A_W = \frac{r^2}{2} \left(2\arccos\left(\frac{r-h_W}{r}\right) - \sin\left(2\arccos\left(\frac{r-h_W}{r}\right)\right) \right), \tag{5}$$

$$A_{W-IO} = \frac{r^2}{2} \left(2\arccos\left(\frac{r-(h_W-h_{IO})}{r}\right) - \sin\left(2\arccos\left(\frac{r-(h_W-h_{IO})}{r}\right)\right) \right). \tag{6}$$

After differentiating (4)–(6), we receive the expression

$$\begin{aligned}
\frac{dA_{IO}}{dt} =& \frac{dh_{IO}}{dt}\left[2\sqrt{(h_W-h_{IO})(2r-(h_W-h_{IO}))}\right] \\
&+ \frac{dh_W}{dt}\left[2\left(\sqrt{h_W(2r-h_W)}-\sqrt{(h_W-h_{IO})(2r-(h_W-h_{IO}))}\right)\right],
\end{aligned} \tag{7}$$

where $\frac{dh_W}{dt}$ is introduced in (2) leading to

$$\begin{aligned}
\frac{dA_{IO}}{dt} =& \frac{dh_{IO}}{dt}\left[2\sqrt{(h_{IO}+h_W)(2r-(h_{IO}+h_W))}\right] \\
&+ \frac{dV_W}{dt}\frac{1}{L}\left(1-\sqrt{\frac{(h_{IO}+h_W)(2r-(h_{IO}+h_W))}{h_W(2r-h_W)}}\right).
\end{aligned} \tag{8}$$

Ultimately, we receive the differential equation for the oil interface layer

$$\begin{aligned}
\frac{dh_{IO}}{dt} =& \frac{dV_{IO}}{dt}\frac{1}{2L}\frac{1}{\sqrt{(h_W-h_{IO})(2r-(h_W-h_{IO}))}} \\
&- \frac{dV_W}{dt}\frac{1}{2L}\left(\frac{1}{\sqrt{(h_W-h_{IO})(2r-(h_W-h_{IO}))}}-\frac{1}{\sqrt{h_W(2r-h_W)}}\right),
\end{aligned} \tag{9}$$

with $\frac{dV_W}{dt} = q_{W,in} - q_{W,out}$ and $\frac{dV_{IO}}{dt} = q_{IO,in} - q_{IO,out}$; latter is calculated using the algebraic part of the model.

2.2. Water interface layer h_{IW}

For the water interface layer (index IW) forming on the bottom of the oil-continuous layer, it holds

$$A_{IW} = A_{O+G} - A_{O+G-IW} \tag{10}$$

with the two cross-sectional areas A_{O+G} (index $O+G$ for the sum of the oil-continuous layer plus the gas phase) and A_{O+G-IW} (index $O+G-IW$ for oil-continuous layer plus gas phase minus water interface layer) defined as

$$A_{O+G} = \frac{r^2}{2} \left(2\arccos\left(\frac{r-h_{O+G}}{r}\right) - \sin\left(2\arccos\left(\frac{r-h_{O+G}}{r}\right)\right) \right), \tag{11}$$

$$A_{O+G-IW} = \frac{r^2}{2} \left(2\arccos\left(\frac{r-(h_{O+G}-h_{IW})}{r}\right) - \sin\left(2\arccos\left(\frac{r-(h_{O+G}-h_{IW})}{r}\right)\right) \right). \tag{12}$$

Differentiating (10), (11), and (12) and defining $h_{O+G} = 2r - h_W$, we obtain

$$\begin{aligned}
\frac{dA_{IW}}{dt} =& \frac{dh_{IW}}{dt}\left[2\sqrt{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}\right] \\
&+ \frac{dh_W}{dt}\left[2\left(\sqrt{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}-\sqrt{h_W(2r-h_W)}\right)\right]
\end{aligned} \tag{13}$$

where, again, $\frac{dh_W}{dt}$ is presented in (2) and hence

$$
\begin{aligned}
\frac{dA_{IW}}{dt} =& \frac{dh_{IW}}{dt}\left[2\sqrt{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}\right] \\
&+ \frac{dV_W}{dt}\frac{1}{L}\left(\sqrt{\frac{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}{h_W(2r-h_W)}}-1\right).
\end{aligned}
\tag{14}
$$

Finally, we receive the differential equation for the water interface layer

$$
\begin{aligned}
\frac{dh_{IW}}{dt} =& \frac{dV_{IW}}{dt}\frac{1}{2L}\frac{1}{\sqrt{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}} \\
&- \frac{dV_W}{dt}\frac{1}{2L}\left(\frac{1}{\sqrt{h_W(2r-h_W)}}-\frac{1}{\sqrt{(h_{IW}+h_W)(2r-(h_{IW}+h_W))}}\right)
\end{aligned}
\tag{15}
$$

with $\frac{dV_W}{dt}=q_{W,in}-q_{W,out}$ and $\frac{dV_{IW}}{dt}=q_{IW,in}-q_{IW,out}$. It must be pointed out that here $\frac{dV_W}{dt}=q_{W,in}-q_{W,out}$ excludes the oil leaving the water into the interface. Furthermore, $\frac{dV_{IW}}{dt}=q_{IW,in}-q_{IW,out}$ is calculated using the algebraic part of the model.

3. Controller Design

The controllers of PI type in the shape $K(s)=K_P+T_I\frac{1}{s}$ have the aim to regulate the gas pressure and the levels of overall liquid and water as well as the oil and the water interface layer levels. The first three controllers have already been introduced and developed in Backi and Skogestad (2017) and Backi et al. (2018), where the manipulated variables (MVs) are the outflows of water $q_{W,out}$, oil $q_{O,out}$ and gas $q_{G,out}$. Hence, in this work the focus lies on the design of the controllers for the oil and water interface layers.

3.1. Theoretical developments

In order to control the layer thickness of emulsions in gravity separators, the addition of demulsifiers to the inlet stream is necessary. Depending on the type of oil and the thickness of the emulsion, more or less demulsifier has to be added. We derive a relationship between the outflow of oil and water from the respective interface layers into their bulk phases and the coalescence time t_c for droplets with the volumetric outflow given by

$$
q_{I,out} = A_I\int_0^\infty\frac{r_d}{3t_c}f(r_d)dr_d\cong\frac{A_Ir_1}{3t_c},
\tag{16}
$$

where $A_I=2L\sqrt{h_W(r-h_W)}$ is the interfacial area, r_d are droplet radii, r_1 is a lumped, unified, theoretic droplet radius and t_c is the coalescence time

$$
t_c = 1.046\frac{\mu_c(\rho_d-\rho_c)g_zr_1^{9/2}}{\sigma^{3/2}Ha^{1/2}},
\tag{17}
$$

where μ_c is the dynamic viscosity of the continuous phase, ρ_d and ρ_c are the densities of the dispersed and continuous phases, respectively, g_z is the gravitational acceleration, and finally Ha describes the retarded Hamaker constant and σ is the interfacial tension. Latter is the manipulated variable for the controller, hence by changing σ we can affect the volumetric outflow (16). In a first step, we aim to find a relation between the retarded Hamaker constant and the interfacial tension in order to affect the coalescence time, which affects the outflow of oil or water from the respective interfaces. Since the retarded Hamaker constant and the interfacial tension are related by the function

$$
\Gamma = \sigma^{3/2}Ha^{1/2}
\tag{18}
$$

we first investigate pairings of these values that give reasonable values for Γ and then ultimately find the theoretic, lumped droplet radii r_1 for water and oil droplets in the respective interfaces. Furthermore, we can reduce the parameter space by one if we find an expression that links the retarded Hamaker constant Ha with the interfacial tension σ, namely $Ha = f(\sigma)$, and hence $\Gamma = \sigma^{3/2}[f(\sigma)]^{1/2}$. A function that satisfies the property that the retarded Hamaker constant is decreasing as the interfacial tension is rising is

$$f(\sigma) = \sigma \left[1.7564 \cdot 10^{-\left(20 + \frac{\sigma}{\sigma_{min}}\right)} \right] ln\left(1 + \frac{0.0001}{\sigma}\right), \tag{19}$$

where $\sigma_{min} = 0.005$ N m^{-1}.

Expressions for the outflows can be obtained by combining (16), (17) and (18)

$$
\begin{aligned}
q_{IO,out} &= \frac{A_I r_{IO,1}}{3 t_{IO,c}} = \frac{2L\sqrt{h_W (r - h_W)}}{3.138\, \mu_{IO,c} (\rho_d - \rho_c)\, g_z} \frac{\Gamma_{IO}}{r_{IO,1}^{7/2}}, \\
q_{IW,out} &= \frac{A_I r_{IW,1}}{3 t_{IW,c}} = \frac{2L\sqrt{h_W (r - h_W)}}{3.138\, \mu_{IW,c} (\rho_d - \rho_c)\, g_z} \frac{\Gamma_{IW}}{r_{IW,1}^{7/2}},
\end{aligned}
\tag{20}
$$

and it becomes apparent that the only tuning variables affecting the outflow are the water level h_W and furthermore the combined parameters Γ_{IO} and Γ_{IW} as well as the theoretic, lumped droplet radii $r_{IO,1}$ and $r_{IW,1}$.

As can be seen from (19) and ultimately (20), the interfacial tensions σ_{IW} and σ_{IO}, which are the MVs for the two controllers, can never be zero or negative. From these equations it can be inferred that large σ give small outflows and vice versa.

4. Results

Figure 2 shows simulation results incorporating the model and the controllers presented in sections 2 and 3, respectively. The subplots $S_{i,i}$ are thereby numerated according to entries in a matrix, hence $S_{1,1}$ is the top left plot, etc.

$S_{1,1}$ and $S_{2,1}$ show the liquid level h_L and the water level h_W in solid lines with their respective reference values in dashed lines. The water level is increased at time $t = 200$ s from initially 1.2 m to 1.4 m while the liquid level is held constant at 2.5 m. This is done to demonstrate that all controllers can handle this occurrence. $S_{1,2}$ and $S_{2,2}$ depict the outflows from the oil- and water-continuous phases, $q_{W,out}$ and $q_{O,out}$, respectively.

$S_{3,1}$ presents the oil interface level with its outflow $q_{IO,out}$ in $S_{3,2}$. One can see the that $q_{IO,out}$ is initially held constant at a very low flow rate resulting in the oil interface level to increase. The controller and hence the addition of demulsifier is activated at $t = 100$ s causing the oil interface level to be brought back to zero. Accordingly, the water interface level is depicted in $S_{4,1}$ with its outflow $q_{IW,out}$ in $S_{4,2}$. Like for the oil interface level described above, initially $q_{IW,out}$ is constant and the water interface level increases. Again, the controller is turned on at $t = 100$ s, which leads to a decrease in the water interface level.

For completeness, the interfacial tensions for the two interface layers over time are presented in $S_{3,3}$ and $S_{4,3}$, respectively. Furthermore, the oil-continuous level is shown in $S_{1,3}$ and $S_{2,3}$ depicts the water-continuous level.

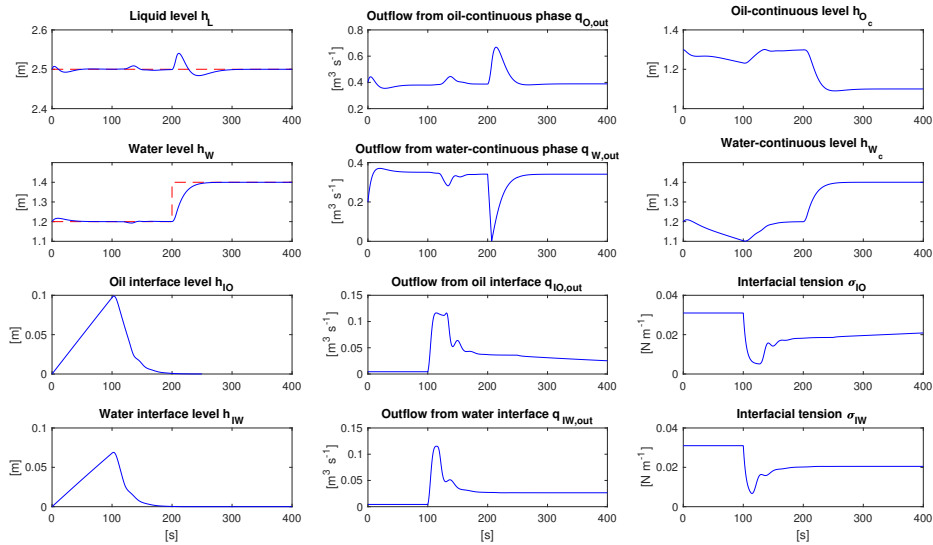
Due to space limitations we refer to Backi et al. (2018), where the majority of simulation parameters are presented. The only simulation parameters specific for this work are $r_{IO,1} = 90$ μm and $r_{IW,1} = 110$ μm as well as the tuning parameters for the interface layer controllers, $K_{P,IW} = 1.84$, $T_{I,IW} = 0.092$, $K_{P,IO} = 2.19$ and $T_{I,IO} = 0.11$.


Figure 2: The different state variables with the manipulated variables

5. Conclusion

We presented a simple modeling approach in order to regulate the thickness of emulsion layers in gravity separators. The simplicity of the model makes it usable for easy controller design, as is demonstrated in the Results section. Although the approach describing two interface layers on top of each other does not strictly fulfill physical principles, the model showed itself useful. However, it must be noted that from a strict physical viewpoint, the water interface forming on top of the oil interface will not happen in reality. It rather is a way to describe the emulsion interface between the water- and oil-continuous phases in a systematic manner. We refer to Hartland and Jeelani (1987), who describe sedimentation and dense-packed zones, which inspired our approach.

Abstract

Wastewater Treatment Plant (WWTP) is a very important part of every urban infrastructure, which has to achieve the desired effluent quality with cost-effective operation. Modelling and simulation help to find better operation scenarios and design alternatives, but also to investigate different control strategies. A dynamic WWTP simulator implemented in Matlab and Simulink was first calibrated with the configuration and process measured data from the local municipal WWTP. Then, the calibrated model was used for the investigation of different control strategies. This paper presents the investigation of five different ammonia based aeration control (ABAC) structures applying feedback and feedforward control. The latter is based on the ammonia influent disturbance. Five different return activated sludge (RAS) ratio control structures, coupled to the influent flow rate of wastewater, are also investigated in association to the nitrate recirculation (NR) control. According to the performed simulations, when applying ABAC with a feedforward component added to the setpoint of the dissolved oxygen (DO) controller, the air flow rate and the aeration energy can be reduced up to 45% and the effluent quality can be improved. Following the investigation of the RAS ratio-control, it was shown that flow rate of RAS and the pumping energy can be reduced up to 37% while the effluent quality remains high. This research demonstrated the benefits of applying ABAC and RAS control.

Keywords: wastewater treatment, modelling, simulation, ammonia based aeration control, return activated sludge control.

1. Introduction

Control of the Wastewater Treatment Plants (WWTPs) is a complex task due to the disturbances consisting in the wastewater influent concentrations and flow rates, the complicated behaviour of the microorganisms and the prescribed effluent quality requirements. WWTPs confront with the problem of high operational costs represented by the aeration and pumping energy, asking for control strategies to reduce them. Control strategies may be investigated by modelling and simulation, before their implementation in the WWTPs (Ostace et al., 2012).

Ammonia based aeration control (ABAC) is a cascade control in which the dissolved oxygen (DO) controller is combined with an ammonia controller (Rieger et al., 2014). The reason to apply ABAC is to reduce the aeration costs due to the implied aeration

energy and to react efficiently to the ammonia disturbances appearing in the influent wastewater and at the end of the aerobic zone (Ozturk et al., 2016; Zhu et al., 2017).

Return activated sludge (RAS) flow rate is essential for the biological wastewater treatment because RAS has the role to return the activated sludge from the secondary settlers to the input of the biodegradation basins ensuring the necessary concentration of the biomass in the anaerobic and aerobic tanks (Olsson, 2012).

This paper focuses on two main control strategies: ammonia based aeration control in which the flow rate of air entering the aerated bioreactors is computed by ammonia controller in cascade with three dissolved oxygen controllers and the RAS control which is based on the flow rate of the wastewater entering the WWTP.

2. Development of the Dynamic WWTP Simulator

The WWTP model used in this study is an extension of Benchmark Simulation Model No. 1 (BSM1) (Copp, 2002) with a nonreactive primary clarifier based on Otterpohl model. The model was calibrated with the reactors and flows configuration of the investigated municipal WWTP and the measured data collected during May 2016 from this plant. The municipal WWTP under study has an anaerobic-anoxic-aerobic (A2O) configuration, according to which the nitrate (internal) recirculation from the end of the aerobic zone is entering between the anaerobic and anoxic zones of the basin. The dynamic WWTP Simulator was implemented in Matlab and Simulink. The equations of the primary clarifier, the bioreactors according to the Activated Sludge Model No. 1 (ASM1) and the nonreactive secondary settler based on Takács clarifier model were written in C programming language and introduced in the Simulink environment by S-function blocks. The model was calibrated in steady state using different optimisation methods and then tested by dynamic simulations. This calibrated model was used in the further presented studies.

3. Implemented Control Strategies

In the study of the ammonia based aeration control, the calibrated model was complemented with 3 Proportional-Integral (PI) feedback dissolved oxygen (DO) controllers in cascade configuration, as slave controllers, associated to an ammonia master controller. This control structure was augmented with the ratio based feedforward control of both the RAS and the NR, based on the WWTP leading influent flow rate. The configuration of this control strategy is presented in Figure 1. Ammonia concentration is measured at the aerated zone outlet and is used by the ammonia controller to keep the 1 g NH_3-N/m^3 setpoint value. The ammonia master controller computes the reference value for the first DO controller, which can be supplemented by an extra value based on the ammonia disturbances in the influent. This added value can be a constant, proportional or in linear relationship with the influent ammonia concentration. In this research 5 cases were tested as presented in Table 1: switching the added DO setpoint value from 0 to 0.5 g O_2/m^3 when the ammonia concentration in the influent exceeds 30 g NH_3-N/m^3 (case A), respectively 20 g NH_3-N/ m^3 (case E). Based on the 30 g NH_3-N/m^3 ammonia concentration limit, it was studied a proportional (case B) and a linear (case C) dependency of the supplement. It was also defined a linear function for the DO setpoint supplement, depending on the influent ammonia

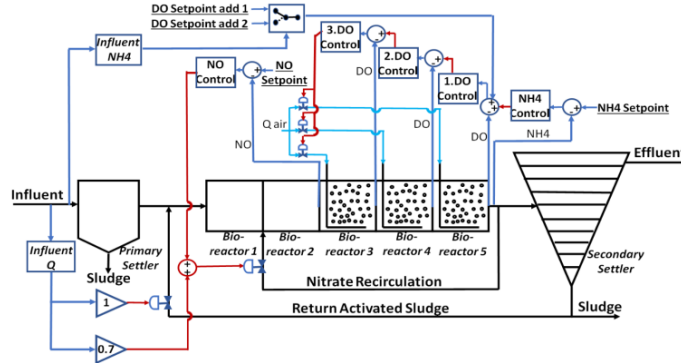
concentration, the coefficients of the linear equation being determined by optimisation. This latter approach was taking into consideration the quality of the effluent and the necessary air flow rate entering the aerobic zone (case D). The third DO controller computes the flow rate of the air entering equally into the 3 aerated reactors. The flow rate of the RAS is considered to be equal with the influent flow rate; the NR is controlled by a nitrate controller combined with a 0.7 factor of the wastewater flow rate. The simulations were performed for 66 days (three times the collected measured data of 22 days).


Figure 1. ABAC with supplementing the dissolved oxygen setpoint computed by the ammonium controller, control of RAS and control of NR based on the wastewater influents

Table 1. Investigated cases of ammonia based aeration control

CASE	DESCRIPTION	
ABAC Case A	If $C_{NH\_inf} \geq 30 gN/m^3$ then $y_{ref\_DO\_R5} = y_{c\_NHcontroller} + 0.5$ else $y_{ref\_DO\_R5} = y_{c\_NHcontroller}$	(1)
ABAC Case B	If $C_{NH\_inf} \geq 30 gN/m^3$ then $y_{ref\_DO\_R5} = y_{c\_NHcontroller} + 0.03 \cdot c_{NH\_inf}$ else $y_{ref\_DO\_R5} = y_{c\_NHcontroller}$	(2)
ABAC Case C	If $C_{NH\_inf} \geq 30 gN/m^3$ then $y_{ref\_DO\_R5} = y_{c\_NHcontroller} + (0.074 \cdot C_{NH\_inf} - 2.217)$ else $y_{ref\_DO\_R5} = y_{c\_NHcontroller}$	(3)
ABAC Case D	$y_{ref\_DO\_R5} = y_{c\_NHcontroller} + (0.0307 \cdot C_{NH\_inf} + 0.0101)$	(4)
ABAC Case E	If $C_{NH\_inf} \geq 20 gN/m^3$ then $y_{ref\_DO\_R5} = y_{c\_NHcontroller} + 0.5$ else $y_{ref\_DO\_R5} = y_{c\_NHcontroller}$	(5)

In the second part of this research, the DO setpoint supplement based on the ammonia influent concentration in the ABAC structure was eliminated; the configuration of the calibrated model with the investigated control structures is presented in Figure 2. Considering the RAS (Q_{RAS}) and NR (Q_{NR}) control, a study was carried out to find the optimal values of the factors k_{RAS} and k_{NR} for the associated flow rates, as described by Eq. (6) and (7). The investigated cases are presented in Table 2. The optimized values were found and simulations were performed the for 22 days period.

$$Q_{RAS} = k_{RAS} \cdot Q_{Influent} \tag{6}$$

$$Q_{NR} = k_{NR} \cdot Q_{Influent} + y_{c\_NOcontroller} \tag{7}$$

Table 2. The investigated cases with RAS control and basic ABAC structure

CASE	DESCRIPTION
RAS Case A	k_{RAS}=0.8323, k_{NR}=0.5509 optimized values for the whole period of time
RAS Case B	k_{RAS} and k_{NR} changing optimized values from day to day – I.
RAS Case C	k_{RAS} and k_{NR} changing optimized values from day to day – II.
RAS Case D	k_{RAS} changing optimized values from day to day, k_{NR}=0.7

4. Results and discussions

4.1. Ammonia Based Aeration Control with variable supplement of the DO setpoint

This control system design proposes the reduction of aeration energy, and consequently the operational costs at the aerated basins and the improvement of effluent quality by applying ABAC. To the ABAC structure found in literature (Rieger et al., 2014), i.e. to the control signal of the ammonia controller, it was added a supplement based on the influent ammonia disturbance. Table 3 shows the comparison between the average values obtained from simulations of the effluent concentrations and the RAS, NR and air flow rates, when the supplemented DO setpoint value was designed based on different principles. In all investigated cases it may be observed the reduction of nitrates and total nitrogen effluent concentration and the reduction of the air flow rate comparatively to the municipal WWTP.

Considering the average effluent concentrations and flow rate values, it can be stated that the most efficient case is ABAC – Case D. In Figure 3 and Figure 4 it is represented the comparison between the municipal WWTP and the simulated WWTP with ABAC – Case D.

Table 3. Comparison between the municipal WWTP measured data and the results of the simulated ABAC cases with supplemented DO setpoint

	Municipal WWTP	ABAC Case A	ABAC Case B	ABAC Case C	ABAC Case D	ABAC Case E
COD Effluent [g/m^3]	19.36	22.18	22.14	22.18	22.05	22.17
NH Effluent [g N/m^3]	0.17	1.00	1.00	1.00	0.99	1.00
NO Effluent [g N/m^3]	3.76	0.60	0.60	0.59	0.57	0.61
N total Effluent [g N/m^3]	5.70	3.60	3.61	3.60	3.57	3.62
Air flow rate [m^3/day]	127,770	70,791	71,133	70,738	70,575	71,115
RAS flow rate [m^3/day]	112,530	119,220	119,220	119,220	119,220	119,220
NR flow rate [m^3/day]	138,350	136,390	133,260	136,380	139,340	134,180
Figure 3. Comparison between the flow rate of air entering one bioreactor measured at the municipal WWTP and the simulated WWTP with ABAC – Case D
Figure 4. Comparison between the concentration of total nitrogen in effluent measured at the municipal WWTP and the simulated WWTP with ABAC – Case D

4.2. Return Activated Sludge Control

The flow rate of the RAS is dependent on the influent flow rate. An investigation, for the different RAS designs of Table 2, was performed in order to find the best factor value for RAS and, in some cases, for NR too. Table 4 presents the obtained results.

Table 4. Comparison between the municipal WWTP measured data and the results of the simulated WWTP with the different RAS cases

	Municipal WWTP	RAS Case A	RAS Case B	RAS Case C	RAS Case D	RAS Case E
COD Effluent [g/m3]	19.36	20.66	21.17	20.07	19.02	20.39
NH Effluent [g N/m3]	0.17	0.99	0.99	0.99	0.99	0.99
NO Effluent [g N/m3]	3.76	0.79	0.69	0.90	1.08	0.83
N total Effluent [g N/m3]	5.70	3.71	3.62	3.80	3.92	3.73
Air flow rate [m^3/day]	127,770	71,178	71,417	70,739	70,317	71,114
RAS flow rate [m^3/day]	112,530	99,231	118,860	86,601	71,336	92,534
NR flow rate [m^3/day]	138,350	114,140	127,930	99,606	113,230	123,330

Considering the cases of the RAS flow rate designs, the case of changing the factor value for RAS every day and setting 0.7 for the k_{NR} (RAS – Case D) led to the flow rate of RAS reduced by 36.6%, associated to pumping energy and cost reduction. RAS – Case D also presents a reduction of the NR flow rate by 18.2%. Figure 5 and Figure 6 show the benefits of applying RAS – Case D. Figure 7 shows reduction of air flow rate entering one bioreactor and Figure 8 presents the effluent total nitrogen concentration.
Figure 5. Comparison between RAS flow rate of measured at the municipal WWTP and simulated WWTP with RAS – Case D
Figure 6. Comparison between the NR flow rate measured at the municipal WWTP and simulated WWTP with RAS – Case D
Figure 7. Comparison between the air entering one aerobic bioreactor measured at the municipal WWTP and simulated WWTP with RAS – Case D
Figure 8. Comparison between total nitrogen effluent concentration measured at the municipal WWTP and simulated WWTP with RAS – Case D

5. Conclusions

New ammonia based aeration control designs associated to the return activated sludge control were investigated by simulation for WWTP control. In the ABAC structure based on the ammonia inlet concentration disturbance, the DO setpoint value handled by the ammonia controller was supplemented with a component calculated based on different principles. The RAS ratio control was coupled with the inlet wastewater flow rate and the implied factor values were computed by optimization. The investigated control strategies demonstrated benefits for WWTPs, reducing the aeration and pumping energies and improving the effluent quality.

Abstract

A solution algorithm that harnesses the strengths of discrete- and continuous-time scheduling models is proposed. It is a three stage algorithm consisting of (i) a discrete-time MIP scheduling model, (ii) a mapping algorithm, and (iii) a continuous-time LP model. It enables fast and accurate solution of scheduling problems, by quickly obtaining approximate solutions and improving their accuracy, while maintaining feasibility. Through a computational study, it is shown that the proposed method is capable of finding high quality solutions up to 4 orders of magnitude faster, compared to stand-alone discrete- and continuous-time models.

Keywords: chemical production scheduling, solution algorithm, continuous-time model, discrete-time model

1. Introduction

All existing grid-based mixed-integer programming (MIP) scheduling models can be classified into two categories based on the type of grids they employ: discrete- and continuous-time models. While continuous-time models provide more accurate solutions, discrete-time models are, in general, faster in large-scale instances and can accommodate various process features without additional computational cost (Floudas and Lin, 2004; Sundaramoorthy and Maravelias, 2011). In this work, we propose a solution algorithm, namely the Discrete-Continuous Algorithm, that combines the advantages of both discrete- and continuous-time scheduling models, while overcoming their limitations.

We consider a short-term chemical production scheduling problem in network environments. Given the facility data, resource availability and demand information, the objective is to find a schedule that satisfies the customer demand, while minimizing makespan. We use the state-task network (STN) representation throughout the paper (Kondili et al., 1993). We use set $\mathbf{I} \ni i$ to denote tasks, $\mathbf{J} \ni j$ to denote units, and $\mathbf{K} \ni k$ to denote materials. We also define the following subsets: $\mathbf{I}_j$ to denote tasks that can be executed in unit j, $\mathbf{I}_k^+/\mathbf{I}_k^-$ to denote tasks that produce/consume material k, and $\mathbf{J}_i$ to denote units that can process task i.

2. Discrete-continuous algorithm

The Discrete-Continuous Algorithm (DCA) consists of three components: (i) a discrete-time MIP scheduling model, (ii) a mapping algorithm, and (iii) a continuous-time LP

model. In the first stage, an approximate solution is obtained with a relatively large discretization step length (δ), which gets mapped on to two new types of continuous-time grids in the second stage. Finally, in the third stage, some components of the first stage solution (e.g. timing of events, batch sizes, etc.) are recomputed to obtain a more accurate, and potentially better, solution. More details can be found in Lee and Maravelias (2018). Although not the scope of this work, we note that extending the algorithm to an iterative procedure may provide guaranteed bounds on the solution quality.

2.1. Stage 1: Discrete-time MIP scheduling model

While the algorithm can employ any discrete-time scheduling model, the STN model proposed by Shah et al. (1993) is used in this study. We divide the horizon into intervals of equal length, δ. The resulting time points are represented by $n \in \mathbf{N}$. We round-up the processing times (i.e. $\bar{\tau}_{ij} = \lceil (\tau_{ij}^F + \tau_{ij}^V \beta_j^{max})/\delta \rceil$), and round-down the horizon (i.e. $\bar{H} = \lfloor H/\delta \rfloor$) to ensure feasibility, where τ_{ij}^F/τ_{ij}^V are the fixed/variable processing time of task i performed on unit j, and H is the horizon. The key decision variable for the first stage model is the *start of task* binary, X_{ijn}, which is equal to 1 if task i starts in unit j at time point n. The readers are encouraged to refer to Shah et al. (1993) for the full model. In the first stage, the model is solved with a chosen δ to obtain an approximate solution fast.

2.2. Stage 2: Mapping algorithm

In the second stage, we map the first stage solution onto two continuous-time grids that we introduce: (i) material-, and (ii) unit-specific grids. The batches in the first stage solution that produce/consume each material are mapped onto the corresponding material-specific grid, collecting the information regarding the sequencing of these batches. The batches that are executed in each unit are mapped onto the corresponding unit-specific grid, collecting information regarding the batch-unit assignment and the batch sequencing within each unit. By denoting the set of grid points as $\mathbf{M} \ni m$, each grid point on a given grid can be represented using an index pair (e.g. 2nd grid point on unit U1 grid is represented as (U1,$m2$)).

We introduce the following binary algorithmic parameters to store the information collected: $f_{ikm}^1 = 1$ if task i is mapped to grid point (k,m); $f_{jkm}^2 = 1$ if a task mapped to grid point (k,m) is performed in unit j; $f_{kmm'}^3 = 1$ if grid point where material k is produced (i.e. (k,m)) is before where it is consumed (i.e. (k,m')); $f_{ijkmm'}^4 = 1$ if task i is mapped to grid points (j,m) and (k,m'). The mapping algorithm is given in Table 1.

2.3. Stage 3: Continuous-time LP model

Based on the algorithmic parameters obtained in the previous stage, the timing of events, batch sizes and inventory levels are recomputed to obtain a more accurate solution. We define the following nonnegative continuous variables: batch size of the task mapped to grid point (k,m), B_{km}^C; inventory level of material k at grid point (k,m), S_{km}^C; time of grid point (j,m), T_{jm}^U; time of grid point (k,m), T_{km}^M.

Table 1: Mapping algorithm

0:	**Initialize:** $M_j^U = 0 \ \forall j$, $M_k^M = 0 \ \forall k$, $f^{1\sim 4} = 0$, $\mathbf{M}_k^P = \mathbf{M}_k^C = \emptyset \ \forall k$
1:	**Loop** $n \in \mathbf{N}$
2:	**Loop** $k \in \mathbf{K}$
3:	**Loop** $i \in \mathbf{I}_k^+$
4:	**Loop** $j \in \mathbf{J}_i$
5:	**If** $X_{ij(n-\bar{\tau}_{ij})} = 1$
6:	$M_k^M \leftarrow M_k^M + 1$; $M_j^U \leftarrow \sum_{n'<n}\sum_{i'\in \mathbf{I}_j} X_{i'jn'}$
7:	$\mathbf{M}_k^P \leftarrow \mathbf{M}_k^P \cup \{M_k^M\}$
8:	$f^1_{ik,m(=M_k^M)} \leftarrow 1$; $f^2_{jk,m(=M_k^M)} \leftarrow 1$; $f^4_{ijk,m(=M_j^U),m'(=M_k^M)} \leftarrow 1$
9:	**EndIf**
10:	**EndLoop x2**
12:	**Loop** $i \in \mathbf{I}_k^-$
13:	**Loop** $j \in \mathbf{J}_i$
14:	**If** $X_{ijn} = 1$
15:	$M_k^M \leftarrow M_k^M + 1$; $M_j^U \leftarrow \sum_{n'\le n}\sum_{i'\in \mathbf{I}_j} X_{i'jn'}$
16:	$\mathbf{M}_k^C \leftarrow \mathbf{M}_k^C \cup \{M_k^M\}$
17:	$f^1_{ik,m(=M_k^M)} \leftarrow 1$; $f^2_{jk,m(=M_k^M)} \leftarrow 1$; $f^4_{ijk,m(=M_j^U),m'(=M_k^M)} \leftarrow 1$
18:	$f^3_{kmm'} \leftarrow 1 \ \forall m < M_k^M, \ m \in \mathbf{M}_k^P, \ m' = M_k^M$
19:	**EndIf**
20:	**EndLoop x4**

We ensure the sequencing of batches on material- and unit-specific grids.

$$T_{km}^M \le T_{km'}^M \ \ \forall k,m,m' : f^3_{kmm'} = 1 \tag{1}$$

$$T_{jm}^U + (\tau_{ij}^F + \tau_{ij}^V B_{km'}^C) \le T_{j(m+1)}^U \ \ \forall i,j,k,m,m' : f^4_{ijkmm'} = 1 \tag{2}$$

Time matching constraints are enforced to ensure that the timing of grid points that originate from the same batch are the same.

$$T_{jm}^U = T_{km'}^M \ \ \forall i,j,k,m,m' \in \mathbf{M}_k^C : f^4_{ijkmm'} = 1 \tag{3}$$

$$T_{jm}^U = T_{km'}^M - (\tau_{ij}^F + \tau_{ij}^V B_{km'}^C) \ \ \forall i,j,k,m,m' \in \mathbf{M}_k^P : f^4_{ijkmm'} = 1 \tag{4}$$

We enforce unit capacity constraints, as well as batch size matching constraints to ensure that the batch sizes that correspond to the same batch are identical.

$$\beta_j^{min} \le B_{km}^C \le \beta_j^{max} \ \ \forall j,k,m : f^2_{jkm} = 1 \tag{5}$$

$$B_{km'}^C = B_{k'm''}^C \ \ \forall i,j,k,k',m,m',m'' : f^4_{ijkmm'} = f^4_{ijk'mm''} = 1, \ k < k' \tag{6}$$

The inventory level of material k at grid point m is equal to the sum of initial inventory, γ_k, and the amount produced/consumed up to that point. We make sure the demand for material k, ξ_k is satisfied.

$$S_{km}^C = \gamma_k + \sum_{m>m'\in\mathbf{M}_k^P}\sum_{i\in\mathbf{I}_k^+ : f^1_{ikm'}=1} \rho_{ik}B_{km'}^C + \sum_{m\ge m'\in\mathbf{M}_k^C}\sum_{i\in\mathbf{I}_k^- : f^1_{ikm'}=1} \rho_{ik}B_{km'}^C \ \ \forall k,m\in\mathbf{M}_k^C \tag{7}$$

$$S_{k,M_k^M}^C \ge \xi_k \ \ \forall k \tag{8}$$

We minimize makespan, *MS*:

$$minMS : MS \ge T_{km}^M \ \ \forall k,m\in\mathbf{M}_k^P \tag{9}$$
Figure 1: Using the error evaluation function, $\varepsilon(\delta)$, as a metric to determine δ's, illustrated for (a) instance 1, and (b) instance 2

3. Determining the key model parameter, δ

As mentioned earlier, DCA requires the user to select the discretization step length, δ, in the first stage model. If chosen carefully, the speed and accuracy of DCA can be improved significantly. However, selecting δ's that bring such results is non trivial.

In order to find the best performing δ, we introduce an error evaluation function denoted as $\varepsilon(\delta)$. For a given instance, $\varepsilon(\delta)$ measures the amount of discretization error introduced by the chosen δ, considering how much the shortage of each unit is constraining the objective value.

$$\varepsilon(\delta) = \frac{1}{\delta} \sum_i \sum_{j \in \mathbf{J}_i} \omega_{ij} \left| \tau_{ij} - \delta \bar{\tau}_{ij} \right| , \quad \omega_{ij} = (\frac{N_{ij}}{\sum_i N_{ij}})(\frac{D_j}{\sum_j D_j}) \tag{10}$$

$$D_j = \sum_n \lambda_{jn}^* \;\; \forall j \tag{11}$$

$$N_{ij} = \sum_n X_{ijn}^* \;\; \forall i, j \in \mathbf{J}_i \tag{12}$$

where, X_{ijn}^* is the solution of the LP relaxed model of the first stage, and λ_{jn}^* is the dual variable associated with the allocation constraints (Eq. 9 in Shah et al. (1993)) in the LP relaxed model.

As shown in Figure 1, $\varepsilon(\delta)$ is an accurate metric to quantify the amount of discretization error introduced. Specifically, DCA obtains high quality first and third stage solutions, whenever δ's that lead to low values of $\varepsilon(\delta)$ are used. Although only shown for two instances, we observed similar results for all other instances tested.

4. Generating multiple solutions

In industrial applications, it is desired to obtain multiple solutions rather than just one. By having multiple options, the operators can choose a schedule that minimizes the potential risks that may arise from the discrepancy between the problem data and the actual plant operation conditions.

DCA offers a systematic way of obtaining multiple solutions with varying degrees of accuracy in problem data approximation. This can be achieved by running DCA with different δ's that are identified by our method (see Figure 1). More importantly, depending on the δ chosen, the users have the flexibility to decide which problem data (e.g. processing time of a specific task) to approximate more accurately.

(a) Performance graph

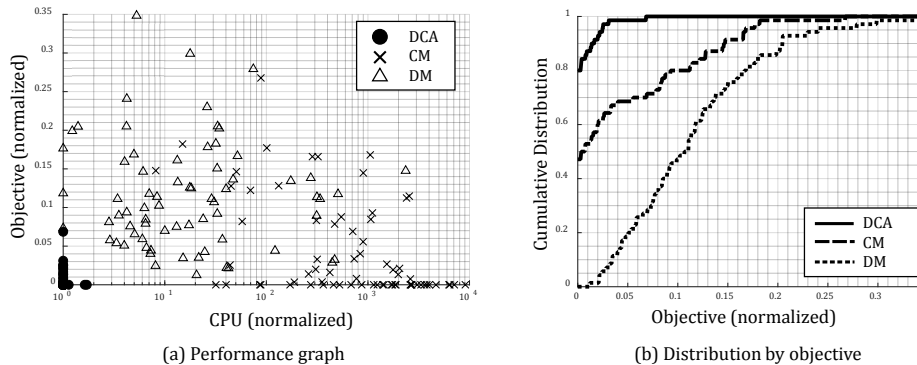
(b) Distribution by objective


Figure 2: Performance comparison between the three approaches, DCA, DM and CM: (a) performance graph, and (b) distribution by objective value

5. Computational study

5.1. Performance test

We compare the performance of DCA with systematically determined δ against a discrete-time model (Shah et al., 1993) and one of the best performing continuous-time model (Sundaramoorthy and Karimi, 2005), denoted as DM and CM, respectively. We consider 7 networks from the literature with 10 variations each (total of 70 instances).

Figure 2a shows the performance of the three approaches. The abscissa of the graph represents the CPU time normalized with respect to the fastest approach, while the ordinate represents the objective value normalized with respect to the best. In terms of computational speed, DCA outperforms the other two approaches by up to 4 orders of magnitude. Figure 2b shows the cumulative distribution of instances as a function of normalized objective value. DCA finds the best solutions in 80% of the instances, and high quality solutions (i.e. 0~3% inferior than best found) in 98% of the instances. In general, DCA yields substantially better and often rather different schedules compared to the other approaches.

5.2. Case study

A network from (Papageorgiou and Pantelides, 1996) that consists of 19 tasks performed on 8 units producing 4 products is considered (Figure 3a). The objective is to minimize makespan while satisfying a given demand until the end of 120 h horizon. The example is solved using three different approaches, and the results are given in Table 2. DCA with δ =1.85 h finds the best solution of 56.4 h in less than 4 seconds, being the fastest approach (see Figure 3b).

Table 2: Computational results

	DM	CM	DCA
δ or #Slots	1.00	25	1.85
Constraints	8,550	5,732	4,598

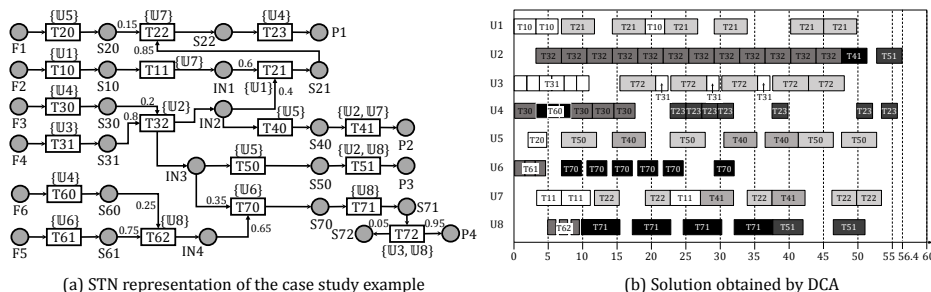

Figure 3: Case study: (a) STN representation, and (b) solution obtained by DCA

6. Conclusion

The two types of grids adopted in grid-based mathematical programming models for chemical production scheduling exhibit distinctive advantages. Discrete-time models are generally faster and have higher modeling flexibility, while continuous-time models provide more accurate solutions.

In this work, we proposed a new solution algorithm, namely the Discrete-Continuous Algorithm, that enable us to exploit the advantages of both time grids. DCA is capable of obtaining accurate solutions fast, while also allowing us to model different process characteristics, such as intermediate shipments and deliveries, limited shared utilities, etc. In addition, we proposed a systematic method to choose the discretization step length, δ, used in the first stage model, which has a significant impact on the performance of DCA. Furthermore, DCA offers a systematic way to generate multiple alternative solutions with varying degrees of accuracy in problem data approximation.

Through computational study, it was shown that DCA is capable of finding high quality solutions much faster than stand-alone discrete- and continuous-time models. Specifically, we showed that it finds the best solution in 80% of test instances while being up to 4 orders of magnitude faster.

Abstract

A modular simulator of dynamic behaviour of the Solid Oxide Fuel Cell (SOFC) system, suitable for use as a training tool is presented in this article, as an alternative to expensive practical tests. This simulator, developed in Aspen Custom Modeller (ACM), captures all of the processes in an SOFC module: mass, energy, and charge balances, overpotentials, ohmic losses and electrochemical reaction kinetics. The challenges relevant to programming and mathematical skills needed for models deployment are minimised. Application of the simulator is demonstrated through i) a basic steady-state simulation and 1D optimisatin followed by estimation of the stack's distributed variables and ii) illustration of the transient behaviour of the SOFC unit. Interpretation of SOFC operation dynamics, in particular, is emphasised to show the effectiveness of the simulator for training purposes and for laboratory demonstrations. The results show the key features of the SOFC module simulator for practical applications and for virtual laboratories. It also opens up opportunities for developing an in-built SOFC simulator module in a flowsheet simulation software such as Aspen Plus and Aspen HYSYS.

Keywords: SOFC, Simulator, Dynamic, Laboratory, ACM,

1. Introduction

Fuel cell, an emerging technology for future green energy production, is an active area of interest as a teaching unit and for research at chemical engineering departments at universities and industrial research and development (R&D) laboratories worldwide (Baker and Ağar, 2011). The expensive fuel cell test rigs have been used for cutting-edge research and occasionally for training purposes. However, lower cost, simplicity, safety, and speed are some of the advantages of numerical simulators compared to the experimental set-up. Moreover, convenient access to a computational tool, in contrast to the real-life experimental set-up, resolves the space and time limitations that are usually a hindrance to laboratory-based work (Aguiar et al., 2005, Lai et al., 2011). Since fuel cell is at its infancy stage, there is a shortage in existence of efficient and user-friendly simulators for it. Aspen Custom modeller (ACM) is used in this paper to develop a user-friendly SOFC simulator as depicted in Figure 1. The mathematical model that predicts the cell performance and behaviour has been demonstrated in our previous work (Amiri et al., 2015). The model provides user with the flexibility needed for an insightful simulation of an SOFC module, as dominant process variables and simulation parameters

are conveniently accessible. The user first sets the main model parameters such as the SOFC configuration parameters. This involves the SOFC physical dimensions and the thermal and electrical properties of its material. Operating conditions such as the cell operating voltage, air and fuel flows and the temperatures at the cell inlet, are also among the user-specified information. The thermal and electrical metrics are the main output of the simulator. The module is modifiable, as its programming interface is readily accessible. In order to estimate the species and mixtures properties, *Aspen Properties* and *ACM* are integrated. Such a modelling framework–founded on the application of ACM for SOFC and other types of fuel cells – contributes to this new technology process taking advantage of the established in-built unit operations and the thermodynamical property estimation packages.

2. Demonstration of the capabilities of the Simulator

The simulator developed in this work is demonstrated by carrying out a number of case studies, which are presented below**.**

2.1. Case study I: Lumped parameter simulation of SOFC

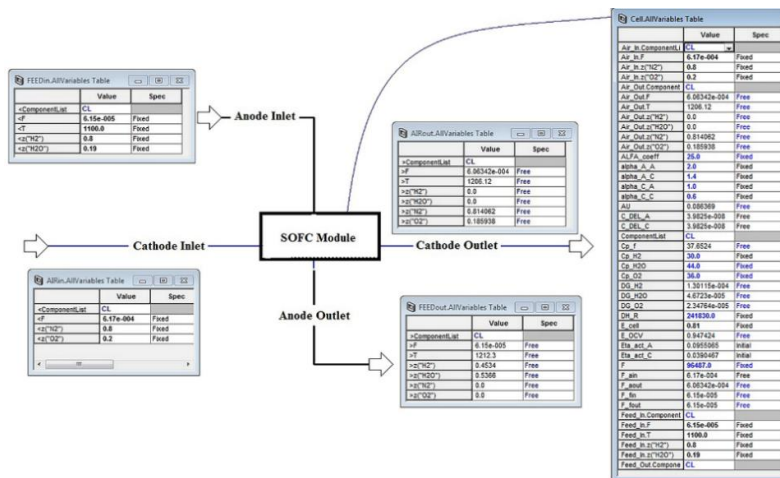
Extraction of essential characteristic information including V-I data is always the preliminary step for the evaluation of fuel cell performance and for an assessment of the model's accuracy. In practice, it can be accomplished through ramping the operating voltage and recording the corresponding current. Normalisation of the estimated current, i.e., current/area, allows comparing cells/stacks with different sizes. Interpretation of the V-I characteristic curve and its connection to the underlying fundamental processes is critical in training and research applications. The V-I simulation results using the simulator developed in this work (Figure 1) is compared against experimental data as shown in Figure 2(a). The simulator is capable of generating V-I curves under various operating conditions as shown in Figure 2(b). Supporting data including detailed information for streams and cell internal variables allow further evaluation of the cell's performance. Figure 2(c) shows the variation of fuel utilisation, caused by a change in the operating current at constant voltage, when the inlet temperature is varying.


Figure 1: User-friendly SOFC simulator interface developed in ACM.

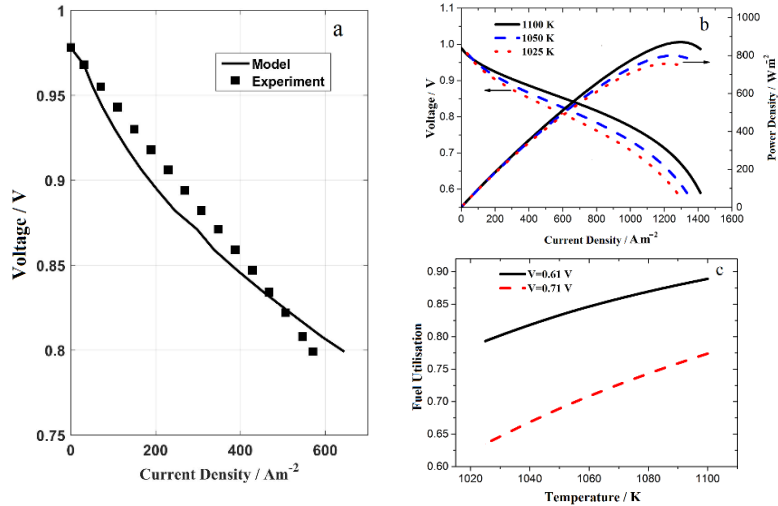
Since a lumped parameter analysis is presented in this section of the paper, the fuel-air flow configuration does not play a role in this case study. However, the flow pattern is important in the distributed parameter simulations that are presented in the following sections. In all of the cases presented in this work, the cell is assumed to operate adiabatically. Moreover, cell-to-cell and cell-to-surroundings heat transfer are ignored in this model, assuming a well-insulated stack.


Figure 2: (a) Model validation using data from Tang et al. (2016); (b) Illustrative generation of V-I characteristics profile for different fuel temperatures

by using modular simulator capable of describing voltage losses regions; (c) cell's fuel utilisation for a range of fuel temperatures and under two operating voltages.

2.2. Case Study II: Distributed parameter simulation of SOFC

Visualisation of the distributed variables along the stack dimensions provides an illustrative tool to present the impact of system's variables on cell/stack performance homogeneity. This feature is of practical importance for process analysis of the entire system along with the stack's distributed variables. For 2D and 3D simulation, researchers have used CFD (Ni, 2013), COMSOL modelling facilities (Lai et al., 2011), finite volume model (Ma et al., 2015), and specifically developed tools (Khaleel, 2012). This type of analysis, however, still faces geometry complexity and calculation load challenges making their applications limited to the specific expertise and computational powers. This paper proposes an approach for capturing the stack's distributed variables in *Aspen Plus*, with drastically reduced computational time, approximately of the same order of magnitude of time needed for the simulation of other BoP components. Networking of 0D compartments allows simulating the SOFC as a more realistic reactor as internal spatial distributions of the state variables always exist. This is a straightforward task after exporting the developed module (Figure 1) from the *ACM* environment to the *Aspen Plus* environment. The number of compartments in series, however, must be estimated based on experimental Residence Time Distribution data (Amiri et al., 2015). The distributed parameter model is used to optimise the air (coolant) supply to each part of a cross flow SOFC to achieve a lower temperature variation across the cell. Optimum design and operation of SOFC needs to be examined against the performance characteristics

measures including, durability, reliability and efficiency (Secanell et al., 2011). Some of these targets are to some extent mutually exclusive. For example, high efficiency necessitates operation at high fuel utilisation but may detrimentally impact on the SOFC lifetime, potentially due to the high rates of degradation at the higher levels of utilisation. Durability also depends on the reduction of thermal stresses. This can be achieved by using surplus coolant gas but the system efficiency will reduce as a consequence of the parasitic loss (Tang et al., 2016). From this viewpoint, the optimisation task for either the stack or the system as a whole is a multi-objective optimisation problem with some compromise in operational measures. The optimisation task in this article is an user-defined single objective function (Eq. (1)),

$$\min f = \frac{1}{\overline{T}} \sqrt{\sum_{i=1}^{n} \left(T_i - \overline{T}\right)^2}, \quad \overline{T} = \frac{1}{n}\sum_{i=1}^{n} T_i \tag{1}$$

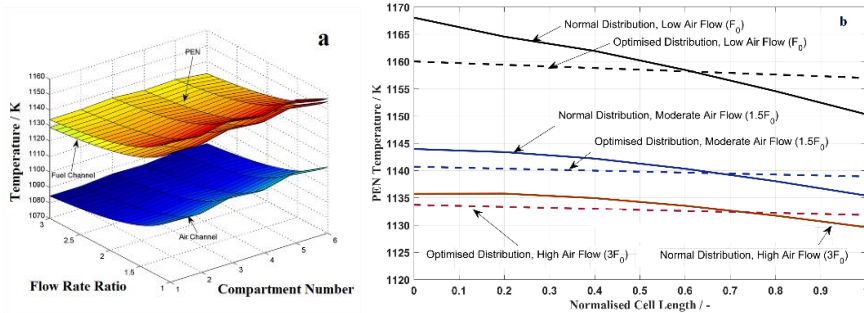
with the constraint: each compartment must receive at least 5% of total air preventing oxygen starvation, where T_i and $\overline{T}$ stand for local and average temperature of the compartment, respectively. Figure 4 depicts the PEN (Positive electrode-Electrolyte-Negative electrode) temperature profile along the cell's length under different total excess air and with normal and optimised air flow distributions. As can be seen, this strategy is more influential at the lower range of the excess air flows. The wavy temperature profile in Figure 3(a) might be attributed to the discretisation method which is a limitation for developing the distributed models inside the flowsheeting platform. Either increasing the number of intervals or interpolating the values inside the intervals resolves such a flaw as can be seen in Figure 3(b). However, it must be noted that the profiles' trends suffice for schematically presenting the overall performance of the objective function and optimisation effort in a training task.


Figure 3. 3D and 2D presentations of the temperature gradient minimisation along the fuel flow path by coolant (air) distribution strategy and for different coolant's flow ratio (ratio of flow to basis-flow).

2.3. Case Study III: Transient simulation of SOFC

The open loop responses of current density, solid temperature, hydrogen concentration, voltage losses, and air/fuel utilisations, upon the inlet gas temperature changes in a stepwise pattern, are shown in Figure 4. Variation of ±20 K in the inlet gas temperature significantly impacts the cell's dynamics and also the final steady values of the state variables. The significant increase in the PEN temperature has its roots in two causes,

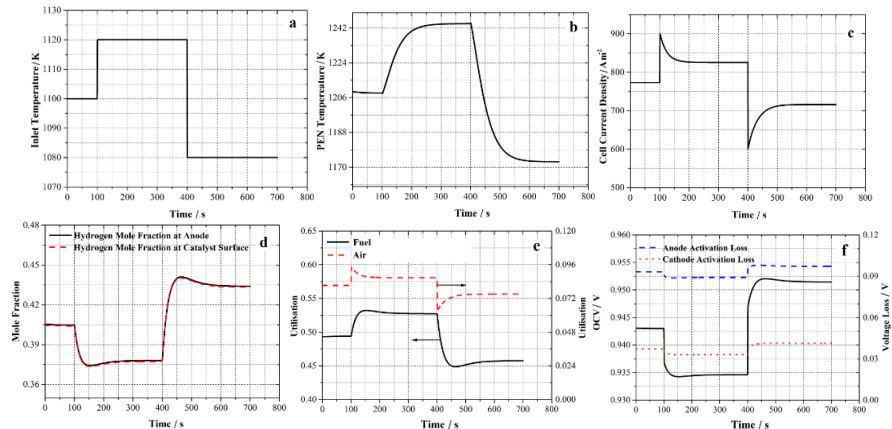
namely the decline in cooling rate due to use of the hotter air, +20 K, and the extra heat released from the promoted exothermic electrochemical reaction. The rate of reaction increases as a result of the increase in the PEN temperature. A feature of the transient temperature behaviour is the equality of absolute value of the final temperature change ($\approx$ 36K) and also the settling time ($\approx$ 200s), for both, negative and positive inlet changes. From this viewpoint it might be concluded that the solid's temperature responses are almost linear. However, the average current shows under- and over-shoots which are not equal in absolute values. This is the case for the hydrogen concentration and OCV histories too. The trainee could explore and interpret the connection between these observations to understand how a non-linear system may behave in unstable circumstances. For instance, the presented scenario indicates the impact of the initial temperature in estimation of the current value at the moment of change implementation. In other words, the higher the difference between initial and final values of the temperature, the more significant is the under/over-shoots in current and other temperature-dependent profiles. Explanation of the dynamic observations based on the utilised empirical and physical correlations allows for the demonstration of the application of these predictive equations. As an example, one may focus on the OCV profile aiming to explain the connection between this voltage and the state variables' profiles based on the Nernst equation. OCV profile, Figure 4, is a strong function of temperature and the species concentration changes. Explanation of reaction rates by using the current profile along with the temperature and concentration histories is another learning practice. Analysis of the dynamic voltage losses will lead to a detailed understanding of the share of each term in the total voltage losses and thus the operating voltage dynamics. A stable operation requires the voltage fluctuations to be minimised. Since oscillations in the operating voltage are caused by instability in OCV and overpotentials, an insight of the time-dependent weight of each term of voltage equation (i.e., OCV, anode and cathode activation loss, concentration loss, ohmic loss) can help to understand the voltage element(s) that dominate(s) the operating voltage dynamics and to propose control strategies for steady operation of the SOFC.


Figure 4. Dynamics of the SOFC state variables in response to a stepwise change in the inlet gases temperature.

3. Conclusions

This article provides an effective modelling simplification without compromising the dominant SOFC process phenomena. Complicated mathematics and the necessity of professional numerical skills make the application of academic models difficult particularly for non-academic users. This is an important motivation to develop simulators that reduces the demand of such skills for applied purposes. Compared to the literature, for instance the authors' previous publications (Amiri et al., 2015, 2016), the simulation approach presented in this work offers a considerable simplicity without sacrificing the model details. While the formers are beneficial for technical research purposes, the later, this work, is beneficial for both training and research. ACM further offers advanced applications including, but not limited to, model predictive control, process optimisation, knowledge based decision-making, model-based fault diagnosis, and process flowsheet simulation which makes it a very effective and convenient tool for intelligent automation of fuel cell process operations. The dynamic analysis presented in this article was to demonstrate this.

Abstract

Molten salt-based nanofluids (nano-salts) form an important class of thermal fluids that can act as both heat transfer and thermal energy storage media for high temperature applications, including solar thermal systems. Among these, the class of binary nitrate salts (60:40 wt. % $NaNO_3$:KNO_3) and their mixtures with metal oxide nanoparticles are the most prominent. This study evaluates the stability of nano-salts using a computational technique based on Lagrangian particle tracking, with the model considering the motion of solid nanoparticles suspended in a molten fluid. The technique enables various multiscale forces, with different characteristics, to be established. The system considered consists of 25-71 nm Al_2O_3 ceramic nanoparticles at volume fractions ranging from 1.0 to 5.0% suspended in fluids of different density ratios, with homogeneous temperature distributions from 250-600 °C. The simulation results demonstrate the effectiveness of the technique, with predictions elucidating the role of oscillatory structural, Brownian motion and particle collision forces, and their influence on the enhancement of thermal conductivity. The liquid structuring of salt melts around the embedded nanoparticles is found to play a key role in the nano-salts' thermal behaviour, with predictions in agreement with previous theoretical and experimental studies. The outcome of this research forms the basis for the potential use of nano-salts in solar thermal systems.

Keywords: Nanofluids, oscillatory structural force, thermal conductivity, energy storage.

1. Introduction

Binary mixtures of $NaNO_3$:KNO_3, like many other salts, contain ionic compounds such as sodium (Na^+), potassium (K^+) and nitrate (NO_3^-) ions and are, therefore, classified as alkali metal nitrates. When two nanoparticles (with smooth surfaces) are immersed in an ionic liquid such as molten nitrate salt, an oscillatory force exists between the particles due to the ordering of the confined liquid molecules in the thin film between the two surfaces. Theoretical predictions demonstrate that the ordering of liquid molecules reaches an energetic minimum at separations which correspond roughly to the diameter of a liquid molecule, as illustrated in Fig 1. At present, little is known about the thermal properties of this interfacial layer, however, theoretical analyses and numerical simulations predict that it acts as a thermal bridge, particularly in high temperature ionic fluids like molten salts. It is believed that these layered fluid molecules are in an intermediate physical state between that of the bulk fluid and the solid surfaces, thus

forming a solid-like nanolayer of liquid molecules which leads to higher thermal conductivity than that of the bulk fluid (Choi, 2003).

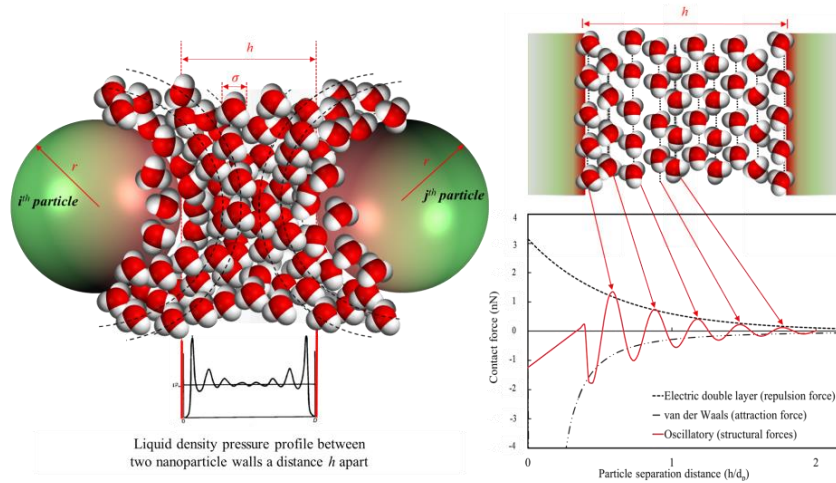
In this study, a novel method is used to describe the oscillating layered structure of molten salt fluids (represented by the matrix of liquid molecules around the nanoparticles), and the influence of the interfacial layer thickness on the system conductivity. An explanation of this phenomenon was first given by Israelachvili (2011) who noted that the structural force arises once there is a change in the liquid density at the surface of nanoparticles, as they approach one other. This force may be thought of as the van der Waals force at small separations, with the molecular properties and density variations of the medium taken into account. This force is consequently dependent on the size, type and surface properties of the particles as well as the ionic concentration and density of the continuum.


Figure 1. Schematic of structuring of molten nitrate molecules between two smooth spherical particles submerged in an ionic continuum (left); and period of force, i.e. diameter of small liquid molecules, causing oscillatory structural forces with monotonically decaying amplitude (right).

2. Computational Setup and Model Description

This work extends previous simulations (Mahmoud et al, 2018) performed using an in-house code embodying the multiscale numerical model. The model applies a Lagrangian particle tracking approach to investigate the dynamics of, and heat transfer mechanisms in, high temperature salt-based nanofluids. The three-dimensional computational region examined consists of a 1 μm cube filled with stagnant molten nitrate salt. This volume element is composed of a collection of 25-71 nm Al_2O_3 ceramic nanoparticles (50-1500 in number) that are injected uniformly across the domain. The motion of the embedded nanoparticles in the fluid is treated using an Eulerian-Lagrangian approach with fixed time stepping. The dynamic properties of both phases are coupled to the ambient temperature of the fluid suspension, that being molten nitrate salt at 250-600 °C.

The model describes the dynamic interactions between the *i*-th and *j*-th spherical nanoparticles in the normal unit direction, $\boldsymbol{n}_{ij}$, according to the approach of Fujita and Yamaguchi (2007). Particle collisions are resolved using a soft sphere approach as

described by the Hertzian normal contact theory (Timoshenko and Goodier, 1970). The oscillatory structural force is considered by adding an extra term, $\boldsymbol{\Pi}^{os}$, to the classical DLVO expression for the disjoining pressure (Denkov and Kralchevsky, 1995):

$$\boldsymbol{\Pi}(h) = \boldsymbol{\Pi}^{vW}(h) + \boldsymbol{\Pi}^{el}(h) + \boldsymbol{\Pi}^{os}(h) \tag{1}$$

where $\boldsymbol{\Pi}^{vW}$ is the van der Waals attractive force:

$$\boldsymbol{\Pi}^{vW} = -\frac{A_H}{6\pi h_{ij}^3} \tag{2}$$

and h is the film thickness, A_H the Hamaker constant, and $\boldsymbol{\Pi}^{el}$ is the electric double layer repulsive force:

$$\boldsymbol{\Pi}^{el} = \frac{64\pi r n k_b T \Theta^2 e^{-\kappa h_{ij}}}{\kappa} \tag{3}$$

Here, r is the sphere radius, n the number density of electrolyte ions, k_b the Boltzmann constant, T the temperature of the suspension, Θ the polarisability factor, and κ the inverse of the Debye length.

The dependence of the oscillatory structural component of disjoining pressure on the film thickness can be specified using the formula of Denkov and Kralchevsky (1995):

$$\boldsymbol{\Pi}^{os}(h) = P_0 \cos\left(\frac{2\pi h}{d_1}\right) \exp\left(\frac{d^3}{d_1^2 d_2} - \frac{h}{d_2}\right), \ for \ h > d$$
$$\boldsymbol{\Pi}^{os}(h) = -P_0, \ for \ 0 < h < d \tag{4}$$

where σ is the diameter of the smaller fluid hard spheres ($\approx$0.45 nm for molten salt molecules), d_1 the oscillatory period and d_2 the characteristic decay length, which are related to the particle volume fraction, φ, as follows:

$$\frac{d_1}{d} = \sqrt{\frac{2}{3} + a_1 \Delta\varphi + a_2 (\Delta\varphi)^2}; \ \frac{d_2}{\sigma} = \frac{b_1}{\Delta\varphi} - b_2 \tag{5}$$

Here, $\Delta\varphi = \varphi_{max} - \varphi$, with $\varphi_{max} = \pi/3\sqrt{2}$ the value of φ at close packing, and a_1, a_2, b_1 and b_2 are correlation coefficients determined theoretically with respect to φ. The particle osmotic pressure, P_0, is taken from the formula of Carnahan and Starling (1969):

$$P_0 = \rho_s k_b T \frac{1 + \varphi + \varphi^2 - \varphi^3}{(1-\varphi)^3} \tag{6}$$

in which ρ_s is the particle number density of the small fluid spheres given by $\rho_s = 6\varphi/\pi\sigma^3$. For $h > \sigma$ the structural disjoining pressure oscillates around P_0 as defined in Eq. (6). However, for $h < \sigma$ the small particles are expelled from the gap into the neighbouring bulk suspension by the depletion attraction, described by Eq. (4). When $h = \sigma$ there is a finite discontinuity as the interaction switches from an oscillatory to a depletion regime. The contribution of the interaction free energy per unit area of the film can be obtained by integrating the oscillatory structural forces:

$$f_{os}(h) = \int_h^\infty \boldsymbol{\Pi}^{os}(h') \ dh' \tag{7}$$

and from Eq. (4) and (7) one obtains:

$$f_{os}(h) = \boldsymbol{F}(h), \ for \ h \geq \sigma$$
$$f_{os}(h) = \boldsymbol{F}(\sigma) - P_0(\sigma - h), \ for \ 0 \leq h \leq \sigma \tag{8}$$

where

$$\boldsymbol{F}(h) = \frac{P_0 \, d_1 \, exp(d^3/d_1^2 d_2 - h/d_2)}{4\pi^2 + (d_1/d_2)^2} \left[\frac{d_1}{d_2} \, cos\left(\frac{2\pi h}{d_1}\right) - 2\pi sin\left(\frac{2\pi h}{d_1}\right) \right] \tag{9}$$

It should be noted that although soft sphere particle collisions are assumed, Eqs. (4) and (9) are applicable for hard sphere fluid molecules of diameter σ. However, the interparticle potential may still be 'soft' due to the actions of some long range forces.

3. Results and Discussion

Simulations were performed using the model, with results analysed to consider the forces and mechanisms responsible for nanoparticle dynamics, structural and surface property effects, and thermal conductivity enhancement. First, the spontaneous ordering process of nanoparticles in a suspension was examined, followed by the formation of a structured nanolayer (of liquid molecules around the seeded nanoparticles) and of percolation networks of nanostructures using a system under forced aggregation conditions.

A schematic diagram of the structural forces is given in Fig. 1 illustrating the dynamic properties of liquid films confined between two smooth particle surfaces. This shows the concentration dependence of the structural force in the oscillatory regime and how it is dominated by the decay length d_2, in line with Eqs. (4) and (9). The period of the force is equivalent to the diameter of the small liquid molecules σ, and shows an oscillatory nature close to the particle surface with an amplitude that decays monotonically with h (e.g. for a given h, the disjoining pressure increases almost five times for a 10% increase in the volume fraction φ of the liquid molecules). Furthermore, the model predicts the effect of temperature and nanoparticle size on the overall thermal conductivity of the system, with Fig. 2 giving model predictions (coloured) for pure molten salt which are in good agreement with experimental data (Ma and Banerjee, 2017). The figure also gives predictions of thermal conductivities of nanofluids for a fixed concentration of 1 vol. % and temperatures over the range shown. The results are compared with the theoretical work of Maxwell (1892), the data of Ma and Banerjee (2017) and other model predictions (Xuan and Li, 2000; Pang et al., 2016; Prasher et al., 2005), with good agreement found. It should be noted that the existing model showed more sensitivity to particle size in predicting conductivity than the other theoretical models illustrated in Fig. 2

Regarding size dependence, the model predicts that the conductivity of nanofluids containing 20nm Al_2O_3 particles is significantly greater than those containing 25nm and 71nm particles, by nearly 11% and 22%, respectively, although no systematic experimental investigation of size-dependant conductivities has been performed. Fig. 3 shows the thermal conductivity of the nanofluids, normalised by the conductivity of the base fluid, plotted as a function of the solid volume fraction, Φ, for the 71nm Al_2O_3 particles. The results show the contribution of the nanolayer and aggregation, and the nanolayer only, to the thermal conductivity, and how this increases with particle volume fraction. With regards to the effect of the nanolayer, at concentrations < 3 vol. % the majority of nanoparticles collide, although the formation of aggregates remains low. Hence, the thermal conductivity enhancement is dominated by the formation of

nanolayers between particles. At $\Phi \geq 3$ vol. %, however, the combined effect curves show that the conductivity is enhanced by a factor of two to three, and at such concentrations aggregates (nanoclusters) form in addition to the nanolayers between them, although the interparticle distance is very small (0.5-1 nm). This leads to the conclusion that at high concentrations the effect of Brownian motion is dramatically reduced and instead percolation effects dominate due to reduced interparticle distances and increased particle nanolayering and aggregation.
Figure 2. Comparison of model predictions of thermal conductivity with experimental measurements and analytical models for molten salt (Al_2O_3) nanofluids.
Figure 3. Nanoparticle concentration dependent thermal conductivities of nanofluids and effect of nanolayer and number of aggregates formed at 350 °C.
Figure 4. Effect of particle diameter d_p on thermal conductivity ratio. Insert shows conductivity ratio of nanolayer plotted as function of temperature.
Figure 5. Thermal conductivity ratio of nanolayer as function of particle diameter at fixed concentration of 1 vol. %.

Fig. 4 shows the effect of particle diameter on the thermal conductivity for $\Phi = 1$ vol. %. The predictions indicate that as the particle size is decreased, the interparticle distance decreases and, consequently, conduction-like effects become dominant, increasing the conductivity. The smaller the nanoparticles, therefore, the more the enhancement in the conductivity of nano-salts. Corresponding results for the effect of particle diameter on the nanolayer thickness are given in Fig. 5, with predicted values at different temperatures.

This demonstrates that the thickness of the nanolayer increases with reducing particle diameter, and with temperature due to Brownian motion effects. Hence both particle size and system temperature can be used to enhance the thermal conductivity of nanofluids.

4. Conclusions

Key variables related to the oscillatory structural force acting between two spherical nanoparticles, and the thermal conductivity of salt-based ionic nanofluids, have been examined using multiscale simulation. The thermal properties of nanofluids were found to be enhanced compared to those of the pure molten salt bulk fluid. The model has been found to perform well in comparison with similar studies, and provides confirmation of the effect of interparticle distance, particle concentration, temperature, and the formation of nanolayer and percolation networks, on the thermal conductivity of nano-salts. Future work will extend the current model's application to include the dynamic forces considered to be important in three-dimensional flows, as found in solar thermal heat storage systems, by coupling the tracking approach with direct numerical simulations.

Abstract

The behaviour of dispersed nanoparticles within a turbulent wall-bounded flow is investigated, with the fluid phase properties chosen to represent a thermofluid flow typical of those present in solar thermal power plants. The continuous phase is modelled using direct numerical simulation with the open source spectral element-based solver, Nek5000, with predictions of a statistically steady turbulent channel flow at shear Reynolds number $Re_\tau = 180$ first obtained and validated. A Lagrangian particle tracking routine is subsequently implemented to simulate the dispersed phase, and is capable of accommodating one-, two- and four-way coupling between the fluid and discrete phases. In order to investigate the effect that the turbulence field has on the dispersion properties of the solid nano-particulate phase, mean fluid and particle velocities, and turbulence statistics, are obtained and presented. Particle mean velocities are observed to lag behind the fluid flow in the outer layer for all coupling methods. Particle streamwise velocity fluctuations are lower than those of the fluid in the bulk region of the flow, but are greater than the latter in the buffer layer, with the addition of particle agglomeration augmenting this effect. Particle concentrations in the near-wall region are observed to increase over time due to turbophoresis.

Keywords: Direct numerical simulation, Lagrangian particle tracking, nanofluids, agglomeration, turbophoresis

1. Introduction

Particle-laden fluids have gained a lot of attention in recent years because of their existing and potential industrial applications. Of particular interest are nanofluids, which are dilute fluid suspensions of nanoparticles (1-100 nm) at relatively low concentrations (0.05-2.0% volume fraction) (Choi, 1995). They are prepared by dispersing nanoparticles with significantly higher thermal conductivity values (i.e. 10-430 $Wm^{-1}K^{-1}$ for pure elements) in conventional thermofluids with modest thermal conductivity (i.e. 0.1-0.6 $Wm^{-1}K^{-1}$ at 25ºC) such as water, oil, molten salt or ethylene glycol. Unlike conventional fluids, the significant enhancement of thermal properties when solid nanoparticles are added presents new application opportunities, particularly in the energy sector. In this sector, the efficiency of heat removal and thermal management systems presents the greatest technological challenge. Hence, the heat transfer potential of nanofluids is now gaining interest by researchers and developers in the academic and industrial communities due to their advantageous thermal properties.

On the other hand, understanding transport phenomena such as the dispersion behaviour of particles in nanofluid flows is challenging, particularly in experimental studies where obvious difficulties occur. Hence, apart from constraints due to the size of nanoparticles and potentially difficult conditions (e.g. high temperatures), many other complications arise from the various forces acting on the particles at various magnitudes and time scales. In addition, there is currently a lack of a reliable theory capable of making accurate predictions of the flow and heat transfer behaviour of nanofluids (with relatively low solid volume fractions). A numerical approach is therefore proposed to investigate dispersion behaviour. More specifically, the work described develops a multi-scale computational model using Lagrangian particle tracking coupled with direct numerical simulation (DNS) to investigate the influence of dispersed nanoparticles on the surrounding carrier fluid, and the effect of the turbulence field on the dispersion and aggregation properties of the solid nano-particulate phase. The advantage of the model developed is its ability to study in detail phenomena such as interparticle collisions, turbophoresis and thermophoresis, with the approach also of value in investigations of the long-term stability of nanoparticle dispersions which as yet has not been considered in detail. It is also possible that the agglomeration of nanoparticles to form larger particles could lead to their deposition, surface impact and erosion, although evidence of this in the literature is contradictory (Buongiorno, 2009), with very few existing quantitative studies.

2. Computational Setup and Model Description

The simulations were performed using a numerical multi-scale model with the continuous phase predicted using the open source spectral element-based DNS code, Nek5000 (Fischer et al, 2008). This code was chosen based on its extensive testing, efficient parallelization capabilities and validation history. Within the code, the incompressible Navier-Stokes equations (mass and momentum conservation) are solved to high accuracy, with the code applied to a Cartesian grid consisting of $27\times18\times23$ 8th order elements (i.e. 5.7 M nodes) used to represent a turbulent channel flow at shear Reynolds number $Re_\tau = 180$. The elements were scaled such that those closest to the wall were distributed more densely. The geometry of the channel was $14\delta\times2\delta\times6\delta$, with $\delta = 0.1$ mm. For the purpose of this study, the computational coordinates (x, y, z) were used to represent the three-dimensional geometry of the channel, with x being the streamwise direction, y the wall-normal direction, and z the spanwise direction. Periodic boundary conditions were enforced in the streamwise and spanwise directions, while the wall-normal axis used no-slip conditions at $y = \pm\delta$. The flow was driven and maintained by a constant pressure gradient.

The dispersed phase was represented by 500k 100 nm diameter Al_2O_3 particles which were tracked through the fluid field. These were simulated using a Lagrangian particle tracking routine, which was developed for this work and implemented to interface concurrently with Nek5000. The motion of each nanoparticle is described using the Langevin equation (Sloan et al, 2012), where the translational velocity of the i-th particle is obtained from the principle of conservation of linear momentum. At each timestep, the force on each particle was calculated accounting for the particle contact force, the electric double layer repulsive force, the van der Waals attractive force, the fluid force and the random Brownian motion force. Other body forces such as gravity and buoyancy were found to be negligible for all length and time scales since their magnitudes are much

smaller than the aforementioned surface forces. Further details can be found elsewhere (Mahmoud et al, 2018).

The model described was used to simulate the dynamics and mechanisms responsible for nanoparticle dispersion and aggregation using different levels of coupling. Consideration of solely fluid forces acting upon the particulate phase is known as one-way coupling. Two-way coupling was achieved by implementing the point-source-in-cell method whereby particle forces are fed back to the local fluid cells. Particle collisions (four-way coupling) were resolved using the soft sphere approach, as described by Hertzian normal contact theory (Timoshenko and Goodier, 1970). Finally, four-way coupled predictions were extended to include DLVO interparticle van der Waals attractive and electric double layer repulsive forces to allow the prediction of particle-particle agglomeration events (see Mahmoud et al, 2018). Chemical and mechanical properties were chosen to match Al_2O_3 in water, with the parameters used in the simulations provided in Table 1.

Table 1. Parameters used in the simulations.

Parameter	Carrier phase (water)	Particle phase (Al_2O_3)
Shear Reynolds number, Re_τ	180	-
Bulk Reynolds number, Re_B	2800	-
Particle diameter, d_p / nm	-	100
Number of particles, N_p	-	500,000
Volume, V / m^3	1.58×10^{-10}	4.07×10^{-13}
Volume fraction, Φ / vol %	-	0.26
Temperature, T / °C	25	25
Bulk velocity, U_B / m s^{-1}	25.67	25.68
Density, ρ / kg m^{-3}	997.1	3850
Viscosity, η_F / m^2 s^{-1}	0.917×10^{-6}	-

The simulations were first run as an unladen single-phase flow using a standard initial turbulence profile with added chaotic terms in the wall-normal and spanwise directions. Once turbulence was established, fluid statistics were monitored every 1.95 ns until the mean and fluctuating velocities reached a statistically steady state. Particles were then injected uniformly throughout the channel and given an initial velocity equal to that of the local fluid. Particle statistics in the wall-normal direction were obtained by splitting the domain into 120 equal volume cuboidal regions, and by averaging over all particles within each region. The statistics presented below represent those at a state where the near-wall particle concentration was approximately stationary with respect to time. From this steady state condition, two-way coupled runs were started, reducing the fluid and particle time step initially to avoid divergences in the flow field due to the impact of particle forces. Fluid and particle statistics were then recorded to determine when the system had finished responding to the addition of momentum-coupling. Once satisfied, statistics were determined as noted. This approach was repeated to obtain four-way coupled simulations, and results for four-way coupling plus particle agglomeration.

3. Results and Discussion

The results of each simulation were analysed to elucidate the behaviour of the fluid and the nanoparticles within the channel flow. The predictions demonstrated how particle concentrations increased with time in the near-wall regions due to turbophoresis, as illustrated in Fig 1. Preferential concentration of particles within low-speed streaks close to the walls was also noted.

Figures 2 and 3 compare the fluid streamwise mean velocity profile, and normal and shear stress profiles, for the single phase flow with those obtained by Moser et al. (1999) who also used DNS, with excellent agreement obtained.
Figure 1. Particle distribution within $Re_\tau = 180$ channel flow, colours indicate particle to bulk velocity ratio, u_p/U_B (top); and snapshot of streamwise particle velocity on vertical plane (bottom).
Figure 2. Comparison of fluid streamwise mean velocity profiles (— present, ○ Moser et al, 1999).
Figure 3. Comparison of fluid normal and shear stress profiles (— present, ○ Moser et al, 1999).

Figure 4 compares the particulate phase streamwise mean velocity against that of the unladen flow for each coupling mechanism considered. It is observed that for all the coupled cases, the particles lag slightly behind the unladen fluid flow between the turbulent region and the channel centre. This indicates that the coupling and interaction mechanisms all have a slight effect on the mean streamwise motion of the particles, albeit of the same order. However, Fig. 5 shows the root-mean-square of the velocity fluctuations, a measure of turbulence intensity, in each coordinate direction. In this case it is clear that for two-way and four-way coupling, the particulate phase exhibits similar velocity fluctuations in all three directions. More specifically, reduced turbulence fluctuations are observed compared to the single phase in the spanwise and wall normal directions, whilst the streamwise normal stress is greater in the turbulent region of the flow, but lower close to the channel centre. On introduction of the DLVO attractive and

repulsive forces, a further slight increase in the streamwise normal stress is observed which is most significant in the turbulent region. This is likely due to the aggregation of particles in this region which leads to increased particle inertia due to their larger size, with such particles exhibiting greater decoupling from the local fluid velocities.
Figure 4. Comparison of streamwise mean velocity profiles (— unladen flow, $- \cdot -$ particles (two-way), $\cdots$ particles (four-way), $- -$ particles (four-way + agglomeration).
Figure 5. Comparison of normal stresses (— unladen flow, $- \cdot -$ particles (two-way), $\cdots$ particles (four-way), $- -$ particles (four-way + agglomeration).
Figure 6. Fluid normal and shear stress profiles (— unladen flow, $- \cdot -$ two-way).
Figure 7. Particle concentration at 536 μs (— four-way + agglomeration), and 1999 μs ($- \cdot -$ two-way, $\cdots$ four-way, $- -$ four-way + agglomeration).

Figure 6 considers the effect of two-way coupling on the fluid normal and shear stresses in order to determine how the particles modify the turbulence properties of the flow. The results demonstrate that two-way coupling has only a small influence on these statistics. Specifically, all three components of the normal stress and the Reynolds shear stress are attenuated, indicating that the presence of nanoparticles at the concentration considered reduces slightly the magnitude of turbulence in the flow. Since the effect is strongest in those regions which show greatest deviation between particle stresses and those of the unladen flow, this is likely due to greater slip velocities in those regions, meaning that the particles work to dampen the energy in the local turbulent eddies.

Finally, Fig. 7 compares the particle concentration distribution relative to the initial concentration, C_0, for each simulation. It is clear from the results that over the course of the simulations turbophoresis takes place, with a similar final behaviour observed for all

cases considered. Over time this leads to a build-up of nano-particulate concentrations close to the walls. This has consequences for the agglomeration rate since the local concentration in these regions is nearly 100 times greater than the initial concentration once the system has reached a steady state. This also implies that, with time, particle deposition rates will likely increase due to the migration towards the walls. Interestingly, and despite the slight differences in particle velocity fluctuations for the different coupling mechanisms, there is very little difference in the eventual concentration distributions. This implies that the agglomerate structures do not, over the time studied, show preferential concentration in different regions of the channel when compared to the other particle flows considered.

4. Conclusions

The dispersion properties of a nanoparticle-laden channel flow have been studied using various coupling mechanisms between the particles and the fluid flow. The particles are found to be slightly decoupled from the fluid flow in that they lag behind the mean flow beyond the turbulent region for all coupling regimes. Velocity fluctuations indicate that the particles exhibit increased normal stresses in the streamwise direction in the turbulent region, but reduced values in the other coordinate directions. Interestingly, the inclusion of particle agglomeration increases the magnitude of this effect in the streamwise direction. Two-way coupling is shown to lead to a slight dampening effect on the flow turbulence. Concentration plots also indicate a time varying particle distribution, with a noticeable increase in particle concentration in the near-wall regions over the run times considered that is insensitive to the mode of coupling. Future work will further consider relating the effects observed to the rate of particle collision and agglomeration within the channel in order to better understand the dynamics which lead to the particle behaviour observed, and to allow conclusions to be reached regarding the implications for thermal energy storage systems using nanofluids.

Abstract

A sustainable chemical process operation often requires optimality with respect to multiple conflicting objectives as economic, societal and environmental aspects need to be addressed. Multi-objective optimisation aims at solving such problems. A single optimal solution for all objectives does not exist as one cannot improve with respect to one objective without worsening with respect to one of the other objectives. The result of a multi-objective optimisation algorithm is hence a Pareto set comprising equally optimal trade-off solutions. In this contribution an improved version of NSGA-II, one of the current state-of-the-art algorithms in evolutionary multi-objective optimisation, is presented and applied to the optimisation of an industrially relevant case. The proposed novel algorithm overcomes, amongst others, one of the major shortcomings of the currently used evolutionary multi-objective optimisation algorithms: the inability to distinguish between solutions based on their trade-off and distribution. This results in a Pareto front cluttered with irrelevant solutions. The performance of the improved algorithm has been evaluated for the multi-objective optimisation of a methane tri-reforming process for methanol production. Three objectives have been studied: (*i*) minimisation of the total energy demand, (*ii*) maximisation of the carbon efficiency and (*iii*) an economic profit function. For this `INPROP`, the recently developed interface between `Matlab` and `Aspen Plus` for multi-objective optimisation of chemical processes, is extended to perform multi-objective optimisation using the proposed method. Up till now, `INPROP` only exploited scalarisation-based multi-objective optimisation methods. Scalarisation methods convert the multi-objective optimisation problem (MOOP) in a sequence of single objective optimisation problems, which are solved separately using deterministic gradient-based methods. Evolutionary algorithms, like NSGA-II, are vector-based and tackle the MOOP in its entirety. The results obtained with the improved evolutionary algorithm are compared with earlier presented scalarisation-based multi-objective process optimisation results.

Keywords: Multi-objective optimisation, NSGA-II, Evolutionary algorithms, Trade-off, PIT-region, t-domination

1. Introduction

To maintain a competitive position in the current worldwide market, companies need to operate their processes as optimally as possible with respect to different, often conflicting,

objectives (e.g. societal, environmental, and economical aspects). In such case, no one optimal solution exists, and decision makers need to resort to Pareto-optimal solutions. These optimisation problems are called multi-objective optimisation problems (MOOPs) and the solutions of such problems are a Pareto front, comprising all equally optimal trade-off solutions. The decision maker (DM) will choose one optimal solution from the Pareto front as the operating point. Computing (an approximation of) this Pareto front is the main goal when solving a MOOP. It is desirable to produce a diverse Pareto set in a minimal computing time. MOOPs are mathematically challenging problems and are generally solved via the use of dedicated algorithms. The two major algorithm categories are scalarisation methods and vectorisation methods. Since this contribution focuses on vectorisation methods, scalarisation methods will not be further discussed. The interested reader is referred to Das and Dennis (1997, 1998); Messac et al. (2003); Logist et al. (2010) for more information on this type of optimisation methods.

Vectorisation methods use stochastic algorithms to solve a MOOP and tackle the optimisation problem in its entirety (Deb et al., 2002). A sub-field of the stochastic algorithms are the evolutionary algorithms (EA), which are based on Darwin's evolution theory. EAs can generate multiple Pareto-optimal solutions in a single run, making them an excellent choice to solve MOOPs, especially if the decision maker is interested in a diverse set of solutions. Additionally, EAs have no need for derivative information which makes them suitable for black box optimisation. The considered evolutionary algorithm in this article is Non-dominated Sorting Genetic Algorithm-II (NSGA-II) (Deb et al., 2002). NSGA-II is an elitist evolutionary algorithm, equipped with a fast non-dominated sorting algorithm and a crowding distance parameter to obtain a diverse solution set.

The overall goal of this contribution is (*i*) to present a novel EA that overcomes the shortcomings of the NSGA-II algorithm, (*ii*) demonstrate its performance in the `INPROP` interface between `Matlab` and `Aspen Plus` and (*iii*) apply for the tri-objective optimisation of a methane tri-reforming process.

2. Multi-objective optimisation problems

2.1. Mathematical description of a MOOP

The following MOOP formulation is used throughout this article (Das and Dennis, 1997):

$$\min_{(\mathbf{u}) \in C} \mathbf{F}(\mathbf{x}, \mathbf{u}) = \{J_1(\mathbf{x}, \mathbf{u}) \ldots J_M(\mathbf{x}, \mathbf{u})\} \tag{1}$$

with $\mathbf{u} \in \mathbb{R}^{n_u}$ the controls of the considered process, $\mathbf{x} \in \mathbb{R}^{n_x}$ the variables, $J_i(\mathbf{x}, \mathbf{u})$ the *i*-th objective function ($i \in \{1 \ldots M\}$), and with C the constraint solution space:

$$C = \{(\mathbf{x}, \mathbf{u}) : \ \mathbf{h}(\mathbf{x}, \mathbf{u}) = 0; \ \mathbf{g}(\mathbf{x}, \mathbf{u}) \leq 0; \ \mathbf{a} \leq \mathbf{u} \leq \mathbf{b}\} \tag{2}$$

$$y = [\mathbf{u}^T, \mathbf{x}^T]^T \tag{3}$$

With $\mathbf{h}(\mathbf{x}, \mathbf{u}) : \mathbb{R}^{n_u + n_x} \mapsto \mathbb{R}^{ne}$ the *ne* equality constraints, $\mathbf{g}(\mathbf{x}, \mathbf{u}) : \mathbb{R}^{n_u + n_x} \mapsto \mathbb{R}^{ni}$ the *ni* inequality constraints and $\mathbf{a} \in \mathbb{R}^{n_u}$ and $\mathbf{b} \in \mathbb{R}^{n_u}$ the respectively lower and upper boundaries for the controls. A solution $\mathbf{y}^*$ of the MOOP is Pareto-optimal or non-dominated if there exists no other solution $\mathbf{y}$ for which $\mathbf{F}(\mathbf{y}) \leq \mathbf{F}(\mathbf{y}^*)$ and $\exists k : J_k(\mathbf{y}) < J_k(\mathbf{y}^*)$ with $k \in \{1 \ldots M\}$ (Das and Dennis, 1997; Munoz Lopez et al., 2018).

2.2. Non-dominated sorting genetic algorithm II (NSGA-II)

NSGA-II is an evolutionary algorithm developed as an answer to the shortcomings of early evolutionary algorithms, which lacked elitism and used a sharing parameter in order to sustain a diverse Pareto set. NSGA-II uses a fast non-dominated sorting algorithm, sharing, elitism, and crowded comparison. Elitism implies that the best solutions of the previous iteration are kept unchanged in the current one. This significantly increases the convergence speed of the algorithm. Additionally, its use of a fast non-dominated sorting algorithm contributes to a significant reduction of its computational complexity. For more details, the interested reader is referred to Deb et al. (2002).

3. The tDOM-algorithm

Despite its significant improvement in comparison to its evolutionary predecessors, NSGA-II has two major shortcomings: (*i*) its inability to distinguish between solutions based on their trade-off, and (*ii*) its use of an arbitrary and problem-irrelevant stopping criterion. The presented novel tDOM-algorithm is based on the general framework of NSGA-II and is developed to remedy these shortcomings. To achieve this, the tDOM-algorithm employs t-domination instead of non-domination, via the introduction of a trade-off function and PIT-regions. This enables the tDOM-algorithm to distinguish between solutions based on their trade-off. Additionally, this allowed for the introduction of a non-arbitrary stopping criterion.

3.1. Preliminaries

PIT-region: Regions of practical insignificant trade-off (PIT-regions) are spatial structures which are constructed around the solutions in the objective space. The dimensions of the PIT-region are defined by a minimal trade-off Δt and distribution Δr. If two solutions are located in each others' PIT-region, both solutions are considered insignificantly different from one another by the DM and therefore one of these solutions can be filtered out of the population set (Mattson et al., 2004).

t-Domination: A solution $\mathbf{p}$ t-dominates solution $\mathbf{q}$ if $\mathbf{F}(\mathbf{p}) \leq \mathbf{F}(\mathbf{q})$, $\exists\, k : J_k(\mathbf{p}) < J_k(\mathbf{q})$, and $\mathbf{p} \notin PIT(\mathbf{q})$.

Trade-off function: The trade-off function determines the crowdedness of the PIT-regions of the obtained solutions. During the selection step, solutions are additionally sorted in ascending order according to crowdedness of their PIT-region, thus more emphasis is set on high trade-off solutions. Concurrently, the trade-off function establishes whether all the solutions of two subsequent generations are located within each others' PIT-regions. If this is the case, the `stop` Boolean is set to `true`, and the algorithm stops.

3.2. Algorithm description

The tDOM-algorithm uses the NSGA-II framework, but it is equipped with the multi-functional trade-off function that determines the trade-off between solutions and the algorithm's stopping criterion. Hashem et al. (2017) presented the idea of using the trade-off of solutions as a stopping criterion. In their divide and conquer scheme for deterministic algorithms, the exploration of a certain area of the Pareto front is ceased if the generated solutions no longer display the required trade-off or distribution. This idea is adapted for evolutionary algorithms via the PIT-regions in the tDOM-algorithm.

During the first iteration, N initial random solutions are generated in the parent set P_0, which is used to generate a first offspring set Q_1 ($|Q_1| = N$). Offspring solutions are obtained via crossovers and mutations of the parent solutions. At the t-th generation of the tDOM-algorithm, after offspring solutions are generated, the parent set P_{t-1} and offspring set Q_t are merged into a combined solution set R_t ($|R_t| = 2N$), enabling elitism. Subsequently, the solutions of R_t are sorted into their non-dominated front, and their crowding distance and trade-off are determined. Additionally, the stopping parameter `stop` is determined via the trade-off function. Based on the rank of their non-dominated front, their crowding distance, and their trade-off, only the best N solutions of R_t are retained. These solutions form the parent set P_t of the $(t+1)$-th iteration. The tDOM-algorithm is interrupted when the stopping parameter `stop` is set to `true` during the trade-off function.

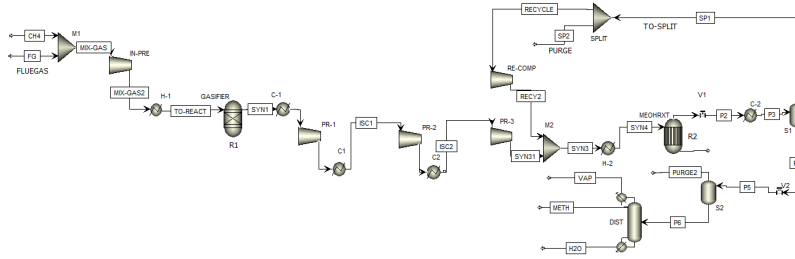
4. Results and discussion


Figure 1: Methanol production via methane tri-reforming (Munoz Lopez et al., 2018).

A methane tri-reforming process converts flue gasses and a methane stream into methanol and water. This process was modelled by Munoz Lopez et al. (2018) in `Aspen Plus` (see Figure 1). To optimise this process the tDOM-algorithm is implemented in `Matlab 2018a`. The interface between the process simulator `Aspen Plus` and `Matlab` is referred to as INterface for PRocess OPtimisation (`INPROP`) (Munoz Lopez et al., 2018). During the optimisation, the controls **u** and variables **x** are transferred from `Aspen Plus` to `Matlab`. The controls **u** are subsequently optimised using the tDOM-algorithm and are send back to `Aspen Plus`, where the corresponding variables **x** are determined and send back to `Matlab`, continuing the optimisation procedure. This process repeats itself until the stopping criterion is satisfied. Three objectives were optimised, subject to a minimal required methanol purity of 98 % and a maximum methanol fraction of 85 % in the water stream (Munoz Lopez et al., 2018):

$$J_1(\mathbf{x},\mathbf{u}) = -\frac{[MEOH]_{METH}}{([CH_4]+[CO_2]_{FG})} \ [-] \quad (4) \qquad J_2(\mathbf{x},\mathbf{u}) = \frac{(|\dot{W}|+|\dot{Q}|)}{([MEOH]_{METH}/3600)} \left[\frac{MJ}{kmol}\right] \quad (5)$$

$$J_3(\mathbf{x},\mathbf{u}) = -\left(a_1[MEOH]_{METH} - \left(a_2[CH_4] + 3600 \times a_3\left(|\dot{Q}|+|\dot{W}|\right)\right) - \frac{ann.cc}{8000}\right) [\text{€}/h] \quad (6)$$

subject to

$$0 < p_{S1} - p_{S2} \le 70 \qquad (7) \qquad 0 < p_{S2} - p_{DIST} \le 25 \qquad (8)$$

$$p_{PR-3} - p_{R2} = 0 \qquad (9) \qquad 0.98 - [MEOH]_{METH} \le 0 \qquad (10)$$

$$[MEOH]_{H2O} - 0.85 \le 0 \qquad (11)$$

Objective J_1 is the carbon efficiency of the process, with $[MEOH]_{METH}$ the methanol stream [kmol/h], $[CH_4]$ the methane stream [kmol/h], and $[CO_2]_{FG}$ the carbon dioxide in the flue gas stream [kmol/h]. Objective J_2 is the total energy demand required for the production of 1 kmol $MEOH$, with $|\dot{W}|$ the total amount of work [MW], and $|\dot{Q}|$ the total

amount of thermal energy [MW]. Objective J_3 is the profit-cost balance with a_1 the unit price of *MEOH*, a_2 the unit price of *CH*$_4$, and a_3 the unit price of electricity. The obtained results and Pareto fronts are represented in Table 1 and Figure 2 respectively. For more information on the controls, the interested reader is referred to Munoz Lopez et al. (2018).

Figure 2: Pareto fronts generated via tDOM-algorithm, NSGA-II, and scalarisation method.

For all the objectives, Δt was defined as 10% and Δr as 15%. Note that in practical applications Δt and Δr can have different values for each objective. The values of Δt_i and Δr_i quantify the importance attached to the *i*-th objective. Visual analysis of the results displayed in Figure 2 raises two main observations. First, the results obtained via the scalarisation method (blue dots) and the surface interpolated from them seem to offer a well-defined approximation of the Pareto front for this MOOP. However, numerous solutions generated via the scalarisation method are non-Pareto-optimal, and therefore could be misleading for the DM. Logist et al. (2010) confirms this observation by stating that scalarisation methods can be prone to generate non-Pareto-optimal solutions, in contrast to EAs and the proposed tDOM-algorithm. Secondly, if the results generated by the tDOM-algorithm are compared with the results generated with the original NSGA-II algorithm, the tDOM-algorithm outperforms the NSGA-II algorithm. When the same conditions in terms of population size and number of generations were kept for both algorithms, the proposed algorithm converges to the actual Pareto front while the solutions from NSGA-II remain far from it. The normalised average distance to the Utopia point (i.e., all the individual objective minimisers) of the tDOM-solutions is 0.6914, while that of the NSGA-II solutions amounts to 1.0447, placing it significantly closer to the Nadir point (i.e., all the individual objective maximisers). This proves that the proposed tDOM-algorithm overcomes the limitations of the NSGA-II algorithm and produces a more informative Pareto front that is not affected with the presence of non-optimal solutions.

Finally, regarding the numerical results as presented in Table 1, the original process is non-optimal. All the generated solutions result in lower integral costs than those of the reference conditions. For instance, the most carbon efficient solution results in a gain of 20.55%. Strikingly, the energy consumption of this solution is only 1.80% higher than the original process. Despite this, a 57.51% loss in profit is displayed, compared to the original process, making the process economically infeasible. Again, note that the density of tDOM-solutions in this Pareto front area is sparser than in the more economically interesting knee of the Pareto front.

5. Conclusions

A sustainable process requires optimality with respect to multiple, often conflicting, objectives. In such cases, no single optimal solution exists, but instead multiple trade-off solutions. Determining the most optimal solutions is achieved via a multi-objective optimisation problem (MOOP). NSGA-II is a widely applied optimisation algorithm, used to solve MOOPs. However, it is unable to distinguish between solutions based on their trade-off, and it uses an arbitrary stopping criterion. To overcome these shortcomings, the tDOM-algorithm is presented. Via the introduction of regions of practically insignificant trade-off (PIT), solutions with a high trade-off are emphasised. Additionally, by applying the concept of t-domination, the tDOM-algorithm is equipped with a problem-relevant stopping criterion. The advantages of the tDOM-algorithm were demonstrated for the MOO of the methane tri-reforming process. Using the `INPROP` interface it was found that tDOM-algorithm is able of producing a diverse set of relevant Pareto-optimal solutions. This in strong contrast to solutions produced by NSGA-II, which do no converge to the Pareto front, and the solution set generated via a scalarisation method, which is populated with non-Pareto-optimal solutions.

Abstract

Multi-product air separation units produce important gases such as nitrogen and oxygen from ambient air. Their high electricity demand suggests an economic advantage of flexible operation depending on fluctuating electricity prices. Flexible operation can be achieved using economic model predictive control by solving an economic dynamic optimization directly on the process controller level. The goal of the controller is to operate economically optimal with respect to operational cost while satisfying product purities and other operational constraints in the presence of disturbances, such as varying feed air temperatures. We solve the resulting large-scale dynamic online optimization problem using a suboptimal method based on direct single-shooting. The results show that economic model predictive control is viable for the optimal operation of air separation units in real-time. We demonstrate that it improves the process economics by around 4% compared to the stationary benchmark operation while satisfying all operational constraints. The control strategy is implemented in Python using a Modelica model and our dynamic optimization framework DyOS.

Keywords: economic model predictive control, demand side management, air separation process

1. Introduction

The integration of renewable energy sources into the electricity grid leads to fluctuating energy prices and promises an economic advantage of flexible process operation and demand side management (e.g., Daryanian et al. (1989); Ghobeity and Mitsos (2010)). This advantage is significant in the case of energy-intensive processes, like cryogenic air separation units (ASUs). Since the dominant time constants of the ASU are in the same range as the electricity price fluctuations, the process dynamics have to be taken into account by the process operation strategy.

Economic nonlinear model predictive control (eNMPC) (e.g., Engell (2007); Amrit et al. (2013) can be used for flexible and economically optimal process operation. To reduce the solution times of the dynamic optimizations required for eNMPC, fast-update methods (cf. Wolf and Marquardt (2016)) have been proposed, which approximate the optimal solution. In the considered suboptimal fast-update methods the iteration number of sequential quadratic programming (SQP) algorithms used for dynamic optimization are restricted (e.g., Diehl et al. (2005)).

The application of eNMPC to an ASU has been in the focus of research recently. Huang and Biegler (2012) used an advanced-step model predictive controller for the rectification column section of a multi-product ASU. However, the heat exchanger and compressor

were not considered, although they are main parts of an ASU. Pattison et al. (2016) applied a combined dynamic scheduling and tracking controller approach to a liquid nitrogen ASU. Caspari et al. (2018) applied a suboptimal method to an ASU for liquid nitrogen production based on direct single-shooting.

The application of eNMPC to a complete multi-product ASU comprising a heat exchanger, two columns, a feed air compressor, and additional utilities has not yet been focused on. We show that eNMPC can be applied to realize demand side management without using a scheduling layer for a large-scale process in real-time.

The article is structured as follows: Section 2 describes the process, and process model and the eNMPC framework. Section 3 discusses the closed-loop case-study results before the work is finally concluded in Section 4.

2. Air Separation Process and Economic Model Predictive Control Method

We consider a multi-product ASU producing both liquid and gaseous oxygen and gaseous nitrogen. The flowsheet of the process, shown in Fig. 1, is similar to the one presented by Miller et al. (2008). However, the argon part of the ASU and the nitrogen product liquefier are not considered here. We add an oxygen storage tank to buffer the product to improve the process flexibility. Ambient air enters the process and is compressed at the beginning to 58 bar before one part of the stream is expanded to 5.5 bar and enters the high pressure column (HPC). The other part is cooled down further in the heat exchanger and is fed to the HPC and to the low pressure column (LPC) at a pressure of 1.424 bar.

Figure 1: Process flowsheet of the multi-product ASU. The control variables for the eNMPC are illustrated in blue letters. $\dot{n}_{air}$ is the feed air stream entering the process, ξ_i are split factors for the respective streams.

The two columns are interconnected by the heat integrated condenser and reboiler. Gaseous and liquid oxygen product (GOX and LOX, respectively) is withdrawn from the reboiler. The gaseous nitrogen product (GNP) is taken from the LPC top. One part of the oxygen product stream is stored in the buffer tank, the other part is compressed to 5.5 bar and vaporized in the heat exchanger to cool down the feed air stream and exits the process as GOX. We developed a first-principle model of the ASU. The models used are similar to the models used by Huang and Biegler (2012) and Pattison et al. (2016). The main model assumptions are summarized in the following.

Thermodynamics: The vapor-liquid equilibrium is calculated using the isofugacity condition. The vapor pressure of the pure components are computed using the extended Antoine equation. The ideal gas law is used for the vapor phase. The liquid phase activity coefficient is calculated using the NRTL model. All parameter values for the thermody-

namic models are retrieved from Aspen Plus version 8.8 (Aspen Technology, 2018).

LPC/HPC: The rectification columns are described by a stage-by-stage model. The column stages are modeled with dynamic MESH-equations using the following assumptions: (i) negligible vapor hold up, (ii) quasi-stationary energy balance, (iii) a constant pressure difference between neighboring stages and (iv) a linear relation for stage hydraulics. We modeled the LPC with 60 stages and the HPC with 30 stages.

Heat exchanger: The heat exchanger is described by a spatially-distributed model discretized using steady-state energy and mass balance equations for the fluid streams and dynamic energy balances for the heat exchanger wall elements. A discretization of 10 segments is used for each stream and the wall. The temperature profile has been regressed as function of enthalpy, pressure, and composition, allowing to handle phase transitions in the heat exchanger easily.

Compressors/Turbine: The compressors and the turbine are modeled using isentropic efficiencies of maximum 80% at steady-state operating point and quadratically decreasing in off-design operation.

The entire model results in a nonlinear index-1 differential-algebraic equation system (DAE) comprising of 300 differential and about 22500 algebraic equations.

2.1. eNMPC framework

In eNMPC, a dynamic optimization problem is solved repeatedly online during process operation on a moving horizon. An economic objective function is minimized subject to a DAE system defined by the model equations and further operational constraints, such as the product quality. As we use a large-scale nonlinear model, the high computational effort for solving the dynamic optimization problem impede real-time tractability and thus the application in process control. To overcome this issue, we use a suboptimal fast-update method (Diehl et al., 2005) to approximate the optimal solution of the dynamic optimization problem. We restrict iterations of the optimization algorithm, such that the optimization stops before the optimality conditions are satisfied. The optimization problems are solved using direct single-shooting (Brusch and Schapelle, 1973; Sargent and Sullivan, 1978), where a DAE integrator is used inside the optimization algorithm to solve the DAE. This guarantees the model equations to be solved exactly within the integrator tolerances at each iteration of the optimization algorithm and the NLP solver does not influence the physical reliability of the solution. In that sense, single-shooting is particularly suited for suboptimal fast-update methods. Moreover, delay compensation by prediction (Wolf and Marquardt, 2016) is used to improve the eNMPC performance; we use the control variable values from the last controller iteration to predict the system state over a time horizon that is defined by the computational time required to solve the eNMPC problem. This leads to a more aggressive controller reaction since the controller has less time to react to potential disturbance. The time delay is estimated a priori. All disturbances that may occur during operation are assumed to be time invariant over the complete control horizon.

2.2. Implementation

We implement the mechanistic model in Modelica (Modelica, 2018). We export it as functional mock-up unit (FMU) (FMI 2 standard, 2014) and use it in the dynamic optimization framework DyOS (DyOS, 2018). We apply the integrator NIXE (Hannemann et al., 2010) and the SQP optimization algorithm SNOPT (Gill et al., 2005). Integrator and optimizer are implemented in C++ and Fortran. Thus, the numerics are performed in those languages. We implement the overall eNMPC framework in Python (Python,

2018). We use a Windows 7 desktop computer equipped with an Intel Core(TM) i3-6100 processor running at 3.7 GHz and 8 GB RAM.

(b) Liquid oxygen product rate withdrawn from the storage tank. (c) Heat transfer rate to each tray due to solar radiation. (d) Feed air temperature entering the heat exchanger.

3.1. Operational Scenario and eNMPC formulation

The goal of the eNMPC is to control the process economically optimal with respect to the electricity cost, satisfy the product demand, and reject disturbances. We compare the eNMPC performance to a constant production rate as benchmark, i.e., time-invariant process input variables. The values of the input variables are the same as the initial input variable values of the eNMPC. We assume full state feedback and the electricity prices profile shown in Fig. 2a. Using the eNMPC problem formulation, we ensure that both the closed-loop process and the benchmark produce the same amount of product. We use an operation scenario where liquid oxygen product is withdrawn from the tank six times every day (cf. Fig. 2b) in an amount that corresponds to the oxygen produced by the benchmark production. This may correspond to product withdrawal and distribution by tank wagons. The eNMPC has to control the process such that the initial storage tank content is achieved again by the end of each control horizon. Additionally, the eNMPC has to guarantee the gaseous oxygen product amount to be the same as in the benchmark by using an endpoint constraint. We constrain product purities by path-constraints in order to guarantee the required product quality during the complete time horizon. We bound column stage temperatures to additionally support the product purities. We assume two disturbances during operation: (i) the feed air temperature profile corresponding to temperature fluctuations and (ii) heat streams entering the columns (Fig. 2c and 2d). In the eNMPC, we minimize the economic objective function $\phi = \int_{t_0}^{t_0+\Delta t_c} c_{el}(t)(P_{com}(t) - P_{tur}(t))dt$, where t_0 is the initial time of the eNMPC controller, i.e., the current time on the moving horizon, Δt_c is the control horizon, i.e., the horizon over which the optimization problem is solved in the eNMPC controller, c_{el} is the fluctuating electricity price. P_{com} and P_{tur} are the compressor and turbine electricity demand, respectively. We bound control variables (cf. Fig. 1) by: $\dot{n}_{air} \in [1500, 2800]$ mol/s, $\xi_{GA} \in [0.31, 0.41]$, $\xi_{LA} \in [0.83, 0.9]$, $\xi_{LOX} \in [0.65, 0.84]$,

$\xi_{HP} \in [0.536, 0.579]$, and $\xi_{CGN} \in [0.56, 0.64]$. In order to compare the two operational modes we use the economic improvement measure $\eta = 1 - \frac{\Phi^*_{eNMPC}/n^*_{eNMPC}}{\Phi_{benchmark}/n_{benchmark}}$, where Φ^*_{eNMPC} and n^*_{eNMPC} is the objective function value and the total product amount resulting from the eNMPC controlled closed-loop simulation, respectively, and $\Phi_{benchmark}$ and $n_{benchmark}$ are the respective values corresponding to the constant benchmark operation. An eNMPC sampling time of 7.5 min and a control horizon of 8 h are used. We restrict the SQP algorithm to a single iteration. We assume full state feedback and no plant-model missmatch. Partial state feedback or plant-model missmatch would require the use of state estimation techniques. A PI controller is used for the HPC liquid tank holdup. We use absolute and relative integrator tolerances, and the optimality and feasibility tolerances of SNOPT of 10^{-3}. We select 0.1 as maximum major step length in SNOPT.

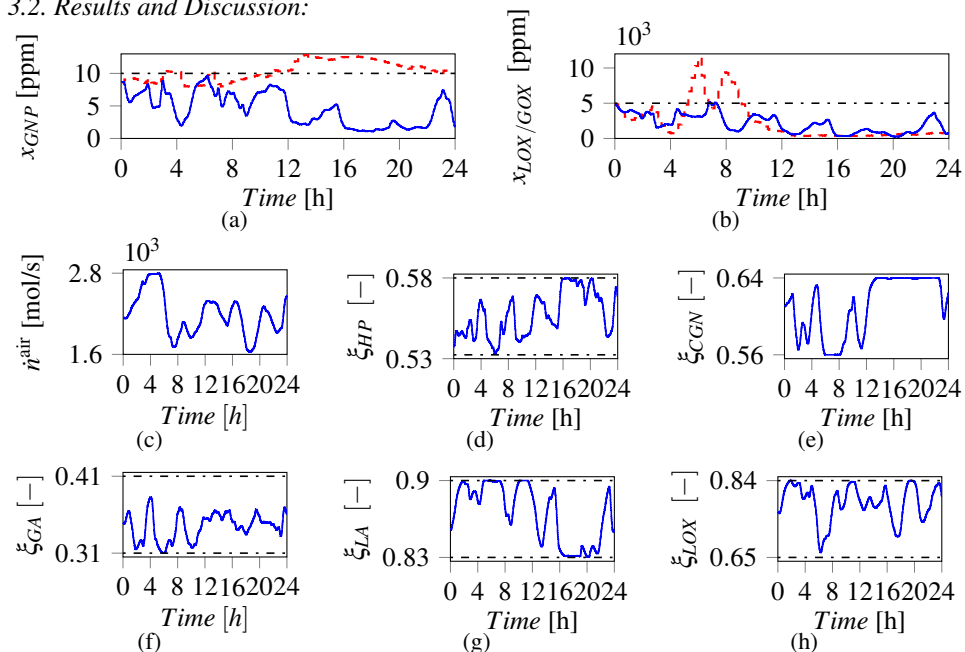
3.2. Results and Discussion:


Figure 3: Top: Selected state profiles of benchmark operation (dashed red lines) and closed-loop (solid blue lines) simulation; dash-dotted lines the upper bounds. Rows 2 - 3: selected control profiles of the closed-loop simulation. (a) Impurities of the GNP product stream. (b) Impurities of the LOX and GOX product streams. (c) Feed air stream. (d)-(h) Split factors.

The eNMPC achieves an economic improvement of 3.7 % compared to the benchmark operation. The cost effectiveness can be expected to be further improved by using additional SQP iterations (Caspari et al., 2018). For comparison, we simulated the process benchmark operation, i.e., open-loop without eNMPC, using the same disturbance and electricity price profiles. From Fig. 3a and 3b, we see that the product quality constraints are violated in the benchmark operation due to the presence of the disturbances, as expected. The nitrogen product quality is violated especially in times of high heat streams after 16 h. The oxygen product impurity exceeds its upper bound in those times when the feed air temperature is higher. With eNMPC, the constraints are satisfied, as shown in Fig. 3a and 3b. The corresponding control variable profiles are depicted in Fig. 3c -

3h. We see, that the eNMPC varies the control variables in the whole range within the allowed bounds. The air feed stream (Fig. 3c) is low in times of low electricity prices (Fig. 2a). This is intuitive, since this stream directly corresponds to the electricity consumption of the main compressor. The split factor shown in Fig. 3d corresponds to the reflux ratio of the HP. A high split factor leads to a high reflux ratio and, thus, to higher purities. Increased reflux ratios are, hence, reasonable in times of high heat streams into the column in order to achieve the product purities. The average computational time for the suboptimal fast-update is about 50 s, i.e., about 18% of the control horizon.

4. Conclusion

We present a case study of eNMPC applied to a multi-product ASU based on direct single-shooting.We limit the number of SQP iterations of the NLP solver to reduce compuational time. We use a large-scale first principle model as controller model and considered disturbances in the closed-loop simulation. Using the eNMPC we improved the process operational cost by almost 4 % compared to stationary operation. The constraints that are violated in the benchmark operation are satisfied using the eNMPC operation. The computational times indicate that the method presented is applicable in real time. Further computational time reduction could be achieved using model reduction techniques or further algorithmic improvements, such as neighboring extremal updates (cf. Wolf and Marquardt (2016)), which however require the efficient computation of the second order sensitivities. SNOPT uses a BFGS approximation to calculate these starting with the unity matrix.. The use of exact second order sensitivities can improve both computational times and process economics (Würth et al., 2009).

Abstract

Dynamic optimization problems arise in many fields of engineering. Typically, they are subject to models of differential-algebraic equations and further process constraints. To promote and investigate the application of methods based on dynamic optimization, an efficient and modular implementation of numerical algorithms for their solution is essential. We present the current status of the open-source software DyOS for the solution of large-scale dynamic optimization problems. DyOS has been applied to optimal operation, model-predictive control and process design problems in various case studies. DyOS is based on direct adaptive shooting algorithms and it allows for multi-stage problem formulations including binary decision making. Models can either be imported as standardized functional mock-up units, flat Modelica models, or C++ models. The modular implementation of DyOS enables the use of various open-source and commercial integrators and nonlinear programming solvers based on various numerical methods. DyOS can be accessed via Matlab or Python interfaces. As an illustrative large-scale application, we present the results of optimal operation of an air separation process under fluctuating electricity prices. An open-source version of DyOS including several parts of the framework presented is available at `http://permalink.avt.rwth-aachen.de/?id=295232`.

Keywords: dynamic optimization, direct adaptive shooting, open-source framework

1. Introduction

The solution of optimization problems constrained by differential algebraic equation systems (DAEs) is a common challenge in many fields. Among others, dynamic optimization of DAEs is used in process control, operation, and design. The direct optimization methods full discretization (Cuthrell and Biegler, 1987), single shooting (Brusch and Schapelle, 1973; Sargent and Sullivan, 1978; Kraft, 1985), and multiple shooting (Bock and Plitt, 1984) make use of discretization to treat the DAEs. There are already several software frameworks, which implement these methods. A list can be found in Nicholson et al. (2017). Open source implementations include pyomo:dae (Nicholson et al., 2017), ACADO (Houska et al., 2010), Optimica and JModelica (Åkesson et al., 2010), and TACO (Kirches and Leyffer, 2013). We present the current status of the open-source framework DyOS (Dynamic Optimization Software) for dynamic optimization based on direct adaptive shooting methods, which is tailored to large-scale DAEs. DyOS integrates several software packages including different integration and optimization methods, dif-

ferent nonlinear and linear equation solvers, and a graph coloring algorithm into a large framework for the efficient solution of dynamic optimization problems. Using the standardized modeling language Modelica and the standard Functional Mockup Unit (FMU), it allows straightforward model provision and optimization problem set-up. The remainder of the manuscript is structured as follows. The methods used, the implementation and the problems solved in the past are summarized in Section 2. A large-scale case study is shown in Section 3, before the work is concluded in Section 4.

2. Methods and Implementation

The optimization framework DyOS solves a multi-stage mixed-integer dynamic optimization problem of the form

$$\min_{\mathbf{u},\mathbf{z},\mathbf{p}} \sum_{i}^{N} \Phi(\mathbf{x}(t_i^-)) \tag{1a}$$

$$\text{s.t. } \mathbf{M}\dot{\mathbf{x}}(t) = \mathbf{f}_i(\mathbf{x}(t),\mathbf{y}(t),\mathbf{u}(t),\mathbf{p},\mathbf{z}), \qquad \forall t \in \mathscr{T}_i, \ 0 \leq i < N \tag{1b}$$

$$\mathbf{0} = \mathbf{g}_i(\mathbf{x}(t),\mathbf{y}(t),\mathbf{u}(t),\mathbf{p},\mathbf{z}), \qquad \forall t \in \mathscr{T}_i, \ 0 \leq i < N \tag{1c}$$

$$\mathbf{0} = \mathbf{h}_i(\mathbf{x}(t_i^+),\mathbf{x}(t_i^-),\mathbf{y}(t_i^-),\mathbf{p},\mathbf{z}), \qquad 1 \leq i < N \tag{1d}$$

$$\mathbf{0} \geq \mathbf{c}_i(\mathbf{x}(t),\mathbf{y}(t),\mathbf{u}(t),\mathbf{p},\mathbf{z}), \qquad \forall t \in \mathscr{T}_i, \ 0 \leq i < N \tag{1e}$$

on a finite time horizon $\mathscr{T} = \bigcup_{i=1}^{N} \mathscr{T}_i$, where N is the number of stages and $\mathscr{T}_i = [t_i, t_{i+1}]$ are the time horizons of the stage i, $\mathbf{f}_i : \mathbb{X} \to \mathbb{R}^{n_x}$ and $\mathbf{g}_i : \mathbb{X} \to \mathbb{R}^{n_y}$ define the semi-explicit differential-algebraic system of index 1 with the invertible matrix $\mathbf{M} \in \mathbb{R}^{n_x \times n_x}$, while $\mathbf{h}_i : \mathbb{R}^{n_x} \times \mathbb{R}^{n_x} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_p} \times \mathbb{R}^{n_z} \to \mathbb{R}^{n_x}$ indicates the initial conditions and $\mathbf{c}_i : \mathbb{X} \to \mathbb{R}^{n_c}$ the constraints, with $\mathbb{X} := \mathbb{R}^{n_x} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_p} \times \mathbb{R}^{n_z}$ Problem (1) aims at finding optimal control trajectories $\mathbf{u} : \mathscr{T} \to \mathbb{R}^{n_u}$, differential and algebraic state trajectories $\mathbf{x} : \mathscr{T} \to \mathbb{R}^{n_x}$ and $\mathbf{y} : \mathscr{T} \to \mathbb{R}^{n_y}$, respectively, for parameter values $\mathbf{p} \in \mathbb{R}^{n_p}$ and integer variables $\mathbf{z} \in \mathbb{N}^{n_z}$, that minimize an objective in Mayer form $\Phi : \mathbb{R}^{n_x} \to \mathbb{R}$. The superscripts $+$ and $-$ denote the upper and lower one-sided limits of t_i. The algorithms in DyOS are based on adaptive direct single- and multiple-shooting (Schlegel et al., 2004; Assassa and Marquardt, 2014), where the control variable profile discretization is automati-

Figure 1: DyOS implementation structure.

cally adapted. Two types of grid adaptation methods can be selected: one based on the objective function improvement using wavelet analysis (Schlegel et al., 2004) and the other based on the necessary optimality conditions (Assassa and Marquardt, 2016). Grid adaptation allows the user to start the optimization using a coarse discretization grid and get a fine grid at the end of the optimization. Thus, grid adaptation can reduce the overall

CPU time by avoiding an abundant parameterization. This can be used to avoid over-parameterized solution, and the use of control structure detection can significantly reduce the granularity of the discretization without loosing information (Assassa and Marquardt, 2015). Using a branch-and-bound algorithm, DyOS can solve mixed-integer optimization problems (Oldenburg et al., 2003; Frankl et al., 2012). Moreover, a unique feature of DyOS are the special approaches to provide the Jacobian and the Hessian of the Lagrangian. The first- and second-order sensitivities can be provided by forward sensitivity integration and first-order adjoint equations. The Hessian can be provided using composite adjoints of the Lagrangian (Hannemann and Marquardt, 2007; Jorgensen, 2007). The modified discrete adjoint solver NIXE (Hannemann et al., 2010) serves as an integrator for the composite adjoint sensitivity system. The Jacobian of the models can be calculated in both forward and reverse mode, and the Hessian matrix can be calculated in reverse mode. A generic integrator interface implementation facilitates coupling of existing DAE integrator codes to DyOS. Wrappers for three different integrators are currently implemented: the semi-implicit extrapolation methods NIXE (Hannemann et al., 2010) and sLIMEX (Schlegel et al., 2004), as well as the backward differentiation formula IDAS (Serban et al., 2018). The architecture of DyOS is shown in Fig. 1. A generic optimizer interface enables coupling nonlinear programming codes to DyOS. Four different NLP solvers are currently available: SNOPT (Gill et al., 2005), NPSOL (Gill et al., 1986), IPOPT (Wächter and Biegler, 2005), and FilterSQP (Fletcher and Leyffer, 2002). A generic model interface is implemented, which allows to couple different models to DyOS. The model interface currently supports the functional mockup interface standard (FMI, 2014) and parsed Modelica models. In the latter case C++ code of the model residuals is generated and processed by the algorithmic differentiation tool `dcc` (Naumann, 2012) to generate first- and second-order derivatives. DyOS focuses on the solution of large-scale optimization problems by making use of adaptation strategies and the integration of efficient numerical software packages. Thus, several packages are used to support this purpose: the graph coloring package ColPack (Gebremedhin et al., 2013) for efficient Jacobian and Hessian calculation, nonlinear solver CMINPACK, as well as linear solvers KLU, SuperLu, and CSparse. Three front ends are implemented to access DyOS from C++, Matlab and Python. A minor limitation is the restriction to a constant matrix **M** and a system with a differential index of 1. However, every non-index-1 system can be reformulated to an index-1 system with constant matrix **M**, and, thus, this limitation is not severe. In the past, DyOS has been used for solving many challenging chemical engineering problems either as standalone solver, e.g., for dynamic optimization of batch recipes or as a subsolver embedded in an algorithm, e.g., in nonlinear model predictive control (NMPC) applications. Table 1 presents a non-exhaustive, yet exemplary, list of problems solved with DyOS which shows its wide range of applicability and its capability to handle large-scale DAE systems.

3. Dynamic Optimization of an Air Separation Process
Since air separation units (ASU) are electricity intensive processes, their flexible operation for demand-side management is economically promising due to the penetration of fluctuating renewable energy. In this section, an offline dynamic optimization of an ASU using DyOS is presented based on the work of Caspari et al. (2018). The flowsheet of the process is depicted in Fig. 4. Air is compressed from its ambient state at 1 bar to 10 bar and cooled down by a heat-exchanger and expansion in a turbine. It is separated into its components in a rectification column at a pressure of 6.6 bar comprising of an integrated

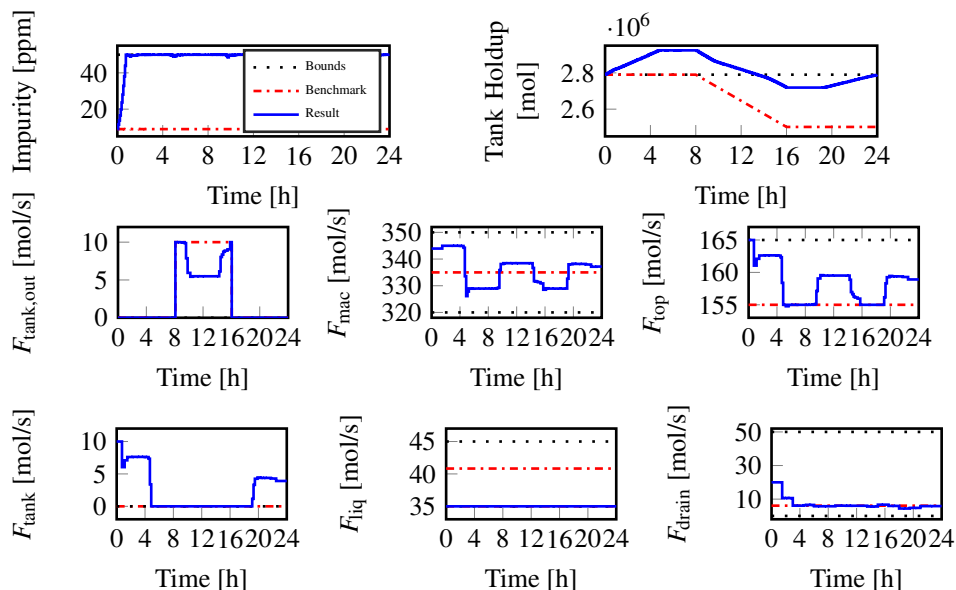
reboiler and condenser. Nitrogen is withdrawn either from the storage tank or directly from the heat exchanger. The main energy consumers of the process are the feed air compressor and the nitrogen product liquefier. A nonlinear first-principle process model is used comprising of 127 differential and 2940 algebraic states and 5 input variables. The model is implemented in Modelica and connected via the Functional Mock-Up Interface. The economic objective function $L(t) = \int_{t_0}^{t_{end}} c_{el}(t)(P_{comp}(t) + P_{liq}(t) - P_{tur}(t))dt$ is minimized, where $P_{comp/liq/tur}$ is the power demand/supply of the compressor, liquefier, and turbine, respectively, and c_{el} is the fluctuating electricity price. t_0 and t_{end} are the initial and final time of the control horizon. The operational cost is compared to a constant operation benchmark. The electricity price profile used is shown in Fig. 2a. The profile of the product flowrate from the process is shown in Fig. 2b. The product purity is path-constrained to guarantee a predefined product quality. The storage tank holdup is endpoint-constrained to guarantee a minimum amount of product produced during the optimization horizon. The process operation is optimized over a time horizon of one day. We use wavelet-based grid adaptation with an adaptation of maximum five adaptation steps and an initial equidistant grid with eight piecewise constant control elements. SNOPT is used as NLP solver and sLIMEX as integrator with the tolerances set to 10^{-6}. The results of the dynamic optimization and of the benchmark operation strategy are shown in Fig. 3. We see that the tank is loaded when the electricity price is low and unloaded when it is


Figure 3: State and input trajectories of ASU case-study. The optimal operation (solid blue) is compared to a benchmark (dash-dotted red) corresponding to constant production rate. Top: Trajectories of selected constrained states. Rows 2 - 3: Trajectories of input variables.

high, as expected. The highest tank level is kept constant when the electricity price is at is maximum value, which is less intuitive. However, it can be explained by the increased product stream from 8 h on. In the benchmark operation the tank is unloaded due to the higher product demand. This difference is accounted for by the economic evaluation.

Moreover, the product impurity are at their bounds throughout the considered time horizon. The control variable profiles are shown in Fig. 3, where successful grid adaptation is demonstrated. They have a fine discretization where needed, e.g., for F_{mac}, and a coarse if not, e.g., for F_{liq}. The total runtime including the five grid adaptation steps took about 8 hours of CPU time. A Windows 7 computer is used with an Intel Core i3-6100 processor having 3.7 GHz and 8 GB RAM. The optimization results in a cost reduction of about 2 % with respect to the benchmark operation.

Figure 4: Air separation process flowsheet with control variables (bold red letters).

4. Conclusion

We present the dynamic optimization framework DyOS that is tailored to large-scale DAE systems. We review existing work which used DyOS for large-scale optimization problems. Finally, we demonstrate the application of the wavelet-based adaptation to an optimization of an air separation process.

Abstract

The multi effect distillation (MED) process has been extensively used for seawater desalination as a prominent process to produce high quality freshwater. However, the impact of number of effects in the MED process-based seawater desalination on the fresh water production cost has not been critically evaluated in the literature. Therefore, the aim of this study is to resolve this particular challenge via the simulation for a given seawater concentration and temperature conditions. The simulation is carried out using a comprehensive MED process model coupled with appropriate cost functions within gPROMS model builder software. The simulation results show that selecting the optimal number of the MED effects as 17 is important to achieve the lowest fresh water production cost for a given seawater operating conditions.

Keywords: Seawater desalination, MED process, Simulation, Fresh water production cost.

1. Introduction

The Multi Effect Distillation (MED) process is the oldest technique for seawater desalination and was first reported back in the middle of the 19th century. Essentially, the thermal and membrane processes are considered as the main adopted technologies used for seawater desalination. These technologies are employed to overcome the scarcity of fresh water due to restricted available resources (Sadri et al., 2017). Specifically, the thermal process characterises by using heat to evaporate and distil the seawater. However, massive research efforts need to be paid to improve the system's efficiency and decrease the fresh water production cost. In this respect, the main concern of thermal process is to improve the steam economy and specifically the Gained Output Ratio GOR (defined as the ratio of the produced distilled water in kilograms to steam consumed in kilograms) (Darwish and AL-Juwayhel, 2006). Recently, MED process gained more attention than other thermal processes (such as Multi Stage Flash, MSF) due to its high effectiveness, straightforward operation and maintenance and feasible economic characteristics. Ettouney and El-Dessouky (1999) stated that the thermal desalination processes, in particular MED process is the more

significant method for desalting seawater to obtain conductivity in very low level, which has a strong impact in power plant. More specifically, the MED process becomes a superior desalination processes due to its low specific energy consumption (Darwish and Abdulrahim, 2008) and low top brine temperature which ranges between 60 – 70 °C (Al-Sahali and Ettouney, 2007). Therefore, it is not surprised to notice that about 65% of the total capacity of production in the desalination industry is attributed to the thermal desalination including the MED process. Up to the authors' knowledge, the research on MED process is still required to alleviate the fresh water production cost by enhancing the performance efficiency besides keeping high-quality water. Specifically, the optimal number of effects in the MED process-based seawater desalination that attains the lowest fresh water production cost via model-based simulation has not been yet explored. Therefore, this research focuses on the implementation of an earlier model developed by the authors for MED process and an economic model gathered from the literature to investigate the optimal number of effects which can attain the lowest fresh water production cost for specified sweater operating conditions.

2. MED process model

Figure 1 shows the MED process that involves of a number of effects. External heat is used to rise the brine temperature within the first stage in order to evaporate the brine. The vapour from each stage supplies energies to the brine in subsequent stages. MED process is typically designed at different capacity that vary from 600 to 30,000 m^3/day, and the design is made according to two main arrangements: (a) the seawater boils in a vertical tube in a thin film flowing within the tube and vapour condensate on the heat-transfer tubes (b) the horizontal tube where the seawater feed is sprayed onto the outside surface of the tubes and vapour flows inside the horizontal tubes, which is condensed to produce the water. Table 1 shows the process model taken from our earlier work (Filippini et al., 2018)
Figure 1. Schematic diagram of MED process (Adapted from Alkaraghouli, 2013)

3. Economic model of MED process

The economic model developed by Druetta et al. (2014) and given in Table 2 was used to calculate the total production cost for MED process. In this respect, Table 3 presents the parameters used in the economic model of MED process. In this respect, the fresh

water production cost is the division of total annual production cost and the total annual productivity of MED process. Specifically, for any seawater thermal desalination process, the total annual cost (TAC) is the sum of the total capital cost (TCC) and annual operational cost (AOC). Principally, the total capital cost comprises the installation, equipment, and indirect costs. However, some other related costs such as the steam cost, chemicals cost, labour, etc. are listed in the operational and maintenance cost.

C_{steam}	External steam	0.004	($/kg)	K_{cond}	Coeff. for condenser	2.8	-

4. Simulation of the MED Process

The simulation of the MED process is carried out at specified seawater conditions of feed concentration and temperature of 39000 ppm and 25 °C, respectively. Moreover, Steam flow rate Ms and steam temperature Ts are assumed to be known as 8 (kg/s) and 70 (°C), respectively. The case study analysed in this paper corresponds the desalination plants installed in Gulf regions with somehow high seawater salinity. Figure 2 (a) shows the fresh water production cost ($/m^3) against the number of effects in MED process. This in turn showed that the optimum number of effects of 17 has entailed the lowest fresh water production cost for seawater desalination at the selected seawater operating conditions. Specifically, the lowest fresh water production cost is around 0.615 $/m^3. Interestingly, the fresh water production cost exponentially decreases with number of effects below 17. However, a slow progress in the fresh water production cost is observed as a result to increasing number of effects up to 17. Also, the simulation results of the Figure 2 (b) shows that the total annual cost is increased with increasing the number of effects. Basically, this is attributed to increasing both capital costs (from 5118362.5 $ to 19055098 $) and operating costs (from 862693.1 $/yr to 1190574 $/yr) as a result to increasing the number of effects from 8 to 20 in the MED process. Therefore, the minimum fresh water production cost observed in Figure 2 (a) can be ascribed to the progress of distillate flow rate that rapidly increased as a result to increasing number of effects. This in turn causes a rapid decrease in fresh water production cost despite the increase of total annual cost (Eq. (5) presented in Table 2). However, the increase of distillate flow rate beyond 17 effects was insignificant compared to a continuous increase in the total annual cost, which in turn results in a slow increase in the fresh water production cost (Figure 2 (a)). Figure 2 (c) shows the improvement in Gained Output Ratio (GOR) due to increasing number of effects. GOR value raised to its optimum of 17.06 as the number of effects hits 20. However, GOR alone cannot be the unique tool to measure the performance of thermal process as it does not account the impact of capital and other operating costs (such as pumping etc.). More important, the minimum fresh water production cost corresponds to an optimum GOR of 14.5 at 17 effects.

5. Conclusions

In this paper, an earlier model developed by the authors for multi effects desalination MED process was coupled with cost model to estimate the fresh water production cost under different number of effects and fixed seawater operating conditions. The cost model accounts for both capital and operating costs (such as steam, pumping, etc). The optimum number of effects was investigated via repetitive simulation, which illustrates the lowest fresh water production cost for seawater desalination. In this research, the optimum number of effects was obtained to be 17 with the corresponding minimum cost of 0.614 $/m^3. In this respect, the optimum GOR has been discovered for the optimum design. This current research can be used as a powerful tool to design the MED process and specially to address the optimum number of effects for any specified seawater operating conditions. It is fair to realise the insignificant implementation of the current methodology for an already instilled MED plant. Therefore, a comprehensive simulation-based optimisation methodology needs to be explored to investigate the optimal seawater operating conditions and steam flow rate that minimises the fresh water production cost for a fixed number of effects. This would be an interesting scope of the future research.

Abstract

Batch distillation is perhaps the oldest operation used for separation of liquid mixtures. It is commonly used to produce fine chemicals and specialised products as alcoholic beverages, essential oils, perfume, pharmaceutical and petroleum products. Rigorous modelling of batch distillation can be developed by assuming phase equilibrium, or by rate-based approaches. The last approach represents in a more realistic way the phenomena occurring in the column, since it considers the heat and mass transfer rates for vapor and liquid phases. Due to the nature of their operation, batch distillation columns are modelled by a set of differential and algebraic equations (DAE). The present work concerns the simulation of a batch distillation column using the rate-based model, using a simplified approach for the calculation of the mass transfer rates. The pilot scale column modelled in this work has four trays, a total condenser and a pot. This column was used for separating a mixture of 75% mol methanol and 25% mol ethanol. As a first approach, mass transfer rates are obtained through rate-based simulations in Aspen Plus V8.8 for a pseudo-batch distillation column, using the Ideal thermodynamic model. The set of equations representing the rate-based batch column was solved using a specialized software (Polymath 6.0), taking the mass transfer rates as constant and equal to those obtained in the Aspen Plus simulation. The operating time of the batch column was 80 minutes, the thermal duty was kept as 500 W for the whole operation time, and the final composition in the pot was 72% mol methanol. The proposed strategy allows obtaining the composition and temperature profiles for the column, although it is still necessary to develop a proper mass transfer model to be included in the set of equations.

Keywords: batch distillation, rate-based modelling, mass transfer rates.

1. Introduction

Batch distillation is commonly used in the chemical, petroleum, polymers and pharmaceutic industries, and in the production of other fine chemicals. It is preferred over continuous distillation when the production is relatively small, when high added-value products are obtained, or it is required to produce different products in a single column.

For years the modelling and simulation of distillation columns has been the subject of several research. Several works have been presented for the modelling of the batch columns starting with the most elementary, as the one presented by Rayleigh, to the most robust formulation presented by Mujtaba (2004).

Two different approaches are available for the rigorous modelling of the interactions between phases in batch distillation columns, namely, equilibrium model and rate-based (nonequilibrium) model. The first one assumes vapor and liquid to be in thermodynamic equilibrium, using the efficiency of Murphree to describe the deviation from equilibrium. Thus, the accuracy of the predictions depends on the values assumed for this efficiency. The rate-based model doesn't require assuming the efficiency of Murphree, however, it requires good predictions of mass transfer coefficients, interfacial areas and diffusion coefficients (Sorensen, 2014).

In a trayed distillation column, the vapor from a lower stage is brought into contact with the liquid from an upper stage, allowing the two phases to exchange mass and energy across their common interface. Krishnamurthy and Taylor (1985) developed a nonequilibrium model based on general multicomponent mass and energy transport and using different correlations for the calculation of the binary mass transfer coefficient. A nonequilibrium or rate-based model employs the film model and equations based on transport phenomena to predict the mass transfer rates. This model is based on the MERSHQ equations, which consist of total and component material balances, energy balances, mass and energy rates of transfer across the interface, summation of mole fractions, hydraulic equation for pressure drop and equilibrium equations at vapor-liquid interface. The rate-based model is accurate (Taylor et al. 2000), but much more complicated than equilibrium model, therefore a more robust computing equipment is required to solve the system of equations. Ramesh et al. (2007) comments that an accurate mathematical model is necessary for the study of the dynamic characteristics and control of a distillation column, which is particularly important for batch distillation. López-Saucedo et al. (2016) presented the rigorous modelling for the simulation and optimization of a reactive batch distillation column. In the present work, a model for the representation of a pilot-scale batch distillation column is developed, taking as bases the model developed by López-Saucedo et al. (2016) but avoiding the reactive terms, and adding the mass and heat transfer contribution. As a first approach, mass transfer rates are assumed as constants, and a strategy to determine preliminary values for such rates is presented. The accuracy of such assumption is validated by comparison with experimental data.

2. Case of study

The present work concerns the modelling and simulation of a batch distillation column using the rate-based model. The work in divided in four stages: experimental, modelling of the pilot scale column, simulation in Aspen Plus V8.8 and solution of the obtained system of equations (DAE), using a specialized software (Polymath 6.0).

The experimental work was performed in a batch distillation column consisting of four sieve trays, a pot and a total condenser (Figure 1). This column was used to separate a mixture of alcohols with initial composition of 75% mol of methanol and 75% mol of ethanol, with initial charge of 0.196 kmol of the mixture. The characteristics of the column are shown in Table 1. The operating time of the batch column was 80 minutes, the thermal duty was kept as 500 W for the whole operation time. Samples were taken in each stage and then analysed in a gas chromatographer.

Figure 1.-Pilot scale column

Table 1.-Physical parameters of the batch column

Parameter	Value
Pot diameter	0.3 m
Pot height	0.27 m
Tray diameter	0.06 m
Tray Spacing	0.09 m

The rate-based mathematical model was developed for the column under study, with the following assumptions: the vapor-liquid interface reaches thermodynamic equilibrium, the trays are in mechanical equilibrium, the condenser operates at total condensation, the pot and the condenser are equilibrium stages, and the pressure along the column is constant. This last assumption is valid due to the small size of the column.

To obtain a preliminary estimate of the mass and heat transfer rates, a simulation of the pilot scale column was performed in Aspen Plus V8.8, representing the system a pseudo-batch column, by simulating a continuous column with feed on the bottoms and a reflux ratio of 1 and heat duty of 500 W. The column is represented with the RadFrac module, using the rate-based option. Thermodynamic equilibrium is modelled through the *Ideal* thermodynamic model.

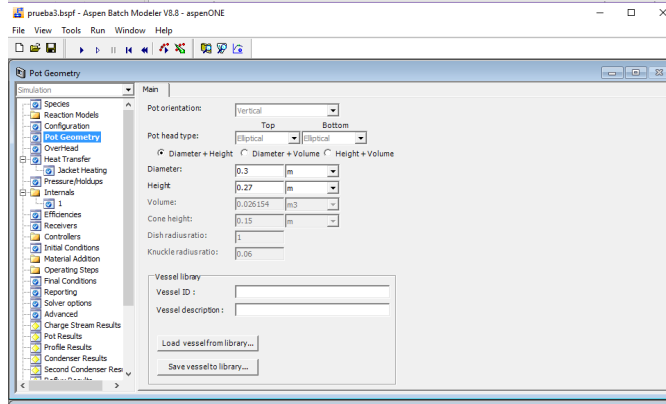
The solution of the model for the batch column requires initial values for all the time-dependent variables. Such values are estimated by using the Aspen Batch Modeler V8.8, which assumes equilibrium for all the stages. The main specifications for this simulation are shown in Figure 2. Using the initial values obtained in this simulation for an initial condition of total reflux, the rate-based model is codified and solved in Polymath 6.0, aiming to obtain the liquid composition profile.


Figure 2.-Data for Aspen Batch Modeler

3. Results

The equations used to model the behaviour of the trays on the column are presented in this section. The total material balances for the vapor and liquid phases are:

$$\frac{dM_j^V}{dt} = V_{j-i} - V_j - N_{T,j} \tag{1}$$

$$\frac{dM_j^L}{dt} = V_{j+i} - V_j + N_{T,j} \tag{2}$$

The component material balances for component i in vapor and liquid phases on stage j are:

$$\frac{dy_{i,j}}{dt} = \frac{V_{j-1}}{M_j^V} y_{i,j-1} - \frac{V_j}{M_j^V} y_{i,j} - \frac{N_{i,j}^V}{M_j^V} \tag{3}$$

$$\frac{dx_{i,j}}{dt} = \frac{L_{j+1}}{M_j^L} x_{i,j+1} - \frac{L_j}{M_j^L} x_{i,j} + \frac{N_{i,j}^L}{M_j^L} \tag{4}$$

The energy balances of vapor and liquid phases on stage j are:

$$\frac{dH_i}{dt} = \frac{V_{j-1}}{M_j^V} H_{j-1} - \frac{V_j}{M_j^V} H_j - \frac{e_j^V}{M_j^V} \tag{5}$$

$$\frac{dh_i}{dt} = \frac{L_{j+1}}{M_j^L} h_{j+1} - \frac{L_j}{M_j^L} h_j + \frac{e_j^L}{M_j^L} \tag{6}$$

Rate of mass and energy transfer across interface is given by:

$$N_{i,j}^V = N_{i,j}^L \qquad (7)$$

$$e_j^V = e_j^L \qquad (8)$$

The mass and heat transfer rates in each stage are shown in Table 2. The stage 1 corresponds to the tray over the pot and the stage 4 corresponds to the tray below the condenser.

Table 2.-Mass and heat transfer rates (kmol/s)

	Mass transfer rates (kmol/s)		Heat transfer rates (kJ/s)
Stage	Methanol	Ethanol	Liquid
4	-3.30E-07	2.93E-07	-0.00211
3	-2.75E-07	2.44E-07	-0.00181
2	-2.23E-07	1.99E-07	-0.00151
1	-1.78E-07	1.59E-07	-0.00123

The trend of the composition in the pot is to increase because the amount of methanol in the reboiler decreases, while the distillate contains mostly methanol. As expected, the mol fractions of methanol tend to decrease from the upper to the lower stages for both, experimental and simulated results (Figure 3).
Figure 3.- Comparison of simulated and experimental profiles for liquid composition of methanol.

For the studied mixture, the composition of the pot changed from 75 mol% to a final composition of 74 mol% of methanol in the experimental system, while the model

predicts a variation from 75 mol% to 69.13 mol% of methanol. This represents a difference of approximately 5.87 mol% between the experimental and the numerical results. This gap is reduced as the profile reaches the top of the column. The difference between experimental and numerical data is attributed to the assumption of constant mass transfer rates. Thus, as a part of our future work, a mass transfer model applicable to the studied system will be developed and validated.

4. Conclusions

A rate-based model has been developed to represent the separation of an alcohol mixture in a pilot scale batch column, assuming constant mass and heat transfer rates.

The mol compositions are similar between the experimental and simulation of the case of study. The experimental time was 80 minutes, while the simulation time was 53 minutes; in both case the same amount of distillate was obtained. The error between the experimental and simulated composition of methanol was 6% maximum and 1% minimum. The rate-based model developed provides a good approximation with the experimental results, although a reliable mass transfer model is still required.

An MPEC model for Strategic Offers in a Jointly Cleared Energy and Reserve Market under Stochastic Production

Evangelos G. Tsimopoulos, Michael C. Georgiadis[*]

Aristotle University of Thessaloniki, Department of Chemical Engineering, 54124 Thessaloniki, Greece

mgeorg@auth.gr

Abstract

This work, based on Stackelberg hypothesis, considers a conventional power producer exercising their dominant position in an electricity pool with high penetration of wind power production. A bi-level optimization model is used to provide optimal offer strategies for the aforementioned producer in a jointly cleared energy and reserve pool settled through an hourly auction process. The upper-level problem illustrates the expected profit optimization of the strategic producer while the lower-level problem represents the energy-only market clearing process through a two-stage stochastic program. The first stage clears the day ahead market, and the second stage presents the system operation in balancing time though a set of plausible wind power production realizations. The bi-level problem is recast into mathematical programming with equilibrium constraints (MPEC) which is then reformulated into an MILP. These transformations occur using the Karush-Kuhn-Tucker optimality conditions and the strong duality theory. The suggested model provides optimal strategic offers and local marginal prices under different levels of wind penetration and network line transmission capacities.

Keywords: MPEC, energy-only markets, LMPs, strategic offers, wind uncertainty

1. Introduction

In recent years the electricity generation industry has experienced a remarkable penetration of renewable energy resources. However, the inherently uncontrollable fluctuations of renewable generation have resulted in the change of operational framework, the development of new tools to handle the stochastic nature of non-dispatchable production, and the redesign of market clearing algorithms (Conejo et al. 2011). Concerning the strong penetration of renewable sources supported by a generous mechanism of subsidized production and priority dispatch, the role of conventional energy production is diminishing. Although the market recognises the critical role of the thermal plants as capacity providers, the latter are faced with unequal treatment and have to adopt specific strategic behaviour to ensure competitiveness. Within the above context, and considering the conventional energy production, this work investigates the reaction of an incumbent firm and examines its incentives to exert market power and ensure its dominant position to avoid energy profit losses.

2. Problem Statement

This work analyses the optimal offering strategies of a conventional (thermal) power producer which participates with other conventional as well as wind power producers in a jointly cleared energy and balancing auction under network constraints. A bi-level programming model is developed based on Stackelberg leader-follower hypothesis. The upper-level problem determines expected profit maximization of the considered strategic producer which depend on clearing local marginal prices (LMPs) of day ahead (DA) and real time (RT) $\lambda_{n\omega}^{RT}$ market obtained at the lower level problem. On the other hand, the lower-level problem represents the clearing price process ensuing the least cost of energy dispatch conducted by the system operator (SO). Thus, the lower-level problem is formulated in a linearized DC network as two-stage stochastic programming. The first stage facilitates the DA market and results in the optimal anticipated dispatch (DA scheduled energy production), and the LMPs received as dual variables. The second stage represents the balancing market under the realization of all the plausible wind production scenarios and derives real time dispatch (reserve deployments) and RT prices (Morales et al. 2012).For the following formulation the indices *i, o* and *j* indicate the strategic conventional units, the nonstrategic conventional units and the wind farms respectively while the index *d* indicates the demands of the system. Additionally, the indices *b* and *f* refer to power blocks offered by the conventional units *i, o* and the wind farms *j*, the index *k* refers to power blocks consumed by load *d* and the index *ω* refers to wind power production scenarios. The sets Ψ_n^i, Ψ_n^o, Ψ_n^j and Ψ_n^d map the generation units and loads on to the system and the set Θ_n defines the connection of the bus *n* with the other buses of the network. The parameters c_{ib}, c_{ob}, c_{jf}^{DA} and u_{dk} represent the marginal cost of offered power blocks of generation units and the marginal utility of load blocks. In addition, the parameters c_i^{up}, c_o^{up}, c_i^{down}, c_o^{down} and $c_{j\omega}^{RT}$ indicate the cost of offered regulations and wind power realization at balancing stage. In addition, the parameter B_{nm} denotes the susceptance of the line *n-m*. The *here* and *now* decision variables P_{ib}^{DA}, P_{ob}^{DA} and W_{jf}^{DA} represent the scheduled production of conventional units and wind farms respectively and the δ_n^o represents the voltage angle at DA stage. The *wait* and *see* variables $r_{i\omega}^{up}$, $r_{o\omega}^{up}$, $r_{i\omega}^{down}$ and $r_{o\omega}^{down}$ refer to upward and downward reserves offered by units *i* and *o*, the $W_{j\omega}^{sp}$ indicates the wind power production spillage of wind farm *j* under scenario *ω*, the $L_{d\omega}^{sh}$ indicates the load shedding of demand d under scenario *ω* and the $\delta_{n\omega}$ indicates the voltage angle at RT stage. Finally, O_{ib}^{DA} defines the price offer of generation block *b* of strategic unit *i* in DA market while O_i^{up} and O_i^{down} define the price offerσ of upward and downward reserveσ of strategic unit *i* in RT market respectively.

2.1 Bi-level Formulation

The bi-level stochastic optimization model is formulated to derive its optimal offers as follows:

Upper level problem

$$
\begin{aligned}
maximize \quad & \sum_{(i\in\Psi_n^i)b} \lambda_n^{DA} P_{ib}^{DA} - \sum_{ib} c_{ib} P_{ib}^{DA} + \sum_{(i\in\Psi_n^i)\omega} \lambda_{n\omega}^{RT} \\
& - \sum_{i\omega} \pi_\omega c_i^{up} r_{i\omega}^{up} - \sum_{(i\in\Psi_n^i)\omega} \lambda_{n\omega}^{RT} r_{i\omega}^{down} + \sum_{i\omega} \pi_\omega c_i^{down} r_{i\omega}^{down}
\end{aligned}
\tag{1}
$$

Lower level problem

minimize

$$\sum_{ib} O_{ib}^{DA} P_{ib}^{DA} + \sum_{i\omega} \pi_\omega O_i^{up} r_{i\omega}^{up} - \sum_{i\omega} \pi_\omega O_i^{down} r_{i\omega}^{down}$$

$$+ \sum_{ob} c_{ob} P_{ob}^{DA} + \sum_{o\omega} \pi_\omega c_o^{up} r_{o\omega}^{up} - \sum_{o\omega} \pi_\omega c_o^{down} r_{o\omega}^{down}$$

$$+ \sum_{jf} c_{jf}^{DA} W_{jf}^{DA} + \sum_{j\omega} \pi_\omega c_{j\omega}^{RT} \left(W_{j\omega}^{RT} - \sum_f W_{jf}^{DA} - W_{j\omega}^{sp} \right)$$

$$- \sum_{dk} u_{dk} L_{dk}^{DA} + \sum_{d\omega} \pi_\omega vLOL_d L_{d\omega}^{sh} \tag{2}$$

s.t.

$$- \sum_{(i\in\Psi_n^i)b} P_{ib}^{DA} - \sum_{(o\in\Psi_n^o)b} P_{ob}^{DA} - \sum_{(j\in\Psi_n^j)f} W_{jf}^{DA}$$

$$+ \sum_{(d\in\Psi_n^d)k} L_{dk}^{DA} + \sum_{m\in\Theta_n} B_{nm}(\delta_n^o - \delta_m^o) = 0 \quad :(\lambda_n^{DA}) \quad \forall n \tag{3}$$

$$- \sum_{i\in\Psi_n^i} r_{i\omega}^{up} + \sum_{i\in\Psi_n^i} r_{i\omega}^{down} - \sum_{o\in\Psi_n^o} r_{o\omega}^{up} + \sum_{o\in\Psi_n^o} r_{o\omega}^{down} - \sum_{d\in\Psi_n^d} L_{d\omega}^{sh}$$

$$- \sum_{j\in\Psi_n^j} W_{j\omega}^{RT} + \sum_{(j\in\Psi_n^j)f} W_{jf}^{DA} + \sum_{j\in\Psi_n^j} W_{j\omega}^{sp}$$

$$+ \sum_{m\in\Theta_n} B_{nm}(\delta_{n\omega} - \delta_n^o + \delta_m^o - \delta_{m\omega}) = 0 \quad :(\lambda_{n\omega}^{RT}) \quad \forall n, \forall \omega \tag{4}$$

$$\sum_b P_{ib}^{DA} + r_{i\omega}^{up} \leq \sum_b P_{ib}^{MAX} \quad :(\mu_{i\omega}^{max}) \quad \forall i, \forall \omega \tag{5}$$

$$\sum_b P_{ob}^{DA} + r_{i\omega}^{up} \leq \sum_b P_{ob}^{MAX} \quad :(\mu_{o\omega}^{max}) \quad \forall o, \forall \omega \tag{6}$$

$$r_{i\omega}^{down} - \sum_b P_{ib}^{DA} \leq 0 \quad :(\mu_{i\omega}^{min}) \quad \forall i, \forall \omega \tag{7}$$

$$r_{o\omega}^{down} - \sum_b P_{ob}^{DA} \leq 0 \quad :(\mu_{o\omega}^{min}) \quad \forall o, \forall \omega \tag{8}$$

$$0 \leq W_{j\omega}^{sp} \leq W_{j\omega}^{RT} \quad :(\kappa_{j\omega}^{min}, \kappa_{j\omega}^{max}) \quad \forall j, \forall \omega \tag{9}$$

$$0 \leq L_{d\omega}^{sh} \leq \sum_k L_{dk}^{DA} \quad :(v_{d\omega}^{min}, v_{d\omega}^{max}) \quad \forall d, \forall \omega \tag{10}$$

The objective function (1) optimizes the expected profit of the strategic producer, and it is defined by the revenues from the day DA and RT market minus the actual incurred cost. The objective function (2) optimizes the expected cost of the power system operation conducted by SO. It consists of the scheduled production cost and the scenario dependent reserve deployment, spilling wind power and shedding load cost in real time operation. Constraint (3) enforces the energy balance at each node and the transmission capacity limits between them at DA. Thus, the total power flowing into bus *n*, which is the algebraic sum of generation and load at the bus, should be equal to the power flowing away from the bus. Constraint (4) counterbalances the imbalance occurred in RT due to the uncertain wind production arranging the reserve deployment

and the load curtailments. Constraints (5), (6), (7) and (8) ensure that unit generation is above zero and below maximum capacity P_{ib}^{MAX} and P_{ob}^{MAX} of units i and o capturing the coupling between anticipated dispatch and deployed reserve. Constraints (9) and (10) indicate that the wind energy spillage cannot exceed the scenario dependent actual wind energy production $W_{j\omega}^{RT}$ and the involuntary load curtailment cannot exceed the actual load consumption. Moreover, other constraints enforce transmission capacity limits between two buses, upper and lower bounds of voltage angle at each bus. Finally, the bus $n1$ is defined as slack bus thus δ_{n1}^{o} and $\delta_{(n1)\omega}^{o}$ equal to zero.

2.2 MPEC formulation and linearization

Considering the continuity and the convexity of the lower problem, the bi-level problem is reduced to an MPEC through first-order KKT optimality conditions. In this case, the Lagrange multipliers have the same meaning with the dual variables in linear programming. Using disjunctive constraints to linearize the KKT complementarity constraints (Fortuny-Amat and McCarl, 1981) as well as the strong duality theorem in combination with some of the KKT equality constraints to eliminate the non-linear terms within objective function (1) (Ruiz and Conejo, 2009), the MPEC is reformed in an MILP solvable by commercial solvers such as GAMS/CPLEX.

3. Illustrative example

The proposed clearing market formulation is applied in a six-node system sketched in Fig. 1. The conventional generating units i1, i2, i3 and i4 belong to the strategic producer and the o1, o2, o3 and o4 belong to non-strategic producers. The technical data of the units is taken from Ruiz and Conejo (2009). Two wind farms j1 and

Figure 1. six-bus system

j2, located at bus n2 and n5, have installed capacity of 100 MW and 70 MW, and their scheduled power production is offered in one block with zero marginal cost. Wind farms' uncertain power production is realized through three scenarios, ω1 (high production) with 100 MWh and 70 MWh, ω2 (medium production) with 50 MWh and 35 MWh, and ω3 (low production) with 20 MWh and 15 MWh while occurrence probability of each scenario is 0.2, 0.5 and 0.3 respectively. A total demand of 1 GWh is allocated according to Figure 1. Load d1 accounts for 19 % and loads d2, d3 and d4 account for 27 % of the total demand each. Additionally, data about demand bids (energy and utility marginal cost) for each period of time comes from Ruiz and Conejo (2009). Finally, the value of the involuntary load reduction is 200 euro/MWh for all demands and all the connecting lines have a transmission capacity of 500 MW with susceptance equal to 9412 per unit.
4. Results

4.1. Uncongested network solution

Based on the above information the proposed MILP model is applied to the system and solved using GAMS/CPLEX. When the strategic producer offers at marginal cost, the DA clearing price is constant throughout the 24-period time at a level of 11.260 /MWh. However, when the strategic producer exerts their market power the DA
Figure 2. DA clearing prices [€/MWh]
Figure 3. RT clearing prices [€/MWh]

clearing price is raised, while fluctuating between 16.130 and 19.200 €/MWh as shown in Figure 2. Similarly, the RT clearing prices are raised too. More specifically, in high wind scenario

$\omega 1$ realization the RT price increases from 9.280 to 9.570 €/MWh, in medium wind scenario $\omega 1$ the RT clearing price leaves the level of 11.470 €/MWh and moves in a range between 14.254 and 20.394 €/MWh, and in low wind scenario $\omega 3$ the price rockets from 12.230 to 23.630 €/MWh as presented in Figure 3. In both cases, the prices are the same in all buses at each time period as line capacities are enough to facilitate the energy transaction. The proposed model results in an increase in the total expected profit of the strategic producer from 9,326 € to 67,556 € even though the producer's scheduled power production as well as its deployed reserve decreases in all wind scenarios.

4.2. Congested network solution

In the previous case the maximum power flow through line 3-6 is 227 MW. If the line capacity is reduced at the level of 240 MW, slightly above the maximum flow, the results

remain the same when the strategic producer acts as price taker. However, the proposed MILP formulation shows that the strategic producer can make offers in such a way that the system becomes congested resulting in different LMPs of DA and RT clearing prices at specific time periods as illustrated in Figures 4 and 5 respectively. It can be seen that bus n6 exhibits the highest price giving the strategic producer the opportunity
Figure 2. DA clearing prices [/MWh]
Figure 3. RT clearing prices [/MWh]

to increase the profit of unit i4. In that way the total expected profit of the strategic producer is slightly higher compared to that of uncongested network. Additionally, in the uncongested case the maximum power flow through line 4-6 is 24 MW. If the capacity of the line is reduced to 20 MW, slightly below the maximum flow, the network becomes congested under cost offer optimization, resulting in different LMPs and profit losses for the strategic producer. However, applying the proposed MILP formulation, the strategic producer changes the mixture of units' production keeping the line uncongested and the profit high.

4.3. Wind power production increment

In this case, the level of wind power penetration increases from 10 % to 14.16 % of the total installed capacity. More specifically, the power production of the wind farms j1 and j2 is 150 MW and 100 MW respectively in high wind scenario ω1, 75 MW and 50 MW in medium wind scenario ω2, and 30 MW and 20 MW in low wind scenario ω3. It can be seen in Fig.6 that the

Figure 4. Profit of strategic units under different

level of wind power penetration

expected profits of unitς i1 and i2 are reduced in all wind scenarios. Considering unit i4 the expected profits decrease in high wind scenario ω1; however, the expected profits increase in medium and low wind scenarios as the unit becomes more involved in reserve supply. Nevertheless, even if the total expected profits of unit i4 rise, the total expected profits of strategic producer decrease from 67,556 euro to 59,589 euro, indicating that wind power production can be used as a tool for market power mitigation.

5. Conclusions

In this work based on Stackelberg hypothesis, an MILP is developed to derive optimal offer strategies for a conventional power producer participating in a jointly cleared energy and reserve market under high penetration of wind power production. The model concerns energy-only markets. Co-optimizing scheduled energy and reserve deployment through two-stage stochastic programming, it gives insight information on LMPs and the way they are configured when the strategic producer exercises its dominant position in the market. Furthermore, the model provides information about how line capacities and network congestions can be used for the benefit of the strategic producer and indicates that wind power production can be used as an instrument of market power mitigation. Future work should involve a larger number of wind production scenarios and scenario reduction techniques. The model should also incorporate intertemporal constraints such as units' ramp-up and ramp-down limitations as well as non-convexities, e.g., unit minimum power production and unit start-up and shut-down

Abstract

Online scheduling requires appropriate timing of rescheduling procedures, as well as the determination of relevant horizon length. Optimal choices of these quantities are highly dependent on the uncertainty of the scheduling environment and may vary over time. We propose an approach where a neural network is trained to make online decisions on these quantities, as well as on the choice of the rescheduling method (mathematical programming or metaheuristics). In our approach, the neural network is trained using neuroevolution of augmenting topologies (NEAT) in a simulated environment. In this paper, we also optimize the rescheduling interval and horizon length of a conventional periodically occurring rescheduling on a dynamic routing problem. The resulting approach is the baseline for the development of the proposed neural network approach.

Keywords: online scheduling, horizon length, scheduling interval, neural network, NEAT

1. Introduction

Online scheduling of industrial processes is a demanding task, mainly due to a large number of solution candidates and uncertainty in scheduling parameters. Considering batch processes, the most common optimization approach in offline scheduling is mixed-integer programming (MIP), using modeling formalisms, e.g. resource-task network (Pantelides, 1994), state-task network (Kondili et al., 1993) or generalized disjunctive programming (Raman and Grossmann, 1994). Given a reasonably large amount of computational time, these approaches can often find the optimal solution. However, in online scheduling, the duration of the optimization process is constrained due to the moving time horizon, which significantly compromises the optimality of the solution. Another aspect to consider is that the later the optimization process is initiated, the more accurate are its scheduling parameters. This raises questions, such as what is the optimal rescheduling interval and what is a relevant length for the scheduling horizon. For a recent review of online scheduling, the reader may wish to consult the paper by Gupta et al. (2016).

We propose an approach where an artificial neural network trained to decide when to initiate a rescheduling process, what length to define for the time horizon and which optimization strategy (mathematical programming or metaheuristics) to use. In many previous studies, neural networks have been used to learn dispatching rules from the historical data of scheduling decisions (Priore et al., 2014). However, this approach can typically only mimic the historical decisions, and therefore the optimality of the scheduling solu-

tions is highly dependent on the quality of the given historical data. Our neural network approach operates at a higher level; it exploits the strength of MIP at finding the optimal, or near-optimal solution, and focuses on the allocation of the computational resources in the changing scheduling environment.

More specifically, we propose to use neuroevolution of augmenting topologies (NEAT), introduced by Stanley and Miikkulainen (2002), to train the neural network. NEAT is a genetic algorithm that simultaneously evolves the topology and weighting parameters of the neural network. Such et al. (2017) report the performance of the evolutionary neuroevolution algorithms to compare well against the gradient-based backpropagation algorithms. A key feature of NEAT is that the evolution process is initiated from very simple neural networks, the topology of which is then incrementally increased complexity during the evolution. The feature reduces unnecessary complexity of the final neural network, and is not possible using gradient-based algorithms. Recently, Hausknecht et al. (2014) applied NEAT to train a neural network to play 61 different Atari 2600 games, where the controls for the player are to move a joystick and press a button. The controls for our neural network are also of a similar low level of complexity (see the second paragraph), but the critical aspect is their timely execution.

In this paper, we first define a rescheduling problem (Section 2), suitable to be used as a test case for our neural network-based rescheduling approach. For the sake of simplicity, we define the underlying optimization problem to be a routing problem. However, our approach is also applicable to rescheduling of other industrial processes, e.g. batch processes. In Section 3, we tune the horizon length and rescheduling interval of the conventional periodically occurring rescheduling approach. This approach is a benchmark for our neural network-based approach. Finally, in Section, 4, we describe the intended input and output signals for the neural network.

2. Dynamic routing problem

Let us consider a square region, having dimensions 1000×1000 m, and a vehicle traveling in the region at a constant speed of $v = 10$ m/s. The purpose of the vehicle is to visit n sites in the region before site-specific due dates. Each site has an order date, at which the vehicle receives the location and due date of the site. The objective of the optimization problem is to minimize the delay sum of visiting the n sites. Since scheduling decision must be made with limited information, finding the optimal solution to the problem requires rescheduling.

As an optimizer, we here use ant colony optimization (ACO) (Dorigo and Gambardella, 1997), which is a probabilistic metaheuristic search method of finding good paths in a graph. In the method, ants communicate by laying pheromone on paths between nodes. The laid pheromone concentration of an ant is proportional to the objective function value of the route the ant traveled. When a new ant is at node i, it chooses the path to node j with probability

$$p_{ij} = \frac{\phi_{ij}^{\alpha} d_{ij}^{\beta}}{\sum_{i,j=1}^{n} \phi_{ij}^{\alpha} d_{ij}^{\beta}}, \tag{1}$$

where ϕ_{ij} and d_{ij} are the pheromone level and desirability[1] of the path (i, j). where α and β are influence parameters[2]. We use a population size of 200. We have implement ACO using the Python module ACOpy (Grant, 2018).

In this and the next section, we study periodic rescheduling with fixed interval and horizon length. At $t = 0$, the vehicle starts to follow an initial path, determined by a greedy algorithm (which is defined to always choose the node lying closest to the current node). The path is then updated when the first rescheduling procedure is finished. The computational budget of all the rescheduling procedures during the time span is restricted to 50 CPU seconds. The computational budget is distributed evenly between the rescheduling processes. Therefore, a frequent rescheduling will have a small computation budget per rescheduling process, and vice versa. Each rescheduling procedure is associated with times t_{info} and t_{exe}, the difference of which is the duration of the procedure. The rescheduling is conducted using the information available at t_{info}, whereas t_{exe} is the planned start time of the new schedule.

2.1. A simple numerical example

Let us next present a solution to a simple routing problem of nine sites. The sites are randomly distributed inside the region (Figure 1(a)), and their due dates are randomly selected from the time interval of [0, 500s] (Table 1). Further, the order dates of sites 1 to 7 are set to 0 s, while the order dates of sites 8 and 9 are randomly selected from the time interval of $[0, t_{\text{due}}]$, where t_{due} is the due date of the site (Table 1).

Table 1: Order and due dates for the sites in the simple numerical example.

site [-]	order date [s]	due date [s]	site [-]	order date [s]	due date [s]
1	0	46	6	0	400
2	0	198	7	0	346
3	0	343	8	4	43
4	0	14	9	185	439
5	0	279			

In this numerical example, we choose to use a scheduling interval of 50 s and horizon length of 500 s (i.e. the entire time span of the problem). Figure 1(a) shows the initial route (determined by a greedy search) for the vehicle. Further, Figures 1(b)-1(d) visualize intermediate states of the process. At $t_{\text{exe}} = 5$ s, the optimizer schedules the visit to the most critical site 1 before visiting sites 6 and 2. At $t_{\text{exe}} = 55$ s and $t_{\text{exe}} = 205$ s, the optimizer includes visits to sites 8 and 9, respectively, in the schedule. The locations and due dates of these sites were not known at the start of the time span. Figure 1(e) shows the final (realized) route of the vehicle. The delay sum of the final route is 235.30 s, which is caused by the vehicle failing to meet the due dates at sites 1, 4 and 8 (see Figure 1(f)).

3. Tuning of the rescheduling interval and horizon length

The purpose of the numerical example in the previous section was to provide an introduction to the dynamic routing problem, which we intend to study with the neural network

---

[1] In this work, we use the distance of a path as its desirability measure.
[2] In this work, we use values $\alpha = 1$ and $\beta = 3$.

(a) initial route

(b) $t_{\text{info}} = 0$ s, $t_{\text{exe}} = 5$ s

(c) $t_{\text{info}} = 50$ s, $t_{\text{exe}} = 55$ s

(d) $t_{\text{info}} = 200$ s, $t_{\text{exe}} = 205$ s

(e) final realized route

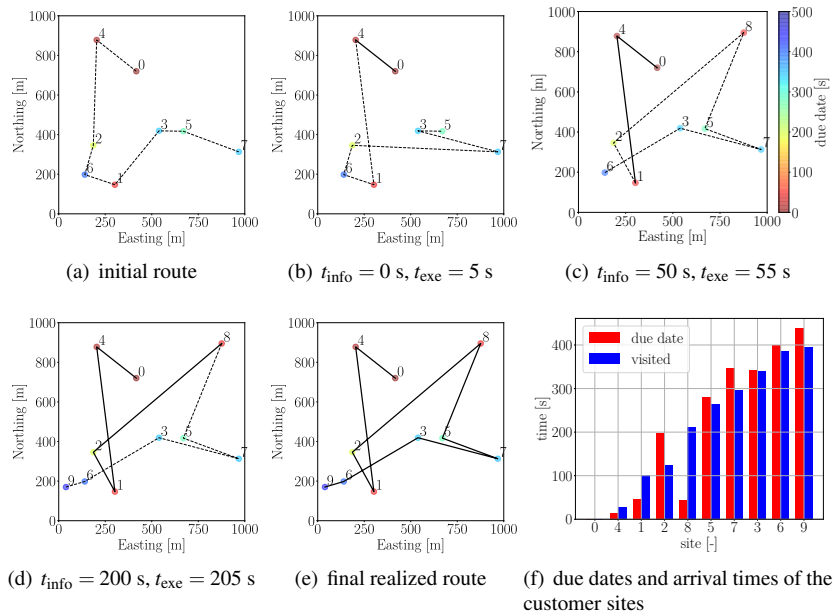
(f) due dates and arrival times of the customer sites


Figure 1: Representative states and the final results of the rescheduling procedure with nine sites to be visited. The locations and due dates of sites 8 and 9 are received at $t = 4$ s and 185 s, respectively, whereas the other orders are already known at $t = 0$. Continuous path represents realized route of the vehicle, and dashed line the scheduled route.

based approach. In this section, we examine a similar, but larger, routing problem with a total of 50 sites, and a time span of 1000 s. The locations and due dates of 40 sites are known at $t = 0$, whereas for the remaining 10 sites the information is obtained again at a random time point in the interval of $[0, t_{\text{due}}]$, where t_{due} is the due date of the site.

When using the periodically occurring rescheduling procedures, the optimal values for the rescheduling interval and horizon length are problem-dependent. Thus, in this section, we also use a grid search to systematically seek an optimized combination of the two parameters. The results of the grid search are shown in Figure 3. Out of the tested parameter combinations, the best final objective value (i.e. the delay sum) is obtained by the scheduling interval of 120 s and the horizon length of 500 s. We omit those parameter combinations, in which the scheduling interval is larger than the scheduling horizon (see the bottom right corner of Figure 3), as the vehicle would need to wait at certain sites for the schedule to be updated. Based on the results, the performance of the rescheduling procedure is poor for combinations lying close to this constraint, but also for combinations with very frequent rescheduling and long horizon length. In the former, the algorithm does not exploit enough information it has about the future, where as in the latter the algorithm does not have enough computational time to find good solutions (to relatively large scheduling problems).

Finally, let us examine the rescheduling procedure with the optimized rescheduling interval and horizon length. Figures 2 and 4 visualize the initial route, the intermediate state at

(a) initial route   (b) $t_{info} = 240$ s, $t_{exe} = 245.56$ s   (c) final realized route
Figure 2: Representative states and the final results of the rescheduling procedure with 50 sites.
Figure 3: A grid search of best-performing rescheduling interval and horizon length. The best parameter combination is highlighted by a circle. Darkest red points exceed the scale.
Figure 4: Due dates and arrival times of the final route (Figure 2(c)).

$t_{exe} = 245.56$ s and the final realized route of the rescheduling procedure. The delay sum of the final route is 992.89 s. Despite being a solution to a larger scale problem, the same features are also present here as in the simple example (Section 2.1): sites with urgent due dates are prioritized and, as the time proceeds, new orders are included in the schedule.

4. Proposed input and output signals

The periodically occurring rescheduling with tuned interval and horizon length seems to work reasonably well for these relatively small-scale scheduling problems. Another possible approach would be to trigger the rescheduling always when new information is obtained. However, the rescheduling decisions made by these approaches may be compromised, especially in larger problems, or if new information is obtained more frequently.

Thus, we propose the scheduling decisions to be made using a neural network that is trained by the NEAT algorithm. Figure 5 shows the input nodes we propose for the neural network. The input signals represent changes in the scheduling environment, the status of the ongoing rescheduling procedure, and the remaining computational resources.

At each evaluation, the neural network decides to either run a rescheduling procedure, using metaheuristics or mathematical programming, or to do nothing (depending which of the three top output nodes receives the highest signal). In addition, the neural network includes signals for the horizon length and allocated computational time for the possible rescheduling procedure.
Figure 5: Proposed input and output signals for the neural network. Here, the neural network is depicted as a box as in NEAT its topology is decided during the training procedure.

5. Conclusions

We propose the rescheduling decision in online scheduling to be made by a neural network, trained using the NEAT algorithm. As a first step, this paper presents a dynamic routing problem suitable to be used as a demonstration and benchmarking problem for our approach. We optimized the rescheduling interval and horizon length of the conventional periodically occurring rescheduling procedure, in order to obtain a relevant baseline approach. The future work involves training and evaluation of the NEAT algorithm for the presented routing problem.

Model-Based Bidding Strategies for Simultaneous Optimal Participation in Different Balancing Markets

Abstract

Due to the increasing share of intermittent renewable energy sources, energy-intensive enterprises are nowadays motivated to actively participate in electricity markets. They can do so by marketing their operational flexibility either at spot markets or by offering ancillary services on demand, such as balancing power. We propose an optimization-based methodology to select which capacity to offer at which market. We extend our framework for optimizing the bidding strategy at the primary balancing market (Schäfer et al. (2019)) to a simultaneous participation in both the primary and the secondary balancing market. We solve the resulting optimization problem using a hybrid stochastic-deterministic approach. The framework applies a genetic algorithm with a subordinated mixed-integer linear solver that allows for marketing the remaining flexibility at spot markets through solving a scheduling problem. For an industrial aluminum electrolysis, we demonstrate the efficacy of the approach to identify profitable bidding strategies. We show for an exemplary week with price data from 2018 that by optimal participation in balancing markets, savings of more than 10 % in weekly costs are enabled compared to a non-flexible operation.

Keywords: Demand side management, Aluminum electrolysis, Ancillary service markets, Mixed-integer nonlinear programming, Model-based bidding strategies

1. Introduction

The increasing share of electricity generation from intermittent renewable sources and the involved increasing volatility at electricity markets represent a severe challenge for the energy-intense industry (Mitsos et al. (2018)). However, at the same time, flexible consumers can also benefit from these circumstances by adapting their consumption to fluctuating market signals (e.g., Ghobeity and Mitsos (2010); Mitra et al. (2012)). In addition to that, consumers also have the opportunity to offer parts of their flexibility range at ancillary service markets, which opens further promising revenue potentials (Paulus and Borggrefe (2011); Dowling et al. (2017)). It is thus crucial to have systematic approaches for selecting which capacity to offer at which market (e.g., Zhang et al. (2015); Otashu and Baldea (2018)), as usually a reserve capacity is not allowed to be marketed at the same time at multiple markets. Furthermore, in some important market environments like the European balancing market, the prices that market participators ask for the provision of the ancillary services are of high relevance as they not only determine the probability of acceptance of an offer but also define the potential revenues. In order to balance these trade-offs, we recently proposed to formulate the optimal bids at the market for primary balancing power (PRL) as a two-stage stochastic optimization problem where remaining capacities after acceptance or rejection of the individual bids can be used for optimization at spot electricity markets (Schäfer et al. (2019)).

In this work, we extend the formulation to cope with more than one balancing market simultaneously. More precisely, we also consider the market for secondary balancing power (SRL) that opens further revenue potentials, but also poses different rules for bidding than the PRL market. In order to cope with the increased complexity of the resulting optimization problem, we use a hybrid stochastic-deterministic solution approach. We apply the approach to an industrial aluminum electrolysis to calculate the optimal bidding strategy for one exemplary week from 2018. Finally, we discuss revenue potentials that are enabled via the optimal strategy in comparison to a pure marketing at the spot market and a single bidding at the PRL market only.

2. Primary and secondary balancing market

Both the German PRL and SRL market are auction markets where all participators are allowed to submit their individual bids. In case of PRL, one bid consists of a capacity [MW] reserved for balancing power for the entire horizon (one week) and a capacity price [EUR/MW] that the bidder is willing to accept as compensation. Once the auction is closed, those bids with the lowest capacity prices are accepted, until the total demand of PRL is satisfied. Note that if the bid is accepted, the capacity price is paid irrespectively of whether the held capacity is actually retrieved. The smallest capacity that can be offered at the PRL market is 1 MW. The increment is 1 MW. At the SRL market, there are three important differences: (i) the horizon is subdivided into periods that take into account the varying demand for balancing power in the course of the horizon, (ii) capacities for a load reduction and a load increase can be offered separately, and (iii) participators need to further submit an asked energy price [EUR/MWh] that is only paid for the actual retrieval of the balancing power. These energy prices determine how often the capacities are retrieved, i.e., capacities with low energy prices are retrieved more often. The smallest capacity that can be offered at the SRL market is 5 MW. The increment is again 1 MW.

3. Model-based bidding

3.1. Definitions and preliminary assumptions

For marketing the remaining flexibility, we herein only consider the day-ahead market. We assume that day-ahead prices for the entire week are known when the bidding takes place. Price data is retrieved from EPEX SPOT (www.epexspot.com). All data concerning balancing power is retrieved from the central auction platform REGELLEISTUNG.NET (www.regelleistung.net).

For each balancing power product j, we consider only one submitted bid. Placing more than one bid has been shown in our previous work to have only minor influences on potential revenues (Schäfer et al. (2019)). A bidding strategy thus comprises 14 variables: a capacity P_j and a capacity price CP_j for PRL as well as for each of the four considered SRL products (two load directions *POS* and *NEG* with each two periods denoted by *HT* and *NT*) plus an energy price EP_j for each of the SRL products. The decision variables are summarized in the vector $\mathbf{x}$. We assume that the individual bids are accepted once the submitted asked capacity prices are lower than the upcoming maximum accepted ask prices for the respective products. For methods to estimate the marginal price, we refer to the relevant literature (e.g., Box and Jenkins (1994)). To simplify the presentation and discussion, we herein assume that the maximum accepted ask price of product j is normally distributed around its real value μ_j with a standard deviation of $\sigma_j = 0.05\mu_j$. Thus, the probability of acceptance p_j for the offered capacity for product j reads

$$p_j = \frac{1}{2}\left(1 - \mathrm{erf}\left(\frac{CP_j - \mu_j}{\sqrt{2}\sigma_j}\right)\right), \quad j \in \{PRL, POSHT, NEGHT, POSNT, NEGNT\}. \quad (1)$$

Other probability distributions can be used as well, as long as the respective cumulative distribution functions can be computed. Note that when using the hybrid stochastic-deterministic solution approach presented, no further assumptions on the probability distribution are required, e.g., concerning availability of gradients or relaxations.

The compensation payments, i.e., the revenues from a balancing power product R_j, can be calculated using the following equations. In case of PRL, capacity and capacity price are just multiplied (Eq. (2)). In case of the SRL products, a second term is added for the compensation of the actual retrieved energy E_j over the entire horizon (Eq. (3)). We express the relation between E_j and OP_j via an exponential function. Parameters of the functions are fitted to historic retrieval data.

$$R_j = CP_j \cdot P_j, \quad j \in \{PRL\} \tag{2}$$

$$R_j = CP_j \cdot P_j + OP_j \cdot E_j, \quad j \in \{POSHT, NEGHT, POSNT, NEGNT\} \tag{3}$$

$$E_j = P_j \cdot \exp(a_j + b_j \cdot OP_j), \quad j \in \{POSHT, NEGHT, POSNT, NEGNT\} \tag{4}$$

3.2. Formulation of the optimization problem

We minimize the expected weekly costs ϕ, wherein the compensation payments from the balancing markets are considered as negative costs. ϕ itself can be written as a probability-weighted sum over mutually exclusive scenarios (Eq. (5)). The scenarios arise from the combination possibilities of acceptance and rejection of the individual bids. Considering one bid for each of the five balancing power products, there are $N = 2^5 = 32$ possible scenarios. Scenario i can be characterized by the set of accepted bids j_i^*. The probability for one scenario p_i as well as the revenues R_i can be calculated by summation or multiplication of the individual p_j's (Eq. (6)) and R_j's (Eq. (7)) respectively. Furthermore, in each of the scenarios, the remaining flexibility range, i.e., the part of the original flexibility range which has not been reserved for provision of balancing power, can be marketed at the day-ahead market in order to lower the weekly costs without the revenues (C_i's). This is done by solving an integrated scheduling model which is denoted as the function $C^*(\cdot)$ in the following.

$$\min_{\mathbf{x}} \ \phi = \sum_{i=1}^{N} p_i (C_i - R_i) \tag{5}$$

$$\text{s.t.} \ p_i = \left(\prod_{j \in j_i^*} p_j \right) \cdot \left(\prod_{j \notin j_i^*} (1 - p_j) \right), \ i = 1 \ldots N \tag{6}$$

$$R_i = \sum_{j \in j_i^*} R_j, \ i = 1 \ldots N \tag{7}$$

$$\text{Eq. (1)-(4)} \tag{8}$$

$$C_i = C^*\left(P_{j \in j_i^*}, E_{j \in j_i^*} \right), \ i = 1 \ldots N \tag{9}$$

$$P_j \in \{1, \ldots, P_{j,max}\} \tag{10}$$

For setting up the function $C^*(\cdot)$ for the process considered in the case study - an industrial aluminum process - we refer to Schäfer et al. (2019). Therein, we describe a mixed-inter linear programming (MILP) scheduling formulation for optimizing the electricity consumption of the process considering operating limits, off-design efficiency losses and opportunity costs due to the provision of balancing power. In this work, we only slightly adjust the model by accounting for surpluses or deficits in the energy balance of the cell due to the retrieval of SRL. The maximum capacity that can be offered in product j are set to 10 MW for PRL and 22 MW for SRL.

3.3. Hybrid stochastic-deterministic solution algorithm

As discussed in Schäfer et al. (2019), the mixed-inter nonlinear optimization program (MINLP) given in Eq. (5)-(9) shows a similarity with two-stage stochastic programs. That is, selecting a bidding strategy **x** represents the first stage, the subordinated MILP scheduling problems (Eq. (9)) represent the second stage. A direct solution of (5)-(9) using state-of-the-art deterministic MINLP solvers is considered prohibitive. One possible approach to a deterministic solution would be the use of tailored decomposition algorithms exploiting the structure.

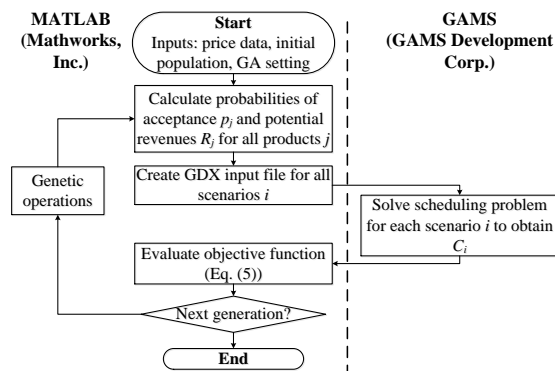
As an alternative, the use of a hybrid stochastic-deterministic method appears promising here. More precisely, the stochastic solver that varies the first-stage variables **x** invokes an external MILP solver in a black-box manner. The single MILP problems for each scenario can be solved efficiently within short time using state-of-the-art MILP solvers. Furthermore, parallelization of the optimizations for single scenarios is easily possible. We herein use a genetic algorithm (GA) as stochastic solver. The framework (see, Figure 1) uses the GA supplied in MATLAB R2018a's Global Optimization Toolbox (Mathworks, Inc). The subordinated scheduling problems are implemented in GAMS v.25.1 (GAMS Development Corp.) and are solved using CPLEX v.12.8 (IBM Corp.).


Figure 1: Flow diagram of the hybrid stochastic-deterministic solution algorithm.

4. Case study

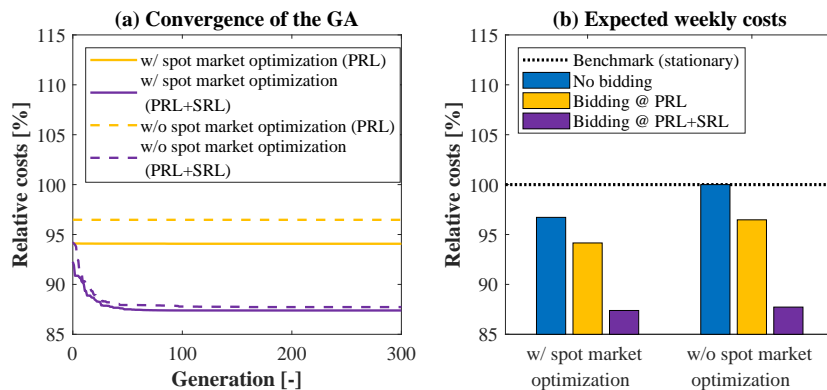
As a case study, we calculate the optimal bidding strategy for the second calender week of 2018. We conduct all calculations on a server with two Intel® Xeon® CPUs X5690 with 3.47 GHz and 96 GB RAM. For solution of the subordinated MILPs in parallel, the GAMS Grid Facility is used. The GA is stopped after evaluation of 300 generations with a population size of 70. The respective convergence plots of the GA are given in Figure 2 (a). Six cases are considered: no balancing market participation, a pure bidding at the PRL market, and a simultaneous bidding at the PRL and the SRL market, each of them once with the possibility to optimally market the remaining flexibility at the spot market (day-ahead) and once without this possibility. The longest run (bidding at PRL and SRL market with optimization at the spot market) took approximately 72 h, all others finished in substantially less time. Note however that all runs converged to the final value within a relative tolerance of 10^{-3} in less than 100 generations. This runtime is not prohibitive considering a horizon of the bids of one week. Calculations have been repeated with


Figure 2: (a) Convergence plot of the GA. Lines indicate strongest individual of each generation. Solid lines: with optimal scheduling at spot market, dashed lines: without. Colors like in (b). (b) Economic evaluation of the optimal bidding strategy once with optimization at spot market and once without. The dotted black line is the benchmark case with constant production and spot prices. Blue bars: no balancing market participation, orange bars: bidding only at PRL market, purple bars: bidding at both PRL and SRL market.

different GA settings, however no significant differences neither in optimal variable values nor in the objective values have been found.

Figure 2 (b) further compares the expected costs following the optimal bidding strategy on both the SRL and the PRL market to a pure optimization at the spot market. We consider a stationary operation under day-ahead prices as a benchmark scenario. One sees strong economic benefits in actively marketing the operational flexibility in the considered week, which allows for overall savings of $> 10\%$ compared to a non-flexible operation. Figure 3 gives additional information about the selected bidding strategies. Note that in both cases (with and without optimization at the spot market) the most probable scenario by far is that all bids are accepted and that therefore all capacities depicted likely have to be reserved for balancing power. One sees only a minor influence of the spot market optimization in the sense that slightly more conservative prices are asked (decreased probability of the scenario) and that only a little larger part of the entire flexibility remains that is not offered as balancing reserves. Together with Figure 2 (b), this indicates a strong advantage of the balancing over the spot markets for that week. That is, the optimal bidding strategy aims - when possible - at offering almost the entire flexibility range at balancing markets and ensures that all offered capacities are likely accepted by asking conservative prices. The ability to market remaining flexibility at the spot market does not significantly change this strategy and consequently, does not enable additional savings.

5. Conclusion

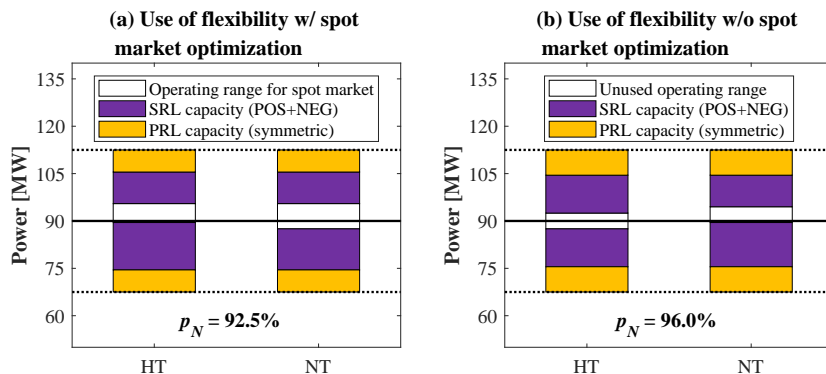
We present a framework for model-based bidding at the market for primary and secondary balancing power simultaneously. We solve the resulting optimization problem using a tailored hybrid stochastic-deterministic solution approach. Considering an exemplary week from 2018, we calculate the optimal bidding strategy for an industrial aluminum electrolysis. We demonstrate that the approach effectively identifies bidding strategies which allow for substantial savings. Furthermore, we show that a balancing market participation can show substantially greater economic potentials than a pure trading at spot markets. Future work should aim at the rigorous deterministic solution of the bidding problem, e.g., through application or tailoring of decomposition techniques


Figure 3: Capacity that is offered as balancing power (orange: PRL, purple: SRL) for the two time periods. (a) is with optimization at spot market and (b) without. Solid black line represents the nominal operating point, dotted black lines correspond to bounds of the operating range. p_N denotes the probability that all bids are accepted. Note that in (a), the remaining white part corresponds to the capacity available for spot market trading.

for MINLPs that would allow for a separation into nonlinear bidding and MILP scheduling sub-problems. Here, the reader is referred to, e.g., Li et al. (2012) for nonconvex generalized Benders decomposition or Mouret et al. (2011) for sophisticated Lagrangian methods.

Optimal CSP-waste based polygeneration coupling for constant power production

Ester de la Fuente, Mariano Martín[*]

Departamento de Ingeniería química- Universidad de Salamanca. Plz. Caídos 1-5, 37008, Salamanca, Spain

mariano.m3@usal.es

Abstract

This work addresses the integration of a biogas-based Brayton Cycle with a concentrated solar power facility. A heat exchanger network generates steam out of flue gas or molten salts to be used in a regenerative Rankine cycle to produce power. A multiperiod scheme is formulated for the design of the hybrid facility determining the waste required as back up to mitigate seasonal solar availability. The steam turbine is responsible for power production while the gas turbine works mainly as a combustion chamber. In the South of Spain, a 50% excess of biogas is produced during summer yielding a production cost of electricity of 0.17 €/kWh with an investment of 380 M€ for a production facility of 25MW. A scale-up study is also carried out.

Keywords: Circular economy, biogas turbine, CSP, renewable power, mathematical optimization

1. Introduction

The transition from fossil-based power to a renewable based economy faces an important challenge, the variability of the largest energy resource on Earth. Solar availability is highly volatile, it is subjected to seasonality in the longer term, but weather also results in hourly or subhourly fluctuations. Meeting power demand over time requires the use of integrated systems to help mitigate the variation in power production (Yaun and Chen, 2012). Hybrid concentrated solar power (CSP) facilities use a second energy source to mitigate the lack of Sun (Peterseim, et al 2013). Apart from the use of fossil resources, renewables have already been considered. Vidal and Martín (2015) optimized the operation of a facility that used lignocellulosic biomass gasification, providing hot streams to heat up the molten salts, and a gas turbine as buffer technology to operate a CSP facility. This integration suggested the use of a syngas powered gas turbine and the possibility of storing power in the form of hydrogen as energy vector if solar availability was enough to meet the power demand. The molten salts where not heated up using thermal energy from the hot gases nor a syngas furnace was used. However, the diversification of the use of lignocellulosic raw materials for the production of chemicals and the large and distributed availability of waste in isolated areas (Taifouris and Martín, 2018) suggest its use as back-up to mitigate the solar variability. In this work a mathematical optimization framework is developed to evaluate the integration of waste and CSP within a renewable-based power plant. The system considers waste anaerobic digestion and a gas turbine to produce power from

residues. The hot flue gas and/or the heat transfer fluid, molten salts, can be used for the production of the steam required by the steam turbine of a regenerative Rankine cycle

2. Process description

The process consists of five major sections: Biogas production and purification, gas turbine, solar collection technologies, heat exchanger network and a regenerative Rankine cycle.

Waste and water are fed to a digestor. The mixture is anaerobically digested for 25 days to produce biogas and a digestate. The biogas is sent to purification to remove CO_2 and traces of NH_3, using a Pressure Swing Adsorption (PSA) system, and to eliminate the H_2S in a fixed-bed reactor. Once biomethane is obtained, a Brayton cycle is used to produce power. The flue gas produced is sent to a heat exchanger network (HEN) to produce steam.

The CSP facility consists of the heliostat field including the receiver and the molten salts storage tanks and a HEN. The salts are used to generate superheated steam to be used in a steam turbine following a regenerative Rankine cycle.

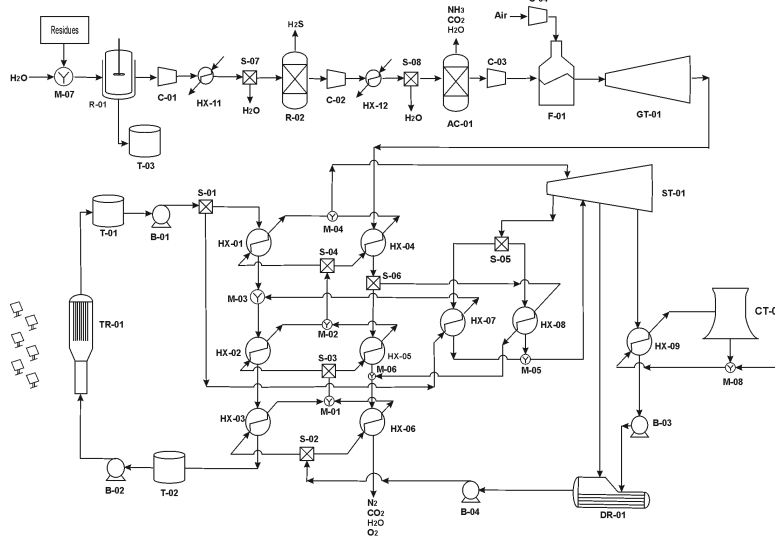
The Rankine cycle is common for both energy resources. In order for the molten salts and the flue gas to be used, a system of heat exchangers in parallel is considered. For heating up and evaporating water, the entire flow of the molten salts is used while only a fraction was used for reheating and overheating the steam. However, the higher temperature of the flue gas suggests a different lay out. The entire flow is used for overheating the steam before feeding the high-pressure turbine whereas it is split to reheat the steam before feeding it into the medium pressure turbine and to heat-up and evaporate the water coming from the deaerator. In the second stage of the turbine, a fraction of the steam is extracted at a medium pressure and it is used to heat up the condensate. The rest of the steam is finally expanded to an exhaust pressure, condensed and recycled. A cooling tower is used to cooldown the cooling water, see Figure 1.


Figure 1. Integrated power facility

3. Problem formulation

The different technologies described in the flowsheet of Figure 1 are modelled using mass and energy balances, for the digester, the heat exchangers, mixers and splitters, thermodynamics for the gas compression and expansion, the steam turbine is modelled based on enthalpy and entropy balances where surrogate models are developed for the enthalpy and entropy of the steam as a function of the temperature and pressure (León and Martín, 2016), rules of thumb are used to estimate the compressor and turbine efficiencies (Walas, 1990), design equations are used to model the solar Receiver, and reduced order models are developed for the adsorption beds. The model is written in terms of the total mass flows, component mass flows, component mass fractions, and temperatures of the streams in the network. These are the main variables whose values have to be determined from the optimization. The components in the system correspond to the ones in the set $J = \{$ Wa, CO_2, O_2, N_2, H_2S, NH_3, $CH_4\}$

The problem is a multiperiod NLP of 9600 vars and 4800 eqs. written in GAMS, that is solved maximizing eq. (1) on a monthly basis for the selection of the best use of waste to mitigate the lack of sun, either the production of power in a biogas fuelled gas turbine and/or the use of the flue gas to produce steam together with the molten salts. The objective function includes the net power production and the annualized cost (K=1/3) of the mirrors, the digesters, each of $6000m^3$ at 365 €/m^3, and the linearized cost for the turbines as a function of the power

$$Z = C_{Electricity} \cdot (W_{(Turbgas)} + W_{Total} - W_{(Comp1)} - W_{(Comp2)} - W_{(Comp3)} - W_{(Comp4)})$$
$$-(120 \cdot AreaTotal + C_{Digestor} \cdot N_{digestor} + (335.27*(W_{(Turbgas)}) + 36.211) - (270.5* W_{Total} + 2 \cdot 10^6))*(K)$$
$$(1)$$

A case study is presented for a region in Spain, Badajoz, where hybrid plants are already installed but using fossil backup energy (http://es.csptoday.com). The large availability of poultry and solar incidence makes its integration an interesting alternative to the use of fossil resources. A net production of 25 MW is considered. The framework is flexible to study the use of other residues and evaluate the operation in other regions.

4. Results

4.1. Plant operation

The plant allocation in the northern hemisphere dictates its operation. Summer operation is based on the use of solar energy, reducing the use of waste and the usage of the digestors, see Figure 2. This is an important feature since the use of the digestors at full capacity can allow the production of chemicals such as methanol or methane (Hernández and Martín, 2016) for energy storage purposes. It turns out that, in summer, additional 12 MW of power are available. Furthermore, an interesting feature unveiled from the optimization is the fact that the gas turbine actually operates as a furnace providing little power but generating a high temperature stream to be used in the heat exchanger network. As a result, the two heat exchanger networks, the one that uses the molten salts and the one that uses the hot flue gas, operate the entire year. Figure 3 summarizes the operation of both turbines and shows the contribution of the solar energy and the poultry manure. In winter up to 40% of the energy is provided by the manure while in summer, the solar energy is enough to reach the desired power production of 25 MW.
Figure 2. Waste consumption and digestors usage.
Figure 3. Contribution of the two sections of the process to power production

4.2. Economic evaluation

The production cost and investment costs of the integrated facility are estimated and compared to the stand alone CSP plant and other integrated facilities.

The investment cost is estimated using the factorial method (Sinnot 1999). It relies on the equipment cost, updated from Matche (Matche 2014). We consider the units described in the flowsheet given by Figure 1. Digesters cost is assumed to be 365 €/m³ (Taifouris and Martín, 2018) and the heliostat costs are 120 €/m². We assume that each heliostat has an area of 120 m². The installed equipment is assumed to represent 1.5 times the equipment cost. Piping, isolation, instrumentation and utilities represent 20 %, 15 %, 20 % and 10 % of the equipment cost respectively. Land and buildings cost are assumed to be 8 M€, and the load of molten salts is priced at 0.665 €/kg. These items add up to the fix cost (319 M€). The fees represent 3 % of the fix cost, other administrative expenses and overheads and the plant layout represent 10 % of the direct costs (fees plus fix capital) and 5 % of the fix cost respectively. The plant start-up cost represents 15 % of the investment. The investment adds up to 380 M€. Figure 4 shows the contribution to the cost of the different sections of the facility, the solar field is the larger contribution, over a third of the total, followed by the turbine and the heat exchanger network. The digestors, a total of 4 in the facility, represent 7.5% of the units. An interesting comparison between this plant and the stand-alone plant presented in (Martín and Martín, 2013) reveals that the investment cost is around 50% larger, but the production capacity was variable over time. Thus, the investment to secure constant production capacity was of around 130 M€.
Figure 4.- a) Contribution of the facility sections to the final cost b) Distribution of the production costs

The production costs of the electricity generated, without considering the possibility of producing additional power, chemicals or credit from the digestate, can be seen in Figure 4b. The labour costs are assumed to be 0.5% of the investment, equipment maintenance around 2.5 % of fix costs, the amortization linear with time in 20 years, the taxes and the overheads 1 % of the investment each, and the administration around 5 % of labour, equipment maintenance, amortization, taxes and overheads. The production costs add up to 0.17 €/kWh, slightly higher than the values reported for the CSP facility of similar sized operating alone (Martín and Martín, 2013) that shows a production costs of around 0.15 €/kWh but that secures constant production using renewable resources. That additional 10% in the electricity cost is to secure the continuous production of power over time.
Figure 5.-Scale up/down of the integrated waste-CSP facility. A) Production cost; B) Investment

An additional comparison can be made with the integration of lignocellulosic biomass and CSP by Vidal and Martin (2015). Note that the collection of miscanthus is easier due to its higher density and easier transportation which allowed considering a larger facility of 340 MW benefiting from economies of scale. Furthermore, in that case, the integration considered the use of hot streams to heat up the molten salts, not to produce steam directly. The optimal integrated process consisted of the use of a syngas fueled gas turbine that produced power in parallel to the one obtained from the steam turbine from the CSP section. Finally, when solar power was enough to meet the power demand, the syngas was used to produce hydrogen using a WGSR, providing additional income. The larger scale allowed electricity production costs of 0.073 €/kWh with an investment cost of 3225 M€. In this work the integration is different since the hot streams were not intended to be used in heating up the molten salts but to directly produce steam. The gas turbine is merely used as a furnace and the excess of biogas can be stored or further processed to methane or methanol. Reaching that production capacity requires more than 50 digesters and processing around a peak of 40 kg/s of

manure which is far larger facility than any available. For the proper comparison, a scale up study is required. Figure 5 shows the results of the scale up/down of the economics of the integrated facility analyzed in this work. For a 340 MW integrated facility, an investment of 4080M€ is required for an electricity production cost of 0.133 €/kWh. Note that no credit is assumed from the digestate or the additional biogas production capacity

5. Conclusions

A superstructure for the integration of waste-to-power and a concentrated solar facility has been proposed embedding anaerobic digestion, a Brayton Cycle, solar field, molten salts system and a regenerative Rankine cycle. The solution of the multiperiod optimization problem decides on the use of each energy source.

The low yield to power of the poultry manure and the allocation of the plant results in an excess of capacity during summer of about 50%, so that the demand of 25MW is met in winter. The steam turbine is the one responsible for producing the power, while the gas turbine operates mostly as a combustion chamber. The production cost to secure power production are 5% larger than the ones of the stand-alone plant, 0.17 €/kWh, but the investment cost increases by 50% up to 380 M€. However, the excess of capacity can be used to produce chemicals that will be an asset to the process in terms of additional income or providing flexibility to its operation. The digestate can also be further used as a fertilizer. The large number of units involved makes difficult that the future lower costs of heliostats result in large investment savings per kW installed. Integration of waste is suggested at smaller scales compared to lignocellulosic biomass. The formulation is useful to evaluate trade-offs related to the location of the plant as function of the availability of the raw materials, solar energy and waste.

Abstract

This work presents a model-based optimization approach to determine the configuration of a petroleum refinery for a new (grassroots) or an existing site for heavy oil processing of atmospheric distillation unit residue. We develop a high-level superstructure representation for the refinery configuration that encompass many possible alternatives comprising the technologies and their interconnections. The superstructure is postulated by decomposing it to include representative heavy oil processing scheme alternatives that center on the technologies for atmospheric residual hydrodesulfurization (ARDS), vacuum residual hydrodesulfurization (VRDS), and residual fluid catalytic cracking (RFCC). We formulate a mixed-integer nonlinear optimization model (MINLP) appended with logic propositions devised from experience and heuristics to aid solution convergence. Implementation on a case study of Kuwaiti refineries demonstrate the applicability and practicality of the proposed approach when validated against existing real-world refinery configurations.

Keywords: petroleum refinery configuration, heavy oil, mixed-integer linear programming, superstructure; logic propositions

1. Introduction

An important aspect of process synthesis and design is to identify the best flowsheet structure that performs a specific task while achieving a set of objectives, which mainly involve maximizing profit or minimizing cost and/or environmental emissions. Within this scope, the task complexity entailed in determining an optimal refinery configuration requires developing systematic approaches that can rigorously consider the interactions among numerous process variables and tradeoffs involving multiple possibly conflicting design objectives. In the literature, three available approaches for process synthesis are heuristic methods, pinch analysis, and optimization for which optimization allows developing decision making tools that can handle the complexities mentioned (Khor and Elkamel, 2010).

In the last decade, the superstructure-based mixed-integer nonlinear programming (MINLP) optimization approach has been proposed for synthesizing biorefinery or biomass-based processes. Zondervan et al. (2011) presents an MINLP based on the transshipment model to determine optimal processing routes to produce fossil fuel substitute chemicals for gasoline blending. The model considers individual objectives for yield maximization and waste minimization besides conventional economic cost functions. Quaglia et al. (2015) extends the superstructure-based MINLP methodology with systematic data management. A simultaneous economic and environmental-based multiobjective MINLP model derived from a large scale superstructure is proposed by del Rio-Chanona et al. (2017). A recent review of this area is offered by Cremaschi (2015).

The present work attempts to contribute by demonstrating the applicability of a MINLP model for large scale grassroots refinery configuration synthesis using a common business tool (Excel). The formulation considers rigorous process models with nonlinearities representative of major commercial refining technologies in terms of material balances, product yields and qualities, and costs. The model is implemented on an industrial case study of Kuwaiti refineries with the results validated against existing real-world refinery configurations to elucidate the practicality of the approach.

2. Problem statement

We consider the structural optimization problem to devise a petroleum refinery configuration. Given the following data is available: amount, properties, and cost of a mixture of crude oils (petroleum) as raw materials; a set of refining process units with known processing or throughput capacities and capital and operating costs; and amount and properties or qualities of a set of refining products. Our goal is to determine an optimal configuration by computing the continuous variables on material stream component flowrates (denoted by F_i for each component i) and the binary variables on selecting and sequencing the process units that satisfy an objective to minimize the total refinery cost (denoted by U_k for each unit k).

3. Superstructure representation

In the superstructure representation in Figure 1, crude oil is separated by a crude oil distillation unit (CDU) into gases, naphtha, kerosene, diesel, and atmospheric residue. CDU products are usually high in sulfur (also called sour products) and require treatment. The sour gas is typically treated for sulfur removal using a gas treating unit (GAS) and amine treating unit (AMN). The recovered hydrogen sulfide gas is converted to sulfur in the sulfur recovery unit (SULF). Straight run naphtha, kerosene, and diesel are hydrotreated in separate catalytic hydrotreaters (NHT, DHT, and KHT, respectively) to lower the amount of sulfur and other objectionable materials to meet environmental regulations for sale. Hydrotreated naphtha is typically separated into light and heavy naphtha using naphtha splitter (NAPS). Heavy naphtha is upgraded in a catalytic reformer (REF) while that of light naphtha in a catalytic isomerizer (ISO) to produce high octane gasoline blending stock. Alkylation (ALK1–2) and polymerization (POLY) units produce alkylate and polymerate blending stocks to supplement gasoline production. The olefin gas feed to the alkylation and polymerization units are supplied by fluid catalytic cracker (FCC), residue fluid catalytic cracker (RFCC), and delayed

coker (DCOK). Three main alternative processing schemes for heavy oil processing are incorporated in the superstructure. In the first alternative for atmospheric residual treating, high sulfur atmospheric residue is first processed in an atmospheric residue desulfurizer (ARDS) to produce low sulfur atmospheric residue that can be sold, or physically separated in a vacuum rerun unit (VRU) to produce low sulfur vacuum gas oil and low sulfur vacuum residue, or catalytically cracked in a residue fluid catalytic cracker (RFCC) to produce gasoline and other fuel types. In the second alternative of vacuum residual treating, the high sulfur atmospheric residue is physically separated in VRU into high sulfur vacuum gas oil and high sulfur vacuum residue. The latter (high sulfur vacuum residue) can be converted to low sulfur vacuum residue in vacuum residue desulfurizer (VRDS) to reduce the sulfur content and produce more valuable products such as transportation fuels. High sulfur vacuum gas oil is either sold after conversion to low sulfur vacuum gas oil in gas oil hydrotreater (GOHT) or converted to lighter products in hydrocracker (HCR) or fluid catalytic cracker (FCC1). We can sell low sulfur vacuum residue as fuel oil or further process it in DCOK or RFCC to produce lighter materials with or without prior visbreaking (VIS). In the third processing alternative called atmospheric residual cracking, the high sulfur atmospheric residue is first desulfurized in ARDS to produce low sulfur atmospheric residue that is either cracked in to produce lighter materials with or without a prior VIS. Typically, there is no vacuum pressure-operated unit in this configuration although some studies have shown the potential to process a feed from such units (Reynolds et al., 1992; Ancheyta, 2011).

4. Model formulation

The MINLP formulation for refinery configuration design is as follows:

$$F_i + \sum_k Q_{ik} X_k = P_i, \quad \forall i \in I \tag{1}$$

$$F_i \le S_i, \quad \forall i \tag{2}$$

$$X_k \le L_k B_k, \quad \forall k \tag{3}$$

$$FP_{i,k,p} = f(VS_{i,k}, VP_{i,k}), \quad \forall i, k, p \tag{4}$$

$$PP_{i,k,p} = f(FP_{i,k,p}, XU_k), \quad \forall i, k, p \tag{5}$$

$$F_k \le M_k U_k, \quad \forall k \tag{6}$$

Eq. (1) describes the material balances where F_i = feed amount of component i, Q_{ik} = yield coefficient of component i in process unit k, X_k = capacity of unit k, and P_i = total amount of component i. Eq. (2) imposes maximum feed supply S_i for each component i. Eq. (3) allows designing additional trains of the same unit as given by a multiple number L_k of the capacity B_k of a single unit k. Eq. (4) and (5) governs feed and product properties of the process units, respectively. The objective function as given by Eq. (7) maximizes product sales minus the associated costs of raw materials (cf), capital (CC), and operation (CR) including utilities, maintenance (CM), and payroll (CP).

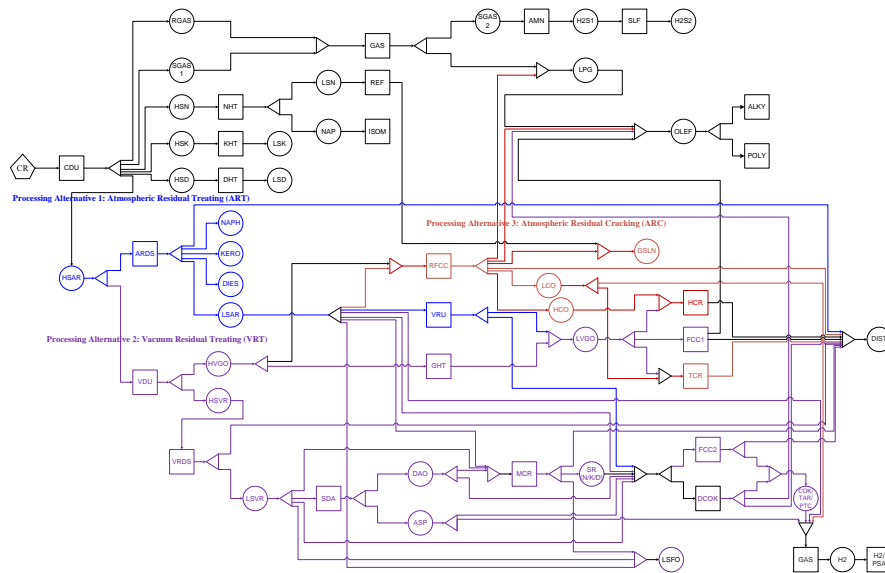
$$\text{maximize} \sum_i \text{sp}_i P_i - \sum_j \text{cf}_j F_j - \sum_k \left(\text{CC}_k + \text{CR}_k \right) - \text{CM} - \text{CP} \tag{7}$$


Figure 1. Superstructure representation of petroleum refinery configurations

5. Solution strategy

We develop a computational procedure that first generates and assigns a set of binary values (0–1) to the structural variables in generating a new refinery configuration at each iteration as based on the superstructure (Step 1). Then the procedure invokes a nonlinear optimizer to compute the unit conversions and product cuts in a corresponding configuration to maximize total profit-based objective function (Step 2). Figure 2 presents the described procedure flow.

The master module alternates the structural variable binary values U_k between 1 and 0 to indicate the selection or rejection, respectively of a process unit in an overall refinery scheme. Thus the algorithm can consider all possible alternatives within the superstructure that give rise to refinery configurations, which are given as inputs into the optimization submodule. The Excel submodule contains information on the superstructure element interconnections as well as their rigorous correlations for the material balances, product yields and qualities, utility requirements, feed and product prices, and associated running costs for all the units. The model accounts for all interconnections between the units and gathering pools for the intermediates and final products, and they involve both linear and nonlinear relations.

The submodule optimizes the unit conversions and product cuts in each configuration developed by the master module to determine the unit capacities and flow rates of intermediate and final product streams. By computing the capital and running costs, the submodule maximizes the objective function of total profit using the generalized reduced gradient-based method called GRG2 available in Excel Solver (Frontline

Systems, 2018). The master module then reads the new configuration profit from the submodule results and compares it with the current value to decide in storing the binary variable and objective variable values associated with that of higher profit; otherwise, we retain that of the previous scheme.

This algorithm terminates when all possible configurations are considered to determine an optimal configuration. Thus, our algorithm is one of complete enumeration as different from a partial enumeration approach such as branch-and-bound. Expectedly, our method entails more iterations to converge to optimality, hence motivating us to incorporate use of 0–1-based logic propositions on design and structural specifications to reduce the computational time but without compromising the solution quality.

6. Results and discussion

The model solution indicates that a configuration resembling the residual fluid catalytic cracking (RFCC) route is more economical than to use a combined vacuum unit and delayed coker with or without visbreaker, which is consistent with the literature on refinery configurations (Khor et al., 2011; Meyers, 2016; Albahri et al., 2018). Using RFCC to process atmospheric residue is favored to physical separation combined with thermal cracking mainly because we can improve the selectivity and yield of the desired product flows. RFCC-based configuration also entails less process units than that of ARDS and VRDS, hence promotes lower capital and running costs.

Although a low sulfur vacuum residue can be produced from the vacuum unit which can then be processed in the RFCC unit, that route is not an optimal choice because it is less economical. Moreover, unless preceded by ARDS, RFCC removes only 30 to 50% of sulfur in the feed, and its products therefore require hydrotreating. The selected optimal technologies show that hydrotreating straight-run products is favored cost-wise and essential too. Hydrotreating straight-run distillates from crude distillation unit is more economic than selling them due to the lower price of high sulfur products. In our model runs over different price sets and scenarios, the solutions preferentially choose naphtha, kerosene, and diesel hydrotreaters as part of the configurations, hence we decide to include these units as fixed structures (i.e., they are not evaluated by means of the binary variables) to enhance convergence and reduce computational time.

The total capital investment estimated is US$2.1 billion, which is consistent with reported values for a refinery of this size (Maiti et al., 2001). Our optimal result run shows that a configuration that employs RFCC is the most profitable with a net profit of 8.40 US$/barrel (20 cent/gallon). While the computed values may differ for a specific case's cost values (e.g. for erection and running expenses) and sale prices, the relative trend and conclusion remain valid for a similar comparison made.

7. Conclusions

This work presents an approach to synthesize an optimal petroleum refinery configuration during the preliminary screening of design alternatives. The configuration determined shows good agreement with refinery configurations in practice. We obtain an optimal processing scheme for a specific crude oil mixture to be that of residual fluid catalytic cracking (RFCC) of desulfurized atmospheric residue, without a need for a vacuum distiller or vacuum residue desulfurizer (VRDS). The latter structure conventionally forms part of the former (as incorporated in our superstructure), but the MINLP approach applied finds such a configuration to be actually suboptimal.

Abstract

The simultaneous lot-sizing and production scheduling problem of a real-life large-scale industrial facility of packaged consumer goods is considered in this work. The problem under consideration is mainly focused on the packing stage which constitutes the major production bottleneck. Several packing lines, illustrating different design and operational characteristics, operate continuously in parallel. An efficient solution strategy is implemented to reduce the high computational cost. A Mixed-Integer Linear Programming model (MILP) is used in parallel with a decomposition-based algorithm. Appropriate constraints, referring to the production/formulation stage of the plant, are also imposed in order to ensure the generation of feasible production schedules. The model relies on tight timing and sequencing and products allocation constraints. The main objective is the minimization of the makespan. A number of different case studies have been considered and detailed optimal production schedules have been generated for over 130 products scheduled weekly. The obtained results lead to nearly-optimal scheduling solutions in reasonable computation times. The proposed model can assist decision makers towards rigorous scheduling plans in a dynamic production environment under realistic uncertainty.

Keywords: production scheduling, consumer goods industry, mixed integer linear programming, decomposition technique

1. Introduction

Modern multi-product, multipurpose plants play a key role within the overall current climate of business globalization, aiming to produce highly diversified products that can address the needs and demands of customers spread over wide geographical areas. The inherent size and diversity of these processes gives rise to the need for planning and scheduling problem, of large-scale industrial production operations. Over the past 20 years the literature illustrates a large-number of scheduling models, which have been mostly applied on generic but relatively small problem instances (Méndez et al., 2006). However, current real-world industrial applications include hundreds of different final products, produced in flexible multi-purposes facilities, under several tight design and operating constraints (Harjunkoski et al., 2014). A few approaches have been used to solve large-scale industrial scheduling problems, utilizing advances in Mixed-Integer

optimisation (Kopanos, Puigjaner and Georgiadis, 2011). Furthermore, hybrid methods for large scale industrial problems have been proposed. Kopanos et al. (2010), proposed a decomposition strategy for large-scale scheduling problems in multiproduct multistage pharmaceutical batch plants. Baumann and Trautmann (2014) proposed a hybrid method for large-scale short-term scheduling of make-and-pack production processes. In this work an MILP-based decomposition algorithm is proposed for large scale scheduling problems in a multiproduct continuous plant. The model focuses on the packing stage, taking also into account constraints referring to the production formulation stage in order to ensure the generation of feasible production schedules.

2. Problem Statement

This work considers the scheduling of packaged consumer goods in a real-life industry. More than 300 products can be produced continuously in parallel packing lines. The production process consists of the formulation/production and the packing stage. In the formulation stage a number of intermediate products are produced. In most cases, more than one final product can be produced from the same intermediate product in the packing stage. Each packing line is connected to its own production/formulation unit. Sequence dependent changeovers take place in both stages. The changeover times differ among the various sequences, depending on the package size, the package color, the intermediate product etc. All changeovers, in the two stages, take place simultaneously and therefore the most time-consuming changeover determines the total changeover time for a product sequence. In addition, in the formulation stage, due to technical plant restrictions, the total number of intermediate products' changeovers should not exceed an upper limit. The short-term scheduling horizon of interest is one week, and both the packing and the formulation units are available 24 hours per day. Products' due dates are taken into account along with the necessary planned maintenance activities. The main objective is the minimization of the makespan and the minimization of products' changeover times.

3. MILP-based Decomposition Algorithm

For the aforementioned problem, an MILP-based decomposition algorithm has been developed. The original large-scale problem is decomposed into smaller scheduling sub-problems in an iterative mode. At each iteration, a subset of the involved product orders is scheduled. The main model decisions are a) the allocation of products to the packing lines, taking into account underlying equipment technical constraints, b) the relative sequence of products in the packing lines and c) the starting and completion time of product orders in the packing stage. The proposed MILP-based decomposition algorithm consists of: a) the insertion policy, b) the MILP model and c) a decomposition technique. If maintenance periods are to be taken into account, extra "maintenance-product" orders are scheduled, with processing time equal to the maintenance time. The ending times of these product orders are fixed to the ending times of the associated maintenance activities.

3.1. Insertion policy

In order to solve the original problem iteratively, the number and sequencing of the inserted products should be decided. Two insertion criteria are used in order to avoid the generation of infeasible schedules. The products with the earliest due dates are inserted first. Furthermore, according to the plant's technical restrictions, the products with the

same recipe (intermediate product) are inserted first, in order to minimize the total number of intermediate products' changeovers. Several real test cases have illustrated, that a 5-by-5 product insertion policy is the optimal one, as by increasing the number of products the solution is not improved while the computational cost is increased. In case that maintenance periods have to be taken into account these "maintenance-product" orders are inserted first.

3.2. MILP model

The MILP model applied in this case study is an extension of a general-immediate precedence framework as developed by Kopanos, Mendez and Puigjaner (2010). A brief description of the model is presented below:

$$\sum_{j\in i_j} Y_{i,j} = 1 \quad \forall i \tag{1}$$

$$X_{i',i,j} + X_{i,i',j} + 1 \geq Y_{i',j} + Y_{i,j} \qquad \forall i, i' > i, j \in \left(i_j \cap i'_j\right) \tag{2}$$

$$C_{i'} \geq C_i + T_{i'} + XX_{i,i',j} changeover_{i,i'} - M\left(1 - X_{i,i',j}\right) \tag{3}$$

$$\forall i, i' \neq i, j \in \left(i_j \cap i'_j\right)$$

$$2(X_{i',i,j} + X_{i,i',j}) \leq Y_{i',j} + Y_{i,j} \qquad \forall i, i' > i, j \in \left(i_j \cap i'_j\right) \tag{4}$$

$$Z_{i,i',j} + XX_{i,i',j} \geq X_{i,i',j} \; \forall i, i', j \in \left(i_j \cap i'_j\right) \tag{5}$$

$$Z_{i,i',j} = \sum_{i'' \neq i,i', j \in (i_j \cap i'_j)} \left(X_{i,i'',j} + X_{i',i'',j}\right) + M\left(1 - XX_{i,i',j}\right) \tag{6}$$

$$\forall i, i', j \in \left(i_j \cap i'_j\right)$$

$$\sum_i \sum_{\substack{i' \neq i, \\ formula_i \neq formula_{i'}}} \left(XX_{i',i,j}\right) \leq Limit_j \qquad \forall j \tag{7}$$

$$\min C_{max} \geq C_i \qquad \forall i, j \tag{8}$$

Constraint (1) forces that every product order i goes through one packing line j via the allocation binary variable $Y_{i,j}$. Constraint (2), (3) and (4) give the relative sequencing of product orders. The big-M constraint (3) determines the completion time $C_{i'}$ of a product order i' to be greater that the completion time and the processing time $T_{i'}$ of whichever product i is produced beforehand at the same unit, and greater than the changeover time, $changeover_{i,i'}$, only if the binary variable $X_{i,i',j}$, is active. The binary variable $X_{i,i',j}$ is active only if product i' is produced after product i. The constraints (2) and (4) state that when two products are produced at the same unit, only one global sequencing binary

variable has to be active and when one of the binary variable $X_{i',i,j}$s and $X_{i,i',j}$ is active at least one of the $Y_{i,j}$ and $Y_{i',j}$ has to be active as well. The variable $Z_{i,i',j}$ signifies the position difference among two products produced in the same packing line. When $Z_{i,i',j}$ is equal to 0, the product i is produced exactly before the i'. The variable $Z_{i,i',j}$ is calculated in equation (6). As a result, from equation (5) the immediate precedence binary variable $XX_{i,i',j}$takes the value 1 only when the variable $Z_{i,i',j}$ is equal to 0. The binary variable $XX_{i,i',j}$takes the value 1 when the product i' is produced exactly after the product i. The constraint (7) ensures that the number of sequences between products with different recipe ($formula_i$) does not exceed an upper limit ($Limit_j$) which is determined by the plants' technical restrictions. In order this constraint to be included in the model both the immediate and the general precedence binary variables are used. Finally, the objective function of the model is expressed by constraints (8), which is the minimization of the total production makespan, C_{max}, hence it also considers the minimization of changeovers and unnecessary idle times.

3.3. Decomposition Algorithm

The large-scale industrial scheduling problem is decomposed into smaller problems in an iterative fashion. In each iteration a subset of the product orders is scheduled. In this way the MILP subproblems are solved much easier while the computational time is significantly decreased. A number of inserted products are scheduled in each iteration until all product orders are scheduled. After the resolution of the MILP model at each iteration, the global sequencing variables, as well as the allocation variables of the inserted products are fixed. However, the timing variables (ending time) and the immediate precedence binary variables remain free. When all products are inserted, the final schedule is constructed. Each iteration, aims to find a solution with a 0% integrality gap. However, industrial requirements impose an upper bound on the total computational time. Therefore, a time limit of 10 minutes, has been set for the solution of each subproblem. Figure 1 illustrates the proposed decomposition technique.
Figure 1: Decomposition-based solution algorithm

4. Results

A representative industrial case study of 178 final products and 6 packing lines is used to illustrate the applicability and efficiency of the proposed solution strategy. All data have been provided from a real-life, large-scale consumer goods industry. Technical packing lines restrictions do not allow full flexibility of the products' allocation. The first 80 products can be solely allocated to the first 3 packing lines, as the remaining 98 products can be processed only in the next 3 packing lines. Utilizing the aforementioned decomposition algorithm 5 products are scheduled at each iteration, except for the last

one, where the remaining 3 products are scheduled. The decomposition technique, was implemented in GAMS and solved using the CPLEX 12.0 solver.. Figure 2. illustrates the final schedule, of the study under consideration. Maintenance activities have also been taken into account.
Figure 2: Gantt chart of the packing lines referring to the examined case study

Table 1: Comparison between the exact MILP model and the decomposition approach applying different insertion policies

	Exact MILP Approach	Decomposition Approach		
		Insertion policy 1-by-1	Insertion policy 5-by-5	Insertion policy 10-by-10
Makespan (hrs)	118.9	122.6	120.2	120.8
Computational CPU Time (minutes)	15	1.6	2.46	31.4

Another medium-scale problem instance including 80 products and 3 packing lines, has been also studied, in order to assess the solutions of the proposed decomposition technique. The study is solved using both the decomposition algorithm and the exact MILP model, described above. The results are illustrated in the Table 1. It is observed that the decomposition algorithm leads to nearly optimal solutions. In addition, the computation time is significantly decreased using the decomposition algorithm, when the products are inserted 1-by-1, or 5-by-5. The application of the 10-by-10 insertion policy, increases the complexity of the subproblems and the zero integrality gap cannot be achieved in several of the iterations without exceeding the underlying solution time limit.

As a result, the computational time is increased and higher makespan values are obtained. The aforementioned exact MILP model can only be applied to medium problem instances. For larger problem instances the computational cost becomes prohibitively high and even a feasible solution can cannot be guaranteed.

5. Conclusions

The main contribution of this work is the application of an MILP-based decomposition technique, in large scale, industrial packing facilities. A continuous, real-life, industrial facility is considered. More specifically, the packing stage of a consumer goods facility is scheduled, taking also into account constraints related to the formulation/production stage. The proposed decomposition-based approach leads to nearly optimal solutions for large-scale problem instances. On the other hand, the exact MILP model can only be applied to medium-sized problem instances. The solution strategy can assist decision makers to take rigorous scheduling plans in a dynamic production environment under realistic uncertainty. Current work considers an additional improvement algorithm step to further improve the efficiency of the proposed scheduling technique.

Abstract

The description of several transport phenomena requires the information about the viscosity of fluids. One application is a capillary tube that is operated as throttle device in the context of a heat pump. The two-phase pressure drop in the capillary tube can commonly be described using the homogenous flow model, which requires a valid correlation of the two-phase viscosity. Yet, no reliable correlation is available in literature, such that it is predictive for an extensive operation area. A lack of consistent and detailed experimental data as well as the lack of precise capillary specification complicates the matching of experimental and numerical results of the two-phase viscosity. For this reason, this work presents a systematic and comprehensive procedure in order to be able to identify a reliable two-phase viscosity. The procedure is a symbiosis of systematical numerical and experimental analysis of a two-phase refrigerant flow through a capillary tube. The numerical pre-analysis serves to identify sensitive parameters, which are experimentally refined afterwards. Comprehensive experimental investigations of the two-phase flow through the capillary provide understanding of different flow phenomena, which are inadequately described up to now. Numerical pre-analysis and extensive experimental investigations are the precondition for a computer-aided identification of the two-phase viscosity based on the experimental database.

Keywords: Computer-Assisted Experiments, Two-Phase Viscosity, Two-Phase Pressure Drop, Metastability, Hysteresis Effect

1. Introduction

Correlations of the two-phase viscosity of fluids are needed in order to describe various transport phenomena of fluids in process engineering. One application is the two-phase flow of a refrigerant through a capillary tube as a part of a heat pump system. The capillary serves as throttle device in rather smaller heat pump applications where it substantially determines the operation point. A predictive overall model of the heat pump is highly worth aspiring for, since it makes affordable a vast investigation of part components and their sensitivity towards the whole system. A precondition for this is a valid dynamic and predictive capillary model, i.e., the description of the two-phase flow through the capillary. The homogenous flow approach is a common assumption for the flow through a capillary tube. It requires the description of the two-phase viscosity of the considered refrigerant that is still an unsatisfactorily explored subject. Little data exists on natural and/or green refrigerants as statistics show (Dubba and Kumar, 2017). However, the latter are of growing importance in the context of the F-Gas Regulation. Sempértegui-Tapia and Ribatski (2017) stressed that a lot of the existing database on two-phase flow through

capillaries goes along with imprecise data on the inner diameter and the absolute roughness of the inner surface of the capillary. Nevertheless, these parameters have a strong influence on the two-phase pressure drop in the capillary as numerical sensitivity investigations show. Imprecise parametrization of the according flow model leads to difficulties in validation and identification of an appropriate two-phase viscosity. The numerical results can hardly match the experimental data provided when only the viscosity correlation serves as adjusting screw.

Furthermore, experimental databases seldom provide information on metastability as well as the hysteresis effect on vaporization of the flow in a capillary tube. In fact, experimental investigations show that the impact of these effects on e.g. the measured pressure drop in a capillary tube are significant, hence, they need to be considered. Meyer and Dunn (1998) discussed the presence of a hysteresis curve that correlates with the metastability of the refrigerant flow. They proposed a coherent collection of experimental data since the experimental results depend on the history of previous measurements and conditions, respectively. Yet, little researchers followed the proposed experimental technique. Consequently, most experimental data is inconsistent in terms of the mentioned flow phenomena. Meyer and Dunn also advised to implement a memory function into the numerical capillary model that is able to capture the hysteresis effect. Especially, within the context of an overall heat pump model, the effect needs to be considered, as the hysteresis of the capillary is passed through within the operation of the heat pump. However, existing experimental data are insufficient to develop and implement a memory function that predicts a broad operation range, yet.

This work presents a computer-aided approach for a systematic gathering of experimental data that enables the identification of an appropriate correlation of the two-phase viscosity of fluids.

2. Homogenous Flow Model

The homogenous flow model is a common way to describe the pressure drop in a capillary tube. The total pressure drop Δp is simplified to the sum of the pressure drop of the liquid refrigerant Δp_{liq} and the two-phase pressure drop Δp_{tp}, see Eq. 1-3.

$$\Delta p = \Delta p_{liq} + \Delta p_{tp} \tag{1}$$

$$\Delta p_{liq} = \left(L_{liq} \cdot \frac{f}{2 \cdot d} + \xi \right) \cdot \frac{G^2}{\rho} \tag{2}$$

$$\Delta p_{tp} = \Delta \left\{ \frac{G^2 \cdot x^2}{\alpha \rho_v} + \frac{G^2 \cdot (1-x)^2}{(1-\alpha) \cdot \rho_v} \right\} + f \cdot \frac{G^2}{2 \cdot d \cdot \rho} \cdot L_{tp} \tag{3}$$

In Eq. 1-3 d is the inner diameter of the capillary tube. L_{liq} and L_{tp} mark the lengths inside the capillary that are occupied by liquid flow and two-phase flow, respectively. Further, ρ represents the density of the refrigerant and ξ the entrance pressure drop coefficient due to sudden contraction of the flow channel. The indices v and l denote the vapour and liquid density, respectively. G indicates the mass flux, α the void fraction and

x the vapour quality. The friction factor follows the correlation of Colebrook (1939), see Eq. 4.

$$\frac{1}{\sqrt{f}} = 1.14 - 2 \cdot \log\left(\frac{e}{d}\right) + \frac{9.3}{Re \cdot \sqrt{f}} \tag{4}$$

The calculation of the friction factor (Eq. 4) requires the inner diameter d, the absolute roughness of the inner surface of the capillary e, as well as the Reynolds-Number Re of the flow. However, the calculation of the Reynolds-Number depends on the dynamic viscosity μ alongside the inner diameter, the flow velocity v and the density of the refrigerant – see Eq. 5.

$$Re = \frac{v \cdot d \cdot \rho}{\mu} \tag{5}$$

Whereas the dynamic viscosity for the liquid phase of refrigerants is well determined, there is disagreement on the appropriate two-phase viscosity. As stated by Sempértegui-Tapia and Ribatski (2017), imprecise capillary parametrization in terms of diameter and roughness can shadow the actual influence of the viscosity correlation.
Figure 1: Impact of inner diameter uncertainty on the calculated outlet pressure

A sensitivity analysis (see Fig. 1) conducted with the given equation set (Eq. 1-5) shows how sensitive the calculated outlet pressure is towards a small degree of uncertainty of the inner diameter. The deviation of ±1.8 % corresponds to the manufacturer's specification of the tolerance of the inner diameter. It further becomes visible that the sensitivity increases for lower inlet pressures. An uncertainty of the inner diameter of only 1.2 % affects an uncertainty in the calculated outlet pressure of almost 40 %. Comprehensive studies show that the sensitivity increases for smaller degrees of subcooling and higher mass fluxes. It is only reasonable to identify any appropriate viscosity correlation if the uncertainty of the inner diameter is narrowed. The same applies for the absolute roughness. Within this work, the capillary diameter is determined by the means of a light microscope and the roughness by the means of a white light

interferometry. Pre-investigations show that it is possible to narrow the tolerance of the inner diameter for capillaries of one production charge to at least ±0.9 %.

3. Experimental Investigations of the Two-Phase Pressure Drop

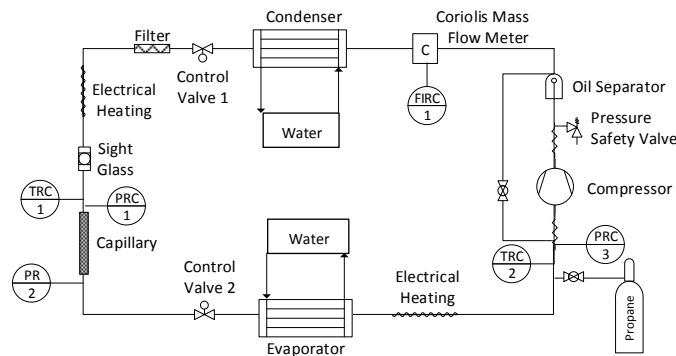
The experimental test rig presented in Fig. 1 serves for a comprehensive collection of two-phase pressure drop of propane for various conditions at the capillary inlet. The inlet condition of propane comprises the inlet pressure (PR-1), the inlet temperature (TR-1) and the mass flux (FIRC-1) of propane. The design of the experimental apparatus enables a wide operation range (PR-1: 10-30 bar, TR-1: 393-453 K, FIRC-1: 2-20 kg/h). The temperature is measured by thermocouples of type T providing a measuring error of ±0.5 K. The measuring error of the piezo-resistive pressure sensors is specified to ±0.7 %; the error of the Coriolis mass flow meter to ±0.3 %.


Figure 2: Experimental Apparatus

The capillary inside a heat pump is operated at flexible conditions depending on the application and outer circumstances of the operation. For a predictive and reliable capillary model, it is indispensable to validate the viscosity correlation against a wide range of operation conditions. However, the occurrence of hysteresis requires a coherent experimental data acquisition that drastically expands the original design of experiments. Hence, a systematic sensitivity analysis is conducted in order to understand whether the hysteresis effect is negligible for certain operation conditions. More precisely, the differences in pressure drop within hysteresis curves are examined for different inlet pressures, inlet temperatures and mass fluxes. Fig. 3 shows one exemplary hysteresis curve that depends on the increasing and decreasing of the subcooling. It makes clear that the different degrees of subcooling cannot be measured independently but depend on the previously performed subcooling. Furthermore, a discontinuity in the recorded pressure drops occurs at a subcooling of 7 °C and 5 °C. Although the operation conditions remained constant at this point, a sudden increase in pressure drop was recorded. Meyer and Dunn (1998) interpreted this phenomenon as the collapse of a metastable region.

Yet, understanding of how the metastable regions develop and what causes the collapse is still not well investigated and modelled (García-Valladares, 2007) (Dubba and Kumar,

2017). Little attention has been paid to explain the phenomenon of the hysteresis on vaporization as it appears in Fig. 3 since Meyer and Dunn presented their findings in 1998. However, knowledge and understanding of the hysteresis is crucial when modelling a capillary in the context of a heat pump.
Figure 3: Hysteresis on vaporization depending on increasing and decreasing subcooling

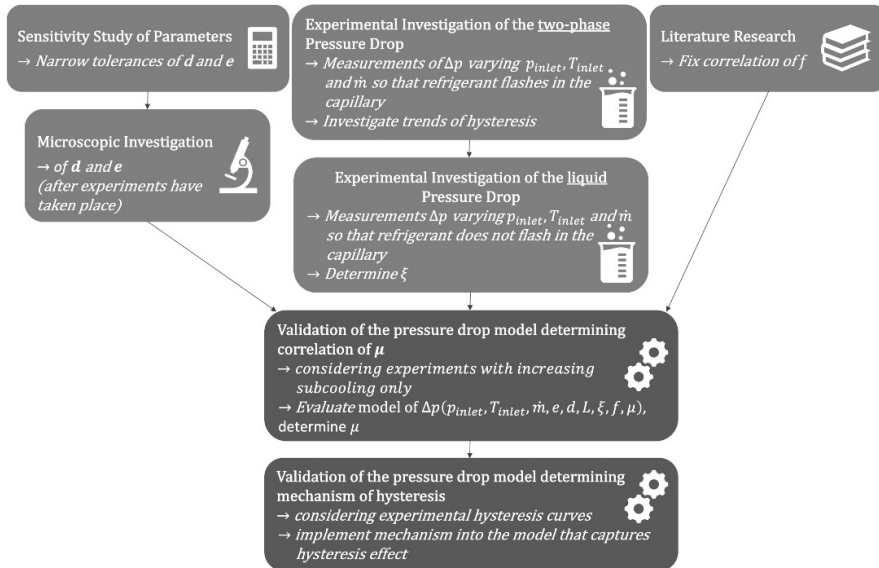
4. Conclusions


Figure 4: Systematic computer-aided approach for the validation of the pressure drop model

One reason for the fact that until today no satisfactory predictive two-phase correlation has been identified, is that the experimental database is not consistent and detailed enough. Because of that, this work aims for a systematic procedure to provide reliable data for the identification of the two-phase viscosity. For the systematic approach to

obtain a predictive two-phase viscosity correlation, the presented experimental apparatus in Fig. 2 serves for extensive data gathering. A wide range of operation conditions is performed whereby hysteresis curves are recorded so that the influence of the inlet pressure, inlet temperature and mass flux through the capillary on the hysteresis becomes clear. Comprehensive data on hysteresis curves also serves to identify and mathematically describe the occurrence and possible correlation between hysteresis and metastability of the flow. This means, that the equation set of Eq. 1-5 needs to be complemented by the gathered understanding of both phenomena, e.g. by implementing a memory function that takes into account the history of simulated capillary inlet conditions. Liquid pressure drop experiments provide a base of validation data against which the entrance pressure drop coefficient is determined. Following the systematic concept for the model validation of the pressure drop in the capillary in Fig 4. and Eq. (2), only ξ is unknown at this point. Once, extensive data collection at the experimental apparatus is completed, the inner diameter and the absolute roughness of the considered capillary are investigated by the designated optical measurement techniques in order to provide a more precise parametrization of the capillary model. The numerical sensitivity analysis indicates that e.g. the diameter should at least be refined to an uncertainty of ± 0.5 % in order to have less than 10 % uncertainty in the calculated outlet pressure. The symbiosis of profound numerical and experimental analysis, thus, is necessary to reduce the overall degree of uncertainties of the capillary model in order to identify a predictive two-phase viscosity correlation of fluids. However, uncertainties still need to be considered when evaluating the viscosity correlation from the gathered experimental data, since any impacts cannot be captured by viscosity correlations. All in all, this work provides a systematic technique that, if followed by more researchers, delivers a reliable and precise data base in order to validate the two-phase pressure drop model of refrigerants.

Abstract

Quite often process simulation is only used as a representation of experimentally developed processes. With today's availability of computation power and advanced simulation and optimization methods much more than providing a closed heat and mass balance and some data for process unit design is possible. There is a need for a shift in paradigm to a model-centric process development. Supporting decision making to find out which design variables or model parameters are significant, which experiments should be done, how optimality could be reached, should be addressed in an iterative workflow and a supporting framework. This is discussed in the present contribution.

Keywords: process simulation, multi-criteria optimization, sensitivity analysis, surrogate modeling.

1. Introduction

Most common process simulation tools are focussing on generating and managing only a single process simulation. However, in process development, for rational decisions in general a broader and more transparent view on achievable simulation and optimization results is desirable. Parallelization reduces computation time to explore the solution space. Therefore, tools for a holistic view on several simulation and optimization runs and for decision support enabling efficient and fast access to large data bases including many simulations are needed. Furthermore, a workflow for an iterative modelling, simulation and optimization should be supported to improve models and results continuously with increasing information and knowledge. The paper is organized as follows: After a brief description of the workflow, examples of applications and visualizations using a multitude of solutions for different tasks within process development will be discussed before a conclusion is given.

2. Process Simulation and Optimization for Decision Making

In the present contribution a concept for an iterative use of process simulation and optimization (cf. Fig. 1) during different stages of process development will be discussed, which relies on comparisons and visualizations of a multitude of process simulations and optimization to support decision making. A more detailed discussion can be found in

Asprion and Bortz (2018). The novelty is the holistic approach to support the various workflow aspects of process development in one simulation environment.

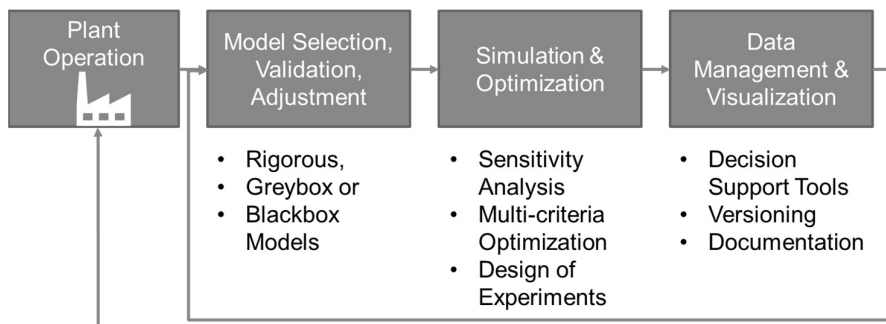
In an early phase of process development, process simulation and optimization might help to identify and compare most promising process concepts. The comparison of Pareto sets (set of best compromises between competing objectives) in a decision support system helps to find sound decisions and allows to investigate trade-offs between the competing objectives. Furthermore, an investigation of the impact of uncertainties (sensitivity analysis) on simulation and optimization results helps to identify model parameters which have to be determined with decreased uncertainty or to minimize risk by a robust or stochastic optimization. This might be useful for the design of mini-plants since in this phase many relationships are rather unclear like for example the impact of impurities on catalyst behavior and expected yield. In a laboratory setup or in a mini-, pilot or production plant, model-based design of experiments enables an efficient (faster, less costly) and effective (doing the right experiments) investigation, which might be used for model discrimination, model parameter estimation or verification of optimization results. Independent of the type of process development – either for a new or an existing plant – in a certain stage there will be plant data available – either from a mini- or pilot plant or from the existing production plant. These data can and should be used for the validation and adjustment of the process model before an extensive simulation or optimization study starts. In case of missing models for specific units greybox modeling can be used to setup a model combining scientific models with data-driven parts (cf. Asprion et al., 2019). Finally, a multi-criteria optimization of the process model will identify Pareto sets for the design of a new plant or design modifications for existing plants. Here again a combination with sensitivity analysis helps to evaluate and/or minimize risks evoked by uncertainties. A framework supporting the workflow of Fig. 1 requires data management and visualization to support decision making and documentation (incl. versioning). Of course, in most cases there will be iteration loops. One such loop might, for example, include design of experiment, experiments in a plant for parameter estimation or for verifying optimization results and subsequent model adjustment until an acceptable parameter estimation or optimization result is obtained. A process simulator should support the different tasks shown in Fig. 1 for an efficient and effective decision making in process development.


Figure 1: Workflow for an iterative use of process simulation and optimization to support decision making in process development

3. Examples

In the following examples for comparisons of a multitude of solutions including visualization for decision support in different phases of process development are presented.

3.1. Decision support for process concepts

In this example, four different concepts for the separation of three different mixtures of hexane, heptane and octane by distillation are compared based on Pareto sets (cf. Fig. 2). The optimization variables are summarized in Tab. 1. As objectives of the multi-criteria optimization the heptane product purity and the molar flow of heptane are maximized, whereas the total costs are minimized. As constraints the hexane and octane product streams should have a purity ≥ 99 mol%.

Table 1: Range of the optimization variables (N-number of stages, f-feed, sd-side draw, RR-reflux ratio, pf-pre-fractionator, ldw, hdw- lower and higher end of dividing wall, s-split) for the design of the column configurations for the separation of hexane, heptane, octane mixtures (600 kmol/h).

	N_1	$N_{f,1}$	RR_1	N_2	$N_{f,2}$	RR_2	n / kmol/h	n / kmol/h
Indirect sequence	20-50	5-45	1-5	20-50	5-45	1-5	Hex:320-480; 160-260;60-140	Hep:60-140; 160-260;60-140
Direct sequence	20-50	5-45	1-5	20-50	5-45	1-5	Oct:60-140; 160-260;320-480	Hep:60-140; 160-260;60-140

	N_1	$N_{f,1}$	RR_1	N_{sd}		n / kmol/h	n / kmol/h	Constraint
Side-draw	20-50	5-45	1-20	10-40		Oct:60-140; 160-260;320-480	Hep:60-140; 160-260;60-140	$N_{sd}> N_{f,1}$

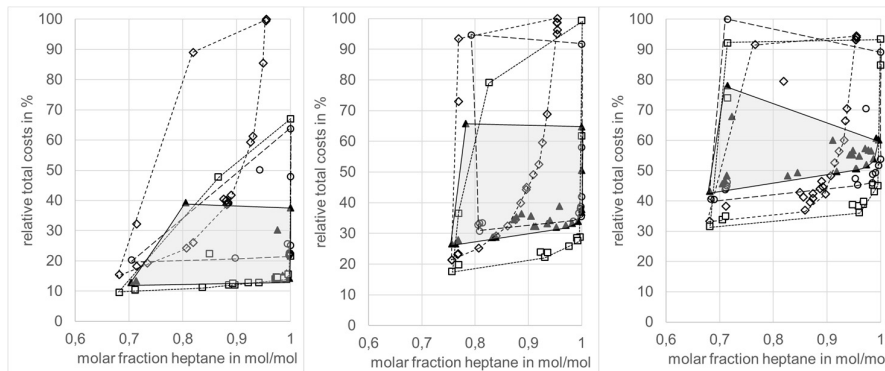
	N_{pf}	$N_{f,1}$	RR_1	N_1	N_{sd}	N_{ldw}	N_{hdw}	S_{ldw}	S_{hdw}	n / kmol/h	n / kmol/h
Dividing wall col.	5-41	5-45	1-20	20-50	10-40	1-40	10-50	0,2-0,9	0,1-0,9	Oct:60-140; 160-260;320-480	Hep:60-140; 160-260;60-140


Fig. 2: Comparison of Pareto sets (lines representing convex hulls covering the full range of solutions also for the third objective, i.e. molar flow of heptane, gray area is only for better distinction) of 4 different concepts to separate mixtures of hexane, heptane and octane. ▲ direct sequence of 2 columns, ○ indirect sequence of 2 columns, ◇ side-draw column, □ dividing wall column. Left: light feed (molar fractions: 2/3 hex., 1/6 hep. and 1/6 oct.), middle: equimolar feed, right: heavy feed (molar fractions: 1/6 hex., 1/6 hep. and 2/3 oct.)

As can be seen for all three mixtures, the dividing wall column is the cheapest concept. The side-stream column is only feasible for heptane purities < 95 mol%. In terms of total

costs at the same heptane purity, for the mixture with high light boiler (hexane) content, as expected, the direct sequence is more favorable as the indirect sequence, whereas for an equimolar feed both concepts are close to each other and for the mixture with large high boiler (octane) content the indirect sequence is more favorable than the direct one. Methods and further examples how to estimate Pareto sets and how a decision support system can be used to explore trade-offs are described in Bortz et al. (2014), Burger et al. (2014) and Hashem et al. (2017).

3.2. Sensitivity Analysis for Process Design

In this case the impact of uncertainties of an activity coefficient model on the design of a distillation column to separate a methanol-water mixture is considered (similar to Asprion et al. (2015), section 6.2 NQ Curve). In Fig. 3 on the left-hand side the impact of the uncertainties on the McCabe-Thiele can be seen, which look rather small, but since the purity specification of the product methanol is very high, there is a huge impact on the design. For the worst case this results in much higher number of stages required for a constant reboiler duty or significant higher reboiler duties at constant number of stages compared to the nominal model.
Fig. 3: Impact of uncertainties of a NRTL activity coefficient model for methanol-water on the design of distillation column with high purity of methanol. Left: McCabe-Thiele diagram at 1 bar and right part: N-Q curve for 3 different models: ●, — : Nominal model, ✕, ---: model with 10% higher limiting activity coefficient of water in methanol, ✚,⋯ model with 10% lower limiting activity coefficient. Uncertainties effect the necessary number of stages and/or reboiler heat duty.

Further examples can be found in Chinen et al. (2018), Bortz et al. (2017), von Harbou et al. (2017) and Asprion et al. (2017), which partly also include examples for robust/stochastic optimization to minimize the impact of uncertainties.

3.3. Surrogate Modeling for Process Optimization

The next example demonstrates that tools originally developed for a different application as described in chapter 2 can be used in different contexts.

In this example for a process model of a cumene plant (for details see Asprion et al., 2017), the whole model is replaced by a surrogate model to be used for a multi-criteria optimization. These results will be compared with the results of the optimization (variables see Table 2) of the original, rigorous process model (cf. Asprion et al., 2017, Fig.7, VLE2; k1; k2) to demonstrate the feasibility of that approach.

In a first step, a sensitivity analysis of the rigorous process model is performed using a Quasi-Monte-Carlo sampling based on Sobol sequences. To start with, this was done in

the range given in Table 2, leading however to a very high number (>70%) of infeasible, divergent simulation runs. Therefore, in a second step the range was reduced as given in Table 3. The number of samples (scenarios considered in the sensitivity analysis) was set to 10 per optimization variable yielding in this case 70 samples. From these a subset of 60 could be used to train surrogate models. The setup of the models was done using a functionality originally developed for greybox modeling (cf. Asprion et al., 2019).

Table 2: Range of the optimization variables for optimization of the rigorous process model: inlet temp. of the reactor T_{in}, propen to benzene ratio (p to b), reflux ratio (RR) and logarithmic cumene split ratio (ln(CR)) of column 1 and 2 (cf. Asprion et al., 2017 for details).

	T_{in}/°C	p to b	RR_1	$ln(CR_1)$	RR_2	$ln(CR_2)$	load
min	340	0.2	0.1	-12	0.1	-12	0.6
max	400	0.9	1	-1	1	-1	1.2

Table 3: Range of the variables for sampling of the rigorous model based on Sobol sequences (taken from Asprion et al., 2019, supplement, Table A1).

	T_{in}/°C	p to b	RR_1	$ln(CR_1)$	RR_2	$ln(CR_2)$	load
min	340	0.5	0.1188	-3.1	0.3	-10.5	0.6
max	345	0.6	0.4188	-2.5	0.4	-9	1.2

The objective *capacity* is proportional to the *load*, which was used directly in the surrogate model. For the objectives *OpEx* (operational expenditure discounted for 10 years per ton of cumene) and *GWP* (global warming potential) artificial neural networks with one hidden and one output layer with 7 neurons each (according to the 7 variables used as input, see Table 3) were trained (regression coefficients R^2=0.99 and 0.92). To account for the 21 constraints used in the original optimization problem, these corresponding functions have also been modeled using neural nets. 15 functions could be modeled without a hidden layer (R^2=0,87-1) and 6 have been modeled (R^2=0,98-1) with a net with the same structure as the net for the objectives *OpEx* and *GWP*. All nets use a α-sigmoid function with α=2. These models have been used in a multi-criteria optimization: minimizing *OpEx*, *GWP*, *load* and maximizing *capacity* as can be seen in Fig. 4.
Fig. 4: Comparison of the results of a rigorous process model (□, ○, △) of a cumene plant with the results of different versions of a surrogate model (●, ▲). First a surrogate model has been created using a quasi-Monte-Carlo sampling (Sobol sequences) of the rigorous model. This model has been used for multi-criteria optimization (●) and is compared with the optimization results of the original model (□). Verification with the rigorous model using the optimization variables of the surrogate (○) shows larger deviation. Therefore, this data has been added and used to retrain the surrogate. ▲, △ are representing the results of the optimization of the improved surrogate and the corresponding verification with the rigorous model.

The surrogate model (●) in general predicts too low values for the objectives and when using the estimated optimization variables as inputs of the rigorous model (○), the objectives are higher than the optimal values of the rigorous model (□). Therefore, in a second iteration the 22 verification runs together with the original samplings have been used to retrain the surrogate model. The optimization with this second surrogate model (▲) shows a good agreement with the objectives obtained from optimizing the rigorous model (□) and also the verification with the optimization variables (△) has only small deviations (mean absolute deviation OpEx < 0,067%; GWP < 0,13%). During the optimization the validity range of the models has been accounted for by using convex hulls, which were used to setup a constraint allowing for an extrapolation of 10% outside the validity range. This is the reason why the load range is not fully covered. One possibility would be to proceed with iterative retraining of the model and optimization until the full range is exploited. The agreement between the objectives of the surrogate and the verification can be used as a stopping criterion for an iterative optimization and retraining of surrogate models.

Further examples for surrogate modeling can be found in McBride and Sundmacher (2019).

4. Conclusions and Outlook

In process development many decisions have to be made concerning process concepts, experiments, models and model parameters, risk quantification and mitigation measures, which can be supported by process modeling, simulation and optimization. As was shown in the examples, it is essential that a process simulator supports methods like for example multi-criteria optimization, sensitivity analysis and surrogate modeling. Here an efficient data management for a multitude of solutions and helpful visualizations are required to enable comparisons, exploring the solution space and thus offering support to arrive at sound, documented decisions.

A Neural Network-Based Framework
to Predict Process-Specific Environmental Impacts

Abstract

Growing environmental concern and strict regulations led to an increasing effort of the chemical industry to develop greener production pathways. To ensure that this development indeed improves environmental aspects requires an early-stage estimation of the environmental impact in early process design. An accepted method to evaluate the environmental impact is Life Cycle Assessment (LCA). However, LCA requires detailed data on mass and energy balances, which is usually limited in early process design. Therefore, predictive LCA approaches are required. Current predictive LCA approaches estimate the environmental impacts of chemicals only based on molecular descriptors. Thus, the predicted impacts are independent from the chosen production process. A potentially greener process cannot be distinguished from the conventional route. In this work, we propose a fully predictive, neural network-based framework, which utilizes both molecular and process descriptors to distinguish between production pathways. The framework is fully automatized and includes feature selection, setup of the network architecture, and predicts 17 environmental impact categories. The pathway-specific prediction is illustrated for two examples, comparing the CO_2-based production of methanol and formic acid to their respective fossil production pathway. The presented framework is competitive to LCA predictions from literature but can now also distinguish between process alternatives. Thus, our framework can serve as initial screening tool to identify environmentally beneficial process alternatives.

Keywords: predictive life cycle assessment, artificial neural network, early process development stage, comparison of pathway alternatives

1. Introduction

Today, the chemical industry is mainly based on fossil fuels leading to greenhouse gas (GHG) emissions. To reduce these GHG emissions and the dependency on fossil resources, process alternatives are developed using renewable resources such as CO_2 as feedstock. To quantify environmental reduction potentials resulting from technological change and to support the investment decision process, these process alternatives have to be assessed environmentally in an early design stage. An accepted method for environmental assessment is Life Cycle Assessment (LCA). Life Cycle Assessment is a holistic approach, which avoids emission shifting between life cycle phases or types of environmental impacts. However, LCA requires detailed data, which is limited in early process design stages. Therefore, so-called streamlined LCA approaches approaches are required.

Streamlined LCA approaches reduce the scope of the assessment or simplify the required data

(Hunt et al., 1998; Casamayor and Su, 2012). One possibility of streamlining is the use of machine learning. Current machine learning approaches for predictive LCA of chemicals are based on artificial neural networks (ANN). To transform the characteristics of a molecule into an input vector for the ANN, these models use molecular descriptors, e.g., molecular weight or functional groups (Song et al., 2017; Calvo-Serrano et al., 2017; Wernet et al., 2009). The main drawback of molecular descriptors is that the ANN cannot distinguish between production pathways leading to the same chemical. Therefore, molecular descriptors cannot resolve environmental reduction potentials due to process alternatives.

In this work, we propose an ANN-based framework that considers both, molecular and process descriptors. Thereby, the model can obtain process-dependent impacts and capture trade-offs of different production pathways.

2. Fully Automated Algorithm for Environmental Impact Prediction

Artificial neural networks are non-linear function approximators (Hornik et al., 1989), which usually have a greater generalization ability than linear regression models. The network consist of input, output and hidden layers, whereby each layer consists of neurons (see Figure 1, upper part). The neurons of each layer are connected by edges to the following layer. In a neuron, the inputs x_j are weighted according to their edge weight $w_{k,j}$, summed and the result is projected into a non-linear space by the activation function φ (see Figure 1, lower part). The edge weights are determined during the training process.

In this work, we propose a fully automated framework including the selection of a suitable subsets of descriptors, also called feature selection, and optimization of the network architecture (see Figure 2): In a first step, suitable descriptors are selected using stepwise regression. Afterwards, a genetic algorithm (GA) determines the optimal network architecture to predict a given environmental impact. The prediction quality of the resulting network is quantified and compared to the prediction error of a former loop. If the tolerance ε is reached, the GA stops and the optimal architecture is stored. In the last step, the generated ANN is used to predict the environmental impact for a given chemical.

$$y_k = \varphi(v_k) = \varphi \left(\sum_j w_{kj} \cdot x_j + b_k \right)$$

Figure 1: General structure of an ANN, including a zoom of a single neuron. The input values x_j of a general neuron k are weighted by $w_{k,j}$ and summed subsequently. The bias b_k allows for shifting the output by constant value. The resulting output v_k is passed to an activation function φ, which is usually a sigmoid function. As a results of the sigmoid function, the output y_k lies in a range of $[-1; 1]$. The output is then passed to the neurons of the subsequent layer.

To distinguish between several production pathways leading to the same chemical, we use a combination of molecular descriptors and process descriptors. The process descriptors are based on the environmental indicators proposed by Patel et al. (2012).

2.1. Feature Selection

Feature selection reduce the input dimension by selecting a subset of suitable descriptors from all available descriptors to . We use stepwise regression as feature selection algorithm under the assumption that a sufficient linear correlation indicats also a non-linear correlation. Due to limited LCA data available for the training and to avoid overfitting, the final number of descriptors used in the ANN is limited to 10 % of the number of training samples.

We consider 185 possible descriptors in total, consisting of 178 molecular descriptors and 7 process descriptors. Molecular descriptors describe the main product of a process based on physical and chemical properties as well as classical functional groups. Process descriptors are based on the impact indicators proposed by Patel et al. (2012). E.g., the concentration of each component at the reactor outlet is calculated assuming ideal phase and chemical equilibrium. This process descriptor is assumed to correlate to the required separation effort. The temperature-dependent enthalpies and entropies are obtained from quantum mechanics calculations for each component. An additional process descriptor is given by the environmental impact EI of the reactants. The environmental impacts are summed according to the stoichiometric reaction equation $EI_{stoichio} = \sum_i \frac{v_i M_i}{v_{mp} M_{mp}} \cdot EI_i, i \in [1,...n]$, wherein v_i

Figure 2: Algorithm to set up a neural network to predict environmental impacts. $\Delta error$ is the difference between the objective value of the former loop and the objective value of the current loop for a given architecture. ε is the chosen tolerance for convergence.

is the stoichiometric coefficient of reactant i out of n reactants, M_i is the molar weight of reactant i, v_{mp} is the stoichiometric coefficient and M_{mp} the molar weight of the main product. Considering the sum of environmental impacts of the reactants transforms the reaction equation into a scalar input for the ANN and thus delivers a lower bound of the expected environmental impact of the product. If co-products occur in the reaction, mass allocation is applied to divide the impact of the upstream on all products. After feature selection, the descriptors are normalized to the range of $[-1;1]$.

2.2. Network Setup

Our framework generates automatically a feedforward neural network for a given training set. The set up procedure of the neural networks requires the definition of so-called hyperparameters. These hyperparameters include the number of hidden layers, the number of neurons in each hidden layer, the regularization parameter, the number of maximum epochs and the kind of training algorithm. Typically, hyperparameters are chosen based on expert knowledge or using genetic algorithms. In this work, we use the GA of the MATLAB toolbox (The MathWorks, Release 2016a). The objective of the GA is to minimize the ratio between the root mean squared error (RMSE) and the coefficient of determination (R_P^2)). The coefficient of determination is given as

$R_P^2 = \left(\frac{\sum_i (t_i - \bar{t})(y_i - \bar{y})}{\sqrt{\sum_i (t_i - \bar{t})^2 \sum_i (y_i - \bar{y})^2}} \right)^2$, wherein t_i is the target value of sample i, $\bar{t}$ the mean of all target values, y_i the estimation of sample i and $\bar{y}$ the mean of all estimations. A value of 1 repre-

sents perfect correlation, while a value of 0 corresponds to no prediction ability of the ANN. The objective is defined as ratio of two error measures to minimize the absolute error (RMSE) as well as possible trends (R_P^2). Minimizing only the RMSE tends to lead to constant predictions of the average impact value, while minimizing only the coefficient of determination improves predictions of trends but increases absolute prediction errors.

Initially, the available training data is divided into 3 sets: (1) a training set (containing 85% of the overall data), which is used to train the ANN in each loop of the GA, (2) a validation set (10%), which is used to qualify the generalization ability of the regarded network architecture in each GA loop, (3) and a final test set (5%), which is used to qualify the results generated by the GA. The validation set is used to calculate the objective value of the GA in each loop. The test set is used to calculate the final objective value and to validate the final optimized network architecture.

The GA suggests possible hyperparameters in each loop. Using the suggested hyperparameters, an ANN is trained on the training set. Afterwards, the generalization ability is tested on the validation set. This loop is iterated until the GA has found a local optimum. Due to the local nature of the GA, we use a multistart approach, running several GA instances parallel. The optimal architecture is used afterwards for estimating the regarded environmental impact category.

3. Case study: Component vs. Process-Specific Networks

The proposed framework is employed to generate 17 neural networks, each predicting one of 17 Recipe v1.08 (H) Midpoint categories (Goedkoop et al., 2009). Here, we exemplified the framework for predicting the impact on Climate Change of methanol and formic acid. For training, we use LCA data of 63 organic chemicals obtained from the Gabi Database (PE International, 2012). The training data includes two alternative pathways for methanol and formic acid, respectively. Since the number of data samples is limited, the number of descriptors selected during feature selection is set to 6. For the validation set, 6 samples are chosen randomly in the beginning of each GA run, corresponding to 10 % of the available training data. The samples are kept constant during the optimization of one GA run to guarantee convergence of the GA. For the test set, the two process alternatives for methanol and formic acid, respectively, are chosen manually to test the assessment of competing process alternatives. This procedure allows for validating the process-specific prediction ability.

3.1. Prediction Performance

To validate the prediction performance of the process-specific network, we compare the process-specific ANN to an ANN solely based on molecular descriptors, called component-specific ANN in the following (Figure 3). The ANN are compared based on the coefficient of determination R_P^2. The coefficient of determination is calculated for the training set of each network using leave-one-out cross validation. Each sample in the training set is left out once, the ANN is trained based on the remaining training set and the left out sample is predicted. Thus, the coefficient of determination is calculated using the prediction of each sample.

The process-specific ANN increase the prediction performance for 10 of 17 Recipe v1.08 (H) Midpoint indicators (Figure 3). The maximum improvement in terms of the coefficient of determination is achieved for Marine Ecotoxicity (MET) with an increase of 0.64 using the process-specific network in contrast to the component-specific network. The maximum decline is obtained for Photochemical Oxidant Formation (POF) with an reduction of 0.29. Although the absolute coefficient of determinations are still small with values lower than 0.4 for 16 of 17 impact categories, the use of process-descriptors has improved clearly prediction performance.

To compare our results to literature, we apply an literature-based ANN on our training data using the architecture and hyperparameters proposed by Wernet et al. (2008, 2009). The literature ANN achieves worse coefficients of determination for 14 of 17 impact categories compared to the process-specific ANN (Figure 3). Since Wernet et al. (2009) obtained coefficients of determina-
Figure 3: Comparison of the coefficient of determination for the process-specific ANN (black) and the component-specific network (grey), respectively, given for 17 Recipe 1.06 Midpoint categories: Marine Ecotoxicity (MET), Freshwater Ecotoxicity (FET), Climate Change exclusive biogenic carbon (CC-B), Climate Change (CC), Water Depletion (WD), Fossil Resource Depletion (FD), Freshwater Eutrophication (FE), Terrestrial Ecotoxicity (TET), Human Toxicity (HT), Terrestrial Acidification (TA), Ozone Depletion (OD), Photochemical Oxidant Formation (POF), Ionising Radiation (IR), Agricultural Land Occupation (ALO), Marine Eutrophication (ME), Mineral Resource Depletion (MRD), and Particulate Matter Formation (PMF). The shaded bars are the results from an ANN based on the descriptors and architecture given in Wernet et al. (2008, 2009).

tion of 0.41 up to 0.69 using similar hyperparameters, but other training data, the lower coefficient of determination shown in Figure 3 results from small training data set and its poor data quality. The coefficient of determination obtained for Climate Change by leave-one-out on our training set is comparable to the $R^2_P = 0.31$ presented in Song et al. (2017).

3.2. Process-Specific Prediction

The proposed process-specific network is able to distinguish between alternative production pathways. To show this potential, the impact on Climate Change is predicted for two production alternatives for both methanol and formic acid (Figure 4). For this purpose, a network is trained without data for the production pathways of methanol and formic acid. Two pathway alternatives are then predicted: a fossil-based pathway, utilizing synthesis gas from steam methane reforming as carbon source, and a CO_2-based pathway utilizing CO_2 from an ammonia plant as carbon source. For both pathways, hydrogen is supplied by steam methane reforming and electricity is assumed as the current European grid mix. The impacts on Climate Change of both pathways are predicted using both the component-specific and the process-specific

Figure 4: Comparison of the reduction potential in Climate Change for methanol and formic acid, calculated as the difference between fossil-based pathway and CO_2-based pathway alternative.

network. The predictions are compared to literature LCA values from Gabi (PE International, 2012) for the fossil-based pathways and from Artz et al. (2018) for the CO_2-based pathways.

In literature, the CO_2-based production of formic acid causes a smaller impact on Climate Change than the fossil-based production pathway, resulting in a positive reduction potential (Figure 4). In contrast, the CO_2-based production of methanol is less environmentally friendly than the fossil-based pathway, resulting in a negative reduction potential. The component-specific ANN is not able to distinguish between different production pathways. Therefore, no reduction potential can be identified using the component-specific ANN. In comparison, the pathway-specific ANN can distinguish between process alternatives, resulting in a positive predicted reduction potential of the CO_2-based pathway for formic acid and a negative predicted reduction potential of the CO_2-based pathway for methanol. Although the potentials are overestimated by the process-specific ANN, the trends in reduction potentials are predicted correctly. Thus, the process-specific neural network can be used for comparison of pathway alternatives in early design stages.

4. Conclusion

In this work, we present a neural network-based framework to predict process-specific environmental impacts. The framework is fully automated including feature selection and architecture optimization of the ANN. In addition to molecular descriptors, process descriptors are used to enable process-specific predictions. The process descriptors increase the coefficient of determination up to 0.64. Importantly, process descriptors enables the network to distinguish between production pathways. The process-specific prediction ability is exemplified for methanol and formic acid: for each chemical, two production scenarios are predicted, one fossil-based and one CO_2-based. The trends in the environmental impact are predicted correctly, showing that our framework can serve as initial screening tool for identifying environmentally beneficial process alternatives. More training data would be desirable to increase the quantitative accuracy.

Abstract

Reverse Osmosis (RO) process can be considered as one of the most widely utilised technologies for brackish water desalination due to its capabilities of retaining salts and producing high-quality water. This paper focuses on the retentate recycle design of an industrial medium-sized spiral wound brackish water RO desalination plant (1200 m³/day) of Arab Potash Company (APC) located in Jordan. The plant is essentially designed as a multistage and multi pass RO system including a low salinity retentate recycle stream from the 2nd pass and a high salinity retentate disposal from the 1st pass. However, in this work, we have considered recycle of high salinity retentate stream from the 1st pass and explored the impact of different recycled ratio on the process performance indicators such as the fresh water salinity, overall recovery rate, and specific energy consumption. The simulation is carried out using the model developed earlier by us for the specified RO plant using gPROMS software. The results indicate the possibility of increasing the product capacity by around 3% with 100% retentate recycle ratio.

1. Introduction

Broadly speaking, water scarcity is a major environmental challenge facing Jordan since the early 1960s until these days. Jordan occupies the 10th rank in the world in terms of the shortage and insufficient of water resources (Hadadin et al., 2010). Therefore, it is important to exploit the brackish water using desalination to be used as a main source of drinking water and industrial requirements. In this respect, the Arab Potash Company (APC) implemented a power plant including brackish water RO desalination plant capacity of 1200 m³/day to produce low-salinity water (i.e. conductivity of less than 0.641 ppm) to be used in the ion exchangers (Al-Obaidi et al., 2018).

The RO process has affirmed its robustness as a superior technology for brackish water desalination due to its high performance of salt rejection and water permeation

(Ghaffour et al., 2015). Moreover, the application of RO process is interestingly increased due to its low cost and energy consumption compared to other conventional thermal technologies (Al-Karaghouli and Kazmerski, 2013). The multistage RO process is originally designed in several configurations to satisfy the specifications of the produced water. Specifically, the permeate and retentate recycling designs were employed by several researchers and their impacts on the process performance were investigated. For instance, Al-Bastaki and Abbas (1999) used a small-scale spiral wound RO water desalination plant of water solution (with concentration of 10,000 mg NaCI/I) in a cyclic mode to study the performance of permeate flow rate and salt rejection. They confirmed a reduction in the concentration polarisation that increased the permeate flux as a result to applying the cyclic mode of operation. Al-Bastaki and Abbas (2003) studied the impact of permeate recycled design on the performance of a small-scale spiral wound RO desalination plant. The simulation results of permeate recycle ratios between 0% to 25% confirmed a reduction in the concentration polarisation which entirely improved the product quality despite a reduced production rate. Specifically, the product concentration is reduced by 15% at 25% of recycling ratio compared to the case of no recycle mode. Whereas, the production rate is reduced by 22% compared to the case of no recycle mode.

Al-Obaidi et al. (2018) have demonstrated an extensive study to evaluate the performance of brackish water desalination plant of APC located in Jordan and based on multistage RO process via modelling and simulation. The model developed is validated with an actual data collected from APC and then used to carry out a sensitivity analysis to predict the plant performance against the variation of operating conditions. However, up to the authors' knowledge, the influence of different ratios of retentate stream recycle (that combined with raw water stream) on the process performance indicators has not yet been explored. In this respect, the performance of RO process with 10% to 100% high salinity retentate stream of the 1st pass will be investigated. Then, the process performance would be compared against the original experimental data of no recycle mode that carried out at specified operating conditions.

2. Description of BWRO desalination plant of APC

Fig.1 depicts the configuration of BWRO plant which contains 120 membranes, 20 pressure vessels (6 membranes in each) and includes two passes with retentate reprocessing design. The 1st pass comprises 2 stages arranged in parallel of 6 pressure vessels with configuration (4:2) and the 2nd pass comprises 3 stages of 4 pressure vessels with configuration (2:1:1).

The low-pressure permeates of 1st pass (position 1) are combined and pumped to the 2nd pass. Therefore, two forwarding high pumps are used to drive the water through the membranes in the 2nd pass. However, the high salinity retentate from the 1st pass is discharged into drain system (position 4). The permeate streams of 2nd pass are gathered to form the plant product stream, which is collected in product tank with salinity around 2 ppm (position 3). However, the low salinity retentate stream from the 2nd pass (position 2) is recycled back to be coupled with the main stream of raw water (with salinity 1098.62 ppm).

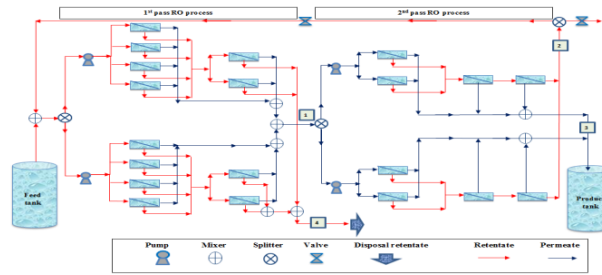
Table.1 shows the transport parameters and membranes specification. Also, the operating parameters of BWRO plant of APC are listed in Al-Obaidi et al. (2018).


Figure 1. Schematic diagram of BWRO desalination plant of APC (Adapted from Al-Obaidi et al., 2018).

Table 1. Specifications of the spiral wound membrane element (Adapted from Al-Obaidi et al., 2018).

Parameter	Feed water salinity [ppm]	Feed water flow rate [m³/h]	Feed temperature [°C]	Daily production capacity [m³/day]	Average product salinity [ppm]	Total system rejection [%]
Value	(1098.62)	(74)	(25)	(1200)	(1.96)	(99.80)

3. RO process modelling

The steady state model for an individual spiral wound RO process is developed by Al-Obaidi et al. (2018) and successfully used to characterise the complete mathematical model of multistage brackish water RO plant of Arab Potash Company (APC). The complete mathematical model has been coded and solved within the gPROMS software suite. The model developed is validated with the actual data collected from APC and showed a good agreement.

4. Impact of recycling the retentate of 1st pass on process performance

The performance of the BWRO process of APC plant is investigated in this section by varying the 1st pass retentate stream recycle ratio from 10% to 100% in a step change of 10%. It is noteworthy to confirm that the RO plant is currently working at no recycle mode of 0% retentate recycle ratio. More importantly, this study is based on investigating the process performance against a step change of a spontaneous retentate recycle. The process performance indicators include the total plant recovery (Rec), total plant rejection (Rej), product flow rate and concentration (Qp, Cp), retentate flow rate and concentration (Qr, Cr), and energy consumption. Also, the current simulation is carried out at fixed values of 1098.62 ppm, 74 m3/h, 9.22 atm, and 25°C, of raw water concentration, feed flow rate, operating pressure, and temperature, respectively.

Fig. 2. shows insignificant variation of total plant rejection in an exponential relationship and a continuous drop in total plant recovery in a linear relationship against the increased retentate recycle ratio of 1st pass. In this respect, it can be said that 40% of recycled ratio has attained the optimal value of rejection. More importantly, the reduction of water recovery ratio can be attributed to an increase in the plant feed flow rate due to an increase in the retentate recycle ratio of 1st pass coupled with retentate

stream from the 2nd pass and with the raw water stream. This in turn causes an increase in the bulk velocity of all the membrane stages that accompanied with a reduction in the residence time of solution inside the feed channel. Moreover, the continuous increase of feed concentration has passively impacted the concentration polarisation that entirely reduces the permeated water through the membranes. Therefore, the total permeate flow rate of 1st pass is decreased as a response to increasing retentate ratio. This in consequence had reduced the total water recovery as noticed in Fig. 2. Subsequently, it is fair to expect an increase of the energy consumption due to increasing the recycle ratio. It is worth noting that a decrease in total recovery means that the requirements for energy consumption will be higher. This is already highlighted in Table.3.
Figure 2. Impact of ratio variation on total plant recovery and rejection.

The influence of increasing the 1st pass recycle ratio of retentate on the product and retentate plant flow rates is shown in Fig. 3. It is clear that the product flow rate and retentate flow rate are significantly increased and decreased, respectively. The increasing of product flow rate is belonging to a lower velocity inside the module caused by decreasing the inlet feed flow rate of 2nd pass with increasing recycled ratio of retentate. It is important to realise that the total permeate of 1st pass is used as feed stream of 2nd pass. Up to this point, this would be associated with a lower residence time that reduced the retentate flow rate and increased water recovery of 2nd pass. However, the total water plant recovery keeps down due to a high progress of feed flow rate compared to a lower progress in product flow rate.
Figure 3. Impact of ratio variation on product and retentate plant flowrate.

The simulation results of Fig. 4 confirm that increasing of recycled retentate ratio causes a considerable increase in both product and retentate concentrations. This is ascribed to increasing the plant feed water concentration due to increasing the recycle ratio of high-

salinity stream. Furthermore, these results support the findings of Fig. 2 that associated with a continuous reduction of total water recovery.
Figure 4. Impact of ratio variation on product and retentate plant concentration.

Table 3 presents the simulation results of energy consumption with the tested recycle ratios of the 1st pass retentate at fixed operating pressure and raw water concentration. Basically, the energy consumption is significantly increased by around (15%) as a response to this variation. This is might attributed to the progress of plant feed flow rate that dominated the energy consumption despite the noticeable improvement of product flow rate with increasing recycle ratio.

Table 3. The energy consumption simulation results with variation of recycled retentate.

Recycle ratio	10%	20%	30%	40%	50%
Power consumption [kWh/m³]	0.860	0.873	0.887	0.900	0.914

Recycle ratio	60%	70%	80%	90%	100%
Power consumption [kWh/m³]	0.929	0.944	0.959	0.975	0.992

To understand the performance of multistage RO process with no recycle mode (0% retentate ratio), Table. 4 presents the simulation results of several performance indicators with 40% and without recycle mode for comparison purposes. Specifically, it is noticed that no recycle mode can keep the process at the lowest product concentration and highest water recovery that commensurate with the lowest energy consumption.

However, the highest total product flow rate is achieved at 100% retentate recycle of the 1st pass which involved a slight increase of product concentration from 1.937 to 2.974 ppm at the same operating conditions. Therefore, this would enhance the productivity of fresh water which might be a possible negotiable point despite the necessity of increasing the requirements of energy consumption by around 17% within almost fixed solute rejection.

5. Conclusions

The performance of multistage and multi pass RO brackish water desalination plant of Arab Potash Company (APC) with different recycled ratios of 1st pass retentate is investigated via simulation. This is occurred in terms of several performance indicators. The simulation is carried out at fixed raw water flow rate, concentration, pressure, and temperature. This in turn explored that 100% retentate recycle can perform the highest production capacity with increased energy consumption.

This is originally compared to no recycle mode that currently used in the RO process of APC plant, and showed the lowest product concentration at the minimum product capacity.

Table 4. The simulation results of process performance indicators with 100%, 40%, and without recycle mode.

Indicators of process performance at recycle ratio from 1st pass = 0 % [APC plant]		Indicators of process performance at recycle ratio from 1st pass = 40 %		Indicators of process performance at recycle ratio from 1st pass = 100 %	
Rej_plant [%]	99.804	Rej_plant [%]	99.811	Rej_plant [%]	99.801
Rec_plant [%]	51.898	Rec_plant [%]	46.889	Rec_plant [%]	40.981
Qp_plant [m³/h]	43.991	Qp_plant [m3/h]	44.578	Qp_plant [m3/h]	45.297
Qr_recycle from 2nd pass [m³/h]	15.005	Qr_recycle from 2nd pass[m3/h]	12.095	Qr_recycle from 2nd pass[m3/h]	8.139
Cp_plant [ppm]	1.937	Cp_plant [ppm]	2.319	Cp_plant [ppm]	2.975
Cr_recycle [ppm]	169.159	Cr_recycle [ppm]	228.545	Cr_recycle [ppm]	368.465
power consumption pump [kWh/m³]	0.848	power consumption pump [kWh/m3]	0.900	power consumption pump [kWh/m3]	0.991

Deciphering Latent Uncertainty Sources with Principal Component Analysis for Adaptive Robust Optimization

Chao Ning, Fengqi You[*]

Cornell University, Ithaca, New York, 14853, USA

fengqi.you@cornell.edu

Abstract

This paper proposes a novel data-driven robust optimization framework that leverages the power of machine learning for decision-making under uncertainty. By performing principal component analysis on uncertainty data, the correlations among uncertain parameters are effectively captured, and latent uncertainty sources are identified. Uncertainty data are then projected onto each principal component to facilitate extracting distributional information of latent uncertainties with kernel density estimation technique. To explicitly account for asymmetric uncertainties, we introduce forward and backward deviation vectors in an uncertainty set. The resulting data-driven uncertainty set is general enough to be employed in adaptive robust optimization model. The proposed framework not only significantly ameliorates the conservatism of robust optimization but also enjoys computational efficiency and wide applicability. An application of optimization under uncertainty on batch process scheduling is presented to demonstrate the effectiveness of the proposed general framework. We also investigate a data-driven uncertainty set in a low-dimensional subspace and derive a theoretical bound on the performance gap between ARO solutions due to the dimension reduction of uncertainties.

Keywords: big data, optimization under uncertainty, principal component analysis

1. Introduction

As a promising alternative paradigm, robust optimization characterizes uncertain parameters using an uncertainty set (Mulvey et al. 1995; Ben-Tal et al., 2009;). Uncertainty set-induced robust optimization can be divided broadly into two categories, namely static robust optimization and adaptive robust optimization (ARO). In static robust optimization, all the decisions are made "here-and-now" before uncertainty realizations. By introducing "wait-and-see" decisions, ARO approach well models the sequential nature of decision-making processes, and ameliorates the conservatism issue (Ben-Tal and Nemirovski, 2002). In recent years, robust optimization methodology has found a fruitful of applications, such as biomass processing network (Gong et al., 2016), production scheduling (Shi et al., 2016), supply chain (Yue et al., 2016), energy systems (Gong et al., 2017), and model-based control (Shang et al., 2019).

Despite the burgeoning popularity of robust optimization, conventional robust optimization methods have some potential limitations (Ning and You, 2017a). First, they do not take advantage of the power of machine learning and big data analytics to leverage uncertainty data for decision-making under uncertainty (Shang and You,

2017). Moreover, their adopted uncertainty sets fail to account for the correlations or asymmetry among uncertainties. Neglecting relevant information embedded in uncertainty data, such as correlations and asymmetry, could render the induced robust optimization solution conservative. With the explosion in uncertainty data and great advances in machine learning techniques, data-driven optimization paves a new way to decision-making under uncertainty (Ning and You, 2017b). Based on all the concerns above, the research objective of our work is to develop a general data-driven robust optimization framework that exploits uncertainty data for decision-making under uncertainty. In this paper, we propose a general data-driven decision-making framework that bridges machine learning with robust optimization methodology directly. A theoretical analysis on the impact of uncertainty dimension reduction on the quality of ARO solutions is also performed within the proposed framework.

2. Data-Driven Uncertainty Set Construction

Consider an uncertainty data matrix $\mathbf{X} = \left[\mathbf{u}^{(1)}, \dots, \mathbf{u}^{(N)} \right]^T \in R^{N \times m}$, in which each row represents an uncertainty data point in m-dimensional space. There are a total number of N uncertainty data points. We first scale matrix X to zero-mean in (4) for principal component analysis (PCA) modelling (Murphy, 2012; Friedman et al. 2001), as shown in Eq. (1).

$$\mathbf{X}_0 = \mathbf{X} - \mathbf{e}\boldsymbol{\mu}_0^T \tag{1}$$

where $\mathbf{X}_0$ is an uncertainty data matrix after scaling, $\mathbf{e}$ denotes a column vector of all ones, and $\boldsymbol{\mu}_0$ represents the mean vector of uncertainty data.

The covariance matrix of uncertain parameters can be approximated with the sample covariance matrix $\mathbf{S}$, as shown in $\mathbf{S} = 1/(N-1)\mathbf{X}_0^T\mathbf{X}_0$. Through the eigenvalue decomposition, we can obtain $\mathbf{S} = \mathbf{P}\boldsymbol{\Lambda}\mathbf{P}^T$. The square matrix $\mathbf{P} = \left[\mathbf{p}_1, \dots, \mathbf{p}_m \right] \in R^{m \times m}$ consists of all the m eigenvectors (corresponding to the principal components), and $\boldsymbol{\Lambda} = diag\{\lambda_1, \mathrm{K}, \lambda_m\}$ is a diagonal matrix consisting of all the eigenvalues.

Consider the projection of an uncertainty data point $\mathbf{u}^{(i)}$ onto the k-th principal component, shown as follows,

$$\mathbf{t}_k^{(i)} = \mathbf{p}_k^T \left[\mathbf{u}^{(i)} - \boldsymbol{\mu}_0 \right] \tag{2}$$

Let ξ_k be a latent uncertainty along the k-th principal component, $\hat{f}_{KDE}^{(k)}(\xi_k)$ denotes the estimated probability density function of ξ_k by using the kernel density estimation approach, and $\hat{F}_{KDE}^{(k)}(\xi_k)$ be the corresponding cumulative density function. The corresponding quantile function can be expressed as follows:

$$\hat{F}_{KDE}^{(i)\,-1}(\alpha) = \min\left\{ \xi_k \in R \middle| \hat{F}_{KDE}^{(k)}(\xi_k) \geq \alpha \right\} \tag{3}$$

which provides the minimum value of ξ_k based on a specific parameter α.

We propose the data-driven uncertainty set with uncertainty budget, as shown below.

$$U = \left\{ \mathbf{u} \left| \begin{array}{l} \mathbf{u} = \boldsymbol{\mu}_0 + \mathbf{P}\boldsymbol{\xi}, \ \boldsymbol{\xi} = \underline{\boldsymbol{\xi}} \circ \mathbf{z}^- + \overline{\boldsymbol{\xi}} \circ \mathbf{z}^+, \\ \mathbf{0} \le \mathbf{z}^-, \ \mathbf{z}^+ \le \mathbf{e}, \ \mathbf{z}^- + \mathbf{z}^+ \le \mathbf{e}, \ \mathbf{e}^T\left(\mathbf{z}^- + \mathbf{z}^+\right) \le \Phi \end{array} \right. \right\} \tag{4}$$

where $\mathbf{z}^-$ is a backward deviation vector, $\mathbf{z}^+$ is a forward deviation vector, $\mathbf{e}$ is a column vector of all ones, and Φ is an uncertainty budget. $\boldsymbol{\xi}$ is the latent uncertainty vector, its lower bound vector $\underline{\boldsymbol{\xi}}$ is defined in Eq. (5), and the upper bound vector $\overline{\boldsymbol{\xi}}$ is defined in Eq. (6).

$$\underline{\boldsymbol{\xi}} = \left[\hat{F}_{KDE}^{(1)\,-1}(\alpha), \dots, \hat{F}_{KDE}^{(m)\,-1}(\alpha) \right]^T \tag{5}$$

$$\overline{\boldsymbol{\xi}} = \left[\hat{F}_{KDE}^{(1)\,-1}(1-\alpha), \dots, \hat{F}_{KDE}^{(m)\,-1}(1-\alpha) \right]^T \tag{6}$$

A novel feature of the data-driven uncertainty set in Eq. (4) is that PCA and kernel density estimation are utilized to accurately capture the principal components and distributions embedded within the uncertainty data. Additionally, the proposed uncertainty set U does not necessarily be symmetric by introducing the positive and negative deviations separately.

3. Data-Driven Adaptive Robust Optimization Framework

In this subsection, we propose a data-driven two-stage ARO model to organically integrate uncertainty data with adaptive optimization model, as shown in Eq. (7).

$$\begin{aligned} &\min_{\mathbf{x}} \ \mathbf{c}^T\mathbf{x} + \max_{\mathbf{u}\in U} \min_{\mathbf{y}\in\Omega(\mathbf{x},\mathbf{u})} \ \mathbf{b}^T\mathbf{y} \\ &\text{s.t.} \ \ \mathbf{A}\mathbf{x} \ge \mathbf{d}, \ \ \mathbf{x} \in R_+^{n_1} \times Z^{n_2} \\ &\quad\ \ \Omega(\mathbf{x},\mathbf{u}) = \left\{ \mathbf{y} \in R_+^{n_3} : \mathbf{W}\mathbf{y} \ge \mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{M}\mathbf{u} \right\} \end{aligned} \tag{7}$$

where $\mathbf{x}$ is the first-stage decision made "here-and-now" before the uncertainty $\mathbf{u}$ is realized, while the second-stage decision or recourse decision $\mathbf{y}$ is postponed in a "wait-and-see" mode after the uncertainties reveal themselves. $\mathbf{x}$ includes both continuous and integer variables, while $\mathbf{y}$ only includes continuous variables. $\mathbf{c}$ and $\mathbf{b}$ are the vectors of the cost coefficients. U is the data-driven uncertainty set in Eq. (4).

This data-driven adaptive robust optimization model is a tri-level optimization problem, which cannot be solved directly by any off-the-shelf optimization solvers. The key idea is to decompose the multi-level MILP shown in (7) into a master problem and a sub-problem. The master problem (8) contains only a part of extreme points, so it provides a relaxation of the original problem.

$$\begin{aligned} &\min_{\mathbf{x},\eta,\mathbf{y}^k} \ \mathbf{c}^T\mathbf{x} + \eta \\ &\text{s.t.} \ \ \mathbf{A}\mathbf{x} \ge \mathbf{d} \\ &\quad\ \ \eta \ge \mathbf{b}^T\mathbf{y}^k, \ \ k = 1, \dots, r \\ &\quad\ \ \mathbf{T}\mathbf{x} + \mathbf{W}\mathbf{y}^k \ge \mathbf{h} - \mathbf{M}\mathbf{u}^k, \ \ k = 1, \dots, r \\ &\quad\ \ \mathbf{x} \in R_+^{n_1} \times Z^{n_2}, \ \ \mathbf{y}^k \in R_+^{n_3}, \ \ k = 1, \dots, r \end{aligned} \tag{8}$$

where $\mathbf{u}^k$ is the enumerated uncertainty realization at the kth iteration, $\mathbf{y}^k$ is its corresponding recourse variable, and r represents the current number of iterations.

4. Application on Batch Process Scheduling

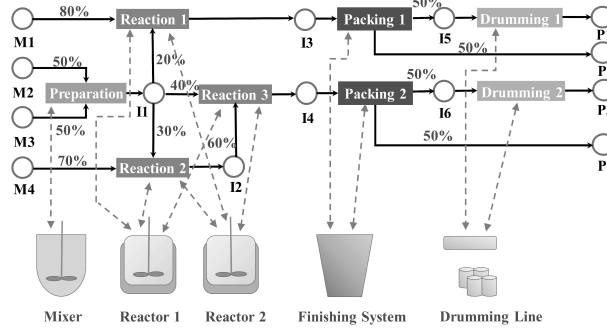
Planning and scheduling are typical operations in process systems engineering. Batch process scheduling plays a critical role in manufacturing industries (Chu et al., 2015). In this section, an industrial multipurpose batch process is presented to demonstrate the advantages of the proposed data-driven ARO approach. Figure 1 depicts the state-task network of this batch process (Chu et al., 2013). In this application, the product demands are uncertain.


Figure 1. State task network of a multipurpose batch process.

The conventional method only utilizes the bounds of demand data, whereas the proposed approach leverages machine learning to dig out the correlation information among different product demands for scheduling decisions. As a result, the proposed approach is less conservative, and returns $299 more profits than the conventional ARO method, and the Gantt chart of the proposed approach is displayed in Figure 2.
Figure 2. Optimal schedule decisions determined by the proposed data-driven approach.

5. Theoretical Analysis

High-dimensional uncertainty data often lies close to a low-dimensional subspace (Ferreira et al., 2012). Therefore, an extension of the proposed approach is to decipher the low-dimensional structure to perform "uncertainty dimension reduction" for ARO. Moreover, the discovered low-dimensional structure holds the potential to provide insights into the management of uncertainty. Only a small number of principal

components can be used to retain much uncertainty information (Xu et al., 2016). The ARO problem without performing uncertainty data compression is shown as (ARO-H).

(ARO-H) $$\min_{\mathbf{x} \in X} \left\{ \mathbf{c}^T \mathbf{x} + \max_{\mathbf{u} \in U} Q(\mathbf{x}, \mathbf{u}) \right\}$$

where $Q(\mathbf{x}, \mathbf{u})$ is the recourse function. We define problem (ARO-L) as follows:

(ARO-L) $$\min_{\mathbf{x} \in X} \left\{ \mathbf{c}^T \mathbf{x} + \max_{\mathbf{u} \in \hat{U}} Q(\mathbf{x}, \mathbf{u}) \right\}$$

where the uncertainty set $\hat{U} = \left\{ \hat{\mathbf{u}} \mid \exists \mathbf{u} \in U \ \ \hat{\mathbf{u}} = \Pi(\mathbf{u}) \right\}$.

Note that $\Pi(g)$ is an operator of projecting uncertainty onto a low-dimensional subspace. The projected vector has the same dimension as the original vector. Suppose that $\mathbf{x}^*$ and $\hat{\mathbf{x}}$ are the optimal solutions of problems (ARO-H) and (ARO-L), respectively. We are concerned with the difference in their worst-case performance in an uncertain environment where the real uncertainty realization is still in a high-dimensional space. The following theorem provides a theoretical bound on the solution quality due to the uncertainty data compression for the ARO problem.

Theorem. Given that $\mathbf{x}^*$ and $\hat{\mathbf{x}}$ are the optimal solutions of problems (ARO-H) and (ARO-L), respectively. We have

$$0 \leq \left[\mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in U} Q(\hat{\mathbf{x}}, \mathbf{u}) \right] - \left[\mathbf{c}^T \mathbf{x}^* + \max_{\mathbf{u} \in U} Q(\mathbf{x}^*, \mathbf{u}) \right] \leq \alpha \cdot \beta \tag{9}$$

where parameter $\alpha = \max_{\mathbf{u} \in U} \left\| \mathbf{u} - \Pi(\mathbf{u}) \right\|_2$, parameter $\beta = \max_{\boldsymbol{\varphi} \in \Phi} \left\| \mathbf{M}^T \boldsymbol{\varphi} \right\|_2$ and set $\Phi = \left\{ \boldsymbol{\varphi} \mid \mathbf{W}^T \boldsymbol{\varphi} \leq \mathbf{b}, \ \boldsymbol{\varphi} \geq \mathbf{0} \right\}$.

Proof of Theorem. Since $\mathbf{x}^*$ is an optimal solution of problem (ARO-H), and $\hat{\mathbf{x}}$ is a feasible solution of problem (ARO-H), we can arrive at the following inequality: $0 \leq \left[\mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in U} Q(\hat{\mathbf{x}}, \mathbf{u}) \right] - \left[\mathbf{c}^T \mathbf{x}^* + \max_{\mathbf{u} \in U} Q(\mathbf{x}^*, \mathbf{u}) \right]$. Similarly, because $\hat{\mathbf{x}}$ is an optimal solution of problem (ARO-L), and $\mathbf{x}^*$ is a feasible solution of problem (ARO-H), we can arrive at the following inequality: $\mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in \hat{U}} Q(\hat{\mathbf{x}}, \mathbf{u}) \leq \mathbf{c}^T \mathbf{x}^* + \max_{\mathbf{u} \in \hat{U}} Q(\mathbf{x}^*, \mathbf{u})$. Based on strong duality, we can have $Q(\mathbf{x}, \mathbf{u}) = \max_{\boldsymbol{\varphi} \in \Phi} \left[\mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{M}(\bar{\mathbf{u}} + \mathbf{u}) \right]^T \boldsymbol{\varphi}$, where dual feasible region is $\Phi = \left\{ \boldsymbol{\varphi} \mid \mathbf{W}^T \boldsymbol{\varphi} \leq \mathbf{b}, \ \boldsymbol{\varphi} \geq \mathbf{0} \right\}$. Based on $\hat{U} \subseteq U$, we have $\mathbf{c}^T \mathbf{x}^* + \max_{\mathbf{u} \in \hat{U}} Q(\mathbf{x}^*, \mathbf{u}) \leq \mathbf{c}^T \mathbf{x}^* + \max_{\mathbf{u} \in U} Q(\mathbf{x}^*, \mathbf{u})$. Next, we can have:

$$\begin{aligned}
&\mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in \hat{U}} Q(\hat{\mathbf{x}}, \mathbf{u}) \\
&= \mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in U} \max_{\boldsymbol{\varphi} \in \Phi} \left[\mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{M}(\bar{\mathbf{u}} + \Pi(\mathbf{u})) \right]^T \boldsymbol{\varphi} \\
&\geq \mathbf{c}^T \hat{\mathbf{x}} + \max_{\substack{\mathbf{u} \in U \\ \boldsymbol{\varphi} \in \Phi}} \left[\mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{M}(\bar{\mathbf{u}} + \mathbf{u}) \right]^T \boldsymbol{\varphi} + \min_{\substack{\mathbf{u} \in U \\ \boldsymbol{\varphi} \in \Phi}} \left[\mathbf{M}(\mathbf{u} - \Pi(\mathbf{u})) \right]^T \boldsymbol{\varphi} \\
&= \mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in U} Q(\hat{\mathbf{x}}, \mathbf{u}) - \max_{\substack{\mathbf{u} \in U \\ \boldsymbol{\varphi} \in \Phi}} \left[(-1) \cdot \mathbf{M}(\mathbf{u} - \Pi(\mathbf{u})) \right]^T \boldsymbol{\varphi} \\
&\geq \mathbf{c}^T \hat{\mathbf{x}} + \max_{\mathbf{u} \in U} Q(\hat{\mathbf{x}}, \mathbf{u}) - \max_{\substack{\mathbf{u} \in U \\ \boldsymbol{\varphi} \in \Phi}} \left\| \mathbf{u} - \Pi(\mathbf{u}) \right\|_2 \cdot \left\| \mathbf{M}^T \boldsymbol{\varphi} \right\|_2
\end{aligned} \tag{10}$$

which concludes the proof.   □

6. Conclusions

In this paper, we proposed a novel data-driven ARO framework based on PCA. By employing PCA on uncertainty data matrix, latent uncertainty sources were identified. The forward and backward deviation vectors were introduced into the data-driven uncertainty set. An application on batch scheduling was presented. The results showed that the proposed data-driven ARO approach enjoyed a less conservative solution compared with other methods. Additionally, a theoretical bound was also derived.

Abstract

The reliability of flowsheet simulation results depends heavily on the knowledge of model parameters, among which are, for example, kinetic parameters of chemical reactions or substance property data describing thermodynamic behavior. These parameters are usually estimated by nonlinear regression with respect to data from a laboratory setup, mini-plant or operating data from a production process. Applying model-based design of experiments (DoE), operating conditions can be identified which maximize the information content of the resulting data for the regression problem. In this contribution, we present gradient-plots in order to make DoE-plans more transparent to the engineer. In a second step, we report on the implementation of an iterative DoE-scheme in a flowsheet-simulator. Thus, the interplay between estimating model parameters, planning experiments, adding resulting experimental data and re-adjusting the parameters is supported.

Keywords: process simulation, design of experiments, nonlinear regression, parameter estimation.

1. Introduction

To maximize the accuracy of least-square estimates of model parameters, model-based design-of-experiment-strategies have been established. Assuming a reasonable initial guess of the model parameters, these strategies yield a set of operating conditions by finding the optimal value of a scalar measure of the Fisher information matrix. After implementing the optimal set of operating conditions at the real plant, the model is adjusted to the measured responses in order to obtain more accurate model parameter estimations. The application of this approach to flowsheet simulations has previously been reported by Asprion et al. (2018).
In industrial applications, when implementing the optimal experimental plan, deviations from the proposed operating conditions might occur. A poor initial guess of the model parameters model-based design of experiments can lead to a poor experimental plan. Furthermore, in real experiments, generally deviations occur when applying the optimized experimental plan, i.e. realizing the different operating conditions.
To cope with these issues, we propose two extensions: In a first step, gradient plots are exploited to make the DoE-result more transparent to the planner. Together with the DoE-

results for different criteria, these gradient plots, give an insight into how much the quality of an experimental plan depends on each of the experimental inputs.

In a second step, the following iterative approach is described in this contribution: Again, an initial estimate of the model parameters is assumed. A reduced experimental plan is then obtained from a Fisher information matrix that is calculated from derivatives. After the realization of the resulting reduced experimental plan at the plant, a new estimate of all model parameters is obtained. One then modifies the Fisher matrix of the previous step by including the already realized experiments and allowing a small number of additional experiments as new degrees of freedom. A new experimental plan is obtained and realized at the plant. This procedure can be repeated until some termination criterion is reached.

This article is organized as follows: In the next section, the formalism of iterative DoE is presented. Section three contains the concept of gradient plots, illustrated for the estimation of binary NRTL-parameters of different binary mixtures. Section four illustrates the iterative workflow. The article ends with a conclusion. Throughout, to generate the simulation results, the BASF inhouse flowsheet simulator Chemasim was used.

2. Iterative DoE approach

First, the notation required to formalize the iterative DoE-workflow is introduced.

In order to obtain a new estimate p_0^* of the model parameter vector p of length N_p, a weighted sum of squared residuals is minimized. Hereby, the deviation between the model predictions and the measured data is reduced.

$$p_0^* = \arg\min_p \sum_{i=1}^{N_e^0} \sum_{j=1}^{N_m} r_j(p, x_i)^2 \text{ with } r_j(p, x_i) = \sqrt{w_{i,j}} \left(\frac{\tilde{y}_{i,j} - y_j(p, x_i)}{\sigma_{\tilde{y}_{i,j}}} \right) \tag{1}$$

The j-th measured property in the i-th experiment is denoted by $\tilde{y}_{i,j}$. The corresponding model prediction $y_j(p, x_i)$ depends on the model parameter vector p and the design variable vector x_i of the i-th experiment. Additionally, weighting factors $w_{i,j}$ and standard deviations $\sigma_{\tilde{y}_{i,j}}$ of $\tilde{y}_{i,j}$ are included. N_e^0 corresponds to the number of experiments and the number of measured outputs is denoted by N_m.

The uncertainty of p_0^* stems from two sources (cf. Bates, Watts, 1990), namely the accuracy of the measurements (described by $\sigma_{\tilde{y}_{i,j}}$) and the correlation within x_i. This correlation is measured with respect to x_i's impact on the gradients of y_j with respect to p. On a more formal level, the Fisher information matrix (FIM) F (dimension $N_p \times N_p$) has to be calculated (cf. e.g. Schittkowski, 2007a) in order to estimate the covariance matrix of the p_0^*

$$F^0 = \sum_{i=1}^{N_e^0} \sum_{j=1}^{N_m} J_j(p_0^*, x_i)^T J_j(p_0^*, x_i) \tag{2}$$

with the Jacobians J_j (dimension $N_e^0 \times N_p$) consisting of column vectors

$$J_j(p_0^*, x_i) = \left(\left(\frac{\partial r_j}{\partial p_1}(p_0^*, x_i) \right)^T ; \dots ; \left(\frac{\partial r_j}{\partial p_{N_p}}(p_0^*, x_i) \right)^T \right) \tag{3}$$

The covariance matrix C^0 corresponds to the inverse of the FIM F^0.

Let us now extend F^0 as follows: Apart from the x_i that defined the conditions of the already realized measurements $\tilde{y}_{i,j}$, additional $x_{i=N_e^0+1,\ldots,N_e^0+N_e^1}$ are included. These additional x_i describe experiments still to be realized, on the basis of the estimates p_0^*. This extended Fisher matrix is called F^1. Well-known scalar DoE-criteria ϕ are considered as a function of $x_{i=N_e^0+1,\ldots,N_e^0+N_e^1}$ and used to formulate an optimization problem to determine a new experimental plan:

$$\min \phi\left(x_{i=N_e^0+1,\ldots,N_e^0+N_e^1}\right) \qquad (4)$$

Possible DoE-criteria ϕ are , for example, for the A-criterion, $\phi = \text{trace}\left([F^1]^{-1}\right) = \sum_{i=1}^{N_p} \frac{1}{\lambda_i}$, or the D-criterion, $\phi = \det\left([F^1]^{-1}\right) = \prod_{i=1}^{N_p} \frac{1}{\lambda_i}$, where λ_i are the eigenvalues of F^1. The resulting x_i constitute the new experimental plan.

After the experiment, new parameter estimates p_1^* are found by minimizing a sum of squared residuals as in Eq. (1), now augmented by the additional experiments. Their covariance matrix can be estimated from the Fisher matrix F^1. New experiments follow from extending this matrix to a new F^2 by including $x_{i=N_e^0+N_e^1+1,\ldots,N_e^0+N_e^1+N_e^2}$ as optimization variables, determined by solving a DoE task analogous to Eq. (4). This procedure is repeated until some termination criterion is fulfilled. A certain limit on the number of experiments or a threshold value for the accuracy of the estimates present suitable termination criteria.

In the following, a concrete example, namely a binary vapor-liquid flash, is used in order to illustrate the procedure described above. In a given experimental set up, the pressure P and the concentration of substance 1 in the liquid phase x_1 can be adjusted. The temperature T and the concentration of substance 1 in the vapor phase y_1 are measured as experimental outputs. The NRTL-parameters $A_{12}, A_{21}, B_{12}, B_{21}$ are to be estimated. Applying the procedure, P and x_1 should be chosen such that the reliability of the parameter estimates are maximized.

3. Gradient plots

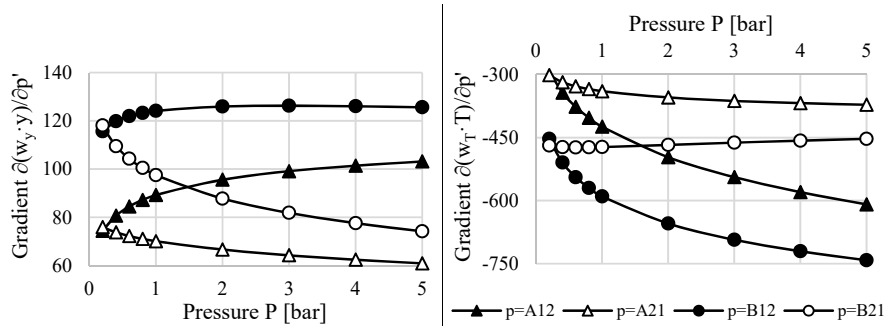
First, $N_e^0 = 0$ is set and an experimental plan is to be designed from scratch. To gain some intuitive insight, the gradients $\partial(w_{y_1}y_1)/\partial p'$ and $\partial(w_T T)/\partial p'$ with $p' = 5\frac{p-p_{min}}{p_{max}-p_{min}} + 5$, $p \in \{A_{12}, A_{21}, B_{12}, B_{21}\}$, $w_{y_1} = 100, w_T = 10$, are calculated for all x_1 at fixed P and for all P at fixed x_1. Using p' turned out to show favorable numerical results. For a mixture of methanol and water, these gradients are visualized in Figs. 1 and 2.
Figure 1: Gradient plots for experimental output functions y_1 (left) and T (right) for a mixture of water and methanol for constant $P = 1$ bar .


Figure 2: Gradient plots for experimental output functions y_1 (left) and T (right) for a mixture of water and methanol for constant $x_1 = 0.1$ mol/mol.

From Fig. 1 it follows that the highest dependence on the NRTL-parameters is observed for concentrations $x_1 < 0.4$.. The monotonic dependence of the gradients on the pressure at $x_1 = 0.1$ mol/mol is shown in Fig. 2. Hence, designs at the upper and lower boundary for the allowed pressure values are favored. Furthermore, the relative variation of the gradients with respect to the pressure at constant x_1 is much smaller than its variation with respect to x_1 at constant P(Fig. 1). Thus, we expect the optimal design points in the $x_1 - P$-plane to be located at P-values close to the bounds imposed by the experimental set up ($P = 0.1$ bar and $P = 5$ bar), and at x_1-values between 0 mol/mol and 0.4 mol/mol. Furthermore, it is to be expected that the parameter estimates will be highly correlated as the gradient plots show correlated behavior of the gradients over the entire P and x_1 ranges. These findings will be confirmed in section 4.

For a comparison, a binary azeotropic mixture of methanol and acetone is considered in an equivalent setup. The corresponding gradient plots are presented in Figure 3 and 4.
Figure 3: Gradient plots for experimental output functions y_1 (left) and T (right) for a mixture of methanol (1) and acetone (2) for constant $P = 1$ bar.

In contrast to the binary system of methanol-water, significant contributions to $\partial(w_{y_1}y_1)/\partial p$ now occur in two regions, namely for $0.1 < y_1 < 0.5$ and $0.5 < y_1 < 0.9$. But for the pressure, again a monotonic dependence is observed.
Figure 4: Gradient plots for experimental output functions y_1 (left) and T (right) for a mixture of methanol (1) and acteone (2) for constant $x_1 = 0.3$ mol/mol.

4. Illustration of iterative workflow

The gradient plots in the section 3 give some useful insights to how the optimal experimental plans will look like. In this section, the DoE-task in Eq. (4) is solved as a non-linear optimization problem for four experimental points from scratch, i.e. $N_e^0 = 0$, starting from different initial configurations. The results are presented in Fig. 5 which are in agreement with the gradient plots in section 3.
Figure 5: A- and D-optimal designs for mixtures of methanol-water (left) and methanol-acetone (right). These designs meet the expectations based on the gradient plots in section 3.

In the following, the discussion focuses on the binary mixture of methanol and water. In total, eight additional experiments should be realized after having performed the first experiments as shown in Fig. 5. Three different implementations of the additional experiments are considered:

I. $N_e^0 = 4$, $N_e^{1,2,3,4}=1$, that is, four additional iterations with one experiment in each iteration.

II. $N_e^0 = 4$, $N_e^1=4$, i.e., one additional iteration with four experiments

III. Four experiments at $P = 1$ bar and four experiments at $P = 5$ bar, each with $x_1 = 0.05, 0.35, 0.75, 0.95$ mol/mol.

The first $N_e^0 = 4$ experiments of alternatives I and II are shown in Fig. 5. Pseudo-measurements are generated by adding a random Gaussian error to the predictions of the true model in each iteration. The corresponding experimental plans are shown in Fig. 6. One observes that if model-based DoE-strategies are applied, the designs cluster in the regions where the gradients are highest, in agreement with the gradient plots shown in the previous section. In order to avoid the clustering, one could also imagine a hybrid DoE

strategy, where the model-based approach is combined with a space-filling strategy, if a sufficient number of experiments are available. This is the subject of current research.

To assess the quality of the plans, residual plots are shown in Fig. 7 for the differences between the measured and predicted values for T and y_1. From the values of these residuals, all of the three alternatives I-III seem to lead to comparable results.
Figure 6: Experimental plans obtained for the three alternatives I-III (from left to right) described in the main text.
Figure 7: Residual plots for the three alternatives I-III, where the symbols in the plots have the same meaning as in Fig. 6. The axes show the residuals between measured and adjusted data for temperature (ΔT) and methanol concentration in the vapor phase (Δy).

5. Conclusion and outlook

Two extensions of the common DoE approach have been developed and implemented in BASF's inhouse flowsheet simulator Chemasim: The first extension consists in gradient plots which help to gain an intuitive insight into the correlations between parameter estimates and into promising regions for optimal experimental plans. The second extension supports an iterative workflow, where additional experiments are planned by fixing the ones already realized. The results suggest the development of a hybrid strategy, where a model-based DoE is combined with a space-filling strategy.

Abstract

The design of heat exchangers in general, including double pipe, is typically performed using methods based on simplifying assumptions (e.g. uniform overall heat transfer coefficient based on averaged physical properties, mostly). However, these assumptions may sometimes result in considerable under or oversizing, especially when ample variations of the physical properties with temperature take place. Aiming at circumventing this limitation, we present a novel MILP (globally optimal) formulation of the optimization of hairpin double-pipe heat exchangers using rigorous models and discretization. Numerical results illustrate the importance of the utilization of the proposed approach in relation to the traditional analytical models, showing to what extent one can undersize or oversize severely the heat exchanger.

Keywords: optimization, mathematical programming, linear programming, double pipe heat exchanger.

1. Introduction

Due to the importance of heat exchangers in chemical process plants, a large number of papers has focused on optimal design optimization procedures. Gonçalves et al. (2017) contains a brief overview of the main solution approaches. Independently of the approach, all of these papers rely on calculating the heat transfer coefficients using constant values of the physical properties.

This paper presents a novel mathematical programming formulation that is able to consider the variation of the overall heat transfer coefficient along the heat transfer surface. The resultant formulation, applied for hairpin double-pipe exchangers, is a mixed-integer linear programming problem (MILP), thus rendering globally optimum solutions.

2. Proposed Approach

The optimization problem corresponds to the minimization of a structure composed of a set of hairpin heat exchangers connected in series, as it is illustrated in Figure 1. One

wants to find the inner tube diameter, the outer tube diameter, the length of each hairpin and the number of hairpins that minimize the heat transfer area. The model encompasses energy balances, heat transfer coefficient equations and flow velocity bounds. The flow is assumed to be turbulent, without phase change.
Figure 1: A set of three double pipe hairpins arranged in series.

Instead of modelling the heat exchanger using overall analytical descriptions, like the LMTD approach (i.e. $Q = U.A.\Delta T_{LM}$), which may involve large prediction errors, we propose to explore the original differential equations in the modelling:

$$\frac{dQ}{dz} = U \cdot (T_h - T_c) \cdot \pi \cdot dte \tag{1}$$

When applying a discretization procedure, the value of the overall heat transfer coefficient at each point along the mesh depends on the stream temperatures. As a consequence, the resultant model would be nonlinear and therefore would present the usual numerical problems (need of good initial estimate and possible existence of multiple local optima).

Our proposal to circumvent this problem is to apply the discretization procedure to one of the streams temperature range (in this case the hot stream, as shown in Figure 2) rather than to the length of the equipment. This approach is used so that the temperatures in the discretization points become known parameters, while the distance between mesh points becomes the variable. In this way, the physical properties also become parameters, eliminating all nonlinearities in the model equations.
Figure 2: Hot stream discretization mesh.

For each adjacent pair of discrete temperature points, there is a corresponding length between them required for heat transfer. Thus, we rewrite Eq. (2), as follows:

$$\frac{dz}{dT_h} = \frac{\dot{m}_h \cdot Cp_h}{U \cdot (T_h - T_c) \cdot \pi \cdot dte} \tag{2}$$

For the corresponding cold stream temperatures between both intervals, we have (the mark (^) above symbols represents known parameters):

$$\frac{dT_c}{dT_h} = \frac{\hat{m}_h \cdot Cp_h}{\hat{m}_c \cdot Cp_c} \tag{3}$$

We highlight that the uniform mesh in the hot stream temperature does not correspond to a uniform mesh in the length of the equipment. Figure 3 illustrates it by showing, in a generic temperature curve, the relation between both meshes:
Figure 3: Discretization applied to the hot stream temperature curve.

For the discretization shown in Eq. (2), a second order central finite difference approximation for the intermediary points and a second-degree polynomial approximation for the last point, as well as a boundary condition for the first point are used, yielding, where $\Delta\hat{T}$ is the increment associated to the temperature mesh:

$$z_j = 0 \qquad\qquad \text{for } j = 1 \tag{4}$$

$$\frac{z_{j+1} - z_{j-1}}{2 \cdot \Delta\hat{T}} = \frac{-\hat{m}_h \cdot \hat{C}p_{h,j}}{U_j \cdot \left(\hat{T}_{h,j} - \hat{T}_{h,j}\right) \cdot \pi \cdot dte} \qquad\qquad \text{for } j = 2, ..., N \tag{5}$$

$$\frac{z_{j-2} - 4z_{j-1} + z_j}{2 \cdot \Delta\hat{T}} = \frac{-\hat{m}_h \cdot \hat{C}p_{h,j}}{U_j \cdot \left(\hat{T}_{h,j} - \hat{T}_{h,j}\right) \cdot \pi \cdot dte} \qquad\qquad \text{for } j = N+1 \tag{6}$$

Knowing that tubes come in discrete options, we use discrete representations of the design variables. One of these, the one for inner tube diameter is shown in Eq. (7):

$$dte = \sum_{sd=1}^{sdmax} \hat{p}dte_{sd} \cdot yd_{sd} \tag{7}$$

$$\sum_{sd=1}^{sdmax} yd_{sd} = 1 \tag{8}$$

Similar equations are written for the other design variables. We now replace the design variables by the corresponding binaries and reformulate to obtain an equivalent linear

formulation (no loss of rigor). Gonçalves et al., (2017) show specific details of this procedure. After such manipulations, Eq. (5) becomes:

$$\frac{z_{j+1} - z_{j-1}}{2 \cdot \Delta \hat{T}} = \frac{-\hat{m}_h \cdot \hat{C}p_{h,j}}{(\hat{T}_{h,j} - \hat{T}_{h,j}) \cdot \pi} \sum_{sd=1}^{sd\max} \sum_{sD=1}^{sD\max} \hat{X}_{j,sd,sD} \cdot wdD_{sd,sD}$$

(9)

where $\hat{X}_{j,sd,sD}$ is now a parameter representing the value of $\left[U_j dte \right]^{-1}$ written for each instance of yd_{sd} and yD_{sD}.

$$\hat{X}_{j,sd,sD} = \frac{\hat{p}dti_{sd}^{0.8}}{\hat{k}_{c,j} \cdot 0.023 \cdot \hat{P}r_{c,j}^{0.4} \cdot \left(4\hat{m}_c \middle/ \pi\hat{\mu}_{c,j} \right)^{0.8}} + \frac{\hat{R}f_c}{\hat{p}dti_{sd}} + \frac{\ln\left(\hat{p}dte_{sd} \cdot \left[\hat{p}dti_{sd} \right]^{-1} \right)}{2 \cdot \hat{k}_{tube}} +$$

$$+ \frac{\hat{R}f_h}{\hat{p}dte_{sd}} + \frac{\hat{p}As_{sd,sD}^{0.8} \cdot \hat{p}dh_{sd,sD}^{0.2}}{\hat{k}_{h,j} \cdot 0.023 \cdot \hat{P}r_{h,j}^{0.3} \cdot \left(\hat{m}_h \middle/ \hat{\mu}_{h,j} \right)^{0.8} \cdot \hat{p}dte_{sd}}$$

(10)

$$wdD_{sd,sD} \le yd_{sd}$$

(11)

$$wdD_{sd,sD} \le yD_{sD}$$

(12)

$$wdD_{sd,sD} \ge yd_{sd} + yD_{sD} - 1$$

(13)

3. Results

The formulation proposed was applied to obtain the optimal design for the service described in Table 1. Polynomial fittings were applied to experimental data from Incropera et al (2011) to obtain the functions that describe the variation of the physical properties with the temperature. The sets of discrete options available for the optimization are depicted in Table 2.

Table 1: Stream data for the optimization problem.

	Stream	Flow mass (kg/s)	Inlet Temperature (K)	Outlet Temperature (K)
Hot stream	Engine Oil	1.3	310	295
Cold stream	Cooling water	1.3	280	286

Table 2: Structural discrete options (pipe schedule 40).

Parameter	Discrete Options								
Number of hairpins	1	to	20						
Tube length (m)	3.048	6.096	9.144	12.192	15.240				
Inner tube OD (m)	0.021	0.027	0.033	0.042	0.048	0.060	0.073	0.089	0.102
Outer tube OD (m)	0.042	0.048	0.060	0.073	0.089	0.102	0.144	0.127	0.168

In order to illustrate the importance of accounting for the property's variations, four scenarios were considered. Scenario 1 shows the results using the proposed approach, taking into account the temperature influence on the physical properties. The other three scenarios explored consider the physical properties constant, which incidentally generates the same results as the usual analytical approaches. Scenario 2: properties calculated using a mean temperature for each stream; Scenario 3: properties calculated using the lowest temperature for each stream, a more conservative approach; and Scenario 4: the overall heat transfer coefficient is set to be the mean between its values calculated in the inlet and outlet temperatures. The results obtained are shown in Table 3.

Table 3: Optimal solutions obtained for the three different scenarios.

Scenario	Inner tube OD (m)	Outer tube OD (m)	Tube length (m)	Number of hairpins	Total heat exchanger area (m²)
1	0.042	0.060	15.24	15	30.28
2	0.042	0.060	15.24	14	28.26
3	0.042	0.060	15.24	20	40.37
4	0.042	0.060	9.144	20	24.22

For constant physical properties (Scenario 2) and using an average value of the overall heat transfer coefficient (Scenario 4), we obtain severe underestimation of the area. The conservative approach (Scenario 3) renders an area that is 32% higher.

These results point out the risk that a designer takes by using the simplified approach of adopting average or conservative temperatures, achieving a design that cannot fulfil the heat transfer task, or one that exceeds it, rendering a larger cost.

These disparities can be explained due to the nature of the hot stream. The example studied involves an engine oil stream with a large variation of the viscosity with the temperature. Such a large variation in viscosity affects the heat transfer coefficient on the oil side (from 144.7 W/(m²K) in the inlet to 57.7 W/(m²K) in the outlet).

4. Conclusions

We showed that modeling a double-pipe exchanger using the LMTD analytical method with uniform overall heat transfer coefficient can involve significant deviations from a more accurate solution obtained through discretization. When applied to a problem where physical properties vary substantially with temperature (the viscosity in our case), there is a significant risk of either obtaining an infeasible solution for the heat transfer task, or a significantly oversized exchanger. The implications for other cases (i.e. shell and tube exchangers) and other thermal tasks (i.e. condensers or vaporizers) is obvious. In addition, we also show that the spatial discretization, which leads to a nonlinear model, can be replaced by a temperature discretization, which generates a linear MILP, thus allowing globally optimal solutions.

5. Appendix

The symbols applied in this paper are shown in Table 4

Table 4: Stream data for the optimization problem.

Symbol	Description	Symbol	Description
ΔT	Temperature increment (K)	Pr	Prandtl number
Cp	Heat capacity (J/(kg.K))	Q	Heat load (W)
dte	Internal tube OD (m)	T	Stream temperature (K)
k	Thermal conductivity (W/(m.K))	U	Global heat transfer coefficient (W/(m².K))
m	Stream flow mass (kg/s)	wdPd	Substitution for binary product yd.yD.yP
pAs	Annular flow areas (m²)		
pdh	Hydraulic diameters (m)	yd	Binary for internal tube diameter selection
pdte	Internal tube ODs (m)	yD	Binary for external tube diameter selection
pdti	Internal tube ID (m)	z	Position (m)

Abstract

Industrial process monitoring deals with three main activities, namely, fault detection, fault diagnosis, and fault prognosis. Respectively, these activities seek to answer three questions: 'Has a fault occurred?', 'Where did it occur and how large?', and 'How will it progress in the future?' As opposed to abrupt faults, incipient faults are those that slowly develop in time, leading ultimately to process failure or an emergency situation. A recently developed multivariate statistical tool for early detection of incipient faults under varying operating conditions is the Canonical Variate Dissimilarity Analysis (CVDA). In CVDA, a dissimilarity-based statistical index was derived to improve the detection sensitivity upon the traditional canonical variate analysis (CVA) indices. This study aims to extend the CVDA detection framework towards diagnosis and prognosis of process conditions. For diagnosis, contribution maps are used to convey the magnitude and location of the incipient fault effects, as well as their evolution in time. For prognosis, CVA state-space prediction and Kalman filtering during faulty conditions are proposed in this work. By covering the three main process monitoring activities in one framework, our work can serve as a baseline strategy for future application to large process industries.

Keywords: canonical variate analysis (CVA), incipient fault, Kalman filter (KF), dynamic process monitoring

1. Introduction

Data-driven methods for industrial process monitoring, known in general as multivariate statistical process monitoring (MSPM) techniques, have attained significant development in the last few decades (Reis and Gins, 2017). By addressing challenges such as high-dimensionality, temporal correlation, nonlinearity, non-Gaussianity, etc. in the plant data, MSPM tools have become more reliable for the automated detection of various faults in the plant (Ge et al., 2013).

However, in the larger perspective, fault detection must be followed by fault diagnosis and prognosis (Chiang et al., 2005). Fault diagnosis aims to determine the location and magnitude of a detected fault, while fault prognosis aims to predict its evolution in time. Indeed, Reis and Gins (2017) noted an increasing trend of research focus in the area of fault diagnosis and prognosis in the process industries. By developing more reliable diagnostic and prognostic tools, well-informed decisions can be made during production and maintenance operations planning, even when the fault continues to degrade the process performance. In addition, the ability to address

the aforementioned challenges in handling plant data must be present in all three process monitoring activities. Hence, it is beneficial to establish them under an integrated framework.

Among the various types of faults, the incipient fault is deemed as that which requires prognosis (Li et al., 2010). As opposed to abrupt faults, incipient faults are those that start at small magnitudes, but slowly worsen in time (Isermann, 2005). If an incipient fault is left to degrade the process, it may ultimately lead to process failure or an emergency situation (Pilario and Cao, 2017). Hence, incipient fault monitoring is an important issue that needs to be addressed by more advanced diagnostic and prognostic tools.

For the sensitive detection of incipient faults under dynamically varying conditions, the Canonical Variate Dissimilarity Analysis (CVDA) method was recently developed (Pilario and Cao, 2018). This method is based on the well-known Canonical Variate Analysis (CVA) (Odiowei and Cao, 2010) but uses a dissimilarity-based statistical index for enhanced sensitivity by measuring the predictability of the hidden states of the process. In this work, the CVDA fault detection methodology is extended to fault diagnosis and prognosis. Specifically, we aim to: (i) formulate a contributions-based approach for diagnosis using the canonical variate dissimilarity index; and, (ii) propose a prognostic tool using CVA state-space modelling and Kalman filtering under faulty conditions.

This paper is structured as follows. The CVDA methodology is revisited in Section 2. The proposed diagnosis and prognosis procedures are given in Section 3. Section 4 demonstrates the monitoring performance in a simulated CSTR case study. Lastly, concluding remarks are given.

2. CVDA for Fault Detection

The CVDA detection method proceeds by performing CVA to calculate the state and residual variables from the input-output process data, and then computing the statistical indices T^2, Q, and D, which serve as health indicators of the process.

Given N samples of input and output data at normal conditions, denoted as $\mathbf{u}_k \in \mathbb{R}^{m_u}$ and $\mathbf{y}_k \in \mathbb{R}^{m_y}$ at the kth sampling instant, respectively, the past and future column vectors are formed as:

$$\mathbf{p}_k = [\mathbf{u}_{k-1}^T \quad \mathbf{u}_{k-2}^T \quad \cdots \quad \mathbf{u}_{k-p}^T \quad \mathbf{y}_{k-1}^T \quad \mathbf{y}_{k-2}^T \quad \cdots \quad \mathbf{y}_{k-p}^T]^T \in \mathbb{R}^{mp} \tag{1}$$

$$\mathbf{f}_k = [\mathbf{y}_k^T \quad \mathbf{y}_{k+1}^T \quad \mathbf{y}_{k+2}^T \quad \cdots \quad \mathbf{y}_{k+f-1}^T]^T \in \mathbb{R}^{m_y f} \tag{2}$$

where p and f are the number of lags in the past and future windows of data, respectively, and $m = m_u + m_y$. The number of lags are chosen large enough to capture autocorrelation in the output data (Odiowei and Cao, 2010).

The sample covariance matrices are then obtained using $\boldsymbol{\Sigma}_{pp} = \frac{1}{M-1}\mathbf{Y}_p\mathbf{Y}_p^T$, $\boldsymbol{\Sigma}_{ff} = \frac{1}{M-1}\mathbf{Y}_f\mathbf{Y}_f^T$, and $\boldsymbol{\Sigma}_{fp} = \frac{1}{M-1}\mathbf{Y}_f\mathbf{Y}_p^T$, where $\mathbf{Y}_p = [\mathbf{p}_{p+1} \ \mathbf{p}_{p+2} \ \cdots \ \mathbf{p}_{p+M}]$ and $\mathbf{Y}_f = [\mathbf{f}_{p+1} \ \mathbf{f}_{p+2} \ \cdots \ \mathbf{f}_{p+M}]$ are the past and future Hankel matrices, respectively, and $M = N - p - f + 1$.

CVA aims to find vectors $\mathbf{a} \in \mathbb{R}^{m_y f}$ and $\mathbf{b} \in \mathbb{R}^{mp}$ so that the correlation between the linear combinations $\mathbf{a}^T\mathbf{f}_k$ and $\mathbf{b}^T\mathbf{p}_k$ are maximized (Odiowei and Cao, 2010). The algebraic solution is given by the singular value decomposition (SVD) of the scaled Hankel matrix:

$$\mathbf{H} = \boldsymbol{\Sigma}_{ff}^{-1/2}\boldsymbol{\Sigma}_{fp}\boldsymbol{\Sigma}_{pp}^{-1/2} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T \tag{3}$$

where $\mathbf{U} = [\boldsymbol{\upsilon}_1, \boldsymbol{\upsilon}_2, \ldots, \boldsymbol{\upsilon}_r]$ and $\mathbf{V} = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_r]$ are the left and right singular matrices, $\boldsymbol{\Sigma} = \text{diag}(\sigma_1, \sigma_2, \ldots, \sigma_r)$ is the diagonal matrix of descending non-zero singular values, and r is the rank of $\mathbf{H}$. The singular values, σ_i, are the maximum solutions of Eq. (3), which are also the canonical correlations between projected past and future data. Taking only the first n projections, corresponding to the n largest canonical correlations, the states, residuals, and dissimilarity

features at the kth sampling instant are computed as:

$$\mathbf{z}_k = \mathbf{J}_n \mathbf{p}_k \in \mathbb{R}^n \tag{4}$$

$$\mathbf{e}_k = \mathbf{F}_n \mathbf{p}_k \in \mathbb{R}^{mp} \tag{5}$$

$$\mathbf{d}_k = \mathbf{L}_n \mathbf{f}_{k-f+1} - \mathbf{\Sigma}_n \mathbf{J}_n \mathbf{p}_{k-f+1} \in \mathbb{R}^n \tag{6}$$

where $\mathbf{J}_n = \mathbf{V}_n^T \mathbf{\Sigma}_{pp}^{-1/2} \in \mathbb{R}^{n \times mp}$, $\mathbf{F} = (\mathbf{I} - \mathbf{V}_n \mathbf{V}_n^T) \mathbf{\Sigma}_{pp}^{-1/2} \in \mathbb{R}^{mp \times mp}$, $\mathbf{L}_n = \mathbf{U}_n^T \mathbf{\Sigma}_{ff}^{-1/2} \in \mathbb{R}^{n \times m_y f}$, $\mathbf{V}_n$ and $\mathbf{U}_n$ are the first n columns of $\mathbf{V}$ and $\mathbf{U}$, respectively, and $\mathbf{\Sigma}_n$ is a diagonal matrix of the n largest singular values in Eq. (3). Finally, the statistical indices at the kth sampling instant are given by:

$$T_k^2 = \mathbf{z}_k^T \mathbf{z}_k \tag{7}$$

$$Q_k = \mathbf{e}_k^T \mathbf{e}_k \tag{8}$$

$$D_k = \mathbf{d}_k^T (\mathbf{I} - \mathbf{\Sigma}_n^2)^{-1} \mathbf{d}_k \tag{9}$$

which measure departures from the usual state subspace, residual subspace, and predictability of future states from the past states, respectively.

In the CVDA training phase, the distributions of T^2, Q, and D, are estimated using kernel density estimation (KDE) without any assumption of Gaussianity in the data. Upper control limits (UCLs) are computed as the values of T_{UCL}^2, Q_{UCL}, and D_{UCL} at which $P(T^2 < T_{\mathrm{UCL}}^2) = \alpha$, $P(Q < Q_{\mathrm{UCL}}) = \alpha$, and $P(D < D_{\mathrm{UCL}}) = \alpha$, respectively. Throughout this paper, a significance limit of $\alpha = 99\ \%$ is adopted. During online monitoring, the process condition is deemed faulty when either of the indices exceeded their respective UCLs.

3. CVDA for Fault Diagnosis and Prognosis

3.1. Fault Diagnosis

To achieve fault diagnosis, the value of a statistical index at time point k can be decomposed into parts contributed by each measured variable. Hence, the measured variable/s with the largest contributions can be identified as most associated with the fault that occurred. Incipient fault diagnosis results must be reported using contribution maps instead of the traditional contribution bar plots, so that the fault evolution and propagation across time can be visually illustrated.

Contributions from the traditional CVA indices were already given by Jiang et al. (2015). In this paper, we derive the contributions for the dissimilarity index, D, as well. Altogether, the contributions of the ith measured variable ($i = 1, \ldots, m$) to statistical index J at time point k, denoted by $C_{i,k}^J$ with $J \in \{T^2, Q, D\}$, are given by:

$$C_{i,k}^{T^2} = \sum_{j=0}^{p-1} \left| \mathbf{z}_k^T \left(\mathbf{J}_n^{(i+mj)} \mathbf{p}_k^{(i+mj)} \right) \right| \tag{10}$$

$$C_{i,k}^{Q} = \sum_{j=0}^{p-1} \left| \mathbf{e}_k^T \left(\mathbf{F}_n^{(i+mj)} \mathbf{p}_k^{(i+mj)} \right) \right| \tag{11}$$

$$C_{i,k}^{D} = \begin{cases} \sum_{j=0}^{p-1} \left| \mathbf{d}_k^T (\mathbf{I} - \mathbf{\Sigma}^2)^{-1} \left(\mathbf{L}_n^{(i-m_u+m_y j)} \mathbf{f}_{k-f+1}^{(i-m_u+m_y j)} - \mathbf{\Sigma}_n \mathbf{J}_n^{(i+mj)} \mathbf{p}_{k-f+1}^{(i+mj)} \right) \right| & i > m_u \\ \sum_{j=0}^{p-1} \left| \mathbf{d}_k^T (\mathbf{I} - \mathbf{\Sigma}^2)^{-1} \left(-\mathbf{\Sigma}_n \mathbf{J}_n^{(i+mj)} \mathbf{p}_{k-f+1}^{(i+mj)} \right) \right| & i \leq m_u \end{cases} \tag{12}$$

where $\mathbf{J}_n^{(l)}$, $\mathbf{F}_n^{(l)}$, $\mathbf{L}_n^{(l)}$ denote the lth columns in matrices $\mathbf{J}_n$, $\mathbf{F}_n$, $\mathbf{L}_n$, respectively, and $\mathbf{p}_k^{(l)}$, $\mathbf{f}_k^{(l)}$ denote the lth element in column vectors $\mathbf{p}_k$, $\mathbf{f}_k$, respectively. For Eq. (12) to apply, we assume that $p = f$ and that measured variables are sorted as all inputs followed by all outputs.

Using Eqs. (10)-(12), contributions from a fault-free training data set are first taken. For online use, relative contributions are computed by removing the mean normal contribution from $C_{i,k}^J$, and scaling by the standard deviation of the normal contributions (Deng and Tian, 2011):

$$C_{i,k}^{J,\text{rel}} = \frac{C_{i,k}^J - \text{mean}(C_{i,k}^J|\text{normal})}{\text{std}(C_{i,k}^J|\text{normal})}. \tag{13}$$

3.2. Fault Prognosis

CVA is distinguished from other process monitoring methods in that it is also a system identification method (Larimore, 1990). This benefit is useful for prognosis under the CVDA framework. In CVA, the system is assumed to be represented by the following state-space model:

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{B}\mathbf{u}_k + \mathbf{w}_k \tag{14}$$
$$\mathbf{y}_k = \mathbf{C}\mathbf{x}_k + \mathbf{D}\mathbf{u}_k + \mathbf{v}_k \tag{15}$$

where $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}$ are the state-space matrices, $\mathbf{w}, \mathbf{v}$ are the process and measurement noise, respectively, and $\mathbf{x}, \mathbf{y}, \mathbf{u}$ are the states, outputs, and inputs, respectively. After Eq. (4), CVA identification is achieved by letting $\mathbf{x}_k := \mathbf{z}_k$ and performing multivariate regression to estimate $\hat{\mathbf{A}}, \hat{\mathbf{B}}, \hat{\mathbf{C}}, \hat{\mathbf{D}}$ as follows (Larimore, 1990):

$$\begin{bmatrix} \hat{\mathbf{A}} & \hat{\mathbf{B}} \\ \hat{\mathbf{C}} & \hat{\mathbf{D}} \end{bmatrix} = \mathbf{\Sigma}\left[\begin{pmatrix} \mathbf{x}_{k+1} \\ \mathbf{y}_k \end{pmatrix}, \begin{pmatrix} \mathbf{x}_k \\ \mathbf{u}_k \end{pmatrix} \right] \cdot \mathbf{\Sigma}^{-1}\left[\begin{pmatrix} \mathbf{x}_k \\ \mathbf{u}_k \end{pmatrix}, \begin{pmatrix} \mathbf{x}_k \\ \mathbf{u}_k \end{pmatrix} \right] \tag{16}$$

where $\mathbf{\Sigma}[\cdot, \cdot]$ denotes the sample covariance operation. Moreover, since the noise can be recovered as $\hat{\mathbf{w}}_k = \mathbf{x}_{k+1} - \hat{\mathbf{A}}\mathbf{x}_k - \hat{\mathbf{B}}\mathbf{u}_k$ and $\hat{\mathbf{v}}_k = \mathbf{y}_k - \hat{\mathbf{C}}\mathbf{x}_k - \hat{\mathbf{D}}\mathbf{u}_k$, then the noise covariances can be computed as $\hat{\mathbf{Q}} = \mathbf{\Sigma}[\hat{\mathbf{w}}_k, \hat{\mathbf{w}}_k]$ and $\hat{\mathbf{R}} = \mathbf{\Sigma}[\hat{\mathbf{v}}_k, \hat{\mathbf{v}}_k]$. Meanwhile, $\hat{\mathbf{P}}_0 = \mathbf{\Sigma}[\hat{\mathbf{x}}_k, \hat{\mathbf{x}}_k]$ is the initial state covariance.

Given a future input sequence, the estimated state-space model can be used for predicting the output variables during normal operation. When a fault occurs, the state-space model must be re-trained by applying Eq. (16) to the samples obtained during the early stages of degradation (Ruiz-Cárcel et al., 2016). However, an incipient fault can bring changes in both the state-space model parameters and the states $\mathbf{x}_k$ themselves. Re-training only corrects the model parameters. Hence, in this paper, we propose the use of Kalman filtering (KF) to correct changes in the states in conjunction with model re-training. In KF, the pertinent equations are:

$$\mathbf{x}_{k|k-1} = \hat{\mathbf{A}}\mathbf{x}_{k-1|k-1} + \hat{\mathbf{B}}\mathbf{u}_k \tag{17}$$
$$\hat{\mathbf{P}}_{k|k-1} = \hat{\mathbf{A}}\hat{\mathbf{P}}_{k-1|k-1}\hat{\mathbf{A}}^T + \hat{\mathbf{Q}} \tag{18}$$
$$\mathbf{x}_{k|k} = \mathbf{x}_{k|k-1} + \mathbf{K}_k(\mathbf{y}_k - \hat{\mathbf{C}}\mathbf{x}_{k|k-1}) \tag{19}$$
$$\hat{\mathbf{P}}_{k|k} = (\mathbf{I} - \mathbf{K}_k\hat{\mathbf{C}})\hat{\mathbf{P}}_{k|k-1} \tag{20}$$

where $\mathbf{K}_k = \hat{\mathbf{P}}_{k|k-1}\hat{\mathbf{C}}^T(\hat{\mathbf{C}}\hat{\mathbf{P}}_{k|k-1}\hat{\mathbf{C}}^T + \hat{\mathbf{R}})^{-1}$ is the Kalman gain.

To apply Eq. (17)-(20), the initial states are first estimated using Eq. (4) on the first p samples. Assuming that $\mathbf{x}_k$, $\hat{\mathbf{w}}_k$ and $\hat{\mathbf{v}}_k$ are Gaussian-distributed, KF is used to update $\mathbf{x}_k$ at every time step. Note that changes due to other incipient faults, such as drifts in the noise statistics, may be difficult to track upon using the Kalman filter. This is a topic for future work.

4. Case Study

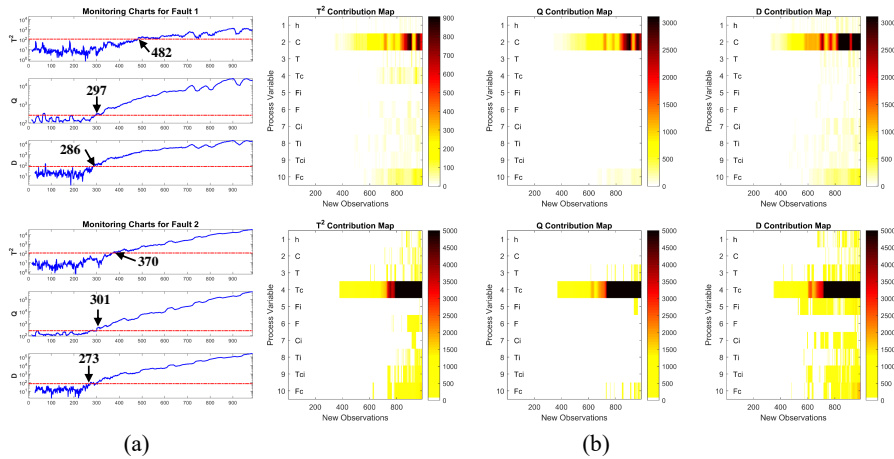
To evaluate the performance of CVDA for fault diagnosis and prognosis, a closed-loop CSTR case study is used, which is available in (Pilario, 2017). Data are simulated from a system of 4 state


Figure 1: Monitoring results for: (a) fault detection (Arrows - detection time, mins; Red dash - UCLs; Blue solid - detection index); and (b) fault diagnosis. Top: Catalyst decay, Bottom: Fouling. For (b), the contributions maps are for T^2, Q, and D from left to right.

equations, with 2 cascade control loops to maintain liquid level, h, and reactor temperature, T. The measured variables are $\mathbf{u} = [F_i, C_i, T_i, T_{ci}]^T$ and $\mathbf{y} = [h, C, T, T_c, F, F_c]^T$. The input variables are being perturbed every 30 sampling times to simulate disturbance changes.

Using a data set of 1000 samples at normal operation, CVDA was trained so as to generate the projection matrices, the UCLs, and the state-space model. The number of lags and number of states are selected as 14 and 8, respectively. These are chosen using autocorrelation analysis and the dominant singular values method (Odiowei and Cao, 2010). Two incipient faults are studied in the CSTR, namely, catalyst decay (Fault 1) and heat transfer fouling (Fault 2). In the faulty data sets, both faults are slow drifts introduced after an initial 200 min of normal operation.

Fig. 1(a) shows detection results for the faulty data sets. As shown, the D index incurs the earliest detection time for both faults. To locate and track the magnitude of the detected fault, contribution maps are generated using Eqs. (10)-(13), and are shown in Fig. 1(b). The most associated variables to catalyst decay and fouling faults are shown to be the outlet concentration, C, and outlet temperature of the coolant, T_c. These are, indeed, the expected results for fault diagnosis. Moreover, the maps were able to illustrate how the fault effects propagate to other variables further in time. Notably, the D contribution maps revealed not only the fault-affected variables, but also the input variables that contributed to the dissimilarity between past and future states. Hence, we suggest to use all three contribution maps in conjunction to better capture incipient fault signatures.

The 1-step ahead prediction of the top 2 faulty variables in each fault case is given in Fig. 2. The estimated data are Kalman-filter predictions from a state-space model re-trained every 20 sampling times using the latest 400 samples while under faulty conditions. Table 1 gives the R^2 measure of fit of the predictions, showing that without KF, the faulty variables cannot be tracked accurately. Hence, KF improves CVDA fault prognosis in this case study.

5. Conclusion

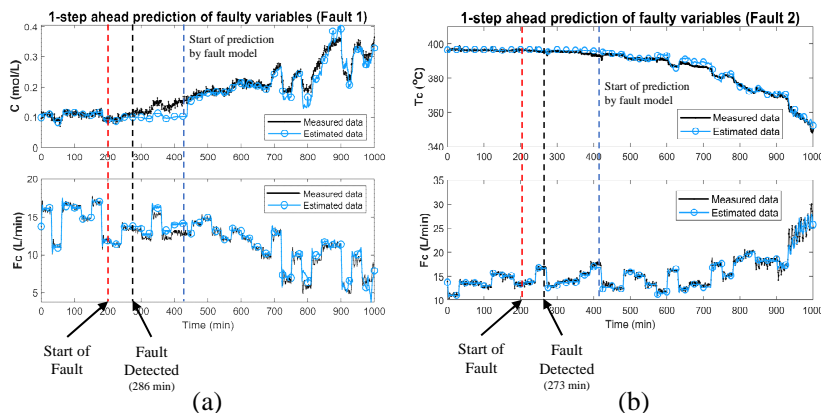
In this paper, an incipient fault detection, diagnosis, and prognosis methodology is presented under an integrated framework, namely, Canonical Variate Dissimilarity Analysis (CVDA). Using a CSTR case study involving 2 parametric incipient fault scenarios, the method was shown to


Figure 2: Fault prognosis results for the top 2 faulty variables in: (a) Catalyst decay fault; (b) Fouling fault. See Table 1 for R^2 fitness on all the charts.

Table 1: R^2 fitness values of the predictions of the faulty variables

Fault 1	with KF	without KF	Fault 2	with KF	without KF
C	90.57 %	−135.0 %	T_c	98.32 %	−35.3 %
F_c	94.41 %	27.30 %	F_c	96.52 %	12.93 %

provide early detection, reliable diagnosis, and accurate tracking of faulty variables. Hence, the framework constitutes a baseline strategy for industrial process monitoring.

Abstract

A recent study introduced a new class of control structures using one-point temperature control applicable to heterogeneous reactive distillation. The feed rate of one reactant sets the plant capacity. The inventory of the other reactant is inferred from measuring the reflux rate or reflux ratio and is managed by adjusting the second feed flow. This idea can be implemented in different ways. Here, the applicability of these structures to various esterification systems of industrial importance is assessed. The analysis is based on key thermodynamic data: boiling points, azeotropy and liquid-liquid equilibria. As a rule-of-thumb, if water is the lightest and the ester the heaviest boiler in the system, and if at least the alcohol forms a minimum boiling heterogeneous azeotrope with water, then the new class of control structures may be applicable.

Keywords: acetates, acrylates, esterification, propionates, process control

1. Introduction

Reactive distillation (RD) offers significant advantages such as reduced investment and operating costs. However, the controllability of the process is as important as the economics, in order to meet important objectives such as process stability, production rate and product purity. Recently, we proposed a new class of control structures using one-point temperature control that are applicable to heterogeneous reactive distillation (Moraru et al., 2018). The *heterogeneous* attribute refers to systems that present minimum boiling heterogeneous azeotropy making possible a liquid-liquid split after vapor condensation. Hence, these control structures are appropriate for industrially important chemical systems which share this particular thermodynamic property.

Many acetates, acrylates and propionates are esters of industrial importance which have in common the minimum boiling heterogeneous azeotropy. They are produced in large quantities and used in a variety of applications. These esters are usually obtained in the reaction between an alcohol and the respective acid, which is typically performed in liquid phase and in the presence of a homogeneous catalyst. Whenever feasible, the RD technology using solid catalysts is preferred as alternative to the conventional processes (i.e., reactors followed by distillation systems).

In the perspective of showing the broad applicability of these new control structures using one-point temperature control, we study the basic thermodynamic properties of six important esterification systems: two acetates, two acrylates and two propionates;

the two acrylates were already used to test the concept of the new control structures and serve here as comparison for the other esterification systems. In the first part, the basic control idea applicable to the heterogeneous reactive distillation is presented; dynamic simulation results proving the control performance are also briefly presented. In the second part of the study, the common key properties that suggest the applicability of the new control structures are described. The azeotropy and liquid-liquid equilibria of each system are compared and discussed in detail. Aspen is used as computer-aided process engineering tool to make the analysis.

2. Basic control idea

The basic idea behind the new one-point temperature control structures addresses three basic control objectives: setting plant capacity, achieving the required product purity, and maintaining the component inventory. The latter is the key element of the concept.

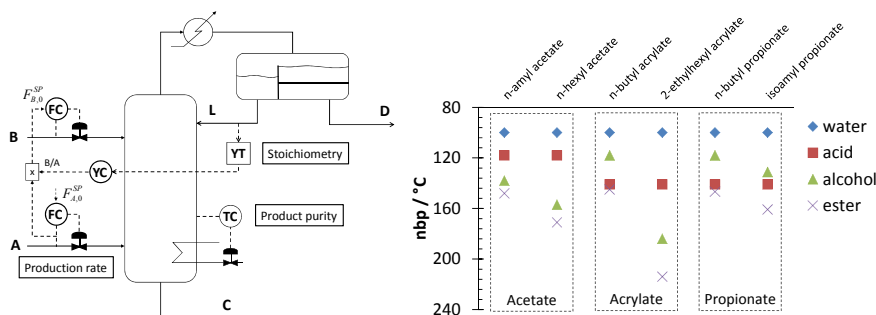
To better describe the concept, we start by describing the RD process. A general esterification system which can be efficiently performed by RD comprises two reactants (A, B) and two products (C, D). Often, one product is the high-boiling species and is obtained as bottom stream, while the other is involved in a low-boiling azeotrope and is obtained as distillate. This azeotrope has the beneficial effect of displacing the chemical equilibrium, but also the disadvantage of an impure distillate. However, when the heterogeneity of the azeotrope makes possible a liquid–liquid split of the condensed distillate, the reactant-rich phase can be returned to the column as reflux, while the product-rich phase has the composition on the side of the distillation boundary which allows obtaining the top-product with a relatively high-purity. Figure 1 (left) shows a typical example. The heavy reactant B (acid or alcohol) is fed as liquid at the top of the reactive zone of the RD column. The light reactant A (acid or alcohol) is fed as vapor at the bottom of the reactive zone. The reactants flow in counter-current and reaction takes place in the liquid phase. The heavy product C (ester) is recovered in the stripping zone of the column, being obtained as high purity bottom stream. The light product D (water) forms several binary and ternary low-boiling heterogeneous azeotropes. Thus, water is removed from the liquid mixture with the result of increased reaction rate due to equilibrium displacement. The distillate is condensed, cooled, and sent to liquid–liquid separation. The organic phase is refluxed. The aqueous phase is the top product. If required, a flash can remove the small amounts of organics that are still dissolved.


Figure 1. Basic control idea for RD process (left); different types of esterification systems (right)

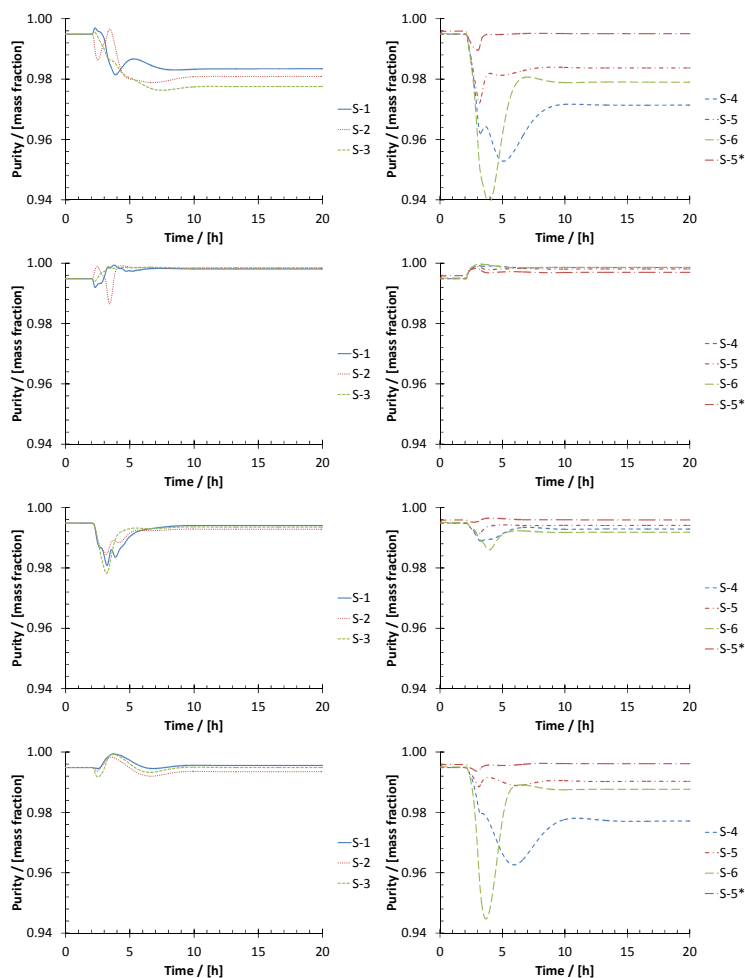
During operation, the feed flow rate of one reactant sets the plant capacity. The requirement to feed the reactants in the stoichiometric ratio is addressed by feedback control. The inventory of the other reactant is inferred from the reflux rate or reflux ratio, which both can be easily measured. When this reactant is not fed in the correct stoichiometric ratio, it will either accumulate in the system or get depleted, which will be reflected by a change of the reflux rate. Thus, corrective action (change of the fresh feed rate) can be taken. This simple solution does not require concentration measurements and does not use any temperature control loop. Consequently, the reboiler duty becomes available to be used as manipulated variable in a quality-control loop. Several control strategies are possible based on this idea.


Figure 2. Process dynamics associated with each control structure (left column: literature structures S-1, S-2, S-3; right column: novel structures S-4, S-5, S-6 (S-5* uses pressure-compensated control and can be implemented to any of these six structures)) at various perturbations: top diagrams: +25% production; middle-top diagrams: -25% production; middle-bottom diagrams: 5 %mass water in fresh acid; bottom diagrams: 5 %mass water in fresh alcohol.

Figure 2 compares the performance of several control structures from the literature (S-1, S-2, (Luyben and Yu, 2008) and S-3 (Zeng et al, 2004)) with control structures based on the idea presented above (S-4, S-5, S-6). S-1 sets the production rate by the reboiler duty and uses two temperature measurements for inferential control of reactants inventory: the top feed controls a temperature in the stripping section while the bottom feed controls a temperature on the top of the reactive zone. S-2 sets the production rate directly, by changing the feed rate of the light reactant. The second reactant and the reboiler duty are used to control two temperatures in the stripping and reactive sections, respectively. S-3 uses only one temperature control loop, fixing the ratio between the reboiler duty and the flow rates of fresh reactants. In S-4 and S-5, the accumulation / depletion of one reactant is inferred from the reflux ratio and the reflux rate, respectively. S-6 takes a different approach: the reflux ratio is fixed and the alcohol is fed at two different locations: at the top of the reactive section, and directly in the decanter. This second feed provides an additional degree of freedom which is used to control the level of the organic phase, maintaining in this way the component balance. Among the new control structures, S-5 is the best, showing comparable performance with S-1 in terms of speed of disturbance rejection and offset in product purity.

3. Common key properties

The applicability of the new control concept to reactive distillation processes of industrial importance can be assessed based on key physical properties. This perspective is discussed in the remaining of this chapter.

3.1. Thermodynamic model
The model parameters for calculating the physical properties of pure components and mixtures are available in the Aspen database. The azeotropes and phase equilibria are calculated using the UNIQUAC or NRTL liquid activity coefficient models. The HOC equation of state is also considered to account for the dimerization of acids in the vapor phase. The binary interaction parameters are taken from published literature or retrieved from the Aspen databanks, including the parameters for the HOC equation.

3.2. Boiling points of pure components
The order of boiling points of the pure components in the system determines the structure of the RD column: addition of feeds and withdrawal of products. Figure 1 (right) orders by their normal boiling points the components (alcohol, acid, water and ester) of each of the esterification system considered in this work. In all systems, the ester is the highest boiler, and is obtained as bottoms; the heterogeneous azeotropes are the lightest, making possible to obtain the water as distillate (after decantation); the reactants are intermediates (acids lighter or heavier than alcohols), and are fed to the column at the bottom and top of the catalytic section. In addition, these six systems present various characteristics which shows that the proposed control structures are applicable to a wide range of esterification processes: (i) combination between 3 acids and 5 alcohols, (ii) wide boiling range for acids (118-141 °C), alcohols (118-184 °C) and esters (145-214 °C).

Note that other esterification systems (not presented in this study) such as *n*-butyl acetate, *n*-decyl acrylate and cyclohexyl acrylate, can be included in this list of industrially important esters.

3.3. Azeotropy and liquid-liquid equilibria

The formation of heterogeneous azeotropes and formation of two liquid phases after condensation are the key elements on the control concept. This allows to control the inventory of one component by monitoring the refluxed organic phase and adjusting one of the fresh feeds. Table 1 shows the azeotropes calculated at 1.013 bar for all esterification systems. Each system presents at least two binary heterogeneous azeotropes: water/alcohol and water/ester. With the exception of the *2*-ethylhexyl acrylate, all the other systems also present a ternary heterogeneous azeotrope: water/alcohol/ester. All these azeotropes have a boiling point very close to that of water and will be found in the vapor distillate. Excepting the *n*-hexyl acetate system, the acid is involved in homogeneous azeotropy either with water (*n*-butyl propionate) or with the alcohol or ester. These azeotropes have a high boiling point, close to that of the ester in some cases. They are important since they may contaminate the ester product.

Figure 3 shows that all systems have large immiscibility areas, meaning that the water product is obtained with a relatively high purity; when this is not the case (n-butyl acrylate), an additional flash can recover the alcohol and obtain high-purity water. This is possible due to the minimum boiling heterogeneous azeotrope water / alcohol.

Table 1. Azeotropy[a] (mass based) at 1.013 bar of the six esterification systems

4. Conclusions

The applicability to a given esterification system of the basic control concept can be assessed based on key physical property data. As a rule-of-thumb, if the pure components have the right nbp order, and if at least the alcohol forms a minimum boiling heterogeneous azeotrope with water, then the new class of control structures may be applicable.

Abstract

This work presents an optimization approach to compare tri-reforming and super dry reforming for the production of syngas. Next, this section is integrated with the synthesis of Fischer-Tropsch liquids at low and high temperatures. The optimization of the tri-reforming technology is carried out introducing a parametric approach to evaluate different O_2:Biogas ratios. Tri-reforming is always selected to produce syngas. The biogas composition depends on the purpose of the syngas including ethanol, FT or methanol production. The large amount of hydrogen required in the last option is achieved introducing more steam in the WGS reactor in the tune-up section. In the second part of the work, the integration of previous reforming types with FT processes suggests that the operation in the LT mode is more profitable ($3.3/gal of diesel) than the HT ($5.4/gal). However, both are far from other production costs reported in literature that reach up to $0.34/gal.

Keywords: Biogas, CO_2, circular economy, reforming, optimization.

1. Introduction

Current developed societies generate large volumes of wastes. Waste needs to be treated before disposing them. Anaerobic digestion represents a technology that allows not only processing and stabilizing the waste, but that also generates additional value in the form of biogas and digestate. For decades, biogas was only used for the production of power and as a source of methane for natural gas networks (Wellinger et al., 2013). However, biogas is an interesting source of carbon not only because of the methane, but also due to its CO_2 content since it can be used for the production of chemicals via dry reforming (DR) (Hernández et al., 2017). The DR technology has been evaluated by integrating it with other reforming technologies such as in combined steam and dry reforming (Hernández and Martín, 2016) or in tri-reforming (TR) (Chein et al. 2017, Vita et al. 2018). Apart from its combination, another relevant technology has been recently developed by intensifying the process (Buelens et al., 2016). Super-dry reforming (SDR) has been created by intensifying DR with the objective of maximizing the conversion of CO_2. It is based on eliminating the reverse WGS reaction, obtaining the global reaction presented in Eq. (1).

$$CH_4 + 3CO_2 \leftrightarrow 4CO + 2H_2O \tag{1}$$

The optimization and comparison of TR with other reforming technologies was only recently addressed by Balasubramanian et al. (2018). They performed an MINLP

optimization selecting the optimal reforming type for different H_2:CO syngas ratios and using natural gas as raw material. However, SDR was not taken into account. Thus, this work presents a comparison including the SDR technology within the superstructure and using biogas as raw material. Furthermore, the work is extended integrating the previous reformers with the production of Fischer-Tropsch (FT) fuels via low and high temperatures.

2. Modelling Issues.

The problem presented in this work is divided in two parts. First, in section 2.1 the superstructure for the production of syngas with different H_2:CO ratios using biogas as raw material and with parallel TR and SDR is presented. Next, the integration of TR and SDR for the optimal production of FT fuels is presented in section 2.2.

2.1 Tri-Reforming versus Super-Dry Reforming for Syngas Production.

The problem addressed in this section is presented in the superstructure given by Figure 1, where only the main operations of the process are defined. The modelling of these units is briefly defined in the following paragraphs. Other units such as heat exchangers and compressors are not included in Figure 1 but they are also modelled based on thermodynamics, mass and energy balances.

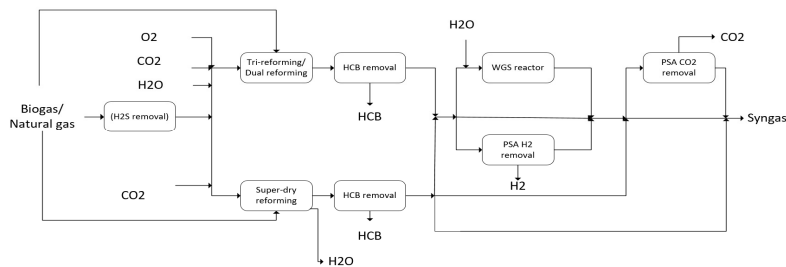
The biogas fed in the system is a mixture of gases whose optimal composition is also desired to be obtained. It is fed in the system, and split into three streams: one for processing and the other two ones used as fuel for heating up the reforming reactors. The biogas fed to the process section is initially sent to a bed for removing the ammonia and H_2S that would reduce the catalyst efficiency of the reformer in later stages.


Figure 1. Superstructure of the Reforming Selection Problem for Syngas Production.

After cleaning the biogas, it is split in two streams. The first is sent to the TR reactor and the other one is sent to the SDR reactor. The TR is modelled dividing the reactor in two stages as presented by Hernández and Martín (2018). In the first stage, partial oxidation occurs and in the second stage the concentration of the components is computed based on chemical equilibrium. The oxygen required in this TR reactor is evaluated using different ratios by mean of a parametric optimization. The SDR reactor is modelled using a reduced order model, Eq. (2), that it is based on the thermodynamic results presented by Buelens et al. (2016). Two streams leave this SDR reactor: one for the water captured by the absorbent during regeneration and another one for the CO and unreacted gases produced.

$$X_{CH_4} = 8.13 + 0.76 \text{gln}(\frac{molCO_2}{molCH_4}) - \frac{4746.4}{T(\text{K})} - 2.6\text{g}10^{-3}\text{g}T(\text{K}) - 6.3\text{g}10^{-4}\text{g}T(\text{K})\text{gln}(\frac{molCO_2}{molCH_4}) \quad (2)$$

The syngas coming out from both reactors needs to be treated and its composition adjusted to ensure the H_2:CO ratio desired in the syngas. First, the traces of methane are removed in order to avoid carbon deposition on the catalyst of future synthesis or WGS reactors. The removal efficiency of the beds is assumed to be 100%. Then, the H_2:CO ratio is adjusted by considering three technologies: a WGS reactor to increase the concentration of H_2 (modeled as an equilibrium), a by-pass to keep constant the ratio and a hybrid membrane-PSA system to remove the H_2. The last stage assumed in the modelling of the tune-up section is the CO_2 removal since large concentrations of CO_2 promote the carbon deposition on the catalyst of synthesis reactors.

2.2 Super-dry and Tri-reforming for Fischer-Tropsch liquids production.

The previous syngas production can be integrated with the production of different chemicals and, among them, FT fuels. The superstructure for FT fuels production is presented in Figure 2. It considers two modes of operation depending on the reactor operating conditions: at high (HT), 590K-630K, and low temperatures (LT), 440K-530K. In both cases, the mass product distribution, w_i, follows the Anderson-Schulz-Flory distribution that depends on the number of carbons of the component, n_c, and the chain growth, α, as presented in Eq. (3). α is also dependent on the reactor temperature and molar fractions (Hernández and Martín, 2018).

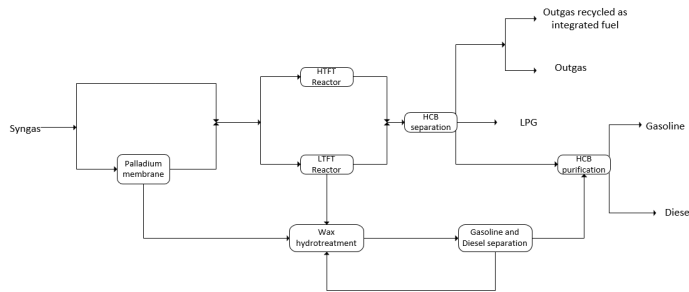
$$w_i = \alpha^{n_c-1}(1-\alpha) \cdot n_c \quad (3)$$


Figure 2. Superstructure for the Integration of FT-Fuels.

When the FT reactor operates at HT, light products are dominant and waxes only appear as traces. Thus, the product obtained from the reactor is sent to a separation stage composed by a flash separator to remove the unreacted gases of the syngas and fractions lighter than C_3. The products heavier than C_3 are expanded and separated in a tri-separator that has three outlets: a gas stream in the top that contains the LPG, a bottom stream with the water fraction and an intermediate stream with the organics with a chain larger than C_4. These organics are later separated in a distillation column in two fractions: gasoline and diesel.

The FT reactor operating at LT produces fuels with larger chain lengths, including waxes. In order to provide an added value to these waxes, an integrated recovering procedure based on hydrogenation is proposed. The hydrogenation reactor is modelled following a reduced model (Hernández and Martín, 2018), It requires H_2, which is

separated from the syngas before the FT reactor, see Figure 2. After separating the H_2, the syngas is sent to the LT-FT reactor, whose products are separated as follows. First, the waxes are separated at the exit of the reactor as liquids. The rest of components are gases that are cooled down and sent to a flash separator. Second, the flash separator removes the unreacted syngas and hydrocarbons (HCB) with a chain length shorter than C_3. The hydrocarbons with a chain larger than C_3 and water are sent to a tri-separator that separates the fractions as in the previous HTFT process. Finally, the hydrocarbons with a chain larger than C_4 (gasoline and diesel) are separated in a distillation column together with the fractions recovered from the waxes hydrogenation.

3. Solution procedure.

3.1 Tri-Reforming versus Super-Dry Reforming for Syngas Production.

The first part of this work focuses on the optimization of the syngas production using two type of reformers: super-dry and tri-reforming. This problem is solved maximizing the profit obtained from the process. It is computed following Eq. (4) as function of the product costs ($\$_i$), the fluxes ($F_i$), power ($W_i$) and heat ($Q_i$) consumptions. This objective function completes the definition of the NLP optimization problem that is composed by 1,200 equations and 1,400 variables that are written in GAMS and solved using a multi-start approach with CONOPT 3.0.

$$profit = \$_{H_2} F_{H_2} - \$_{elec} \sum_{i \in Compressors} W_i - \$_{CH_4} \sum_{i \in CH_4 inlets} F_{CH_4} - \$_{CO_2} \sum_{i \in CO_2 inlets} F_{CO_2} - \$_{O_2} \sum_{i \in O_2 inlets} F_{O_2}$$

$$-\$_{H_2O} \sum_{i \in H_2O inlets} F_{H_2O} - \$_{steam} \sum_{j \in Q_{heat}} Q_j + \$_{H2O ref.} \sum_{k \in Q_{ref}} Q_j - \$_{H_2S} \sum_{i \in H_2S_{recovered}} F_{H_2S} \qquad (4)$$

3.2 Integrated Super-dry and Tri-reforming with Fischer-Tropsch processes.

The second part of this work focuses on the optimization of the integrated process that combines the reforming technology with the production of FT fuels. In this case, the integrated MINLP problem defined in the super-structures of Figure 1 and 2 is divided in two NLP sub-problems that are independently written in GAMS for the maximization of their profit. The problem involving the HT-FT reactor mode is composed over 2,100 equations and 2,500 variables, meanwhile the problem involving the LT-FT reactor model consists of 2,600 equations and 3,100 variables. Both cases are solved in GAMS using a multi-start approach with CONOPT 3.0.

4. Results

4.1 Syngas production from Tri-Reforming and Super-dry Reforming.

The optimization of the syngas production provides the optimal biogas composition for different products, the technologies selected and the operating conditions. The optimal composition of the biogas fed to the process is presented in Table 1. It can be seen that for ethanol production, the biogas composition required is approximately 48% of CO_2 and 52% of CH_4, while for FT and methanol production the methane content is to be at the upper bound. The large amount of hydrogen required to produce methanol is obtained by increasing the steam added in the WGS reactor of the tune-up stage.

After specifying the feed composition, the reforming technology selected is always the TR. Thus, oxygen is also needed in the process requiring 0.275 $molO_2$:mol Biogas for syngas used for methanol and FT, and 0.035 $molO_2$:mol Biogas ethanol. The

temperature in this reactor is suggested to be 1273 K for methanol and FT production and 1231 K for ethanol production.

In the tune-up section, the production of a syngas with a H_2:CO ratio of 1:1 only requires to remove the unreacted HCB. The production of a syngas with a H_2:CO ratio of 1.7 requires the removal of HCB, the use of a WGS reactor and the addition of 0.06 mol of steam per mol of biogas fed in the process. Finally, the production of a syngas with a H_2:CO ratio of 2.5 requires all the units defined in the tune-up section: a silica bed to remove the unreacted HCB, a WGS reactor that needs 0.21 mol of steam per mol of biogas fed in the process and a PSA system that removes the excess of CO_2 and receives the 66% of the syngas produced.

Table 1- Optimal Compositions of Biogas an Boundaries (% vol.).

Comp.	Methanol (H_2:CO=2.5)	FT (H_2:CO=1.7)	Ethanol, DME (H_2:CO=1)	Minimum	Maximum
CO_2	0.25	0.25	0.479	0.37	0.75
CH_4	0.75	0.75	0.521	0.25	0.50
H_2O	$1 \cdot 10^{-10}$	$1 \cdot 10^{-10}$	$1 \cdot 10^{-10}$	$1 \cdot 10^{-10}$	0.17
N_2	$1 \cdot 10^{-4}$	$1 \cdot 10^{-4}$	$1 \cdot 10^{-4}$	$1 \cdot 10^{-4}$	$2 \cdot 10^{-3}$
H_2S	$2 \cdot 10^{-5}$	$2 \cdot 10^{-5}$	$2 \cdot 10^{-5}$	$2 \cdot 10^{-5}$	0.031
NH_3	$1 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	$3.5 \cdot 10^{-6}$

4.2 *Integrated Super-dry and Tri-reforming with Fischer-Tropsch processes.*

The second part of the problem focuses on integrating the selection of the two previous technologies with the production of FT fuels from syngas. The problem has been divided in two parts according to the operating mode in the reactor.

On the one hand, if the FT reactor operates at HT, the process shows a profit of $\$7 \cdot 10^{-4}$ per mol of biogas fed in the process. This process produces a large amount of HCB with short chain length that are less valuable than other fractions. However, the reduced income is balanced with a lower consumption of utilities. According to the process operation, the suggested biogas composition is 62% of CH_4 and 38% of CO_2. This biogas is processed selecting a TR reactor and the PSA system for removing the CO_2 in the tune-up section. As a result, the syngas obtained to be fed in the FT reactor has a ratio of 1.2. On the other hand, when the FT reactor operates at LT the profitability of the process is improved up to $\$2.2 \cdot 10^{-2}$ per mol of biogas fed in the process. The products obtained from this process are mainly gasoline, diesel and LPG. Thus, in spite of the higher consumption of utilities, the income is larger than in the previous mode and the process profitability is improved. Apart from the utilities, another characteristic variable is the biogas composition in the feed, similar to the previous one, 69% CH_4 and 31% CO_2. In this case, the TR reactor and PSA system for the removal of CO_2 are also selected, obtaining a syngas with a H_2:CO ratio of 1.

The optimization of the process is completed with an economic evaluation. For a plant fed with 12Mm³/y of biogas, the CAPEX is estimated to be $8 M for the HT-FT process and $19M for the LT-FT process. The production cost of the HT-FT process is estimated to be $610/ton for LPG, $2.57/gal for gasoline and $3.02/gal for diesel. For the LT-FT process this production cost is estimated to be $520/ton for LPG, $1.25/gal for gasoline and $1.67/gal for diesel. The production cost of the FT processes developed

can be scaled-up to a facility that processes 3100 kt/y of manure and compared with a previous renewable process as it is presented in Table 2. As a result from this comparison, it can be seen that the HT-FT and LT-FT are less competitive than the previous work (Hernández and Martín, 2017).

Table 2- Production costs of different processes for the production of fuels.

Process	Production cost.
HT-FT	$5.4/gal
LT-FT	$3.3/gal
Hernández and Martín (2017)	$0.34/gal

5. Conclusions

This manuscript presents an optimization of biogas to syngas processes comparing super-dry and tri-reforming technologies. To optimize the TR process a parametric approach has been introduced since different O_2:biogas ratios are required. The results show that TR is always selected as the most profitable technology. However, SDR consumes more CO_2 in the reaction, being necessary further works to analyse its environmental impact. The different H_2:CO ratios are achieved by modifying the biogas compositions operating conditions and technologies in the tune-up section.

The work is completed integrating the syngas production section with two FT processes, at low and high temperature. The LT-FT shows to be more profitable than the HTFT process but none of the processes is not competitive with other renewable processes developed before.

Abstract

The rice value chain, especially in the Philippines, can potentially progress in terms of efficiency and sustainability, as well as create more value by effectively utilising the crop residues of rice production. However, generating multiple products will lead to a complex decision-making process in supply chains, especially in the case of rice crop, which is vital for the Philippines' food security. Thus, systematic planning techniques are needed to address important decisions along the stages in rice value chains. This study presents a mixed integer linear programming (MILP) model developed for the planning, design and operation of multi-product rice value chains. In order to capture the spatial-dependencies of the problem, such as the candidate locations for rice farms and processing facilities, and location of demands, 81 cells represented the Philippines. The temporal aspect of the model considers a long planning horizon, out to 2050, and the time varying demands for white rice and the crop residues of farming and milling. The model determines design and operating decisions such as where to locate the farms and processing facilities, what products to produce, how to transport resources, among others. Different objectives are considered such as maximisation of the net present value and minimisation of CO_2 emissions. The Pareto set generated represents the optimal solutions representing the different trade-offs between economic gain and environmental protection.

Keywords: rice value chain optimisation, multi-product value chain, multi-objective optimisation, spatio-temporal modelling, mixed-integer linear programming

1. Introduction

Rice consumption in many developing countries of the tropics is rapidly growing due to rising population and increasing urbanisation. Compelled to secure sufficient rice supply, these nations had been enhancing farm productivity and expanding agricultural land. Despite resource scarcity, rice production in these nations has remained a highly land-use-, energy-, and water-intensive activity (Sims et al., 2015). Recently, extreme-weather events related to climate change have caused damage and losses to these nations' agricultural sectors such as rice. All of these drivers instil more pressure and inevitably disrupt the food-energy-water nexus that support rice value chains in the tropics (Keairns et al., 2016). Therefore, understanding and formulating better strategies in managing and

operating rice value chains are crucial. In the case of the Philippines, rice sufficiency improvements have yet to result in economic benefits due to mismatched policies and lack of infrastructure (Briones, 2014). Harvest losses and inefficient logistics interrupt the country's rice supply chain (Mopera, 2016). Rice cultivation is a major greenhouse gas emitter in the Philippines because the majority of the carbon-rich crop residues, rice straw and rice husk, are burnt and untapped. If these wasted resources are managed and valorised, the rice value chain can contribute to the country's economic and environmental sustainability. Motivated by the desire for rice value chains to be more secure, efficient, profitable and sustainable, the aim of this work is to develop a mixed integer linear programming (MILP) model for planning, design and operation of multi-product rice value chains. The multi-objective optimisation model is used to perform a number of case studies to determine the Pareto set of solutions that represent a compromise between economic and environmental criteria.

2. Problem statement

The problem involves simultaneous determination of design and operating decisions, such as: where to farm rice crop; how much farm land to allocate; what and how much resources to utilise and what products to generate (e.g. food, energy, fuels and chemicals); what conversion technologies to invest in and where to locate them; whether or not to densify/pre-process crop residues before conversion and/or transportation; and how to transport raw materials and distribute products to customers; all of these in order to maximise of the net present value of the value chain while at the same time minimising CO_2 emissions.

3. Mathematical model

The mathematical model was based on the Value Web Model (Samsatli & Samsatli, 2018; Samsatli et al., 2015), a spatio-temporal MILP model configured for the United Kingdoms' energy value chains for natural gas and wind power. For the first time, this model was applied to rice value chains with a vastly different configuration for the Philippines. A planning horizon of 32 years, from 2018 to 2050, was considered. The model comprised multiple time scales: planning periods $y \in \mathbb{Y}$, seasonal time steps $t \in \mathbb{T}$, day type of the week $d \in \mathbb{D}$ and hourly intervals $h \in \mathbb{H}$. For the spatial representation, Philippines was divided into 81 cells corresponding to its provinces (Fig. 1). Each cell, $z \in \mathbb{Z}$, has information on the available farm land, the paddy rice yield, the cost of paddy rice production, existing technologies, if any, and existing transport infrastructures, if any. In addition, each cell has coordinates (x_z, y_z) calculated from the population density, in order to represent the demand centres and to calculate the transport distance $d_{zz'}$ (km) from cell z to cell z'.
Figure 1. Spatial representation of the Philippines in the model

3.1. Objective function

Eq. (1) shows the objective function to be minimised:

$$Z = \sum_{my} w_m \left(\mathcal{I}_{my}^{\mathrm{p}} + \mathcal{I}_{my}^{\mathrm{Q}} + \mathcal{I}_{my}^{\mathrm{fp}} + \mathcal{I}_{my}^{\mathrm{fq}} + \mathcal{I}_{my}^{\mathrm{vp}} + \mathcal{I}_{my}^{\mathrm{vq}} + \mathcal{I}_{my}^{\mathrm{i}} + \mathcal{I}_{my}^{\mathrm{e}} + \mathcal{I}_{my}^{\mathrm{U}} - \mathcal{I}_{my}^{\mathrm{Rev}} \right) \tag{1}$$

Each term inside the parenthesis represents an impact in year y on performance metrics m. These include the following: the total net present capital impact of technologies for conversion $\mathcal{I}_{my}^{\mathrm{p}}$ and transport $\mathcal{I}_{my}^{\mathrm{Q}}$; the total net present fixed operating impact of technologies for conversion $\mathcal{I}_{my}^{\mathrm{fp}}$ and transport $\mathcal{I}_{my}^{\mathrm{fq}}$; the total net present variable operating impact of technologies for conversion, $\mathcal{I}_{my}^{\mathrm{vp}}$ and transport $\mathcal{I}_{my}^{\mathrm{vq}}$; the total net present impact of importing resources $\mathcal{I}_{my}^{\mathrm{i}}$; the total net present impact of exporting resources $\mathcal{I}_{my}^{\mathrm{e}}$; the total net present impact of utilising resources $\mathcal{I}_{my}^{\mathrm{U}}$; and the total net present revenue from the sale of resources (e.g. white rice, bio-electricity, biofuels, etc.) $\mathcal{I}_{my}^{\mathrm{Rev}}$.

3.2. Constraints

Eq. (2) expresses the resource balance that considers various input and output terms for every resource $r \in \mathbb{R}$ in cell z during hour h of day type d in season t of planning period y. Eq. (3) states that the rate of utilisation, U_{rzhdty}, cannot exceed the maximum availability u_{rzhdty}^{max} (t/h or MW). Eq. (4) states that the total amount of biomass, represented by index c, utilised in each season cannot exceed the seasonal availability. Eqs. (5) and (6) are the local and national land footprint constraints, which respectively ensure that the allocated area A_{czy}^{Bio} (ha) for biomass c in cell z during planting period y, cannot be more than the maximum portion of suitable area in each cell z; and total allocated area for biomass cannot be more than the maximum portion of the total suitable area at the national level. The net rate of resource production (or consumption) P_{rzhdty} (t/h or MW) is expressed by Eq. (7); where α_{rpy} is the conversion factor of a resource r in technology $p \in \mathbb{P}$ in planning period y. The rate of operation of a single conversion technology $\mathcal{P}_{pzhdty}$ is limited by its minimum and maximum capacities, $p_p^{\min}$ and $p_p^{\max}$, respectively, as given by Eq. (8). Furthermore, Eq. (9) states that the number of commercial conversion technologies invested N_{pzy}^{PC} cannot exceed the maximum number BR_{py} that can be built in planning period y. The net rate of transport Q_{rzhdty} (t/h or MW) of resource r between cells z and z' is given by Eq. (10) where $\bar{\tau}_{lr,dst,y}$ and $\bar{\tau}_{lr,dst,y}$ are the conversion factors for distance-dependent and distance-independent transport technology $l \in \mathbb{L}$ of resource r during planning period y, respectively. Eqs. (11) and (12) limit the operation of a transport technology $q_{lzz'hdty}$ up to its maximum capacity and the total operation rate of all transport technology up to the capacity of infrastructure $b \in \mathbb{B}$, respectively. The model categorises between two demands: those that must always be complied $D_{rzhdty}^{\mathrm{comp}}$ (t/h or MW) and those that may be optionally complied $D_{rzhdty}^{\mathrm{opt}}$. Since the optimisation determines what and how much product to generate from a resource and what demands to satisfy, Eq. (13) determines the optional demand satisfied $D_{rzhdty}^{\mathrm{sat}}$. Lastly, the rate of import I_{rzhdty} in Eqs. (14) and rate of export E_{rzhdty} in Eq. (15) cannot exceed the maximum import and export capacities $I_{rzhdty}^{\max}$ and $E_{rzhdty}^{\max}$, respectively (all in t/h or MW).

$$U_{rzhdty} + I_{rzhdty} + P_{rzhdty} + Q_{rzhdty} \geq D_{rzhdty}^{\mathrm{comp}} + D_{rzhdty}^{\mathrm{sat}} + E_{rzhdty} \tag{2}$$

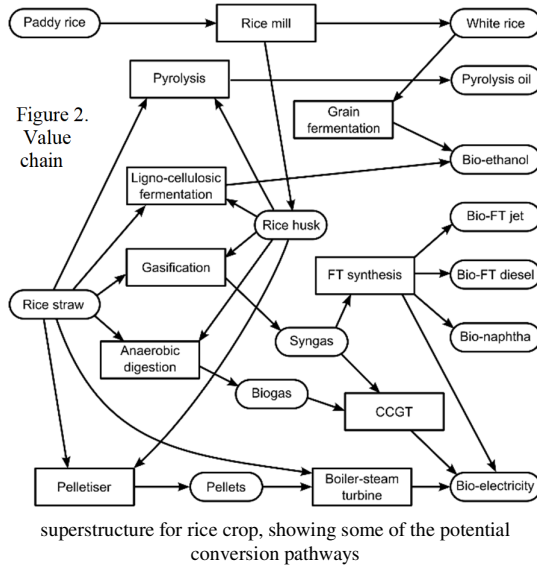
3.3. Network superstructure

Whereas food only (i.e. white rice) is produced in conventional rice value chains, many non-food products can also be generated as supplementary sources of income. The value chain superstructure in Fig. 2 shows potential pathways for multi-product generation from rice crop and its residues, e.g. the rice straw from farming and the rice husk from milling. The residues can be processed via thermo- and bio-chemical conversion technologies such as boiler-steam turbine, anaerobic digestion and combine cycle gas turbine (CCGT) for energy (i.e. bio-electricity); lignocellulosic (LC) fermentation and pyrolysis for fuels (i.e. bio-ethanol, pyrolysis oil);

Figure 2. Value chain superstructure for rice crop, showing some of the potential conversion pathways

and gasification and Fischer Tropsch (FT) synthesis for chemicals (i.e. bio-naphtha). The value chain (Fig. 2) also includes a pelletiser for the densification of the residues. The inputs to the optimisation model include the spatial and temporal availability of paddy rice and product demands (white rice, bio-electricity, bio-ethanol and bio-naphtha). The model also requires the characteristics of each conversion and transport technologies (capital expenditure, operation and maintenance costs, conversion factors etc). The key constraints are given in Section 3.2. For a given objective (maximise NPV or minimise CO_2 emissions), the model determines the optimal location for rice crop farming and the sites of the conversion technologies. The demands for food has to be satisfied all the time but the model can choose whether to produce non-food products from rice straw and/or rice husk, up to a specified maximum demand for a non-food product. Furthermore, the model also decides between barge and/or truck transport of white rice and/or paddy rice and the operation of these transport networks.


3.4. Multi-objective optimisation

The model was formulated as a multi-objective optimisation problem to allow the evaluation of trade-offs between conflicting objectives (Samsatli & Samsatli, 2018). The weighting method was used to transform the multi-objective optimisation problem into a single objective optimisation problem using different combinations of the weighting factors for the economic and environmental impacts. The weighting method can be expressed as $\min Z = \sum_1^N w_m Z_m$, where Z_m represents the individual impacts; w_m are the weighting factors, which can assume values between 0 and 1, with $\sum_{1=1}^N w_m = 1$.

Figure 3. Pareto set for the multi-objective rice value chain optimisation problem

1. The optimal solutions obtained at different combinations of the weighting factors form a Pareto set, which represents the compromise between the different objectives (Ang et al., 2010). In this study, the performance metrics are $m \equiv \{Cost, CO_2\}$. Therefore, when $w_m \equiv \{1, 0\}$, the problem is the maximisation of net present value; and when $m \equiv \{0, 1\}$ the problem is the minimisation of CO_2 emissions.

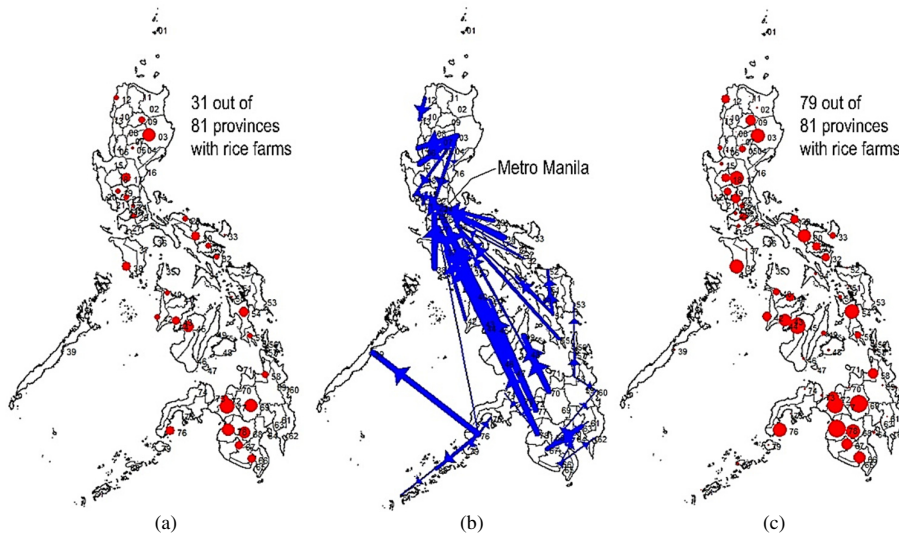
4. Case studies


Figure 4. Optimisation results: (a) allocated farm lands in case 1; (b) transport of white rice by barges in case 1; and (c) allocated farm lands in case 2.

Two cases have been considered for this paper. Case 1 examines the optimal solution for maximising NPV and minimising CO_2 emissions for the Philippine rice value chains considering food production only. The Pareto set generated in Fig. 3 shows the compromise between these two objectives for a planning horizon of 32 years with white rice demand of 11 Mt/yr. The highest point on the right represents the optimal solution for maximising NPV. For this solution, the NPV is PhP 2.14 T (USD 40.26 bn) and the CO_2 emissions are 439 $MtCO_2$. The lowest point in the left represents the optimal solution for minimising CO_2 emissions, with NPV of PhP 1.99 T (USD 37.43 bn) and CO_2

emissions of 392 MtCO$_2$. Moving from the bottom-left of the curve to the top-right represents solutions with increasing profit at the expense of higher CO$_2$ emissions. Depending on the policies, this Pareto set presents an opportunity for the Philippines to decarbonise its current rice value chain. The model has also determined barges as the main mode of transport mode in delivering white rice to provinces with the highest demand (for example Metro Manila the capital city in cell 23), as shown in Fig. 4(b). Compared to transport by truck, the cost and CO$_2$ emissions of transport by barge is significantly lower, which is more beneficial for an archipelagic country like the Philippines. Furthermore, compared to the existing trend of farming rice, despite suitability, in all provinces of the country (e.g. using >50% of the total farm land area), the model recommends rice crop farming in selected provinces of the country with high paddy rice yield and low farming cost as shown in Fig. 4(a). The Case 2 study determined the profitability of a multi-product rice value chain wherein demand for white rice at 11 Mt/yr was always satisfied while annual demands for bio-electricity, bio-ethanol and bio-naptha were *optionally* satisfied at up to 908 GWh/yr, 2.1 TWh/yr, and 17 GWh/yr, respectively. The model revealed that this multi-product rice value chain is profitable at NPV of PhP 2.41 T (or USD 45 bn) with 1.3 GtCO$_2$ emissions. In contrast to Case 1, the model suggested rice crop farming throughout the country (rice farms are now present in 79 out of 81 provinces – see Fig. 4(c)). When transformed into a multi-product rice value chain, the currently food-only rice value chain in the Philippines can become more profitable at PhP 0.6 m/ha (USD 11 k/ha), a 12% increase in NPV, since the non-food products can become additional revenue sources. Furthermore, the model recommended an optimal integrated rice value chain with *full* utilisation of rice husk and rice straw processed by LC fermentation, gasification, FT synthesis, boiler-steam turbine and CCGT. The model sited these technologies locally where the resources are available. Finally, the model also recommended transport by barge for both white rice and paddy rice. Paddy rice transport facilitated movement of rice husk to comply with demands of non-food products.

5. Conclusions

A multi-objective, spatio-temporal MILP model was developed for the simultaneous planning, design and operation of multi-product rice value chains. For the food-only scenario in the Philippines, the model generated a Pareto set representing the trade-offs between economic gain and environmental protection. The model recommended rice crop farming in provinces with high yields and low farming cost. To meet the demand for white rice, model showed that it is more cost-effective and environmentally sound to use barge over truck. For the multi-product rice value chain for the Philippines, the model was able to demonstrate that it was more profitable over a food-only rice value chain. Furthermore, advanced biomass conversion technologies to process rice straw and rice husk are going to be important for the feasibility of a multiproduct rice value chain.

Abstract

Batch distillation experiments on laboratory scale are conducted in order to estimate NRTL parameters describing thermodynamic mixture properties. For this purpose, distillate composition and column temperatures are measured as functions of the batch hold-up and then used to fit model parameters with a non-linear regression approach. Two different models are presented, a semi-rigorous model relying on the assumption of constant molar overflow and a rigorous model from the commercial flowsheet simulator Aspen Custom Modeler. For both models, the NRTL parameters are estimated with good agreement to the experimental data. However, the semi-rigorous model is much simpler and therefore requires far less computational effort.

Keywords: batch distillation, constant molar overflow, non-linear regression, NRTL parameter estimation

1. Introduction

The knowledge of thermodynamic mixture properties is most relevant for reliable distillation process simulations. For many industrial applications, lab scale batch distillation experiments can be used to gain information about the separation behavior of complex multi-component mixtures. In this contribution, we address the question to which extent it is possible to estimate NRTL parameters reliably from this data. The estimation of such parameters from mixture properties is a numerically challenging problem as discussed by Gau et al (2000).

A detailed simulation of a distillation process based on a rigorous model requires expert knowledge for the fine-tuning of the model and is often computationally demanding. In order to reduce the complexity of the problem, a semi-rigorous model is set up based on the equilibrium stage model assuming constant molar overflows within the column and empty column hold-ups. This leads to decoupled mass and energy balances and therefore to considerable simplifications of the MESH equations, and allows for a product stream composition parametrized by the batch hold-up. Such a simplification has already been discussed by Doherty and Perkins (1978) in detail and has been applied to batch distillation column models by Dongen and Doherty (1985), however, with an additional simplification of the column profile.

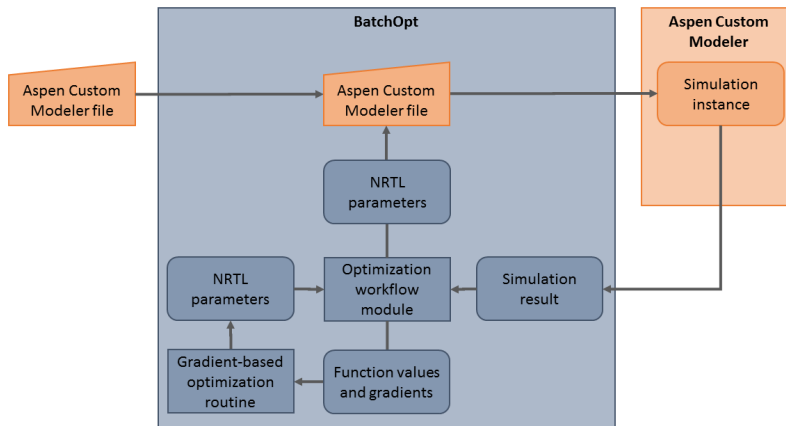
Both semi-rigorous and rigorous model are used to estimate NRTL parameters from minimizing the sum of squared residuals between calculated and experimentally measured compositions and temperatures. For this purpose, the semi-rigorous model makes use of Matlab's native Levenberg-Marquardt optimizer. The rigorous model is realized in a prototypic software framework, which combines numerical simulation with Aspen Custom Modeler based on an implementation in its specific modeling language with a gradient-based optimization routine, see Schittkowski (2009). This software feeds NRTL parameters into a simulation instance and obtains simulation results from there, computes function values and numerical gradients for the optimization routine and obtains updated NRTL parameters from there, see Figure 1.


Figure 1: Software framework BatchOpt with its interfaces to Aspen Custom Modeler and gradient-based optimization routine.

This paper is organized as follows: Section 2 presents the semi-rigorous model and derives the equations used for the numerical simulation. Section 3 contains a short account on the experimental setup in the laboratory and compares measured data with simulated data from the two models using NRTL parameters from literature. Section 4 contains the results obtained from solving the corresponding regression problem. The paper ends with a conclusion.

2. Semi-rigorous model

The rigorous model used to model a batch distillation is based on coupled theoretical equilibrium stages within the MESH equation framework, see Stichlmair and Fair (1998). This means that each equilibrium stage i is described by variables H_i (liquid hold-up in kmol), V_i (vapour stream leaving stage i, in kmol/h), L_i (liquid stream leaving stage i, in kmol/h), x_i (composition of L_i in mol/mol), y_i (composition of V_i in mol/mol), temperature T_i (in K) and pressure p_i (in bar). The stages are numbered such that $i = 0$ corresponds to the batch, and $i = N$ corresponds to the topmost stage. Above the topmost stage a total condenser ($i = N + 1$) is fed with the vapor stream V_N and a liquid distillate stream D with composition $x_{N+1} = x_D$ is withdrawn in addition to the liquid backflow L_{N+1} to the topmost stage. The reflux ratio $R = L_{N+1}/D$ describes the relation of these streams. To model the hold-up in each equilibrium stage as a function of time, the

MESH-equations must be combined with a suitable hydrodynamic model. For a detailed discussion of the rigorous model, we refer to the aforementioned literature.

For the semi-rigorous model the stage hold-ups in the packed column are neglected based on the assumption of a comparatively small packing hold-up in comparison to the pot. Therefore, the $H_{i>0}$ are dropped such that no further model of the column hydraulics is required. Component Mole balances then read

$$\frac{d}{dt}(\boldsymbol{x}_0 H_0) = -D\boldsymbol{x}_D$$

$$V_i \boldsymbol{y}(\boldsymbol{x}_i) = L_{i+1}\boldsymbol{x}_{i+1} + D\boldsymbol{y}(\boldsymbol{x}_N), i = 0, \dots, N-1$$

$$D\boldsymbol{x}_D = V_N \boldsymbol{y}(\boldsymbol{x}_N) - L_{N+1}\boldsymbol{x}_D$$

The first equation contains the total balance, the second the balances for the intermediate stages and the last for the top stage. Here the VLE relation $\boldsymbol{y} = \boldsymbol{y}(\boldsymbol{x})$ has been used. Dependence on the constant pressure $p_i = p$ and stage temperatures T_i have not been included in order to keep the notation simple. The total condenser enforces $\boldsymbol{y}(\boldsymbol{x}_N) = \boldsymbol{x}_{N+1} = \boldsymbol{x}_D$. In the next step, the approximation of constant molar overflows is made, which eliminates the stage dependence of internal streams, resulting in constant streams $V_i \equiv V$ and $L_i \equiv L$. Furthermore, a new pseudo-time variable $\tau = \ln\frac{H_0(t=0)}{H_0(t)}$ is introduced in order to parametrize the complete solution in terms of the relative batch hold-up. Time dependence is therefore completely eliminated, which means that energy balance is decoupled from mass balances.

These steps yield

$$(R+1)\boldsymbol{y}(\boldsymbol{x}_i) - R\boldsymbol{x}_{i+1} = \boldsymbol{x}_0 - \frac{d}{d\tau}\boldsymbol{x}_0, i = 0, \dots, N-1$$

$$\boldsymbol{y}(\boldsymbol{x}_N) = \boldsymbol{x}_0 - \frac{d}{d\tau}\boldsymbol{x}_0$$

This differential-algebraic system of equations constitutes the semi-rigorous model. It is completely determined once R and $\boldsymbol{x}_0(t=0)$ are given.

3. Experimental setup

The experimental data is obtained from a real experiment in an industrial lab. The batch distillation column that was used for the experiment is a DN 50 column with 1.3 m of random packing (glass rings, 4 mm diameter, 4 mm length). Approximately 2 kg of the initial solvent mixture was prepared for the experiment. The mixture consisted of 30 wt% acetone, 30 wt% methanol, and 40 wt% butanone. The distillation was performed at 1 bar. During the start-up at the beginning of the experiment and after an intermediate shut-down the column was initialized at infinite reflux ratio R, otherwise a constant reflux ratio of 5 was applied. The medium temperature of the sump heat bath was continuously adjusted to ensure a constant pressure drop within the expected limits of the packing. The head temperature as well as the pot vapor and liquid temperatures were continuously logged. The distillate was fractionated into approximately 40 separate samples, which were further analyzed using GC analyses with an FID-detector. Additional analyses were performed of the pot content before and after the distillation to ensure agreement with the

mass balance. Feeding the semi-rigorous and the rigorous model with NRTL parameters from the Aspen data base yields good accordance with the measured data, see Figure 2.
Figure 2: Distillate concentrations and head temperatures (violet) for initial NRTL parameters from experiment (dots), semi-rigorous model (solid lines) and rigorous model (dashed lines) for Acetone (blue), Methanol (green) and MEK (red).

The semi-rigorous model clearly achieves a better prediction of the experimental data than the rigorous model. The reason for this surprising behaviour is unknown to the authors, but might be an interesting starting point for further studies. Nevertheless, both models appear suitable for a fitting of NRTL parameters. This presumption will be confirmed in the next section.

4. Fitting of NRTL parameters

We exemplarily fit the two NRTL parameters B_{12} and B_{21} describing the mutual interactions between Acetone and Methanol and use fixed literature values for all other NRTL parameters. Thus, the joint fitting parameter $\Theta = (B_{12}, B_{21})$ is two-dimensional and the regression problem can be formulated as

$$\widehat{\Theta} = \text{argmin}_{\Theta} \sum_n w_n |d_n - m_n(\Theta)|^2$$

Here $\widehat{\Theta}$ denotes the optimal NRTL parameters, d_n describes the measured data point n and $m_n(\Theta)$ the corresponding calculated data point obtained from the chosen model (semi-rigorous or rigorous) for a specific choice of Θ. The sum index n over all measured mixture concentrations in distillate x_D and measured head temperatures T_N. The non-negative weights w_n allow for a tuning of the influence of different measurement points on the fitting result.

An appropriate pre-processing of the measurement data has been performed in such a way that outliers are omitted and all data points operate on the same scale. The weights w_n have been defined proportional to the inverse density of the neighboring data points. This choice compensates the varying density of the data with respect to the batch hold-up and therefore avoids an overfitting of densely measured regions. As an initial guess for the fitting parameters we choose deliberately displaced values $\Theta_{\text{guess}} = (-50, -500)$ in

relation to the Aspen values $\Theta_{Aspen} = (102, 114)$. In case of the rigorous model fit we have neglected the initial data points d_n in the sum of squared residuals so that the transient behavior of the simulation has no effect on the fitting. Moreover, we also reduced the total number of data points in order to reduce the influence of numerical noise on numerical gradient computation and thereby improve the convergence of the optimization process. Such a data-dependent noise arises because the Aspen simulation has a relatively low numerical accuracy which can accumulate with an increasing number of sampling points in the regression problem. To suppress this effect we have excluded all temperature data and used only about one sixth of the measured concentrations suitably distributed over the hold-up. A major benefit of our semi-rigorous model becomes apparent: Although the rigorous model might in principle lead to simulations which are closer to the physical reality, its numerical evaluation can still be less precise for practical purposes than a simplified model.

The fitting results are shown in Figures 3 and 4. We find that both the semi-rigorous and the rigorous model lead to a reasonably good fit.
Figure 3: Distillate concentrations for fitted NRTL parameters from experiment (dots), semi-rigorous model (solid lines) and rigorous model (dashed lines) for Acetone (blue), Methanol (green) and MEK (red).
Figure 4: Phase diagram with liquid (blue) and vapour (orange) Acetone fractions for initial (dotted lines) and literature (solid lines in dark color) NRTL parameters and NRTL parameters fitted with semi-rigorous (solid lines) and rigorous model (dashed lines).

Summarized, starting from the initially chosen parameters $\Theta_{guess} = (-50, -500)$ we have recovered two different sets of optimal parameters $\widehat{\Theta}_{semi-rigorous} = (-57, \ 284)$ and $\widehat{\Theta}_{rigorous} = (272, \ -36)$, respectively, from the two different models by numerically solving a regression problem with data from a real experiment. Despite the quality of the fits, it is interesting to mention that the two resulting sets of parameters are different and do both not correspond to the original values from the Aspen data base $\Theta_{Aspen} = (102, 114)$. This ambiguity of the NRTL parameters is well-known and poses a major challenge for their estimation, see Gau et al. (2000). Further research would be required to analyze in detail to which extend the resulting parameters depend on the chosen models or the formulation of the regression problem.

5. Conclusions

Using the approximation of constant molar overflow we have derived a semi-rigorous batch distillation model for which energy balances are decoupled from mass balances. This approach yields a simplified system of differential-algebraic equations, where distillation time is replaced by the relative batch hold-up. We have shown that although evaluations of this semi-rigorous model require far less computational effort than evaluations of a rigorous model from a commercial flowsheet simulator, it is still able to predict the experimental data from an industrial lab with equally good precision. Furthermore, we have used both semi-rigorous and rigorous model to successfully fit NRTL parameters to the experimental data by means of a non-linear regression approach as a proof of concept. Our results highlight the ambiguity of the NRTL parameters and show that our semi-rigorous model can in practice be superior to the rigorous model despite its simplifications.

In conclusion, the semi-rigorous model approach presented herein allows for estimation of thermodynamic mixture properties based on experimental data from batch distillations using a packed column with multiple stages.

Abstract
This study investigates the effect of indirect greenhouse gas (GHG) emissions on the optimal long-term planning and short-term operational scheduling of a desalination-based water supply system. The system was driven by grid-electricity and surplus output from residential rooftop photovoltaics to deliver water and energy to urban areas. The interactive two-level mixed integer linear programming model took into account demands, system configurations, resources capacities and electricity tariffs as well as GHG emission factor associated with the source of grid electricity. Both system and carbon abatement costs were considered in the formulation of the objective function. The optimal decisions for Perth (Australia) resulted in $47,449,276 higher discounted total cost but 51,301.3 tCO$_2$eq less GHG emissions over 15 years planning horizon compared to when only system costs were minimised. Finally, the predominant effect of the indirect GHG emissions costs over system costs on the optimal solutions indicated their high sensitivity towards the source of purchased grid electricity.

Keywords: Grid electricity, Photovoltaics, GHG emissions, Desalination, Optimisation.

1. Introduction
Climate change and increasing water demand in urban areas have made it inevitable to incorporate drought-proof technologies such as desalination in water supply systems. However, meeting their intensive energy demand from fossil-fuel sources leads to higher indirect greenhouse gas (GHG) emissions, which adversely affects the existing water resources and therefore adds further complexities to sustainable supply. Considering renewable energy sources in the energy mix of this water supply option, therefore, could be a potential solution to decrease this effect.

In (Vakilifard et al., 2017), we proposed the idea of employing surplus residential grid-connected photovoltaics (PVs) output in conjunction with grid electricity to drive urban desalination-based water supply system. Using this source of energy not only assists in sustainably meeting the water-related energy demand but also mitigates the barrier of increasing the PVs installation to the existing electrical grid. In (Vakilifard et al., 2018), we developed a mixed integer linear programming (MILP) model to provide optimal strategic decisions of such water supply system incorporating short-term operational scheduling considering PV installation density as a parameter for any given year. In this paper, we extended the model to also investigate the effect of indirect GHG emissions costs associated with purchasing grid electricity on the optimal solutions and to determine to what extent they vary by the source of this energy. Additionally, the interactive effect of added water-related energy demand and installation density (as variable) was addressed through the two-run solving strategy. The results for an urban area located in the north-western corridor of Perth (Australia) were then discussed.

2. Problem statement

The problem was defined in three time frames (yearly, seasonal and hourly) for the planning horizon of 15 years (beginning from 2017). Water and energy needs were determined in 4 distinct zones in the studied area based on the demands per capita, annual population growth and service area of zone substations using ArcGIS 10 integrated with Excel analysis. It was assumed that a decentralised water supply system consisting of desalination plants, storage tanks, and a pipeline network delivers water to the zones. Plants were presumed to be operated in flexible (hourly) mode. The extra water could be desalted when renewable energy was available and could be stored for later use. Plant capacities were selected from 6 discrete values (20,000-120,000 m^3/day) considering the plant factor of 0.85. For storage tanks, the capacities were chosen from 10,000 and 20,000 m^3. Two pipeline capacities associated with the diameters of 30 and 54 in were also taken into account. The potential locations of water supply components in each zone, energy consumption per unit of water produced, stored and distributed as well as the capital and operational and maintenance (O&M) costs were according to (Vakilifard et al., 2018). Grid electricity and PV output supplied residential and water-related electricity demands. The maximum grid electricity that could be delivered to each zone was ascertained based on the associated substations capacities. The maximum capacity of available renewable energy was achieved based on the performance analysis of a 4 kW PV system output conducted in system advisor model (Vakilifard et al., 2017) and the installation density. The latter is the number of households equipped with PV systems in each zone divided by the total number of households and was determined by the model considering the economic-subjectivity index.

This index, in fact, is the product of economic and subjectivity indexes accounting for the economic preference of PV uptake and households' free will, respectively. To determine the economic index, Excel analysis was done based on the methodology described in (Miranda et al., 2015). This binary index is considered to be 1 if it is beneficial to install a PV system. The subjectivity index could be determined by the decision maker and could get any value between 0 and 1. It is the ratio of the households who decide to uptake PV systems (in case it is economically beneficial) to the total households. In this study, it was assumed the economic-subjectivity index is 1 meaning that in case it is economical to install a PV system, all households would decide to be equipped with one. Grid electricity price tariffs as well as the net feed-in tariff were taken from Synergy, the electricity retailer of Perth. The real discount rates for residential and business sectors were adopted from (AEC, 2017; ERA, 2017). The GHG emission factor of 0.7 for purchasing grid electricity from the south west interconnected system (SWIS), the electricity network in Perth, was adopted from (DEE, 2017). It is to be noted that this emission factor is only associated with the environmental impact of the fuels combustion in stationary sources (operational stage). The cost of carbon abatement was considered $ 40/tCO_2eq, taken from (WSAA, 2012). All cost data was converted to 2017 real Australian dollar using appropriate exchange rates from (RBA, 2017).

3. Optimisation strategy

The model was formulated as a two-level MILP model. In the first level of optimisation, the objective function maximised the economic benefits for the households equipped with PV systems (z1). This included savings from avoiding purchasing grid electricity as well as revenues from feeding surplus PV output back into the grid. The outcome of this level of optimisation, namely PV installation density, share of grid electricity in

supplying residential energy demand and surplus PV output, were introduced to the level-two optimisation where the optimal decisions for the water supply system were achieved. The objective function at this stage concerned minimisation of the discounted total cost of the water supply system including indirect GHG emissions costs associated with purchasing grid electricity for water supply (z2). The model constraints of the level-one optimisation are presented in Eqs. (1)-(10). The constraints of level-two optimisation were based on our previous study (Vakilifard et al., 2017, 2018).

$$z_1 : Max \sum_t DF_t^r \cdot \sum_s nd_s \cdot \left[\sum_i \sum_b Ce_{t,s,b}^r \cdot RE_{t,i,s,b}^r + Cr_t \cdot Surp_{t,i,s,b} \right]$$

$$z_2 : Min \sum_t DF_t^{bi} \cdot \sum_s nd_s \cdot \left[Cfe_t^{bi} + \sum_i \sum_b Cr_t^{bi} \cdot RE_{t,i,s,b}^w + Ce_{t,s,b}^{bi} \cdot P_{t,i,s,b}^w + COM_t \cdot Q_{t,i,s,b} + Cs_t \cdot V_{t,i,s,b} \right]$$

$$+ \sum_t DF_t^{bi} \cdot \sum_i \left[\sum_c Cap_{t,c}^{DP} \cdot XW_{t,i,c} + \sum_m Cap_{t,m}^{STT} \cdot X_{t,i,m} \right]$$

$$+ \sum_t DF_t^{bi} \cdot \left[\sum_{(i,j) \in \{AL_{i,j} | i=j\}} Cap_t^{PI} \cdot np_{t,i} \cdot L_{i,j} \cdot convf_2 + \sum_{(i,j) \in \{AL_{i,j} | i \neq j\}} Cap_t^{PI} \cdot npIJ_{t,i,j} \cdot L_{i,j} \cdot convf_2 \right]$$

$$+ \sum_t DF_t^{bi} \cdot CTax \cdot f^{GHG} \cdot \sum_i \sum_s nd_s \cdot \sum_b p_{t,i,s,b}^w$$

Residential energy balance (with PVs): $\quad P_{t,i,s,b}^r + RE_{t,i,s,b}^r = k_{t,i} \cdot D_{t,i,s,b}$ (1)

Added share of each energy source: $\quad P_{t,i,s,b}^r = P_{t-1,i,s,b}^r + addP_{t,i,s,b}^r$ (2)

$$RE_{t,i,s,b}^r = RE_{t-1,i,s,b}^r + addRE_{t,i,s,b}^r$$ (3)

Residential energy balance (without PVs): $\quad P_{t,i,s,b}^{rn} + RE_{t,i,s,b}^{rn} = (1 - k_{t,i}) \cdot D_{t,i,s,b}$ (4)

Max. potential PV output: $\quad MaxR_{t,i,s,b} = k_{t,i} \cdot dur_b \cdot PV_{s,b} \cdot exisR_{t,i}$ (5)

$$MaxR_{t,i,s,b} = MaxR_{t-1,i,s,b} + addk_{t,i} \cdot kp_t \cdot dur_b \cdot PV_{s,b} \cdot (exisR_{t,i} - exisR_{t-1,i})$$ (6)

Surplus PV output: $\quad Surp_{t,i,s,b} = MaxR_{t,i,s,b} - RE_{t,i,s,b}^r$ (7)

PV share constraints: $\quad RE_{t,i,s,b}^r \leq MaxR_{t,i,s,b}$ (8)

Grid share constraint: $\quad P_{t,i,s,b}^r + P_{t,i,s,b}^{rn} + P_{t,i,s,b}^w \leq dur_b \cdot MaxPS_{t,i}$ (9)

Unused surplus energy: $\quad Surp_{t,i,s,b} - RE_{t,i,s,b}^{rn} - RE_{t,i,s,b}^w \cong 0$ (10)

The optimal solution was achieved in two runs using an interactive approach. In the first run, the initial estimation of the optimal water supply system was obtained regardless of remaining unused surplus PV output (relaxation of Eq. (10)). This led to the maximum PV installation density in the area and the initial estimation of the optimal decisions for water supply system while there was the highest access to the renewable energy. Considering this constraint (Eq. (10)), the initial estimation was then applied in the second run to adjust the installation density and achieve the final optimal solution. Each run included both levels of optimisation.

4. Optimal strategic and operational decisions

The model was coded into GAMS 24.3.1 software and solved by CPLEX 12.6. Two scenarios were considered. In the "minimum system and GHG costs" scenario, the objective function minimised the discounted cost of the system including capital and O&M costs as well as the carbon abatement cost over the planning horizon. This scenario was then compared with "minimum system costs" scenario, which only concerned the minimisation of discounted capital and O&M costs of the system. The

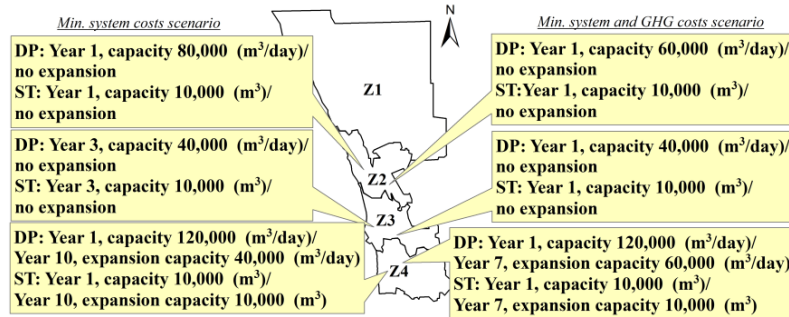
optimal results for the minimum system and GHG costs scenario led to $ 2,291,309,369 discounted total cost, around $ 47,449,276 higher than minimum system costs scenario. It also resulted in 51,301.3 tCO_2eq less GHG emissions over 15 years of system operation. The optimal results are presented in Figures 1 and 2.


Figure 1: Optimal desalination plants (DP) and storage tanks (ST) capacities located in 4 discrete zones (z) in Min. system costs and Min. system and GHG costs scenarios
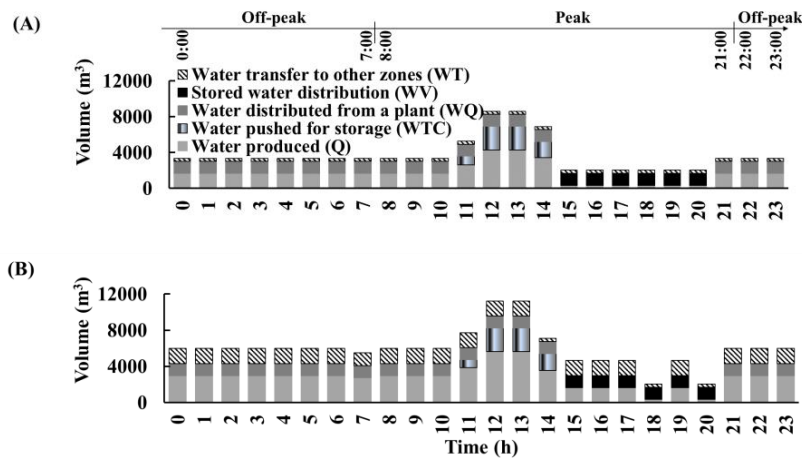

Figure 2: Operational scheduling of the water supply system in the representative zone 2 and year 2018 in: (A) Min. system costs and (B) Min. system and GHG costs scenarios

In both scenarios, three zones of 2, 3 and 4 were equipped with desalination plants (Figure 1); however, in terms of capacities and the timing of construction/expansion of the water supply components, they were different. In minimum system and GHG costs scenario, the model equipped both zones of 2 and 3 with desalination plants and associated storage tanks from the beginning of the planning horizon. Thus, despite the lack of economies of scale of the smaller desalination plants, it located a desalination plant with the capacity of 60,000 m^3/day in zone 2 as opposed to the capacity of 80,000 m^3/day in minimum system costs scenario. Instead, it placed a desalination plant with the capacity of 40,000 m^3/day in zone 3 in year 1 versus year 3 in minimum system costs scenario. The reason is to reduce the energy consumption of water transfer among allowable zones (around 3,640 MWh over 2 years) and decrease indirect GHG

emissions costs. It is worth mentioning that although the expansion capacity of the desalination plant in zone 4 in the minimum system and GHG costs scenario was larger than minimum system cost scenario, the earlier time of the expansion neutralised the economic benefits of the larger scale expansion capacity.

Figures 2(A) and 2(B) show the optimal operational scheduling of the water supply system in both scenarios for a representative zone 2 and year 2018. Given flexible mode of operation for water supply system, the paradigm of the daily operational scheduling was achieved relatively the same for both scenarios. Accordingly, the highest water production and storage occurred when renewable energy was available, although it was concurrent with the peak electricity pricing hours. The stored water was then used for providing the water demand in the same zone when it was still during the peak electricity hours but no surplus PV output was available that could be assigned to the water-related electricity demand. The level of water production in zone 2 during peak electricity hours when there was no access to the renewable energy was limited to the demand of its adjacent zones (1 and/or 3). In off-peak electricity hours, the water demand was supplied directly from the desalination plant located in this zone.

5. Sensitivity analysis

Figure 3 depicts the sensitivity of the optimal solution towards purchasing grid electricity from 6 different sources in the minimum system and GHG costs scenario. The associated data was achieved from (Gifford, 2011). The results indicate a relatively high sensitivity towards emission factors higher than 0.148 (municipal waste). In fact, in higher emission factors, the effect of environmental impact was more significant and thus the optimal solution was mainly driven by indirect GHG emissions costs, which led to higher discounted total cost. By decreasing the emission factor, the effect of indirect GHG emissions costs reduced and from a certain point, it did not change the optimal decisions. Thus, the system cost turned to the predominant factor affecting the optimal results. This also explains the relatively same discounted total costs of the system with the minimum system costs scenario in lower emission factors.
Figure 3: Sensitivity analysis towards purchasing electricity generated from different sources

6. Conclusions

In this study, we proposed an interactive optimisation model for the strategic and operational decisions of an urban water supply system driven by surplus PV output and grid electricity considering both system and carbon abatement costs in the formulation of the objective function. The optimal solutions for an urban area located in the north-western corridor of Perth (Australia) led to less GHG emissions but higher discounted total cost compared to the case where the system costs were the only components of the objective function. Finally, the results of the sensitivity analysis towards purchasing

grid electricity from different sources showed the predominant effect of indirect GHG emissions costs over system costs on the optimal solutions in higher emission factors.

Nomenclatures

Sets:

AL= allowable zones for water transfer

c= discrete points of plant capacities

i, j= zone

m= discrete points of storage tank capacities

t,s,b= planning horizon, season and time block, respectively

Continuous variables:

$addP$= added share of grid electricity (kWh)

$addRE$= added share of PV output

$addk$= added PV installation density (%)

k= PV installation density (%)

$MaxR$= Max. PV output (kWh)

P= share of grid electricity (kWh)

Q= desalinated water produced (m^3)

RE= share of renewable energy (kWh)

V= existing water storage (m^3)

Parameters:

Cap = capital cost for plant ($) and for pipeline ($/km)

Ce= variable grid electricity cost ($/kWh)

Cfe= fixed grid electricity cost ($/day)

COM= plants O&M cost ($/$m^3$)

$convf2$= conversion factor (km/m)

Cr= renewable electricity cost ($/kWh)

Cs= O&M cost of water storage ($/$m^3$)

D= residential energy demand (kWh)

$CTax$= Carbon abatement cost ($/kgCO$_2$)

$exisR$= number of existing residential rooftops

f^{GHG}= GHG emission factor (kgCO$_2$/kWh)

DF= discount factor

dur= duration of the time block (h)

kp= economic-subjectivity index

L= distance (m)

$MaxPS$= Max. substation capacity (kW)

nd= number of days (day)

PV= PV system output (kW)

$Surp$= surplus PV output (kWh)

Binary variables:

$np, npIJ$= decisions for construction/ expansion capacity of the pipeline

X,XW= decisions for storage tank size and plant capacity, respectively

Superscripts associated with:

bi= business sector; w= water

DP= plant; PI= pipeline; STT= storage tank

r, rn= households with and without PVs, respectively

Abstract

In this paper, we address the short-term scheduling of multipurpose batch plants, a challenging problem that has received growing attention in the past few years. We present a new mixed integer linear programming (MILP) framework based on the state-task network (STN), which employs a multi-grid continuous-time approach. Compared to other formulations in the literature, the proposed model leads to smaller and simpler mathematical models with strong LP-relaxations, which is reflected in the ability to find the optimal solutions in shorter CPU times. We demonstrate the performance of our model with a complex and comprehensive case study from the literature.

Keywords: Batch plant, Scheduling, MILP, Mathematical modeling.

1. Introduction

Short-term scheduling of batch processes has received growing attention over the past two decades. It consists of allocating limited resources to activities over time to optimize the plant operation in terms of some specific performance criteria such as maximum profit or minimum makespan. Earlier work in this area can be found in Vaselenak et al. (1987). Research on the short-term scheduling of multipurpose batch plants has used mixed integer linear programming (MILP) considering the time representation within the planning horizon as either discrete or continuous. Discrete-time representations divide the time horizon into slots of equal and fixed duration, whereas continuous- time representations relax such assumption. Extensive reviews can be found in Floudas and Lin (2004) and Harjunkoski et al. (2014). Continuous-time models can be further classified into two: single-grid (Castro et al., 2004; Maravelias and Grossmann, 2003; Sundaramoorthy and Karimi, 2005) and multi-grid (Ierapetritou and Floudas, 1998, Shaik and co-workers 2009; 2012). In the former, time slots are common for all units, while the latter provides each unit to have its own set of time intervals, which is not shared with other units.

Kondili et al. (1993) were the first to develop a discrete-time MILP based on the state-task network (STN) representation. In this model, the length of the time slots are determined from the greatest common factor among the processing times involved in the problem. For the same problem, Ierapetritou and Floudas (1998) developed an efficient multi-grid continuous-time MILP formulation that defines the duration of tasks by the optimization. The model needs less number of events (or time slots) compared to the single-grid models (Castro et al., 2004; Maravelias and Grossmann, 2003; Sundaramoorthy and Karimi, 2005). Based on the model by Ierapetritou and Floudas (1998), Shaik and Floudas (2009) presented an MILP formulation that can be utilized in

both batch and continuous plants. In this paper, we propose a new multi-grid continuous-time MILP scheduling model for multipurpose batch plants, based on the STN representation. Compared to other models in the literature, the proposed model is very tight and does not use any tightening constraint to generate a small integrality gap. We define a new set of sequencing constraints, which result in fewer continuous variables and constraints compared to previous multi-grid approaches. Furthermore, compared to literature, the proposed model leads to the same number of binary variables without decoupling tasks from units.

2. Problem statement

We focus on short-term scheduling of multipurpose batch plants, where a set of products are manufactured using a number of shared production units. Given the processing time data and the state-task network (STN) representation for the plant, we aim to optimally define the sequencing and timing of tasks in each units in order to maximize the total profit during a specific time horizon or minimize the total time required to meet demands. To sequence tasks in units, we use the concept of run $r \in R$; run r should start after the completion of $r-1$ in unit j. If run r is executed in unit j, one of tasks $i \in I_j$ (set of tasks that can be processed in unit j) is being processed in this unit.

3. Scheduling model

3.1. Task allocation, batch size and processing time

If binary variable $X_{i,j,r} = 1$, a certain volume of task i is being processed in unit j during run r ($V_{i,j,r}$). The processing time of task i in unit j at run r is assumed to be given by a constant plus a term proportional to the related batch size, where $cp_{i,j}$ and $vp_{i,j}$ are the constant and variable processing times of task i in unit j, respectively. In turn, $X_{j,r}^{\text{no task}} = true$ means that task i is not allocated to unit j and so the continuous variables $LR_{i,j,r}$ and $V_{i,j,r}$ are set to zero. We have thus the following disjunction (Mostafaei and Castro 2017; Castro and Mostafaei 2017; Castro et al. 2018):

$$\bigvee_{i \in I_j} \begin{bmatrix} X_{i,j,r} \\ v_{i,j}^{\min} \leq V_{i,j,r} \leq v_{i,j}^{\max} \\ LR_{i,j,r} = cp_{i,j} + vp_{i,j}V_{i,j,r} \end{bmatrix} \vee \begin{bmatrix} X_{j,r}^{\text{no task}} \\ V_{i,j,r} = 0 \quad \forall i \in I_j \\ LR_{i,j,r} = 0 \quad \forall i \in I_j \end{bmatrix} \quad \forall j,r \tag{1}$$

The MILP format of the above disjunction is described through eqs. (2)-(4).

$$\sum_{i \in I_j} X_{i,j,r} \leq 1 \quad \forall j,r \tag{2}$$

$$v_{i,j}^{\min} X_{i,j,r} \leq V_{i,j,r} \leq v_{i,j}^{\max} X_{i,j,r} \quad \forall i \in I_j, j,r \tag{3}$$

$$LR_{i,j,r} = cp_{i,j}X_{i,j,r} + vp_{i,j}V_{i,j,r} \quad \forall i \in I_j, j,r \tag{4}$$

3.2. Material balance

The excess amount of state s at the start of run r $(F_{s,r})$ is computed through eq. (5), where f_s^{initial} is the initial inventory of state s. In eq. (5), $\rho_{i,s}^p$ and $\rho_{i,s}^c$ are the proportion of state s produced or consumed from task i, respectively.

$$F_{s,r} = f_s^{\text{initial}} + \sum_{r'<r} \sum_{i\in(I_s^p \cap I_j)} \rho_{i,s}^p \sum_j V_{i,j,r'} - \sum_{r'\leq r} \sum_{i\in(I_s^c \cap I_j)} \rho_{i,s}^c \sum_j V_{i,j,r'} \quad \forall s,r \tag{5}$$

3.3. Sequencing process runs

Process run r in unit j should not start before the end of run $r-1$ in the same unit. Besides, the start of run r in unit j consuming state s should be after the end of process run $r-1$ in unit j' feeding the same state. The sets J_s^p and J_s^c in (7) include units that feed and consume state s, respectively.

$$SR_{j,r} \geq SR_{j,r-1} + \sum_{i\in I_j} LR_{i,j,r-1} \quad \forall j,r \geq 2 \tag{6}$$

$$SR_{j,r} \geq SR_{j',r-1} + \sum_{i\in I_{j'}} LR_{i,j',r-1} \quad \forall j \in J_s^c, j' \in J_s^p (j \neq j'), s \in S, r \geq 2 \tag{7}$$

The completion time of the last process run in each unit should not surpass the horizon length, $h_{\max}$.

$$SR_{j,r} + \sum_{i\in I_j} LR_{i,j,r} \leq h_{\max} \quad \forall j, r \geq |R| \tag{8}$$

3.4. Sequence-dependent changeovers

If tasks i' and i are processed in unit j during runs $r-1$ and r respectively, there will be a constant changeover time of $\tau_{i',i,j}$ associated to the start of run r in unit j.

$$X_{i,j,r} \wedge X_{i',j,r'} \wedge \neg (\bigcup_{r''=r'+1}^{r-1} \bigcup_{i''\in I_j} X_{i'',j,r''}) \Rightarrow X_{i,i',j,r',r}^{\text{changeover}} \quad \forall i,i' \in I_j (i \neq i'), j \in J, r \geq r' \tag{9}$$

$$\bigvee_{i\in I_j} \bigvee_{i'\in I_j} \left[\begin{array}{c} X_{i,i',j,r',r}^{\text{changeover}} \\ SR_{j,r} - (SR_{j,r-1} + LR_{i',j,r-1}) \geq \tau_{i',i,j} \end{array} \right] \quad \forall j, r > r' \tag{10}$$

We can now eliminate variable $X_{i,i',j,r',r}^{\text{changeover}}$ from the formulation by combining the constraints derived from form Eqs. (9-10), giving rise to the following equation:

$$SR_{j,r} - (SR_{j,r-1} + LR_{i',j,r-1}) \geq \tau_{i',i,j}(X_{i',j,r} + X_{i',j,r'} - \sum_{r''=r'+1}^{r-1} \sum_{i''\in I_j} X_{i'',j,r''} - 1) \tag{11}$$

$$\forall i,i' \in I_j (i \neq i'), j \in J, r \geq r'$$

3.5. Meeting demand

Demands at states $s \in SM \subset S$ storing final products are enforced as a hard constraint in eq (14).

$$\sum_r \sum_{i\in I_s^p} \rho_{i,s}^p \sum_{j\in J_i} V_{i,j,r} \geq d_s \quad \forall s \in SM \tag{12}$$

3.6. Objective function

Two alternative objectives are considered. They are:

(1) The maximization of profit given in eq (13), where the parameter vs_s is the value of state s :

$$\max z = \sum_s vs_s \sum_r \sum_{i \in I_s^p} \rho_{i,s}^p \sum_{j \in J_i} V_{i,j,r} \qquad (13)$$

The model for profit maximization consists of eqs. (2)-(8),(11) and (13).

(2) The minimum makespan given in (14):

$$\min z = H \qquad (14)$$

where the continuous variable H is an upper bound on the completion time of last run in each unit:

$$SR_{j,r} + \sum_{i \in I_j} LR_{i,j,r} \leq H \quad \forall j, r \geq |R| \qquad (15)$$

The model for makespan minimization consists of eqs. (2)- (7), (11)-(12), (14) and (15).

Remarks: Eq (16) below, the so-called *tightening* constraint, is a common constraint used e.g. in Shaik and co-workers (2009, 2012) and Marvelias and Grossmann (2003) and leads to strong LP-relaxations. It helps speed up the branch and bound solution search, and consequently decrease the solution CPU times. When minimizing the makespan the time horizon parameter in (16) needs to be replaced by the continuous variable H. We will show that our proposed model does not need the tightening constraint.

$$\sum_r \sum_{i \in I_j} LR_{i,j,r} \leq h_{\max} \quad \forall j \qquad (16)$$

4. Case Study: A complex and comprehensive problem in the literature

The performance of our model is compared to a similar previous work by Shaik and Floudas (2006), hereafter referred to as SF. We consider a complex and comprehensive case study (Example 3) in Sundaramoorthy and Karimi (2005). Since our model does not allow tasks to span over multiple events and for the sake of a fair comparison, we only consider $\Delta n = 0$ in SF model and remove the big-M term in constraint (16), which makes it exactly equivalent to the model by Vooradi and Shaik (2012). Both the proposed model and SF model were implemented in GAMS/ CPLEX 12.7.1 (using 4 threads in parallel) on an Intel Core i5-7300U (3.33 GHz and 8 GB of RAM).

The model statistics and computational results when maximizing the total profit for two different time horizons are given in Table 1. From this table, both approaches need the same number of runs (events) to confirm the optimum and perform equally well. However, our model has fewer continuous variables and constraints and exhibits strong LP-relaxations with 6 runs for the first scenario and with 8 runs for the second scenario. Table 1 also summarizes the results for both models without the tightening constraint (16). As can be observed, the LP-relaxations (RMILP) do not change without the tightening constraint for the purposed model, which is not the case for the SF model.

Table 1: Results for the case study when maximizing total profit

	$|R|$	CPU (s)	Nodes	Binary variables	Total variables	Eqs	MILP ($)	RMILP[a] ($)
					($h_{\max} = 8$ h)			
SF	5	0.43	304	55	286	457	1583.4	2100.0

*Results without the tightening constraint (16), [a]Relaxed Solution of MILP

Table 2 shows the results for the case study when minimizing the makespan for two different demand scenarios. In the first scenario i.e., $d_{S12} = d_{S13} = 250$ mass unit (mu), both models work equally well, but our model again leads to smaller and tighter mathematical models. For the second scenario and with the tightening constraint, our purposed model finds the optimum in just 2.95s and confirms it in 44.54 s. This represents a one-order-of-magnitude time saving compared to the SF's model, which takes 1567.2 s to confirm the optimality of solution confronted with 26 events. Without the tightening constraint, the purposed model again exhibits the same LP-relaxation and can confirm the optimality just in few seconds (12.92s). This is not the case for the SF model, which exhibits week LP-relaxations and takes minutes to prove the optimality.

5. Conclusions

A multi-grid continuous-time MILP formulation for the short term scheduling of multipurpose batch plants has been developed. We relied on the STN representation to derive the problem constraints. It has been shown that the proposed model exhibits the same LP-relaxation with and without the tightening constraint frequently used in the literature. We validated the proposed model using a complex and comprehensive case study from the literature. The results demonstrated that the proposed model is smaller and significantly faster than previous similar work.

Abstract

Previous works have developed methodologies for hydrogen network optimization, with a simplistic assumption of constant equilibrium distribution coefficient (K-value) for separation process, which leads to an inaccuracy of the solution. To address this problem, a surrogate-assisted modeling and optimization method for the design of refinery hydrogen network has been developed. The established models fully considered the changing characteristics of K-value in flash units, as well as the chemical processes happened in hydrotreaters, such as property of the processed crude oil (mainly the sulfide and 3+ring core aromatic content), formation of H_2S and light hydrocarbons (C1-C5). These process characteristics were reflected through the employment of surrogate modelling technique, which can be employed to compensate the computationally time-consuming nature of the corresponding first-principles-based models, due to its versatility. Polynomial surrogate model can be easily built using the least square method, and low order models are sufficient to approximate equipment models. A case study involving four hydrogen consumers is solved to indicate the efficacy of the proposed approach, and an NLP model is formulated. Compared to the result obtained by method proposed by the literature, the proposed method suggests more of gas flow to fuel system, since the calculated H_2S content in the product flow is comparatively high. Therefore, it can be concluded that the proposed method can deliver a more realistic result.

Keywords: Hydrogen network, Surrogate model, Design, Optimization

1. Introduction

The methodologies for the synthesis and optimization of refinery hydrogen networks can be divided into two categories: pinch analysis and mathematical programming. The latter shows more advantages because it takes into account some underlying constraints. It was originally developed by Hallale and Liu (2001). The research was continued by Kumar et al. (2010), considering several practical constraints (such as pressure constraints and hydrogen purity constraints) to obtain realistic solutions. Jia and Zhang (2011) proposed an improved modeling approach which defined the K-values in the flash separation units and incorporated the flash units into hydrogen consumer models. Umana et al. (2014) introduced an empirical model to predict the hydrogen consumption and the formulation of light hydrocarbons, and modeled the new hydrogen networks synthesis problem as an NLP (nonlinear programming).

Simplified equipment models were employed in the superstructure of optimization mod-

els in the previous works. In order to capture a more realistic behavior of the system, more accurate models should be used to represent equipments. However, the use of realistic models would be difficult due to high computational time in solution of the hydrogen network synthesis problem in an optimization algorithm.

This work proposes the use of surrogate modelling technique for hydrogen networks synthesis problems. It can capture the complicated chemical and physical processes involved in the hydrotreating and flash process, in the meanwhile, it requires less computation effort. Hence, more realistic solutions can be obtained in a reasonable time by applying the proposed methodology. This paper is structured as follows. Section 2 describes the methodology of building surrogate models. Section 3 provides a case study and shows a methodology to solve the hydrogen network synthesis problem by using surrogate models to represent equipment models, while Section 4 presents some conclusions.

2. Surrogate modeling and optimization: steps and strategies

The use of surrogate models in synthesis and optimization problems has been reported in many cases, e.g. Graciano and Le Roux (2013) and Sikorski et al. (2016). A surrogate model can be used to approximate the behaviors of a complicated system by only taking into account nature of the input-ouput relationship. Due to the simplicity of forms, a surrogate model can usually be solved with much lower computational efforts, compared to the original model. The steps of surrogate-assisted modeling and optimization used in this study are summarized below:

1. Selecting a set of input-output variables that are independent, as the characteristic indicators for the concerned processes.
2. Generating a set of sampling data for the selected input variables within the respective operational ranges (as described in Section 2.2).
3. Producing output values for each sampling point, by employing first principle models or commercial software packages.
4. Training the selected surrogate models with a portion (80% in this case) of the generated input-output data sets. The selection of a preferable surrogate model will be described later in Section 2.1.
5. Validating the obtained surrogate model with the remaining portion (20% in this case) of the generated input-output data sets.
6. Integrating the established surrogate models into the hydrogen network optimization problem.

2.1. Selection of surrogate models

There are several types of surrogate models such as polynomial, kriging, support vectors machine and artificial neural network. Polynomial can be built easily by using least square method and are sufficient to fit most models or data. In this work, polynomial surrogate model was employed to approximate hydrotreaters and flash unit models, due to its simplicity of forms and accuracy. For more detailed information about the selected surrogate models, the readers are referred to Forrester et al. (2008).

2.2. Sampling and validating plans

The sample sets were generated using Sobol sequences, developed by Sobol (1967), a type of quasi-random and low-discrepancy sequences which can achieve faster space-filling over other sequences. A number of accuracy measures were used including R^2, root-mean-square-error (*RMSE*) and residual plot.

3. Case Study

The case study was taken from Umana et al. (2014), it consists of two possible hydrogen producers and four consumers, which again contains one hydrotreater and one flash unit.

3.1. Surrogate model fitting for flash units and hydrotreaters

3.1.1. Flash units

In order to overcome the drawback of constant K-value assumption in the previous works, Aspen Plus was used to model the flash separation units based on the operation conditions given in Jia and Zhang (2011). The model then served as a data generator for surrogate model fitting. In this case, ten indicators for the reaction effluent were chosen as the input variables, and eight were chosen for the gaseous stream, which is given in 1.
Figure 1: Flash unit model indicating input variables and output variables.

where T_{fin} is temperature, P_{fin} is pressure, Fin_{H2} is inlet hydrogen flow rate, Fin_{HC} is inlet light hydrocarbons flow rate, Fin_{H2S} is inlet H_2S flow rate, $Fout_{H2}$ is outlet hydrogen flow rate, $Fout_{H2S}$ is outlet H_2S flow rate, $Fout_{Ci}$ is outlet light hydrocarbons flow rate and $Fout_{gas}$ is outlet gas flow rate of the flash unit.

The results are represented in Table 1 and residual plots are illustrated in Fig 2. The R^2 is close to 1 and RMSE are relatively minor, indicating a good correlation by the surrogate models. Meanwhile, residual plots show that residuals are in random distribution.
Figure 2: Plot of residuals for polynomial fit.

Table 1: Indicators for the flash unit model fitting results.

Output variables (t/h)	Polynomial RMSE	Polynomial R^2
$Fout_{H2}$	9.18×10^{-5}	
$Fout_{C1}$	3.78×10^{-3}	
$Fout_{C2}$	3.20×10^{-3}	
$Fout_{C3}$	5.24×10^{-3}	0.999997
$Fout_{C4}$	1.12×10^{-3}	
$Fout_{C5}$	4.85×10^{-4}	
$Fout_{H2S}$	1.40×10^{-2}	
$Fout_{gas}$	1.25×10^{-2}	

3.1.2. Hydrotreaters

The empirical model for the hydrotreaters provided by Umana et al. (2014) was reformulated into a much simpler form. For the hydrotreater, six input variables and eight output variables were chosen which is illustrated in Fig 3.
Figure 3: Hydrotreater model with input variables and output variables.

where T_{rin} is temperature, S_{feed} is sulphur content in the feed flow, $3+R_{feed}$ is 3+ring core aromatic content in the feed flow, FF is inlet oil flow rate, P_{H2} is hydrogen partial pressure, F_{gas} is inlet gas flow rate, $S_{product}$ is sulphur content in the product, C_{formed} is amount of light hydrocarbons formed, Ci=C1-C5, H_2S_{formed} is amount of H_2S formed, and $H_{2consumed}$ is hydrogen consumption of the hydrotreater.

Table 2: Indicators for the hydrotreater model fitting results.

Output variables	Polynomial RMSE	Polynomial R^2
$S_{product}$ (ppwm)	9.88×10^{-2}	
$C1_{formed}$ (t/h)	2.09×10^{-6}	
$C2_{formed}$ (t/h)	3.90×10^{-6}	
$C3_{formed}$ (t/h)	1.27×10^{-5}	
$C4_{formed}$ (t/h)	1.40×10^{-5}	0.999986
$C5_{formed}$ (t/h)	4.86×10^{-6}	
H_2S_{formed} (t/h)	8.53×10^{-4}	
$H_{2consumed}$ (t/h)	7.17×10^{-5}	

Table 2 and Fig. 4 give the results for the hydrotreater surrogate model fitting. The indictors and residual plots all suggest good fitting.
Figure 4: Plot of residuals for polynomial fit.

3.2. Synthesis and optimization of the hydrogen network

As noticed, the use of first-principles-based models in an optimization platform would be unfeasible due to high computational time and technical difficulties. Surrogate models developed in Section 3.1 can be employed in the solution of the synthesis problem, due to their great versatility. The objective function is to minimize the operating cost that accounts for the hydrogen production cost and fuel gas value. Operation conditions (T and P) for the flash units were set as fixed, constraint for sulphur content in oil product were imposed and the required hydrogen consumption for each hydrotreater were optimization variables for this problem. It was solved in GAMS which takes 0.172 s to give a result. The result is shown in Figure 5. For the flash unit, the established surrogate models fully consider the changing characteristics of K-value along with the conditions of feed flow. The details of inlet conditions were provided by Umana et al. (2014). When compared with the previous work (Table 3), it indicates a comparatively higher production rate of H_2S in the outlet of the flash unit which may cause more H_2S in the recycle stream sent to the reactor. As a result, more of the purge gas from DHT unit was suggested to be sent to the fuel system.In other words, the necessary constraint for H_2S accumulation in the system prevented further reuse of the DHT purge gas. Thus, it can be concluded that a more accurate model for the flash process is necessary in obtaining a more accurate simulation result for the hydrotreating process.

Table 3: Results comparison between the proposed method and the literature.

		Outlet of DHT flash units

4. Conclusion

This paper introduces a methodology to optimize the design of refinery hydrogen network by using surrogate models to reflect the chemical and physical process in the hydrotreaters and flash units. When applied in a case study, the established surrogate models achieved reasonable fit, and the synthesis problem can be solved efficiently. Compared with results provided in the previous work, it was notice that necessary constraints of inlet H_2S flow rate should be considered, causing by a large amount of outlet H_2S flow of the DHT flash unit. This difference can be attributed to the consideration of the changing separation efficiency of flash units along with the feed flow conditions. As a result, more realistic results can be obtained by using the proposed models.

Abstract

Carbon capture and storage is considered a key option for decarbonising the energy sector. However, both the necessity of deploying large-scale infrastructures between the nodes of production and sequestration of CO_2, and the uncertainty related to the effective storage availability of sequestration basins still represent major challenges. Here, a mixed integer linear programming approach is proposed for the optimisation of a European supply chain model for carbon capture, transport, and storage. A quantitative assessment of storage uncertainty is incorporated to represent the volumetric capacity of basins to date considered capable of efficiently trapping the anthropogenic CO_2 emissions (i.e., deep saline aquifers, hydrocarbon fields and coal fields). The objective is to minimise the total expected cost required to install and operate, over a 10 years' time horizon, the overall network for carbon capture, transport and storage, while also taking into account the financial risk that is generated by uncertainty in geological capacity. The model defines economically optimal European supply chains, whilst simultaneously minimising the financial risk generated by uncertainty in local sequestration availability to ensure a robust design.

Keywords: Carbon capture transport and storage, European supply chain optimisation, Mixed integer linear programming, Uncertainty in storage capacity and risk.

1. Introduction

Addressing global warming through the reduction of CO_2 emissions is a crucial international goal. To constrain the mean global temperature rise below 2 °C by 2100, the planet must collectively keep the level of CO_2 equivalent below 550 ppm (Luderer et al., 2013). The power and industry sectors combined dominate current global CO_2 emissions, accounting for about 60 % of the total anthropogenic CO_2 generation, which must be drastically reduced by 2050 to meet COP21 targets (IPCC, 2018). Accordingly, carbon capture, transport, and storage (CCS) technologies have been highlighted as potential key players, considering their efficacy in delivering low carbon heat and despatchable power, decarbonising industry, and facilitating the net removal of CO_2 from the atmosphere. The

feasibility of implementing a European CCS infrastructure has been investigated through a number of studies and demonstration plants in different countries, and this resulted in the development of a variety of technological and infrastructural options, whilst providing no clear consensus on which to deploy in any given context. To tackle this complexity, it is fundamental to establish engineering and cost analyses related to the whole CCS supply chain (SC), and in this sense, mathematical programming and optimisation techniques constitute the ideal methodological approach, in order to assess high-level, highly-combinatorial decisional problems, such as CCS. In particular, mixed integer linear programming (MILP) is frequently used in the modelling of large-scale energy systems, occasionally of continent-level CCS networks (Han and Lee, 2013; d'Amore and Bezzo, 2017; d'Amore et al., 2018). When designing CCS SCs, comparatively little attention has been paid to storage-related uncertainties such as geological volumes and long-term storage capacity, which are not usually known to a sufficient degree of accuracy before operation. As geological uncertainties may have a significant impact on overall sequestration costs, a more flexible pipeline network may be necessary rather than that designed using deterministic storage capacity data alone. Accordingly, the necessity of dealing with geological uncertainties in the planning and design of the infrastructure in terms of capacity must be highlighted as a primary action to improve the economic feasibility and manage the risks of large-scale CCS infrastructure. Amongst recent advances in the optimisation of process systems under uncertainty (Grossmann et al., 2016; Yue and You, 2016), several MILP models have been proposed for the optimisation of CCS networks under uncertainty, typically through either stochastic/probabilistic or robust techniques (e.g., Jin et al., 2017). Despite underlying the broad variety of investigated parameters (e.g., economics, storage injectivity, leakage, policy) and the abundancy of employed methodologies (e.g., multiple scenario realisation, inexact optimisation), none of the previous studies focused on the quantification of risk that may emerge as a consequence of uncertainty in the actual geological volume that is available for CO_2 sequestration. This paper proposes a novel adaptive methodology for the calculation of risk based on uncertainties in local storage capacities in the European context. A MILP methodology that optimises the SC in terms of resiliency on risk was developed and applied. The model defines economically optimal designs of European SCs, whilst simultaneously minimising the economic risk generated by uncertainties in local sequestration availability to ensure a robust design. Risk is quantified as additional infrastructure costs that may emerge from the rerouting of CO_2 flowrates, upon realisation of geological uncertainty. Therefore, monetary consequences can be interpreted as additional investment costs that may need to be incurred to improve the flexibility of a European CCS infrastructure.

2. Material and methods

This contribution proposes a MILP optimisation under uncertainty based on the deterministic CCS SC model described in d'Amore and Bezzo (2017). Here, we address uncertainty related to the effective volumetric efficacy of those European basins that are nowadays considered capable of efficiently trapping the anthropogenic CO_2 emissions for long-term storage. The objective is to minimise the total costs required to install and operate, along a 10 years' time horizon, the overall network for CCS, considering the financial risks that are generated by uncertainties in both onshore and offshore European sequestration basins. The 10 years' time horizon is discretised according to a set $t=\{1, \ldots, 10\}$. European large-stationary sources are described according to data retrieved from

d'Amore and Bezzo (2017). The capture stage and associated constraints are implemented through a set of technological options $k=${*post-combustion from coal power plant*, *post-combustion from gas power plant*, *pre-comb from gas power plant*, *oxy-fuel combustion*}. The transport set includes different options $l=${*onshore pipeline*, *offshore pipeline*, *ship*}, each discretised through a set of possible flowrate capacities $p=\{1, \ldots, 7\}$ that ranges from a minimum of 1 Mt of CO_2/year to a maximum of 30 Mt of CO_2/year. The entire European area is discretised based on a grid of regions $g=\{1, \ldots, 134\}$. A terrain factor is implemented to consider local geomorphology. The sequestration basins are distinguished into different categories according to a set $s=${*deep saline aquifers*, *hydrocarbon fields*, *coal fields*} (EU GeoCapacity Project, 2009). Overall, the main inputs are: the spatial distribution of European upstream sources of CO_2; the techno-economic parameters of capture options k; the European carbon reduction target α to be pursued along the time horizon t; the techno-economic parameters of transport means l; the spatial distribution of deterministic minimum and maximum upper bounds of local geological potential of sequestration basins s; the random matrix (generated through Mersenne Twister algorithm) of uncertain minimum upper bounds of local geological potential of sequestration basins. The key variables to be optimised are: location, scale and cost of the capture system, of the transport infrastructure, and of the deterministic-driven sequestration system; the adaptive, uncertainty-dependent upper bound of local geological potential for storage; location, scale and consequent risk of the uncertainty-driven sequestration system; the differential flowrates that may be generated (i.e., surplus and deficit) between the deterministic and the uncertainty-driven sequestration stage; the total risk generated by uncertainty according to the planning features and the location of the sequestration infrastructure.

3. Mathematical formulation

The model addresses uncertainty through a unique objective function that aims to minimise the total cost TC [€] of CCS, including cost for capture TCC [€], transport TTC [€], sequestration TSC [€], and total financial $risk$ [€] generated by the sequestration stage:

$$\forall it, loop\left[objective = \min(TC); TC = TCC + TTC + TSC + risk(it)\right] \tag{1}$$

Quantities TCC, TTC, and TSC of Eq.(1) are evaluated as in d'Amore and Bezzo (2017). Uncertainty is here introduced through a novel approach that aims at evaluating adaptive regional sequestration potential and, therefore, minimising its associated $risk$ through Eq.(1). The latter is given by the contribution on risk of both inter-connection between regions g and g' ($risk^I_{it,g,t}$ [€]), and intra-connection within region g ($risk^{II}_{it,g,t}$ [€]):

$$risk = \sum_{it,g,t} \left(risk^I_{it,g,t} + risk^{II}_{it,g,t}\right) / N_{it} \tag{2}$$

Indeed, either inter-connection or intra-connection related risks can be defined, at each sample it in region g at time period t, as the additional costs (i.e., with respect to TTC) to install and operate further transport links between different regions or basins:

$$risk^I_{it,g,t} = \sum_{g'} \Delta Q_{it,g,g',t} \cdot c^I \cdot LD_{g,g'} \cdot \tau_g \qquad \forall it,g,t \tag{3}$$

$$risk^{II}_{it,g,t} = \sum_{s} S^{deficit}_{it,s,g,t} \cdot c^{II} \cdot LD_g \cdot \tau_g \qquad \forall it,g,t \tag{4}$$

In particular, c^I [€/t/km] and c^{II} [€/t/km] (i.e., the average inter- or intra-connection unitary costs, respectively), $LD_{g,g'}$ [km] and LD_g [km] (i.e., the linear distances between region g and g' and the size of region g, respectively) and the tortuosity factor τ_g, are retrieved from d'Amore and Bezzo (2017). Variable $\Delta Q_{it,g,g',t}$ [t/year] represents the flowrates of CO_2 that must be transported at sample it between regions g and g' at time period t according to sequestration discrepancies between the deterministic and the uncertain models, whereas $S_{it,s,g,t}^{deficit}$ (t/year), together with its specular $S_{it,s,g,t}^{surplus}$ (t/year), are variables that define the differences between the uncertain and the deterministic amounts of CO_2 that are stored on basin s in region g at time period t. Overall, the yearly deterministic $S_{s,g,t}^{D}$ (t/year) and uncertain $S_{it,s,g,t}^{U}$ (t/year) stored amounts, are compared with surpluses ($S_{it,s,g,t}^{surplus}$) and deficits ($S_{it,s,g,t}^{deficit}$) in local sequestration capacities and with potential additional flowrates ($\Delta Q_{it,g,g',t}$) through the following mass balances:

$$S_{it,s,g,t}^{U} = S_{s,g,t}^{D} - S_{it,s,g,t}^{deficit} + S_{it,s,g,t}^{surplus} \qquad \forall it,s,g,t \qquad (5)$$

$$\sum_s S_{it,s,g,t}^{deficit} + \sum_{g'} \Delta Q_{it,g',g,t} = \sum_{g'} \Delta Q_{it,g,g',t} + \sum_s S_{it,s,g,t}^{surplus} \qquad \forall it,g,t \qquad (6)$$

According to Eq.(5) for each sample it, if a basin s in region g presents at time period t a value of $S_{it,s,g,t}^{U} \geq S_{s,g,t}^{D}$, this implies that $S_{it,s,g,t}^{surplus} \geq 0$ is generated in g (which is capable at receiving a deficit from g'). Conversely, when $S_{it,s,g,t}^{U} \leq S_{s,g,t}^{D}$, then $S_{it,s,g,t}^{deficit} \geq 0$, implying that a deficit occurs in region g and must be transported either to a different basin s, or region g' according to Eq.(6). The overall uncertain stored amount $S_{it,s,g,t}^{U}$ is then constrained to be lower than the local adaptive sequestration capacity:

$$\sum_t S_{it,s,g,t}^{U} \leq \sum_t \left[S_{it,s,g}^{U,min} \cdot Y_{it,s,g,t}^{start} + 0.1 \cdot \left(S_{s,g}^{D,max} - S_{it,s,g}^{U,min} \right) \cdot Y_{it,s,g,t}^{keep} \right] \qquad \forall it,s,g \qquad (7)$$

In particular, $S_{it,s,g}^{U,min}$ [t] is the matrix of uncertain minimum upper bounds of local sequestration capacity, constituted by random values comprised within the deterministic range $\left[S_{s,g}^{D,min}, S_{s,g}^{D,max} \right]$ (EU GeoCapacity Project, 2009). Furthermore, $Y_{it,s,g,t}^{start}$ and $Y_{it,s,g,t}^{keep}$ are binary variables that define, respectively, when the injection starts and/or continues being performed at it on basin s in region g at time period t. Overall, Eq.(7) defines the uncertainty in sequestration according to two contributions: a precautionary base storage potential preventively defined at the beginning of the operations, and the possibility of a yearly rate of increase (fixed to 0.1 year^{-1} to exploit 10 years' simulation).

4. Results and discussion

Scenario A will be considered, in which the aim is to achieve a yearly European carbon reduction target α=50 % of CO_2 emissions from large stationary sources. Results are compared with those from Scenario 0 (a risk-neutral network in which risk is not included within the objective function). The model was implemented in GAMS and optimised using the CPLEX solver on a 24-Core cluster (96 GB RAM). The uncertainty in sequestration capacity is approximated by $10 \leq N_{it} \leq 400$ random samples in order to test the efficacy of the proposed methodology, and show that the model achieves reliable results

for *it*=100 (Figure 1a). The design resulting from this sampling should constitute the initial design for future CCS optimisations.

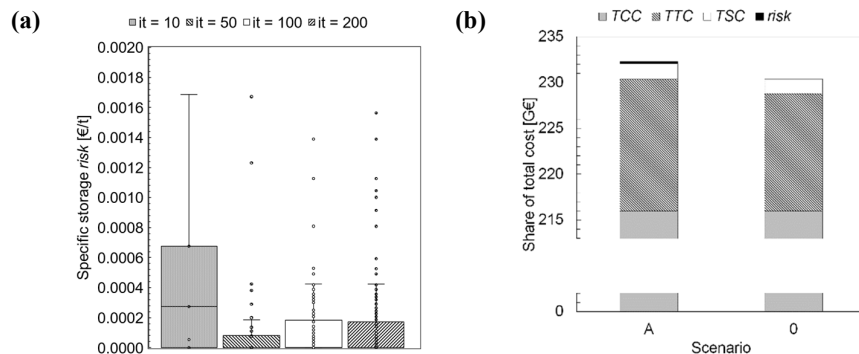
Scenario A entails (Figure 1b) a *TC* for installing and operating the CCS system (including the contribution of financial risk) of 232.1 G€ (i.e., 38.302 €/t of sequestered CO_2), of which the major contribution is represented by *TCC* of 216.0 G€ (i.e., 35.637 €/t of sequestered CO_2). Interestingly, *TTC* (with 14.4 G€, i.e. 2.377 €/t of sequestered CO_2) and *TSC* (with 1.8 G€, i.e. 0.287 €/t of sequestered CO_2) constitute altogether only the 7 % of *TC*. With respect to *risk*, its final value is negligible, thus demonstrating the robustness of this solution on storage uncertainty. However, comparing the results with those from Scenario 0, despite having almost identical *TC* (+0.1 % with respect that of Scenario 0), the drawback of managing to keep such low values of risk is constituted by higher *TTC* (+11.2 % with respect to that of Scenario 0) and *TSC* (+5.5 % with respect to that of Scenario 0) costs. These additional infrastructural costs are a direct consequence of the choice of improving flexibility to nullify the contribution of risk to overall costs. In fact, regarding the SC configuration, under Scenario A (Figure 2a), the number of basins in which a deficit may occur is minimised and in general it is strategically chosen to exploit the sequestration potential of a larger number of regions (and basins) compared to Scenario 0 (Figure 2b), with the drawback of increasing transport costs. Accordingly, to distribute the investment for storage across different European regions, is an effective hedging strategy. In fact, the regions near the Baltics and Northern Poland are the only areas in which storage risk necessitates the balancing of deficits and surpluses, but these result in a range of $33 \leq \Delta Q_{g,g',t} \leq 720$ kt of CO_2/year, therefore minimal with respect to the CO_2 shipped between regions (up to 30 Mt/year). When some risk is unavoidable, slightly risky basins are chosen in areas in which nearby regions are likely to receive a surplus of CO_2, in order to minimise additional transport costs. In fact other deficits are scattered in Slovenia and near the Black Sea, but the CO_2 is diverted towards different basins within the same region and constitutes only a minor contribution to total economic risk, overall still negligible with respect to the total cost to install and operate the CCS network.


Figure 1. Scenario A, **(a)** dependency of *risk* [€/t] from *it*; and **(b)** share of costs [G€].

5. Conclusions

This contribution proposed a MILP modelling framework for the economic optimisation of a European CCS SC, with uncertainty in effective volume capacity of sequestration basins. The effects of uncertainty were quantified in terms of risk related to the necessity of installing further transport links with respect to the risk-neutral solution of the model, with the aim of improving the intrinsic flexibility of European CO_2 infrastructures in

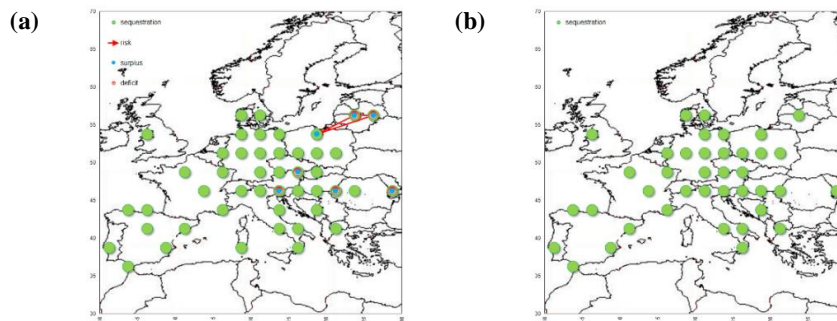
opposition to geological uncertainties. The proposed tool provides economically optimal network configurations resilient on risk and allows a decision-maker to understand the financial penalties associated with designing infrastructure in the absence of uncertainty. It was shown that only minor modifications and investments should be taken into account with respect to a European deterministic CO_2 network, in order to increase the level of flexibility of the transport infrastructure long enough to guarantee that uncertainty in storage capacity does not affect the final deployment of the overall system.


Figure 2. SC configuration for **(a)** Scenario A; and **(b)** Scenario 0.

Abstract

In this paper, we present a methodology to assist the offline description and online maintenance of the design space of a pharmaceutical product. The methodology is intended as a proactive risk-management tool to be included in a design space submission. First, classical feasibility analysis is exploited to obtain an offline model-based description of the design space (e.g., at the process development stage). Then, a dynamic state estimator is used to continuously adapt the model during plant operation, using measurements available from plant sensors. Surrogate-based feasibility analysis is used to continuously update the model-based description of the design space based on the up-to-date model returned by the state estimator. The tracking effectiveness of the methodology is shown for a co-milling process of a pharmaceutical production.

Keywords: quality by design, design space, state estimation, pharmaceutical manufacturing, model maintenance

1. Introduction

Following the recent FDA ICH Q12 draft guideline (ICH, 2018), the design space (DS) of a pharmaceutical product represents a set of established conditions (raw material properties and critical process parameters, CPPs) that guarantee to fulfill predefined specifications on the product critical quality attributes (CQAs).
The DS is typically obtained at the product/process development stage by exploiting a process model (either mechanistic or data-driven) and targeted laboratory experimentation. In principle, if all disturbances and sources of uncertainty that may affect the model predictions were accounted for at this stage, working within the resulting model-based representation of the DS would guarantee the desired product quality. In practice, however, there is no guarantee that the prediction fidelity of the model will remain unchanged as process operation progresses (Pantelides and Renfro, 2013). Process-model mismatch may in fact arise from parameter drifts (e.g., a heat exchange coefficient may change due to fouling), or insufficient/inappropriate description of the underlying physical phenomena driving the process (e.g., unmodeled physical phenomena that could not be observed at the laboratory scale, such as the effect of downstream/upstream units or of environmental factors). The fact that, along a plant lifecycle, the model may not be able to accurately reproduce the actual plant behavior, questions the appropriateness of the operating conditions selected by using the DS description obtained at the development stage. In this regard, the recent ICH Q12 draft

guideline (ICH, 2018) acknowledges that "(…) it may be necessary to change approved established conditions as a result of knowledge gained during product lifecycle…" and aims at providing a comprehensive regulatory framework on how to perform this in practice.

In this study, we propose a methodology to perform two sequential tasks: *i*) obtain an offline model-based description of the design space at the development stage; *ii*) obtain an up-to-date description of the design space as process operation progresses, by continuously reconciling the model predictions with the observed plant behavior. We intend the two activities (offline DS description and online DS maintenance) as complementary, making them appealing for a joint inclusion in a design space submission (i.e., for regulatory approval), in such a way as to reduce the burden of post-approval revision processes. We discuss the ability of the methodology to track the DS of a simulated de-lumping process of a pharmaceutical production using a conical miller.

2. Proposed methodology

Let us consider a dynamic system for the production of a pharmaceutical drug. The state-space representation of a pharmaceutical unit (or process) is typically given by a system of nonlinear differential-algebraic equations (DAEs) of the form:

$$\begin{bmatrix} \dot{\mathbf{x}}_1(t) \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_1(\mathbf{x}_1(t), \mathbf{x}_2(t), \mathbf{q}(t), t) \\ \mathbf{f}_2(\mathbf{x}_1(t), \mathbf{x}_2(t), \mathbf{q}(t), t) \end{bmatrix} + \begin{bmatrix} \mathbf{w}_1(t) \\ \mathbf{w}_2(t) \end{bmatrix} \tag{1}$$

subject to initial conditions:

$$\mathbf{x}_1(0) = \mathbf{x}_{1,0} + \mathbf{w}_1(0) \tag{2}$$

where $\mathbf{x}_1(t)[N_1 \times 1]$ is the differential state vector, $\mathbf{x}_2(t)[N_2 \times 1]$ is the algebraic state vector, $\mathbf{w}_1(t)[N_1 \times 1]$ and $\mathbf{w}_2(t)[N_2 \times 1]$ are zero-mean random processes with unknown statistics representing the model error related to the differential and algebraic states respectively, and $\mathbf{q}(t)$ $[M \times 1]$ is the vector collecting the raw material properties and CPPs (i.e., process parameters that have a strong effect on the product critical quality attributes). Formulation (1) assumes that there are no control variables (i.e., an open-loop scenario is considered). The model equations can also be concisely expressed in the implicit form:

$$\mathbf{F}(\dot{\mathbf{x}}_1(t), \dot{\mathbf{x}}_2(t), \mathbf{x}_1(t), \mathbf{x}_2(t), \mathbf{q}(t), t) = \mathbf{0} \ . \tag{3}$$

We assume the availability of measurements from plant sensors at each time step t_k. The L-dimensional measurement vector at time t_k is denoted as $\mathbf{y}(t_k)$, and its relation $\mathbf{h}(\cdot)$ with the state vector is given by:

$$\mathbf{y}(t_k) = \mathbf{h}(\mathbf{x}_1(t_k), \mathbf{x}_2(t_k), t_k) + \mathbf{v}(t_k); \ \ k = 1, 2, \dots, K \quad , \tag{4}$$

where $\mathbf{v}(t_k)$ $[L \times 1]$ is the measurement noise.

The proposed methodology can be summarized in four steps.

Step #1: offline DS description. This activity is typically performed at the development stage. Given the process model (3), we define the feasibility function $\boldsymbol{\Psi}(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t)$ as the maximum value of the I quality constraints imposed on the product CQAs:

$$\Psi(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t) = \max_{i \in I} g_i(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t), \quad i = 1, \dots, I \tag{5}$$

where $g_i(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t), i = 1, \dots, I$ is the set of quality constraints.. Based on this definition, the model-based description $\widehat{DS}$ of the design space (i.e. the set of CPPs and raw material properties that allow satisfying all quality constraints) is obtained by exploiting classical feasibility analysis (Halemane and Grossmann, 1983) according to:

$$\widehat{DS} = \{\mathbf{q}(t) | \Psi(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t) \le 0\}. \tag{6}$$

The description of the DS as expressed by Eq. (6) requires the solution of the following bilevel optimization problem (also called flexibility test problem (Halemane and Grossmann, 1983)):

$$\chi = \max_{\mathbf{q}(t) \in \mathbf{Q}(t)} \Psi(\mathbf{q}(t), \mathbf{x}_1(t), \mathbf{x}_2(t), t) \qquad \text{subject to} \tag{7}$$

$$\mathbf{F}(\dot{\mathbf{x}}_1(t), \mathbf{x}_1(t), \mathbf{x}_2(t), \mathbf{q}(t), t) = \mathbf{0}; \quad \mathbf{x}_1(0) = \mathbf{x}_{1,0}$$

$$\mathbf{Q}(t) = \{\mathbf{q}(t) | \mathbf{q}^{lo}(t) \le \mathbf{q}(t) \le \mathbf{q}^{up}(t)\} \quad . \tag{8}$$

The DS description obtained according to Eq. (6) through the solution of (7)-(8) represents the best representation of the DS that can be obtained with the available process model and with the best estimate of the model parameters obtained at the laboratory scale.

Step #2: uncertain model parameters determination. The underlying assumptions that we make is that process-model mismatch can be compensated for by continuously updating the system state and recalibrating some of the original model parameters. The parameters that should be recalibrated online can be chosen according to two criteria:
   a) if prior knowledge on the uncertainty or disturbances that may affect plant operation is available, the parameters are determined by preliminary qualitative diagnosis of the model structure;
   b) if condition a) does not hold true, sensitivity analysis can be used to determine the parameters that most affect the product CQAs. Only these parameters will be continuously adjusted during plant operation, as they are strongly related with the accuracy of the model-based description of the DS.
The set of parameters that are recalibrated online is denoted as $\mathbf{p}(t)[V \times 1]$, with $V \le L$.

Step #3: state estimation and online parameter recalibration. The state estimator proposed by Cheng *et al*. (1997) is exploited to obtain the current system state and to perform the parameter recalibration at each time step t_k. The peculiarity of this state estimator is that, despite the traditional extended Kalman filter (EKF), its derivation is directly obtained from the DAE formulation (1) and does not require any assumptions on the form of the distributions of the state vector and measurement vector (which are assumed as normally distributed in the standard EKF formulation). The ability of this state estimator to handle large nonlinear DAE systems (involving more than 200 differential equations and 14,000 algebraic equations) has been discussed recently (Pantelides *et al*., 2016). The mathematical formulation of this estimator can be found in the cited reference.
The online parameter recalibration is obtained through a state augmentation procedure (Ricker and Lee, 1995), by augmenting the differential state vector $\mathbf{x}_1(t)$ with the set of

uncertain parameters $\mathbf{p}(t)$. At each time step t_k, the state estimator returns the up-to-date values of $\mathbf{x}_1(t_k)$, $\mathbf{x}_2(t_k)$ and $\mathbf{p}(t_k)$.

Step #4: online DS maintenance. The up-to-date system state and parameter values returned by the state estimator are used to update the model-based description of the DS. The DS can be updated with the same measurement interval Δt_k at which measurements are collected from the plant or with a user-defined time interval Δt_m, provided that $\Delta t_m \geq \Delta t_k$. At each time t_m, the up-to-date DS representation is obtained according to:

$$\widehat{DS}_m = \{\mathbf{q}(t_m) | \Psi_m(\mathbf{q}(t_m), \mathbf{x}_1(t_m), \mathbf{x}_2(t_m), \mathbf{p}(t_m), t_m) \leq 0\} \tag{9}$$

by solving the flexibility test problem. The computational time required for the solution of the flexibility test problem must be smaller than the DS update interval Δt_m. If this condition does not hold true, surrogate-based feasibility analysis using a kriging or radial-basis function (RBF) surrogate can be used to make the online implementation viable. Mathematical details on this approach are discussed in Wang et al. (2017). For multidimensional design spaces (i.e., when the number of CPPs and raw material properties is greater than two), the joint projection to latent structures/RBF feasibility analysis approach proposed by Bano et al. (2018) can be exploited to reduce the problem dimensionality.

3. Test example

The application of the proposed methodology is illustrated for a simulated de-lumping operation of a pharmaceutical powder using a conical miller. The model proposed by Wang et al. (2017) is used to simulate the system behaviour. The model equations are given by Eq. (10)-(13) with the initial conditions and nominal values of the parameters reported in Table 1. The three state variables to be collected in vector $\mathbf{x}_1(t)$ are the mass holdup $M(t)$ in the co-mill, the outlet mass fraction w_{API}(t) of the active pharmaceutical ingredient (API), and the outlet mass fraction $w_{ex}(t)$ of the excipient. The only algebraic state variable is the 90% D-value of the particle size distribution of the bulk material at the outlet $d_{90}^b(t)$, i.e. the diameter at which 90% of the bulk mass is comprised of smaller particles. Following the regulatory parlance, d_{90}^b is the product CQA, the impeller blade speed ω is a CPP, and the 90% D-value of the API at the inlet $d_{90,API}^{in}$ is a raw material property affecting the product CQA. Both ω and $d_{90,API}^{in}$ are considered as time-invariant.

4. Simulation set-up and results

It is desired to obtain a bulk material that satisfies the condition $222.5 \leq d_{90}^b \leq 224 \, [\mu m]$ within 100s of co-milling operation. The design space for this process is defined as the set of combinations of $(\omega, d_{90,API}^{in})$ that guarantee to obtain the desired specifications for $d_{90}^b(t)$ within the desired time frame.

Table 1. Initial conditions for the differential state variables and nominal values of the parameters of model (10)-(13).

Variable/parameter	Units	Value
M_0	[kg]	0.19
$w_{API,0}$	[-]	0
$w_{ex,0}$	[-]	1
τ_{max}	[s]	40
ω_{min}	[rad/s]	104.62
a	[rad/s]	10.47
b	[m³/s]	1

$$\bar{\tau} \frac{dM(t)}{dt} + M(t) = \bar{\tau} F^{in} ; \tag{10}$$

$$\frac{d(w_i^{out} M(t))}{dt} = w_i^{in} F^{in} - \frac{w_i^{out} M(t)}{\bar{\tau}} \quad \text{i= API,ex} ; \tag{11}$$

$$\bar{\tau} = \tau_{max}\left[1 - \exp\left(-\frac{a}{\omega-\omega_{min}} - \frac{b}{F^{in}}\right)\right]; \tag{12}$$

$$d_{90}^b(t) = w_{API}(t)d_{90,API}^{in} + w_{ex}(t)d_{90,API}^{in} \tag{13}$$

The empirical relation (12) for the mean residence time is obtained from residence time distribution (RTD) experiments performed at the laboratory scale, and the regression parameters (τ_{max}, a, b) are therefore subject to a high degree of uncertainty when used to simulate a full-scale operation. Moreover, obtaining accurate initial values for the mass holdup and mass fractions (which both depend on upstream units) can be cumbersome.

In order to test the DS tracking performance of the proposed methodology, a situation was investigated where the model structure was correct, but erroneous values of the model parameters were used as well as an incorrect initial estimate of the system state. Specifically, a +10% deviation on the initial state estimate M_0 and a +35% deviation on the nominal value of parameter τ_{max} were enforced. The choice of enforcing a parametric mismatch on τ_{max} was dictated by the fact that its effect on the product CQA is considerably stronger than the other two regression parameters (a, b). Synthetic measurements of mass holdup to be fed to the estimator were generated at a frequency of 1 Hz; noise was simulated by adding the random error $v(t_k) \sim N(0,0.01^2)$ to the simulation results. The covariance for the model error $\mathbf{w}_1 \sim (0, \mathbf{Q})$ state estimator was set by trial and error to the value $\mathbf{Q} = diag(0.05^2; 0.001^2; 0.001^2)$ for each time step t_k

The DS that can be obtained from model (10)-(13) with the correct initial state and nominal values of τ_{max} of Table 1 is denoted as the actual DS of the process. On the other hand, the DS as predicted by the estimator is denoted as the estimated DS. The actual DS is shown in the contour plot of Fig. 1a (i.e., the portion of the input domain within which the feasibility function is smaller than 0). Fig. 1b shows the discrepancy between the actual DS and the estimated DS that would be obtained at the development stage with a wrong estimate of the initial state of the system and of the parameter τ_{max}. Fig. 1c-1f show the tracking ability of the proposed methodology after 5,10,15 and 20 s of process operation (i.e., Δt_m= 5s). A RBF surrogate was exploited to reconstruct the boundary of the DS given the up-to-date model returned by the state estimator. The actual DS is recovered after ~20 s of operation, i.e., in less than 1/5 of the total co-milling operation.

5. Conclusions

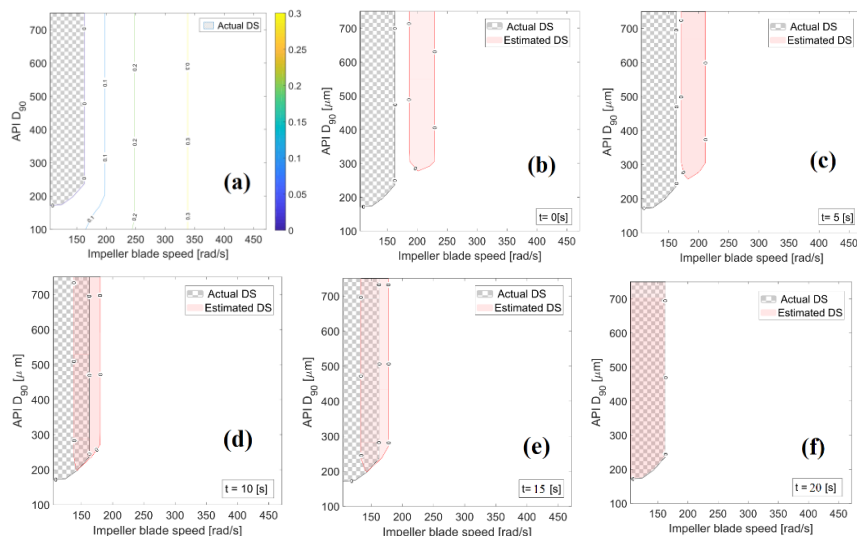
The aim of this study was to propose a systematic methodology to assist the offline description and online maintenance of the design space of a pharmaceutical product. First,


Figure 1. (a) Actual design space, (b) Estimated DS and actual DS at the development stage; estimated DS and actual DS after (c) 5s, (d) 10s, (e) 15s and (f) 20s of plant operation.

surrogate-based feasibility analysis was exploited to obtain an initial offline description of the design space using the available process model. Then, given few online measurements made available by plant sensors, an automatic strategy was proposed to continuously update the design space as plant operation progresses. The ability of the proposed approach to track a 35% parametric mismatch and a 10% error on the initial state estimate for a co-mill process of a pharmaceutical powder was shown. Applications of the proposed DS maintenance tool include open-loop decision support, real-time optimization, definition of optimal set-points or set-point trajectories within the boundary of the up-to-date design space.

Abstract

Fouling is a typical type of degradation in the process industries, which results in significant negative effects on the efficiency of plants. This paper considers a case study, where production tasks with different recipes contribute to the batch-to-batch fouling evolution depending on their sequence. The scheduling of the production tasks is improved by explicit consideration of the degradation effects, resulting in an optimized production sequence. A set of continuous-time MILP-based scheduling models integrated with degradation models are employed to formulate this batch scheduling problem. The proposed formulations are tested for different problem sizes of the case study illustrating the effectiveness of each of the proposed approaches.

Keywords: multipurpose batch scheduling, sequence-dependent degradation, continuous-time MILP formulation, disjunctive model, precedence model

1. Introduction

Multipurpose chemical batch plants are often a challenge to schedule. These processes typically produce a large number of products requiring several processing steps. When scheduling such processes several factors must be taken into account including, but not limited to, process throughput, storage constraints, equipment condition, and maintenance concerns. When creating scheduling models, one of the major decisions is the time representation chosen for the problem. The time representation can either be continuous or discrete. Continuous time problems in general result in far fewer variables than their discrete counterparts and provide an explicit representation of timing decisions. Continuous time scheduling formulations are broadly classified into precedence, single, or multiple time grid based models (Méndez et al., 2006). Continuous time models have been applied to many different scenarios. Castro and Grossmann (2012) used generalized disjunctive programming to derive generic continuous-time scheduling models.

One aspect of scheduling that has been gaining attention in literature lately is that of integrating equipment condition into production scheduling. Vieira et al. (2017) studied the optimal planning of a continuous biopharmaceutical process with decaying yield. They formulated the problem as a continuous single-time grid formulation making both production scheduling and maintenance scheduling decisions. Other applications of combined maintenance and production scheduling can be found in Biondi et al. (2017) and Dalle Ave et al. (2019) who studied the joint production and maintenance problem of steel plant scheduling under different conditions.

The goal of this work is to investigate the production scheduling of a chemical batch plant with unit degradation. A batch reactor case study considering fouling is presented in which the fouling

prolongs the time needed to complete a batch and is highly influenced by the sequence of products produced in the reactor. The problem is formulated using a set of continuous-time MILP-based scheduling models which will be described and compared in the remainder of this work.

2. Problem description

This case study focuses on a batch polymerization process. Firstly, the product monomers are mixed in a single tank before being homogenized and dispatched to the reactors. Once the monomers have reacted they are dispatched via a shared piping system to storage. The major cause of degradation in this process is fouling in the reactors; polymer residues are accumulated on the inner surfaces of the reactors, heat exchangers, and pipes. This causes reduced heat transfer from the product to the coolant thereby decreasing cooling efficiency and prolonging batch duration. Moreover, the flow resistance due to fouling leads to an increased pressure drop over the heat exchanger. A pressure-based key performance indicator (KPI) was developed to indicate the degree of fouling for each batch run using a state estimation approach, and in this approach many interfering factors due to batch production are excluded from the fouling KPI (Wu et al., 2019). The batch-to-batch behaviors of the fouling evolution discussed in Wu et al. (2018, 2019) indicate that different batch recipes contribute to the fouling evolution differently. Hence, a linear model based the fouling KPI is developed to describe the effects of batch sequences on the batch-to-batch fouling growth, given as:

$$f_{k,j} = A_{R_{k-1,j}\ j} \cdot f_{k-1,j} + B_{R_{k-1,j}\ j} \tag{1}$$

where, $R_{k,j} = r$ indicates Recipe r at the kth batch of Unit j; $f_{k,j}$ is the fouling KPI for the kth batch of Unit j, which is assumed to follow recipe-based unit-specific linear dynamics $\{(A_{rj}, B_{rj}) \mid r = 1, 2, ..., |R|, \ j = 1, 2, ..., |J|\}$.

The recipe determines the total processing time at each unit, and the reaction duration, which is also affected by the coolant temperature and the fouling. The degree of fouling is approximated using eq. (1), and the coolant temperature is considered as an external disturbance due to uncertainties among the cooling capacities and the demands. Moreover, the reactors and other units are not identical, which also leads to differences in the processing time. A linear model structure is applied to fit the processing time as a function of the fouling KPI and the coolant temperature given the recipe $R_{k,j}$ in Unit j, the coolant temperature is assumed to be fixed for the scheduling scenario. Therefore, the processing time is calculated using only the fouling KPI as eq. (2) shows:

$$Du_{k,j} = AD_{R_{k,j}\ j} \cdot f_{k,j} + BD_{R_{k,j}\ j} \tag{2}$$

where, $Du_{k,j}$ is the reaction processing time at the kth batch of Unit j; $\{AD_{rj},\ BD_{rj}\}$ are the model parameters for Recipe r at Unit j. The degradation impairs the batch production capacity and therefore needs to be explicitly considered in production scheduling. Provided the quantitative models in eqs. (1) and (2), a new scheduling problem considering degradation effects is formulated by integrating the degradation models into existing scheduling optimization approaches. In the next section, continuous-time MILP approaches using precedence concepts are presented for the aforementioned batch scheduling problem.

3. Methodology

In this section, four continuous-time MILP scheduling formulations are presented which integrate the sequence-dependent degradation model using precedence-based constraints. Furthermore, no changeover time and no intermediate storage are considered for the process specifications. Note that while this work focuses on a particular case study, the methodology presented here is generic and could be adapted to other scenarios.

3.1. Nomenclature

I, J, L, R	Sets of batch orders ($i = 1, 2, ..., |I|$), units ($j = 1, 2, ..., |J|$), stages ($l = 1, 2, ...,$ $|L|$) and batch recipes ($r = 1, 2, ..., |R|$),
J_l, J_{de}, L_{de}	Sets of units belonging to Stage l, units suffered from degradation and stages containing units suffered from degradation,
Ts_{il}, Te_{il}	Start time and end time of Order i in Stage l,
Tp_{ij}, Tr_l	Processing time of Order i at Unit j, transfer time in Stage l,
Ta_{ij}	Additional processing time of Order i at Unit j due to degradation,
f_{ij}, FI_j, R_{ri}	Degradation (fouling) KPI for Order i at Unit j, initial fouling KPI at Unit j, recipe binary indicator for Order i using Recipe r,
A_{rj}, B_{rj}	Degradation model parameters for Recipe r at Unit j, see eq. (1),
AD_{rj}, BD_{rj}	Duration model parameters for Recipe r at Unit j, see eq. (2),
$X_{i'ij}^{ui}, W_{ij}$	Sequencing binary variables for a unit-specific immediate precedence model,
$X_{i'il}^{im}, Y_{ij}, W_{ij}$	Sequencing binary variables for an immediate precedence model,
$X_{i'il}^{g}, Y_{ij}$	Sequencing binary variables for a general precedence model,
S_{ij}	Absolute position of Order i in the sequence of Unit j,

3.2. Sequence-dependent degradation

The continuous-time immediate precedence fits the form of the sequence-dependent degradation model as shown in eq. (1). Using a unit-specific immediate precedence model, the degradation initialization and propagation are presented in the form of disjunctive constraints as eqs. (3) and (4) show: if Order i is immediately processed after Order i' at Unit j ($X_{i'ij}^{ui} = 1$), then the batch degradation KPI (f_{ij}) is calculated from its previous value ($f_{i'j}$) using eq. (1); if Order i is processed first in the sequence of unit j ($W_{ij} = 1$), then f_{ij} equals an initial value of the fouling KPI. To avoid nonlinear constraints, the processing time of Order i at Unit j is further divided into a varying duration due to fouling (Ta_{ij}) and a constant duration (Tp_{ij}) according to eq. (2), where the calculations of Ta_{ij} and Tp_{ij} are presented in eq. (4).

$$\bigvee_{i,i' \in I: i \neq i', j \in J_{de}} \begin{bmatrix} X_{i'ij}^{ui} \\ f_{ij} \geqslant AS_{ij} \cdot f_{i'j} + BS_{ij} \\ f_{ij} \leqslant AS_{ij} \cdot f_{i'j} + BS_{ij} \end{bmatrix}, \quad \bigvee_{i \in I, j \in J_{de}} \begin{bmatrix} W_{ij} \\ f_{ij} \geqslant FI_j \\ f_{ij} \leqslant FI_j \end{bmatrix} \tag{3}$$

$$Ta_{ij} = \sum_{r \in R} R_{ri} \cdot AD_{rj} \cdot f_{ij}, \quad Tp_{ij} = \sum_{r \in R} R_{ri} \cdot BD_{rj}, \ \forall i \in I, j \in J_{de} \tag{4}$$

where, $AS_{ij} = \sum_{r \in R} R_{ri} A_{rj}$, and $BS_{ij} = \sum_{r \in R} R_{ri} B_{rj}$.

3.3. Unit-specific immediate precedence model [M1]

A single-stage unit-specific immediate precedence model is proposed in Cerdá et al. (1997), and an adapted version for multistage problems considering unit degradation is presented as follows: given the sequence binaries ($X_{i'ij}^{ui} = 1$, if Order i is processed immediate after Order i' at Unit j, $W_{ij} = 1$ if Order i is processed in the first place of the sequence at Unit j), the unit-specific immediate precedence constraints are presented in eqs. (5) and (6); the order timing constraints for a single order are presented in eq. (7); the order sequencing and timing constraints for two orders in a single unit are presented using disjunctive constraints as shown in eq. (8). The order sequencing and timing constraints for two orders in neighboring stages considering no immediate storage are presented in eq. (9) (the transfer procedure occupies both units in the two stages); the degradation and duration model constraints are presented in eqs. (3) and (4).

$$\sum_{i \in I} W_{ij} = 1, \ \forall \ j \in J \tag{5}$$

$$\sum_{j' \in J_l} W_{ij'} + \sum_{i' \in I: i' \neq i, j' \in J_l} X_{i'ij'}^{ui} = 1, \ \sum_{i' \in I: i' \neq i, j' \in J_l} X_{ii'j'}^{ui} \leqslant 1, \ \forall \ i \in I, \ l \in L \tag{6}$$

$$Te_{il} = Ts_{il} + \sum_{j \in J_l} [Tp_{ij}(W_{ij} + \sum_{i' \in I: i' \neq i} X_{i'ij}^{ui}) + Ta_{ij}], \ Ts_{i(l+1)} \geqslant Te_{il} + Tr_l, \ \forall \ i \in I, \ l \in L \tag{7}$$

$$\bigvee_{i,i'\in I: i\neq i',\, l\in L} \left[\begin{array}{c} \sum_{j\in J_l} X^{ui}_{i'ij} \\ Te_{i'l}+Tr_l \leqslant Ts_{il}-Tr_{(l-1)} \end{array} \right] \quad (8) \qquad \bigvee_{i,i'\in I: i\neq i',\, l\in L: l<|I|} \left[\begin{array}{c} \sum_{j\in J_l} X^{ui}_{i'ij} \\ Ts_{il} \geqslant Ts_{i'(l+1)}+Tr_l \end{array} \right] \quad (9)$$

3.4. Immediate precedence model [M2]

In contrast to M1, the immediate precedence model (Gupta and Karimi, 2003) uses two types of binary variables $\{X^{im}_{i'il}, Y_{ij}\}$ ($X^{im}_{i'il}=1$ indicates Order i is immediately processed after Order i' in some units of Stage l; $Y_{ij}=1$ indicates Order i is assigned to Unit j), which fits into the sequence-dependent degradation in eq. (3) by replacing $X^{ui}_{i'ij}$ with $X^{im}_{i'il} \wedge Y_{ij} \wedge Y_{i'j}$. The order assignment and immediate precedence constraints are presented in eqs. (5), (10) and (11), and the order timing constraints for a single order are presented in eq. (12). Lastly, the order sequencing and timing constraints for two orders in a single unit and neighboring stages are presented in eq. (13).

$$\sum_{j\in J_l} Y_{ij}=1,\; \sum_{j\in J_l} W_{ij}+\sum_{i'\in I: i'\neq i} X^{im}_{i'il}=1,\; \sum_{i'\in I: i'\neq i, l\in L} X^{im}_{ii'l} \leqslant 1,\; \forall\, i\in I,\, l\in L \tag{10}$$

$$Y_{ij} \leqslant Y_{i'j}+1-X^{im}_{ii'l}-X^{im}_{i'il},\; \forall\, i,i'\in I: i\neq i',\, j\in J_l, l\in L \tag{11}$$

$$Te_{il}=Ts_{il}+\sum_{j\in J_l}(Tp_{ij}Y_{ij}+Ta_{ij}),\; Ts_{i(l+1)} \geqslant Te_{il}+Tr_l,\; \forall\, i\in I, l\in L \tag{12}$$

$$\bigvee_{i,i'\in I: i\neq i',\, l\in L} \left[\begin{array}{c} X^{im}_{i'il} \\ Te_{i'l}+Tr_l \leqslant Ts_{il}- \\ Tr_{(l-1)} \end{array} \right], \quad \bigvee_{i,i'\in I: i\neq i', l\in L: l<|I|} \left[\begin{array}{c} X^{im}_{i'il} \\ Ts_{il} \geqslant Ts_{i'(l+1)}+Tr_l \end{array} \right] \tag{13}$$

3.5. Hybrid precedence model [M3]

When comparing to M1 and M2, general precedence models proposed by Méndez and Cerdá (2003) generally prevail with less computation cost. These models use binary variables $X^{g}_{i'il}=1$, $Y_{ij}=1$, $Y_{i'j}=1$ to represent that Order i is processed after i' at Unit j in Stage l. But unlike M1 and M2, it does not provide immediate precedence relations. Given that the sequence-dependent degradation only occurs in certain stages, a hybrid precedence model is developed by replacing M2 with general precedence constraints in the stages requiring no immediate precedence information ($l\in L_n=L\wedge\neg L_{de}$). The precedence constraints are presented in eq. (14), and the order timing constraints for a single order are the same as M2 as eq. (12) shows. The order sequencing and timing constraints for two orders in the same stage or neighboring stages are presented in eq. (15).

$$\sum_{j\in J_l} Y_{ij}=1,\; X^{g}_{ii'l}+X^{g}_{i'il}=1, \forall i,i'\in I: i\neq i', l\in L-L_{de} \tag{14}$$

$$\bigvee_{\substack{i,i'\in I: i'\neq i,\\ j\in J_l, l\in L_n}} \left[\begin{array}{c} X^{g}_{i'il}\wedge Y_{ij}\wedge Y_{i'j} \\ Te_{i'l}+Tr_l \leqslant Ts_{il}-Tr_{(l-1)} \\ Ts_{il} \geqslant Ts_{i'(l+1)}+Tr_l \end{array} \right], \quad \bigvee_{i,i'\in I: i'\neq i, l\in L_n} \left[\begin{array}{c} X^{g}_{i'il} \\ Ts_{i'l}+Tr_l \leqslant Ts_{il} \end{array} \right] \tag{15}$$

3.6. General precedence based model [M4]

A general precedence based model for sequence-dependent changeovers is proposed in Aguirre et al. (2012, 2017), which also can be adapted to the scheduling problem considering sequence-dependent degradation. The general precedence model presented in M3 is extended to all stages, and the immediate precedence binary variables $X^{im}_{i'il}$, W_{ij} are introduced for the stages and units having sequence-dependent behaviors ($j\in J_{de}, l\in L_{de}$). By introducing a continuous variable S_{ij}, defined as the absolute position of batch i in the sequence of Unit j, the immediate precedence variables are connected to the general precedence model using eq. (16).

$$\bigvee_{i,i'\in I: i\neq i', j\in J_l, l\in L_{de}} \left[\begin{array}{c} X^{g}_{i'il}\wedge Y_{ij}\wedge Y_{i'j} \\ S_{ij} \geqslant S_{i'j}+1 \\ X^{im}_{i'il}+S_{ij}-1 \geqslant S_{i'j}+1 \end{array} \right], \; Y_{ij} \leqslant S_{ij} \leqslant \sum_{i\in I} Y_{ij},\; \forall i\in I, j\in J_{de} \tag{16}$$

3.7. Big-M reformulation and objective function

The disjunctive programming constraints in the precedence models are reformulated into the MILP frameworks using the big-M approach. More details can be found in Castro and Grossmann (2012). This objective function considered in this work is the minimization of makespan considering fouling-influenced batch time.

4. Case study: computational results

Size	M1	M2	M3	M4
12(6,6)	3495.02 (53%)	**3495.02(74sec)**	3495.02(37%)	3495.02(37%)
15(7,8)	4315.79 (70%)	**4266.73(979sec)**	4282.61(42%)	4266.73(42%)
18(7,8,3)	5164.13 (79%)	5589.43(84%)	5116.97(46%)	5164.13(47%)
25(6,5,4,5,5)	7237.93 (91%)	13339.37(94%)	7034.91(51%)	7375.89(53%)

Table 1: Computational results of different formulations: objective function and optimality gap

Referring to the aforementioned case studies, the monomer make-up section and the reaction section are taken as the two production stages with one monomer vessel (U1) in Stage L1 and two non-identical reactors (U2 and U3) in Stage L2. The process topology can be viewed in Figure 1. Due to the lack of intermediate storage, the homogenization section (L1-Tr) is modeled as a transfer procedure between the stages. This transfer occupies both the discharging mixer as well as the reactor that is being charged, which is modeled using eq. (9) for model M1. Additionally, the only pipeline (L2-Tr) transfers product from either U2 or U3 into storage. To prevent multiple orders overlapping in L2-Tr, the ordering and timing constraints are used in a similar way as shown in eq. (8) by introducing an artificial precedence binary for this unit. In this case study, when minimizing makespan, it is not possible for jobs to overtake one another in L2 and therefore the precedence binary variable for L2-Tr same one for L1. In addition, an operational threshold is added on the degradation indicator.
Figure 1: The topology of of the batch process

Each of the four models defined earlier were tested for varying problem sizes. Take 15(7,8) for example, 15 refers to the total amount of product demand, and the values inside the parentheses (7,8) refer to the demands for different recipes. The parameters of the scheduling problem are obtained from the case study and the historical data. The models are implemented in GAMS 25.1 and solved using CPLEX 12.8, and the time limit is set to 1200 CPU seconds. The Gantt chart and fouling curves for the 25-order case using M3 are illustrated in fig. 2; the normalized fouling KPI data are presented for two units (U2 and U3) with different symbols denoting the recipes from R1 to R5, and the threshold for the normalized fouling KPI is one. Furthermore, the computational results are presented in table 1 with objective values and relative optimality gaps. Results show that the small-size problems using M2 are solved to zero gap before 20 minutes but the computation cost increases dramatically with larger problem size; M3 has better computational performance (smaller value of objective function and smaller relative optimality gap) for the problem sizes 18(7,8,3) and 25(6,5,4,5,5).

5. Conclusions

A short-term batch scheduling problem considering sequence-dependent degradation was formulated using different continuous-time MILP methods. Taking an industrial case study as example,
Figure 2: Result of the 25-order problem using M3

the recipe-based degradation models are integrated with the precedence models to improve the scheduling of batch production. Four integrated MILP formulations are compared by running the scheduling models with different problem sizes, and the hybrid precedence model is shown to have the best computation performance for relatively large-size problems. However, the investigated formulations do not find a provably optimal solution within 20 minutes; future work involves improving the computational performance of such models.

Abstract

This work presents a systematic methodology to determine in real-time the optimal durations of the three stages of a new Ca-Cu looping process for H_2 production with integrated CO_2 capture. Economic and quality criteria are proposed to determine the appropriate time to switch between the stages. These criteria rely on the time-profiles of some key variables, such as product concentrations. Given the delayed nature of hardware sensor measurements, the real-time determination of such variables is based on soft-sensors. For this purpose, Gaussian Process Regression models are employed. The predictive capabilities of these models are tested on several datasets, yielding reliable predictions in most of the cases. The values of the optimal switching times computed with the proposed method differ from the actual values by 4 %, at most.

Keywords: machine learning, gaussian process regression models, CO_2 capture, process intensification, process monitoring.

1. Introduction

The calcium-copper (Ca-Cu) looping technology is a cyclic, three-stages process for H_2 production with integrated CO_2 capture conducted in dynamically operated packed bed reactors (Abanades et al., 2010). While a satisfactory understanding of the underlying phenomena is available, investigations in the field of process automation are needed to efficiently upscale the process. Since the behaviour of each stage is inherently dynamic, one issue is the assessment of the optimal duration. The main aim of this work is to develop a methodology to identify the appropriate time instant to switch between stages. This is crucial to match satisfactory operating targets, including economic profitability and product quality specifications. Once suitable switching criteria have been defined, the optimal duration of the stages can be either scheduled or computed in real-time. The second approach is preferable, because it allows more flexibility in dealing with disturbances and process uncertainties. In practice, not all the variables needed for the evaluation of the switching criteria can be sensed in real-time. This is the case of composition measurements obtained via hardware analysers, which are often affected by substantial time-delays. Instead, soft-sensors can be employed as virtual analysers. Soft-sensors are models that allow the estimation of hard-to-measure, primary variables, making use of
Figure 1: The three stages Ca-Cu chemical looping process for H_2 production.

secondary variables, that are easily sensed online. Several soft-sensing techniques have been reported in literature. A common classification is based on the type of models employed, either first principle or data-driven. First principle models usually allow reliable extrapolation (Porru et al., 2013), but lack of knowledge in some aspects of the underlying physics might result in poor performance (Porru and Özkan, 2017). Moreover, model complexity might make their solution too computationally demanding for real-time applications (Shokry et al., 2017). Conversely, data-driven models may suffer from limited extrapolation capabilities, since they only encode information available in the training data (Bonvin et al., 2016). Hence, the amount of data required for their training is usually large. A major advantage compared to first-principle models is that a deep knowledge of the process is not necessary. Hence, data-driven soft-sensors are particularly suitable to monitor complex and recursive processes, such as the Ca-Cu looping for H_2 production. Among a plethora of data-driven models, Gaussian Process Regression (GPR) is a method for supervised learning (Rasmussen and Williams, 2006). It allows performing regression without giving explicit parametrization to the underlying function, instead determining a distribution over the possible functions that are consistent with the observed data. The application of GPR has several advantages over popular machine learning methods used in process engineering, such as artificial neural networks. These include limited number of parameters to be estimated, the capability of automatically providing confidence intervals for the predictions and that of dealing with noisy measurements, by acting as *smoothing devices*. Although GPR has received great interest in recent years, its use for soft-sensing is still rather limited (Mei et al., 2016). Here, GPR models are proposed as soft-sensors to evaluate the conditions that trigger the switch from one stage to the next.

2. The Ca-Cu looping process

The Ca-Cu looping process is a novel concept for high purity H_2 production from CH_4 with integrated CO_2 capture. The process has been gaining increasing attention as a low-CO_2 emission solution for both power generation and H_2 production (Martini et al., 2016, 2017). The process consists of three stages, conducted cyclically in packed bed reactors. Switching between stages is performed by alternating the gaseous reactants fed to the reactor and changing the operating conditions in the fixed bed, mainly temperature and pressure. Figure 1 schematically shows the inlet and outlet flows of the stages and the main reactions involved in the solid phase. Data sets employed in the present work are collected via an experimental campaign. The solid bed contains three different solids: a Ni-based catalyst, to catalyse the reforming reactions, CaO, employed as CO_2-sorbent

material and Cu which is involved in the regeneration of CaO. The available set up allows the measurement of the following variables: temperature of the solid bed along the axial profile, $T_s(z)$, inlet and outlet gas temperatures, T_G^0 and T_G^{out}, inlet and outlet gas pressure, P_G^0 and P_G^{out}, outlet (dry) volume fractions, x_i^{out} and outlet (dry) volume flow rate, $\dot{V}_{tot}^{out}$.

In Stage A, sorption enhanced reforming takes place. The reactor is fed with a mixture of CH_4 and steam with a given steam-to-carbon ratio (S/C). The three main reactions are steam-methane reforming (SMR), water-gas shift (WGS) and carbonation of CaO. The last reaction allows the removal of the CO_2 formed, increases H_2 purity, CH_4 and CO conversions by shifting the SMR and WGS equilibria toward the products. In addition, the combination of these reactions makes the overall stage exothermic, so that the only energy duty is the one needed to compensate for the heat losses. This stage is considered terminated when the CaO is fully converted to $CaCO_3$, indicating that no more CO_2 can be captured by the fixed bed. To allow continuous operation, the $CaCO_3$ formed in this stages is regenerated to CaO by the Cu/CuO chemical loop carried out in stages B and C. In stage B, Cu is oxidized to CuO by feeding pressurized diluted air to the reactor. This stage is considered concluded when most of the Cu has been oxidised. The high pressure and low O_2 content prevent the calcination of $CaCO_3$.
Switching to stage C is performed by changing the feed to H_2 or other reducing species at lower pressure, such as syngas or CH_4. The reduction of CuO to Cu provides the energy required for the calcination of $CaCO_3$ that regenerates the CO_2 sorbent. When most of the CuO has been reduced, switching to stage A is performed again.

3. Switching criteria

Economic and quality criteria are proposed to determine the appropriate time to switch (t_s) to the next stage. In the previous section the definition of end times was based on the state assumed by the solid bed. However, measurements of the solid bed composition are not available, nor easy to perform in-situ at industrial scale. Therefore, the course of each stage should be monitored employing other variables, such as temperature or gas composition. In this work, t_s is determined via an optimization-based approach. Table 1 reports the objective functions to be maximized and constraints. P (€/time) is a profit

Table 1: Switching criteria employed for stages A, B and C.

Stage	Objective Function	Constraint
A	$\int_0^t P(\tau)\,d\tau$	$x_{H_2}^{out}(t) \geq 0.85$
B	$T_s^{out}(t)$	$\dot{M}_{O_2}^{out}(t)/\dot{M}_{O_2}^0(t) \leq 0.35$
C	$T_s^{out}(t)$	$\dot{M}_{H_2}^{out}(t)/\dot{M}_{H_2}^0(t) \leq 0.35$

function, depending on several variables, including V_{tot}^{out}, x_i^{out}, prices of chemicals, carbon tax on CO_2 emissions etc. $\dot{M}_i$ is the mass flow rate of species i, computed with the ideal gas law. T_s^{out} is the outlet bed temperature. Although quite simple, the selected criteria aim to fulfil multiple requirements. For stage A, operation should last until it is economically profitable while the required H_2 purity constraint is not violated. For stages B and C, the proposed criteria aim to maximize the amount of Cu oxidation and reduction, respectively.

The constraint is motivated by the fact that a release of considerable amounts of O_2 and H_2 is an indication of the two stages coming to an end. The behaviour of the objective functions has been studied offline (i.e. after completion of the batches, and collection of the data), finding that they admit a unique maximum. These criteria are applied to all the datasets collected, considering the stages separately, resulting in a wide dispersion of the optimal durations, even at fixed operating conditions. Such differences are mainly linked to run-to-run variations of hardly controllable variables, such as the solid bed state. This makes it necessary to implement the criteria in real-time (i.e. during the batch run, as soon as a new data point is collected), to enable timely switching. The application of these criteria lies on the availability of the time-profiles of concentrations of several components with delayed measurements. Therefore, an inferential model is needed to allow their estimation in real-time. This is achieved by employing GPR.

4. Method: Gaussian Process Regression models

Let $\mathscr{D} = \{(\mathbf{x}_i, y_i) \,|\, i = 1, \ldots n\}$ be a training set of input-output pairs, where n is the number of measurement points, $\mathbf{x}_i$ is a vector collecting the inputs (often collected in a matrix X) and y_i is the measured output at point i (often collected in a vector $\mathbf{y}$). The goal of GPR is to perform nonlinear regression without giving explicit parametrization of the underlying function. A prior probability is assigned to any possible function, such that higher probabilities are given to those functions which are considered more likely to describe the input-output observations (Mackay, 1998). The functions providing the best representation of the data are found by performing Bayesian inference collectively at the training points. Training of GPR models consists of two main steps:

a. Model selection. It consists of the choice of a kernel, k, which is a function of two arguments that set qualitative properties of the unknown function, such as smoothness or periodicity. The kernel measures the similarity between two training points x_i and x_j.

b. Model training. This step involves the tuning of a few hyperparameters, denoted by $\boldsymbol{\theta}$, through which k is parametrized in order to give flexibility to the selected model. In this work, the estimation of $\boldsymbol{\theta}$ is achieved by maximization of marginal likelihood (we refer to Rasmussen and Williams (2006), Ch. 5, for details on marginal likelihood estimation).

Once the model is trained, the prediction of the output y_* at any point x_* that does not belong to the training set is computed assuming that its conditional probability given the training data follows a Gaussian distribution, namely $y_* | \mathbf{y} \sim \mathcal{N}(K_*(K + \gamma I)^{-1}\mathbf{y}, K_{**} - K_*(K + \gamma I)^{-1}K_*^{\top})$, where K is a covariance matrix containing kernel evaluation of each pair of points that belong to the training set, γ is a hyperparameter tuning the smoothness of the function, K_* is the vector containing the kernel evaluations between all training points and the test point and K_{**} is the variance on the test point. The predicted value y_* is computed as the mean of the previous distribution: $y_* = \bar{y}_* = K_*(K + \gamma I)^{-1}\mathbf{y}$. The method automatically provides the confidence interval of the predicted value of the function as the posterior variance of the Gaussian distribution through the simple expression: $var(y_*) = K_{**} - K_*(K + \gamma I)^{-1}K_*^{\top}$.

5. Online determination of the switching time

The use of criteria in Table 1 makes it necessary to predict in real-time the following primary variables, $\mathbf{y}$: $\dot{V}_{tot}^{out}, x_{H_2}^{out}, x_{CO_2}^{out}$ during stage A, $\dot{V}_{tot}^{out}, x_{O_2}^{out}$ during stage B and $\dot{V}_{tot}^{out}, x_{H_2}^{out}$

during C. Separate GPR models have been trained for each of them, because the method holds for scalar outputs. Both training and test sets are a subset of the data sets employed in the previous section. As the computational time needed to train a model is $\mathcal{O}(n^3)$, model training is performed offline. The MATLAB® routine `fitrgp` is employed for this purpose. Among all the variables sensed in the set up, the predictors are selected as the ones satisfying two requirements: (i) being influential on the outputs, since employing non-influential variables is observed to cause overfitting and large prediction variances; (ii) being available in real-time. Based on these considerations, t, P_G^0 and inlet compositions, specifically S/C, $x_{O_2}^0$ and $x_{H_2}^0$ in stages A, B and C, respectively, are employed as predictors to target all the outputs. Other variables are expected to be influential on the outputs. However, their variability in the available datasets is rather limited, hence including them would be of little use. The predictor matrices, X_A, X_B and X_C for the three stages are constructed as $X_A = [\mathbf{t} \quad \mathbf{P_G^0} \quad \mathbf{S/C}]$, $X_B = [\mathbf{t} \quad \mathbf{P_G^0} \quad \mathbf{x_{O_2}^0}]$ and $X_C = [\mathbf{t} \quad \mathbf{P_G^0} \quad \mathbf{x_{H_2}^0}]$, respectively. Bold symbols identify vectors, whose entries are the values of the variable along the time series, $\mathbf{t}$. Due to the computational demand of GPR, the number of training data is set equal to a few thousand, building matrices of dimensions $\dim X_A = 1464 \times 3$, $\dim X_B = 3927 \times 3$ and $\dim X_C = 1791 \times 3$, respectively. The observations included in X_A belong to 24 datasets, 4 for each set of nominal operating conditions (S/C = 3, 4, 5 and $P_G^0 = 2$ and 7 bar), those in X_B belong to 49 datasets, 7 for each set of operating conditions ($x_{O_2}^0 = 3$ %, 5 %, 10 % and P_G^0 variable in the interval 3-8 bar) and the ones in X_C belong to 36 datasets, 12 for each value of $x_{O_2}^0$ (equal to 20 %, 39 % and 58 %). Predictors are standardised to reduce complexity during calculation and to avoid those having greater order of magnitude dominating those of a smaller one. The squared exponential (k_{se}) and rational quadratic (k_{rq}) kernels are employed to model $\dot{V}_{tot}^{out}$ and x_i^{out}, respectively.

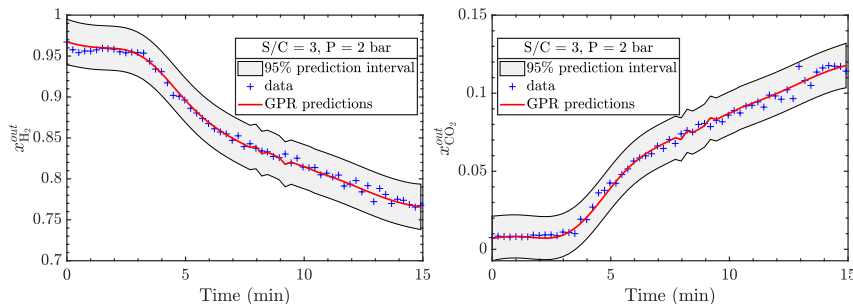
The predictive capabilities of the models are tested on 38, 97 and 221 datasets of the three stages. Figure 2 shows the predicted profiles of two key variables employed in stage A. These plots are representative of most of the results. GPR provides very reliable predictions, the underlying functions are quite smooth and the confidence intervals are sufficiently tight.


Figure 2: Time-profiles of: (a) $x_{H_2}^{out}$ and (b) $x_{CO_2}^{out}$ for stage A.

The real-time determination of t_s is simulated for several runs of each stage, by employing the GPR-based soft-sensors. At each sampling time (1 s), GPR soft-sensors use the measured values of the secondary variables to infer the values of the primary variables.

This way, the value of the objective function and constraints in Table 1 are computed. When the value of the objective function at the current time is smaller than the previously calculated one or the constraint is being hit, then switching is triggered (assuming that the constraint has a unique maximum). The use of GPR-based soft sensors, even in critical experimental runs, results in satisfactory performance. As an example, the actual value of t_s computed for one experimental run of stage A at S/C = 5, P_G^0 = 5 bar, results in 9.43 min. Conversely, scheduling the duration of t_s as the average of the values computed offline for all the data sets at the same operating conditions would result in $t_s = 11.59$ min, corresponding to an error of 23 %. In addition, such a time duration would not have allowed satisfying the constraint. The use of the GPR-based soft-sensors allows a real-time estimation of $t_s = 9.80$ min, which corresponds to a reduction in the error to only 3.89 %, which is a satisfactory performance for this application.

6. Conclusions

This work deals with the real-time determination of the switching instants of a cyclic process for H_2 production with integrated CO_2 capture. The proposed methodology is based on online evaluation of switching criteria, aiming to maximize economic and quality indicators. GPR-based soft sensors have been developed to make online predictions of these criteria. The use of GPR-based soft-sensors allows a real-time estimation of the optimal times to switch with a maximum error of only 4 % in the investigated runs. Future work should be devoted to identify reliable principles for a quantitative assessment of model performance and to improve model update techniques. This fact is crucial to abate process-model mismatches.

Abstract

The demand for energy, water and food (EWF) resources will continue to increase, especially as the population is expected to reach 9 billion by 2050. The consequences of this include resource exhaustion and environmental degradation. Global pressures, such as climate change and resources depletion have encouraged the deployment of alternative energy systems and integration of carbon capture and sequestration processes. Currently, most chemicals and energy carriers are derived from finite fossil fuels which are susceptible to price fluctuation. Biomass, a renewable carbon-based fuel can be considered a promising substitute that can reduce environmental footprints in various applications. Gasification is a preferred route for handling biomass, in which the gas mixture (syngas) product is utilised to drive gas turbines and produce clean energy. Moreover, it can also be used to substitute natural gas in the petrochemical plants for methanol and ammonia production. Analysing the utilisation strategy of diverse biomass feedstocks represents a fertile research problem that can be addressed from a EWF Nexus perspective, which enables the quantification of impacts of biomass utilization strategies on the EWF systems. In this study, the utilisation strategy of biomass gasification feedstock for the poly-generation of different products is evaluated from an economic perspective. The Aspen Plus simulation models an oxygen-steam gasification technology to generate the optimal characteristics for each utilisation technique. Moreover, a sustainability metric was utilised to quantify the effect of each technique on EWF resources and to extend the investment decision making. Preliminary results generated from the simulation are integrated into a linear programming optimisation model that identifies the optimum biomass utilisation techniques that consider environmental and economic performances. The framework developed enables the selection of the optimal mix of biomass techniques that maximises sustainability indices for EWF resource systems, whilst ensuring a positive generation of the three corresponding resources. The results demonstrate that urea production and power generation are the most viable biomass utilisation techniques.

Keywords: Biomass Gasification, EWF Nexus, Sustainability, Optimisation, Decision Making

1. Introduction

The notion of producing renewable chemicals and fuels is driving sustainable development in the modern society towards a decreasing dependency on fossil fuels. The annual global production of petrochemicals is very large and implies a need to identify alternative routes to replace the fossil-based feedstocks to reduce GHG emissions as part of the global sustainable development agenda (Andersson, 2013). One of the main solutions considered for achieving large reductions in GHG emissions, is the increased production and usage of bioenergy. Considering the current total energy supply of 475 EJ, the International Panel on Climate Change (IPCC) expects that 120 to 155 EJ of the annually supplied primary energy can be extracted from biomass by 2050 (IPCC, 2011). Gasification is considered as the most flexible biomass feedstock route for the generation of various advanced biofuels, such as Fischer-Tropsch diesel or methanol. Bio-methanol produced via gasification of biomass has the potential to replace petrol in conventional combustion engines which can secure the transportation sector with renewable energy. Biomass gasification is also useful for green chemical production where green ammonia can be produced, thereby reducing the dependency on fossil fuels and reducing the emissions of greenhouse gases from the fertiliser industry (Andersson, 2013).

Numerous studies have been conducted to highlight the potential for producing value added products from biomass recycling. Arora et al. investigated the production of a small-scale ammonia plant from biomass to ensure sustainable and profitable production. The study emphasised the techno-economic benefits resulting from ammonia biomass-based production. Calculations produced using Aspen Plus simulation illustrated a 54-68% reduction in CO_2 emissions in comparison to the fossil-based conventional ammonia plants. Moreover, a wider spectrum of studies have been conducted to review the current status of the biomass technology and its utilisation in the production of value added products (Arora et al., 2016). Pike et al. discussed the wide range of opportunities to produce value added products generation from biomass. The study adopted the chemical complex analysis system to evaluate the introduction of plants producing multiple biomass-based chemicals. The developed superstructure of biomass-based chemical production system determined the optimal configuration of plants, considering economic, environmental and sustainable perspectives (Pike et al., 2008).

EWF Nexus systems have been widely used in recent years to address complex resource management challenges, and assess the significance and magnitude of the environmentally possible impacts when supplying a service or product. Integrated analysis considering an EWF Nexus approach enables the identification of key synergies and trade-offs that may exist in the design and operation of EWF sub-systems. Moreover, renewable energy technologies when integrated into EWF Nexus system analysis can address some of the trade-offs between EWF resources (Ferroukhi et al., 2015). Al-Ansari et al. developed an EWF Nexus tool based on a life cycle assessment (LCA) where EWF Nexus sub-systems are transformed from a linear system to highly efficient closed loop systems. The Nexus tool integrates biomass gasification combined cycle (IBGCC) and CO_2 capture to assess the environmental impact of a hypothetical food security scenario in Qatar. The results illustrated near relative carbon neutrality can be achieved through the integration of photovoltaic (PV), biomass gasification coupled with carbon capture for the system considered (Al-Ansari et al., 2016, 2017).

In this study, the utilisation strategy of biomass gasification feedstock for the poly-generation of different products is evaluated from an economic perspective. An Aspen

Plus model simulating gasification technology is utilised to generate the optimal characteristics for each utilisation technique. Moreover, a sustainability metric is integrated into the model in order to quantify the effect of each utilisation technique on EWF resources and to improve the investment decision.

2. Model development

Advanced system models are necessary in order to undertake reliable process economic and energy efficiency analyses of integrated biomass gasification routes. As such, a flowsheet of the biomass gasification system is simulated using Aspen Plus software evaluating Qatar's biomass characteristics. This study is an expansion of previous work (AlNouss et al., 2018) and is novel as it optimises a unique set of biomass feedstock which includes date pits, food waste, manure and bio-sludge. The simulation takes advantage of oxygen and steam in the gasification of different feedstocks to generate H_2-rich syngas, utilized in the production of value-added products i.e. methanol, urea, power through IBGCC and Fischer-Trospch liquids (FTL). Table 1 summarizes the elemental analyses of the biomass feedstocks considered in the study based on Qatar's characteristics.

Table 1: Proximate and ultimate analyses of biomass feedstock

	Manure	Dried Sewage Sludge	Date Pit waste	Food Waste
Mass Flow (tons/y)	5.27×10^5	3.65×10^4	7.60×10^3	7.0×10^3
Proximate analyses (wt %)				
Volatile matter	65.0	8.8	81.8	86.1
Fixed carbon	13.5	19.4	17.2	7.7
Ash	21.6	71.8	1.0	6.2
Moisture	27.4	8.3	5.0	75.1
Ultimate analyses (wt %)				
C	37.1	19.1	49.8	46.4
H	5.1	2.3	6.8	6.9
O	31.4	5.7	37.9	37.4
N	3.7	1.1	4.5	3.1
S	0.5	0.1	0.0	0.0
Cl	1.0	0.0	0.0	0.0
Ash	21.4	71.8	1.0	6.2
LHV (dry basis) (MJ/kg)	19.09	16.40	25.30	19.84

The generated H_2-rich syngas is utilized in the production of value-added products: methanol, urea, power through IBGCC and Fischer-Trospch liquids (FTL). Both urea and methanol production are described as petrochemical processes that utilise the produced syngas in a series of sections to produce the aforementioned value-added products. The main uses of methanol are as fuel, solvent and anti-freeze, whereas urea is mainly used as fertilizer. The liquid fuels and power production are described as emerging processes that utilise the produced syngas in a series of sections to produce the value-added products. Liquid fuels are used in many sectors such as aviation, transportation, heating and lightning, whereas power is mainly used to drive turbines. After the simulation of the four processes, an economic evaluation was conducted to quantify revenue, capital and operating costs. In addition, the EWF Nexus system considered is quantified based on the footprint of each of the three resources for every utilisation technique. Preliminary results from the simulation are integrated into a linear program to identify the optimal biomass utilisation strategies that enhance both economic and environmental performances, through minimising sustainability indexes for EWF systems while ensuring a positive generation of the three corresponding resources.

3. Results and discussion

The results from EWF footprints for each utilisation technique are quantified by comparing the consumption and generation of each resource. Table 2 summarises the main results from the economic evaluation and the EWF Nexus system. Subsequently, a sustainability metric introduced recently by (El-Halwagi, 2017), is used to quantify the effect of the footprints compared to the economic benefit for each process. To do this, the return on investment (ROI) is first calculated using equation 1, and then compared to the EWF footprints using the sustainability weighted return on investment metric (SWROIM) calculated using equation 2.

Table 2: EWF net values for the four utilization techniques

	Ammonia/ Urea	Methanol	Liquid Fuels	IBGCC
Total Capital Cost [$]	1.4E+08	1.2E+08	1.3E+08	1.4E+08
Revenue [$/y]	4.2E+07	3.1E+07	3.0E+06	1.1E+07
Water Consumption [kg/h]	4.4E+04	9.2E+04	2.0E+04	1.7E+05
Water Generation [kg/h]	5.0E+04	9.2E+04	3.6E+04	2.1E+05
Net [ton/h]	5.8E+00	-8.2E-02	1.6E+01	3.5E+01
Food Waste Consumption [kg/h]	8.0E+02	8.0E+02	8.0E+02	8.0E+02
Food/Fertilizer* [kg/kg] ((MDPS), 2018; WorldBank, 2018)	2.6E+03			
Food Generation [tons/h]	3.1E+04			
Net Food [tons/h]	3.1E+04	8.0E-01	8.0E-01	8.0E-01
Energy Consumption [kW]	4.2E+04	4.0E+04	4.2E+04	3.9E+04
Energy Generation [kW]				8.1E+04
Net Energy (MW)	-4.2E+01	-4.0E+01	-4.2E+01	4.2E+01

$$ROI_p = \frac{AEP_p}{TCI_p} \qquad \text{eq.(1)}$$

Where the term AEP abbreviates the net annual economic profit, and the term TCI abbreviates the total capital investment.

$$SWROIM_p = \frac{AEP_P\left[1 + \sum_{i=1}^{N_{Indicators}} w_i\left(\frac{Indicator_{p,i}}{Indicator_i^{Target}}\right)\right]}{TCI_p} \qquad \text{eq. (2)}$$

Where the index *i* is for the considered sustainability indicators apart from the net annual economic profit with *i=1,2,..., N_{indicators}*. w_i is the weighing factor indicating the relative importance ratio of the *i*th sustainability indicator compared to the net annual economic profit. The associated rations with EWF footprints are all assumed to be 0.25. They are manipulated to determine the effect of each footprint on the overall sustainability metric. *Indicator_{p,i}* term corresponds to the value of the *i*th sustainability indicator linked with the *p*th alternative. The term *Indicator_i^{Target}* represents the benchmark value of the *i*th sustainability indicator. The comparison between results generated from sustainability metric (SWROIM) computations for each EWF Nexus system and the corresponding return on investment (ROI) demonstrated that urea production and power generation are the only techniques selected. Methanol and liquid fuels production are excluded due to their low SWROIM value which illustrates their negative impact on sustainability. Figure 1 illustrates the results of the ROI and SWEOIM for each utilisation technique.
Figure 1: ROI and SWROIM results for different utilization techniques

In order to further refine the results and identify the best performing biomass utilisation techniques that considers both environmental and economic performances; a linear programming optimisation model is developed allowing the selection of optimal mix of biomass techniques that maximizes sustainability indices for EWF systems. The model, presented in Table 3 also takes into consideration the flow of resources into each application through imposing a positive net generation of EWF.

Table 3. Model formulation

Objective function	Water	$\max\sum_{i=1}^{4} w_i \times x_i^w$
	Energy	$\max\sum_{i=1}^{4} e_i \times x_i^e$
	Food	$\max\sum_{i=1}^{4} f_i \times x_i^f$
Constraints	$\sum_{i=1}^{4} nw_i \times x_i^w \geq 0$	$\sum_{i=1}^{4} x_i^w = 1$
	$\sum_{i=1}^{4} ne_i \times x_i^e \geq 0$	$\sum_{i=1}^{4} x_i^e = 1$
	$\sum_{i=1}^{4} nf_i \times x_i^f \geq 0$	$\sum_{i=1}^{4} x_i^f = 1$

Where x_i^w, x_i^e and x_i^f are decision variables representing the percentage of contribution of each technology in each sector. w_i, e_i and f_i are the SWROIM for water, energy and food, respectively, for each technique. The first three equations ensure a positive net amount of EWF such that nw_i, ne_i and nf_i are the net values defined by the difference between generation and consumption amounts of a source. The final three equations impose the sum of percentages of each type of decision variable to be 100%. The results generated support findings from the first part as urea is selected again as a sustainable biomass utilisation technique as it demonstrates the largest SWROIM for both water and food. As for energy, utilising a combination of urea generation and power production results in a high SWROIM and a positive net energy generation. The results from the two methods are illustrated in Table 4.

Table 4: Optimal sustainability indexes results

Technique	Urea	Methanol	Liquid Fuels	IBGCC
ROI (%)	32%	11%	5%	10%
SWROIM (%) (0.25 each)	33%	11%	5%	12%
SWROIM (%) (0.5 Water, 0.25 others)	39%	11%	5%	10%
SWROIM (%) (0.5 Food, 0.25 others)	24%	8%	3%	12%
SWROIM (%) (0.5 Energy, 0.25 others)	32%	11%	5%	10%
Decision variable (Water)	1	0	0	0
Decision variable (Food)	1	0	0	0
Decision variable (Energy)	0.504	0	0	0.496

4. Conclusion

There has been significant global progress worldwide to diversify resource utilization options in order to limit GHG emissions and to prolong natural resources. This study is novel as it considers an EWF Nexus framework with an emphasis on biomass utilisation to design a system that will utilize the waste biomass from built environment in Qatar to produce a high-energy combustible gas. A utilisation strategy of biomass gasification feedstocks is evaluated from an economical perspective considering oxygen-steam gasification technology. Quantification of the effect for each utilisation technique on the EWF resources is conducted in which a EWF sustainability metric is utilised to inform and enhance investment decisions. Finally, urea production demonstrated that it is the most attractive amongst the utilisation techniques considered.

Abstract

We propose the integration of a holistic sustainability assessment framework in computer-aided molecular design (CAMD). The framework enables the assessment of life cycle (LCA) and safety, hazard and environmental (SHE) impacts from cradle-to-gate of chemicals designed through CAMD. It enables the calculation of an overall of 14 sustainability-related indices, with some of them aggregating several impact categories. Lack of models and data gaps in property prediction are addressed systematically through a data mining approach which exploits on-line similarity assessment with existing molecules for which data exist or can be predicted. The framework is implemented both simultaneously with CAMD or after CAMD to assess the designed solvents. A case study is presented on the design of phase-change solvents for chemisorption-based post-combustion CO_2 capture. Results indicate that the proposed approach enables the identification of verifiably useful phase-change solvents which exhibit favourable performance trade-offs compared to a reference CO_2 capture solvent.

Keywords: CAMD, Sustainability, LCA, SHE, Post-combustion CO_2 capture

1. Introduction

CAMD has been used widely in applications to design molecules of improved performance (Papadopoulos et al., 2018). The most common performance criteria include molecular or process properties pertaining to the thermodynamic and/or process performance of the evaluated molecular structures. While these are very important, the sustainability behavior of the evaluated molecules is also worth investigating; many chemicals exhibit significant environmental, health and safety impacts, rendering them undesired despite their otherwise favorable performance. Previous efforts incorporate sustainability-related considerations into CAMD, such as the work of Ten et. al (2016) where inherent safety and occupational health indices are considered and the work of Khor et. al (2017) which includes safety and health indices to select sustainable solvents for palm oil extraction. While these are among the few works which attempt to consider aspects of sustainability, in most publications the potential impact to the environment is either not assessed or considered to a limited extent through indices such as toxicity,

flammability, emissions etc. Systematic sustainability assessment requires a holistic view of the chemical life-cycle, at least considering all the upstream processes employed for the chemical production together with the potential hazards associated with its use. Such an approach, and its incorporation in CAMD, calls for the use of much more comprehensive indices including resource depletion and requirements, energy demands, emissions etc., to achieve a reliable differentiation over a certain, typically large, number of molecules. However, due to data gaps, several of the necessary properties cannot be predicted using group contribution (GC) methods which are predominantly used in existing CAMD implementations. Data mining methods (Lu et al., 2014) can be used to analyse, interpret and exploit molecular similarities to supplement GC models to predict dangerous properties, to potentially improve their predictive capabilities and to expand the range of sustainability indicators that can be predicted. However, such approaches have not yet been investigated as part of sustainability-based CAMD implementations.

2. Proposed approach

2.1 Framework overview

Papadopoulos et al. (2016) proposed the integration of CAMD with sustainability assessment in an approach where the latter was considered as an afterthought to solvent design. We hereby propose for the first time an approach for simultaneous CAMD and sustainability assessment. Compared to Papadopoulos et al. (2016) we employ the same sustainability indicators, but here data gaps in sustainability property prediction are addressed through data mining, while the method may account for solvents exhibiting either vapour-liquid or vapour-liquid-liquid phase-changes.

The framework supports evaluation of two main categories: (1) the holistic environmental benefit at the cradle-to-process gate level and (2) the substance hazard identification for evaluation of the harm potential in accidental scenarios (Table 1). Category (1) is approached through a Life Cycle Assessment (LCA) methodology used to calculate indices such as cumulative energy demand, global warming potential and EI99, with the latter comprising impacts over 11 categories, defining human health, eco-system quality and resource depletion damages. The LCA metrics are predicted by "black box" type models in the form of neural networks based on the molecular structure of the studied compound (for details see Wernet et al., 2009). Category (2) includes safety, health and environmental hazard (SHE) assessment Predictions for the necessary properties are performed using GC models when available. Lack of models and data gaps are addressed systematically through a data mining approach which exploits on-line similarity assessment with existing molecules for which data exist or can be predicted. In SHE assessment, single S, H and E scores are calculated based on various dangerous property values, shown in Table 1. Dangerous property parameters are obtained from a database (if available), calculated by the GC+ method (Hukkerikar et al., 2012a) or estimated by a similarity approach based on the local lazy learning method (LLL). For a given compound with a missing experimental or GC+ method parameter, the LLL method identifies its nearest neighbours (the most structurally similar molecules) in a given dataset and then uses these molecules to predict the compound property as follows:

$$y_{pre} = \sum_{i=1}^{n} \frac{S_i}{\sum_{j=1}^{n} S_j} * y_{i,db} \qquad (1)$$

where y_{pre} is the predicted value of the query compound, $y_{i,db}$ is the property value of the i-th nearest neighbour from the dataset, S_i is the Tanimoto coefficient indicating the similarity value between the compound and the i-th neighbour, and n is the optimized

number of employed nearest neighbours. Details are reported in Shavalieva et al. (2018).

Table 1: Dangerous properties and estimation methods used for SHE assessment.

Dangerous Property	Parameter	Estimation method
Safety (*S*)		
Mobility	Difference between boiling point of the pure substance and highest process temperature	GC (Hukkerikar et al., 2012b)
Fire/ Explosion	Difference between flashpoint of the pure substance and highest process temperature	GC (Hukkerikar et al., 2012b)
Acute toxicity	LD50$_{oral}$ (rat) – the amount of orally ingested chemical that causes death to 50% of rats (mg/kg body weight)	GC+ (Hukkerikar et al., 2012a)
Health (*H*)		
Chronic toxicity	Permissible exposure level (PEL) – a US legal exposure limit (mg/m^3) of an employee to a chemical, given as the average exposure concentration over 8 hours	GC+ (Hukkerikar et al., 2012a)
Environment (*E*)		
Water-mediated effects	Toxicity (LC50/EC50$_{aquatic}$) - concentration (mg/l) of a chemical in water causing death to 50% of most sensitive aquatic species	Similarity (Lu et al., 2014; Shavalieva et al., 2018)
Degradation in the environment	Persistency (days) - half-life of a chemical in the environment (water)	Similarity (Lu et al., 2014; Shavalieva et al., 2018)
Air-mediated effects	Chronic toxicity index	GC+ (Hukkerikar et al., 2012a)
Accumulation	Bioconcentration factor (BCF) assesses chemical accumulation in a living organism.	Similarity (Lu et al., 2014; Shavalieva et al., 2018)

2.2 Incorporation into CAMD

The framework obtains molecular structure information from CAMD and returns the values of the desired sustainability indices. It can be used either simultaneously with CAMD or after the molecules are obtained from CAMD, using criteria to evaluate their sustainability performance. The molecular structures in CAMD are represented by first order functional groups, hence they are compositions of the contained groups and their appearance frequency. For each structure the proposed implementation enables the generation of all potential isomers through RDKIt (Landrum, 2016) in the form of SMILES (Simplified Molecular Input Line Entry System). For each isomer, the corresponding SMILE is further used for the calculation of SHE and LCA scores. LCA values are computed and incorporated to FineChem models (Wernet et al., 2009). Dangerous properties required to compute *S* and *H* scores are generated by the GC+ method (Hukkerikar et al., 2012a). The dangerous property values required for *E* are computed by the similarity and GC+ methods. When the similarity approach is used, the numbers are calculated for each isomer and then averaged to give a single index to be used for *E* score calculation. The outcome of the calculation for *CED*, *GWP*, *EI99*, *S*, *H* and *E* values is returned back to CAMD to be used in the molecule selection process.

3. Case study details and mathematical problem formulation

The aim is to design solvents for chemisorption-based, post-combustion CO_2 capture. In this work we focus for the first time on phase-change solvents, exhibiting vapour-liquid-liquid phase changes, which hold great promise to reduce the regeneration energy

requirements of CO_2 capture processes by over 50% (Zhang et al., 2012). Such solvents exhibit a liquid-liquid phase change upon reaction with CO_2 and increase of temperature. This enables mechanical solvent separation prior to introducing a reduced amount of CO_2-solvent product into the thermal regeneration step, which occurs at lower temperature than in conventional solvents, hence reducing regeneration energy. Results from the following cases are discussed:

1) Case A, where we use the proposed sustainability model simultaneously with CAMD.
2) Case B, where solvents are first designed using CAMD and their sustainability characteristics are calculated at a post-design step.

The implementation follows the multi-objective CAMD formulation of Papadopoulos et al. (2016), as shown in Table 2 for cases A (Eq. (2) and (4)) and B (Eq. (3) and (4)). In case B the sustainability properties are evaluated only for the solvents of the Pareto front obtained from CAMD.

Table 2: Mathematical formulation of Cases A and B

Case A		Case B	
$\max\limits_{G}$ ρ		$\max\limits_{G}$ ρ	
$\min\limits_{G}$ $P_{vp}, C_p, n, RED,$	(2)	$\min\limits_{G}$ P_{vp}, C_p, n, RED	(3)
$GWP, CED, EI99, S, H, E$			
s.t. $\quad T_m < T_{Abs}, T_{bp} > T_{Des}, \left|\delta^s - \delta^{CO_2}\right|_{T_{Abs}} < \varepsilon, \left|\delta^s - \delta^{H_2O}\right|_{T_{Des}} > \varepsilon$			(4)

Based on Papadopoulos et al. (2016) density (ρ) should be maximized, whereas vapour pressure (P_{vp}), heat capacity (C_p), viscosity (n) and relative energy difference (*RED*) should be minimized. *RED* is a scaled measure of CO_2 solubility in the solvent. Melting point temperature (T_m) should be less than absorption temperature (T_{Abs}) and boiling point temperature (T_{bp}) should be higher than desorption temperature (T_{Des}). The solubility parameter difference between solvent (δ^s) and CO_2 (δ^{CO2}) should be lower than a value ε to ensure solvent-CO_2 miscibility and the same difference between δ^s and δ^{H2O} should be higher than ε at T_{Des} to support liquid-liquid phase separation. We consider the following groups: CH_3-, -CH_2-, >CH-, >C<, -OH, -CH_2-NH_2, -CH_2-NH-, -CH_2-N<, >CH-NH_2, >CH-NH-, CH_3-NH-, CH_3-N<. The total number of groups allowed in each molecule range from 6 to 16, with up to 1 amine group. The latter allows for generation of simpler molecules, with fewer isomers, hence facilitating the use of the similarity approach in Case A. T_{Abs} is set to 40ºC and T_{Des} to 90ºC. The ε value is set to 7 $(MPa)^{0.5}$ (Papadopoulos et al., 2016). The sustainability indices are calculated as averages over all generated isomers for each molecule. Properties P_{vp}, ρ, δ^s and *RED* are calculated from Hukkerikar et al. (2012b), n from Conte et al. (2008) and C_p from Kolska et al. (2008).

Comparison between cases is facilitated by an aggregate index J_i to generate Pareto fronts between the index and each property. The latter indicates how the overall performance of each solvent (i.e. in all properties considered simultaneously) is affected by changes in each property separately (Papadopoulos et al., 2016). The resulting multi-criteria selection problem includes the identification of the Pareto structures by generation of a Pareto front per property $j \in Pr$, with $Pr = \{\rho, P_{vp}, C_p, n, RED, GWP, CED, EI99, S, H, E\}$, considering the index J for every molecule i against each one of the properties.

4. Results and discussion

Indicative results are shown in Figure 1 (left) as a Pareto front of *RED* vs. *J*, for Cases A and B. The ID numbers correspond to solvents numbered within an original, larger set obtained from CAMD. The Pareto front shows that the two cases include few similar and

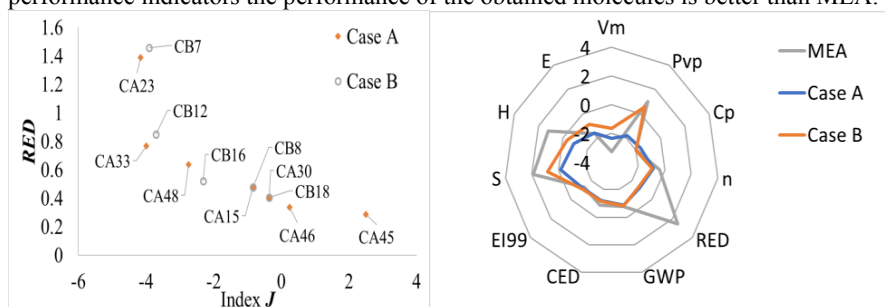
few different solvents. In the latter case their *RED* and *J* values are close. Due to space limitations the Pareto fronts of all properties against *J* are omitted. Observation of all other diagrams shows similar results to Figure 1 (left), except for properties P_{vp}, *S*, *H* and *E*. Consideration of the latter, results in molecules exhibiting better performance in Case A, compared to Case B. A similar trend also appears in Figure 1 (right). It shows the optimum value obtained for each property in Cases A and B (the values may correspond to a different solvent). Values for the 4 aforementioned properties are clearly different, whereas values for C_p, *n*, *RED*, V_m, *GWP*, *CED* and *EI99* are either the same or similar. A very intense difference appears in P_{vp}. This means that when sustainability is considered during CAMD the designed molecular structures exhibit lower P_{vp}. This indicates a reasonable correlation between high sustainability performance and P_{vp}. Solvents with lower P_{vp} exhibit lower emissions hence enhancing some sustainability indicators. Figure 1 (right) also compares the performance of the obtained molecules with MEA (monoethanolamine), which is the reference solvent in CO_2 capture. In several performance indicators the performance of the obtained molecules is better than MEA.


Figure 1: Pareto fronts between RED (sovent-CO_2 solubility) vs. index *J* (left), Optimum property values obtained by solvents in Cases A and B compared to MEA (right).

Table 3: Composition of selected, highly performing solvents from Cases A and B

ID	Groups	Frequency of appearance
CA23	[-CH$_3$,>CH$_2$,-OH,-CH$_2$-N<]	2,3,1,1
CA26	[-CH$_3$,>CH$_2$,-OH,>CH-NH-]	2,3,1,1
CA55	[-CH$_3$,>CH$_2$,-CH$_2$-NH-] (DBA)	2,5,1
CB7	[-CH$_3$,>CH$_2$,-OH,-CH$_2$-N<]	2,2,1,1
CB12	[-CH$_3$,>CH$_2$,-CH$_2$-NH$_2$] (HEXA)	1,4,1
CB16	[-CH$_3$,>CH$_2$,-CH$_2$-NH-] (DPA)	2,3,1

Table 3 shows molecular structures selected through observation of Pareto fronts for all properties vs. index *J*. It includes solvents such as Dibutylamine (DBA), Hexylamine (HEXA) and Dipropylamine (DPA) which are known phase-change solvents (Zhang et al., 2012). This indicates that CAMD identifies such solvents in both Cases A and B. Notice that some structures contain a OH group. In Case A they are 75% of all the designed solvents, whereas in Case B they are only 21% of the entire set. This is a clear indication that when sustainability is considered during CAMD it drives the search toward OH-containing structures. Such structures may not favor phase-change behavior because OH enhances solvent-water miscibility, whereas solvent-water immiscibility is desired. Figure 2 shows the performance of the structures in all properties, compared to MEA. The overall performance, expressed by *J*, is better than MEA for all solvents. In 7 of the 11 properties the performance is better or similar to MEA.

	V_m	P_{vp}	C_p	n	RED	GWP	CED	EI99	S	H	E	J

CB12												
CB16												
Figure 2: Performance of selected solvents compared to MEA, blue bars pointing right indicate better performance, red bars pointing left indicate worse performance

5. Conclusions

This work presents the integration into CAMD of a holistic sustainability assessment framework. The framework can used simultaneously with CAMD or after CAMD (sequentially) for the assessment of the designed molecular structures. Implementation shows that both the simultaneous and sequential approaches enable the identification of solvents which are verifiably good candidates for phase-change, CO_2 capture operations. The solvents obtained from the simultaneous approach exhibit a preference toward hydroxyl containing groups which may hinder the appearance of phase-change phenomena in this particular application. The overall performance of the proposed solvents, obtained with both approaches, is better than MEA.

Abstract

Multicomponent mixtures can be separated into their single components by mean of different distillation train configurations. The standard design procedure consists of the assessment of the optimal columns configuration according to the economic and operational aspects. Anyway this optimal design is strictly related to the operating conditions, i.e. perturbations, when present, can seriously turn the tables. In these cases a flexibility analysis could be of critical importance to assess the operating conditions range of better performance for a system configuration with respect to another one.

This is the typical case of biorefineries (and bio-processes in general) where the composition perturbations downstream the fermenter across the year's seasons are completely normal due to the floating nature of the feedstock. Since no similar studies have been found in literature, a brand new ABE/W (acetone, n-butanol, ethanol, water) mixture separation case study has been set up; this mixture derives from an upstream microbial conversion process and the successful recovery of at least biobutanol and acetone is crucial for the profitability of the operation.

Therefore the purpose of this paper is the comparison between the possible distillation train configurations from a flexibility point of view. We are interested in particular in highlighting the differences, if present, between the economic optimal solution and flexibility optimal configuration that sometimes could not be the same, causing this way a very profitable design to be much less performant under perturbated conditions.

The flexibility assessment has been performed with an established procedure introduced in previous papers; all the flexibility indexes proposed in literature have been used both of simple and most complex usage in order to refine the analysis and a flexibility economic assessment has been carried out as well. Finally the two different configurations as well as the two different procedures (operating conditions based vs perturbated conditions based) have been compared both from a design and an economic point of view; then analogies and differences as well as their consequences from a decision making point of view have been highlighted and discussed.

Keywords: flexibility analysis, design optimization, distillation, column trains

1. Introduction

In refinery operations distillation has always been the leading separation process. In designing a distillation column, given the inlet streams (T, P, partial flowrates), column

top pressure, type of condenser (total or partial) and two design (separation) specifications, one degree of freedom stays unfilled. Either reflux ratio R (or ratio R/R_{min}) or number of stages N should be fixed in order to univocally determine the unit design, anyway no physical constraints can help us to make a choice.

The standard decision making process to select the number of stages is indeed an economic-based optimization. Capital and operating costs for given specifications are calculated at different number of stages N (i.e. reflux ratios); due to the increasing CAPEX and the decreasing OPEX trends with respect to N, the total cost function shows a minimum for the R and N values corresponding to the most profitable column design. However it is worth selecting less profitable solutions whether the optimum point is located close to R_{min} or N_{min} conditions.

When multicomponent mixtures have to be treated, distillation trains need to be designed. Several distillation train configurations are possible according to the amount of components present in the feed and how many of them are worth to be recovered. For instance the simplest configurations for a multicomponent mixture with two components recovery required are shown in Figure 1. They're namely defined as:

  A) indirect configuration (sequential recovery from the heaviest to the lightest component);

  B) direct configuration (sequential recovery from the lightest to the heaviest component);

  C) midsplit configuration (a preliminary split between heaviest and lightest components is performed, then the separation is refined to achieve specification).

Each single column (and related equipment) is then designed on the basis of the lowest total cost and the cheapest train configuration is selected.

This procedure is well established and it has always worked well so far, anyway it has a main limitation: the economic assessment and equipment design are strictly related to the nominal operating conditions, i.e. they don't take into account feedstock or operating conditions perturbations that could occur. This means that, whether a feed composition perturbation occurs, the system could not be able to achieve the separation specifications or at least a relevant increase of operating costs can be detected causing the most profitable design not to be as profitable as expected.

In refinery's operation these problem are less appreciable since long-term contracts for crude oil supplying and blending processes ensure an almost constant and stable feedstock quality. However, during last 15 years there has been an increasing interest for the production of chemicals and fuels from renewable resources because of growing concerns about global warming and climatic change, increasing crude oil price and existing legislations restricting the use of non-renewable energy sources. The direct consequence of this trend results in an even more increasing demand for bio-based fuels and raw materials, i.e. bio-refinery processes. Anyway bio-processes are highly subjected to composition perturbations downstream the fermenter across the year's seasons due to the floating nature of the feedstock.

Being fermentation usually carried out as a batch process, in order to ensure the desired daily productivity, several fermenters working at the same time are required. On the other hand, even when continuous fermenters are used, their scale up and then the feed flowrate that can be processed have a limit. These conditions cause the fermentation process section to be very expensive, therefore a constantly good performance of the products recovery section is of critical importance for the profitability of the plant.

In the light of the above an a priori flexibility analysis of the different distillation train configurations is non-optional for this kind of separation in order to allow the decision maker to make a multi-criteria-based choice about the optimal design to be selected.

2. Objectives and methodology

The purpose of the paper is the economic and flexibility based comparison between different distillation train configurations aimed to the same separation specifications.

As already mentioned, the economic optimal design provided was determined by mean of the usual procedure; capital and operating costs have been estimated using Guthrie (1969) – Ulrich (1984) - Navarrete (2001) correlations.

Flexibility analysis has been performed both from a deterministic (Swaney & Grossmann, 1985; Saboo and Morari, 1985) and a stochastic (Pistikopoulos & Mazzuchi, 1990) point of view and coupled with economics according to the procedure shown by Di Pretoro et al. (2019).

ProSim Plus® process simulator has been used to assess the feasibility of the separation as well as to estimate all process parameters.

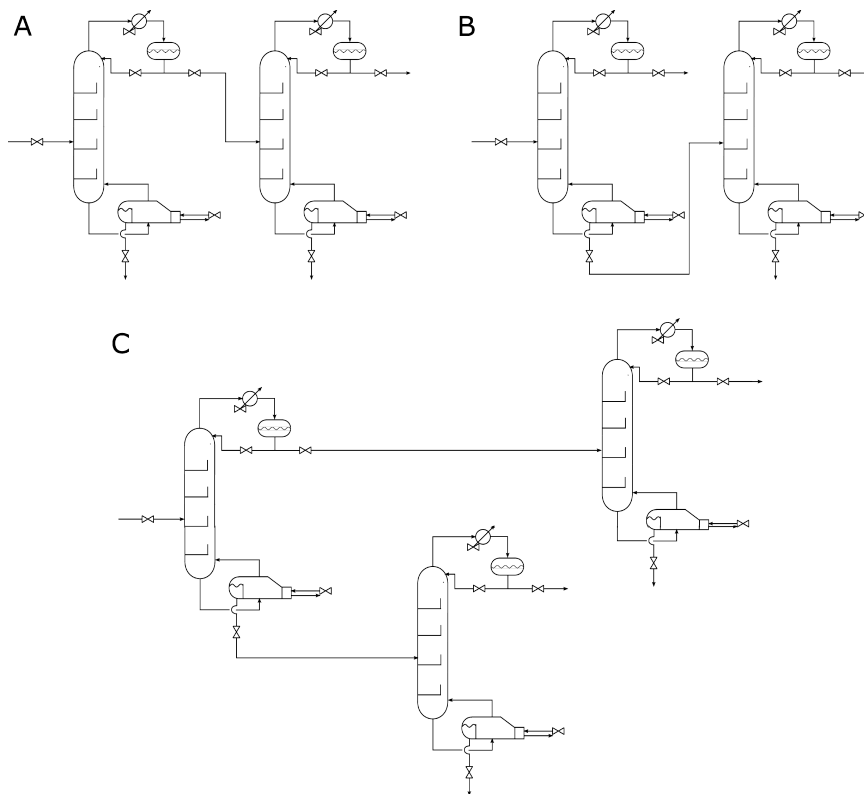
Since no former application of flexibility analysis to distillation trains has been found in literature, a new case study referring to the separation of an ABE/W mixture, coming from a fermentation process and a preliminary dewatering operation, has been proposed. The feed composition is listed in Table 1.


Figure 1 - Distillation train configurations for two components recovery

Table 1 - Feed components partial flowrates

Component	Partial flowrate (mol/s)
Acetone	12.030
Ethanol	3.839
n-Butanol	61.328
Water	12.428

The successful recovery of at least biobutanol and acetone is considered crucial for the profitability of the operation. In order to do this, a minimum of two distillation columns are required and three configurations are possible as previously shown in Figure 1. Midsplit configuration specifications are as follows:

1. Split column:
    1.1. Acetone recovery ratio in the distillate: 0.995;
    1.2. n-Butanol recovery ratio in the bottom: 0.98;
2. Acetone recovery column (top column):
    2.1. Acetone recovery ratio in the distillate: 0.995;
    2.2. Distillate acetone mass fraction: 0.995;
3. n-Butanol recovery column (bottom column):
    3.1. n-Butanol recovery ratio in the bottom: 0.98;
    3.2. Bottom n-butanol mass fraction: 0.99.

Specifications for direct and indirect configuration can be easily deducted from the midsplit ones. The direct configuration has resulted to be highly unfeasible since we should recover in the first column a highly acetone concentrated stream from a feed with a very low acetone molar fraction. Therefore only indirect and midsplit configurations will be compared.

3. Optimal design and flexibility assessment

As already mentioned, the standard design procedure has been conducted as usual; optimal number of stages and relative annual total cost for each column are listed in Table 2. With an overall annual cost of 933,509 \$/y vs 1,084,082 the indirect configuration results to be the most convenient with respect to the midsplit one.
The addition of a preliminary column indeed does not substantially affect the acetone column utilities consumption.

Table 2 - Distillation train optimal design

	1st column		2nd column		3rd column	
	N (feed)	Cost (\$/y)	N (feed)	Cost (\$/y)	N (feed)	Cost (\$/y)
Indirect	16 (10)	580,016	50 (46)	353,493	/	/
Midsplit	35 (9)	455,493	50 (47)	352,224	16 (8)	276,365

First of all a flexibility analysis based only on the actual feasibility of the separation (i.e. without taking into account equipment sizing) has been performed. The most critical parameters, as well as the most likely to change, are water and butanol fractions; therefore water and butanol partial flowrates were then considered the uncertain parameters for the analysis.

Despite what usually happens in these situations and what we expected, the midsplit configuration, i.e. the one with one column more, doesn't result to be more flexible than the indirect one as shown in Figure 2. On the contrary it is slightly less performant. For a water vs. n-butanol ratio higher than 0.23 (0.22 for the midsplit) indeed the separation is not feasible at all.

According to the Swaney & Grossmann index (F_{SG}), that assesses the highest simultaneous perturbation of all uncertain parameters that the system is able to withstand, the indirect configuration flexibility is about 5% (midsplit about 4%). According to Saboo & Morari the Resilience Index (RI), that defines the largest total disturbance load a system is able to withstand independently of the direction of the disturbance, stays around 8% (midsplit about 7%). Finally, according to the Pistikopoulos & Mazzuchi stochastic flexibility index, evaluating the probability that the system could absorb the disturbance, we find SF=77.86% (75.85% for the midsplit) in case of a normal probability perturbation distribution with a 10% variance. These values don't take into account the equipment sizing but thermodynamics only; it means no matter how much we pay for a bigger reboiler or a larger column, no higher flexibility value can be achieved. The same feasibility region has been obtained by changing the columns number of stages between approximately 0.75 and 1.5 times N_{opt}.

Flexibility analysis and economic assessment have then been coupled as shown in Di Pretoro et al. (2019). Total annual costs vs. partial flowrates perturbations have been plotted for the indirect configuration in Figure 3.a. An analogous trend has been obtained for the midsplit configuration.

However, the three columns configuration keeps being more expensive than the two column one, i.e. even under perturbated condition the external duties overconsumption is not compensated by the additional equipment despite what usually happens in standard distillation cases.

Costs result to be higher whether a bigger oversizing is necessary, i.e. positive deviation for both water and butanol flowrates, and along the operating conditions close to the feasibility boundary.

Moreover, the additional cost vs. flexibility plot for the deterministic indexes is reported in Figure 3.b as well; since F_{SG} represents the flexibility related to the simultaneous deviation of all uncertain variables, it implies a higher cost compared to the same RI value.
Figure 2 - Feasibility diagrams (Green = Feasible, Blue = Unfeasible)
Figure 3 - Economic assessment (Indirect configuration): a. Costs vs. partial flowrates; b. Costs vs. flexibility

4. Conclusions

This paper introduces the comparison of distillation trains configurations both on a flexibility and economical basis. Flexibility assessment of distillation trains (involving both series and parallel columns) have been successfully performed with deterministic as well as stochastic indexes. Results have then been coupled with an economic assessment in order to obtain the overcost vs. flexibility analysis plot providing a critical tool to the decision maker.

The indirect configuration, that was the cheapest one, resulted to be also a little bit more flexible than the midsplit configuration, despite the expectation. The economic gap due to the additional column is conserved also under uncertain conditions as well as non-optimal column design. Moreover we can state that beyond a F_{SG}=4% or RI=7% it is less worth investing since the additional costs line becomes steeper.

However, beside the numerical results that are case-specific, the outcome of general validity is that, in thermodynamically constrained system, the feasibility and flexibility boundaries cannot go over a certain value by adding separation stages to the distillation column or, in general, investing more. An a priori flexibility analysis and economic assessment could then be crucial for making the best design choice and to know the limitation of our system if perturbations are likely to occur.

Abstract

Demand for beer products fluctuates throughout the year, with a substantial increase occurring for the duration of global sporting events. Beer fermentation is frequently the production bottleneck due to its significant duration (often exceeding 1 week). Therein lies a strong incentive for fermentation optimisation and batch duration reduction such that maximum production capacity can be elevated during peak demand periods. Beer fermentation optimisation has received considerable attention, however a limitation of prior work is the universal assumption of direct and instantaneous control of fermentor temperature. With the addition of only two more ODEs to the system model, heat transfer dynamics is approximated in this work. A novel, comprehensive visualisation of the attainable performance maps for key process variables is presented, obtained via a large-scale dynamic simulation campaign of viable cooling policies. These attainable performance maps are compared to equivalent results produced previously, to elucidate how fermentor performance varies once production scale increases beyond the point of the previous simplifying assumption. Utilising orthogonal polynomials on finite elements allows a finite dimensional optimisation NLP problem to be formulated for ethanol yield maximisation, which has been solved with IPOPT. Optimal operation involves a novel cooling policy to effectively manage the active yeast population in the fermentor for improved performance versus previous approaches for beer fermentation.

Keywords: Dynamic optimisation, Dynamic simulation, Beer fermentation

1. Introduction

Fermentation is a key step in the production of consumer alcohol products, frequently presenting a production bottleneck due to its significant duration (often >1 week). Demand for beer products fluctuates throughout the year, with a substantial increase occurring for the duration of global sporting events (e.g., the World Cup). Therein lies a strong incentive for process optimisation and batch duration reduction such that maximum production capacity can be elevated during peak demand periods without the need to increase plant equipment sizes, which would incur significant capital investment for vessels which would be underutilised for much of the year. Beer fermentation is an extremely complex biochemical process (Vanderhaegen et al., 2006), whose mathematical representation and parameter estimation are possible only via reduced-order models (Dochain, 2003) considering only the most essential subset of reactions via selective aggregation. The system's complexity (>600 species) renders comprehensive parameter estimation infeasible and dynamic optimisation cumbersome.

A number of studies towards improved beer fermentation via temperature profile optimisation have been performed on the basis of simplified models, exploring the inherent trade-off between attainable ethanol concentration and required batch time. These have addressed both the single objective case for batch time minimisation or

ethanol yield maximisation (de Andrés-Toro et al., 1998; Carrillo-Ureta et al., 2001) or both (Rodman and Gerogiorgis, 2016). A rigorous dynamic optimisation has been performed via a NLP formulation employing orthogonal collocation on finite elements, computing the optimal temperature trajectory for the process duration (Rodman and Gerogiorgis, 2017). It is highly uncommon for brewers to monitor batch progression online during the fermentation process. Rather a prescribed temperature manipulation is followed, after which select terminal state concentrations may be sampled to confirm an adequate product quality. Herein, the design of a model predictive controller would be of little value to industry, who seek off-line computation of optimal dynamic manipulations to be implemented with a generic temperature feedback control loop.

A limitation of prior work (in the interest of simplification towards computational manageability) is the assumption of direct and instantaneous control of fermentor temperature. This is less realistic as the scale increases; industrial fermentation tanks can exceed 4,000 hectolitres, so the characteristic lag time for heat transfer from the reaction broth through the fermentor cooling jacket cannot be reliably considered as negligible. To this end, we build upon our published contributions by explicit modelling of the fermentor cooling jacket heat transfer dynamics. This requires only two addition model ODEs, where the rate of change of the reactor contents' temperature becomes a function of the jacket power supply and thermophysical properties of the system.

2. Beer Fermentation Modelling

The de Andrés-Toro (1998) fermentation model describes five components in the wort: ethanol (C_E), sugar (C_S) biomass (X_i) and two flavour-tarnishing compounds, diacetyl (C_{DY}) and ethyl acetate (C_{EA}). The single sugar species represents the sum of all sugars in the wort. Biomass is distinguished into three forms: active (X_A), latent (X_L) and dead (X_D) cells. Active cells can promote fermentation and duplicate and grow over time; however, a portion will die and no longer contribute to fermentation, settling at the bottom of the vessel. Latent (lag) cells are unable to promote fermentation, but over time they develop into active cells, responsible for consumption of the fermentable material in the wort. A diagram of the model scheme, and the corresponding kinetic rate equations are in Fig. 1. Arrhenius growth rates (μ_i) describe species progression with a stoichiometric yield factor (Y) and an inhibition factor, f, on ethanol production. A fundamental simplifying assumption of the fermentation model is that spatial variation of concentrations and temperature may be neglected. While some degree of variation is inevitable in practice, CO_2 generation from the primary reaction pathway and the cylindroconical vessel leads to considerable mixing. The lumped parameter model has been extensively validated as suitable for representing the process on an industrial scale.

The model is extended to consider heat transfer between the exothermic fermentor contents and the surrounding cooling jacket. Eq. 13 defines the bulk temperature inside the vessel, where energy generated by sugar fermentation at a rate of (ΔH) heats the wort according to its mean physio-thermal properties (ρ_R, C_{PR}).

$$\frac{dX_A}{dt} = \mu_x \cdot X_A - \mu_{DT} \cdot X_A + \mu_L \cdot X_L \quad (1)$$

$$\frac{dX_D}{dt} = -\mu_{SD} \cdot X_{dead} + \mu_{DT} \cdot X_A \quad (2)$$

$$\frac{dC_S}{dt} = -\mu_S \cdot X_A \quad (3)$$

$$\frac{dC_E}{dt} = f \cdot \mu_e \cdot X_A \quad (4)$$

$$\frac{dC_{EA}}{dt} = Y_{EA} \cdot \mu_x \cdot X_A \quad (5)$$

$$\frac{dC_{DY}}{dt} = \mu_{DY} \cdot C_S \cdot X_A - \mu_{AB} \cdot C_{DY} \cdot C_E \quad (6)$$

$$\frac{dX_l}{dt} = -\mu_L \cdot X_L \quad (7)$$

$$\mu_x = \frac{\mu_{x_0} \cdot C_S}{k_x + C_e} \quad (8)$$

$$\mu_{SD} = \frac{\mu_{SD_0} \cdot 0.5 \cdot C_{S_0}}{0.5 \cdot C_{S_0} + C_e} \quad (9)$$

$$\mu_S = \frac{\mu_{S_0} \cdot C_S}{k_s + C_S} \quad (10)$$

$$\mu_e = \frac{\mu_{e_0} \cdot C_S}{k_e + C_S} \quad (11)$$

$$f = 1 - \frac{C_e}{0.5 \cdot C_{S_0}} \quad (12)$$
Figure 1: Model for dynamic simulation of beer fermentation (de Andrés-Toro, 1998).

Table 1: Heat transfer model parameters.

Symbol	Definition	Units	Value
T	Reaction Temperature	°C	–
T_C	Jacket Temperature	°C	–
T_{C0}	Coolant Feed Temperature	°C	4
F	Coolant Feed Rate	m^3 hr^{-1}	–
ΔH	Enthalpy of Reaction	kJ kg^{-1}	587
ρ_R	Mean Density of Wort	kg m^{-3}	1,030
ρ_C	Density of Coolant	kg m^{-3}	1,042
C_{PR}	Wort Heat Capacity	J kg^{-1} K^{-1}	4,065
C_{PC}	Coolant Heat Capacity	J kg^{-1} K^{-1}	3,914
A_h	Heat Transfer Area	m^2	221.4
U	Overall Heat Transfer Coefficient	W m^{-2} K^{-1}	200
V_R	Wort Volume	m^3	400
V_C	Jacket Volume	m^3	3.8

The cooling rate is a function of the jacket temperature (T_C), the jacket/fermentor heat transfer area A_h, overall heat transfer coefficient (OHTC, U) and wort volume (V_h). The temperature of the jacket (volume = V_C) is described by Eq. 14, cooled with fresh coolant at ($T = T_{C0}$) at a volumetric rate (F). Heat losses to the surroundings are negated as the vessel jacket is close to ambient conditions. A typical large capacity industrial specification vessel is modelled. The 400,000 L vessel has a 3,800 L jacket, cooled by a propylene glycol:water mixture. A 4 °C coolant temperature is first assumed, with $U = $ 200 W m^{-2} K^{-1}. Table 1 details the additional parameter values used in Eq. 13–14.

$$\frac{dT}{dt} = \frac{\frac{dC_s}{dt}\Delta H}{\rho_R C_{PR}} + \frac{A_h U}{V_R \rho_R C_{PR}}(T - T_C) \tag{13}$$

$$\frac{dT_C}{dt} = \frac{F}{V_C}(T_{C0} - T_C) + \frac{A_h U}{V_C \rho_C C_{PC}}(T_C - T) \tag{14}$$

3. Dynamic Simulation of Attainable Performance

Prior work investigating the potential for process improvement versus current plant fermentation operation involved an algorithm that rapidly generated and simulated plausible temperature manipulations adhering to realistic operability heuristics, while relying on the simplifying assumption that vessel temperature may be directly manipulated (Rodman and Gerogiorgis, 2016). Attainable performance maps were generated, allowing rapid visualisation of the viable output space permitted by operational modifications. To elucidate how fermentor performance varies once production scale increases, we perform a similar simulation campaign using the extended model. To exhaustively enumerate comparable performance maps for the most simple cooling policies five discrete coolant rates ($F = [0:5:20]$) are permitted, which may be only be switched at the end of a 20 hr interval across the 160 hr span considered. Thus $5^9 = 1,953,125$ cooling policies are considered for implementation.

Fig. 2 depicts the performance maps from the new cooling policy campaign (grey markers) alongside those from Rodman and Gerogiorgis (2016) which assumed direct temperature control (black markers). An immediate observation across all metrics is that the addition of the temperature model considerably reduces the broad range of viable terminal product concentrations, particularly for both by-product species. This is despite the solution set for coolant control being significantly larger ($\sim 1.9 \times 10^6$ policies) than that for direct temperature control ($\sim 1.75 \times 10^5$). The observation can be attributed to the fact that in the absence of any external heat source the vessel temperature can only rise

from its initial temperature at a rate governed by the exothermic fermentation reaction: there is considerably less scope to vary the vessel temperature during primary fermentation, where the temperature is capped by how quickly it can rise from the reaction enthalpy. This contrasts with prior work where the vessel temperature could instantaneously rise as high as 16 °C, which is not feasible in practice, leading to a subset of simulations corresponding to very short batch times and high by-product concentrations, highlighted by the black markers lying to the upper left in Fig. 2a.
Figure 2: Comparison between attainable envelopes: direct $T(t)$ control vs. $F(t)$ control.

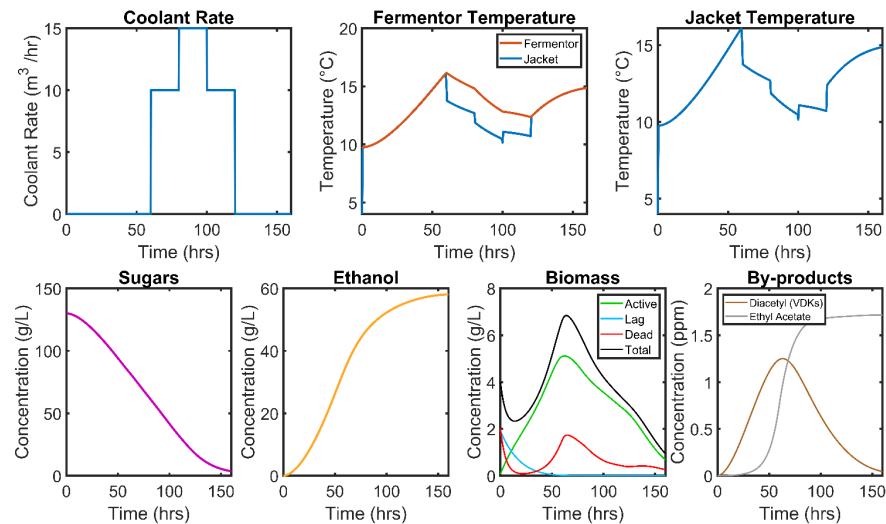
Of all cooling policies considered, the most favorable for alcohol (EtOH) maximisation is presented in Fig. 3 with the corresponding state trajectories. Here, the preferable approach is to begin cooling the jacket once the temperature exceeds 15 °C after 60 hr, increasing the cooling duty at 80 hr and reducing at 100 hr before turning the coolant flow off at 120 hr to allow the temperature to rise. This manages the active yeast population, preventing substantial cell death if the temperature were to rise further.


Figure 3: Best solution from exhaustive cooling policy campaign.

4. Dynamic Optimisation

Here, we describe the formulation of the nonlinear dynamic optimisation problem to maximise EtOH concentration. To formulate a finite dimensional optimisation problem, orthogonal polynomials on finite elements are used to approximate the control (coolant flowrate) and state (system species concentrations) trajectories to produce a large scale nonlinear programme (NLP). The differential algebraic equation (DAE) system is converted to a system of algebraic equations (AEs), where decision variables of the derived NLP problem include the coefficients of the linear combinations of these AEs.

The optimisation is performed using the DynOpt package in MATLAB (Cizniar et al., 2006). Fixing 16 elements across the time horizon, with 3 collocation points per element for the nine state ODEs and one collocation point (piecewise constant) per element for the control (F) leads to a $16 \times (3+1) \times 9 + 16 \times 1 \times 1 = 592$ variable NLP, able to accurately approximate the continuous dynamics of the system. For a single objective ethanol maximisation problem the NLP is solved using IPOPT (Wächter and Biegler, 2006). A multi-start initialisation procedure is used to best approximate global optimality.

The optimal control profile is presented in Fig. 4 with the corresponding jacket and vessel temperature trajectories. Similarities are observed between Figs. 3 and 4, with intermediate cooling to manage the active cell population evident as being the optimal policy to maximise the ethanol yield. The optimal policy computed here is to rapidly begin cooling after a favorable temperature is reached (~15 °C) and to slowly lower the coolant rate over the following 70 hr to facilitate gradual, sustained cooling of the wort.
Figure 4: Optimal solution for maximum EtOH in 160 hrs.

5. Optimal Solution Sensitivity with respect to Jacket Design Variables

We investigate the impact of coolant temperature and U on the optimal cooling policy. The same dynamic optimisation problem is solved for a range of values for these process parameters. Fig. 5 shows the solutions for a range of values of U, while Fig. 6 shows the same for coolant temperatures. It is shown in Fig. 5 that with decreasing U, the same cooling policy profile form is utilised with increasing required coolant rate. Beyond a critical point ($U < 100$ W m^{-2} K^{-1}) the solution is at the maximum coolant rate. The third panel highlights how the jacket temperature differs in these cases with the increasing coolant rate, which lead to near identical temperature trajectories in the fermentor (centre panel), with the exception of the dark blue case ($U = 50$ W m^{-2} K^{-1}), which takes a less favourable path due to being limited by the maximum coolant rate. A wide range of values of U have been considered here; clarification of practiced values will further elucidate promising dynamic coolant rate trajectories for implementation.
Figure 5: Overall Heat Transfer Coefficient (U) effect on optimal coolant supply rate.

In Fig. 6, it is similarly demonstrated how the same cooling policy form is computed regardless of the coolant temperature. Across all cases considered, it is possible to maintain essentially the same jacket-side temperature by adjusting the coolant rate such that the wort temperature and corresponding fermentation progression are unchanged. This highlights that in the common scenario where coolant feed temperature varies over time (ambient condition variability), adjustments can be made by varying the volumetric supply rate to adhere to the same temperature progression within the batch itself.
Figure 6: Coolant temperature effect on optimal coolant supply rate.

8. Conclusions

Consideration of explicit fermentor jacket heat transfer marks a significant improvement over the fidelity of prior work, which assumed that temperature may freely manipulated. Visualisation of attainable performance reveals that a vast portion of operation cases considered previously are unobtainable on an industrial scale, highlighting the importance of the improved approach. Utilising orthogonal polynomials on finite elements allows a finite dimensional NLP optimisation problem to be formulated for ethanol yield maximisation, which has been solved with the IPOPT solver. Optimal operation involves a novel cooling policy to effectively manage the active yeast population in the reactor, capable of improved performance versus established approaches. Sensitivity analysis of the solution dependence on heat transfer process and design parameters shows how adjustments in the coolant rate can be made to maintain the preferred optimal temperature trajectory of the fermenting wort in the vessel.

Abstract

Mash separation is a critical pre-processing step in beer production, ensuring that a high-quality stream of solubilised grain carbohydrates and nutrients (wort) is fed to the fermentors, in which sugars are then biochemically converted to ethanol. This essential pre-fermentation step is performed via either of two key units (lauter tuns or mash filters); the output quality of the clarified liquid stream (wort) depends on numerous critical variables (grain composition and size distribution, mash mixture physicochem. properties, brewing recipe, separation conditions). While first-principles mathematical descriptions may remain elusive, a multitude of available (input-output) industrial data can be used to improve understanding. This paper explores causality via statistical (Partial Least Squares) models for two types of beer, and performs a sensitivity analysis using the proposed input-output correlations towards mash separation improvements. Strong wort volume and incoming feed quality to the mash filter emerge as having the strongest effect on filtration time, a key industrial performance metric for optimisation.

Keywords: Statistical modelling, mashing, separation, beer, Partial Least Squares (PLS)

1. Introduction

Mashing is an enzymatic conversion and extraction process, during which the insoluble high molecular-weight (HMW) substances in the malt are converted into soluble sugars by physical and enzymatic action (Bamforth, 2006), to ensure that a purified stream of dissolved grain carbohydrates is reliably fed to the fermentor (Meussdoerffer, 2009). The ground malt is mixed with hot water in the mash vessel to enhance extraction rates. This process involves the participation of several enzymes, notably α- and β-amylases, whose activity is crucial for high efficiency. Thus, mashing temperature greatly affects the efficiency of mashing. In practice, temperatures close to the upper limit of enzyme activity are used, as they increase the filtration run-off rate. Wort concentration, pH and mashing time are key parameters for high mashing efficiency. Three common variants employed are infusion, decoction, and temperature-controlled mashing (Bühler, 1996).

Mash separation is a solid-liquid separation process, during which malt compounds dissolved during mashing are separated from grain components, thus increasing extract yield and removing substances adversely affecting beer flavour (Bühler, 1996). Modern breweries typically produce 10-12 batches per day, including maintenance downtime. Mash separation is a rate-limiting process, therefore the strategic goal of increasing its efficiency can boost productivity and reduce total production cost (Bamforth, 2006).

The two leading technologies for mash separation employ either a mash filter or a lauter tun, exploiting wort permeability through beds in very different ways (Bamforth, 2006). A *mash filter* is operated under external pressure, which drives a filtrate flow through the bed. The filtrate remaining in the filter cake is extracted by squeezing the latter (spent grains) using flexible membranes incorporated into the unit. A *lauter tun* maintains permeability through large mean particle size and employ mechanical force to loosen the bed (the filtrate is obtained by gravity). Although mash unit design varies, wort separation equipment normally use solid substances in mash as filter medium, and therefore the properties of solid particles play an important role in mash separation. Mash filtering achieves higher filtration performance in terms of wort clarity and filtration efficiency, at a higher capital investment and maintenance cost (Bühler, 1996).

Mash filters are made of rectangular polypropylene plates, which are pressed together by a hydraulic ram to create a water-tight pocket between them. Alternates are equipped with elastic membranes which can be inflated with compressed air to squeeze the mash against permeable polypropylene cloth. The space between uninflated cloths is 40 mm and is reduced significantly to about 25-30 mm when compressed (Bamforth, 2006).

Figure 1 illustrates mash filter operation. Mash is pumped into it via the bottom inlets and chambers are vented until the filter is filled; then point vents are closed and wort outlets are opened (*filling*). Withdrawing strong wort, the mash is continuously pumped into the mash filter, and solid particles deposited in the chambers accumulate, forming a filter cake (*filtration*). When mash transfer is complete, inlets are closed and elastic membranes are inflated by compressed air to squeeze the filter (*pre-compression*). Once membranes are inflated, sparge water is fed to the chamber (*sparging*), and the membrane is inflated again to recover filtrate remaining in the filter (*final compression*). The cycle is repeated until wort concentration is acceptably low: then, plate separation cause spent grain cake drop (*discharge*) to a hopper/screw conveyor (O'Rourke, 2003).
Figure 1. Mash filter operation stages (O'Rourke, 2003).

2. Methodology

The importance of process modelling, simulation and optimisation for the beer industry is well documented (Muster-Slawitch et al., 2014), although biochemical complexity of unit operations, mashing, fermenting and aging is immense (Vanderhaegen et al., 2006). The optimisation of mash separation is crucial, due to the substantial time requirement, and its influence on final product quality (Schneider et al., 2005; Kühbeck et al., 2006). First-principles models of filtration operations are useful (Wakeman & Tarleton, 1999), but their parameterisation may be laborious and elusive. Conversely, a multitude of statistical (data-driven) techniques can be used to improve our understanding of this industrial unit operation, on condition of production data availability and reliability.

This statistical modelling paper aims to explore causality in mash separation variability, develop input-output correlations for beer brands (here, type A) and propose viable improvements to the process by means of the Partial Least Squares (PLS) method, which is an established approach (MacGregor et al., 1994; Esposito Vinzi et al., 2010). A literature survey reveals that statistical (esp. PLS) models have been employed to improve product quality in the food (Poveda et al., 2004) and drink (Aznar et al., 2003) industry, and more specifically in regard to bottled lager beer aging (Liu et al., 2008). Nevertheless, to the best of our knowledge, such a statistical (esp. a PLS) approach has hitherto not been pursued to improve mash separation efficiency, despite its industrial importance (Schneider et al., 2005; Montanari et al., 2005; Kühbeck et al., 2006).

The parameters related to mash separation are not only numerous but also highly correlated, inducing significant modelling challenges. Conventional modelling methods, e.g. multiple linear regression (MLR) and ordinary least squares (OLS) cannot meet the set goals. Therefore, PLS regression is employed to capture mash separation variability. The algorithm is presented in Fig. 2 (Esposito Vinzi et al., 2010; Mehmood et al., 2012).

Step 1. Transform X and Y to normalized matrices F_0, E_0 (m: indep., n: dep. variables)

Step 2. Extract the first component t_1 as the eigenvector corresponding to the largest eigenvalue of matrix $E_0^T F_0 F_0^T E_0$ (score vectors: $\hat{t}_1 = E_0 t_1$).

Step 3. Calculate the residual matrix E_0 as: $E_0 = t_1 p_1' + E_1$, where: $p_1 = \dfrac{E_0' t_1}{\|t_1\|^2}$

Step 4. Replace E_0 with the residual matrix E_1; extract the second component, t_2.

Repeat above steps to get all components.

Step 5. Determine the number of components k by cross-validation.

Step 6. Perform ordinary least squares on F_0 using extracted components ($t_1, \ldots, t_r$).

$$F_0 = \hat{t}_1 \beta_1^T + \cdots + \hat{t}_k \beta_k^T + F_k$$
$$t_i = u_{i1}^* x_1 + \cdots + u_{im}^* x_m \, (i=1,\ldots,k)$$
$$Y = t_1 \beta_1 + \cdots + t_k \beta_k$$

Step 7. Perform regression modelling to obtain the input (x)-output (y) correlation as:

$$y_j = a_{j1} x_1 + \cdots + a_{jm} x_m \, (j = 1, \ldots, n)$$

Figure 2: Partial Least Squares (PLS) algorithm used for input (X) and output (Y) data.

3. Results and Discussion

A statistical (PLS) model is derived for the mash separation of a beer brand (type A) this PLS regression model can accurately predict the filtration time of the mash separation process, as per Table 1 (for r=4 PLS variables selected). The 14 variables (x_i) in order, are: QM1, QM2, QM3: incoming feed quality parameters; MT: mashing time; CTT: compression total time; WTV: wort to copper volume; PVV: presparging volume; SWV: strong wort volume; CT1: compression1 time; SF3: sparge3 flowrate; PCV: precompress volume; SF1: sparge1 flowrate; SF2: sparge2 flowrate; SV3: sparge3 volume.

The variable importance projection (VIP) value is used to determine whether a variable should be retained in the PLS model: it is a weighted sum of squares of PLS weights, calculated from the amount of dependent variable variance of each PLS component, and it is an indicator showing the contribution of each independent variable to the model:

$$VIP = \sqrt{\frac{p}{Rd(Y;t_1,\dots,t_m)} \sum_{h=1}^{m} Rd(Y;t_h) w_{hj}^2} \tag{1}$$

Here, w_{hj} is the weight of the jth predictor variable; $Rd(Y;t_h)$ is the Y-variance fraction explained by component t_h; $Rd(Y; t_1,\dots t_m)$ is the cumulative fraction of Y-variance explained by components $t_1,\dots t_m$, and p are the components retained (this work: $p = 4$). The VIP values that have been computed for the 14 independent variables of our PLS model are presented in Table 2 (all others with VIP < 0.8 scores have been discarded).

Table 2: VIP values of 14 retained independent variables (retention criterion: VIP >0.8)

	QM1	QM2	QM3	MT	CTT	WTV	PVV	SWV	C1T	SF3	PCV	SF1	SF2	SV3
VIP	0.83	0.83	0.84	0.81	1.23	0.81	1.03	1.11	1.10	1.52	0.88	1.32	1.46	0.84

3.1. PLS model from odd-numbered batches validated vs. even-numbered batches

The input-output correlation obtained for filtration time (the critical output of industrial significance) vs. 14 independent variables from odd-batch data (in the order defined):

Filtration time (s) = $y = 626.9886 + 0.2404x_1 + 0.9265x_2 + 0.5015x_3 + 32.2516x_4 +$
$$+ 48.5300x_5 - 0.3995x_6 - 62.6566x_7 + 11.1106x_8 + 23.0814x_9 -$$
$$- 2.2046x_{10} - 2.0042x_{11} - 2.9928x_{12} - 3.3516x_{13} + 2.0214x_{14} \quad (2)$$

The agreement of PLS model with plant data is great (error ca. 4% in outlier batch 24).
Figure 3. Filtration time prediction of odd (model) vs. even (data) separation batches.

3.2. PLS model from even-numbered batches validated vs. odd-numbered batches

Similarly, the input-output correlation obtained for filtration time (the critical output) vs. the same 14 independent variables from even-batch data (in the order defined):

Filtration time (s) = $y = 1879.0100 + 0.2234x_1 - 0.3054\ x_2 + 0.2676\ x_3 + 18.119\ x_4 +$
$$+26.3076x_5 + 3.8418x_6 - 60.2435x_7 + 12.3015x_8 - 3.8380x_9 -$$
$$-2.3208_{10} - 0.8541x_{11} - 3.9576x_{12} - 3.0716x_{13} + 2.8110x_{14} \quad (3)$$

Great agreement of PLS model with plant data, again (error 3%, 4% in batches 1, 19).
Figure 4. Filtration time prediction of even (model) vs. odd (data) separation batches.

3.3. Sensitivity analysis

Clearly, SWV, QM1, QM3, SF1, SF2 (in decr. order) are the strongest filtration drivers.
Figure 5: Sensitivity analysis of relative influence of input variables on filtration time.

4. Conclusions

This paper develops and discusses statistical (Partial Least Squares/PLS) models of mash separation for two beer types, and presents a sensitivity analysis in order to better understand which operational modifications are feasible and most promising in order to improve mash separation efficiency and benefit beer production and its supply chain. The agreement obtained between predicted and real filtration time is very good, and the analysis is repeated for different (odd/even) data subsets, to explore trends and outliers. A sensitivity plot shows that strong wort volume (SWV) and feed quality (QM1, QM3) have the strongest effect on filtration time (y), the key industrial performance metric. This concurs with industrial experience, but none of these are convenient manipulation variables: however, sparging flowrates (SF1, SF2) are, and thus can be effectively used. Mashing time (MT), pre-sparging and (pre-)compression metrics are not key factors. PLS models may require (re-)calibration to avoid drift, but clearly have business value.

Abstract

Continuous pharmaceutical manufacturing (CPM) has the potential to revolutionise the production of active pharmaceutical ingredients (APIs), offering operational and economic benefits over the currently dominant batch methods implemented by industry. Atropine is a nerve agent API, whose demonstrated continuous flow synthesis facilitates process modelling and optimisation. This work implements MINLP optimisation for total cost minimisation of the upstream CPM of atropine for rapid process synthesis. The process model considers reactor design from regressed reaction kinetic parameters, solute partitioning between LLE phases for different solvent systems, UNIFAC-modelled ternary liquid-liquid equilibria and mass transfer correlations for continuous LLE design. Optimisation results indicate toluene as the best (cost optimal) LLE solvent choice. This work demonstrates the utility of the described methodology for rapid process synthesis and comparative technoeconomic evaluation in early CPM process development stages.

Keywords: Continuous pharmaceutical manufacturing (CPM); Atropine; MINLP; Superstructure; Economic analysis.

1. Introduction

Continuous pharmaceutical manufacturing (CPM) is an emerging research field with the potential for significant technical, operational and economic benefits over currently prevalent batch methods (Koenig and Dillon, 2017). Despite demonstrations of active pharmaceutical ingredient (API) continuous synthesis, a lack of integrated continuous separation methods is an important obstacle (Baxendale et al., 2015); elucidation of optimal process designs is imperative for successful implementation (Teoh et al., 2015).

Atropine is a World Health Organisation (WHO) API for the treatment of nerve agents (Marrs and Rice, 2016), whose continuous flow synthesis features two plug flow reactor (PFRs) followed by liquid-liquid extraction (LLE) (Bédard et al., 2016). Systematic comparative evaluation of LLE design configurations can be implemented via MINLP optimisation. This work implements steady-state modelling and MINLP optimisation for atropine CPM, including upstream continuous flow synthesis and continuous LLE. Reactor design using kinetic parameters regressed from published data, thermodynamic models and mass transfer correlations for LLE design and an established costing methodology for pharmaceutical manufacturing are implemented. Optimisation results corresponding to cost optimal LLE design configurations and minimum total costs are then presented for different designs with an outlook on this vibrant research field.

2. Process Modelling and MINLP Optimisation

2.1. Continuous Flow Synthesis

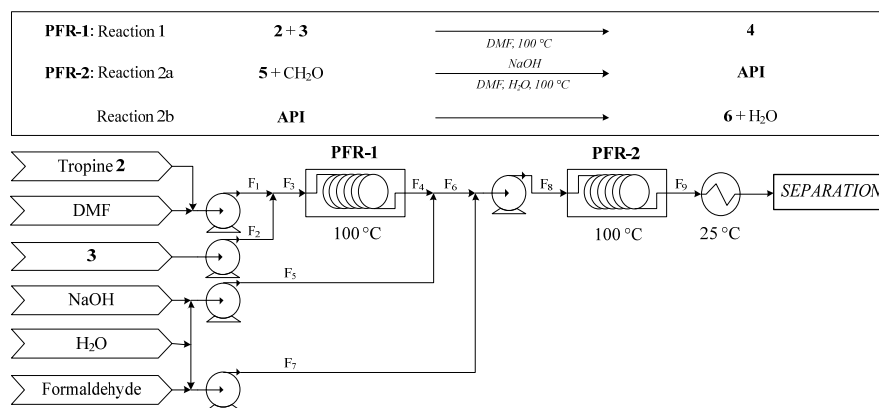
The flowsheet for the CPM of atropine is shown in Fig. 1. The API continuous flow synthesis is demonstrated by Bédard et al. (2016), featuring three reactions in two PFRs. The first (PFR-1) features the esterification of tropine **2** (in DMF) and neat phenylacetyl chloride **3** at 100 °C to form tropine ester HCl **4** (reaction 1), the free form of which (**5**) is formed by the addition of NaOH (aq). It is assumed that PFR-1 attains the same conversion of 99% of **2** to **4** at 100 °C as reported in the literature. The second reactor (PFR-2) features the addition of formaldehyde (CH_2O) to **5** (reaction 2a) under basic conditions to produce API. An undesired elimination of API to apoatropine **6** (reaction 2b) is also reported. Interrogation of the published kinetic data for reaction 2a shows a second-order (first-order in both **5** and CH_2O) to be the most plausible rate law with an estimated second-order rate constant of $k_2 = 1.68$ L mol^{-1} h^{-1}; this allows explicit modelling of reactor performance for PFR volume calculation in the process model.


Figure 1: Flowsheet for the CPM of atropine: continuous synthesis and LLE.

2.2. Continuous Liquid-Liquid Extraction (LLE): Thermodynamics

This work considers a continuous purification via LLE following the API continuous flow synthesis. The continuous LLE is operated at $T_{LLE} = 25$ °C for partitioning of structurally similar impurities (**2**, **5**, **6**) into the extract (aqueous phase) while retaining API in the raffinate (organic phase). Candidate LLE solvents for investigation must induce rapid phase splitting with the feed solvent mixture of DMF + H_2O from the continuous API synthesis; thus, modelling of candidate CPM-LLE designs requires liquid-liquid equilibria data for the ternary solvent system DMF + H_2O + LLE solvent. Ternary systems containing candidate LLE solvents were screened for their propensity to form an immiscible mixture via UNIFAC modelling. According to these criteria, the LLE solvents considered in this work are diethyl ether (Et$_2$O), butyl acetate (BuOAc) and toluene (PhMe), whose ternary diagrams are shown in Fig. 2. Partition coefficients of API and impurity solutes between organic and aqueous phases for different considered solvent systems at $T_{LLE} = 25$ °C are available in the literature (Bédard et al., 2016) and are used here for solute distribution estimation and LLE modelling. Partition coefficients describe the distribution of solute components under equilibrium, i.e. non-steady-state conditions.
Figure 2: Ternary diagrams for the LLE systems DMF + H_2O + {Et_2O, BuOAc, PhMe}.

2.3. Continuous Liquid-Liquid Extraction (LLE): Mass Transfer Correlations

Calculation of inefficiencies associated with continuous (i.e., steady-state) operation compared to equilibrium conditions must be considered in the process model. The continuous LLE efficiency (E_{LLE}) is a function of the overall mass transfer coefficient (K), interfacial area (a) and tank residence time (τ_{LLE}). Here, k_i, Sh_i = phase mass transfer coefficients and Sherwood numbers, respectively, d_{32} = Sauter mean droplet diameter, D_{API} = API diffusivity, ϕ = dispersed phase volume fraction, Sc = Schmidt number, Fr = Froude number, Eo = Eotvos number, Re_i = impeller Reynolds' number, d_i, d_t = impeller and tank diameters, respectively, We = Weber number, N_i = impeller rotation speed, ρ_c = continuous phase density and σ = surface tension. The calculation of all terms uses the Skelland and Moetti (1990) correlation for continuous LLE modelling as mixer-settlers.

$$E_{LLE} = ((Ka\tau_{LLE})^{-1} + 1)^{-1} \tag{1}$$

$$K = \left(k_c^{-1} + k_d^{-1}\right)^{-1} \tag{2}$$

$$a = \frac{6\phi}{d_{32}} \tag{3}$$

$$Sh_d = \frac{k_d d_{32}}{D_{API,d}} \approx 6.6 \tag{4}$$

$$Sh_c = \frac{k_c d_{32}}{D_{API,c}} = 1.25\times10^{-5} Sc_c^{1/3} Fr_c^{5/12} Eo^{5/4}\phi^{-1/2} Re^{2/3} \left(\frac{d_i}{d_{32}}\right)^2 \left(\frac{d_{32}}{d_t}\right)^{1/2} \tag{5}$$

$$d_{32} = \begin{cases} 0.052 d_i We^{-0.6} \exp 4\phi & , We < 10^3 \\ 0.390 d_i We^{-0.6} & , We > 10^3 \end{cases} \tag{6}$$

$$We = \frac{d_i^3 N_i^2 \rho_c}{\sigma} \tag{7}$$

2.4. MINLP Optimisation Problem Formulation

The MINLP LLE superstructure is illustrated in Fig. 3; the location and number of LLE solvent feed points and tanks affects the LLE performance and total costs and is varied in the considered superstructure. The objective of the MINLP optimisation problem is to minimise the total plant cost (*Cost*, Eq. 8). Integer decision variables are the number of LLE tanks, N_{LLE}, allowed a maximum number of 3 (Eq. 9), binary integer variable, y_i, which determines the number and location of fresh LLE solvent feed points (Eqs. 10–11). When the sum of $y_i = 0$, a purely countercurrent LLE configuration is implemented, i.e., no fresh LLE solvent is added; when $y_i > 0$, fresh LLE solvent is fed to tank i in addition to the countercurrent extract entering tank N_{LLE} and flowing through remaining tanks.
Figure 3: MINLP superstructure for the continuous liquid-liquid extraction (LLE), with continuous (tank volume, V_i, solvent feed rate, r_{TOT}) and integer variables (no. tanks, N_{LLE} and allocation of fresh solvent feed, y_i, and solvent choice).

Continuous decision variables are the total solvent-to-feed ratio (r_{TOT}), for which fresh solvent is divided equally between tanks to which a crossflow LLE solvent feed is specified (i.e., where $y_i = 1$) and constrained within values to ensure that the LLE process mixture is always fully immiscible (Eq. 13) for total LLE solvent addition, S_i (Eq. 11) and LLE tank volumes (V_i), each allowed to have a minimum volume of 1 L (Eq. 14). The problem is solved for separate instances of LLE solvent. For N_{LLE} implemented tanks, there are $N_{LLE} + 1$ continuous decision variables (V_i and r_{TOT}) and $N_{LLE}-1$ integer decision variables (y_i), i.e. a total of $2N_{LLE}$ decision variables per instance. A multistart routine using multiple initial guesses of each decision variable is implemented in order to find as near to a global minima as possible. The considered plant capacity in all cases is $Q_{API} = 10^3$ kg API yr^{-1}. The current MINLP formulation has a small number of discrete variables, which could be solved as separate NLP instances; however, the current framework can be easily adapted to consider greater numbers of possible LLE tanks (N_{LLE}), which rapidly increases the number of discrete variables, for which applying MINLP is more suitable.

$$\min Cost = CapEx + \sum_{j=1}^{t} \frac{OpEx}{(1+k)^j} \tag{8}$$

s.t.

$$N_{LLE} \in \{1, 2, 3\} \tag{9}$$

$$y_i \in \{0,1\}, i = 1 \ldots N_{LLE} - 1 \tag{10}$$

$$S_i = \frac{y_i r_{TOT} F}{\Sigma y_j + 1} \text{ for } i = 1 \ldots N_{LLE}, j = 1 \ldots N_{LLE} \tag{11}$$

$$\sum_{i=1}^{N_{LLE}-1} y_i \leq N_{LLE} - 1 \tag{12}$$

$$0.25 \leq r_{TOT} \leq 5 \tag{13}$$

$$1 \leq V_i \tag{14}$$

Total costs (*Cost*) are calculated as the sum of capital expenditure (*CapEx*), assumed spent at year zero, and the sum of time-discounted operating expenditure (*OpEx*) over the considered plant lifetime, $t = 20$ yr. The discount rate ($k = 5\%$) accounts for inflation over the plant lifetime. Annual operation of 8,000 hr is considered. Capital expenditure includes battery limits installed costs, construction and working capital; operating expenditure is the sum of material costs, utilities and waste handling costs. The implemented costing methodology in this work is applicable to both continuous and batch API pharmaceutical manufacturing processes (Jolliffe and Gerogiorgis, 2016).

3. Results and Discussion

Fig. 4 shows the optimal design configuration for each LLE solvent choice. All solvent choices result in the same flowsheet configuration, N_{LLE} = 3 tanks, with an extra fresh solvent feed to the first tank, but varying optimal tank volumes and LLE solvent-to-feed ratios. Tank volumes vary, with the largest being the first tank in all design cases, with the largest tanks required for BuOAc implementation. Consideration of longer cascades (i.e., more tanks), may lead to lower unit volumes and will affect the resulting efficiency and minimum total costs. The total LLE-solvent-to-feed ratio (r_{TOT}) varies between solvents, but all are typically mid-range with respect to the constraints applied to ensure process mixtures remain fully immiscible. The LLE MINLP superstructure considered in this work (Fig. 3) can be expanded further to consider splitting the fresh feed stream as well as splitting product from intermittent stages and the as possible implementation of solvent recycling. Consideration of subsequent crystallisation process requirements on LLE product streams should also be integrated with solvent harmonisation during the early stages of design to aid CPM development and mitigate plantwide operational issues.

	Et₂O	BuOAc	PhMe
V_1 (L)	886	1,578	1,042
V_2 (L)	825	1,353	909
V_3 (L)	824	1,356	901
r_{TOT}	1.813	2.655	2.575
Figure 4: Optimal LLE MINLP superstructure and design and operating parameters corresponding to minimum plant total costs for different design assumptions.

Fig. 5 shows minimum total cost components corresponding to optimal LLE configurations presented in Fig. 4. *CapEx* is dominated by *BLIC* in all cases while material costs dominate *OpEx* due to expensive reagents. Despite high *CapEx* associated with large tank volumes, the benefits associated with increased LLE efficiency on reducing material requirements and waste is required due to the high contribution of *OpEx* components to total costs. Optimisation results show that toluene (PhMe) is the best LLE solvent choice, attaining the lowest total costs. Toluene exhibits the widest envelope of immiscibility of the LLE solvents considered; rapid and wide phase splitting allows for enhanced LLE performance. Further corroboration of optimisation results with experimental validation as well as solvent harmonisation with crystallisation processes is essential. Although toluene is more economically favourable, it has less favourable EHS criteria compared to BuOAc. Explicit consideration of solvent selection heuristics based upon EHS criteria has been useful in previous CPM efforts (Diab and Gerogiorgis, 2017).
Figure 5: Minimum total cost components for different LLE solvent choices.

4. Conclusions

This work has formulated and solved a MINLP optimisation problem for the total cost minimisation of the plantwide CPM of atropine, a societally-important API with a variety of applications. Optimisation of a conceptual continuous LLE following the continuous flow synthesis for different LLE solvent choices was used to elucidate promising designs. Ternary phase equilibria were estimated via UNIFAC modelling and solute distribution between LLE phases used published partition coefficient data. The optimal LLE configuration for all cases implements three LLE tanks in series in a countercurrent arrangement with additional fresh LLE solvent fed to the first tank in the cascade. Investigation of more complex LLE superstructures accounting for greater numbers of tanks and recycle options will further elucidate optimal process design. Toluene emerges as the most economically favourable LLE solvent choice, offering significant total cost savings over other LLE designs with acceptable material efficiencies for pharmaceutical manufacturing applications. Consideration of downstream unit operation requirements for LLE solvent selection and harmonisation following the upstream CPM plant considered here will provide further insight into optimal process configuration and designs. This work demonstrates the value of conducting technoeconomic optimisation studies during the early stages of design towards economically viable end-to-end CPM.

Abstract

Chinese hamster ovary (CHO) cells are widely used in fermentation processes towards biopharmaceutical manufacturing of monoclonal antibodies (mAbs). This work presents dynamic models of two different fermentation modes: batch mode to produce interferon (IFN)-γ and perfusion mode to produce mAbs. The models predict concentration profiles of cells, substrate, by-product and product, which are validated versus experimental results from the literature. Sensitivity analyses were conducted to establish important parameters for dynamic states that can be investigated in process design. Time and operating costs were evaluated using dynamic models for batch and perfusion modes. Varying initial cell concentration shows a trade-off between production time and cost towards modelling and optimisation of advanced biopharmaceutical manufacturing.

Keywords: Chinese hamster ovary (CHO) cells; Fermentation; Process design.

1. Introduction

The biopharmaceuticals market is growing rapidly compared to that of conventional pharmaceuticals (Otto, Santagostino and Schrader, 2014). Typical manufacturing processes comprise of drug substance manufacturing, including fermentation and purification to produce active pharmaceutical ingredients (APIs), and drug product manufacturing for formulation (Fig. 1). Fermentation of mammalian cells is widely implemented in different operation modes for biopharmaceuticals; batch and fed-batch modes are commonly implemented, and perfusion operations are developed towards continuous manufacturing (Bielser et al., 2018). Dynamic modelling of fermentation processes can be implemented for quantitative comparative evaluation of different designs prior to expensive and laborious experimental campaigns and pilot plant studies.

Chinese hamster ovary (CHO) cell fermentation is often implemented for the production of monoclonal antibodies (mAbs), a class of biopharmaceuticals produced in high sales volumes (Ecker, Jones and Levine, 2015). Different fermentation modes are implemented in the literature for the production of various mAbs (Kelley, 2009). This work implements dynamic modelling incorporating CHO cell fermentation kinetics for two different culture modes (batch and perfusion) for advanced biopharmaceutical manufacturing process design. Model validation versus experimental results is implemented to establish which biological phenomena are well represented by the models. Parametric sensitivity analyses are then implemented to elucidate critical kinetic and design parameters in the models. Process design and economic evaluation under varying assumptions are then presented.

2. Dynamic Process Modelling of Fermentation Processes

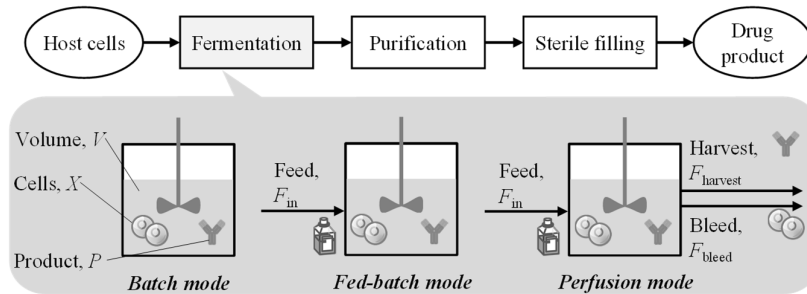
Biopharmaceutical products from fermentation are synthesised as metabolites of biological cells following substrate consumption and accompanied by cell growth and waste generation. Fermentation processes are typically operated in either batch, fed-batch of perfusion modes prior to purification and formulation of the final drug product, as shown in Fig. 1. Batch operation begins with all cells and culture media in the bioreactor, and solution containing products is removed at the end of the run. Fed-batch mode feeds substrate intermittently to control nutrient concentrations throughout the batch cycle. Perfusion mode fermentation constantly feeds and harvests the bioreactor, with bleeding to control cell concentrations, in an effort towards attaining the operational benefits of continuous manufacturing, which is being adopted for certain APIs in conventional pharmaceutical manufacturing. This work considers batch fermentation for interferon (IFN)-γ production and perfusion fermentation to produce fully-humanised mAb.


Figure 1: Typical biopharmaceutical manufacturing process and different culture modes.

2.1. Batch Mode Fermentation

Fox et al. (2004) developed a dynamic model for the batch CHO cell fermentation to produce IFN-γ, described by Eqs. 1–5. The model describes concentration profiles of cells (X), substrate (glucose, S), and product (IFN-γ, P) as a function of time (t). The specific cell growth (μ) and substrate consumption (q_S) are explicitly considered via Monod kinetics; the specific product formation rate (q_P), maximum specific growth rate (μ_{max}), maximum specific substrate consumption rate (q_{max}), Monod constant (K) and substrate consumption rate (K_S) are defined in the literature. The value of μ depends on S with respect to the threshold substrate concentration (S_t) (Fox et al., 2004).

$$\frac{dX}{dt} = \mu X \tag{1}$$

$$\frac{dS}{dt} = -q_S X \tag{2}$$

$$\frac{dP}{dt} = q_P X \tag{3}$$

$$q_S = \frac{q_{max} S}{K_S + S} \tag{4}$$

$$\mu = \frac{\mu_{max} S}{K + S} \ (S \geq S_t); \ \mu = 0 \ (S < S_t) \tag{5}$$

2.2. Perfusion Mode Fermentation

Karst et al. (2017) developed a dynamic model for the perfusion mode fermentation of CHO cells to produce fully-humanised mAb, described by Eqs. 6–10. In addition to concentration profiles of cells (X), substrate (S) and product (mAb, P), the perfusion model also describes concentration profile of waste product ammonia (A), which requires a value for the specific ammonia production rate (q_{amm}), defined in the literature (Karst et al., 2017), as well as the working volume variation (V). Steady-state operation and constant working volume are assumed by controlling the feed (F_{in}) and product (F_{out}) stream flowrates of the perfusion reactor; thus the time differential of the working volume (Eq. 9) is equal to zero. The outlet flowrate is controlled via the harvest ($F_{harvest}$) and bleed (F_{bleed}) rates, which depends on the working volume and the specific growth rate (μ). Bleed and harvest rates are calculated via Eq. 9. Monod kinetics describe μ, μ_{max} and the ammonia growth inhibition constant ($K_{\mu,amm}$) available in the literature (Karst et al., 2017).

$$\frac{d(VX)}{dt} = \mu VX - F_{bleed}X \tag{6}$$

$$\frac{d(VP)}{dt} = q_P VX - F_{harvest}P \tag{7}$$

$$\frac{d(VA)}{dt} = q_{amm}VX - F_{out}A \tag{8}$$

$$\frac{dV}{dt} = F_{in} - F_{out} = 0; \; F_{out} = F_{harvest} + F_{bleed} \; ; F_{bleed} = \mu V \tag{9}$$

$$\mu = \frac{\mu_{max} \, K_{\mu,amm}}{K_{\mu,amm} + A} \tag{10}$$

The implemented models for batch (Fox et al., 2004) and perfusion (Karst et al., 2017) mode fermentations do not account for cell death or the production or consumption of other compounds, e.g. lactate produced during the reaction due to the lack of parameters available for such phenomena. Development of these models to account for concentration profiles of additional species should be implemented given sufficient experimental data.

3. Results and Discussion

3.1. Dynamic Model Sensitivity Analysis

Sensitivity analyses were conducted for dynamic states for different fermentation modes to establish design and operating parameters for investigation during process design. Model parameters are perturbed individually by ±20% from their base values. The sensitivity of dynamic states on various design and operating parameters is measured by:

$$R = \frac{i_{0,perturbed} - i_{end,perturbed}}{i_{0,basecase} - i_{end,basecase}} - 1 \tag{11}$$

Here, R is the sensitivity ratio, $i_{0,perturbed}$ and $i_{0,basecase}$ are initial dynamic states with and without perturbations, respectively, while $i_{end,perturbed}$ and $i_{end,basecase}$ are the equivalent final dynamic states. The sensitivity of product concentration, P, to various kinetic and operating parameters is considered for both batch and perfusion fermentation processes.

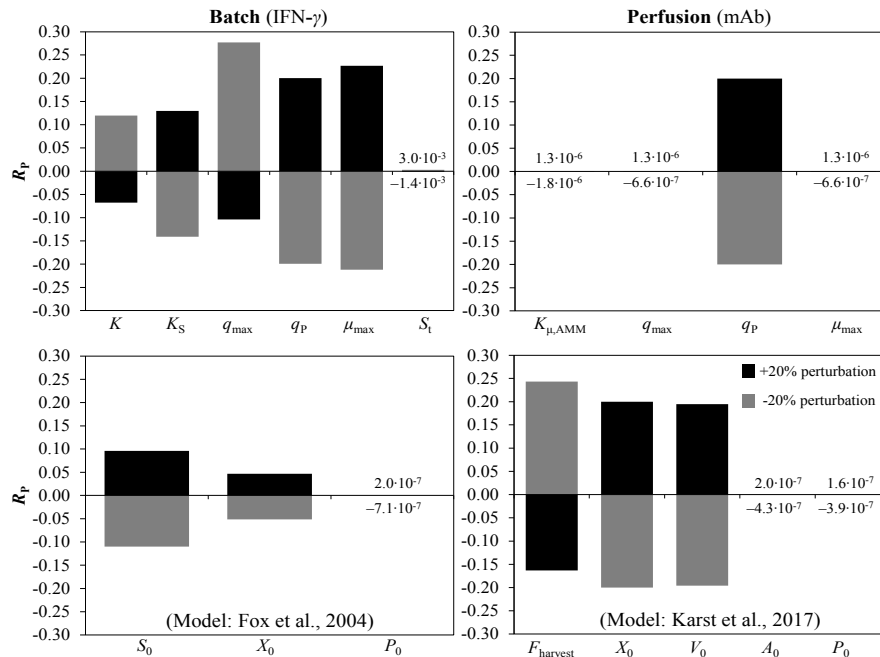
Fig. 2 shows the sensitivity of product concentration (R_P) to various kinetic and operational parametric perturbations. For the batch fermentation, kinetic parameters K, K_S, q_{max}, q_P and μ_{max} have the greatest effect on product concentration, while S_t has a lesser effect. The batch fermentation initial cell and substrate concentrations (X_0 and S_0, respectively) affect product concentration more than initial product concentration (P_0). For the perfusion mode fermentation, product concentration is very sensitive to the value of q_P compared to other model kinetic parameters. The perfusion mode values for $F_{harvest}$, X_0 and V_0 have the most significant effect on product concentration compared to A_0 and P_0. Sensitivity analyses on dynamic models are important to elucidate key kinetic parameters that must be fit to a high degree of accuracy during parameter regression from experimental data as well as operating parameters that can be tuned during process design.


Figure 2: Product concentration sensitivity to different kinetic and operating parameters.

3.2. Dynamic Model Validation

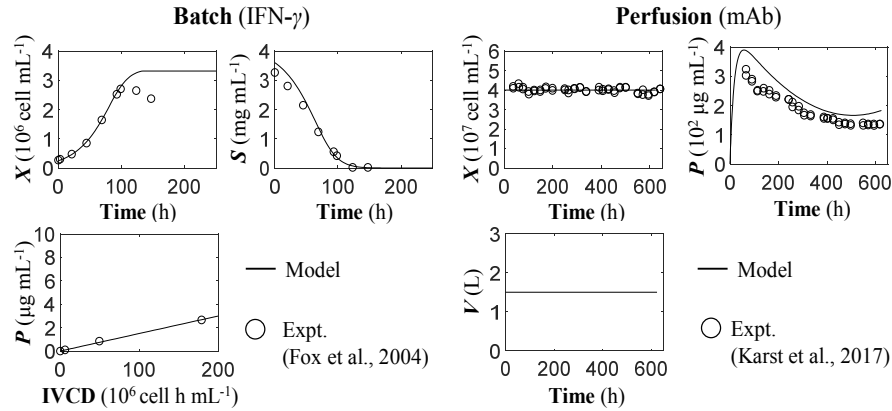
The implemented dynamic models for batch and perfusion fermentation modes were compared versus published experimental data for model validation purposes. Fig. 3 shows profiles of X, S, A, P, and V for the batch and perfusion fermentation modes. The models were validated by t-testing, which showed good reproducibility with a significance level of 0.05 for both modes. The batch model reproduces the data well until $t = 98$ hr, after which cell concentration profiles significantly deviate due to the lack of cell death expressions in the model. For process design purposes, the maximum batch run time is assumed to equal 98 hr to ensure the model is viable. The perfusion model generally reproduces the experimental data well, with a slight over-prediction of P. Consideration of cell death in the model as well as concentration profiles of other significant biological compounds will enhance our understanding of the kinetic behaviour of this process.


Figure 3: Model validation vs. experimental data (IVCD = integral of viable cell density).

3.3. Process Design Space Investigation and Economic Analysis

Economic evaluation of different process designs is imperative to elucidate promising cost-effective configurations. The current analysis investigates the effect of varying initial cell concentration on required production time and the corresponding normalised operating costs with respect to mass of product and bioreactor working volume. Operating costs (C_{OpEx}) are composed of cell (C_{cells}), media (C_{media}) and agitation ($C_{agitation}$) costs.

$$C_{OpEx} = C_{cells} + C_{media} + C_{agitation} \tag{12}$$

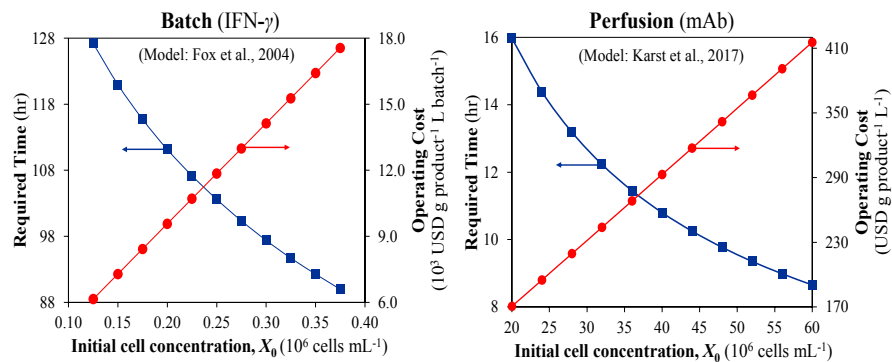
Fig. 4 shows production time and operating costs per unit product mass per unit bioreactor working volume for both batch and perfusion fermentation processes. In both cases, there is a trade-off between the processing time and the operating cost with varying initial cell concentration; as cell concentration increases, production time decreases, but a corresponding increase in cost is observed associated with increased cell quantities present in the fermentation broth. Cost calculations do not account for optimal batch numbers, sizes and scheduling, which will allow for improved costs and provide further insight into optimal design of the considered batch fermentation. Provision of production requirements, product sales prices and additional economic data for these particular processes will elucidate absolute cost components for clarification of economic viability.


Figure 4: Production time and operating costs for batch and perfusion operations.

Consideration of perfusion downtimes and numbering-out/up of unit operations is another important consideration. Incorporation of detailed capital expenditure calculations into the total costs requires reliable cost-capacity correlations for specific biopharmaceutical manufacturing unit operations in order to gain insight into forecasted total costs. Provided accurate economic parameters, unit cost correlations and reduced model discrepancies with respect to experimental data, a dynamic optimisation problem formulation incorporating the kinetic models described in this work can allow elucidation of optimal control strategies of different dynamic parameters to meet specific economic objectives.

4. Conclusions

Dynamic models of different modes of fermentation of CHO cells were developed for manufacturing of different biopharmaceutical products: batch mode to produce IFN-γ and perfusion mode to produce fully-humanised mAb. The models were validated with experimental values from the literature, with the models for batch and perfusion modes showing good reproducibility. Sensitivity analyses of different operating parameters' effects on product concentrations established initial cell and substrate concentrations as important design variables for batch and perfusion modes. A trade-off between the production time and costs is observed for both fermentation modes. This work is the first to implement the described dynamic models for batch (Fox et al., 2004) and perfusion (Karst et al., 2017) CHO cell fermentation for process design and economic analysis of different biopharmaceutical manufacturing routes. Future work will implement the models into a dynamic optimisation problem formulation to establish optimal operating and design parameters for advanced biopharmaceutical manufacturing from CHO cells.

A Multiperiod Optimisation Approach to Enhance Oil Field Productivity during Secondary Petroleum Production

Emmanuel I. Epelle, Dimitrios I. Gerogiorgis[*]

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

D.Gerogiorgis@ed.ac.uk

Abstract

Water injection rate allocation across different injection wells in an oil and gas field undergoing secondary production is one of the most economical ways to increase hydrocarbon production. Exploiting a process systems engineering description of a rate allocation problem via mathematical optimisation can improve operational planning. We simultaneously address a production and injection optimisation problem with an economic objective function, the net present value (NPV), subject to practical constraints ensuring operational feasibility. A case study with a constant water injection rate is compared to another in which optimal dynamic injection rates and water sharing ratio among the respective injection wells are determined. With the formulated optimisation (NLP) problem, an optimal water injection strategy that reduces field water consumption and increases profitability is obtained. MATLAB's fmincon and IPOPT optimisation solvers are employed for solution, observing superiority of IPOPT compared to fmincon.

Keywords: Net present value (NPV), Optimal injection strategy, Production optimisation

1. Introduction

Secondary production via water flooding is one of the most implemented enhanced oil recovery methods in the oil and gas industry, involving the injection of water to increase the reservoir's pressure and sweep residual oil in order to consequently increase oil production. Cost reductions and improved productivity during secondary production are dependent on the dynamic rate allocation to different injection wells, the underlying reservoir permeability distribution and other rock and fluid properties. Applying reservoir and multiphase flow simulation (wellbore and pipeline hydraulics) in an integrated manner can aid practical operational decisions during early design stages (Kosmidis et al., 2004, Gerogiorgis et al., 2006; Van Essen et al., 2011). Current oil and gas production optimisation studies in the literature address problems such as well placement, production and drill rig scheduling, pipeline and surface facility routing, infrastructure installation and geological and economic uncertainty (Scheidt et al., 2010; Gupta and Grossmann, 2012; Gunnerud et al., 2013; Tavallali et al., 2013; Epelle and Gerogiorgis, 2017).

A common limitation of these studies that motivates our work is the lack of a detailed water flooding model that incorporates the intricacies of the reservoir behaviour and its dynamic fluid and well properties (gas oil ratio, water cut, productivity indices and well allocation factors). Here, we demonstrate that streamline simulation is a powerful tool that facilitates accurate and optimal determination of the injection rates to different wells. Compared to previous studies, in which the adopted wellbore geometries are vertical, the multiphase flow complexities in deviated well geometries are also incorporated in our approach. Furthermore, the inherent property of the petroleum production system that allows its components to be treated independently is significantly exploited. This is achieved by optimising an economic objective function that captures the overall system behaviour. The coupling of reservoir and pressure drop simulation via proxy-modelling enhances the adaptability of the implemented framework to real field operations via speedy computation.

2. Simulation Methodology and Optimisation Formulation

The model is first built in a numerical reservoir simulator using permeability, porosity and saturation data of a sandstone reservoir. The field contains four production wells and four injection wells (Fig. 1). Two of each class are horizontal wells and the others are vertical. In running the reservoir model, ECLIPSE 100 (Schlumberger, 2017), it is assumed that water injection commences in the third year. A production forecast for a 6-year duration is done to obtain the field pressure, productivity indices, water cut and gas oil ratios of the wells at each time step ($\Delta t = 1$ yr). These data are fed into a multiphase flow simulator, PIPESIM 2017 (Schlumberger, 2017), in which the wellbore and pipeline models are built.
Figure 1: Reservoir structure with drilled wells. The surface network built in PIPESIM additionally consists of 2 main pipelines, 2 manifolds, 8 valves and 2 separators.

The objective function and operational constraints of the proposed formulation are outlined in Table 1. Compared to previous studies which maximise production (Kosmidis et al., 2004; Gunnerud et al., 2013), we maximise the net present value (NPV) by maximising oil and gas production (Eqs. 2–3) and limiting water production rates (Eq. 4) and injection costs (Eq. 5) (Guo and Reynolds, 2018). Here, *TOP* and *TGP* are the revenues from total oil and gas produced, respectively, *TWP* and *TWI* represent the cost incurred for water production and injection, respectively, r_{OP} and r_{GP} are oil and gas prices, respectively, r_{WP} and r_{WI} are the water production and injection unit costs, respectively, N_{prod} and N_{inj} are the number of producers and injectors, respectively, Δt is the timestep, b is the discount rate for reference time, $t_{ref.}$; q_{OP}, q_{GP}, q_{WP} and q_{WI} are the flow rates of produced oil, produced gas, produced water and injected water at time t, respectively. Subscripts i, j and l represent the injection wells, production wells, and pipelines, respectively. The capacity constraint of the field is represented by Eq. 6, where $C_{p,sep}$ is the separator capacity.

The pressure-rate relationship of the production and injection wells and pipelines are described via proxy-modelling. Deciding which form of surrogate modelling technique to be used considered various factors, such as the feasibility of implementation for our particular case studies, the ability to capture the system's dynamic nonlinearities and accuracy, the solution time and the modelling effort and ease of automation. Of all candidate forms considered, an algebraic/polynomial proxy model was best suited for application, yielding an error of <2 % with respect to the simulation data obtained for

wells and pipelines (Gunnerud and Foss, 2010). These proxy models developed for each time period in the entire time horizon constitute the constraints fed to the optimisation routine. The proxy models for description of component flowrates and pressure drops in pipelines are shown in Eqs. 7–9. Here, subscript l indicates the pipeline, superscript m the manifold and s the separator, so P_l, P_m and P_s represent the pipeline, manifold and separator pressures, respectively, while the subscript t denotes their values at the particular time interval. Variables q_{lo}, q_{lw} and q_{lg} are flowrates of oil, water and gas in pipeline l, respectively. Sensitivity analyses are performed over wells and pipelines at each Δt to obtain the proxy model coefficients a_n, b_n and c_n for $n = 1, 2, 3, 4$. Other constraints include the separator capacity and formation fracture pressure limitations. Forward flow of fluids towards the separator is described via Eqs. 10–11. Formation fracture due to high injection pressures (reducing the sweep efficiency) is avoided via Eq. 12, material balance constraints between wells and pipelines are denoted by Eq. 13 and the maximum allowable injection rate for the respective injection wells is limited by the available field water via Eq. 14. Here, P_l, P^m, P^s and P_j^w are the pipeline, manifold, separator and wellhead pressures, respectively, P_{inj} and P_{frac} are the water injection and formation fracture pressures and $Q_{inj,tot}$ is the total daily volumetric flowrate of water available for injection.

The number of variables, model nonlinearities and non-convexities and the adopted local optimisation solvers (fmincon and IPOPT) imply that solutions will be sensitive to the initial guess supplied. To address this challenge, streamline simulation is adopted for the determination of the dynamic well allocation factors (WAFs), which are used in the calculation of the dynamic injector efficiencies (Theile and Batycky, 2006; Azamipour et al., 2018). With these calculated efficiencies, the best performing injection well can be identified and consequently allocated the highest injection rate as an initial guess. Using these practical initial guesses obtained by applying streamline simulation, we enforce bounds on the decision variables, assuming a uniform distribution between the upper and lower bounds of the respective variables and perturb the initial guess 1,000 times between the bounds, thus facilitating convergence to a global solution. The final optimisation formulation consists of 198 variables and 252 constraints (nonlinear, linear, equality and inequality). These constraints and the objective function are written in MATLAB and solved using the fmincon and IPOPT solvers via the object-based OPTI toolbox platform.

3. Simulation and Optimisation Results

Two optimisation case scenarios are presented. In Scenario-1, the injection rates and production rates are optimised and in Scenario-2, the injection rates are maintained at the maximum allowable rate (constant) for each injection well and only the production rates optimised. Before discussing the optimisation results, the results of the simulation procedure are analysed. These results (Fig. 2) are the production and injection performances, based on a 6-year simulation forecast. It is observed that PROD_WELL-1 slightly outperforms PROD_WELL-2 (Fig. 2a); their respective equidistant locations from the INJ_WELL-1 (in the reservoir model – Fig. 1) and the similarity of the underlying local permeability distribution implies they experience similar levels of pressure support from the injection well. Also observed is the reduced productivity of the vertical wells (PROD_WELL-3 and 4) compared to the horizontal wells (PROD_WELL-1 and 2). This is inevitably due to the higher drainage area that the horizontal wells are exposed to in the reservoir. The large disparity observed in the well productivity profiles is not present in the streamline-derived injection efficiencies (Fig. 2b). Despite the favourable well geometry of INJ_WELL-2 (horizontal) compared to INJ_WELL-4 (vertical), they both exhibit similar efficiencies. The interaction of INJ_WELL-1 with the horizontal producers is the main factor contributing to its high efficiencies as determined from the WAFs obtained from streamline simulation. With the available daily field water injection rate and injection efficiencies, it was possible to propose initial injection rates for the optimisation algorithm.
Figure 2: Production and injection well performances.

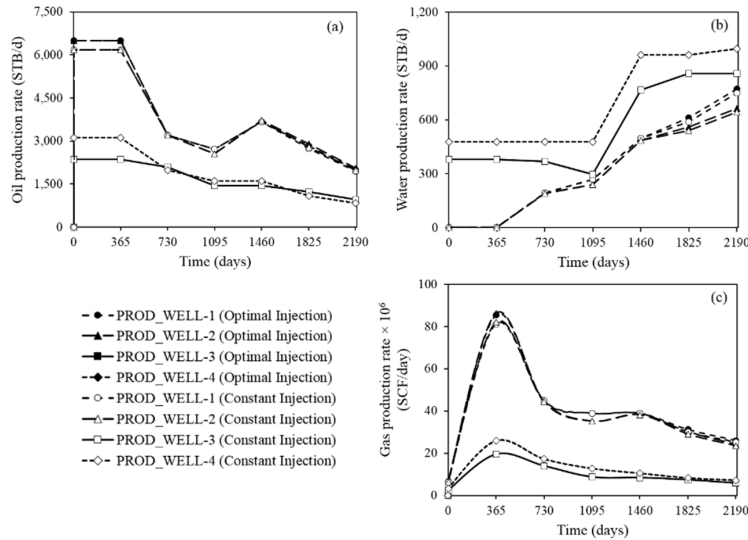
The production rate profiles for the oil, gas and water phases of the respective production wells for the two optimisation scenarios considered are compared in Fig. 3. The optimisation algorithm captures the increment in oil production at the start of injection (at 1,095 days) and the reduced decline rate after injection commences (Fig. 3a). Similar to the oil production rate profile, the gas production rates (Fig. 3b) of the respective wells also show an increment in production due to water injection and is more significant for the horizontal wells. The commencement of water injection is accompanied by a rapid increase in the water production rates, particularly for PROD_WELL-3 and 4. The horizontal wells (PROD_WELL-1 and 2) display a rather gradual increase in the water production rate compared to the vertical ones. It is also observed that the superior performance of the horizontal wells has been exploited by the optimisation algorithm for the improvement of the total oil production (Fig. 3a). This improvement mostly occurs in the plateau region (i.e. when constant oil production is observed). Compared to the oil production rates, the water and gas production rates of the horizontal wells only increase marginally; this happens towards the end of the production horizon (Fig. 3b–c). As for the other vertical producers, there is no difference between the observed production rates for the optimal and constant injection scenarios; this difference can be increased by incorporating well placement optimisation for the exploration of highly productive sites (with good permeability) in the reservoir. This would require the application of stochastic optimisation techniques and integer variables representing a grid block allocation method, introducing further complexity to the considered problem, which is beyond the scope of this paper.


Figure 3: Optimal flow rates of oil gas and water from the production wells.

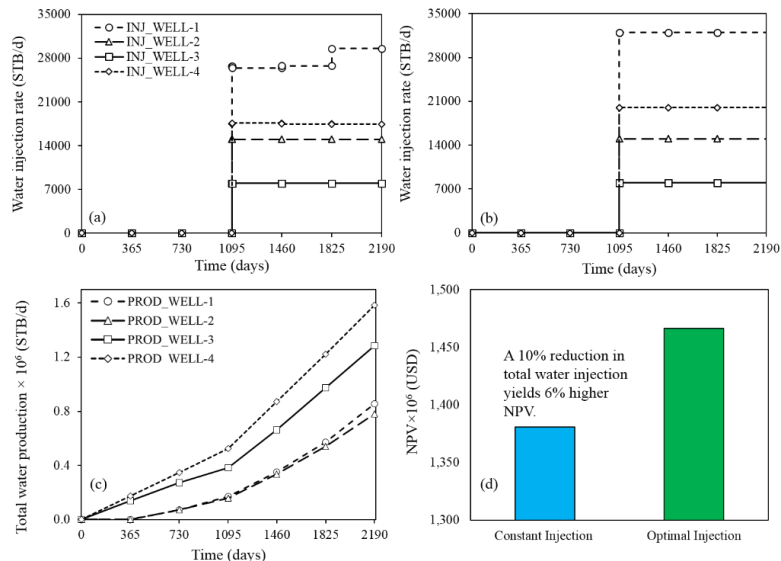
The optimal injection strategy and the corresponding cumulative injection rate for each well are shown in Figs. 4a–b. It is shown that a stepwise increase in the injection rate for INJ_WELL-1 and a constant injection for the rest of the wells is guaranteed to increase the NPV of the field by 6% (Fig. 4d) and reduce total water consumption by 11%. Furthermore, it is shown in Fig. 4c that the water production rates of PROD_WELL-3 and 4 (vertical wells) are higher than those of the horizontal wells, further demonstrating the desirable performance of the horizontal wells. Additionally, PROD_WELL-3 experiences a significantly lower water production compared to PROD_WELL-4 but with a similar oil production. Hence, PROD_WELL-3 can be considered the best performing vertical well.


Figure 4: Water injection rates for (a) the optimal scenario and (b) the constant injection scenario; (c) cumulative water production rates of the optimal scenario and (d) the economic analysis of both scenarios.

A comparison of the solver performances showed that the MATLAB's fmincon was unable to yield satisfactory results that met convergence criteria. The IPOPT solver implementing an interior point line-search filter method was able to converge successfully.

4. Conclusion

A production and injection optimisation problem with an economic objective function subject to practical constraints that ensure operational feasibility has been thoroughly addressed. The application of streamline-based well allocation factors and injector efficiencies served as a reliable method of obtaining good initial guesses for the time-dependent injection rates, enabling faster performance of the optimisation algorithm. The implementation of algebraic proxy models was sufficient for accurate representation of the simulator output with a maximum error of <2 %. The optimisation framework has shown that a systematic variation of the injection rates, well head pressures and production rates yields increased field profitability. In the considered scenario, a 6% improvement in the NPV and a corresponding 11% decrease in the total field water consumption is attained.

Statistical diagnosis of process-model mismatch by means of the Lagrange multiplier test

Marco Quaglio[a], Eric S. Fraga[a] and Federico Galvanin[a,*]

[a]*Department of Chemical Engineering, University College London (UCL), Torrington Place, WC1E 7JE London, United Kingdom*

*f.galvanin@ucl.ac.uk

Abstract

Modelling chemical processes frequently requires the construction of complex systems of differential and algebraic equations involving a high number of state variables and parameters. Whenever a model structure is proposed, its adequacy is checked with a goodness-of-fit test. The goodness-of-fit test is capable of detecting the presence of over-fitting or under-fitting. However, when some modelling error is detected, the test does not provide guidance on how to modify the model equations to match the behaviour of the physical system under analysis. In this work, a test statistic is derived from a tailored Lagrange multiplier test with the aim of diagnosing potential sources of process-model mismatch and to provide guidance on how to evolve approximated model structures towards a higher level of complexity. The proposed test is applied on a simulated case study of a yeast growth model in a fed-batch bioreactor.

Keywords: model misspecification, model building, Lagrange multiplier, maximum likelihood, Fisher information

1. Introduction

The construction of a parametric model from observations of process behaviour generally requires significant effort both for i) building an opportune functional form for the model equations and ii) for precisely estimating its parameters. The former aspect frequently leads to the formulation of approximate model structures. A classical approach for assessing the adequacy of a process model is the goodness-of-fit test, which compares the model residuals against their expected distribution under the null hypothesis that the model structure is exact (Silvey, 1975). Two types of modelling errors can be detected with a two-tailed goodness-of-fit test:

- Over-fitting. The model involves an excessive number of free parameters, i.e. a simpler model structure shall be preferred to describe the process behaviour.

- Under-fitting. The model is neglecting relevant parameters and/or variables, i.e. the model structure is not sufficiently complex to capture the process behaviour. When the model is under-fitting there is a significant discrepancy between process observations and model predictions, i.e. a process-model (PM) mismatch.

Systematic approaches are available to amend the structure of an over-fitting model. One may perform further tests, e.g. the Wald test (Wald, 1943) or the univariate *t*-test for

parameter significance (Asprey and Naka, 1999), with the aim of testing the hypothesis that some model parameters satisfy certain constraints. As an example, one may test the null hypothesis that some parameters equal zero. If there is not enough evidence to disprove this hypothesis, one shall favour the constrained model and fix those parameters to zero. This is frequently equivalent to excluding parameters (and the variables whose presence is controlled by those parameters) from the model structure. In the under-fitting case, the amendment of the model structure generally poses substantial challenges to the modeller. In fact, there may be significant uncertainty on which model components are correlated to the PM mismatch and on how to evolve the model structure for reducing and eventually eliminating the mismatch.

The importance of diagnosing the sources of PM mismatch is recognised in the literature on process monitoring (Wang et al., 2012; Badwe et al., 2009), but the problem is considered only in the context of linear, black-box models for control applications. An approach for diagnosing PM mismatch in first principle models was proposed by Meneghetti et al. (2014), where a latent variable model is used to highlight differences between process and model in the distribution of some auxiliary variables. These auxiliary variables represent user-defined combinations of variables and parameters appearing in the model. However, defining opportune auxiliary variables may not be obvious and the diagnosis is sensitive to their definition. A superstructure-based approach was suggested by Engle (1982), where the under-fitting model is regarded as a constrained instance of one or multiple alternative superstructures. A Lagrange multiplier test (Silvey, 1959) is then employed to challenge the model against the more complex alternatives. A limitation of this approach is that the definition of the superstructures relies entirely on the intuition of the modeller.

In this work, a model building approach is proposed where a Lagrange multiplier test is used to diagnose PM mismatch. The test does not require the definition of alternative model structures or the use of superstructures. Instead, the test aims at falsifying the hypothesis that a given model parameter is a state-independent constant. The test involves the computation of a score statistic which is proportional to the marginal fitting cost associated to the aforementioned hypothesis. It is shown that the score provides a useful index for guiding the evolution of the model towards a higher level of complexity. A high score associated to a parameter indicates strong evidence for justifying the evolution of the parameter into a state-dependent function.

2. Methodology

A model structure is proposed in Eq. (1) to describe a physical process of interest. In Eq. (1), $\mathbf{f}$ is a $N_f \times 1$ array of model functions, $\mathbf{x}$ is a $N_x \times 1$ array of state variables, $\dot{\mathbf{x}}$ is a $N_x \times 1$ array of time derivatives for the state variables, $\mathbf{u}$ is a $N_u \times 1$ array of manipulable system inputs, t is time and $\theta \in \Theta$ is a $N_\theta \times 1$ array of model parameters $\theta_1, ..., \theta_{N_\theta}$. In Eq. (1), $\hat{\mathbf{y}}$ is a $N_y \times 1$ array of model predictions for N_y measurable system states $\mathbf{y}$. Model predictions are expressed as a $N_y \times 1$ array of functions $\mathbf{h}$.

$$\mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, t, \theta) = \mathbf{0}; \quad \hat{\mathbf{y}} = \mathbf{h}(\mathbf{x}, \mathbf{u}, t, \theta) \tag{1}$$

A dataset Y is available to estimate the parameters θ. The dataset Y consists of N samples of $\mathbf{y}$ where the i-th sample $\mathbf{y}_i$ is collected setting the system inputs to $\mathbf{u}_i$ and sampling at time t_i, i.e. $Y = \{(\mathbf{u}_i, t_i, \mathbf{y}_i) \text{ with } i = 1, ..., N\}$. Measurements for $\mathbf{y}$ are affected by Gaussian
Figure 1: Simplified diagram showing the proposed model building approach.

noise with covariance matrix Σ. A model building framework implementing a step of PM mismatch diagnosis is introduced in Figure 1. The procedure involves the following steps:

1. A parameter estimation step. At this stage the model parameters θ are fitted to the available dataset Y employing a maximum likelihood approach.

2. A goodness-of-fit test. A test on the goodness-of-fit is performed to detect the presence of PM mismatch.

3. A Lagrange multiplier test. If PM mismatch is detected, a Lagrange multiplier test is performed to test the hypotheses that model parameters are state-independent constants by computing a likelihood-based score statistic.

4. A model evolution step. Parameters with the highest score statistic are evolved into state-dependent functions and the procedure is repeated from Step 1.

The iterative process interrupts when no PM mismatch is detected. One shall then proceed with additional model validation procedures, e.g. improving the precision of parameter estimates. Steps 1-3 in the procedure are further detailed in the following subsections. It is recognised that the convergence of the proposed approach relies on the selection of appropriate functional forms to evolve model parameters in the model evolution step. This aspect is going to be the focus in future research activities.

2.1. Parameter estimation

Let $\Phi(\theta|Y)$ be the log-likelihood function (Bard, 1974). The maximum likelihood estimate $\hat{\theta}$ is obtained solving the N_θ unconstrained likelihood equations Eq. (2).

$$\nabla\Phi(\hat{\theta}|Y) = \mathbf{0} \tag{2}$$

2.2. Goodness-of-fit test

The goodness-of-fit is evaluated with a 95% χ^2 test. The critical value χ^2_{ref} is computed from the χ^2 distribution with degree of freedom $N \cdot N_y - N_\theta$. If the test fails, PM mismatch is diagnosed by means of the Lagrange multiplier test illustrated in the following section.

2.3. Lagrange multiplier test

It is assumed that the elimination of the mismatch requires the replacement of a certain parameter with an opportune state-dependent function. A statistical test for diagnosing PM mismatch is now introduced with the aim of testing the hypothesis that a certain parameter θ_i is a state-independent constant. The competing hypotheses under test are:

- Null hypothesis: θ_i and θ_j, with $j \neq i$, are all state-independent constants.

- Alternative hypothesis: θ_i is a state-dependent quantity and θ_j, with $j \neq i$, are state-independent constants.

Without loss of generality, it is assumed that the parameter under analysis is $\theta_i = \theta_1$. The log-likelihood function is written assuming that θ_1 is a state-dependent quantity, i.e. $\theta_1 = g(\mathbf{x}, \mathbf{u}, t)$ (knowledge of the functional form of g is not required in the test). The parameter set θ is extended to the $(N + N_\theta - 1) \times 1$ array of parameters $\theta_E = [\theta_{11}, \theta_{12}, ..., \theta_{1N}, \theta_2, \theta_3, ..., \theta_{N_\theta}]$. In θ_E, parameter $\theta_{1i} = g(\mathbf{x}, \mathbf{u}_i, t_i)$ represents the value of function g at experimental conditions $\mathbf{u}_i$ and sampling time t_i. Let $\Phi_E(\theta_E|Y)$ be the log-likelihood function written for dataset Y under parametrisation θ_E.

$$
\begin{aligned}
\Phi_E(\theta_E|Y) = -\frac{N}{2}[N_y \ln(2\pi) + \ln(\det(\Sigma))] \\
- \frac{1}{2}\sum_{i=1}^{N}[\mathbf{y}_i - \hat{\mathbf{y}}(\mathbf{u}_i, t_i, \theta_{1i}, \theta_2, ..., \theta_{N_\theta})]^T \Sigma^{-1}[\mathbf{y}_i - \hat{\mathbf{y}}(\mathbf{u}_i, t_i, \theta_{1i}, \theta_2, ..., \theta_{N_\theta})]
\end{aligned}
\tag{3}
$$

Under parametrisation θ_E, the i-th element in the sum in Eq. (3) is a function of parameters $\theta_{1i}, \theta_2, ..., \theta_{N_\theta}$. The set of $N-1$ constraints $\mathbf{s} = (\theta_{11} - \theta_{12}, ..., \theta_{1N-1} - \theta_{1N}) = \mathbf{0}$ is defined. The imposition of constraints $\mathbf{s} = \mathbf{0}$ is equivalent to assuming that g is a parameter, i.e. the functional form g is constant and independent from the states. The constrained maximum likelihood estimate $\hat{\theta}_E$ is obtained solving the constrained likelihood equations.

$$
\nabla \Phi_E(\hat{\theta}_E|Y) + \nabla \mathbf{s} \hat{\alpha} = \mathbf{0}
$$
$$
\mathbf{s} = \mathbf{0}
\tag{4}
$$

In Eq. (4), $\hat{\alpha}$ is the estimate for the $N-1 \times 1$ array of Lagrange multipliers. Notice that $\hat{\theta}_{1i} = \hat{\theta}_1 \; \forall i = 1, ..., N$ because of the constraints $\mathbf{s} = \mathbf{0}$. As shown by Silvey (1959); Engle (1982), if the null hypothesis is true, the score statistic ξ_1 in Eq. (5) (subscript 1 refers to the parameter θ_1 under diagnosis) is distributed as a χ^2 distribution with degree of freedom equal to the number of imposed constraints, i.e. $N-1$.

$$
\xi_1 = \hat{\alpha}^T \nabla \mathbf{s}^T \mathbf{H}^{-1} \nabla \mathbf{s} \hat{\alpha} \sim \chi^2
\tag{5}
$$

In Eq. (5), $\mathbf{H}$ is the $(N + N_\theta - 1) \times (N + N_\theta - 1)$ Fisher information matrix associated to the estimates $\hat{\theta}_E$ (Bard, 1974). The critical value for the test ξ_{ref} is calculated from a χ^2 distribution with $N-1$ degrees of freedom and 95% of significance. A $\xi_1 > \xi_{ref}$ shall be interpreted as evidence of θ_1 being a state-dependent quantity given that $\theta_2, ..., \theta_{N_\theta}$ are state-independent parameters. The score ξ_i may be computed for the generic i-th parameter following the above procedure. If $\xi_i > \xi_{ref}$ and $\xi_j > \xi_{ref}$, the fitting quality is expected to increase by relaxing the constraints either on θ_i or on θ_j. However, a $\xi_i > \xi_j > \xi_{ref}$ suggests that the evidence for justifying the evolution of parameters into state-dependent functions is stronger for parameter θ_i than for parameter θ_j.

3. Case study and results

The illustrated Lagrange multiplier test is demonstrated with a case study on a fed-batch bio-reactor system simulated in silico (Asprey and Macchietto, 2000). The process be-

haviour is described by the set of equations Eq. (6) with a Cantois-type kinetic Eq. (7).

$$\frac{dx_1}{dt} = (r - u_1 - \theta_4)x_1; \quad \frac{dx_2}{dt} = -\frac{rx_1}{\theta_3} + u_1(u_2 - x_2); \quad \frac{dx_3}{dt} = \theta_5 u_2 \tag{6}$$

"true" process rate: Cantois $\rightarrow r = \dfrac{\theta_1 x_2}{\theta_2 x_1 + x_2}$ \hfill (7)

In Eq. (6) and Eq. (7), $x_1(t)$ is the biomass concentration [g/L], $x_2(t)$ is the substrate concentration [g/L], $u_1(t)$ is the dilution factor [h^{-1}], $u_2(t)$ is the substrate concentration in the feed [g/L] and x_3 is a dummy process variable with no physical meaning. The set of equations involves a set of five parameters $\theta = [\theta_1, \theta_2, \theta_3, \theta_4, \theta_5]$. The candidate model structure involves the set of equations Eq. (6) with a Monod-type kinetic Eq. (8).

$$\text{assumed rate: Monod} \rightarrow r = \frac{\theta_1 x_2}{\theta_2 + x_2} \tag{8}$$

Experimental data are generated in-silico by integrating the model equations with the "true" Cantois-type rate law. The parameter set assumed to simulate the experiments is $\theta^* = [0.310, 0.180, 0.550, 0.050, 0.200]$. The dataset Y consists of $N = 28$ samples of $\mathbf{y} = [x_1, x_2, x_3]$ collected in four dynamic experiments performed at different combinations of dilution factor and substrate concentration in the feed considering two levels for each variable $u_1 = \{0.050, 0.20\}$ and $u_2 = \{5.0, 35.0\}$. In each experiment, seven samples are collected at intervals of 3.0 hours. Initial conditions are fixed at $x_1(0) = 1.0$, $x_2(0) = 0.01$ and $x_3(0) = 0.1$. Measurements are affected by uncorrelated Gaussian noise with standard deviation $5 \cdot 10^{-2}$ [various units].

The estimate $\hat{\theta} = [0.305, 0.288, 0.524, 0.047, 0.199]$ for the candidate model parameters is obtained fitting the dataset Y. Subsequently, a 95% goodness-of-fit test is performed. A sum of squared residuals of 2301.6, larger than $\chi^2_{ref} = 100.7$, highlights the presence of PM mismatch.

The mismatch is diagnosed using the proposed Lagrange multiplier test. The critical value used in the test is $\xi_{ref} = 40.1$. Score statistics are reported in the radar chart in Figure 2a. As one can see from Figure 2a, the smallest score is associated to θ_5, i.e. $\xi_5 = 21$. The score suggests that parameter θ_5 is the least correlated to the root of the PM mismatch. Since $\xi_5 < \xi_{ref}$, the replacement of θ_5 with a function of the states is not expected to significantly improve the fitting quality. The scores associated to parameters $\theta_1 - \theta_4$ are higher than the reference value, i.e. $\xi_i > \xi_{ref} \; \forall i = 1, ..., 4$. The highest scores are $\xi_2 = 2245$ and $\xi_1 = 2218$, suggesting that parameters θ_2 and θ_1, which appear in the misspecified Eq. (8), are the most correlated to the source of PM mismatch. Also the scores associated to θ_3 and θ_4, i.e. $\xi_3 = 684$ and $\xi_4 = 1829$, are significantly higher than $\xi_{ref} = 40.1$. However, since $\xi_2 > \xi_1 > \xi_4 > \xi_3$, the evidence for justifying the replacement of a parameter with a state-dependent function is stronger for θ_2 and θ_1 when compared to the evidence associated to parameters θ_4 and θ_3. The scores can be interpreted as indexes for driving parameter evolution into functions, as represented in Figure 2b.

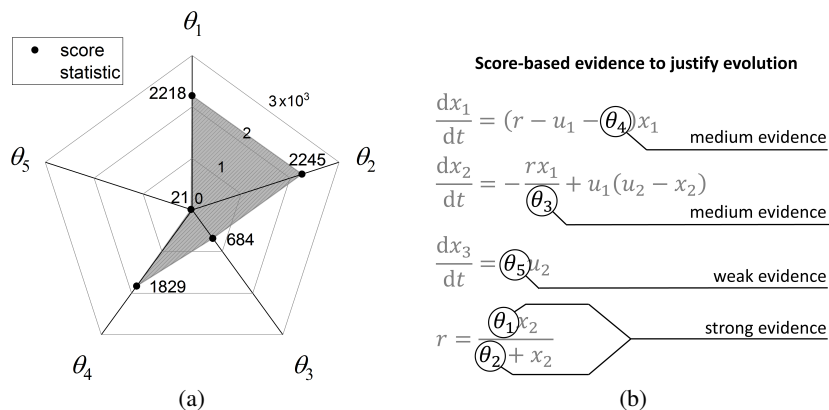
The modelling activity may proceed by evolving the parameters with the highest score into state-dependent functions. The PM mismatch can be eliminated by evolving θ_2 into the function $\theta_2 x_1$, but also by evolving θ_1 into $\theta_1(\theta_2 + x_2)/(\theta_2 x_1 + x_2)$. In future research activities, further tests will be formulated for evolving parameters into functions by supporting the construction of appropriate functional forms of the process variables.


Figure 2: (a) Score statistics for parameters in the candidate model. (b) Score-based evidence for justifying the evolution of parameters into state-dependent functions.

4. Conclusions

When under-fitting is detected by challenging a parametric model against process data, model complexity shall be increased. The lack of systematic approaches to increase model complexity frequently leads to the full rejection of the model and the formulation of alternative model structures from scratch. A statistical test is proposed in this work to diagnose process-model mismatch which could inform the evolution of the model. The proposed score statistic is proportional to the marginal fitting cost associated to the assumption that a given parameter is a state-independent constant. A high score indicates strong evidence for expecting an improvement on the fitting quality if the parameter were evolved into a state-dependent function. Future work will focus on developing tests for unravelling functional relationships between state variables and the parameters selected for evolution.

Abstract

Solar panels and wind turbines are key technologies for a sustainable low-carbon energy transition. The large diffusion of weather-dependent renewable energy generators face the challenge to fit the demand of uncertain loads with the most appropriate mix of distributed energy resources. The availability of accurate climate variables projections is essential to identify the best combination among distributed generators, energy storages and power loads in each geographical location. From the European Centre for Medium-Range Weather Forecasts (ECMWF) datasets of several climate variables are available for renewable energy resources yield forecasting. This paper presents different approaches to manipulate ECMWF datasets by combining Fast Fourier Transform with polynomial and forest tree regression models to predict climate variables over a one-year period, typical for microgrid simulations. An example of climate datasets forecasts related to the city of Bremen is presented with the evaluation of performances during test and training scenarios phases.

Keywords: FFT, IFFT, ECMW, Renewable Energy Systems, Climate Monthly Datasets.

1. Introduction

1.1. Scope of this work

The European Centre for Medium-Range Weather Forecasts (ECMWF) provides a large number of climate datasets for public use updated until three months of real time; these datasets are available in ERA5, the fifth generation ECMWF atmospheric reanalysis of climate variables, built by combining models from across the world into a globally consistent database. Our work has been focus on developing an approach to extrapolate multiple ERA5 datasets by manipulating just a single dataset. In order to reach this result, Fast Fourier Transform (FFT) has been combined with Inverse Fast Fourier Transform (IFFT) and polynomial regression. The novelty of work mainly consists in the application of this method to the most updated ERA5 gridded datasets. The result is a viable route for improving the accuracy in wind and solar energy simulations, by avoiding the errors introduced with real weather data (D. Quiggin et al. - 2012) and old average climate datasets (NASA/SSE - 2008).

1.2. State of Art

The spectral transform method has been successfully applied in climate datasets for more than thirty years. The Fourier Transform method was introduced to numerical weather prediction starting from the work of Eliasen et al. (1970) and Orszag (1970).

Later works show an extensive use of monthly climate data: Joly and Voldoire, (2009) have developed a method to manipulate gridded datasets with Fast Fourier Transform (FFT) to better understand the coupled ocean–atmosphere processes. Kentat et al. (2013) analysed climate measurements, satellite retrievals of monthly mean marine Wind Speed to validate the accuracy required in calculation of air–sea heat fluxes. Wang and Zeng (2015) have elaborated climate data to quantify the land surface air Temperature. Amendola et al. (2017) used Fourier Transform to recombine Gaussian distributions obtained via Neural Network for seasonal weather forecasts. Wang et al. (2018) using monthly mean, have constructed indices of boreal sea surface Temperature in equatorial Pacific. Andres and Agostaa (2014), elaborated the correlations among atmospheric, oceanic gridded data with lunar nodal by using filtered climate data and Fast Fourier Transform.

2. Methods to manage the climate datasets and detect the errors

Fourier analysis is a method for expressing a complex function as a sum of periodic components, and for recovering the function from those components. Cooley and Tukey (1965) and later Press et al. (2007) provided a computing approach to Fourier analysis for discretized counterparts: the Fast Fourier Transform (FFT).

2.1. Fast Fourier Transforms for monthly climate predictions

Manipulation of datasets arrays, computing optimizations, FFT algorithms and regression analysis has been conducted with Python programming language. The following ECMWF monthly means of daily means has been elaborated: solar net surface Radiation [kWh/m^2], 10 meter Wind Speed [m/s] Temperature at 2 meters from soil [K], Cloud Cover [%]. Two predicting curves of n-dimension respectively: n=72 and n=12 inherent the four climate datasets are generated. The first set of curves (n=72) was utilized to train the IFFT model; the second set (n=12), to test the model over one-year timeframe (June 2017 to June 2018). The developed FFT models (1) returned a transformed complex array ($y_d[k]$) and the corresponding frequency spectrum. A first complex array in the frequency domain (CAY) of k_1-dimension was generated with original n=72 datasets. A second complex array (CAA) of k_2-dimension, with n=12 array was created with the averages of monthly datasets.

$$y_d[k] = \sum_{n=0}^{N-1} e^{-2\pi j\frac{kn}{N}} x_d[n] \tag{1}$$

The two complex arrays have been used as input to return into the time domain the training and test predicting curves by using the inverse discrete transform (IFFT) as defined as:

$$x_f[n] = \frac{1}{M} \sum_{k=0}^{M-1} e^{2\pi j\frac{kn}{N}} y_f[k] \tag{2}$$

For testing purposes a typical test period of a simulation (n=12) was selected, suitable for conversion in hourly solar Radiation data (T. Khatib, and W. Elmenreich, 2015).

Three different routes have been pursued to return in the time domain, the predicting curves. The first and the second, the predicting curves were based on CAY and CAA

complex arrays, where original spectrum have been considered. A third approach was based on a CAY complex array generated with a subset of the original frequencies, minimizing the Mean Squared Error (MSE). The MSE and the predicted array $x_f[n]$ were minimized with an optimization algorithm that embeds a low-pass filter (LPF). LFP iterates the cut-off frequency of the complex array and attenuates signals with the frequencies (k_3) higher than the cut-off frequency as defined in Eq. 3 until the optimal MSE result were obtained. The best complex final array with k_3 spectrum, returned in the time domain thru the IFFT algorithm, the predicting curves (model validation).

$$\min f(k) = \frac{1}{N}\sum_{n=1}^{N}(x_d[n] - \frac{1}{M}\sum_{k=0}^{M-1}e^{2\pi j\frac{kn}{N}}y_f[k])^2$$

$$0 \leq f_f[k] \leq \frac{f_s}{2}$$

(3)

Finally the performances with R^2 index, which estimates the ratio between the square error and the variance. $R^2=1$ indicates the best performance:

$$R^2 = 1 - \frac{\sum_{n=1}^{N}(x_d[n] - x_f[n])^2}{\sum_{n=1}^{N}(x_d[d] - \mu_x)^2}$$

(4)

2.2. Detection of climate variable interrelations with different regression analysis

The scope was to define an alternative indirect method to build the predicting curves, starting from one of the variables. As proposed by S. Raschka (2015) an exploratory data analysis was executed to identify the presence of outliers, the distribution of the data, and the relationships between the variables, and then scatterplot was created from the matrix to visualize the pair-wise correlations. To quantify the linear relationship between the variable, a correlation matrix embedding the Pearson product-moment covariance coefficients was defined:

$$P_{x,y} = \frac{\sum_{n=1}^{N}\left[(x_d[n]-\mu_x)(y_d[n]-\mu_y)\right]}{\left[\sum_{n=1}^{N}(x_d[n]-\mu_x)^2\right]^{-2}\left[\sum_{n=1}^{N}(y_d[n]-\mu_y)^2\right]^{-2}}$$

(5)

where μ denotes the sample mean of the corresponding variable. The linear dependence between pairs of variables is strictly related to the value of Pearson coefficient within the range -1 and 1. A perfect positive linear correlation is expressed by $P_{x,y} = +1 / -1$, while no correlation if $P_{x,y} = 0$. The relationship among monthly climate variables with the Pearson's coefficient higher than 0.7 has been modeled by using: linear, quadratic and cubic polynomials. For variables with a weak Pearson's coefficient, as proposed by A. Liaw and M. Wienerthe (2002) the random forest method has been used. This method allows dividing a continuous regression curve into a sum of linear functions. The performance of the forest regression was again evaluated with the following parameters: R^2 and MSE.

3. Results

Three FFT-IFFT methods have been utilized to generate the predicting curves, reproducing the climate monthly data and compared the result with ERA5 datasets over the period June 2017 to June 2018. The reference location was: the city of Bremen, where the Latitude is 53.07 and the Longitude is 8.80; both in Decimal Degree. After detecting the frequency domain, the peak frequency of each dataset was identified. As showed in table 1, Radiance, Cloud Cover, Temperature were predictable with a limited spectrum (1,16-2,83 [Hz]), while Wind Speed reached the minimum MSE at a highest cut-off frequency (4,16 [Hz]). The Pearson's coefficient correlation matrix indicated a linear interrelation among the most predictable variables (Radiation, Temperature and Cloud Cover). After generating all the predicting training curves by filtering the frequencies at minimum MSE the R^2 index was measured. As reported in table 1 the best performing curves has been obtained with the filtered frequency dataset for Radiance while for Cloud Cover, Temperature and Wind Speed the average datasets has returned a better extrapolation.

Dataset	Radiance	Cloud Cover	Temp	Wind Speed
R2 test – average all spectrum	0,937	0,226	0,890	0,549
R^2 test - all spectrum	0,955	-0,014	0,868	0,172
R^2 test - filtered spectrum	0,956	0,196	0,877	0,114
Peak Frequency	1	1	1	1
Cutoff Frequency	1,16	1,16	2,83	4,16
MSE	0,058	0,003	4,025	0,223

Table 1 – Summary of the datasets performances.

An example of test results (Radiance) with a comparison among the three predicting curves is showed in fig.1. The profile of the curve of Temperature reflects a similar behavior. Although the predicting curves of Cloud Cover and Wind Speed did not match the original dataset, tendency of these curves were coherent to the original datasets.
Fig. 1 - Comparison of test curves for Radiance.

After modeling the predicting curves, and visualizing a scattered matrix, the pair-wise correlations between the different variables and the Pearson Coefficients have been measured. The relationship between the Radiation and the other variables is characterized by a value higher than 0.6 (ssr-t2m = 0.81, ssr-tcc = 0.71, srr-si10 = 0.63), which reflects a stronger linear correlation. Looking at these Pearson's correlation coefficients, three different regression models have been implemented. The results delivered linear, quadratic and cubic polynomial regressions (fig. 2). The R^2 (0.65) was the same for all degree of regressions and confirmed the strong correlation among these variables.
Fig. 2 - Linear, Polynomial regression and performance of two variables with a strong linear interrelation.

For the variables correlated with a lower Pearson coefficient (tcc-si10) the random forest regression obtained by subdividing the space into smaller regions and connecting these regions with piecewise linear functions gave a better result: in contrast to the polynomial regression models that returns $R^2=0.30$ with linear, and $R^2=0.34$ with quadratic and cubic regressions, forest tree regression has given $R^2=0.85$.

4. Conclusions

The world is facing massive energy and environment challenges due to global warming and the increase of energy demand. Renewable energy systems play an important role for a sustainable low-carbon energy transition thru microgrid, a major emerging technology concept that enables a tight integration of photovoltaic systems and wind turbines, with residential, commercial, industrial buildings. The design and management of a microgrid has to accomplish several challenging requirements while dealing with uncertainty of the renewable energy sources and the variability of load profiles. Model-based simulation tools are extensively used to identify the best-fit combination of distributed energy sources and the accuracy of input climate variables is pivotal for the quality of the simulations. The European Centre for Medium-Range Weather Forecasts (ECMWF) provides a large number of climate datasets but later works show that since now, their main use is in climate models and weather forecasts. In this paper, we

presented a new application of these climate datasets for improving microgrid simulations. An innovative method based on Fast Fourier Transform combined with Inverse Fast Fourier Transform was used to convert original gridded ECMWF Solar Radiation, Wind Speed, Temperature, and Cloudiness datasets into the frequency domain and then the complex arrays have been transformed back into the time domain by filtering the frequency spectrum. The objective was minimizing the mean square error between the predicted and original climate variables. Three different routes have been utilized to train the algorithm. R^2 index applied to a further testing dataset indicated the resulting performances. Finally the Pearson's correlation coefficient among coupled datasets was used for the choice of the most suitable regression method to generate multiple strings of climate data, starting from a predicted dataset. This innovative method combining FFT-IFFT with linear regression proved to be easy and effective to predict accurate discrete climate variables suitable for microgrid simulations, avoiding errors introduced by historical climate records and observed data.

End-of-Pipe Zero Liquid Discharge Networks for different brine water qualities

Fatima Mansour, Sabla Y. Alnouri[*]

Department of Chemical and Petroleum Engineering, American University of Beirut, P.O.Box 11-0236, Riyad El-Solh, Beirut, Lebanon
sa233@aub.edu.lb

Abstract

More often than not, wastewater generated from any sort of industrial process poses a problem in terms of disposal cost and hazardous environmental impact. Systems that seek to eliminate wastewater discharge from any given process are known as Zero Liquid Discharge (ZLD) systems. Such systems, often composed of a combination of different technologies, aim to minimize wastewater volume and maximize the amount of water that can be recovered. Economically speaking, it is challenging to alter existing processes in a way that can achieve zero discharge. End-of-pipe ZLD systems provide an intermediate solution, whereby additional units can be added, forgoing the need for structural change in the existing process. In addition, environmental discharge standards can be satisfied. This paper presents an overarching ZLD network structure and model that can be customized to yield a cost-effective end-of-pipe ZLD discharge system based on user specified data and conditions. In particular, this paper focuses on the design of different End-of-pipe ZLD systems using brine wastewater data from two different industries: i) wastewater from a coal seam gas plant, and ii) wastewater from a steel plating industry.

Keywords: Brine, Zero-Liquid-Discharge, Wastewater

1. Introduction

Increasing water scarcity and a growing water crisis worldwide have heightened the search for alternative water sources (Subramani and Jacangelo, 2014). Although desalination technologies are highly sought after to amend water scarcity, the brine they generate has also evolved to be a weighty problem (Morillo et al., 2014). Brine is the main by-product of many desalination process, and is always characterized by a high content of dissolved salts and a high salinity. As such, ZLD systems are gaining more attention, as they possess the ability to reduce wastewater discharge, generate recovered product water, and allow for compliance with strict environmental and wastewater disposal regulations. The optimal option for brine discharge depends on a number of factors, mainly brine quantity, quality, and cost (Giwa et al., 2017). Because of this, ZLD systems tend to be customized for each system based on individual system characteristics (Tillberg, 2004). As such, long term brine management has become of utmost importance, particularly with increasing environmental scrutiny and decreasing water supplies. Existing brine disposal methods, such as surface water discharge, deep well injection, and land application, do not eliminate the problem, but attenuate its impact. That and increasingly stringent environmental regulations have propelled the search for more suitable alternatives, mainly ZLD methods. Zero liquid discharge (ZLD) technologies have been gaining more attention as a means for brine minimization. The introduction of

these options has encouraged their integration as end-of-pipe solutions to brine disposal (Subramani and Jacangelo, 2014). Moreover, the water quality generally plays a vital role in the design of any wastewater handling system (Alnouri et al. 2016). To provide a more generic methodology through which users can easily determine the best ZLD scheme for a certain system, this paper proposes an MINLP optimization model in which an economic objective, has been utilized to minimize system design costs, whilst selecting an optimal brine treatment system based on user input.

2. Methodology

The proposed model has been devised based on a ZLD superstructure that is illustrated in Figure 1 below. The ZLD network proposed consists of four different technology sets: chemical processing (set P), thermal (set T), membrane (set M), and brine processing (set B). The chemical processing technologies generally requires a chemical feed stream and results in the production of some salt product, aside from the concentrated brine produced. On the other hand, thermal and membrane technologies take in concentrated brine, and produce product water and further concentrated brine. Brine processing technologies use its feed of concentrated brine to produce salt and product water. The system is designed such that the entering feed water first undergoes chemical processing. Placing the chemical processing blocks first provides a starting point for treatment by removing salts and "softening" the brine for further treatment. The treated water stream can then move to either the thermal or membrane technology blocks, or to both of them. A portion of the streams leaving these two bins is recycled to the start of the system. A recycle stream is included in the design for enhanced system performance. The recycle is split from the concentrated brine leaving the thermal technology block, and another from the concentrated brine leaving the membrane technology block. These two streams then converge to join the original feed stream. The remaining brine enters the brine processing block. This block comes last because it essentially separates the salt from the water, thus resulting in water and salt production.

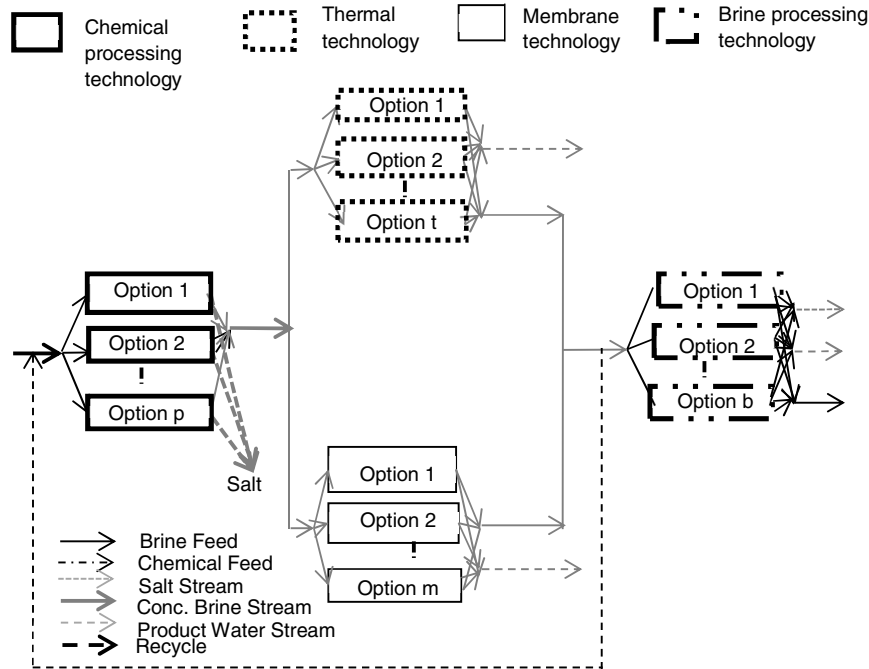
In accordance with the requirements for a specific system, a selection of technologies must be assessed in each block. The proposed approach selects the optimal technology in each block, or forgoes certain blocks altogether (mainly thermal or membrane), depending on mass balance consistency and other user specified requirements. Each technology comes with its own set of specifications, such as capacity limits and feed water characteristics (e.g. permissible inlet TDS and hardness content). Furthermore, each technology must have a specified water recovery, in addition to component rejection values that have been accounted for and included in system calculations. The system is designed such that different requirements can be met in terms of required product water yield and allowed purge quantities. Constraints can be placed on these values, and the overall ZLD scheme may be assessed based on those input parameters. The splits between technologies within a block, between different blocks, and for recycle and purge purposes can all be controlled by the user and specified to meet any particular standards. Hence, the constraints placed on the system can be specified according to one of the following forms: i) capacity constraints (the flowrate a particular technology can withstand), ii) composition constraints (the inlet or outlet composition limit to a particular technology), iii) and product water production (where the user specifies a certain requirement in terms of how much product water must be generated, as a percentage of the feed flow).


Figure 1. General ZLD superstructure scheme

3. Mathematical Formulation

The mathematical formulation of the proposed optimization model falls under the general form of a Mixed Integer Non-Linear problem, where a cost objective function (f(x)) is subjected to various equality and inequality constraints:

$$\min f(x) \tag{1}$$

$$h_i(x) = 0, \forall i \in I = \{1,,p\} \tag{2}$$

$$g_j(x) \leq 0, \forall j \in J = \{1,,m\} \tag{3}$$

Eq. (1) represents the objective function, f(x), which in the case of this work, is to minimize the overall cost of the ZLD system. The overall cost covers both capital and operating costs. nit. This is where the nonlinearity arises; the cost equations are derived from data sets collected from different literature sources (Mickley, 2008); each technology unit has two cost functions: one for operating costs) and another for capital costs. It should be noted that energy requirements are embedded in the operating cost models. Moreover, the total system cost is determined by summing the operating and capital costs of the technologies selected. The central variable in this model (x) is the split fraction vector, and it is of a continuous type. Hence, the split ratios for the flows between technology blocks, for individual feed flows between technologies within each block, and for the amount to be recycled, are all variables. The objective is subjected two sets of constraints. The first set, h(x), consists of equality constraints (Eq. (2)); these constraints

cover the mass and component balances of the different flowrates and material throughout the system. The mass balance equations take into account technology specifications, particularly salt rejection and water recovery. The second set, g(x), pertains to inequality constraints (Eq. (3)). These constraints can be of several types: i) production and performance requirements, which refer to imposing a minimum or maximum amount of product (product water or salt) or waste (concentrated brine to be purged) to be generated, ii) capacity constraints, which place a limit of the feed flow allowed into a certain limit and/or a limit on the recycle flow, and iii) composition constraints, which place a restriction on the amount of a specific component allowed into (or out of) a technology (such as salinity). Aside from the constraints imposed for the mathematical consistency and practicality, the number and nature of constraints can be tailored to represent any reasonable user imposed constraints.

4. Case Study Illustration

This case study features two types of industrial wastewater: (1) wastewater generated from a steel plating mill and (2) wastewater from a coal seam gas plant. Each of these feed water types has different characteristics and would be expected to require different treatment methods. The main difference showcased for the purpose of this case study is TDS content, as provided in Table 1. In terms of technology appropriation, a handful of the commonly used ZLD technologies are selected for each block, as summarized in Table 2 below.

Table 1. Feed water Parameters, adapted from

Feed water Type	Flow (m^3/h)	TDS (ppm)	Reference
Coal seam gas wastewater	100	62,450	(Pramanik et al., 2017)
Steel Plating Mill Wastewater	100	2,400	(Chimeng, 2014)

Table 2. Technology Selection

Chemical Processing	Thermal	Membrane	Brine Processing
Lime Softening	Multi-Effect Distillation	Brackish Water Reverse Osmosis (BWRO)	Brine Crystallizer
	Brine Concentrator	Seawater Reverse Osmosis (SWRO)	Evaporation Pond

As noted above, each technology comes with its own set of characteristics and constraints. An overall constraint is imposed such that 95% of the feed must be converted to product water. Aside from this constraint, there are capacity constraints (maximum inlet feed flow) on all of the selected technologies. The BWRO technology has a feed composition constraint in that the maximum allowed Total Dissolved Solids (TDS) into the unit is 6000 mg/L, whereas the brine concentrator can concentrate its feed stream up to 300,000 mg/L, placing a maximum on the allowed exit TDS. All of these values, in addition to each technology's water recovery (γ) and salt rejection (θ) values, are obtained from the

literature and used to characterize the system, as summarized in Table 3. The "what'sBest9.0.5.0" LINDO Global Solver for Microsoft Excel 2010, on a laptop with Intel® Core ™ i7-2620M, 2.7 GHz, 8.00 GB RAM, 64-bit Operating System, was used.

Table 3. Summary of system parameters and constraints, (Masnoon and Glucina, 2011)[a], (Mickley, 2008)[b], (Burbano and Brandhuber, 2012)[c], (Tillberg, 2004)[d]

Sets	Technology	Flow capacity (L/h)	γ	θ	TDS
Set T	Multi-Effect Distillation (MED)	625,000	0.3[a]	0.99[b]	NA
	Brine concentrator	158,987	0.95[c]	0.9[b]	300,000[d] (exit)
Set M	SWRO	5,333,333	0.5[b]	0.99[b]	NA
	BWRO	4,083,333	0.7[b]	0.99[b]	6000[b] (inlet)
Set P	Lime softening	NA	NA	0.5[b]	NA
Set B	Evaporation pond	157,725	NA	NA	NA
	Brine crystallizer	11,354	0.95[c]	0.85[b]	NA

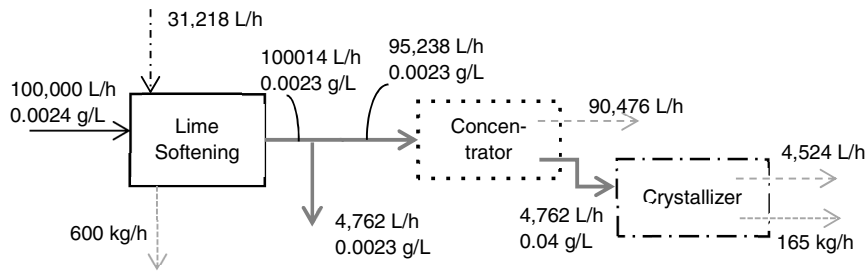
The ZLD schemes illustrating the results generated from the solver simulations for each scenario are shown in Figures 2 and 3, respectively. In the first scenario, after the chemical processing unit, 5% of the concentrated brine is purged from the system. The solver only takes 95% of the feed into the thermal technology block, because that is all that is needed to satisfy the product water requirement (95% of the feed), purging the remaining 5% to reduce costs (as the cost functions depend on flow). In the thermal technology block, the concentrator technology is selected as the optimal technology, whereas in the brine processing block, the crystallizer is selected. This scheme train is of significance because the brine concentrator and brine crystallizer are the typical technologies most commonly implemented to achieve ZLD (Mickley, 2008).


Figure 2. ZLD scheme for steel plating mill wastewater feed

The MED option is selected as a result of the exit TDS constraint being placed on the brine concentrator. Because of the higher inlet TDS in this scenario (62,450 versus 2,400) mixed with the recycled concentrated brine, the brine entering the thermal technology block has high salinity. Concentrating it further renders the exit TDS over the 0.3 composition limit placed on the concentrator, yielding MED as the only feasible choice. A recycle stream appears, where over 90% of the concentrated brine is exiting the MED unit is recycled back and mixed with the original feed. This option is feasible because the product water constraint (yielding 95% of the feed as product water) is already satisfied; and with the objective of minimizing cost, recycling becomes economical, instead of

moving the entire flow to the brine processing block. In the brine processing block, both technologies are included in the scheme, due to the capacity constraint placed on the brine crystallizer (allowing a maximum of 11,354 L/h inlet flow). Consequently, the rest of the concentrated brine is re-diverted to the solar pond.
Figure 3. ZLD scheme for coal seam gas wastewater feed

5. Conclusions

The proposed assessment approach provides a simple and effective means of optimally designing ZLD systems, based on cost effectiveness. ZLD systems were found to depend on numerous factors, including but not limited to: the quality and quantity of the brine feed stream, the technologies that have been incorporated into the different technology blocks and their respective design parameters and constraints. In addition, any user-specified product water production or waste limit requirements can be incorporated.

Abstract

Data collected in industrial processes are often high-dimensional, with dynamic and multi-granular characteristics that need to be properly accounted for in order to extract useful information for high level tasks, such as process monitoring, control and optimization. While the first two characteristics are already well addressed by state-of-the-art analytic methods, multi-granularity has received far less attention from the scientific community. Furthermore, data aggregation offers a suitable solution to handle the data deluge in Big Data scenarios, avoiding the loss of information of subsampling and multirate approaches. In this paper, we highlight the main aspects of multi-granularity data and present a novel multi-granularity framework that successfully addresses two fundamental problems: (i) handling multi-granularity data in a rigorous and consistent way; (ii) creating optimal multi-granularity structures for predictive modeling, even when raw data are available at a single granularity.

Keywords: Multi-granularity, Soft sensors, Batch processes, Continuous processes, Process Analytical Technology.

1. Introduction

Among the defining characteristics of industrial data, high-dimensionality and process dynamics are the most well-known and widely explored. They are typically handled through the use of projection-based (or latent variable) methods such as Principal Component Analysis (PCA) (Jolliffe, 2002) and Partial Least Squares (PLS) (Geladi et al., 1986) and their dynamic extensions with time-shifted variables (Ku et al., 1995, Kaspar et al., 1993, Rato et al., 2013). Alongside with these characteristics, multi-granular (or multiresolution) structures are often present in data. However, multi-granularity is often ignored and wrongly treated as a multirate problem, which is not the case. In the multirate case the recorded values regard instantaneous (pointwise) observations taken at regular sampling times. Conversely, in the multi-granularity case the recorded values contain information about the process with different levels of granularity (different resolutions) due to the aggregation of data during successive periods of time where high resolution data are merged and combined in order to produce a single low resolution observation per aggregation period. Another source of granularity can be found in situations where variables represent measurements made on composite samples collected during a certain time period (e.g., production lot, working shift, etc.), and therefore the recorded values regard specific windows of time. These windows of time are here defined as the variable's "time support". This characteristic makes multi-granular data sets fundamentally different from their multirate counterparts. Thus, they require the use of dedicated analytical methodologies that

simultaneously account for high-dimensional, dynamic and multi-granular characteristics, which, until now, were not available.

To achieve the aforementioned goal, two main classes of multi-granular (or multiresolution; these terms are here used interchangeably) modelling approaches must be defined. These classes, as well as their application scope are summarized in Figure 1. The first class of methodologies addresses the case where data already presents a multi-granularity structure. Consequently, the goal of these methodologies is to properly account for the relationships caused by the multi-granularity structure and obtain models that are more parsimonious and able to accommodate this reality. On the other hand, the second class of methodologies relates to the case where raw data is available at a single-granularity (i.e., all variables have the same resolution). In this case, the goal is to change the native granularity of each variable to an optimal granularity level that maximizes the data analysis performance. By doing so, the modelling framework also becomes more flexible, as well as able to smooth noisy variables and to remove redundant information. For these reasons, multi-granularity models are also more parsimonious, accurate and interpretable than single-granularity models.

For the sake of space, only the second class of methodologies are discussed in this paper. As for the first class of methodologies (handling multi-granularity data structures), we refer to reader to (Reis et al., 2006a, Reis et al., 2006b, Rato et al., 2017), where applications to process monitoring and predictive modelling are covered.

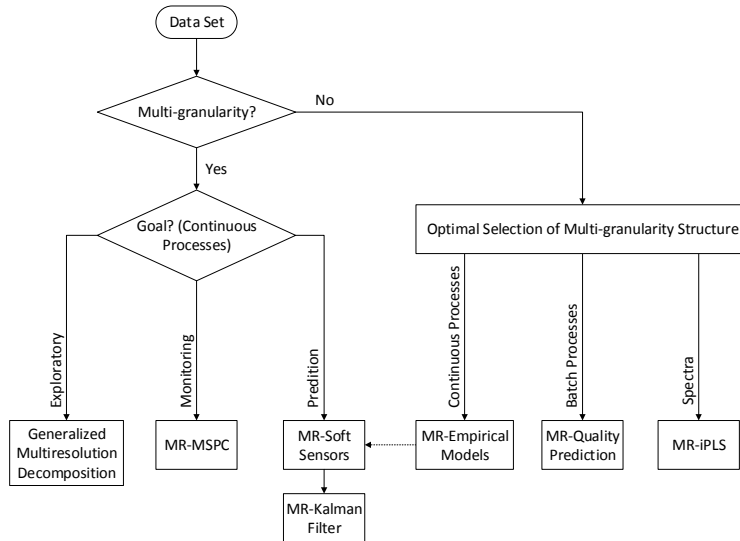
The rest of this paper is organized as follows. In Section 2, the modelling framework used for selecting optimal multi-granular structures is described. Afterwards, in Section 3, the application of this methodology is exemplified for (i) continuous processes, (ii) batch processes and (iii) spectroscopy data. Finally, the main conclusions of this work are summarized in Section 4.


Figure 1 Organogram of the multi-granularity framework and its application scope.

2. Multi-granularity parsimonious models

To introduce the concepts behind the multi-granularity models, let us consider that a variable at a given granularity is represented by $x_{i,t}^{(q_i)}$, where i is the variable index, t is the time index and q_i is an integer defining the variable's granularity level (note that different variables may be at distinct granularities). Without loss of generality, the multi-granularity structure is assumed to follow a dyadic tree with a time support of 2^{q_i}. That is, variables at the granularity level q_i are set to be an average over 2^{q_i} time instants in the finest time domain.

For the class of modelling methodologies discussed in this paper, it is considered that all predictor and response variables are originally available at level 0 (finest granularity or highest resolution). Therefore, multi-granularity is introduced by the modelling methodology, being the optimal granularity level determined by the selection algorithm described below. Furthermore, the approach used to change the predictors' granularity can be adapted to the specificities of each type of data. For instance, in the case of continuous processes, the changes in granularity are performed over moving windows (to preserve process dynamics), while for batch processes they are applied over non-overlapping windows (to accommodate for asynchronous batches and reduce the number of observations).

The multi-granularity selection algorithm used to find the optimal granularity of the predictors is based on the standard stepwise forward algorithm for variable selection with an additional search over the granularity dimension. This search is constrained to fall between the native granularity of the variables (0) and a maximum granularity level defined by the user (q_{max}). From our experience, a maximum granularity level of $q_{max} = 5$ is usually a good starting point, when no further information about the process is available.

In general terms, the multi-granularity stepwise forward selection algorithm starts by choosing an initial model by fitting tentative models for each combination of variables and granularities (i.e., for each combination of i and q_i). In each case, a vector of Cross-Validation Root Mean Squared Error (CV-RMSE) is computed using Monte-Carlo sampling. Afterwards, the combination leading to the lowest median CV-RMSE is selected to build the initial reference model. In the following step, the algorithm proceeds to an "adding" stage, where each combination of variables and granularities (except for the variables already in the model) is tentatively added to the reference model and compared against it using the CV-RMSE values, through a pairwise Wilcoxon rank sum statistical test (Wilcoxon, 1945). Finally, the algorithm performs a "removal" stage to tentatively remove variables from the model that become redundant after the "inclusion" stage. These "inclusion" and "removal" stages are repeated until no further improvement in the CV-RMSE is achieved. Following these steps, the output of the algorithm is a multi-granularity model with the best subset of predictors at their optimal granularity.

3. Applications

3.1. Continuous processes

Based on the algorithm shortly described in Section 2, Rato et al. (2018a) proposed a modelling framework for building multiresolution empirical models for continuous processes (MR-EMC). To illustrate the advantages of MR-EMC, the results obtained for a simulated distillation column using the model described in (Skogestad et al., 2005)

will be presented. This system is composed by a column with 41 stages and returns the compositions and temperatures in all stages. For this comparison, standard PLS, Dynamic PLS (DPLS) and MR-EMC models were used to estimate the distillate composition based on the temperature readings. To assess the consistency of the results, 100 replicates were made. Each replicate was composed by 1,000 observations for training the models and another 1,000 observations for testing their performance using the Mean Squared Error (MSE). In Figure 2, the pairwise differences between the MSEs obtained by PLS and DPLS are compared against those of MR-EMC. From this figure, it is clear that PLS presents the worst performance as it only uses the native granularity of the variables and has no information about process dynamics. When time-shifted variables are added, a significant improvement is observed (DPLS). Nevertheless, MR-EMC is still the best methodology since its MSEs are generally lower than those obtained with PLS and DPLS. These results demonstrate that selecting the optimal granularity for the predictors plays a major role in model accuracy. Furthermore, it was also observed that the MR-EMC models were easier to interpret since the selected combinations of variables and granularities were closely related to the true dynamic dependencies of the process.
Figure 2 Pairwise differences of the MSE over 100 replicates of the distillation column case study. For reference, the variance of the response is 1.37×10^{-9}.

3.2. Batch processes

A multiresolution quality prediction (MRQP) framework for predicting the end-batch quality by exploiting the structured correlation in both the time and variables dimensions was originally proposed by Gins et al. (2018) and later on extended by Rato et al. (2018c) to account for processes with different operational phases. The selection algorithm is similar to the one presented in Section 2, but now observations are also included as predictors (batch-wise unfolding). Furthermore, the batch is divided in stages in order to allow for a finer modelling of the variables importance. Thus, this methodology can effectively select the key process variables and the prominent operational phases affecting the end-batch quality. Adjusting the granularity of the variables also reduces the number of observations, which can significantly decrease the number of predictors when batch-wise unfolding is applied. This approach was tested with several systems, including simulated and real world processes. For the real world case, regarding an industrial batch polymerization process, the improvement achieved in prediction (*PRESS*) with respect to the standard Multiway PLS approach (Nomikos et al., 1995) was of 54 % (Gins et al., 2018).

3.3. Spectroscopy

The interval PLS (iPLS) algorithm proposed by Nørgaard et al. (2000) is typically applied to compare the performance of a full-spectrum model to that of local models based on subintervals of equal length. However, as this approach does not directly select the most relevant wavebands, sequential approaches based on forward (FiPLS) or backward (BiPLS) algorithms have been suggested (Xiaobo et al., 2007). Still, these methodologies are unable to optimally aggregate the original signal and denoise/merge redundant information within the interval, which ultimately reduces their prediction capabilities. To overcome this limitation, Rato et al. (2018b) proposed a multiresolution interval PLS (MR-iPLS) methodology that also selects the optimal granularity for each interval. Again, the selection algorithm is similar to that presented in Section 2, but since there is no time dimension, the changes in granularity are applied over non-overlapping intervals of wavelengths.

To exemplify the advantages of MR-iPLS against the standard iPLS models, the data set given in (Kalivas, 1997) is here used for comparison purposes. This data set is composed by near infrared (NIR) spectra (with a total of 401 wavelengths) for 60 gasoline samples with known octane numbers. In this study, the samples were randomly divided into a training data set with 40 samples and a testing data set with the remaining 20 samples. The models were fit on the training data set using 12 intervals with 32 wavelengths and one interval with 17 wavelengths. The independent testing data set was then used to evaluate the prediction performance of each model through the MSE, leading to the results presented in Table 1. These results clearly show that the FiPLS model has the worst performance due to its inability to overcome local optima. On the other hand, BiPLS provides better results due to the exclusion of irrelevant intervals. Nevertheless, it is noticeable that using MR-iPLS to optimize the granularity of the selected intervals, a model with even lower MSE is obtained. In this case, the 9 intervals selected by MR-iPLS were all placed at a coarser granularity level ($q = 5$). Consequently, instead of using the original 288 wavelengths in these intervals, only their averages are included in the model, which reduces the number of predictors to 9.

Table 1 MSE and number of predictors included in each model for the spectroscopy case study.

	PLS	FiPLS	BiPLS	MR-iPLS
MSE	0.0409	0.0451	0.0410	0.0381
Number of predictors	401	160	256	9

4. Conclusions

The presence of multi-granularity structures in industrial data limits the application of current data analysis methodologies since they are neither able to accommodate for this aspect, nor to take advantage of the intrinsic relationships. Furthermore, even when data is available at a single-granularity, it is not guaranteed that the native granularity of the predictors is the most appropriate one for process modelling. To address this situation, a set of multi-granularity modelling frameworks that simultaneously select the best subset of predictors to be included in the model along with the optimal granularity for each predictor have been proposed for several types of industrial data. In all the data scenarios considered, results show that the multi-granularity methodologies perform consistently better than their single-granularity counterparts, while leading at the same time to more parsimonious and interpretable models.

Abstract

This work presents the optimal operation and control of a Fluidized Bed Membrane Reactor (FBMR) for Steam Methane Reforming (SMR). First, a nonlinear distributed parameter dynamic model is developed. Next, the optimal operation of the system is studied by solving a dynamic optimization problem that maximizes the conversion and separation in the reactor. Based on the optimization result, reduced order linear models are developed and used in the design of conventional and model based controllers. The performance of these controllers are tested considering the variation in the inlet concentration of the feed to the reactor and the initial conditions.

Keywords: Fluidized Bed Membrane Reactors, Steam Methane Reforming, Optimal Operation, Model Based Controllers.

1. Introduction

Hydrogen is one of the most important chemicals used in the chemical industry, and lately, it has gained particular attention due to the wide range of applications also as an energy carrier. There are several technologies available for the production of hydrogen; however, the conventional steam methane reforming (SMR) is currently still the most common and economical way to produce hydrogen. The conventional SMR process consists of two main reactions given by:

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2, \Delta H_{298\,K} = +206\,\text{kJmol}^{-1}$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2, \Delta H_{298\,K} = -41\,\text{kJmol}^{-1}$$
In order to intensify this process and enhance the yield of hydrogen and shift the reaction equilibrium in the direction of producing hydrogen, new reactor concepts have been developed and investigated. The Fluidized Bed Membrane Reactor (FBMR) is one of the most promising membrane reactors for integrated reforming/dehydrogenation, separation and purification (Rahimpour et al. 2017). In the FMBR, a bundle of hydrogen-selective membranes are immersed into the fluidized catalytic bed in order to carry out the separation and reaction steps simultaneously. Such reactor concepts can reduce capital costs and improve process efficiency, but at the cost of losing degrees of freedom in the operation. Despite the substantial amount of work done on process design based on steady state modelling of FBMR's the study of operational aspects such as controllability, stability, and operational feasibility have not been investigated as extensively. Only a limited number of works is available with the application of control theory for a fluidized

bed reactor (FBR). However, these controllers cannot always be applied to an FBMR, because the intensified FBMR exhibits a quite different dynamic behaviour due to small equipment but same or larger process efficiency. Considering the impact of the intensification on the operation, the control design of a FBMR is very relevant.

In this work, we have studied the optimal operation and control of an FBMR for SMR. First, a dynamic model extending the steady-state models proposed by Medrano et al. (2018) is described. Next, the optimal operation of the system is studied. To this end, a dynamic optimization problem that maximizes conversion and separation in the reactor is proposed. Based on the result obtained from the optimization problem, and the dynamic model, linear models of the system have been developed. However, as the linear model is infinite dimensional (the dynamic model is given by a set of Nonlinear Partial Differential Equations), and control design based on these models is challenging, model reduction techniques have been applied. Finally, with the reduced linear model, low-level and Model Predictive controllers have been designed. The performance of these controllers has been tested in simulation in case of variations in the inlet composition of the feed to the reactor.

2. Dynamic Modelling of FBMR

Consider a FBMR where pure hydrogen is recovered via palladium-based membranes inserted into the fluidized bed (Gallucci et al. 2008). The dynamic model obtained in this work is an extension of the model proposed by Medrano et al. (2018) by including accumulation terms in the gas phase mass (bubble/wake and emulsion phases) and energy balances yielding the following set of Partial Differential Equations (PDEs),

$$
\frac{\partial}{\partial t}
\begin{bmatrix}
\left(f_{bw}C_{i,bw}\right) \\
\left(f_e C_{i,e}\right) \\
\left(\rho C_p f_{bew}T\right)
\end{bmatrix}
= -\frac{\partial}{\partial z}
\begin{bmatrix}
\left(f_{bw}u_b C_{i,bw}\right) \\
\left(f_e u_e C_{i,e}\right) \\
\left(\rho C_p f_{bew}uT\right)
\end{bmatrix}
+
\begin{bmatrix}
\xi_i + r_{i,bw}f_{bw}(1-\varepsilon_{mf}) + S_{mb} \\
-\xi_i + r_{i,e}f_e(1-\varepsilon_{mf}) + S_{me} \\
\sum_{k=1}^{p}\sum_{i=1}^{m}(-\Delta H_{r,k})r_{i,k}f_k(1-\varepsilon_{mf})
\end{bmatrix}
+
\begin{bmatrix}
0 \\
0 \\
\dfrac{4}{d}H_J(T_J - T)
\end{bmatrix}
\quad (1)
$$

$$\forall i = \left\{CH_4, CO_2, CO, H_2O, H_2\right\}$$

where ξ_i, $S_{\{mb,me\}}$ are the mass transfer rates between the bubble and emulsion phases,

and the membrane, and $r_{i,\{bw,e\}}$ are the reaction rates. The model given by Eq. (1) is

subject to a set of algebraic equations which are not included in this paper due to space limitations. However, a summary of the hydrodynamics and mass transfer correlations used in this work is reported in Medrano et al. (2018).

2.1. Discrete Model

In order to solve the dynamic model, the spatial derivatives of Eq. (1) are replaced by a backward differences approximation such that the model can be written as a set of ODEs,

$$\frac{d}{dt}\begin{bmatrix} (f_{bw}C_{i,bw}^j) \\ (f_e C_{i,e}^j) \\ (\rho C_p f_{bew} T^j) \end{bmatrix} = -\frac{1}{\Delta z}\begin{bmatrix} \Delta(f_{bw} u_b C_{i,bw}^j) \\ \Delta(f_e u_e C_{i,e}^j) \\ \Delta(\rho C_p f_{bew} u T^j) \end{bmatrix} + M\begin{bmatrix} \xi_i^j \\ S_i^j \\ r_i^j \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \frac{4H_J}{d}(T_J - T) \end{bmatrix}, \quad \forall j = 1,\dots,N \quad (2)$$

where Δ is defined as $\Delta C_i^j = C_i^j - C_i^{j-1}$, N is the number of sections in which the reactor is divided, and M is a matrix related to the mass transfer and reaction rates. After some algebraic manipulations Eq. (2) can be expressed as: $\dot{x} = f(x,u,d)$, $y = g(x,u)$, where

$$x = \left[C_{i,bw}^j, C_{i,e}^j, T^j \right]^T \in \mathbb{R}^{11N}, \quad y = \left[X_{CH_4,out}, C_{H_2,out} \right]^T \in \mathbb{R}^2 \text{ and } u = [F, T_J]^T \in \mathbb{R}^2 \quad \text{are the}$$

states, manipulated, and controlled variables respectively, with F the feed flow of the reactor, T_J the jacket temperature, and $X_{CH_4,out} = C_{CH_4,in}^{-1}(C_{CH_4,in} - C_{CH_4,out})$ the methane conversion. In addition, $d = \left[C_{i,bw}^{in}, C_{i,e}^{in}, T^{in} \right]^T \in \mathbb{R}^{11}$ are the disturbances of the system.

3. Optimal Operation of FBMR

The main objective of the FBMR is to maximize both the conversion of methane and the separation of the hydrogen throughout the membrane. By defining $X_{CH_4}^j \in [0,1]$ as the conversion of methane and $S_{H_2}^j \in [0,1]$ as the hydrogen separation factor along the reactor, we formulate the following optimization problem to achieve these objectives:

$$u_{opt} = \arg\min_u \int_{t_0}^{t_f} \left(\sum_{j=1}^N \omega \left\| 1 - X_{CH_4}^j \right\|_2^2 + (1-\omega)\left\| 1 - S_{H_2}^j \right\|_2^2 \right) dt \quad (3)$$

subject to: $\dot{x} = f(x,u,d)$, $y = g(x,u)$, $x \in \mathbf{X}$, $u \in \mathbf{U}$

Where $\omega \in [0,1]$ is a weighting parameter. In this optimization problem, the feed flow F and the jacket temperature T_j are the decision variables. From the practical point of view, the objective function of problem (3) is selected because it takes a minimum value when the raw material and the hydrogen produced are completely consumed and separated. Finally, the problem (3) is solved by parametrizing u and converting Eq. (3) into a Nonlinear Programming problem (NLP). The results of the optimization problem are shown in Figure 1.
Figure 1. Optimal Trajectories for the inlet feed flow and the jacket temperature.

Notice that in Figure 1, T_J does not change significantly. That means, during the normal operation (no disturbances), this variable must remain constant around 823 K. However, it is important to clarify that the controllers can still manipulate T_J, to reject disturbances and to keep the system in the optimal trajectory.

4. Control Design for FBMR

In this paper, two control techniques are used to keep the operation of the FBMR around the optimal trajectory presented in Section 3, MPC and PID. To design these controllers, a linear model of the process must be obtained.

4.1. Linear Model and Model Reduction

The linear model of the FBMR is obtained by linearizing $\dot{x} = f(x,u,d)$, $y = g(x,u)$ around the optimal operating profiles using Taylor series expansion and considering only the first order terms as follows,

$$\dot{x} = Ax + Bu + B_d d, A = f_x(x,u)\big|_{x^*,u^*}, B = f_u(x,u)\big|_{x^*,u^*}, B_d = f_d(x,u)\big|_{x^*,u^*}$$

$$y = Cx + Du, C = g_x(x,u)\big|_{x^*,u^*}, D = g_u(x,u)\big|_{x^*,u^*} \tag{5}$$

where $x \in \mathbb{R}^{11N}$, $y \in \mathbb{R}^2$, and $u \in \mathbb{R}^2$. In this paper, the spatial domain of the reactor is divided into 100 sections, resulting in 1100 number of states. The controllability analysis shows the system has uncontrollable states. These two facts, a large number of states and uncontrollable states, make the design and implementation of model-based controllers for the FBMR very difficult. A good solution to this issue is to eliminate the uncontrollable states. This also reduces the number of states . To this end, a model reduction technique called balance truncation (Gugercin and Antoulas, 2004) is implemented in the FBMR model, and briefly described in Table 1.

Table1: Mathematical formulation of the reduced order model

Full order Model	Reduced Order Model
$G(s): \begin{cases} \dot{x} = Ax + Bu + B_d d \\ y = Cx + Du \end{cases}, x \in \mathbb{R}^{11N}$	$\tilde{G}(s): \begin{cases} \dot{\tilde{x}} = \tilde{A}\tilde{x} + \tilde{B}u + \tilde{B}_d d \\ y = \tilde{C}\tilde{x} + \tilde{D}u \end{cases}, \tilde{x} \in \mathbb{R}^n, n \leq 11N$
$\tilde{x} = Tx, \tilde{A} = TAT^{-1}, \tilde{B} = TB, \tilde{B}_d = TB, \tilde{C} = T^{-1}C, \tilde{D} = D$, where T is computed using reachability and observability Gramians of $G(s)$. It is important to highlight that $\tilde{x}$ does not preserve the physical meaning of x , because $G(s)$ is not unique.	

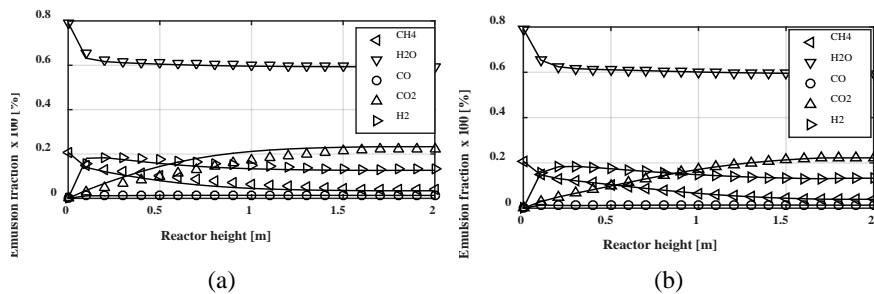
Figure 2 shows the steady state concentration profile of the nonlinear, linear and the reduced order models for CH_4, H_2O, CO, CO_2, and H_2 in the emulsion phase. In Figure 2, it can be observed that the reduced order model with only 11 states provides a good approximation of the linear and the nonlinear model.


Figure 2: Models comparison: concentration of CH_4, H_2O, CO, CO_2, and H_2 in the emulsion phase in steady state for: (a) the nonlinear (—) and linear ($\triangle$, ∇, $\triangleright$, $\triangleleft$, $\circ$) models. (b) Linear (—) and reduced order ($\triangle$, ∇, $\triangleright$, $\triangleleft$, $\circ$) models.

4.2. PID Control

We present the PID control design in Table 2. As the PID controller is a SISO control technique, the Relative Gain Array ($\Lambda(j\omega)$) method is used in this work to calculate the best input-output pairing for the process.

Table 2: Mathematical formulation of the PID including RGA

Model	PID
$y(s) = \tilde{G}(s)u(s)$ $\Lambda(j\omega) = \tilde{G}(j\omega) * \tilde{G}(j\omega)^{-T} = \begin{bmatrix} -0.0028 & 1.0028 \\ 1.0028 & -0.0028 \end{bmatrix}$	$u_i(s) = \left(K_p + \dfrac{K_i}{s} + K_d s \right) e_i(s)$ $e_i(s) = y_{ref} - y_i(s)$

Based on the RGA the input-output pairing must be $T_J - X_{CH_4,out}$ and $F - C_{H_2,out}$. Additionally, the transfer function $\tilde{G}(s)$ is identified based on the step response of the reduced order model. The results of this controller are presented in Section 4.4.

4.3. Model Predictive Control (MPC)

MPC has been widely adopted by the industrial process control community and has been implemented successfully in many applications. MPC can handle constraints, which often have a significant impact on the quality and safety in process operations. To design predictive controllers, a discrete time model of the process must be obtained. To this end, a Zero-Order Hold discretization method is used. In Table 3, the discrete time version of the reduced order model is described.

Table 3: Mathematical formulation of the discrete time model

Reduced Order Model	Discrete Time Model
$\tilde{G}(s): \begin{cases} \dot{\tilde{x}} = \tilde{A}\tilde{x} + \tilde{B}u + \tilde{B}_d d \\ y = \tilde{C}x + \tilde{D}u \end{cases} \xrightarrow{ZOH}$	$\tilde{G}(z): \begin{cases} \tilde{x}_{x+j+1} = \tilde{A}_k \tilde{x}_{k+j} + \tilde{B}_k u_{k+j} + \tilde{B}_{k,d} d_{k+j} \\ y_{k+j} = \tilde{C}_k \tilde{x}_{k+j} + \tilde{D}_k u_{k+j} \end{cases}$
The notation $k + j \triangleq (k + j)\Delta t$ where Δt is the sampling time	

The MPC control problem can be written as,

$$u_{MPC} = \arg \min_{\{u_{k+j}\}_{j=0}^{j=H_p-1}} \left\| x_{k+H_p} \right\|_P^2 + \sum_{j=0}^{H_p-1} \left\| x_{k+j} \right\|_Q^2 + \left\| u_{k+j} - u_{opt} \right\|_R^2$$

Subject to: $\hspace{10cm}$ (6)

$\tilde{x}_{x+j+1} = \tilde{A}_k \tilde{x}_{k+j} + \tilde{B}_k u_{k+j} + \tilde{B}_{k,d} d_{k+j}$, $y_{k+j} = \tilde{C}_k \tilde{x}_{k+j} + \tilde{D}_k u_{k+j}$, $x_{k+j} \in \mathbf{X}_k$, $u_{k+j} \in \mathbf{U}_k$

where H_p is the prediction horizon, and $\mathbf{X}_k$ and $\mathbf{U}_k$ are convex polyhedrons. The optimization problem (6) can be solved efficiently converting Eq. (6) into a Quadratic Programming (QP) problem.

4.4. MPC and PID comparison

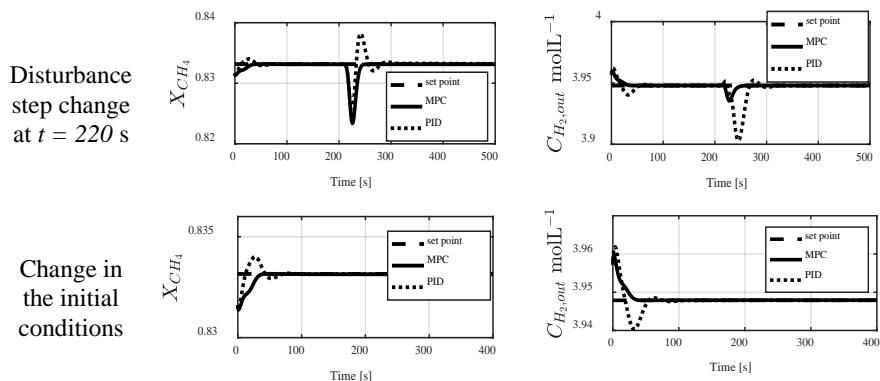
In order to test the performance of the controllers for the FBMR, two experiments have been carried out: step changes in the disturbances of the process at $t = 220s$, and different initial conditions. Figure 3 shows the comparison between the MPC and PID controllers.


Figure 3: Controllers Comparison: Closed-loop trajectories of the outputs, MPC (—) and PID (··) controllers.

Clearly, from Figure 3, the performance of the MPC is better than the one of PID. Of course, solving an MPC problem in real time is more complex; however, the constraint handling is an advantage. In this case, the inlet flow rate should be kept above minimum fluidization velocity.

5. Conclusions

In this paper, the optimal operation and control of an FBMR for SMR are studied. A dynamic model of the process is obtained, and an offline dynamic optimization problem is proposed to maximize the conversion of methane and separation factor in the FBMR. Based on the optimal operation, and the dynamic model, a reduced order linear model is developed using balance truncation methods. Finally, PID and MPC controllers are designed, and their performance tested in simulations considering variation in the inlet concentration of the feed to the reactor and initial conditions.

Abstract

The increasing issues about the use of fossil raw materials advocate for an expanding utilization of biomass-based fuels and chemicals. Among the bio-based furan compounds, the 5-hydroxymethylfurfural (HMF) has received considerable attention in the chemical industry since it can be hydrogenated to 2,5-dimethylfuran (DMF) that is a valuable alternative fuel. The identification of a suitable kinetic model, where all the non-measurable kinetic parameters can be reliably estimated, is crucial to pursue the process optimization. In this work, the kinetic models currently available in literature for the HMF hydrogenation process are investigated to underline their strengths and weaknesses using a sensitivity-based identifiability analysis. The application of identifiability analysis techniques allows to define a set of fully identifiable kinetic models to be used for statistically reliable predictions. Furthermore, the use of design of experiments techniques leads to the characterization of design space regions that maximize the quality of the statistics related to the different estimates.

Keywords: 5-hydroxymethylfurfural, identifiability analysis, kinetic models

1. Introduction

Diminishing fossil fuel reserves and growing concerns about global warming indicate that sustainable sources of energy are needed in the near future (Roman-Leshkov et al. (2007)). Thus, the interest toward *renewable fuels* is rapidly growing and the new biomass-derived fuels seem to be an alternative suitable solution, clean and environmental safe, to fossil fuels (Demirbas (2010)) used for vehicles. However, for fuels to be useful in transportation sector, they must have specific physical properties that allow for efficient distribution, storage and combustion. While these properties are fulfilled by non-renewable petroleum-derived liquid fuels, the low energy density, high volatility and tendency to absorb water, are the reasons that bring the researchers to keep looking for a more efficient substitute to currently existent alternative fuels. The catalytic production of 2,5-dimethylfuran (DMF) from 5-hydroxymethylfurfural (HMF) seems to be a potential answer. The use of a catalytic process leads indeed to the identification of a route for transforming abun-

dant carbon-neutral renewable biomass resources into a liquid fuel suitable for the transportation sector (Parikka (2004)), with the final result of a diminished reliance of world's economy on petroleum derivatives and an increased environmental safety. Since HMF hydrogenation is a relatively new process, a well validated kinetic model capable of giving reliable predictions of the process, has not been defined yet: the identification procedure is complex and, in the full range of expected process conditions, a structural identifiability analysis on the existing kinetic models available in literature has never been proposed. Different assumptions and mechanisms lead to different kinetic model structures and determine the overall model complexity: from the simple power law to more complex structures involving adsorption coefficients (Gawade et al. (2016); Gyngazova et al. (2017); Luo et al. (2015); Jain and Vaidya (2016), Grilc et al. (2014)). In this paper an identification analysis is carried out on one of the aforementioned kinetic models, and a correlation study is carried out to underline potential parametric identifiability issues. Finally, model-based design of experiments (MBDoE) techniques are employed to define the most informative experiments to be performed in a batch reactor system.

2. Methodology

2.1. Procedure for the identification of HMF hydrogenation kinetic models

The block flow diagram of the proposed procedure for the study of the HMF hydrogenation kinetic models, is given in Figure 1. As a first step, a set of candidate kinetic models
Figure 1: General procedure for the model identification.

is retrieved from the literature available. On each candidate, the identifiability analysis based on the study of the correlation between parameters is conduced by exploiting the local sensitivities. Once a set of identifiable kinetic models is found, MBDoE is applied to generate the optimal experimental conditions meant to maximize the Fisher Information Matrix (FIM) trace (Fisher (1935)). The results of the two analyses determine whether the kinetic models gathered at the beginning are affected by structural or practical unidentifiability issues. Moreover, they allow to define the most suitable regions of the experimental design space in which experiment must be carried out to maximize the quality of the statistics related to each estimate.

2.2. Identifiability analysis and MBDoE

Model identifiability procedures are used to recognize in advance structural and practical weaknesses related to models structure and application conditions. Structural identifiability is a property of the model structure and depends on the specific form of the differential-algebraic equations used to describe the phenomenon. Once an identifiable

model is available, the problem moves to the reliable estimation of its non-measurable parameters: to reduce the weight of this procedure, in terms of time and resources, MB-DoE techniques can be used to select the best experiments to be performed among a set of possible conditions (Galvanin et al. (2016)). With the sensitivity analysis, the local sensitivities for any m-th measurable output are evaluated perturbing one-at-time each N_θ non-measurable parameter and the result is a $n_m \times N_\theta$ sensitivity matrix. By repeating the analysis for each sampling time, it is possible to build a $n_{sp}n_m \times N_\theta$ *estimability matrix* and it can be used as an index of the model identifiability condition. A model can be classified as structurally identifiable if $rank(\mathbf{P}_E) < N_\theta$ (Shaw, 1999). This condition is satisfied when each column of the matrix $\mathbf{P}_E$ is independent on the others. Once the identifiability study has been performed, the sensitivities can be used to calculate the FIM trace and assess the amount of information available for each parameter that requires estimation (see (4.3)).

$$Tr\left[\mathbf{H}\right]_{kl} = Tr\left[\sum_{k=1}^{N_\theta}\sum_{i=1}^{N_{exp}}\sum_{j=1}^{N_m}\left[\frac{1}{\sigma_{ij}^2}\left(\frac{\partial \hat{y}_{ij}}{\partial \theta_k}\frac{\partial \hat{y}_{ij}}{\partial \theta_l}\right)\right]\right] \cong Tr\left[\mathbf{V}_\theta^{-1}\right] \tag{1}$$

where $Tr\left[\mathbf{H}\right]_{kl}$ represents the kl-th element of a metric function (trace) of the FIM and $\mathbf{V}_\theta$ is the variance-covariance matrix. Notice that, once the FIM is available for a kinetic model, according to Bard (1974) the variance-covariance matrix can be approximated to the FIM inverse. While the FIM does not take into account the correlation between parameters, the variance-covariance matrix does and allows to figure out the best experimental conditions capable of maximizing the estimates quality. It is possible to demonstrate that by improving the fitting of the model, the quality of the approximation improves as well. The expected correlation between model parameters can be computed from the elements of $\mathbf{V}_\theta$ through the correlation matrix $\mathbf{C}$, whose elements are:

$$c_{ij} = \frac{\mathbf{V}_{\theta,ij}}{\sqrt{\mathbf{V}_{\theta,ii}\mathbf{V}_{\theta,jj}}} \tag{2}$$

Notice that the correlation matrix is a function of the experimental conditions: by perturbing the design variables also the correlation, hence the model identifiability, changes.

3. Case study: kinetic model and design space

For lack of space, only the study of one among kinetic model of Gawade et al. (2016), among the most promising and complex, is reported. In this kinetic model, from now on called M1, the dual-site Langmuir-Hinshelwood-Hougen-Watson (LHHW) theory is used to describe the adsorption and desorption mechanisms of the various species. The differential balances for the species are shown in the following. A = HMF, B = bis-hydroxymethylfuran, D = DMF, E = 2,5dimethyltetrahydrofuran, W = water.

$$-\frac{dC_A}{dt} = \frac{k_1 K_A C_A \sqrt{K_{H_2} p_{H_2}} w}{[1 + K_A C_A + K_B C_B + K_D C_D + K_E C_E][1 + \sqrt{K_{H_2} p_{H_2}} + K_W C_W]} \tag{3}$$

$$\frac{dC_B}{dt} = \frac{[k_1 K_A C_A - k_2 K_B C_B] \sqrt{K_{H_2} p_{H_2}} w}{[1 + K_A C_A + K_B C_B + K_D C_D + K_E C_E][1 + \sqrt{K_{H_2} p_{H_2}} + K_W C_W]} \tag{4}$$

$$\frac{dC_D}{dt} = \frac{[k_2 K_B C_B - k_3 K_D C_D] \sqrt{K_{H_2} p_{H_2}} w}{[1 + K_A C_A + K_B C_B + K_D C_D + K_E C_E][1 + \sqrt{K_{H_2} p_{H_2}} + K_W C_W]} \tag{5}$$

$$\frac{dC_E}{dt} = \frac{k_3 K_D C_D \sqrt{K_{H_2} p_{H_2}} w}{[1 + K_A C_A + K_B C_B + K_D C_D + K_E C_E][1 + \sqrt{K_{H_2} p_{H_2}} + K_W C_W]} \tag{6}$$

where C_i are the concentrations and K_i are the adsorption coefficients of the various species, k_i are the kinetic constants of the different reactions, w is the catalyst loading in g/L and p_{H_2} is the hydrogen partial pressure in atm.

3.1. Definition of design space

For the study of this transformation in a batch system, initial concentrations of HMF and DMF are considered as the most meaningful design variables to be investigated. To the aim of reducing the computational expenditure of the study, the Latin Hypercube Sampling is used to select 10 couplets of initial concentrations uniformly distributed in the entire range of concentrations (see Table 1). To study the effect of a limited number of measurements on the collected information, hence on the quality of the estimates, only 10 samplings are simulated and their allocation is evenly spaced along the experiment duration.

Table 1: Values of HMF and DMF initial concentrations.

Exp.	1	2	3	4	5	6	7	8	9	10
C_{HMF}^0 [M]	0.1556	0.0667	0.0000	0.1333	0.0889	0.2000	0.0222	0.1778	0.1111	0.0444
C_{DMF}^0 [M]	0.0667	0.0222	0.0444	0.0000	0.0889	0.2000	0.1111	0.1333	0.1556	0.1778

4. Kinetic model identification results

4.1. Identifiability analysis results

In Table 2 it is possible to appreciate that at least three couples of parameters are totally correlated and rank$(\mathbf{P}_E) = 6 < 9 = N_\theta$. Moreover, although some minor changes, by varying the sampling points schedule adopted, the three total correlations do not disappear and the kinetic model remains structurally unidentifiable. To solve the correlation problem,

Table 2: Correlation matrix for the kinetic model M1 based on the sampling distribution S1: values and colormap.

R	k_1	k_2	k_3	K_A	K_B	K_D	K_E	K_{H_2}	K_W

since the non-linearity of the system is high, a simplified version of the kinetic model is proposed.

4.2. Simplified version of the kinetic model M1 (M1.2)

The purpose of this simplified version is to by-pass the identifiability issues previously highlighted in order to end up with a simpler version whose non-measurable parameters would be easier to estimate in a statistically reliable way. The new kinetic model is:

$$-\frac{dC_A}{dt} = \frac{k_1\,C_A\,\sqrt{K_{H_2}\,p_{H_2}}\,w}{1 + \sqrt{K_{H_2}\,p_{H_2}}} \tag{7}$$

$$\frac{dC_B}{dt} = \frac{[k_1\,C_A - k_2\,C_B]\sqrt{K_{H_2}\,p_{H_2}}\,w}{1 + \sqrt{K_{H_2}\,p_{H_2}}} \tag{8}$$

$$\frac{dC_D}{dt} = \frac{[k_2\,C_B - k_3\,C_D]\sqrt{K_{H_2}\,p_{H_2}}\,w}{1 + \sqrt{K_{H_2}\,p_{H_2}}} \tag{9}$$

$$\frac{dC_E}{dt} = \frac{k_3\,C_D\,\sqrt{K_{H_2}\,p_{H_2}}\,w}{1 + \sqrt{K_{H_2}\,p_{H_2}}} \tag{10}$$

where the nomenclature is analogous to the one used with M1. The comparison of the concentration profiles obtained from the process simulation using the original kinetic model M1 and the simplified version M1.2, allows to quantify the magnitude of the approximation. No substantial differences are present such that the two kinetic models are equivalent: a simpler kinetic model, whose parameters are not affected by correlation issues, can still represent accurately the hydrogenation process.

4.3. Model-based information analysis

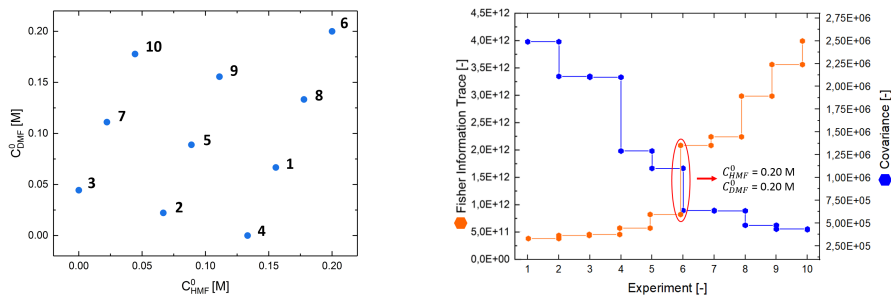
In Figure 2 the information and covariance analysis results are illustrated for a sequence of 10 experiments to be performed. The figure shows the cumulative information as given by the trace of FIM and the trace of the variance-covariance matrix $\mathbf{V}_\theta$ for 10 in-silico experiments. The conclusions are that conditions of simulations 2 and 4 lead to the high-


Figure 2: Profiles of Fisher information trace and variance-covariance matrix trace for the kinetic model M1.2 (T = 383 K, P_{H_2} = 5 atm)

est covariance reduction while conditions of simulation 6 allow to obtain the greatest increment in the information content.

5. Conclusions

In this paper a sensitivity-based identifiability analysis has been applied to kinetic models of HMF hydrogenation developed from batch reaction data. Through the study of the correlation matrix and its evolution for different values of the design variables, it has been possible to detect and classify the presence of identifiability issues for the kinetic models. Given the high complexity of the kinetic model proposed by Gawade et al. (2016), a simplified version of the same model has been suggested to overcome the impossibility to estimate the full set of kinetic parameters for this model. On the newly proposed model, the information analysis results highlighted that high initial concentrations of HMF and DMF lead to higher amounts of information while low initial concentrations lead to a greater covariance reduction. To conclude, the work presented here represents a first step toward the identification of a more complete kinetic model that contemplate the explicit dependency of reaction rates on both temperature and pressure. It highlights how to obtain reliable predictions on concentration, an extremely complex representation of the chemistry at the basis of the process is not required: kinetic models with many parameters are likely to be unidentifiable and not suitable to be validated through simple kinetic experiments.

Abstract

In this contribution, a discrete-time medium-term production scheduling model of an industrial formulation plant for crop protection chemicals is presented. As the optimization model has to provide feasible solutions in a real-world environment, all relevant processing characteristics, as e. g. sequence- and unit-dependent changeovers, timing relations between different units and processing tasks or shift patterns must be represented in order to yield feasible and implementable schedules. In order to cope with the computational complexity of the problem, an iterative scheme is employed in which the production orders are scheduled in a sequential fashion. After each iteration a set reduction step is performed, removing all infeasible unit allocations from the feasible set of the next iteration.The proposed framework is tested on a realistic industrial case study.

Keywords: Production scheduling, MILP Model, Formulation Plants, Optimization

1. Introduction

Scheduling in the process industry describes the allocation of limited resources to manufacture several products over a given time horizon (Méndez et al., 2006). The increased global competition increases the need to generate good production schedules fast and efficiently. In order to satisfy varying customer demands, a key feature of the production systems is a high flexibility, e. g. by multipurpose lines and intermediate storage. This flexibility results in a high complexity of scheduling problems. Due to this inherent complexity, scheduling without optimization support is challenging (Harjunkoski et al., 2014). Rigorous mathematical programming-based solution approaches can find optimal schedules for suitably formulated models. However, for the use of optimization based scheduling algorithms in an industrial environment good schedules must be generated within reasonable response times, but the schedules do not necessarily have to be strictly optimal. A way to shorten the computation time is the combination of exact and heuristic methods. This contribution presents a hybrid approach combining a detailed MILP model and a sequential scheduling heuristic for the fast generation of (sub-) optimal schedules for a formulation plant.

2. Case Study

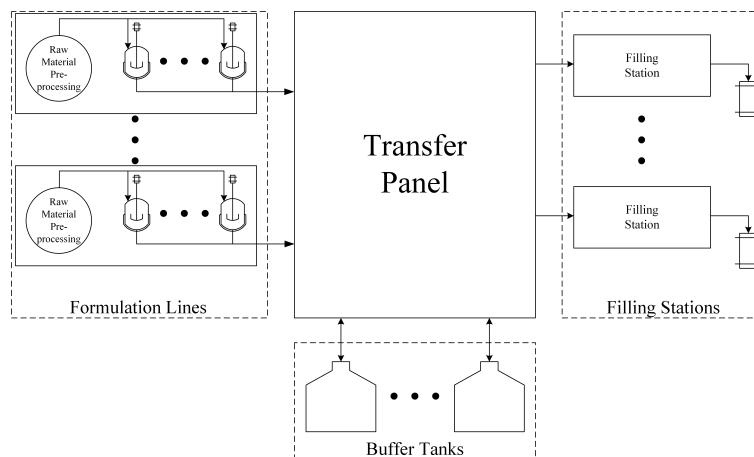
The formulation plant for the production of crop protection chemicals which is considered in this contribution is depicted in Fig. 1. After an initial raw material pre-processing step which mainly includes the preparation of the active ingredient (AI) and solvents, a standardization (mixing)


Figure 1: Schematic representation of an industrial formulation plant.

operation is performed in one of several identical standardization tanks within the formulation line, which process batches of a fixed and unit specific size. After a minimum standardization time has elapsed, the finished product can be sent to a filling station where it is filled with an order and unit specific flowrate, resulting in the final product. Since the plant includes fewer filling stations than standardization tanks and the filling stations operate on a shift system with two working and one non-working (night) shift, the filling step constitutes the bottleneck of the production. In order to utilize the full capacity of the plant, the formulation lines and filling stations are decoupled through the use of buffer tanks for finite intermediate storage. The transfer times between the standardization and buffer tanks can be neglected, while the transfer times between the different tanks and the filling stations depend on the flowrate of of the latter, since the tanks are gradually drained by the connected filling stations. The objective of the optimization is to satisfy all customer orders over a given time horizon, while minimizing the makespan. The due dates usually lie beyond the scheduling horizon and are considered here.

3. Solution Approach

In order to solve the scheduling problem, a hybrid approach is chosen in which an MILP optimization model is combined with a heuristic. Both elements of the scheduling framework are presented in the following sections.

3.1. MILP Model

The optimization model is based on a discrete representation of time (Méndez et al., 2006), in which a set of orders I are processed in the available units J over a scheduling horizon $T_H = \{1,\ldots,H,H+1\}$, while the makespan is to be minimized. The units can be split into three subsets, the standardization tanks of the formulation lines J^{FL}, the filling stations J^{FS} and the buffer tanks J^{ST}. The subset of units that can process order $i \in I$ is denoted by J_i. The same notation is used for the units of the subsets, except for the buffer tanks, for which $J_i^{\mathrm{ST}} = J^{\mathrm{ST}}$, $\forall i \in I$ holds. The set L denotes the formulation lines, each of which contains a set of standardization tanks $J_l^{\mathrm{FL}} \subset J^{\mathrm{FL}}$, $\forall l \in L$. The decisions taken during the optimization are the start times of processing or storage of material corresponding to order i in unit j (standardization and buffer tank respectively) at time t, expressed by the binary variable W_{ijt}. The release of material from a tank is similarly expressed through the binary variable W_{ijt}^R. The start of a filling process is expressed by the binary

variable X_{ijkt}, where the index $k \in K$ contains information on the filling time (see constraints (5)-(7) below). The amount of material being sent to or being released from processing or storage is modeled through the continuous variables B_{ijt} and B_{ijt}^R. The amount of material stored in a buffer tank at each time point is tracked through the variable B_{ijt}^{ST}. The model contains a large number of constraints, only some of which can be discussed in this paper.

$$\sum_{\forall t \in T_H} \sum_{\forall j \in J_i^{FS}} B_{ijt} \geq D_i, \ \forall i \in I \tag{1}$$

$$B_{ij(t+1)}^{ST} = B_{ijt}^{ST} + B_{ijt} - B_{ijt}^R, \ \forall i \in I, \ j \in J^{ST}, \ t \in T_H \setminus \{H+1\} \tag{2}$$

$$\sum_{\forall j \in J_i^{FL}} W_{ijt}^R \cdot B_j + \sum_{\forall j' \in J^{ST}} B_{ij't}^R = \sum_{\forall j'' \in J_i^{FS} \cup J^{ST}} B_{ij''t}, \ \forall i \in I, \ t \in T_H \tag{3}$$

$$B_{ijt}^{ST} \leq V_j^{max}, \ \forall i \in I, \ j \in J^{ST}, \ t \in T_H \tag{4}$$

$$\frac{B_{ijt}}{F_{ij}} \leq Y_{ijt} < \frac{B_{ijt}}{F_{ij}} + 1, \ \forall i \in I, \ j \in J_i^{FS}, \ t \in T_H \tag{5}$$

$$\sum_{\forall k \in K} X_{ijkt} \cdot p_k = Y_{ijt}, \ \forall i \in I, \ j \in J_i^{FS}, \ t \in T_H \tag{6}$$

$$\sum_{\forall k \in K} X_{ijkt} \leq 1, \ \forall i \in J_i^{FS}, \ t \in T_H \tag{7}$$

$$W_{ijt} + \sum_{t'=t}^{t+p_{ij}-1} W_{ijt'}^R \leq 1, \ \forall i \in I, \ j \in J_i^{FL}, \ t \in T_H \tag{8}$$

$$W_{ijt}^R + X_{ij'kt} + \sum_{\forall i' \in I} \sum_{t'=t}^{t+p_k+co_{ii'j}-1} W_{i'jt'} \leq 2, \tag{9}$$
$$\forall i \in I, \ j \in J_i^{FL} \cup J^{ST}, \ j' \in J_i^{FS}, \ k \in K, \ t \in T_H$$

$$W_{ijt}^R + W_{ij't} + \sum_{\forall i' \in I} \sum_{t'=t}^{t+co_{ii'j}-1} W_{i'jt'} \leq 2, \ \forall i \in I, \ j \in J_i^{FL}, \ j' \in J^{ST}, \ t \in T_H \tag{10}$$

$$W_{ijt} + \sum_{\forall i' \in I} \sum_{\forall j \in J_i^{FL} \setminus \{j\}} \sum_{t'=t}^{t+p_{ij}^c+co_{ii'l}-1} W_{i'j't'} \leq 1, \ \forall i \in I, \ l \in L_i, \ j \in J_i^{FL}, \ t \in T_H \tag{11}$$

$$W_{ijt}^R + X_{ij'kt} + \sum_{t'=t+1}^{t+p_k-1} W_{ijt'}^R \leq 2, \ \forall i \in I, \ j \in J^{ST}, \ j' \in J_i^{FS}, \ k \in K, \ t \in T_H \tag{12}$$

$$X_{ijkt} + \sum_{\forall i' \in I} \sum_{\forall k' \in K} \sum_{t'=t+1}^{t+p_k+co_{ii'j}-1} X_{i'jk't'} \leq 1, \ \forall i \in I, \ j \in J_i^{FS}, \ k \in K, \ t \in T_H \tag{13}$$

$$C_{max} \geq X_{ijkt} \cdot (t+p_k), \ \forall i \in I, \ j \in J_i^{FS}, \ k \in K, \ t \in T_H \tag{14}$$

Constraints (1) ensure that at least the ordered amount corresponding to order i, D_i is produced within the scheduling horizon. An inequality constraint is employed due to the fixed batch sizes B_j in the standardization tanks, which could lead to infeasibilities if the ordered amount had to be met exactly. Constraints (2)-(3) model the material balances around the buffer tanks and the transfer panel respectively. The amount stored in a buffer tank is limited by the maximum capacity V_j^{max} (4). A major challenge for the discrete-time formulation of the scheduling problem are the variable filling times which depend on the amount to be filled, B_{ijt}, and the order and unit

specific flowrate F_{ij}. Constraints (5) emulate the ceiling function through the non-negative integer variable Y_{ijt} $(= \lceil B_{ijt}/F_{ij} \rceil)$. Constraints (6)-(7) capture the information on the filling time (in time intervals) through the binary variable X_{ijkt}, by selecting the corresponding filling time p_k, with $p_1 = 0$, $p_2 = 1, \ldots, p_{|K|} = 2 \cdot p^s$, where $2 \cdot p^s$ is the maximal duration of a filling process, corresponding to two consecutive shifts. The plant exhibits a complex timing behavior due to the interconnection of and the material transfer between the various units. These timing relations are modeled through the timing constraints (8)-(13). The formulation of Méndez et al. (2006) is used, which exhibits stronger relaxations than the commonly used big-M constraints. Constraints (8) enforce the minimum standardization time p_{ij}. If material is sent from a standardization or buffer tank to a filling station, the next standardization or storage can only start after the filling has been completed and an additional changeover time $co_{ii'j}$ between the two orders has elapsed (9). As material transfer between a standardization and a buffer tank is assumed to be instantaneous, only a changeover is required for the standardization tank, if such a material transfer is executed (10). Each formulation line contains multiple identical standardization tanks, but only one raw-material pre-processing line. Therefore processing can not start in all tanks of a line simultaneously. After one standardization has started, the charging time p_{ij}^c, during which the tank is filled and a line changeover time $co_{ii'l}$ have to elapse before a standardization can start in another tank of the same line (11). Two consecutive releases from a buffer tank are constrained by the filling time of the station to which material is sent (12). Lastly, the filling time and a changeover time have to elapse between two filling operations (13). The makespan of the schedule is used as the objective function. It is modeled by the constraints (14), where $C_{\max}$ is set to be larger than the end of all filling operations.

3.2. Iterative Scheduling and Set Reduction

Solving the optimization problem for a realistic set of orders simultaneously leads to a computationally intractable model size, even when using state-of-the-art MILP solvers. A way to deal with this limitation is to employ iterative scheduling (see e.g. Georgiadis et al. (2018)) in which the different orders are scheduled sequentially, while all decisions associated to previously scheduled orders are fixed. The main requirement for this approach is that the generated schedule represents a feasible solution of the original problem, i.e. that the constraints modeling the (timing) interactions of different orders in the model are satisfied. One way to ensure this feasibility is to include all variables and constraints of the model up to the order scheduled in the current iteration, while fixing all variables associated to the previous orders. In this way, each solution is guaranteed to be feasible together with the results of the previous iterations. However, a drawback of this approach is the increasing model size as the iteration progresses, since more variables and constraints are added to the model, resulting again in a computationally intractable approach. In order to maintain feasibility, we propose the implicit inclusion of the previously scheduled orders through a feasible set reduction. As the allocation and timing decisions of the preceding orders remain fixed, the time points can be identified which would result in an infeasible assignment in the current iteration. They can directly be derived from the timing constraints (8)-(13). The idea is demonstrated for constraints (13):

$$X_{i'jkt} = 1 \Rightarrow \{t - co_{ii'j+1} + 1, \ldots t, \ldots, t + p_k, \cdots t + p_k + co_{i'ij} - 1\} \subset T_{ij}^{\mathrm{I}}.$$

If a filling process of a previously scheduled order i' started at time point t, the time points corresponding to the processing time in addition to the preceding and subsequent changeovers would lead to infeasible assignments of the current order i. The set T_{ij}^{I} includes all infeasible time points for order i in unit j. The infeasible time points for the other units are derived in a similar fashion from their respective timing constraints. For the scheduling of order i, all infeasible assignments due to previous allocations are eliminated through the constraints

$$\sum_{\forall t \in T_{ij}^{\mathrm{I}}} W_{ijt} + W_{ijt}^R = 0, \ \forall j \in J_i^{\mathrm{FL}} \cup J^{ST} \tag{15}$$

$$\sum_{\forall t \in T_{ij}^{I}} X_{ijkt} = 0, \ \forall j \in J_i^{FS}. \tag{16}$$

The time points corresponding to a non-working shift of the filling stations can also easily be added to the infeasible set. Due to the time consuming material transfer from the tanks and the variable filling time, the end of an operation is not solely determined by the variables associated to one unit. In order to still maintain feasibility, it must be guaranteed that each processing task finishes before the start of the next infeasible time points. This is achieved by identifying the feasible time points T_{ij}^{F} and splitting them into disjoint continuous sets $T_{ij}^{F,s} \subset T_{ij}^{F}$

$$T_{ij}^{F} = T_H \backslash T_{ij}^{I} = \bigcup_{\forall s} T_{ij}^{F,s}, \ T_{ij}^{F,s} \cap T_{ij}^{F,s'} = \emptyset, \ \forall s, s'. \tag{17}$$

It is ensured by additional constraints that an operation that starts within a feasible subset is finished until the end of that set.
Figure 2: Algorithmic framework for the solution of the scheduling problem.

4. Computational Considerations and Results

Test runs showed a drawback associated to the minimization of the makespan. As only the maximum completion time affects the objective value of the optimization, standardizations that could finish earlier exhibit unnecessary waiting times. This leads to an underutilization of the available production capacity, as more time points are excluded from the feasible set of the next iteration. In order to resolve this limitation, the optimization is performed in two steps. In the first step the makespan $C_{\max}$ is minimized. In the second step the completion times of the formulation lines C_l are added to the model through constraints (18)

$$C_l \geq W_{ijt}^R \cdot t, \ \forall l \in L_i, \ j \in J_l^{FL}, \ t \in T_H. \tag{18}$$

The total line completion time is then minimized, while ensuring that the makespan stays below that of the first stage $(C_{\max}^*)$

$$\min \sum_{\forall l \in L_i} C_l, \ C_{\max} \leq C_{\max}^*. \tag{19}$$

The test runs also showed that the computation time of each iteration strongly depends on the ordered amount D_i and the resulting number of batches that have to be scheduled. The computational effort can be decreased by splitting large orders into multiple artificial smaller orders, which are then also scheduled sequentially. The splitting can be performed in a pre-processing step according to a specified maximum number of standardizations that are allowed to be scheduled in each iteration. The complete proposed framework is illustrated in Fig. 2. It was tested for a plant consisting of 7 formulation lines, each with 3 standardization tanks, 8 filling stations and 5 buffer tanks. In total 20 different orders were scheduled over a one week horizon, with a time interval length of one hour. At most 5 standardizations were scheduled in each iteration. The framework was implemented in Julia 0.6.1.1 (Bezanson et al., 2017) with IBM ILOG CPLEX 12.7.1 as an MILP solver on a MS Windows 7 desktop PC (Intel Core i7-4790S CPU @ 3.20 GHz,
Figure 3: Gantt generated with the proposed scheduling framework.

16 GB RAM). Even for small instances, including just a few orders, no feasible solutions could be obtained due to the model size and complexity and the resulting failed model initialization due to memory limitations. Using the proposed approach the problem was solved in 38 minutes, where a relative gap tolerance of 5 % was used in each iteration. The generated Gantt-chart with a makespan of 133 h is shown in Fig. 3. The black regions in the charts of the filling stations represent non-working shifts. Although the schedule still exhibits unnecessary waiting times and release postponements in the standardization tanks, it finishes more than one day prior to the end of the scheduling horizon. It should also be noted that solving all iterations to global optimality (0 % gap) resulted in a nearly identical schedule, where the overall makespan was improved by only one hour, but the solution required 4.5 hours of computation time. This further underlines the good tradeoff between optimality and computation time that is achieved with the proposed framework.

5. Conclusion

In this contribution an approach for the fast generation of feasible and good schedules that includes an MILP model and a set reduction approach was proposed. The results show that good schedules can be found within relatively short computation times. This is preferable over the time consuming search for an optimal schedule in an industrial environment. Since the scheduling problem is solved in an iterative fashion, the quality of the schedule strongly depends on the sequence in which the orders are scheduled. Therefore further improvements can be achieved by employing a sorting of the orders in the pre-processing step, either through a prioritization of orders according to specified criteria, or based upon operational considerations provided by planners and operators.

Abstract

The continuous Smoluchowski coagulation equation, which is known as the population balance equation (PBE) for particle coagulation, is a nonlinear integro-partial differential equation with no general analytical solution. In this work, we are concerned with extending our discrete formulation of the PBE for particle breakage using a Conservative Discretization Approach (CDA) (Attarakih et al., 2004) to solve the Smoluchowski coagulation equation coupled with particle growth. The method is based on introducing auxiliary functions to modify the discrete loss and formation terms in the discrete PBE. These are then uniquely determined by exactly reproducing two arbitrary chosen integral quantities from the continuous PBE. The CDA is validated using many test cases with known analytical solutions including coupled particle coagulation and growth dynamics as a simplified model for a batch crystallizer. The discrete approximate solutions for the number concentration function is found to converge with an order $O(1/M)$ where M is the number of grid points.

Keywords: CDA, Population Balances, Coagulation, Smoluchowski.

1. Introduction

The continuous nonlinear Smoluchowski coagulation equation (also known as the population balance equation for particle coagulation) is an integro-partial differential equation with no general analytical solution. It finds many applications in process system engineering and on individual unit operation level in pharmaceutical and chemical processes with mono and multivariate number density functions. This equation can describe the system behaviour up to any degree of detail which is necessary for understanding many single processing units such as crystallizers, turbulent flame reactors, polymerization reactors, bubble phase reactors, and extraction columns (Attarakih and Bart, 2014, Ramkrishna, 2014, Ferreira et al., 2017). In spite of the intensive research in the last decades, which is concerned with fast numerical solvers based on the moment methods, numerical solutions which are able to conserve particle integral properties suffer from losing the particle size distribution. The latter is required in industrial particulate systems where it is used to determine mechanical and physiochemical system properties, for online control purposes (Attarakih et al., 2012, Attarakih and Bart, 2014), to evaluate the negative particle fluxes at zero particle size as in the case of droplet evaporation (Vie et al., 2013) and to accommodate time varying boundary conditions in age-structured models of hematological disease (Foley and

Mackey, 2009). When numerical solutions are concerned, our successful discrete formulation of the population balance equation for particle breakage using a Conservative Discretization Approach (CDA) (Attarakih et al., 2004) laid down a solid foundation for the solution of the highly nonlinear and stretched (w.r.t. particle property space) Smoluchowski coagulation equation. The discrete set of equations is derived by treating the number of particles in each size subdomain as a single particle with known fixed position. Starting from a discrete and consistent initial number density, these particles are allowed to coagulate with a given probability and frequency to produce particles of large sizes. Prior to coagulations events, the newly born particles are allowed to adjust their local positions within each subdomain such that two selected integral properties are conserved. This is called internal consistency of the discrete Smoluchowski coagulation equation w.r.t the continuous one. Similar to our CDA for particle breakage, this internal consistency is enforced by introducing a set of two unique and general auxiliary functions (formation and loss auxiliary functions) that are uniquely determined by matching the integral properties obtainable from the discrete set against those from the continuous Smoluchowski equation. These auxiliary discrete functions are converted into matrices which are computed offline and thus placing no new computational burden during the time evolution of the particle-particle coagulation events. The computed matrices depend on the particle grid structure and are functions only of the arithmetic mean volume (mass) of the coagulating pair of particles and the representative volume in which the coagulated pair falls.

2. Discretization of Smoluchowski Equation using the CDA

The Conservative Discretization Approach (CDA) for droplet breakage (Attarakih et al., 2004) when applied to the Smoluchowski coagulation equation with particle growth provides not only the discrete number concentration function, but also its zero and third moments (or any two prior selected population integral properties). The key idea behind the CDA is to constraint the integral particle properties derived from the discrete Smoluchowski coagulation by those derived from its continuous counterpart. This not only reduces the number of ODEs to be solved, but also increases the accuracy of both the calculated particle size distribution and its desired moments. Following these lines, one can introduce auxiliary functions to the formation and loss terms in a hope to force the discrete Smoluchowski coagulation to conserve two desired integral properties of the particle size distribution:

$$\frac{dN_i(x;t)}{dt} = \sum_{k=0}^{i}\sum_{j=k}^{i}\Big[\alpha_{k,j}\Psi_{k,j}^i\Big]\big(1-\tfrac{1}{2}\delta_{k,j}\big)\omega_{k,j}N_kN_j - N_i\sum_{j=0}^{M-1}\eta_{i,j}\omega_{i,j}N_j + S_i \qquad (1)$$

In this equation N_i is the total number concentration in the ith subdomain that is defined as $V_i = [v_{i-1/2}, v_{i+1/2})$, $i = 0,1...M$ with a representative particle diameter $d_i^* = \sqrt[3]{v_i^*}$ where v^* is the arithmetic mean of the V_i. subdomain boundaries and M is the total number of subdomains. The coagulation binary interaction matrix (Ψ^i) records the occurrence of successful coagulation events between pair of particles from two subdomains of labels (k and j). The summation $\sum (\Psi^i) = 1$, $\forall i$ is required to conserve the mass of the newly born particles by coagulation. The physical meaning of this constraint is that no newly born particle by coagulation can exist at the same time in

more than one subdomain. The definition of the elements of this matrix are similar to that presented in Attarakih et al. (2009). The two new auxiliary functions α and η are introduced in the respective formation and loss terms to conserve exactly any two targeted population integral properties. For the conservation of zero and third moments w.r.t. particle diameter, these functions are given by:

$$\alpha_{k,j} = \frac{1}{2\chi_{k,j} - 1}, \quad \eta_{i,j} = \frac{\chi_{i,j}}{2\chi_{i,j} - 1}, \quad \chi_{k,j} = \frac{\sum_{i=1}^{M} v_{i-1}^* \Psi_{k,j}^i}{v_k^* + v_j^*} \tag{2}$$

Note that $\chi_{k,j}$ is in the order of one and can be smaller than one if the summation of the volumes of the coagulating particles from the subdomains (k,j) is greater than v^* in the ith subdomain, equals to one when their volume is exactly the same as v^* in the ith subdomain or greater than one otherwise. These functions do not depend on the particle coagulation frequency and probability but depend only on the grid structure. For example, when the grid is linear in terms of particle diameter $\chi_{k,j} = 1$ and hence both α and η are unity. In this case the discrete Smoluchowski coagulation equation is reduced to the special case of Hidy (1965) where all the integral particle properties are correctly predicted; however, at the expense of drastic increase of the number of ODEs.

The discrete term S_i on the r.h.s of Eq.(1) takes into account the discrete particle breakage which conserves total number and volume concentrations (Attarakih et al., 2004) plus the discrete growth term which is derived using the same concept used in deriving Eq.(1). This derivation is constrained by the conservation of total number and volume concentrations and is given by:

$$S_i^g = H_i(d_i^*, r)(g(d_i^*)N_i - rg(d_{i-1}^*)N_{i-1}) \tag{3}$$

Where $g(d)$ is the particle growth rate, r is the ratio between two consecutive discrete particle diameters (r = $[d_{max}/d_{min}]^{(1/M)}$ for geometric grid spanning the domain d $\in [d_{min}, d_{max}]$) and the function H is a simple function of d* and r. The convective flux (w.r.t. particle diameter) in Eq.(3) is a conservative modified first-order upwind scheme which conserves exactly total volume and number concentrations and guarantees the positivity of the reconstructed number concentration function. To this end, the system of Eqs.(1 to 3) presents a consistent discrete model for the numerical solution of the Smoluchowski coagulation equation coupled to particle breakage and growth. To the best of the authors' knowledge, this is the first complete and consistent discrete model for the solution of the population balance equation which takes into account all the possible particle mechanisms including particle nucleation which can be easily added as a birth source term in the first subdomain.

3. Numerical Results and Discussion

3.1. Numerical Analysis

The proposed CDA for Smoluchowski coagulation equation is validated in the first step against well-known analytical solutions. These solutions depend on the coagulation frequency where particle coagulation in a suspension may occur through variety of mechanisms such as Brownian motion, turbulent diffusion and laminar shear (Hidy and Brock, 1970). From physical and analytical point of view, the Brownian motion and turbulent diffusion are the two popular mechanisms. For Brownian coagulation, ω

depends on the sizes of the two coagulating particles. When one particle is in the continuum regime, the coagulation frequency is given by the Smoluchowski kernel:

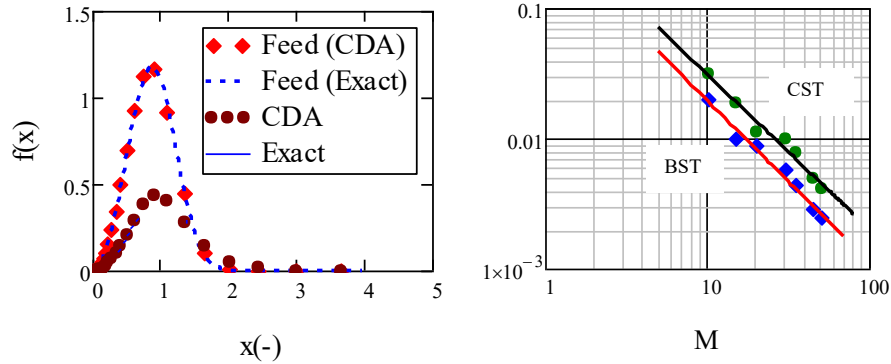
$$\omega(v, v') = \omega_0 (v + v')\left(v^{-1} + v'^{-1}\right) \tag{4}$$


Figure (1): (Left). Solution of Smoluchowski equation with constant kernel particle aggregation (ω_0) in CST using the CDA. (Right). Convergence of the CDA based on the RMSE using $\omega = \omega_0$ in batch and continuous stirred tanks. $d_{min} = 0.01$, $d_{max} = 4$, $\tau = 4$, $M = 30$, the feed PSD is $3x^2\exp(-x^3)$ and the I.C. is zero.

In the initial stage of coagulation of a monodispersed suspension the coagulation frequency is essentially size independent. It has been suggested that ω_0 is a good approximation to ω if the Knudsen numbers ($Kn = 2\lambda/d$) of both coagulating particles are less than 0.1 even for the case of polydispersed suspension. On the other hand, for turbulent diffusion particle coagulation, ω can be approximated by $\omega = \omega_0(v + v')$. These are obviously the only two physically realistic kernels for which analytical solutions of the Smoluchowski equation were derived.

Figure (1, Left) shows the CDA solution as compared to the analytical one (Hounslow, 1990) for constant particle coagulation in a CST (Continuous Stirred Tank) with residence time $\tau = 4$ (dimensionless). Using only 30 subdomains (evolved on a geometric grid) and using AdamsBDF (Adams method with backward differentiation formulas) as an ODE solver, the system of ODEs (Eq.(1)) were integrated from zero initial condition until steady state. As can be seen from this figure, the numerical solution is very accurate with a very high precision reproduction of the first and third moments of the particle size distribution, thanks to the auxiliary functions ($\alpha_{k,j}$, $\eta_{k,j}$).

This convergence of the CDA was tested for both CST and BST as shown in in Figure (1, Right) using uniform grids ($d_{min} = 0$ and $d_{max} = 4$) and the RMSE (Root Mean Squared Error) based on the difference between the CDA and the analytical solutions using the same discrete predefined grid points where a 10-point grid solution results in less than 0.1 RMSE and still conserves total volume and number concentrations. It is clear that the convergence of the CDA is in the O(1/M) for both cases. When the geometric grid was used ($d_{min} = 0$ and $d_{max} = 4$)), the CDA is more accurate than that of the uniform grid with even faster rate of convergence. This increased accuracy is expected since the geometric grid results in new born particles with volumes that are

very close to the representative volumes in each subdomain. This hypothesis is elucidated by careful examination of the $\chi_{k,j}$ elements which were very close to unity.

3.2. Batch Crystallizer: Coupled size dependent growth and coagulation

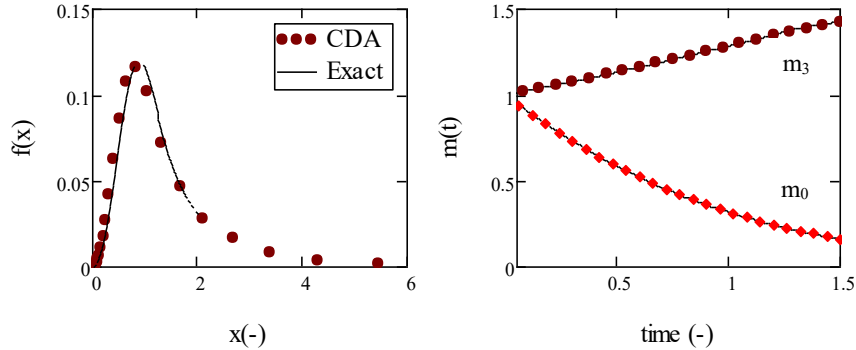
In this section, particle growth and coagulation in a batch stirred tank (BST) is used as a simplified model for a batch crystallizer where the particle size distribution (PSD) depends on time and particle size. In a batch crystallizer, the initial seeds used are carried by the evolution of the PSD and becomes part of it.


Figure (2): (Left). Solution of Smoluchowski equation with sum kernel particle aggregation and linear particle growth in BST using the CDA. (Right). Prediction of the zero and third moments of PSD using CDA. dmin = 0.005, dmax = 6, τ = 1.5, M = 30, initial condition $f(x) = 3x^2\exp(-x^3)$.

The growth rate of crystals g(x) expresses the rate of change of particle volume due to deposition of material on the particle surface. When the Knudsen number (Kn = $2\lambda/d$) is less than 0.1, the rate of deposition is predicted by the classical continuum diffusion theory (Hidy and Brock, 1970). In this regime the growth rate is given by $g(x) = (1/3)g_0 x^\gamma$ where γ = 3. The rate determining step for deposition, based on this growth rate, is the chemical reaction that takes place throughout the volume of the particle. In this case study, we confined our attention to the case when γ = 1 where the growth is linearly proportional to particle diameter. By combining linear particle growth and sum kernel ($\omega = \omega_0(v + v')$) particle coagulation, which is induced by turbulent diffusion, one can use the analytical solution of Ramabhadran et al. (1976). This analytical solution is challenging and is complicated by the product of exponential function and modified Bessel function of the first kind. The exponential part is a manifestation of the exponential initial condition ($f(x) = 3x^2\exp(-x^3)$). Figure (2, Left) shows the predicted PSD using our CDA with 30 subdomains using a geometric grid w.r.t. particle diameter where $\Lambda = g_0/\omega_0 = 0.25$ and τ = 1.5. This means that the dominant mechanism in this example is particle coagulation. This results in a reduction of particle number concentration with little volume growth as shown in Figure (2, Right). In this figure, not only the PSD was accurately predicted, but also the total number and volume concentrations. The conservation of the zero and third moments of the source term is not affected by the number of grid points, but by the discrete form of the initial condition or the inlet feed distribution. This shows the advantage of the CDA when compared to other discrete methods which require very fine grids. The computational time of the CDA is less than that of the fixed-pivot technique which support our previous CPU time analysis for the case of particle breakage (Attarakih et al, 2004).

4. Summary and Conclusions

The numerical analyses of the present CDA show two desirable properties: Firstly, the simplicity of the source term structure (composed of simple summations) which can be easily programmed thanks to the explicit form of the two auxiliary functions and the interaction matrix in which the footprint of the successful coagulation events is saved. Secondly, the two selected conserved integral quantities (e.g total number and volume concentrations) are exactly conserved irrespective of the number of discrete equations. This presents a major advantage over the existing consistent discrete methods (e.g. Fixed-pivot technique). Accordingly, the reconstructed number concentration function converges to the exact solution with exponential decay in terms of the RMSE as function of grid points. As a final conclusion, the CDA is a general discrete formulation framework not only for the Smoluchowski coagulation equation, but also for other deterministic integral equations including simultaneous particle breakage, growth and nucleation in batch and continuous particulate systems and can be easily extended to bivariate population balances.

Abstract

Higher acrylates are used in special applications. However, production at high capacity in continuous reactive distillation (RD) systems, throughout the whole year of only one acrylate, may be hindered by a low market and periodic demands. Thus, for the asset to be fully utilized, one may consider to build a multi-product reactive distillation system. This is a preliminary study that shows what four higher acrylates (i.e., isoamyl acrylate, cyclohexyl acrylate, *2*-ethylhexyl acrylate and *n*-decyl acrylate) have in common to be considered candidates for producing them in the same column, and the methodology to design such a multi-product RD column. The systemic design method uses PSE tools to achieve the design, based solely on thermodynamics and equilibrium information.

Keywords: conceptual design, higher alcohols, process intensification, simulation

1. Introduction

Acrylates are essential chemicals used as precursors in the production of polyacrylates which are employed in a range of industries (e.g. packaging, consumer goods, and construction, automotive) and a variety of applications (e.g. coatings, paints, resins, adhesives, textiles, personal care). Acrylates with a high number of carbon atoms are more preferred in special applications. Reports state that the acrylate market was valued at B\$ 6.86 in 2016, aiming to reach B\$ 9.88 in 2022 (www.marketsandmarkets.com).

Conventional processes using strong homogeneous catalysts (i.e., acid sulfuric) are only briefly presented in the open literature (Ohara et al., 2003). A few new conceptual processes using solid-based catalysts for the synthesis of some higher-acrylates and methacrylates have been also developed, showing a high potential in overcoming the well-known drawbacks of conventional processes: corrosion, product purification, and disposal of spent catalyst, which usually lead to high operating and maintenance costs, and increasing difficulty to comply with environmental regulations (Kiss et al., 2015).

This work considers a generic perspective, by investigating the technical feasibility of producing four industrially important higher-acrylates by esterification employing the

same reactive distillation (RD) process using solid catalysts. The pure component properties are estimated using group contribution methods (due to lack of experimental data in literature), followed by studying key thermodynamic properties relevant for process design. Chemical equilibrium is determined by minimizing the Gibbs energy of the system to indicate the maximum conversion possible. A preliminary RD column design is proposed using an equilibrium model. An additional separation step may be required for the recovery of one reactant (alcohol) while the limiting reactant (acrylic acid) has a conversion close to 100%. The design can be refined later, by including the reaction rate, when kinetics data is available in literature.

2. Higher acrylates and key physical properties

A higher acrylate is produced in the reaction of acrylic acid (AA) with an alcohol which has a number of carbon atoms higher than 4, following the chemical reaction:
Table 1 presents some basic properties for the four acrylates presented in this study. Two of the acrylates (*i*-AA and *2*-EHA) present some branching, one of them (CHA) has a cyclohexane ring, while the remaining (*n*-DA) is a linear acrylate. All have a relatively high molecular weight and normal boiling point.

Table 1. Basic physical properties of some high acrylates

Acrylate[†]	MW [g/mol]	T_b [°C]	DHFORM[‡] [kJ/mol]	DGFORM[‡] [kJ/mol]
isoamyl acrylate (*i*-AA)	142.2	163.8	-398.82	-208.49
cyclohexyl acrylate (CHA)	154.2	206.6	-382.42	-173.18
2-ethylhexyl acrylate (*2*-EHA)	184.3	232.4	-458.61	-183.23
n-decyl acrylate (*n*-DA)	212.3	278.6	-488.18	-163.95

[†]chemical structures:

isoamyl acrylate   cyclohexyl acrylate   *2*-ethylhexyl acrylate   *n*-decyl acrylate
[‡]DHFORM and DGFORM are the ideal gas enthalpy and energy of formation (25 °C) estimated using the Property Constant Estimation System (PCES) of Aspen Properties.

All these acrylate systems have in common important characteristics that make them candidates to be produced in the same reactive distillation system:

- From the view point of process structure, each acrylate is the highest boiler in its system and is obtained as bottom products (note that water is the lowest boiler component). In addition, all acrylate systems present heterogeneous minimum boiling azeotropes containing water in high concentration (Table 2), making thus possible to eliminate the water in the same way, in the overhead of the column: the vapors are condensed; the condensate undergoes a liquid-liquid split; the organic phase is refluxed to the column, while the water is removed from the process.

- From a mass balance perspective, similar acrylate systems catalyzed by solid catalysts present very similar space-time-yields ($t_{product}/t_{cat}$/h): 0.65 for isobutyl acrylate (Moraru et al., 2018), 1.28 for *n*-butyl acrylate (Moraru and Bildea, 2017) and 1.57 for *2*-ethylhexyl acrylate (Moraru and Bildea, 2018).

- From a heat balance perspective, all reactions are slightly endothermic, having similar reaction enthalpy (Table 2). Hence, these three main factors are good indicators that the higher acrylates can be produced in the same RD column.

Table 2. Azeotropy and reaction enthalpies of the four acrylate systems

Physical property	*i*-AA	CHA	*2*-EHA	*n*-DA
Azeotrope comp. / [% wt.]				
water/alcohol	50.21/49.79	70.18/29.82	80.87/19.13	96.15/3.85
water/acrylate	53.58/46.42	79.34/20.66	89.45/10.55	97.45/2.55
water/alcohol/acrylate	48.36/43.17/8.47			96.43/3.55/0.02
Enthalpy of reaction (liquid phase, 25 °C) / [kJ/mol]	15.9	16.4	27.0	35.2

3. Chemical equilibrium

Slightly endothermic / exothermic equilibrium esterification reactions are known as perfect candidates to be performed in RD systems (Kiss, 2018). As the equilibrium is shifted towards the products formation by removing water, very high or even complete per-pass conversions can be achieved. Hence, studying the chemical equilibrium gives basic info which is used in the conceptual design of the RD system. Figure 1 shows the equilibrium conversion of AA as function of temperature for several acrylate systems.

Firstly, take the *n*-butyl acrylate (*n*-BA) system. The *n-BA (Lit)* profiles, triangles and circles, represent calculated data using two equations taken from published literature, which were in turn derived from experimental data (see the right-lower corner). The *n-BA (Aspen Database)* profile is obtained by calculating K_{eq} from Gibbs free energies, for which parameters (for *n*-BA) are available in the Aspen database; although for the low temperatures the agreement is not perfect, it improves for the temperature range of practical interest (over 60 °C) where the reaction rates are higher.

Secondly, consider the *2*-EHA system. The *2-EHA (Lit)* profile uses an equation based on experimental data (see the right-lower corner). The *2-EHA (PCES)* is obtained by calculating K_{eq} from Gibbs free energies, for which the necessary parameters (for *2*-EHA) are estimated using the PCES of Aspen Properties. In this case, the agreement is very good. Thus, one may conclude that the accuracy of the predictive thermodynamic models based on group contributions is reasonable.

For the other three acrylates (*i*-AA, CHA and *n*-DA), the parameters to calculate K_{eq} are estimated by PCES. All reactions are slightly endothermic. Analyses based on experi-mental data are preferred, but when neither equilibrium data nor the required parameters in the Aspen database are available, then one must rely on group contribution methods to estimate the missing parameters. Results presented in Figure 1 also demonstrate that reasonable conversions can be obtained for all the alcohols considered here. However, the chemical equilibrium sets an upper bound on the achievable conversion. This can be overcome by removing one reactant (water) from the reaction mixture due to formation of the low-boiling azeotrope, and/or by performing the reaction with an excess of one reactant, achieved by refluxing the alcohol-rich organic phase from the top decanter.
Figure 1. Equilibrium conversion for acrylic acid esterification with different alcohols, for an alcohol / acid feed molar ratio of 1.

4. Conceptual process design

For the acrylates to be all produced in the same equipment, the design has to take into account those conditions, specific to each acrylate, in which the RD is feasible. These conditions are represented here by the shaded area of the *P-T* diagram showed in Figure 2 (left). The diagram is constructed using four distinct *P-T* areas, one for each acrylate. For illustration purposes, the right-lower corner shows how this feasibility area is constructed for *2*-EHA, using the vapor pressure of the highest (acrylate) and lowest (water/alcohol azeotrope) boilers in this specific system. The area covering all acrylates spans over a large range of conditions: 60-190 °C and 0.1-6 bar. The temperature bounds come from the interval in which the reaction can be performed: the minimum temperature at which the reaction rate becomes fast enough and the maximum temperature the catalyst can withstand. The maximum pressure (about 6 bar) is given by the boiling temperature of most volatile acrylate (i.e. *i*-AA), which should be achieved by using HP steam (240 °C). The minimum pressure constraint (0.1 bar) arrives from the need of using cooling water for condensing the low boiling water-alcohol azeotropes.
Figure 2. Pressure-Temperature conditions considered in design of the reactive distillation system (left) and reactive distillation column including the main sizes and process data (right)

Based on this feasibility window, one can conclude that it will be difficult to design a column that operates at constant pressure and similar temperature intervals, and produces all four acrylates; basically, to operate in that region where the individual feasibility windows overlap. One approach is to set the column pressure depending on the acrylate produced, and verify that the operating temperature in the column is not higher compared to the temperature the catalyst can withstand. Of course, the temperature should not be too low either. Previous studies for higher acrylates produced in reactive distillation systems (Niesbach et al., 2013) showed that above 100 °C, the reaction rate is high enough to be industrially attractive.

5. Column design

The design of the RD column that is able to produce all acrylates consists of two steps:

1. For each acrylate, design one RD column (i.e., theoretical stages and diameter) that meets certain specifications.

2. For all acrylates, select the RD column with the highest number of theoretical stages determined in the previous step, average the diameter of all columns and rate all acrylate processes in this specific column.

Each acrylate-specific design aimed to have the same production rate, and obtain a product with a purity of at least 99.5 %wt. This design step is iterative, and starts by selecting a top-pressure in the column, followed by the number of trays in each section, and for hydrodynamic reasons, a minimum reflux ratio. Then, the number of stages in each zone was varied and aimed at reducing them until the product purity cannot be achieved anymore. If the pressure can be further reduced (but still being able to use cooling water in the condenser), then a new iteration starts; if not, then the design stops and all variables of interest are recorded. Table 3 presents the results of step 1. Based on these results, in step 2 the number of stages specific to *i*-AA column are considered (i.e., the tallest column) and the diameter is calculated by averaging the column diameters. Then, each acrylate process is rated in this specific column.

The results of step 2 are given in Table 4. Start with the *i*-AA process; since the column diameter is with 0.1 m larger, the reflux had to be increased from 4 to 5.5 (again, from hydrodynamic reasons); no further modifications are required. For the CHA process, only the number of stages is updated; the hydrodynamics presents no issues since the column diameter is only 0.05 m larger; the same holds for the 2-EHA process. For the *n*-DA process, the production capacity is reduced to cope with the decrease in diameter from 0.98 to 0.85 m.

Table 3. Key design and operating parameters for each acrylate produced in individual columns

Parameter	*i*-AA	CHA	2-EHA	*n*-DA
N_R	N_{RXN}	N_S	1	4	4	1	3	2	1	3	2	1	4	2
D_{column} / [m]	0.74	0.80	0.85	0.98
$F_{acrylate}$	F_{water} / [kg/h]	2524	330	2525	305	2535	247	2526	215
Reflux / [kg/h]	1322	1225	990	860
Purity acrylate	water / [% wt.]	99.5	96.3	99.5	96.3	99.5	99.6	99.9	99.6
Q_R	Q_C / [kW]	519	508	546	465	486	340	503	320
P_{top}	P_{bottom} / [bar]	0.6	0.609	0.3	0.306	0.2	0.203	0.1	0.104
T_{top}	T_{bottom} / [°C]	96	146	99	161	110	172	129	193

Table 4. Key design and operating parameters for each acrylate produced in the same column

Parameter	*i*-AA	CHA	2-EHA	*n*-DA
N_R | N_{RXN} | N_S		1 | 4 | 4		
D_{column} / [m]		0.85		
$F_{acrylate}$ | F_{water} / [kg/h]	2524 | 330	2539 | 306	2537 | 247	2123 | 181
Reflux / [kg/h]	1814	1224	988	722
Purity acrylate | water / [% wt.]	99.5 | 96.4	99.5 | 96.4	99.5 | 99.9	100 | 99.7
Q_R | Q_C / [kW]	623 | 535	553 | 471	488 | 341	427 | 269
P_{top} | P_{bottom} / [bar]	0.6 | 0.606	0.3 | 0.305	0.2 | 0.207	0.1 | 0.115
T_{top} | T_{bottom} / [°C]	99 | 145	98 | 161	109 | 173	129 | 197

6. Conclusions

Using a PSE methodology based on physical properties and chemical equilibrium data (estimated or reported in the literature), this study shows that higher acrylates are good candidates to be produced in the same reactive distillation column. A follow-up study should reiterate this design based on reaction kinetics and mass transfer considerations.

Stochastic nonlinear model predictive control of a batch fermentation process

Eric Bradford[a]* and Lars Imsland[a]

[a]*Engineering Cybernetics; NTNU; O. S. Bragstads plass 2D, Trondheim 7034, Norway*
eric.bradford@ntnu.no

Abstract

Nonlinear model predictive control (NMPC) is an attractive control approach to regulate batch processes reliant on an accurate dynamic model. Most dynamic models however are affected by significant uncertainties, which may lead to worse control performance and infeasibilities, considering the tendency of NMPC to drive the system to its constraints. This paper proposes a novel NMPC framework to mitigate this issue by explicitly taking into account time-invariant stochastic uncertainties. Parametric uncertainties are assumed to be given by so-called polynomial chaos expansions (PCE), which constitutes a flexible approach to depict arbitrary probability distributions. It is assumed that at each sampling time only noisy output measurements are available. The proposed procedure uses a sparse Gauss-Hermite sampling rule to formulate an efficient scenario-based NMPC algorithm based on the PCE, while a stochastic nonlinear filter is employed to update the PCE given the available measurements. The framework is shown to be effective on a challenging semi-batch fermentation process simulation case study.

Keywords: Chemical process control, Polynomial chaos, Nonlinear filters, Model-based control

1. Introduction

Batch processes are commonly used in many chemical sectors, including pharmaceuticals, bulk chemicals and biotechnology. Batch processes are operated at unsteady state and are highly nonlinear, which motivates the use of nonlinear model predictive control (NMPC). The performance of the NMPC algorithm depends strongly on the accuracy of the dynamic model used and inherent uncertainties may lead to constraint violations and worse control actions. If we assume these uncertainties to be given by known probability distributions, stochastic NMPC (SNMPC) methods can be used (Mesbah, 2016). The main difficulty in SNMPC lies in propagating stochastic uncertainties through nonlinear system models. Several SNMPC algorithms have been proposed using different methods to propagate stochastic uncertainties:

- Unscented transformation sampling (Bradford and Imsland, 2018a)
- Polynomial chaos expansions (Fagiano and Khammash, 2012)
- Markov Chain Monte Carlo (Maciejowski et al., 2007)
- Gaussian processes (Bradford and Imsland, 2018b)
- Quasi Monte Carlo methods (Bradford and Imsland, 2017)
- Particle filters (Sehr and Bitmead, 2017)

Most work in SNMPC assumes full state feedback, which is uncommon for real processes. Instead, the measurements made at each sampling time are both noisy and incomplete. In this paper we therefore propose to use a nonlinear filter to update the stochastic uncertainties at each sampling time. The uncertainties are represented by so-called polynomial chaos expansions (PCE), which allow for complex probability distributions to be given by polynomials of simpler stochastic variables. In addition, we suggest to efficiently formulate the SNMPC problem using a sparse Gauss-Hermite quadrature rule. The framework is verified on a fermentation case study.

2. Problem formulation

We aim to control a discrete-time nonlinear equation system with stochastic uncertainties:

$$\mathbf{x}(t+1) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), \theta(\xi)), \qquad \mathbf{x}(0) = \mathbf{x}_0(\theta(\xi)) \tag{1}$$

$$\mathbf{y}(t) = \mathbf{h}(\mathbf{x}(t), \theta(\xi)) + \mathbf{v} \tag{2}$$

where k is the discrete time, $\mathbf{x} \in \mathbb{R}^{n_\mathbf{x}}$ are the system states, $\mathbf{u} \in \mathbb{R}^{n_\mathbf{u}}$ denote the control inputs, $\theta(\xi) \in \mathbb{R}^{n_\theta}$ are time-invariant uncertainties, $\xi \in \mathbb{R}^{n_\theta} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ describe standard normally distributed random variables parametrizing the PCE of θ, $\mathbf{f} : \mathbb{R}^{n_\mathbf{x}} \times \mathbb{R}^{n_\mathbf{u}} \times \mathbb{R}^{n_\theta} \to \mathbb{R}^{n_\mathbf{x}}$ represents the nonlinear dynamic system, $\mathbf{y} \in \mathbb{R}^{n_\mathbf{y}}$ denote the measurements, $\mathbf{h} : \mathbb{R}^{n_\mathbf{x}} \times \mathbb{R}^{n_\theta}$ are the output equations and $\mathbf{v} \in \mathbb{R}^{n_\mathbf{y}} \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}_\mathbf{v})$ is the measurement noise assumed to be zero mean multivariate normally distributed with known covariance matrix $\mathbf{\Sigma}_\mathbf{v}$. The initial condition $\mathbf{x}(0)$ may also be uncertain and hence is a function of $\theta(\xi)$.

The time-invariant uncertainty described by θ are assumed to be given by a known truncated PCE:

$$\theta_i(\xi) = \sum_{0 \le |\alpha| \le m} a_j^{(i)} \phi_{\alpha_j}(\xi) = \mathbf{a}_i^T \phi(\xi) \tag{3}$$

where each component $\theta_i(\xi)$ is given by an individual polynomial series with multivariate polynomials $\phi_{\alpha_j}(\xi)$ with coefficients $a_j^{(i)}$. We summarise the coefficients as $\mathbf{A} = [\mathbf{a}_1, \dots, \mathbf{a}_{n_\theta}]$. The multivariate polynomials are given by products of univariate polynomials $\phi_{\alpha_j} = \prod_{i=1}^{n_\xi} \phi_{\alpha_{j_i}}(\xi_i)$ with $\phi_{\alpha_{j_i}}(\xi_i)$ being univariate polynomials of ξ_i of degree α_{j_i}. The vector $\phi(\cdot) = [\phi_1(\cdot), \dots, \phi_L(\cdot)]^T$ contains the multivariate polynomials of the expansions, m denotes the order of truncation and $|\alpha| = \sum_{i=1}^{n_\xi} \alpha_i$. Each polynomial series consists of $L = \frac{(n_\xi + m)!}{n_\xi! m!}$ terms and $\mathbf{a}_i \in \mathbb{R}^L$ represents a vector of coefficients of these terms. The univariate polynomials are given by Hermite polynomials:

$$\phi_j(\xi_i) = (-1)^j \exp\left(\frac{1}{2}\xi_i^2\right) \frac{d^j}{d\xi_i^j} \exp\left(-\frac{1}{2}\xi_i^2\right) \tag{4}$$

3. Gauss-Hermite nonlinear model predictive control

Once the uncertainties are defined as PCE as shown in section 2, we aim to exploit this information together with the dynamic equation system in Eq.(1) to formulate an optimal control problem (OCP) to be solved iteratively. To achieve this we use Gauss-Hermite quadrature rules to create several realizations of θ from its PCE representation to formulate a scenario-based MPC problem. The Gauss-Hermite quadrature rules can be seen to give an approximation to the integral:

$$\mathbb{E}[f(\xi)] = \int_{-\infty}^{\infty} f(\xi) p(\xi) d\xi, \qquad p(\xi) = \prod_i \exp(-\xi_i^2)/\sqrt{\pi} \tag{5}$$

where ξ is a standard normally distributed random variable and $\mathbb{E}[\cdot]$ is the expectation operator.

The Gauss-Hermite quadrature rules accomplish this by creating deterministic samples of ξ with corresponding weights. The approximations of expectation and variances of a function $f(\xi)$ are:

$$\mu_f = \mathbb{E}[f(\xi)] \approx \sum_{q=1}^{N_q} w_q f(\xi_q), \quad \sigma_f^2 = \mathbb{E}\left[\left(f(\xi) - \mu_f\right)^2\right] \approx \sum_{q=1}^{N_q} w_q \left(f(\xi_q) - \mu_f\right)^2 \tag{6}$$

where ξ_q and w_q are given by the quadrature rule with overall N_q points. The Gauss-Hermite rule used in this work was taken from Jia et al. (2012), which is a sparse Gauss-Hermite quadrature rule. These require less samples than the full Gauss-Hermite rules for the same order of accuracy.

Using Chebyshev's inequality probability constraints can be robustly reformulated involving only the mean and variance of the random variable. Let γ be a generic random variable, then

$$\mathbb{P}(\gamma \leq 0) \geq 1 - \varepsilon \implies \kappa_\varepsilon \sigma_\gamma + \hat{\gamma} \leq 0, \quad \kappa_\varepsilon = \sqrt{(1-\varepsilon)/\varepsilon} \tag{7}$$

where $\varepsilon \in (0,1) \subset \mathbb{R}$ is the probability that γ exceeds 0, $\hat{\gamma}$ and σ_γ^2 are the mean and variance of γ respectively.

The optimal control problem to be solved can subsequently be stated as follows using the Gauss-Hermite quadrature rule with N_q points, the dynamic system in Eq.(1), the PCE representation of $\theta(\cdot)$ and the initial condition at time t given as a function of $\theta(\cdot)$ as $\mathbf{x}_t(\theta(\cdot))$:

$$
\begin{aligned}
\underset{\mathbf{U}}{\text{minimize}} \quad & \sum_{q=1}^{N_q} w_q J(\mathbf{x}^{(q)}(0), \mathbf{U}, \xi_q) \\
\text{subject to} \quad & \\
& \mathbf{x}^{(q)}(k+1) = \mathbf{f}(\mathbf{x}^{(q)}(k), \mathbf{u}(k), \theta(\xi_q)) && \forall (k,q) \in \mathbb{N}_k \times \mathbb{N}_q \\
& \mu_{g_{jk}} + \kappa_\varepsilon \sigma_{g_{jk}} \leq 0, \quad \kappa_\varepsilon = \sqrt{(1-\varepsilon)/\varepsilon} && \forall (j,k) \in \mathbb{N}_g^{(k)} \times \mathbb{N}_{k+1} \\
& \mu_{g_{jk}} = \sum_{q=1}^{N_q} w_q g_j^{(k)}(\mathbf{x}^{(q)}(k), \theta(\xi_q)) && \forall (j,k) \in \mathbb{N}_g^{(k)} \times \mathbb{N}_{k+1} \\
& \sigma_{g_{jk}} = \sum_{q=1}^{N_q} w_q \left(g_j^{(k)}(\mathbf{x}^{(q)}(k), \theta(\xi_q)) - \mu_{g_{jk}} \right)^2 && \forall (j,k) \in \mathbb{N}_g^{(k)} \times \mathbb{N}_{k+1} \\
& \mathbf{u}(k) \in \mathbb{U} && \forall k \in \mathbb{N}_k \\
& \mathbf{x}^{(q)}(0) = \mathbf{x}_t(\theta(\xi_q)) && \forall q \in \mathbb{N}_q
\end{aligned}
\tag{8}
$$

where $\mathbb{N}_k = \{0, \ldots, N-1\}$, $\mathbb{N}_{k+1} = \{1, \ldots, N\}$, $\mathbb{N}_g = \{1, \ldots, n_g^{(k)}\}$, $\mathbb{N}_q = \{1, \ldots, N_q\}$, N is the time horizon, $\mathbf{U} = \{\mathbf{u}(0), \ldots, \mathbf{u}(N-1)\}$, the objective is given by the expectation of a nonlinear function $J(\mathbf{x}_q(0), \mathbf{U}, \xi_q)$ approximated by the Gauss-Hermite rule, $\mathbb{U}$ represents the constraints on $\mathbf{u}(k)$ and $\mathbf{x}^{(q)}$ represents the state vector for each sampling point q. The chance constraints are approximated by Chebyshev's inequality given in Eq.(7) as nonlinear functions $g_j^{(k)}(\mathbf{x}^{(q)}(k), \theta(\xi_q))$ constrained robustly to be less than 0 with a probability of ε.

4. Polynomial chaos expansion filter

The PCE filter updates θ given the noisy measurements available from Eq.(2) and was first proposed in Madankan et al. (2013). It has further been applied for linear stochastic MPC in Mühlpfordt et al. (2016). Let $D_t = \{\mathbf{y}(1), \ldots, \mathbf{y}(t)\}$ be the measurements collected up to time t. Bayes's rule can be employed to update θ recursively using the previous PCE of θ:

$$p(\theta|D_t) = \frac{p(\mathbf{y}(t)|\theta)p(\theta|D_{t-1})}{p(\mathbf{y}(t)|D_{t-1})} \tag{9}$$

where $p(\theta|D_{t-1})$ is the prior distribution of θ given observations up to time $t-1$, $p(\mathbf{y}(t)|\theta)$ is the likelihood $\mathbf{y}(t)$ is observed given θ at time t. We defined $p(\mathbf{y}(t)|\theta) = \mathscr{N}(\mathbf{h}(\mathbf{x}(t), \theta), \Sigma_\mathbf{v})$ as standard normal distribution in Eq.(2) with mean $\mathbf{h}(\mathbf{x}(t), \theta)$ and covariance $\Sigma_\mathbf{v}$.

If we take both sides of Eq.(9) times $\prod_{j=1}^{n_\theta} \theta_j^{r_j}$ and integrate over both sides we obtain:

$$M_\mathbf{r}^+ = \frac{\int \prod_{j=1}^{n_\theta} \theta_j^{r_j} p(\mathbf{y}(t)|\theta) p(\theta|D_{t-1}) d\theta}{p(\mathbf{y}(t)|D_{t-1})} \tag{10}$$

where $M_\mathbf{r}^+ = \int \prod_{j=1}^{n_\theta} \theta_j^{r_j} p(\theta|D_t) d\theta$ and let $k = \sum_{j=1}^{n_\theta} r_j$. Now $M_\mathbf{r}^+$ refers to the various k-th order moments with respect to the updated distribution of θ, $p(\theta|D_t)$.

In our case the distribution of $\theta(\xi)$ depends on its PCE coefficients $\mathbf{A}$ and hence these need to be updated, see Eq.(3). We can approximate the distribution of $p(\theta(\xi)|D_{t-1})$ using sampling, since it is assumed that ξ follows a standard normal distribution. Let $\theta_t(\xi)$ denote the PCE of θ at time t with coefficients $\mathbf{A}_t$. Applying a sample estimate to Eq.(10) with a sample design of size N_s given by $\{\xi_1, \ldots, \xi_{N_s}\}$, where $\xi_i \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ we obtain the following:

$$M_{\mathbf{r}}^{(s)+} = \frac{1}{\alpha N_s} \sum_{i=1}^{N_s} \prod_{j=1}^{n_\theta} (\theta_{t-1}(\xi_i))_j^{r_j} p(\mathbf{y}(t)|\theta_{t-1}(\xi_i)) \tag{11}$$

where $M_{\mathbf{r}}^{(s)+}$ is the sample approximation of the RHS of Eq.(10) of the posterior moments and $\alpha = \frac{1}{N_s} \sum_{i=1}^{N_s} p(\mathbf{y}(t)|\theta(\xi_i))$. The sample design was created using Latin hypercube sampling and the inverse transform of the standard normal distribution.

To update the coefficients $\mathbf{A}_{t-1}$ of θ_{t-1} to $\mathbf{A}_t$ to represent θ_t we use moment matching. It is possible to determine closed-form expressions of moments of PCE expansions as given in Eq.(3) in terms of their coefficient, see Dutta and Bhattacharya (2010). The difference between these and the sample estimate of the posterior moments is then minimized to update the coefficients:

$$\hat{\mathbf{A}}_t = \underset{\mathbf{A}_t}{\arg\min} \sum_{k \leq m} ||M_{\mathbf{r}}^+(\mathbf{A}_t) - M_{\mathbf{r}}^{(s)+}||_2^2 \tag{12}$$

where $k = \sum_{j=1}^{n_\theta} r_j$ was defined as the order of the moments and hence m defines the total order of moments we want to match. $M_{\mathbf{r}}^+(\mathbf{A}_t)$ denotes the moments of the PCE expansion as a function of the coefficients $\mathbf{A}_t$ and $\hat{\mathbf{A}}_t$ are the updated coefficients to match the posterior moments.

5. Case study

The overall framework is summarised in Algorithm 1 for receding horizon SNMPC. First it is initialized by specifying the problem, including initial coefficients of the PCE expansion of θ.

Algorithm 1: Output feedback SNMPC

Input : $\hat{\mathbf{A}}_0, \boldsymbol{\Sigma}_{\mathbf{v}}, \mathbf{f}(\cdot), \mathbf{h}(\cdot), \mathbf{x}_0(\theta)$
for *each sampling time* $t = 0, 1, 2, \ldots$ **do**

  1. Determine $\mathbf{x}_t(\theta_t(\xi))$ using $\mathbf{f}(\cdot, \cdot, \theta_t(\xi))$ recursively from an updated initial condition $\mathbf{x}(0) = \mathbf{x}_0(\theta_t(\xi))$.
  2. Solve SNMPC problem with $\theta_t(\xi)$ and $\mathbf{x}_t(\theta_t(\xi))$ and obtain optimal control actions.
  3. Apply first part of the control actions to the plant.
  4. Measure $\mathbf{y}(t+1)$.
  5. Apply the PCE filter to update $\theta_t(\xi)$ to $\theta_{t+1}(\xi)$ by determining the coefficients $\hat{\mathbf{A}}_{t+1}$.

end

The case study aims to control a fermentation bioreactor using Algorithm 1. Fermentation is an important process in the biochemical and pharmaceutical industries. Uncertainties are often considerable and disregarding these may lead to inadequate performance. In this paper we consider a semi-batch bioreactor with the inlet substrate flowrate as the control variable. The two variables that are considered uncertain are the inlet concentration of the substrate $C_{S,in}$ and the kinetic parameter μ_{max}. The dynamic model was taken from Petersen and Jørgensen (2014) and describes the fermentation of a single cell protein using Methylococcus Capsulatus:

$$\dot{V} = F \tag{13a}$$

$$\dot{C}_X = -F C_X/V + \exp[\mu_{max}(\xi)] \frac{C_S}{K_S + C_S + C_S^2/K_I} \tag{13b}$$

$$\dot{C}_S = -F(C_S - \exp[C_{S,in}(\xi)])/V - \gamma_s \exp[\mu_{max}(\xi)] \frac{C_S}{K_S + C_S + C_S^2/K_I} \tag{13c}$$

where V is the volume of the reactor in m^3, F is the feed rate of substrate in m^3/h, C_X and C_S are the concentrations of biomass and substrate respectively in kg/m^3. The uncertain parameters are assumed to be given as a PCE in terms of standard normally distributed variables ξ, which were log-transformed to ensure positiveness. This defines $\mathbf{f}(\cdot)$ in Eq.(1) with $\mathbf{x} = [V, C_X, C_S]^T$, $u = F$ and $\theta(\xi) = [\mu_{max}(\xi), C_{S,in}(\xi)]^T$. The parameter values are $\gamma_S = 1.777$, $K_S = 0.021 kg/m^3$ and $K_I = 0.38 kg/m^3$. The corresponding output equation is given as follows:

$$\mathbf{y} = \mathbf{Kx} + \mathbf{v}, \quad \mathbf{K} = \text{diag}([1,0,1]), \quad \mathbf{v} \sim \mathcal{N}\left(\mathbf{0}, \text{diag}\left([3 \times 10^{-4}, 3 \times 10^{-4}]\right)\right) \tag{14}$$

The respective initial PCE expansions are given as, which defines $\hat{\mathbf{A}}_0$ and $\theta_0(\xi)$:

$$\mu_{max}(\xi) = \log(0.37) + 0.04\xi_1 + 0.02(\xi_1^2 - 1) + 0.0067(\xi_1^3 - 3\xi_1) \tag{15}$$

$$C_{S,in}(\xi) = \log(1.00) + 0.04\xi_2 + 0.02(\xi_2^2 - 1) + 0.0067(\xi_2^3 - 3\xi_2) \tag{16}$$

The objective was set to minimize the batch time with a chance constraint to produce a minimum concentration of biomass of $10 kg/m^3$ with a probability of 0.05 with 10 control intervals in a shrinking horizon implementation. The input F was constrained between $0 kg/h$ and $10 kg/h$.

6. Results, discussion and conclusions

Firstly the simulation was run by setting the parameters of the plant model to $[\mu_{max}, C_{S,in}] = [0.41, 1.05]$. The results of this are shown in Fig. 1. Next the initial parameter PCE of μ_{max} and $C_{S,in}$ given in Eq.(15) and Eq.(16) were sampled 100 times randomly and used to simulate the "true" system according to Eq.(13), for which the results are given in Fig. 2. In each case Algorithm 1 was then used to control these systems in closed-loop to verify the performance given the objective and constraints outlined in the previous section. $N_s = 200$ samples were used for the PCE filter, see section 4.

In Fig. 1 it can be seen that given the measurement available at $t = 1$ the initial distribution at $t = 0$ moves towards the correct value. With several more updates it then converges to a sharp distribution at $t = 10$ due to the relatively low measurement noise. The last row highlights the working of the algorithm: The lower left plot shows that less and less time is necessary to reach the required biomass concentration due to the better estimates available of the uncertain parameters, i.e. it becomes possible to reduce the sampling times as it becomes less and less conservative. In the second graph we see that the biomass reaches nearly exactly $10 kg/m^3$ at the final time with the control inputs shown in the last graph.

In Fig. 2 we see that the batch times of the Monte Carlo simulations vary significantly with batch times ranging from 70h to 140h, with most batch times around 110h. In the last two graphs it can be seen that the required biomass of $10 kg/m^3$ was reached in most simulations despite the uncertainties present, however in about 7% of the scenarios this was not achieved. This is due to the parameter update being overconfident from the limited number of samples used. In particular, it can be seen that two scenarios do not reach even $4 kg/m^3$, which happens if the parameters converge to the wrong value due to the limited number of samples used.

In conclusion a novel framework has been proposed by employing PCE to describe parametric uncertainties and exploiting this uncertainty description in a sparse Gauss-Hermite MPC formulation taking into account these uncertainties efficiently. Noisy measurements were used at each sampling time to update the PCE of the uncertain parameters and reduce the inherent uncertainties present significantly. It could be shown that the algorithm is able to achieve the required biomass in 93% of the scenarios, however the parameter update may be overconfident using 200 samples.

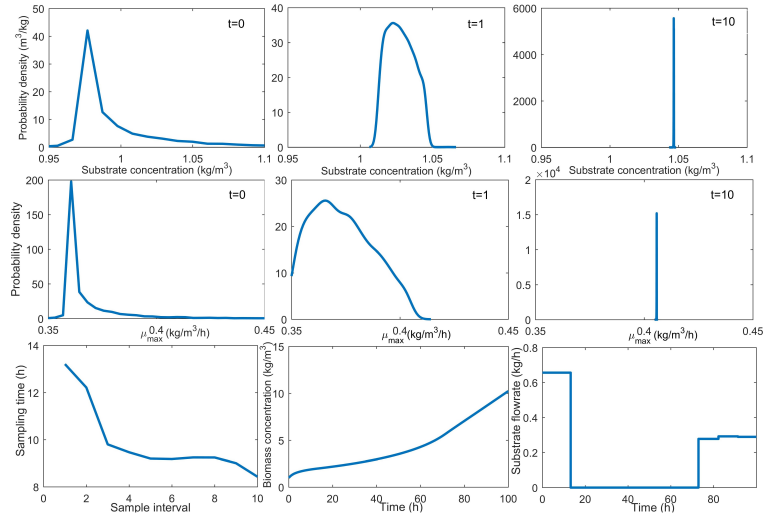
Acknowledgements


Figure 1: Run of Algorithm 1 with $[\mu_{\max}, C_{S,in}] = [0.41, 1.05]$. The first two graph rows show the evolution of the marginal distribution of the inlet substrate concentration and $\mu_{\max}$ at $t = 0$, $t = 1$ and $t = 10$. The last graph row shows the trajectories of the sampling time, biomass concentration and substrate flowrate.

Abstract

In this work, we analyze a generic supercritical CO_2-refrigeration system with parallel compression, based on systems used for supermarket use. In order to maximize energy efficiency, this system has a "heat-recovery" function, in which part of the heat rejected at high pressure and temperature can be recovered to provide heating. Operating conditions and active constraints are strongly affected by seasonal requirements and ambient temperature. Thus, it is necessary to find a control structure that satisfies operational constraints and maintains (near-)optimal operation with different sets of active constraints. In this paper, we use a systematic procedure to define such control structure.

Keywords: constrained operation, self-optimizing control, PID control, control structure

1. Introduction

An appropriately designed control structure should maintain (near-) optimal operation, also when there are disturbances which cause the system to operate under conditions different than the design point. Optimal operation of a process in the presence of disturbances could be maintained using optimization-based control. However, in some cases, it is possible to design and implement advanced PI(D)-based control structures that also maintain optimal operation when constraints are reached (Skogestad, 2000; Reyes-Lúa et al., 2018). The advantage of such a PI(D)-based control structure compared to optimization-based control is simpler tuning and independence of an explicit model for every system (Forbes et al., 2015).

CO_2-refrigeration systems with parallel compression is environmentally attractive. Finding optimal design and operating conditions is an ongoing area of research (Gullo et al., 2018). In order to maximize energy efficiency, some systems have a "heat recovery" function, in which part of the heat rejected at high pressure and temperature can be recovered to provide heating (e.g. district heating or tap water) (Sawalha, 2013). The available energy can be increased by operating the cooler at a higher pressure, at the expense of a higher compression work. In this work, we design a PI(D)-based control structure for the studied CO_2-refrigeration system.

2. Description of the CO_2-refrigeration system with heat recovery

A flow diagram of the analyzed CO_2-refrigeration cycle with parallel compression and heat recovery is shown in Fig. 1, and the pressure-enthalpy diagram is shown in Fig. 2. The main function of this system is to provide cooling ($\dot{Q}_{ev}$) and maintain the desired cabinet temperature (T_{cab}) via heat exchange in the evaporator, which operates at low pressure (P_l). Low-pressure CO_2 in vapor phase is compressed to high-pressure (P_h) and temperature supercritical CO_2, which may be used to heat tap water in the heat recovery section. Excess heat ($\dot{Q}_{gc}$) is rejected to the ambient air in the gas cooler.

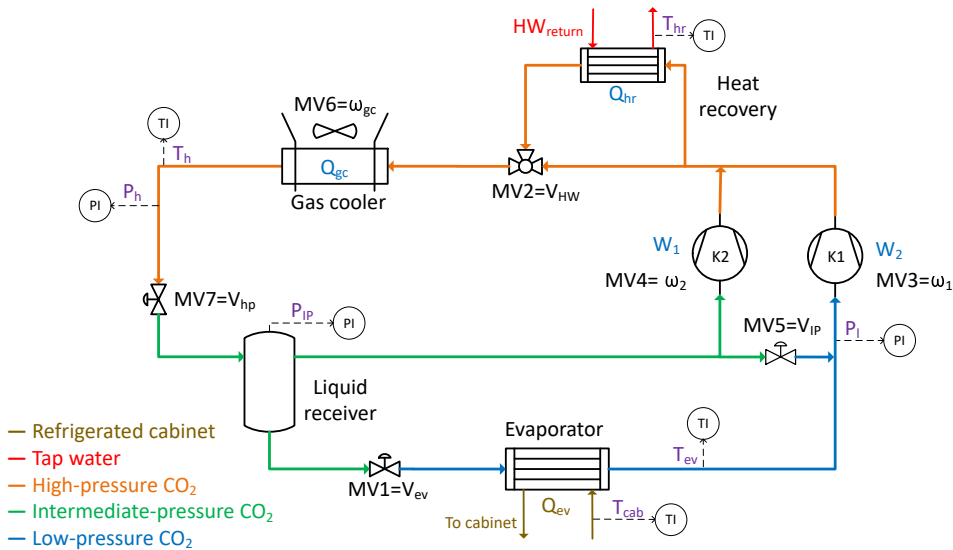
High-pressure CO_2 is expanded to an intermediate (sub-critical) pressure (P_{IP}) in the high-pressure valve (V_{hp}). Vapor and liquid CO_2 are separated in the liquid receiver. The evaporator valve (V_{ev}) regulates the flow of liquid CO_2 from the receiver to the evaporator. By opening and closing V_{hp} and V_{ev}, we regulate the refrigerant charge (mass) at the high and low pressures. Vapor CO_2 from the liquid receiver is recycled to the high-pressure side either via parallel compression ($K2$) or the intermediate pressure valve (V_{IP}) and the main compressor ($K1$). The total compression work can be reduced by utilizing the parallel compressor instead of the intermediate pressure valve and the main compressor.


Figure 1: CO_2-refrigeration system with parallel compression and heat recovery. There are seven available manipulated variables (MV).

2.1. High-side pressure

In the supercritical region, there is no saturation condition and the pressure is independent of the temperature. From the control point of view, this means that it is necessary to control the high pressure (P_h), since it influences the gas cooler exit enthalpy (and evaporator inlet enthalpy). In other words, P_h will determine specific refrigeration capacity. As P_h is determined by the relationship between refrigerant charge, inside volume and temperature in the high-pressure side, we can actively control it using V_{hp} (Kim et al., 2004).
Figure 2: Pressure-enthalpy diagram of CO_2-refrigeration system with parallel compression.

It is relevant to analyze the effect of high pressure on the coefficient of performance (COP). In the case of a refrigeration system, it is defined as the ratio between cooling and compression work ($COP = \dot{Q}_{ev}/W_s$). As the isentropic compression line in the pressure-enthalpy diagram (blue lines in Fig. 2) is linear, compression work will linearly increase as P_h increases. On the other hand, in the supercritical region the isotherm (red lines in Fig. 2) becomes steeper with pressure, reducing the capacity enhancement from a given increase in pressure. For this reason, the COP reaches a maximum above which the added capacity no longer fully compensates for the additional work of compression. Thus, there is an optimal high pressure that maximizes COP (Nekså, 2002).

We should also note that in the supercritical region, at a fixed pressure, a small change in refrigerant exit temperature can produce a large change in gas cooler exit enthalpy (and evaporator inlet enthalpy), making COP very sensitive to the gas cooler refrigerant exit temperature. Previous studies (Liao et al., 2000; Jensen, 2008; Sawalha, 2013) are in line with this and have shown that the optimal set-point for the high pressure (P_h) should be corrected by the outlet temperature of the gas cooler (T_h).

2.2. Heat-recovery section

Part of the heat rejected at high pressure can be recovered to provide hot water in the heat recovery section. Heat is rejected at gliding temperature, as supercritical CO_2 is cooled. This way, the temperature profile of the CO_2 matches the heating-up curve of water, giving reduced thermodynamic losses and high efficiency (Kim et al., 2004). As it can be deduced from Fig. 2, increasing the high pressure increases the available heat for recovery, at the expense of a higher compression work. Additionally, the available heat for recovery in the supercritical region is much higher than with sub-critical CO_2.

3. Design of the PI(D)-based control structure

In this section, we apply part of the systematic plantwide control procedure proposed by Skogestad (2000) to design a self-optimizing control structure which maintains (near-) optimal operation, also in the presence of disturbances. The first step of the procedure is to define the operational objective. Here, we want to maximize the coefficient of performance (COP), subject to the system itself and operational constraints:

$$\min_{u} - COP(u,x,d) = -(\dot{Q}_{ev} + \dot{Q}_{hr})/(W_1 + W_2)$$

$$\text{s.t.} \quad f(u,x,d) = 0 \qquad \text{system equations (model)} \qquad (1a)$$

$$g(u,x,d) \leq 0 \qquad \text{operational and physical constraints} \qquad (1b)$$

$$e(u,x,d) = 0 \qquad \text{set-points} \qquad (1c)$$

where x are the internal states, u are the degrees of freedom, and d are the disturbances.

Physical constraints in Eq. (1b) are related to pressure (P_i), motor velocities (ω_i) and valve openings (z_i), specifically: $P_i \leq P_i^{max} \ \forall i$, $(P_{IP} - P_l)^{min} \leq (P_{IP} - P_l)$, $\omega_j^{min} \leq \omega_j \leq \omega_j^{max} \ \forall j$, and $z_k^{min} \leq z_k \leq z_k^{max} \ \forall k$. The most important set-point in Eq. (1c) is to supply enough cooling ($\dot{Q}_{ev}$) to maintain $T_{cab} = T_{cab}^{sp}$. Additionally, we would like to supply enough heating ($\dot{Q}_{hr}$) to maintain $T_{hr} = T_{hr}^{sp}$.

The next step is to determine the steady-state optimal operation. In order to do this we:

- *Identify steady-state degrees of freedom:* The analyzed system has seven available manipulated variables, MVs in Fig. 1: $u = [\omega_1, \omega_2, \omega_{gc}, z_{Vev}, z_{Vhp}, z_{VHW}, z_{V_{IP}}]^T$. These degrees of freedom can be used to achieve optimal operation. Note that ω_2 and $z_{V_{IP}}$ are not independent, as either would have a similar effect in P_{IP}.

- *Identify important disturbances and their expected range:* In this case study, important disturbances (d) are cooling demand ($\dot{Q}_{ev}$, corresponding to T_{cab}^{sp}), and heating demand ($\dot{Q}_{hr}$, corresponding to T_{hr}^{sp}). The range for both is $\dot{Q}_i^{min} \leq \dot{Q}_i \leq \dot{Q}_i^{max}$.

- *Identify active constraints regions:* Once that the disturbances and their range are specified, the active constraints regions are found. This can be done by optimization or using engineering insight (Jacobsen and Skogestad, 2011). There are three relevant operating regions:

  1. *"Unconstrained" case*: corresponding to spring/fall operation.
  2. *Maximum heating*: corresponding to winter, when $\dot{Q}_{hr} = \dot{Q}_{hr}^{max}$.
  3. *Maximum cooling*: corresponding to summer, when $\dot{Q}_{ev} = \dot{Q}_{ev}^{max}$.

In every case, cooling requirements ($T_{cab} = T_{cab}^{sp}$) must be met. If possible, heating requirements ($T_{hr} = T_{hr}^{sp}$) should also be met. We do not consider $\dot{Q}_{ev} = \dot{Q}_{ev}^{min}$, as it corresponds to shut-down. $\dot{Q}_{hr} = \dot{Q}_{hr}^{min}$ is included in the "unconstrained" and maximum cooling cases. Then, we will design a control structure that works for the three relevant cases mentioned above. Fig. 3 shows the proposed control structure. The procedure to design this control structure is explained below.

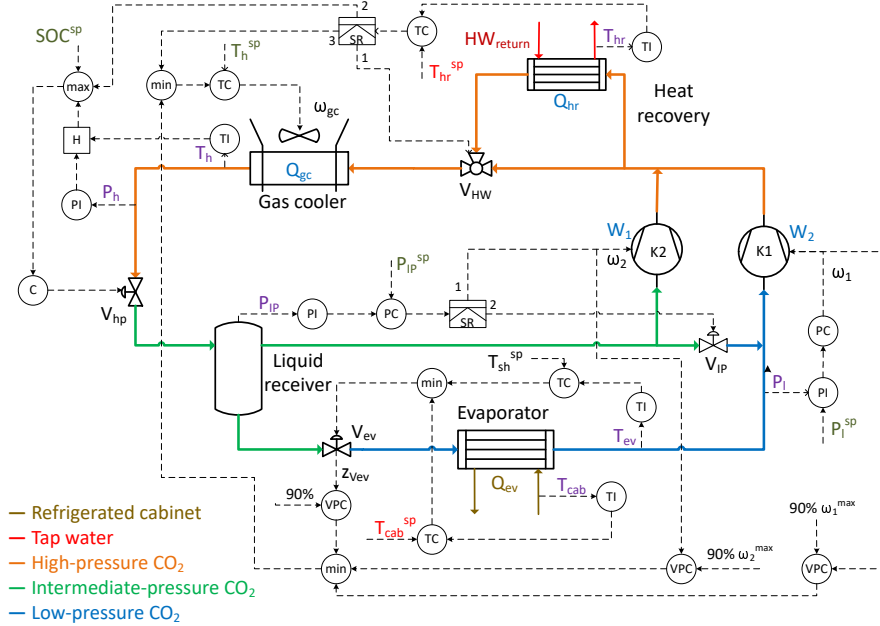
For each region, each steady-state degree of freedom (MV) needs to be paired with a controlled variable. First, we pair active constraints. Then, for the remaining degrees of freedom, we identify self-optimizing controlled variables. These are usually a combination of measurements found by optimization. When designing control structures for systems with changing active constraint regions, it is useful to organize constraints in a priority list (Reyes-Lúa et al., 2018). Physical constraints (Eq. (1b)) have the highest priority. Regarding set-points (Eq. (1c)), $T_{cab} = T_{cab}^{sp}$ has a higher priority than $T_{hr} = T_{hr}^{sp}$.


Figure 3: Control structure for the CO_2-refrigeration system with heat recovery.

3.1. "Unconstrained" case

This is the base case and we can satisfy every constraint. We use MV1=V_{ev} to control T_{cab}, and MV2=V_{HW} to control T_{hr}. The set-points are given by the operator. In order to assure that the evaporator is not over-flooded, we include a controller for the evaporator outlet temperature (T_{sh}). We have five remaining unconstrained degrees of freedom, two of which are not independent (ω_2 and V_{IP}). We pair these degrees of freedom as follows:

1. MV3=ω_1 controls P_l. P_l^{sp} is found by optimization (self-optimizing variable).

2. The parallel compressor (MV4=ω_2) and MV5=V_{IP} are used to control the pressure in the liquid receiver (P_{IP}). The set-point defined by optimization and may be a self-optimizing variable. Normal operation is using ω_2, but when the flow is too low, we use V_{IP}. We can implement this with a split-range controller.

3. MV6=ω_{gc} controls T_h (outlet of the gas cooler). T_h^{sp} is defined by optimization.

4. MV7=V_{hp} controls P_h. As explained in Section 2.1, the set-point is a linear combination (H) of P_h and T_h, which is a self-optimizing variable (Jensen, 2008).

3.2. Maximum heating

When V_{HW} becomes fully open, we must switch the manipulated variable to continue controlling T_{hr}. This is handled using split-range control with selectors. First, we switch to V_{hp} as manipulated variable and increment the available heat for recovery by increasing P_h. To implement this, we include a selector for the set-point of the high-pressure controller. Once we reach P_h^{max}, we get additional capacity for the heat-recovery section by increasing T_h, using ω_{gc} as manipulated variable. This will increase mass flow through the compressors and, as consequence, the discharge temperature.

If we continue to increase T_h, at some point liquid in the low-pressure section may be insufficient and V_{ev} will reach its maximum opening. Alternatively, the compressors could reach maximum capacity due to the increased mass flow. To prevent this, we implement valve-positioning controllers (VPC) with a *min* selector, which will prevent T_h from increasing in such a way that either the valve or the compressors ($z_{V_{ev}}$, ω_1 or ω_2) saturate.

3.3. Maximum cooling

As cooling requirements increase, z_{Vev} will open and reach z_{Vev}^{max}. The valve positioning controller for V_{ev} will adjust T_h (and indirectly P_h) such that the system reaches Q_{ev}^{max}.

4. Final remarks

Using a systematic procedure, we designed a PI(D)-based control structure for a CO_2-refrigeration system, that maintains (near-)optimal steady-state operation, also with changes in the set of active constraints. We should point out that pairing on the low-pressure side could be different (e.g. controlling T_{cab} with the main compressor, and P_l with V_{ev}). The final decision would consider system dynamics. It is important to mention that we can usually reach the same steady-state control objectives we reach with split-range controllers by using valve-positioning control or different controllers with different set-points.

Abstract

Consumer preference investigations are extremely emphasized in marketing management strategy for food enterprises. In this communication, a partial least squares regression (PLSR) model for consumer preference prediction from sensory attributes profiles is developed and three brands of yoghurt are exampled to demonstrate the accuracy and practicability of the method. The model also provides the importance ranking of the analysed sensory variables, which may give a guidance for industrial production and sensory experiment design. Drawing on the results of PCA and hierarchical clustering analysis, the variable filtering process of PLSR is proved to be theoretically correct.

Keywords: Sensory attributes, Consumer preference, PLSR, Yoghurt

1. Introduction

Yoghurt is one of the most important commodities in people's daily life. Odour compounds, such as proteins, amino acids, fats, sugars, organic acids,[1] make a solid contribution in the sensory attributes of dairy. The consumer preferences for yoghurt are directly affected by their sensory quality. For dairy companies, consumer preferences for yoghurt data are essential to market competitiveness. Dairy products should be designed and improved according to consumer demand.[2] However, the data related to consumer is usually hard to be obtained, because the large-scale consumer preferences survey is unfeasible to carry out for new products[3] and the consumer preferences in different regions have significant differences in the flavor of dairy products.

Thus, a data-driven consumer preference prediction model is urgently needed by dairy companies. And in recent years, several researchers have focused on the sensory profiling of dairy products and proposed various correlation models to forecast the consumer overall likings. Bouteille et al[4] applied principal component analysis (PCA) to construct internal mapping between Temporal Dominance of Sensations (TDS) curves and liking scores or freshness sensation scores to evaluate plain yoghurts and yoghurt-like product. Oliveira et al[5] analyzed the relevancy between check-all-that-apply (CATA) frequency and overall linking by threshold statistics and advised the dairy companies to reduce the sugar addition in milk. Farah et al[6] utilized cluster analysis and multiple factor analysis to associate data from CATA test and acceptance test for overall impression and identified two significantly different clusters of yoghurts', whey-based beverages' and fermented milks' consumers. However, these models were lack of generalization ability and hard to deal with high dimensional data, making the model feeble in practicality and versatility.

To improve the overall performance of the model, a novel correlation model with PLSR was proposed to predict the consumers' overall liking of dairy products from sensory attributes profiles. The PLSR model could not only obtain the prediction value from multicollinear variables, but also filter out the key sensory attributes and classify the samples with its principal components. In consideration of the characteristics of data as well as the need in enterprise production, reducing the number of variables without affecting the accuracy of result fitting was also realized to reduce the cost of subsequent experiments.[7]

In summary, this communication intended to use the analytical sensory evaluation team to perform sensory evaluation on yoghurt samples and use multivariate statistical analysis methods to profile the sensory evaluation of different samples' flavors, which provided guidance for the improvement of sensory quality.

2. Sensory evaluation and data profiling method

2.1. Sensory data collection

The sensory attributes data was obtained by evaluators' rating of each sample. Through the training[8] of sensory sensitivity and expressive ability, a total of ten sensory experts were invited to complete the sensory evaluation. After tasting the series of flavored yoghurt samples, these experts were asked to describe all the sensations from the aspects of sight, smell and taste. The evaluation process is carried out in an independent evaluation room. Then the descriptors were screened through preliminary collation and multivariate statistical analysis methods, and the sensory attributes descriptors of the flavored yoghurt were finally determined.[9]

For the selected sensory attributes descriptors, each sensory expert would give the flavor intensities for a specific sample using a 10-point linear scale. The left end of the linear scale is extremely weak, and the right end is extremely strong. The evaluator can select any value from 0 to 10 as the attributes intensity evaluation value.

Consumer preference rating is an output variable in this study. Fifty heavy consumers of yoghurt products in Beijing were invited to the sensory lab to fill the overall liking questionnaires. The consumer preference test also adopted the 0 (extremely weak) to 10 (extremely strong) scoring mechanism.

2.2. Data characterization analysis

After the data collection process, we obtained a set of data including thirty-three kinds of yoghurt with different storage conditions evaluated by ten sensory experts on twenty-one sensory attributes and fifty consumers on overall likings. Due to the complexity of the input and output data, it's better to find out the data characterization before fitting.

For sensory attributes data, there were three brands of yoghurt stored under eleven different conditions that were evaluated by experts. So the input data could be summarized with a 33*21 matrix, where 33 (3*11) was the quantity of samples and 21 was the quantity of sensory attributes. To extract the key information of the data, Principal component analysis (PCA)[10] was applied to search for the relationship between the high-dimensional sensory attributes profiles. To profile the variable multicollinearity of yoghurt odour, the scoring plot of two PCs was generated and displayed in Figure 1.
Figure 1. 2-PCs scoring plot of yoghurt sensory attributes variables

As shown in Figure 1, there were several overlapped variables in the scoring plot, which might contain the almost same information for result fitting and interfere the accuracy of regression analysis. However, only utilizing several PCs to predict the consumers overall liking might lose plenty of information. So a regression model with the function of variable filtering was needed.

2.3. PLSR model for preference prediction

The partial least squares regression (PLSR) was proposed by Wold[11] in 1979, and it was feasible to solve the multivariate regression problem with independent multivariate correlation. This model projected the predicted variables to a new space, so that the difference between the dependent variables was minimized. Then compared to PCA regression method, PLSR also considered the contribution of the input data for the output data, so the correlation during the regression process could be guaranteed.[12] What's more, an importance ranking of sensory attributes could be obtained from the regression process, which could tell the enterprise how to improve the products.

Thus, through the overall liking assignment and PLSR model building with training data, a complete consumer preference prediction of yoghurt from sensory attributes profiles could be applied for dairy companies or sensory labs.
Figure 2. The fluctuation trend of RMSEP value affected by the number of components

3. Result and discussion

To execute the PLSR process, the quantity of variables that were employed to complete regression modeling should be determined. As shown in Figure 2, by analyze the root-mean-square error of prediction influenced by the number of components, a total of nine variables were finally picked up. The cumulative contribution rate of the nine selected variables reached the value of 94.52%, which gave a relatively comprehensive explanation of the origin input data.

Then the PLSR model was built on the R-3.4.1 and simulated on an Inter Core i7 processor of 2.80 GHz to predict the average liking scores of thirty-three collected samples. Figure 3 displayed the calculation results compared to actual data. Obviously, the calculation process demonstrated low relative errors that were below 10%.
Figure 3. Comparison of predicted and actual value of consumers' preference rating.

Table 1. Properties and corresponding objective functions in simulated annealing algorithm

Variables	+/- Correlation	Relevant significance
Sweetness	+	>95%
Grainy	-	>90%
Sourness	+	>85%
Oxidized	-	>85%
Smoothness	+	>85%
Swallowing intensity	-	>80%

In addition to the overall liking information, the PLSR simulation process also provided the correlation properties of each variables. Table 1 listed top six sensory attributes with high relevant significance of the selected nine variables, and all these relevant significances were larger than 80%, showing a strong relationship between sensory attributes and consumers preference rating value.

From Table 1, a diary enterprise could obtain the product improvement plan for a typical brand of yoghurt, such as properly increasing the sweetness, sourness, smoothness and decline the grainy, oxidized, swallow intensity as much as possible. What's more, the PLSR process could give the sensory labs a reasonable streamlined solution to design the sensory attributes test. As shown in Figure 4, though PCA showed that there were several variables expressing the similar information in the 2-PC space, the PLSR only picked up two key attributes (Smoothness, Swallowing intensity) for regression process. And PLSR could found out some attributes with high relevant significance, such as oxidized, which didn't own a good variance explanation in PCA result.
Figure 4. The sensory attributes with similar information in 2D PCA scoring plot

Finally, to demonstrate the description ability of the selected sensory attributes, a hierarchical clustering analysis was carried out. As shown in Figure 5, utilizing the selected sensory attributes as independent variables could clearly classify the three brands (670, 395, 481) of yoghurt, though the storage condition were different (1 to 5 for the storage month, R for Room temperature, H for high temperature, L for low temperature). This result demonstrated the correction of the sensory attributes selection from PLSR because these variables owned the ability to describe a specific b rand of yoghurt.
Figure 5. The hierarchical clustering analysis result using selected sensory attributes from PLSR

4. Conclusion

A PLSR model was developed to make connection between the collected sensory attributes profiles from trained sensory experts and the consumer preference rating. The accuracy and practicability of the method was demonstrated by the regression process of three brands of yoghurt. Besides, nine key sensory variables were selected by PLSR process and the correlation parameters between sensory variables and overall liking could give a reasonable advice for dairy enterprise to improve the yoghurt products. And the sensory labs could also update the experimental scheme according to the importance ranking of the sensory descriptors to save the overall consumption of the sensory evaluation.

Accurate and fast prediction of consumer preference can bring huge profits for food enterprise. The theory reliability of the PLSR method proposed in this work provides feasibility to applied the prediction model in other types of food. Hopefully, the utility of R based programs make the model easier to be applied as plug-in for Industrial Internet and promote the benefits for food industry.

Abstract

Large industrial sites typically consists of multiple production and utility systems. To minimize overall cost, these systems need to coordinate the operation. The problem resulting can be stated as a multi-leader multi-follower Stackelberg game. Thus, we propose a method which coordinates the operation across multiple production systems (leaders) and on-site utility systems (followers). The proposed method performs iterative feedback loops between production and utility systems. The coordination between the production and utility systems is performed by load- and time-dependent energy costs. The proposed method is applied to a case study with two production systems and two utility systems. The proposed mathod saves 7.3 % in total cost compared to the common separated and unidirectional optimization between each production system and the corresponding utility system. Thus, in summary, we provide an efficient method to enable cost optimization across multiple production and utility systems to reduce site-wide energy cost.

Keywords: Utility System, Production System, Multi-Leader Multi-Follower

1. Motivation

In large industrial sites, multiple production and utility systems are operated on-site. Usually, these systems are operated by different companies or business units. Thus, operational optimization is commonly performed individually and sequentially: First, the production systems schedule their production plan and determine the corresponding energy demand. Subsequently, the energy demand is supplied by the utility system corresponding to each production system. Consequently, there is no feedback between the systems and suboptimal overall cost arise. In this paper, we assume that operation for minimal overall cost is desired.

In principle, operation for minimal overall cost can be achieved by an integrated optimization problem of all production and utility systems. Such an integrated optimization has already been proposed for one production and utility system (Agha et al., 2010). The integrated optimization led to significant cost savings compared to sequential optimization. However, an integrated optimization is often practically prohibited, if the systems are operated by different companies. In such cases, the systems are not allowed to exchange their system knowledge. Maxeiner et al. (2017) therefore allocate shared resources by a

central site manager. The problem is solved by an iterative solution approach via price-based coordination. In their case study, a production system with 3 semi-batch reactors is considered. However, the starting times of the reactors are predefined and not scheduled. In the iterations, the degrees of freedom are the inputs and number of intervals. A central coordinator can be avoided by a multi-leader multi-follower Stackelberg game, where the production systems are the leaders and the utility systems are the followers.

A single-leader multi-follower Stackelberg game has been solved iteratively by Yu and Hong (2016) for a smart grid with one utility company (leader) and multiple customers (follower). Besides profit maximization of the leader and cost minimization of the followers, the method flattens the load profile. Maharjan et al. (2013) solve a multi-leader multi-follower Stackelberg game of a smart grid also by an iterative solution approach for a single time step. The exchanged information between leader and follower are the energy price and the energy demand. Ramos et al. (2018) solve a multi-leader single-follower and a single-leader multi-follower Stackelberg game for design of eco-industrial parks with continuous production systems. Thus, no production scheduling is required. The Stackelberg games are formulated as bilevel problems which are solved by replacing the followers' optimization problem by the Karush-Kuhn-Tucker reformulation. Yue and You (2017) propose an algorithm to solve a mixed-integer linear bilevel problem for the design and operation of supply chains in single-leader single-follower Stackelberg games. The above reviewed literature consider continuously operated or pre-scheduled production systems and shows the benefits of coordination by Stackelberg games. In an earlier publication, the authors therefore proposed a coordination method for a single batch production and a single utility system in a single-leader single-follower Stackelberg game (Holters et al., 2018). This paper extends the coordination method to multiple production and utility systems in a multi-leader multi-follower Stackelberg game. This extension allows to capture the complexity of actual industrial sites.

2. Coordination of multiple production and utility systems

In this section, we present a coordination method for multiple production and utility systems in a multi-leader multi-follower Stackelberg game. The method aims at minimizing energy and production cost for all production systems. In the method, all systems optimize themselves and the results are coordinated. The coordination uses only public information. Thus, the coordinating authority can be any participating production or utility system. A central site-manager or authority to handle non-public information is not required.

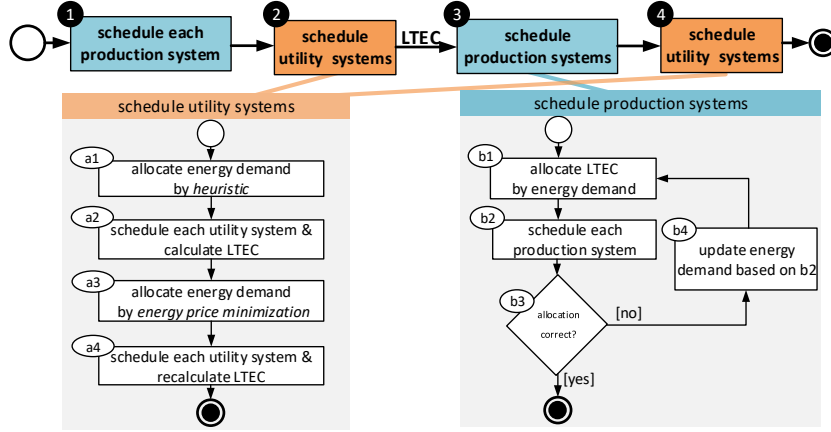
The method consists of 4 steps to optimize and to coordinate production and utility systems (Figure 1). In step ①, each production system schedules its production, assuming constant energy prices. The resulting energy demand is used as input for step ②. In step ②, the utility systems are scheduled. The utility systems coordinate the amount of energy provided by each utility system (Section 2.1). In step ②, load- and time-dependent energy costs are calculated (Holters et al., 2018) and passed to the production systems. The load- and time-dependent energy costs are the input for step ③. In step ③, the production systems re-schedule their production now using the load- and time-dependent energy costs (Section 2.2). The resulting energy demand is passed to the utility systems to finally schedule the utility systems (step ④). Thus, in step ④, the utility systems schedule their final operation to calculate the final energy cost. Step ④ performs the same computations as step ②. Steps ②, ③ and ④ use inner algorithms, which are explained in the following Sections 2.1 and 2.2.


Figure 1: Method to solve the multi-leader multi-follower Stackelberg game by coordination between multiple production and utility systems. Two inner algorithms are employed to schedule utility systems (step ②+④) and schedule production systems (step ③). LTEC: load- and time-dependent energy costs

2.1. Schedule utility systems, step ②+④

In step ② and step ④, the utility systems are scheduled to fulfill the energy demand of the production systems. The amount of energy supplied by each utility system is determined by minimizing the energy price of each energy form e. The coordination of the utility systems is performed in four steps (Figure 1; a1-a4): In step a1, the energy demand of each energy form is allocated to all utility systems based on the maximum capacity of each utility system (=heuristic). An energy price minimization is not possible here, because load- and time-dependent energy costs are not calculated before. In step a2, the utility systems schedule their operation for the allocated energy demand from step a1 and each utility system calculates its load- and time-dependent energy costs. The load- and time-dependent energy costs approximate for each time step the resulting energy costs for changes in the energy demand. For this approximation, the operation of each utility system is scheduled for 2 selected increased energy demands and 2 selected decreased energy demands. The selected energy demands represent loads, at which the supply structure of the utility system needs to change, i.e., an additional unit needs to be switched on or a running unit can be switched off. Between these energy demands, the corresponding energy costs are interpolated to calculate the load- and time-dependent energy costs.

In step a3, the energy price of each energy form e is minimized (Eq. 1) using the load- and time-dependent energy costs of each utility system to allocate the energy demand to the utility systems. This optimization problem is performed by the coordinating authority:

$$\min_{V_{i,e}, C_{i,e}, x} c_e^{min} \tag{1}$$

$$\text{s.t.} \quad \sum_{i \in US} V_{i,e}^{supply} = V_e^{demand} \tag{2}$$

$$c_e^{min} \geq \frac{C_{i,e}}{V_{i,e}}, \forall i \in US \tag{3}$$

$$A(V_{i,e}, C_{i,e}, x)^T \leq b \tag{4}$$

The objective (Eq. 1) is to minimize the energy price c_e^{min} of each energy form e. The energy supply $V_{i,e}^{supply}$ of the utility systems i needs to fulfill the energy demand V_e^{demand} (Eq. 2). The energy price c_e^{min} is the maximum of the energy prices $C_{i,e}/V_{i,e}$ of all utility systems (Eq. 3). $C_{i,e}$ are the absolute energy cost for provided energy form e by utility system i, which are part of the load- and time-dependent energy costs. All additional constraints are given in Eq. 4, i.e., calculation of $C_{i,e}$ from load- and time-dependent energy costs as function of $V_{i,e}$. x summarizes all additional variables. The energy price minimization allocates the energy demand to the utility systems.

In step a4, each utility system re-schedules its operation to fulfill the newly allocated energy demand and calculates the corresponding load- and time-dependent energy costs. The load- and time-dependent energy costs of all utility systems are cumulated. For step ②, the cumulated load- and time-dependent energy costs and the energy cost are the output and provide the input of step ③. For step ④, the output is the cost to fulfill the final energy demand.

2.2. Schedule production systems, step ③

In step ③, the scheduling of the production systems is coordinated. The scheduling of the production systems is coordinated in 4 steps (Figure 1; b1-b4):

In step b1, the cumulated load- and time-dependent energy costs from step ② are allocated to the production systems. In the allocation of load- and time-dependent energy costs, each section of the piecewise linear load- and time-dependent energy costs (Section 2.1) is split and allocated to the production systems. In the first iteration of the inner algorithm, the load- and time-dependent energy costs are allocated equally to the productions systems. In further iterations, the energy demand from the previous iteration is used for allocation to the production systems. In step b2, each production system uses the allocated load- and time-dependent energy costs from step b1 to schedule its production and calculate the energy demand. In step b3, the allocation of cumulated load- and time-dependent energy costs in step b1 is checked by the coordinating authority. If the sum of all energy cost calculated by each production system with the allocated load- and time-dependent energy costs is not equal to the energy cost for the overall energy demand calculated by the cumulated load- and time-dependent energy costs, the algorithm is repeated. If the energy costs are equal, the algorithm terminates. The output of step ③ is the energy demand of all production systems.

3. Case study

3.1. Description

In the case study, an industrial site is considered with 2 production systems and 2 utility systems. The production systems are based on literature examples from Kondili et al. (1993) and Kallrath (2002). Here, we added electricity and heat demands. The product demand is fixed at the time horizon of 30 h. The utility systems are based on the model by Voll et al. (2013). The utility system for the production system from Kondili et al. (1993) has 3 boilers (4000 kW, 1500 kW, 500 kW) and 2 identical combined-heat-and-power engines (1500 kW). The utility system for the production system from Kallrath (2002) has 2 boilers (3000 kW, 1000 kW) and 1 combined-heat-and-power engine (3000 kW). For both utility systems equal prices are assumed to buy (0.16 €/kWh) and purchase (0.1 €/kWh) electricity and buy gas (0.06 €/kWh) from the public grid. All optimization
Figure 2: Cost in the case study for the different approaches: The common sequential approach between each production system and the corresponding utility system (benchmark: sequential = 100 %), the multi-leader multi-follower Stackelberg game solved by the proposed coordination method (multi-leader multi-follower) and the integrated optimization of all systems (integrated). Kond.:Kondili; Kall.:Kallrath

problems are formulated in GAMS 24.7.3. The scheduling problems of production and utility systems (MILP) are solved with CPLEX 12.6.3.0, the energy price minimization problems (MINLP) (Eq. 1-4) are solved with DICOPT and CONOPT 3.17A.

3.2. Results

The case study is solved using the proposed method to coordinate multiple production and utility systems in a multi-leader multi-follower Stackelberg game. The results of the method are compared with the common practice to optimize sequentially each production system and the corresponding utility system, and the ideal benchmark, integrated optimization of all systems (Holters et al., 2017). The integrated optimization is solved in 728 s, the proposed method solves the problem in 1477 s.

The proposed method saves 7.3 % of the total production cost compared to the sequential approach (Figure 2). Compared to the integrated optimization, the method increases the cost by only 1.8 % (Figure 2). Thus, the costs from the proposed method are close to the costs from the ideal benchmark. Costs are saved for energy (14.8 %) while production cost increase slightly (3.4 %, Figure 2). However, overall, the production systems as the leaders still benefit, because they have to cover all cost for the energy supply.

In the proposed method, the energy demand of the production systems changes compared to the sequential approach (Figure 3): The peak demands are reduced for electricity (-25.1 %) and increased for heat (+8.5 %). The overall electricity demand also decreases (-17.7 %) and the heat demand increases (+8.0 %). Thus, the production schedules switched to processes with heat demand, because heat can be generated cheaper than electricity. Furthermore, the share of electricity from the public grid decreases (sequential 31.9 %; multi-leader multi-follower 8.2 %). Thus, utilization of on-site utility systems is increased by better coordination between production and utility system scheduling.

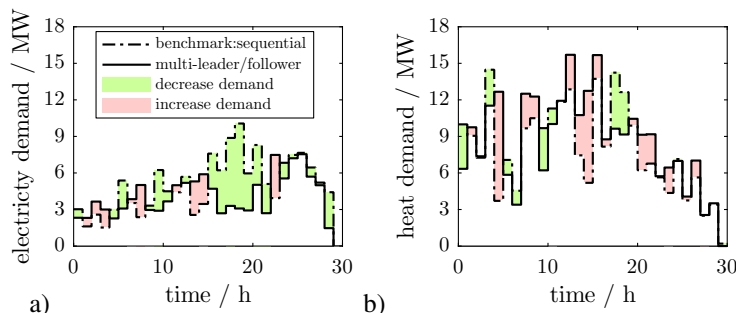
Uncertainty in energy demands, electricity prices and gas prices is not considered in the proposed method, but would be an important extension for practical adaption. To explore the sensitivity of the approach to data, we generated 10 instances with variations of ± 20 % around the original energy demands of the production systems by latin-hypercube sampling. For the instances, the proposed method reduces cost by 9.2 % compared to the sequential optimization and is again close to the integrated optimization which saves 10.2 % . Thus, the proposed method saves even more cost than in the nominal case study. In general, the cost savings depend on the actual energy demand of production systems.


Figure 3: Energy demand of the production systems for the sequential approach and for the proposed method to coordinate the multi-leader multi-follower Stackelberg game.

4. Conclusion

A coordination method is proposed to reduce the overall cost of multiple production and utility systems in a multi-leader multi-follower Stackelberg game. The coordination method employs load- and time-dependent energy costs in one feedback iteration.

In a case study, the coordination method reduces overall cost by 7.3 % compared to the common sequential approach. These cost savings are obtained by a revised production schedule, leading to slightly increased production cost (3.4 %), but significantly decreased energy cost (14.8 %). A computational study of 10 instances shows the general benefit of the proposed method.

Abstract

In this contribution, we propose estimating the means and variances required for calculating back-off terms by using the point estimate method (PEM) as a highly efficient sampling strategy in robust process design. As case studies, we consider an upstream pharmaceutical process which involves the synthesis of 2-hydroxy-ketones via enzyme-catalyzed carboligation and a downstream pharmaceutical process that includes the continuous crystallization of ibuprofen. We show that the proposed PEM-based back-off approach is significantly faster than conventional Monte Carlo brute-force sampling methods while maintaining robust solutions with low approximation errors. In general, the efficient PEM-sampling strategy guarantees the analysis and the robust design of complex (bio)pharmaceutical process chains.

Keywords: pharmaceutical manufacturing, robust optimization, back-off approach, enzyme catalysis, ibuprofen crystallization

1. Introduction

The pharmaceutical industry has a substantial impact on the social and economic welfare of the individual and society. For the industry to continue producing high-quality and effective drugs even in the face of economic constraints, rising population and diseases, regulatory bodies and industry leaders alike have stipulated Quality by Design (QbD) as an essential paradigm. At the heart of QbD are mathematical models which are crucial for analyzing, optimizing, monitoring and controlling pharmaceutical processes (Emenike et al., 2018a,b). These models need to be properly calibrated to ensure that they reflect the physical processes they represent (Schenkendorf et al., 2018). In calibrating these models, a crucial issue that has to be dealt with is the presence of model and parameter uncertainties. A possible way to robustify processes under uncertainty is by using the back-off approach. This approach involves tightening violated constraints and shrinking the feasible region by introducing margins called back-offs. By so doing, the worst-case realization of a given process will still be feasible despite variations in the constraints (Shi et al., 2016). Moreover, these back-offs are usually calculated offline, and thus, do not lead to additional complexity of the optimization problems. Typically, Monte Carlo simulations are used to estimate the statistical moments (i.e., means and variances) required for calculating back-offs (Shi et al.,

---

[1]These authors contributed equally.

2016). However, for these means and variances to be accurately estimated, numerous Monte Carlo simulations are usually required. Thus, this could lead to high computational costs especially when a single Monte Carlo simulation of the process is computationally expensive.

Alternatively, these statistical moments can be approximated efficiently by using the point estimate method (PEM). It has been shown that the PEM is a computationally efficient and relatively accurate sampling strategy for estimating statistical moments (Schenkendorf, 2014; Xie et al., 2018b). Recently, we proposed a systematic robust optimization framework that combines the elementary process functions methodology, global sensitivity analysis, and the back-off approach (Emenike et al., 2019). A key contribution in Emenike et al. (2019) was a new back-off algorithm that uses the PEM instead of Monte Carlo simulations. We showed that the proposed PEM-based back-off approach is at least 10 times faster than the conventional Monte Carlo-based back-off approach while maintaining the quality of robust solutions. Maußner and Freund (2018) used cubature rules in lieu of Monte Carlo simulations and came to similar conclusions.

In this contribution, we build upon our original work (Emenike et al., 2019) by applying the novel algorithm in the presence of correlated parameter uncertainties and show that the robustification algorithm is not limited to upstream processes but is a versatile tool for whole pharmaceutical process chains. To this end, we apply the novel algorithm to an upstream pharmaceutical process that involves the synthesis of 2-hydroxy-ketones via enzyme-catalyzed carboligation and a downstream pharmaceutical process that includes the crystallization of ibuprofen. Details of the algorithm and the results for the case studies are presented in sections 2 and 3, respectively.

2. Methodology

A major advantage of the back-off approach to dynamic optimization under uncertainty is that its formulation is of similar complexity as the nominal dynamic optimization problem. The robust optimization problem (Problem 1) with time-varying back-offs $\mathbf{b}(t)$ is given as:

$$\underset{\mathbf{x}(\cdot),\mathbf{u}(\cdot),\mathbf{z}(\cdot)}{\text{minimize}} \quad \Phi(\mathbf{x}(t_{\mathrm{f}}))) \tag{1a}$$

$$\text{subject to} \quad \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t),\mathbf{z}(t),\mathbf{u}(t),\bar{\mathbf{p}}), \quad \forall t \in \mathscr{T}, \tag{1b}$$

$$\mathbf{g}(\mathbf{x}(t),\mathbf{z}(t),\mathbf{u}(t),\bar{\mathbf{p}}) = \mathbf{0}, \quad \forall t \in \mathscr{T}, \tag{1c}$$

$$\mathbf{h}(\mathbf{x}(t),\mathbf{z}(t),\mathbf{u}(t),\bar{\mathbf{p}}) + \mathbf{b}(t) \leq \mathbf{0}, \quad \forall t \in \mathscr{T}, \tag{1d}$$

$$\mathbf{x}(t_0) = \mathbf{x}_0, \tag{1e}$$

$$\mathbf{u}(t) \in \mathscr{U}, \tag{1f}$$

on the time horizon $\mathscr{T} := [t_0, t_{\mathrm{f}}] \subset \mathbb{R}$, where $\mathbf{x}$, $\mathbf{u}$, $\mathbf{z}$ represent states, controls, and algebraic variables, respectively. $\mathbf{g}$ and $\mathbf{h}$ represent the equality and inequality constraints, respectively. As we can see from Problem 1, the dynamic optimization with back-offs is optimized at the nominal parameter vector $\bar{\mathbf{p}}$. Here, the time-varying back-offs $\mathbf{b}(t)$ in Eq. 1d are included as margins to shrink the feasible region of the dynamic optimization problem and thus, making the optimal operating conditions robust.

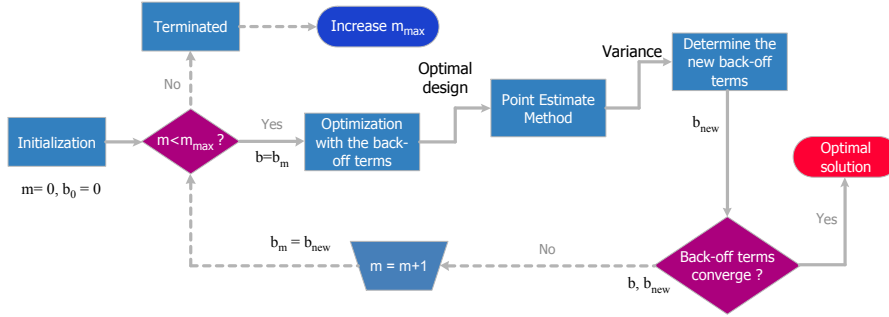
As pointed out by Shi et al. (2016), the solution from Problem 1 is not guaranteed to be optimum, unless the back-offs are insensitive to the decision variables. Therefore, an iterative approach is proposed to update the back-offs with the optimal design from the last iteration. The solution from Problem 1 and back-offs are consistently improved and can be exported once the back-offs converge. We depict the details regarding the iterative algorithm in Fig. 1. Moreover, we use the PEM instead of Monte Carlo simulations used by Shi et al. (2016) to derive the statistical moments required to calculate the back-offs. The PEM utilizes a relatively small number of deterministic


Figure 1: Computational scheme for the point estimate method-based back-off approach for robust optimization, where m is the iteration index.

samples to compute the statistical moments of system states and thus, facilitates an efficient back-off algorithm. For more details regarding the PEM, please refer to Xie et al. (2018b) and Emenike et al. (2019).

3. Case studies

3.1. Enzyme-catalyzed carboligation

First, we consider an upstream pharmaceutical process that involves an enzyme-catalyzed carboligation between propanal (A) and benzaldehyde (B) to form 2-hydroxy-ketones (BA) and benzoin (BB). Here, we aim to maximize the formation of the target product BA under the correlated parameter uncertainties specified in Xie et al. (2018a). The mechanistic model for this reaction is given as:

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{z}(t), \mathbf{u}(t), \mathbf{p}) = \begin{bmatrix} \frac{u_A \cdot C_A^{in}}{V} - \frac{C_A}{V}(u_A + u_B) + r_A \\ \frac{u_B \cdot C_B^{in}}{V} - \frac{C_B}{V}(u_A + u_B) + r_B \\ -\frac{C_{BA}}{V}(u_A + u_B) + r_{BA} \\ -\frac{C_{BB}}{V}(u_A + u_B) + r_{BB} \\ -\frac{C_E}{V}(u_A + u_B) + r_E \\ u_A + u_B \end{bmatrix}, \quad (2)$$

where C_i is the concentration of species i; r_A, r_B, r_{BA}, r_{BB}, and r_E are the reaction rates for A, B, BA, BB, and E, respectively; u_A and u_B are the controlled feed rates; and C_A^{in} and C_B^{in} are the inlet feed concentrations of A and B, respectively. For details on the model and model parameters, we refer to Emenike et al. (2019). First, forward simulations by using 10,000 Monte Carlo simulations were performed on the nominal problem to determine which constraints were violated, and it was found that only the inequality constraint bounding C_{BB} was violated. Therefore, we focus on robustifying only the C_{BB} inequality constraint as shown in Eq. (3):

$$0 \leq C_{BB}(t) \leq 2.78 \text{ mM} - b(t), \quad \forall t \in \mathscr{T}, \quad (3)$$

where 2.78 mM is the solubility limit of BB, $\mathscr{T} := [t_0, t_f] \subset \mathbb{R}$, and final time, $t_f = 300$ min. By applying the robust optimization strategy presented in Section 2 and aiming to satisfy Eq. 3 at a probability of 99.90%, we see in Table 1 that the PEM-based back-off algorithm is able to achieve this after just one iteration of the algorithm.

Table 1: Comparison of the point estimate method-based algorithm with the Monte Carlo-based back-off algorithm for robust dynamic optimization in comparison to to the nominal case.

Scenarios	$C_{\text{BA}}(t_{\text{f}})$ mM	Violation probability [%]	CPU time [s]
Nominal	3.60	57.65	4
PEM-based back-off	3.48	0.16	114
Monte Carlo-based back-off	3.49	0.13	2626

(a)

(b)
Figure 2: Results for the upstream pharmaceutical process: enzyme-catalyzed carboligation. (a) robust controls. (b) comparison between PEM and Monte Carlo simulations.

Moreover, this was achieved at a computation time that is 23 times faster than the conventional Monte Carlo-based back-off algorithm which was used as a benchmark for our algorithm (see Table 1). This speed-up is mainly due to the lower number of PEM sample points ($2 \times 13^2 + 1 = 339$) in comparison to the 10,000 Monte Carlo sample points. It is also possible to further reduce the PEM points by using a global sensitivity analysis as shown in Emenike et al. (2019). It can be seen in Fig. 2b that the time-varying back-offs calculated by both approaches are close with a marginal root-mean-square prediction error (RMSE) of 0.0024. This low RMSE validates the accuracy of our PEM-based approach. Furthermore, we note that the probability of violation and the maximum $C_{\text{BA}}(t_{\text{f}})$ obtained are very close for both approaches, thus, suggesting that our PEM-based back-off approach is very accurate for the case study considered. The robust controls (see Fig 2a) lead to a maximum concentration of 3.48 mmol L^{-1} which is 3.33% lower than the nominal value. This marginal decrease shows that the novel approach is not adversely conservative while ensuring robustness. Therefore, these results demonstrate that the PEM-based back-off strategy is very efficient and useful for the enzyme-catalyzed carboligation considered in this work.

3.2. Crystallization of ibuprofen

Second, we consider the continuous crystallization of ibuprofen in a plug-flow crystallizer (PFC) as a representative downstream pharmaceutical process. The crystal size distribution (CSD) n was chosen as an important key performance indicator for QbD. A population balance equation in combination with mass balance equations in liquid and solid phase was used to predict the evolution of the CSD along the PFC. To reduce the computational complexity, we discretized the PFC model to ordinary differential equations by using the classical method of moments. The resulting moment-based model for PFC is given in Eqs. (4) to (6):

$$\frac{d\mu_0}{dz} = \frac{B}{v} \tag{4}$$

$$\frac{d\mu_l}{dz} = \frac{BL_0^l}{v} + \frac{kG\mu_{l-1}}{v} \quad l = 1,\dots,5 \tag{5}$$

Table 2: The mean value of mass-based mean crystal size d_{43} and the probability of a constraint violation (supersaturation) from the nominal design and the robust design with the PEM-based back-offs.

Scenarios	$\mathbb{E}(d_{43})$	Violation probability [%]
Nominal	109.3	48
PEM-based back-off	108.8	3

$$\text{Liquid:} \quad \frac{\partial C}{\partial z} = -\frac{k_v \rho_s}{v}(BL_0^3 + 3G\mu_2), \tag{6}$$

where z is the axis coordinate of the PFC, m; L_0 is the nuclei size, m; v is the superficial velocity of slurry along the PFC, $\mathrm{m\,s^{-1}}$; k_v and ρ_s are the shape factor and the crystal density, $\mathrm{kg\,m^{-3}}$, and C is the mass of solute per kg slurry, $\mathrm{kg\,kg^{-1}}$. μ_k is the kth moment which is used to describe the major information in CSD and defined with Eq. (7). B and G are the nucleation rate, $\mathrm{\#kg^{-1}\,s^{-1}}$, and the growth rate, $\mathrm{m\,s^{-1}}$, which describe the kinetics of the crystallization of ibuprofen and are determined by the degree of supersaturation S, as shown in Eqs. (8) and (9):

$$\mu_l = \int_0^\infty L^l n dL, \quad l = 0, \ldots, 5 \tag{7}$$

$$B = k_{b_0} S(T) \tag{8}$$

$$G = k_{g_0} \exp\left(\frac{T}{T_g}\right) S(T) \tag{9}$$

This case study aims to maximize the mass-based mean crystal size d_{43} (i.e., the ratio between μ_4 and μ_3) by manipulating the temperature along the PFC. There is an inequality constraint in the design which restricts the supersaturation of ibuprofen in the solution below the primary nucleation threshold to ensure no primary nucleation occurs. Several other inequality constraints on the yield of product and temperature gradient are also satisfied but not discussed in what follows, as they are not violated even in the presence of parameter uncertainties. Rashid (2011) estimated the values of the kinetic parameters k_{b_0}, k_{g_0}, and T_g with designed experiments and showed the estimated values are not accurate and associated with uncertainty. The parameter uncertainties are then described by Gaussian distributions and thus, are taken into account in the robust design of the PFC in this work.

For the nominal design, the parameter uncertainties are neglected. The obtained d_{43} is 109.3 μm (see Table 2). However, the inequality constraint on supersaturation is violated with a probability of 48% due to parameter uncertainties. The violation probability of inequality constraint is determined with 10,000 evaluations of the PFC model with the random samples generated from the probability distributions of kinetic parameters. The PEM-based back-off strategy introduced in Section 2 is then implemented to design a robust PFC tolerant to the parameter uncertainties, where the target violation probability of the inequality constraint is set to smaller than 1%. Results from the iterative back-off approach are depicted in Fig. 3. As we can see in Fig. 3a, the tolerance factor ε_{tol}, which represents the difference between the back-offs in the adjacent iterations, converges within 10 iterations. The resulting time-varying back-offs are plotted in Fig. 3b, in which the supersaturation is shrunk more in the middle and less on both sides of the PFC to mitigate the effect of parameter uncertainties. According to the results listed in Table 2, the d_{43} from the robust design decreases slightly when compared to the value from nominal design. The probability of constraint violation decreases to 3%. Thus, the process robustness is increased at the cost of a deteriorated performance. Although the back-off approach increases the robustness of the process significantly, the obtained violation probability 3% is still three times larger than the target value of 1%. The reason for this is that the back-offs calculated with the variances of system states are actually not accurate when their probability distributions are asymmetric, as shown in Fig. 3c.
Figure 3: Results for the downstream pharmaceutical process: continuous crystallization of ibuprofen. (a) Convergence plot of the back-off terms. (b) value of the time-varying back-off terms at the last iteration. (c) probability distribution of supersaturation S at location $z = 11$m of the PFC.

4. Conclusions

In this work, we proposed a PEM-based back-off approach for the robust design of upstream and downstream pharmaceutical processes. First, the approach was implemented for the design of a fed-batch reactor for enzyme-catalyzed carboligation in the presence of parameter correlations and uncertainty. The results showed that the proposed PEM-based back-off approach is significantly faster than the conventional Monte Carlo-based back-off approach while achieving high accuracy of the robust solutions. The method was also applied to the design of continuous crystallization of ibuprofen in the presence of uncertainties in the kinetic parameters. This approach also lowered the value of constraint violation and significantly improved the robustness of the process. However, the probability of a constraint violation is still three times higher than the given target value due to the asymmetric probability distribution of system states. Future work will include non-Gaussian probability distributions for robust process design.

Abstract

Long-term operation of energy systems is a complex optimization task. Often, such long-term operational optimizations are solved by direct decomposing the problem into smaller subproblems. However, direct decomposition is not possible for problems with time-coupling constraints and variables. Such time-coupling is common in energy systems, e.g., due to peak power prices and (seasonal) energy storage. To efficiently solve coupled long-term operational optimization problems, we propose a time-series decomposition method. The proposed method calculates lower and upper bounds to obtain a feasible solution of the original problem with known quality. We compute lower bounds by the Branch-and-Cut algorithm. For the upper bound, we decompose complicating constraints and variables into smaller subproblems. The solution of these subproblems are recombined to obtain a feasible solution for the long-term operational optimization. To tighten the upper bound, we iteratively decrease the number of subproblems. In a case study for an industrial energy system, we show that the proposed time-series decomposition method converges fast, outperforming a commercial state-of-the-art solver.

Keywords: large-scale MILP, seasonal storage, network charges, emission targets

1. Introduction

In industry, energy is often supplied by on-site energy systems. The efficiency of on-site energy systems can be significantly improved by optimizing operation. Operational optimization typically results in mixed-integer linear programming (MILP) problems. These MILP problems are proven to be weakly NP-hard, and thus computationally challenging for for large problems sizes (Goderbauer et al., 2019).

In the operation of energy systems, the number of variables results directly from the number of considered time steps, and thus long-term operational optimization leads to many variables. An intuitive solution approach is to solve the time steps independently, i.e., use direct decomposition. However, such direct decomposition is only possible without time-coupling constraints and variables (Bradley et al., 1992). In practice, time-coupling constraints and variables are common for energy systems, e.g., by peak power prices, seasonal storage systems, annual emission limits or net connection fees. To cope with time-coupling constraints in the optimization of energy systems, various solution methods have been proposed (Tab.1). A first class of methods is based on simplification of

Table 1: Solution methods for long-term operational optimizations of energy systems with time-coupling constraints and variables

Approach/Idea	Literature	Strengths $(+)$ / Limits $(-)$
Model simplifications	(Piacentino and Cardona, 2008), (Yokoyama, 2013)	$+$ easily applicable $-$ limited model scope
Non-deterministic	(Eglese, 1990), (Kavvadias and Maroulis, 2010)	$+$ allow parallelization $+$ generic $-$ no quality measure
Decomposition	(Yokoyama and Ito, 1996), (Al-Agtash and Su, 1998), (Rong et al., 2008), (Nasrolahpour et al., 2016), (Wang et al., 2016)	$+$ allow parallelization $+$ generic $+$ provide quality measure $-$ slow convergence $-$ complex formulation

component models to reduce the complexity of the optimization, rendering the full optimization problem solvable even with time-coupling constraints and variables. However, model simplification limits the accuracy of the results. Second, non-deterministic methods, such as genetic algorithms, are therefore employed to solve large-scale problems. While these non-deterministic approaches can generate good solutions for difficult problems and often allow for parallelization, they are unable to evaluate the quality of the proposed solution (Hanne and Dornberger, 2017). Therefore, mathematical decomposition methods have been nested to treat both time-coupling constraints and variables in MILP optimizations, e.g., column generation, Lagrangian, and Benders (Wang et al., 2016). However, despite the successful application of mathematical decomposition methods to energy system problems, some challenges remain: Column generation often suffers from slow convergence in practice (Desrosiers and Lübbecke, 2011a). The formulation and implementation of Branch-and-Price is complex (Desrosiers and Lübbecke, 2011b). Lagrangian methods require a good choice of multipliers for fast convergence. However, the selection of Lagrangian multipliers is difficult leading to a large variety of methods (Conejo et al., 2006). Benders decomposition suffers from slow convergence due to a high number of slow iterations. Improvements for the convergence of Benders decomposition have been proposed but their formulation and implementation is complex (Rahmaniani et al., 2017).

In this work, we propose a time-series decomposition-based solution algorithm for solving long-term operational optimization problems. The proposed time-series decomposition handles both time-coupling constraints and variables in the operational optimization. The method combines the strengths of the approaches in literature (Tab.1) using an exact model, is easily applicable, allows for parallelization and shows fast convergence.

2. Time-coupling constraints and variables in operational optimization

To illustrate the complexity of operation optimization problems with time-coupling constraints and variables, we state a generic operational problem for energy systems as mixed-integer linear programming (MILP) problem.

$$\min_{\dot{V}_{n,t}, \delta_{n,t}, \dot{V}_{\text{grid}}^{\max}, V_{n,t}, x} OPEX = \sum_{t \in \mathscr{T}} \left(\Delta t_t \sum_{n \in \mathscr{C}} c_{n,t}^{\text{o}} \frac{\dot{V}_{n,t}}{\eta_n} \right) + c_p \cdot \dot{V}_{\text{grid}}^{\max} + c_{\text{net}} \cdot \sum_{t \in \mathscr{T}} \dot{V}_{\text{grid},t} \qquad (1)$$

$$\text{s.t.} \quad \sum_{n \in \mathscr{C} \backslash \mathscr{C}_{\text{stor}}} \dot{V}_{n,t} + \sum_{n \in \mathscr{C}_{\text{stor}}} (\dot{V}_{n,t}^{\text{out}} - \dot{V}_{n,t}^{\text{in}}) = \dot{E}_t, \qquad \forall t \in \mathscr{T}, \tag{2}$$

$$A_1 \dot{V}_{n,t} + \widetilde{A}_1 \delta_{n,t} \leq b_1, \qquad \forall t \in \mathscr{T}, \forall n \in \mathscr{C}, \tag{3}$$

$$A_2 \left(\dot{V}_{n,t}, \delta_{n,t}, x \right)^{\text{T}} \leq b_2, \qquad \forall t \in \mathscr{T}, \forall n \in \mathscr{C}, \tag{4}$$

$$V_{n,t} + \Delta t_t \cdot (\dot{V}_{n,t}^{\text{in}} - \dot{V}_{n,t}^{\text{out}}) = V_{n,t+1}, \qquad \forall t \in \mathscr{T}, \forall n \in \mathscr{C}_{\text{stor}} \tag{5}$$

$$|\dot{V}_{\text{grid},t}| \leq \dot{V}_{\text{grid}}^{\text{max}}, \qquad \forall t \in \mathscr{T}, \tag{6}$$

$$c_i = \begin{cases} c_i^{\text{high}} & \text{, if } \frac{\sum_{t \in \mathscr{T}} \dot{V}_{\text{grid},t} \cdot \Delta t_t}{\dot{V}_{\text{grid}}^{\text{max}}} \leq 2500h \\ c_i^{\text{low}} & \text{, otherwise} \end{cases} \qquad \text{for } i = \{\text{net}, p\} \tag{7}$$

$$\sum_{t \in \mathscr{T}} \left[(\dot{V}_{\text{grid},t} \cdot c_{t,el}^{\text{CO2}}) + \sum_{n \in \mathscr{C}} (\frac{\dot{V}_{n,t}}{\eta_n} \cdot c_{t,gas}^{\text{CO2}}) \right] \leq C_{\text{CO2}}^{\text{max}}, \tag{8}$$

$$\delta_{n,t} \in \{0,1\}; x \in \mathbb{R}^a \times \{0,1\}^{\widetilde{a}}; \dot{V}_{n,t} \in \mathbb{R}; V_{n,t}, \dot{V}_{\text{grid}}^{\text{max}} \in \mathbb{R}^+.$$

Operational expenses *OPEX* are defined as the sum of the output power $\dot{V}_{n,t}$ of every component $n \in \mathscr{C}$ in every time step t divided by the efficiency η_n and multiplied by the specific operation cost $c_{n,t}^o$ and the duration Δt_t of a time step (Eq.1). A further contribution to *OPEX* (Eq.1) are the network charges C_{net}, which result from the electricity consumption $\sum_{t \in \mathscr{T}} \dot{V}_{\text{grid},t}$ multiplied by network charges $c_{\text{net}}^{(\text{low/high})}$ that depend on the utilization time. The peak power $\dot{V}_{\text{grid}}^{\text{max}}$ multiplied by a peak power price c_p results in additional *OPEX* (Eq.1). As constraint, the component's output power $\dot{V}_{n,t}$ plus the net energy output of the storage units $\dot{V}_{n,t}^{\text{out}} - \dot{V}_{n,t}^{\text{in}}$ has to meet the energy demand $\dot{E}_t$ at every time step t (Eq.2). Further (in)equalities with the coefficient matrices A_1, $\widetilde{A}_1$, and the vector b_1 determine the component's binary on/off status $\delta_{n,t}$ and the current part-load performance (Eq.3). Additional constraints are summarized in the surrogate coefficient matrix A_2, including all other variables of the original problem represented by the vector x (Eq.4). The future storage level $V_{n,t+1}$ is coupled to the current storage level $V_{n,t}$ by the net energy input of the storage units $\dot{V}_{n,t}^{\text{in}} - \dot{V}_{n,t}^{\text{out}}$. Thus, the storage balance equation couples the entire time series (Eq.5). The peak power $\dot{V}_{\text{grid}}^{\text{max}}$ is the maximum electricity exchanged with the grid. Thus, $\dot{V}_{\text{grid}}^{\text{max}}$ is a time-coupling variable for the entire time series (Eq.6). The dependency of prices $c_i^{(\text{low/high})}$ on the utilization time is both a of coupling constraint and variable for the entire time series (Eq.7). Often, annual emission limits $C_{\text{CO2}}^{\text{max}}$ have to be obeyed. Emission limits represent a coupling constraint for the entire time series (Eq.8). To solve such long-term operational problems despite time-coupling (Eq. 5-8), we propose a time-series decomposition method.

3. Time-series decomposition for long-term operational optimization

A time-series decomposition method is proposed to generate feasible solutions of long-term operational optimization problems with known solution quality. The decomposition method provides lower and upper bounds in a parallel computing mode.

For the lower bound, we relax all binary variables ($\delta_{n,t}, x \in \{0,1\}$) of the operational problem (Eq.1-8), thereby converting the complex MILP into an LP, which can be solved efficiently. This solution of the relaxed problem serves as first lower bound. Subsequently, the Branch-and-Cut procedure starts by branching on binary variables and cutting off branches which cannot improve the solution (IBM Cooperation, 2016).

The upper bound is obtained by four steps (Fig. 1):

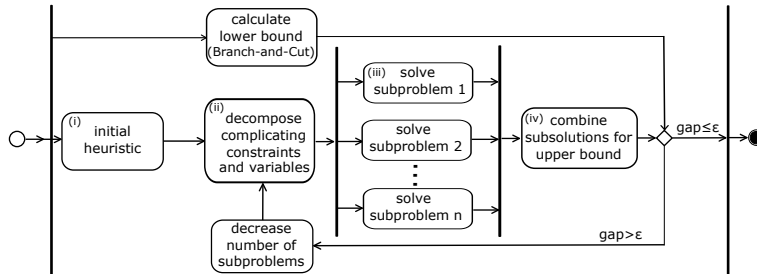
  (i) Initial heuristic to initialize the number of subproblems
 (ii) Decomposition of time-coupling constraints and variables
(iii) Optimizing subproblems in parallel computing mode
 (iv) Combining subsolutions to upper bound


Figure 1: Overview of the proposed time-series decomposition method to create feasible solutions of operational optimization problems with known solution quality.

Using the lower and upper bound, we calculate a solution quality ε and check if the desired optimality gap is satisfied.

$$\varepsilon = \frac{\text{upper bound} - \text{lower bound}}{\text{upper bound}}. \tag{9}$$

If the optimality gap is not satisfied, we iteratively decrease the number of subproblems. In the following, we present the details of steps (i), (ii), and (iv) of the proposed time-series decomposition.

Step (i): Initial heuristic

Initialization of the decomposition method requires an initial number of subproblems. To identify a good estimate for this initial number, a heuristic is employed, aiming at minimal calculation time for the first decomposition.In the heuristic, we consider a wide range for the possible number of subproblems. For each number , we decompose the problem but solve only the first subproblem. The decomposition and solution time is recorded and extrapolated to the full number of subproblems. The number of subproblems resulting in the minimum extrapolated solution time is selected as the initial number of subproblems.

Step (ii): Decomposition of time-coupling constraints and variables

We decompose complicating constraints and variables into smaller subproblems. The decomposition is generic and conducted automatically based on the type of time-coupling constraint or variable:

  (1) For storage-like constraints (Eq. 5), we fix start and end values for each subproblem to ensure feasibility. The fixed values are adapted in the next iteration.
  (2) Time-coupling variables like (Eq. 6-7) are replaced by independent copies in every subproblem, resulting in independent subproblems, e.g., net connection fees and peak power prices are calculated for each subproblem independently.
  (3) For time-coupling constraints like the emission limits in Eq. (8), a fraction of the limit is allocated to each subproblem. This fraction is computed for each subproblem by independent minimization of the emissions within each subproblem.

(4) To improve performance, we extend each subproblem by aggregated time steps and the peak demands of all other subproblems. Thus, in each subproblem, a small part of the long-term operational optimization is solved with the full accuracy of the time series and the rest with low accuracy.

Step (iv): Combining subsolutions to upper bound

The solutions of the subproblems are combined to a feasible solution for the original problem. For this, the independent copies of variables in the subproblems (2) are resubstituted and the added aggregated time steps (4) are deleted. The solution of the final iteration is used to warmstart the original problem to further enhance solution quality.

4. Case study

The proposed decomposition method is applied to a long-term operational problem based on Baumgärtner et al. (2018). We investigate an industrial energy system with three units of each boilers, compression chillers, absorption chillers, and heat exchangers, one combined heat and power engine, a photovoltaic system, an inverter station, a battery, and one storage tank for each hot and cold water. We consider one year of operation with a two-hourly resolution for demands of process heat, hot and cold water, electricity, as well as solar radiation, and electricity grid prices. The original operational problem contains $1.2 \cdot 10^6$ equations and $6 \cdot 10^5$ variables (incl. $2 \cdot 10^5$ binaries) with $3 \cdot 10^6$ nonzero elements. The resulting long-term operational problem is highly coupled due to the storage and battery systems, an annual emission limit, peak power prices and net connection fees (Eq.1-8). To validate the computational results, we repeat the calculation for 5 instances generated by statistical noise ($\pm 5\%$) on the data. As benchmark, we solve the original synthesis problem directly with CPLEX without any decomposition.

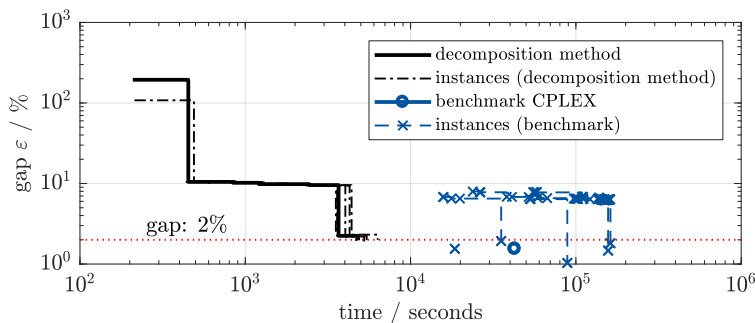
In the initial heuristic (step (i)), the original problem is decomposed into 219 subproblems. The size of the subproblems is iteratively increased until the desired optimality gap of 2 % is satisfied with a decomposition into 20 subproblems.


Figure 2: Gap ε of the proposed decomposition method and the benchmark CPLEX as function of the solution time. The required optimality gap of 2 % is marked in dotted red.

The decomposition method finds a feasible solution, with cost deciating less than 2 % from optimality, in 5,207 s on average (Fig. 2). The average computational time of the benchmark is 16 times larger (83,952 s) to obtain solutions of equal quality. On average, after 203 s, the proposed time-series decomposition method generates a first feasible solution, whereas on average the benchmark requires 175 times longer (35,617

s) to provide a feasible solution. Thus, the proposed decomposition method outperforms the benchmark in all instances by over an order of magnitude.

5. Conclusions

The long-term operational optimization of energy systems leads to computationally challenging optimization problems. In this paper, we propose a time-series decomposition method providing feasible solutions with known quality. The method decomposes the original problem into smaller subproblems, which are efficiently solved in parallel.

The proposed method requires only simple problem reformulations for creating subproblems and recombines their solutions to a feasible solution of the complete problem while still representing a rigorous decomposition. The proposed method is applied to a long-term industrial operational problem, including time-coupling constraints and variables due to storage systems, emission limits, peak power prices, and net connection fees. The proposed method provides fast convergence, outperforming commercial solvers by more than an order of magnitude.

Real-Time Optimisation of Closed-Loop Processes Using Transient Measurements

Jack Speakman* and Grégory François

School of Engineering, The University of Edinburgh, Edinburgh EH9 3FB, UK
jack.speakman@ed.ac.uk

Abstract

Real-time optimisation (RTO) has the ability to boost the performance of a process whilst satisfying a set of constraints by using process measurements to refine the model-based optimal operating conditions towards plant optimality. Modifier adaptation (MA) is a methodology of RTO which can find the optimal operating point of a process even in the presence of plant-model mismatch. This work presents an extension to MA through the combination of two established frameworks. This new combined framework allows for the optimisation of a controlled process using transient measurements whilst using a steady-state open-loop model. In conjunction, an investigation into model-based gradient estimation methods of the controlled process using the open-loop model was undertaken and a correction has been proposed, which allows for the use of limited controller information in gradient estimation using the neighbouring extremals method.

Keywords: Real-time optimisation, Modifier adaptation, Transient measurements, Plant-model mismatch, Model-based gradient estimation

1. Introduction

The optimisation of chemical processes is vital for improving the economic profile, whilst ensuring the meeting of safety and environmental objectives, in the face of increasing global competition and tightening regulations. Process optimisation is typically carried out using a model to calculate the operating conditions which maximise the performance of the process. Fully accurate models are not possible to obtain due to uncertainties, noise, and simplifications, resulting in sub-optimal operation. Real-time optimisation (RTO) solves this through the use of measurements from the process to adjust the operating point towards the true optimal solution.

Modifier adaptation (MA) is an approach to RTO which adds input-affine modifier terms to the cost and constraints (Marchetti et al., 2009), and measurements of the process are used to iteratively update these modifiers. The main advantage of MA lies in the mathematically proven capacity to converge to a KKT point of the process, even in the presence of plant-model mismatch, a case for which the standard two-step approach (Jang et al., 1987) typically fails (Forbes et al., 1994). Recently, an extension to MA has been proposed allowing for the optimisation of a controlled plant using an open-loop model (François et al., 2016), which is mathematically proven to reach a plant KKT point upon convergence. Such cases occur for complex plants using built-in control systems while the model has been developed in the lab. This article aims to extend this framework to allow for the use of transient measurements, and for the use of model-based gradient estimation methods when there is a difference in degrees of freedom between the model and the plant. This paper will state the mathematical optimisation problem, with a brief overview of MA; both extensions will be described, followed by a proposition of the KKT converging nature of the combined framework and associated proof. Finally this new framework will be demonstrated in a case study of a CSTR.

2. Problem formulation

2.1. Steady-State Optimisation Problem

The optimisation of a continuous process consists of finding the inputs ($\boldsymbol{u}$) which minimise the cost (ϕ) whilst satisfying a set of constraints (g_j). These functions are assumed to be known for a measured output ($\boldsymbol{y}_p$), in practice this is modelled by $\bar{\boldsymbol{y}} = \boldsymbol{H}(\boldsymbol{u}, \boldsymbol{\theta})$, resulting in two problems:

Plant Optimisation Problem	Model Optimisation Problem
$\boldsymbol{u}_p^* = arg\min_{\boldsymbol{u}} \Phi_p(\boldsymbol{u}) := \phi(\boldsymbol{u}, \boldsymbol{y}_p)$ (1)	$\boldsymbol{u}^* = arg\min_{\boldsymbol{u}} \Phi(\boldsymbol{u}, \boldsymbol{\theta}) := \phi(\boldsymbol{u}, \bar{\boldsymbol{y}}(\boldsymbol{u}, \boldsymbol{\theta}))$ (2)
$s.t. \quad G_{p,j}(\boldsymbol{u}) := g_j(\boldsymbol{u}, \boldsymbol{y}_p) \leq 0$	$s.t. \quad G_j(\boldsymbol{u}, \boldsymbol{\theta}) := g_j(\boldsymbol{u}, \bar{\boldsymbol{y}}(\boldsymbol{u}, \boldsymbol{\theta})) \leq 0$

Where $\boldsymbol{\theta}$ are the uncertain model parameters, $(.)_p$ refers to the plant and $j = 1, \ldots, n_g$. If there is plant-model mismatch (i.e. $\bar{\boldsymbol{y}} \neq \boldsymbol{y}_p$), the solution to Problem 2 will not match that of Problem 1.

2.2. Standard Modifier Adaptation

Standard MA adds correction terms to the model cost and constraints to reconcile the gradient of the plant and model problems with respect to the inputs at the current operating point, which requires the plant cost and constraints to be measured or estimated from the plant input and outputs.

$$\boldsymbol{u}_{k+1}^* = arg\min_{\boldsymbol{u}} \Phi_m(\boldsymbol{u}, \boldsymbol{\theta}) := \Phi(\boldsymbol{u}, \boldsymbol{\theta}) + \boldsymbol{\lambda}_k^{\Phi,u}(\boldsymbol{u} - \boldsymbol{u}_k^*)$$
$$s.t. \quad G_{m,j}(\boldsymbol{u}, \boldsymbol{\theta}) := G_j(\boldsymbol{u}, \boldsymbol{\theta}) + \varepsilon_k^{G_j} + \boldsymbol{\lambda}_k^{G_j,u}(\boldsymbol{u} - \boldsymbol{u}_k^*) \leq 0, \quad j = 1, \ldots, n_g \tag{3}$$

Where ε and $\boldsymbol{\lambda}$ are the zeroth and first order correction terms, defined as follows:

$$\varepsilon_k^{G_j} = G_{p,j}(\boldsymbol{u}_k^*) - G_j(\boldsymbol{u}_k^*, \boldsymbol{\theta}) \tag{4}$$

$$\boldsymbol{\lambda}_k^{\Phi,u} = \nabla_{\boldsymbol{u}} \Phi_p(\boldsymbol{u}_k^*) - \nabla_{\boldsymbol{u}} \Phi(\boldsymbol{u}_k^*, \boldsymbol{\theta}) \tag{5}$$

$$\boldsymbol{\lambda}_k^{G_j,u} = \nabla_{\boldsymbol{u}} G_{p,j}(\boldsymbol{u}_k^*) - \nabla_{\boldsymbol{u}} G_j(\boldsymbol{u}_k^*, \boldsymbol{\theta}), \quad j = 1, \ldots, n_g \tag{6}$$

This problem is shown to only converge at a KKT point of the plant (Marchetti et al., 2009). This is a key result from MA and is highly sought after from the extensions to MA.

3. Recent Advances

3.1. Controlled Plant, Open-loop model

Standard MA requires the same degrees of freedom between the model and the process. An extension to MA was proposed which allows for the use of an open-loop model in the optimisation of a process which operates in closed-loop with different degrees of freedom ($\boldsymbol{r}$) than the model (François et al., 2016), as illustrated in Figure 1a. This framework has three possible methods of implementation depending on whether the optimisation and modifiers are in terms of $\boldsymbol{u}$ or $\boldsymbol{r}$:

UR:
$$\boldsymbol{u}_{k+1}^* = arg\min_{\boldsymbol{u}} \Phi_{m,k}(\boldsymbol{u}) := \Phi(\boldsymbol{u}) + \boldsymbol{\lambda}_k^{\Phi,r}(\boldsymbol{y}(\boldsymbol{u}) - \boldsymbol{r}_k)$$
$$s.t. \quad G_{m,j,k}(\boldsymbol{u}) := G_j(\boldsymbol{u}) + \varepsilon_k^{G_j} + \boldsymbol{\lambda}_k^{G_j,r}(\boldsymbol{y}(\boldsymbol{u}) - \boldsymbol{r}_k) \leq 0, \quad j = 1, \ldots, n_g \tag{7}$$

UU:
$$\boldsymbol{u}_{k+1}^* = arg\min_{\boldsymbol{u}} \Phi_{m,k}(\boldsymbol{u}) := \Phi(\boldsymbol{u}) + \boldsymbol{\lambda}_k^{\Phi,u}(\boldsymbol{u} - \boldsymbol{u}_k)$$
$$s.t. \quad G_{m,j,k}(\boldsymbol{u}) := G_j(\boldsymbol{u}) + \varepsilon_k^{G_j} + \boldsymbol{\lambda}_k^{G_j,u}(\boldsymbol{u} - \boldsymbol{u}_k) \leq 0, \quad j = 1, \ldots, n_g \tag{8}$$

RR:
$$\boldsymbol{r}_{k+1}^* = arg\min_{\boldsymbol{r}} \Phi_{m,k}(\boldsymbol{r}) := \Phi(\boldsymbol{r}) + \boldsymbol{\lambda}_k^{\Phi,r}(\boldsymbol{r} - \boldsymbol{r}_k)$$
$$s.t. \quad G_{m,j,k}(\boldsymbol{r}) := G_j(\boldsymbol{r}) + \varepsilon_k^{G_j} + \boldsymbol{\lambda}_k^{G_j,r}(\boldsymbol{r} - \boldsymbol{r}_k) \leq 0, \quad j = 1, \ldots, n_g \tag{9}$$

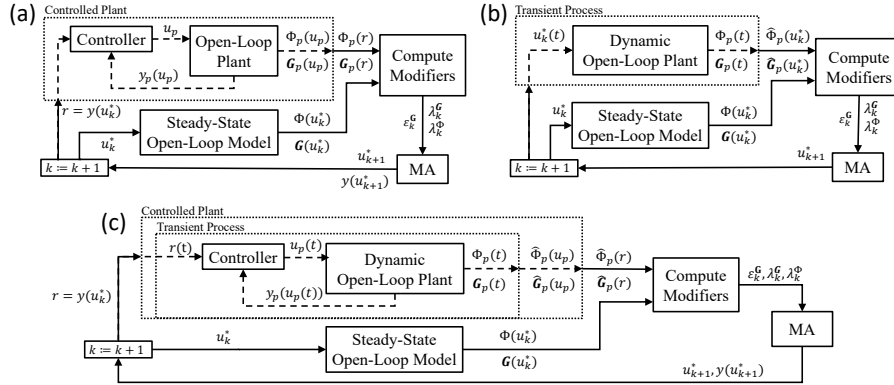
Where $\boldsymbol{\lambda}_k^{\Phi,r}$ and $\boldsymbol{\lambda}_k^{G_j,r}$ are the difference between the plant and model gradients with respect to $\boldsymbol{r}$


Figure 1: Framework schematics. (a) Closed-loop. (b) Transient. (c) Combined.

3.2. Transient Measurements

Standard MA, and the framework described above in Section 3.1, wait until steady-state before calculating the next operating point, ignoring all the transient information between operating points. Therefore, an extension to standard MA was developed that uses these transient measurements to update the operating points before steady-state is achieved (François and Bonvin, 2014), as illustrated in Figure 1b, resulting in a faster convergence to the process optimum. This method estimates the steady-state value as the current measured value ($\hat{\boldsymbol{y}}_p = \boldsymbol{y}_p(t)$) and performs MA with these values, which was proven by François and Bonvin to reach a KKT point of the process upon convergence, *but only when the process is operated in open-loop*.

3.3. Gradient Estimation Methods

The gradient of the process cost and constraints with respect to the degrees of freedom at $\boldsymbol{u}_k^*$ is required to calculate $\boldsymbol{\lambda}$. This cannot be directly measured, but must be inferred from process measurements. This paper will implement two different gradient estimation techniques and extend these to work in the case of a difference in degrees of freedom between the model and the process. The first technique, multiple units (MU) (Srinivasan, 2007), uses the finite differences method by running $n_u + 1$ identical units in parallel, offsetting each unit from the current operating point.

The second method, neighbouring extremals (NE) (Gros et al., 2009), is a model-driven approach which takes the difference between the model and process outputs, and relates it to the parametric uncertainty of the model. This can be used when structural plant-model mismatch is present with imperfect accuracy. This can be written mathematically as follows, where $f = \Phi, G_1, \ldots, G_j$:

$$\nabla_{\boldsymbol{u}_p} f_p \approx \nabla^2_{\boldsymbol{u}\boldsymbol{\theta}} f (\nabla_{\boldsymbol{\theta}} \boldsymbol{H})^+ (\boldsymbol{y}_p - \boldsymbol{y}_0) + (\nabla^2_{\boldsymbol{u}\boldsymbol{u}} f - \nabla^2_{\boldsymbol{u}\boldsymbol{\theta}} f (\nabla_{\boldsymbol{\theta}} \boldsymbol{H})^+ \nabla_{\boldsymbol{u}} \boldsymbol{H})(\boldsymbol{u}_p - \boldsymbol{u}_0) \tag{10}$$

4. Transient MA of Controlled Processes using Open-Loop Models

The frameworks outlined in the previous section are combined hereafter into a single concise framework, allowing for the use of transient measurements in the optimisation of a controlled process using a steady-state open-loop model, as shown in Figure 1c. A proposition and proof using method UR is given, but similar arguments can be made using method UU and method RR.

Proposition 1. *If upon convergence, the estimates of the process ($\widehat{\boldsymbol{\phi}}_p, \widehat{\boldsymbol{g}}_p, \widehat{\nabla_{\boldsymbol{r}} \Phi_p}, \widehat{\nabla_{\boldsymbol{r}} \boldsymbol{G}_p}$), estimated via a function of the transient measurements ($\boldsymbol{u}_p(t), \boldsymbol{y}_p(t)$), approach their true values, then the operating point $\boldsymbol{r}_\infty = \boldsymbol{y}(\boldsymbol{u}_\infty)$ is a KKT point of the process.*

Proof. If the algorithm converges, i.e. $\boldsymbol{u}_\infty = \lim_{k\to\infty} \boldsymbol{u}_k$, then $\boldsymbol{u}_\infty$ must be steady. Hence, $\boldsymbol{r}_\infty = \boldsymbol{y}(\boldsymbol{u}_\infty)$, and the plant must also be steady. Therefore, the steady-state estimates approach their true values, as stated in the proposition. The gradient of the process, along with steady state estimation of the modifier $\boldsymbol{\lambda}_\infty^{\phi,r}$, can be combined and rearranged into the following:

$$\frac{\partial \phi_{m,\infty}^r}{\partial \boldsymbol{u}} \left(\left(\frac{\partial \boldsymbol{y}}{\partial \boldsymbol{u}}\right)^+ \frac{\partial \boldsymbol{y}}{\partial \boldsymbol{u}} \right) = \frac{\partial \phi_p}{\partial \boldsymbol{r}} \left(\frac{\partial \boldsymbol{y}}{\partial \boldsymbol{u}}\right) \tag{11}$$

The same can be applied to $\frac{\partial g_{m,j,\infty}^r}{\partial \boldsymbol{u}}$. From the definition of the zeroth order term $\varepsilon_\infty^{g_j,r}$, the following can be stated: $g_{m,j,\infty}^r(\boldsymbol{u}_\infty) = G_{p,j}(\boldsymbol{r}_\infty)$. Hence, as the modified problem is optimised such that $\boldsymbol{u}_\infty$ is a KKT point, satisfying the following:

$$\frac{\partial \phi_{m,\infty}^r}{\partial \boldsymbol{u}} + \boldsymbol{v}\frac{\partial \boldsymbol{g}_{m,\infty}^r}{\partial \boldsymbol{u}} = \boldsymbol{0} \tag{12}$$

It follows that the operating point of the plant must be a KKT point since the following must be valid:

$$\frac{\partial \Phi_p}{\partial \boldsymbol{r}} + \boldsymbol{v}\frac{\partial \boldsymbol{G}_p}{\partial \boldsymbol{r}} = \boldsymbol{0} \tag{13}$$

$$\boldsymbol{G}_p(\boldsymbol{r}_\infty) \leq \boldsymbol{0} \tag{14}$$

$$\boldsymbol{v}\boldsymbol{G}_p(\boldsymbol{r}_\infty) = \boldsymbol{0} \tag{15}$$

Hence, $\boldsymbol{r}_\infty$ is a KKT point of the closed-loop plant.   □

The above proposition and proof are similar to those from the original frameworks, an in-depth proof of each can be found in the respective papers (François and Bonvin, 2014; François et al., 2016). The estimates must be correct at steady state, this is achieved in the same manner as in (François and Bonvin, 2014), by setting them equal to the current transient value, i.e. $\hat{\phi}_p = \phi_p(t)$.

Model-driven gradient estimation methods, such as NE, applied to an open-loop model will obtain an estimate for the open-loop process ($\nabla_{\boldsymbol{u}_p}\phi_p$). The method described above requires an estimate of the gradient of the process cost and constraints with respect to the controller setpoints ($\nabla_{\boldsymbol{r}}\phi_p$). Therefore, the gradients must be remapped by multiplying by $\partial\boldsymbol{u}_p/\partial\boldsymbol{r}$. However, this relationship is often unknown for complex plants using built-in control systems (whereby the supplier does not provide full information) or when advanced controllers are implemented (e.g. MPC), hence an estimation must be made using some limited information about the controller.

5. Case Study

The methods discussed above have been simulated on the Williams-Otto reactor (Williams and Otto, 1960), which is a benchmark case for MA problems. The open-loop plant follows a three reaction system ($A+B \to C$, $B+C \to P+E$, $C+P \to G$). Whilst the open-loop model follows a 2 reaction system ($A+2B \to P+E$, $A+B+P \to G$). These are illustrated in Figure 2 and the systems of dynamic equations are described in Table 1.
Figure 2: Block flow diagram of controlled plant and open-loop model

Table 1: Dynamic systems for the plant and the model

Plant	Model (steady)

$\frac{dX_B}{dt} = \frac{F_{B,in}}{\rho V} - k_1 X_A X_B - \frac{F}{\rho V} X_B$	$\frac{F_{B,in}}{\rho V} - 2k_1^* X_A X_B^2 - k_2^* X_A X_B X_P - \frac{F}{\rho V} X_B = 0$
$\frac{dX_C}{dt} = 2k_1 X_A X_B - 2k_2 X_B X_C - k_3 X_C X_P - \frac{F}{\rho V} X_B$	$-$
$\frac{dX_P}{dt} = k_2 X_B X_C - \frac{1}{2} k_3 X_C X_P - \frac{F}{\rho V} X_P$	$k_1^* X_A X_B^2 - k_2^* X_A X_B X_P - \frac{F}{\rho V} X_P = 0$
$\frac{dX_E}{dt} = 2k_2 X_B X_C - \frac{F}{\rho V} X_E$	$2k_1^* X_A X_B^2 - \frac{F}{\rho V} X_E = 0$
$\frac{dX_G}{dt} = \frac{3}{2} k_3 X_C X_P - \frac{F}{\rho V} X_G$	$3k_2^* X_A X_B X_P - \frac{F}{\rho V} X_G = 0$

Where the X_i is the mass fraction of component i, F_i is the mass flowrate of component i, k are the reaction rates, and $\rho V = 2105$ kg is the mass holdup. The values for the parameters of the model are the same as in François et al. (2016). There are 2 cases for the model, with differing parameters, case I and case II, both described in the above paper.

The inputs to the open-loop plant and model are the flowrates of both A and B, and the temperature ($\boldsymbol{u} = [F_A, F_B, T]$). The controller on the open-loop plant has been designed to reduce and change the nature of the degrees of freedom of the system, with the setpoints being $\boldsymbol{r} = [F_{B,s}, X_{A,s}]$. This is done by introducing an unmodelled ratio controller on the two input flowrates such that $F_{B,p}/F_{A,p} = 2.4$. Further, the temperature is controlled via a proportional controller of the concentration in component A, $T = T_0 + K_P(X_{A,s} - X_{A,p})$, with $T_0 = 120\,°C$ and $K_P = -1000$. Also, there is an offset in the flowrate of B, $F_{B,p} = F_{B,s} + 2$, introducing additional uncertainty. In practice better controllers would certainly be designed and implemented but the main point of this article is about when the actual controller is unknown and not about its performances. The objective and constraint functions can be written as follows:

$$\phi(\boldsymbol{u}, \boldsymbol{y}(\boldsymbol{u})) = -(1143 X_P F + 25.92 X_E F - 76.23 F_{A,in} - 114.34 F_{B,in}) \tag{16}$$

$$g_1(\boldsymbol{u}, \boldsymbol{y}(\boldsymbol{u})) = X_A - 0.09 \tag{17}$$

$$g_2(\boldsymbol{u}, \boldsymbol{y}(\boldsymbol{u})) = X_G - 0.6 \tag{18}$$

The model optimum, ϕ, for the two cases are -140 and -161 respectively, whilst the process optimum, ϕ_p, is -212. Initially the algorithms were tested using the MU gradient estimation method, which provides perfect estimations with identical units. Figures 3 and 4 show that the new framework approaches the plant optimum more rapidly than for steady-state to steady-state operation.
Figure 3: Plant profit for *RR* Algorithm with *MU* gradient estimation
Figure 4: Controller setpoints for *MU* gradient estimation
Figure 5: Plant profit for *UR* Algorithm with *NE* gradient estimation
Figure 6: Controller setpoints *UR* Algorithm with *NE* gradient estimation

The algorithms were then tested using NE gradient estimation with some controller knowledge. The assumed knowledge is that the flowrates have a fixed, but unknown, ratio control, which is approximated as the flow ratio of the model's previous operating point $\partial F_{A,p}/\partial F_{B,s} = F_{A,k}^*/F_{B,k}^*$. Also, the mass fraction of A is purely controlled by T, however the control law is unknown. This was approximated as $\partial T/\partial X_{A,s} = (\partial X_A/\partial T)^+$, at the previous operating point. As can be seen in Figures 5 and 6, both cases converge to sub-optimal points on the edge of the feasible region, at a ϕ value of -184 and -207 respectively. This is expected for a model-based gradient estimation technique, which is based on a linearisation of the steady-state nominal model.

6. Conclusion

This paper has proposed that the combination of two established frameworks within modifier adaptation, namely the use of transient measurements and the use of a open-loop model in optimising a controlled process, will reach a KKT point of the process if the algorithm converges. This is backed up with a mathematical proof and case study, resulting in a method which can use transient measurements to optimise a controlled plant with only a steady-state open-loop model. An extension to a model-based gradient estimation technique was proposed to allow for use of the open-loop model to estimate the gradient of the controlled process by transforming the estimate to be with respect to the setpoints using limited controller knowledge. This did not converge to a KKT point of the plant, since NE is a model- linearisation-based gradient estimation technique. However, this did approach a point which is on the edge of the feasible region, while significantly reducing the loss in plant optimality with minimal information about the structure of the controller.

Abstract

The built environment contributes up to 50% of the UK's carbon emissions. Most buildings' analyses focus on the "carbon operating cost" of buildings rather than the embodied "carbon capital cost" and do not take into account a building lifespan. In this paper a new carbon accounting framework is presented modelled on financial accounting principles, with a carbon balance sheet and profit and loss. It is argued that it is illogical to discount future emissions of carbon but that it is reasonable to depreciate carbon assets and liabilities. Like Value Added Tax (VAT) accounting in financial transactions, the proposed carbon accounting method enables a proper, explicit and transparent allocation of carbon assets and liabilities to multiple agents in complex supply chains over distinct temporal, spatial and organisational boundaries.

The approach is demonstrated by applying the model to two energy-efficient buildings of the UK National Energy Foundation, a new Light-Weight building and an older High Thermal Mass one, designed for a lifespan of 50 and 150 years, respectively. The analysis shows that cement based materials, metal and insulation are the major carbon liabilities, with concrete foundations the main structural component responsible. On an operating carbon basis, the newest building produces the least CO_2. In aggregate, the new building is more efficient with an annual carbon cost, including depreciated carbon capital costs, of ~14 tonnes of CO_2/year, vs. ~21 tonnes of CO_2/year for the longer lasting building. The best discounted annual capital carbon cost was for a (notional) building constructed by increasing the lifetime of the 50-year building to 150 years. However, in all buildings the discounted carbon capital cost was less than 11% of the total operating costs, showing that improvements in operating efficiency (carbon P&L) are the most important contribution to carbon emissions.

Keywords: CO_2 accounting model, built environment, building lifetime; construction techniques comparison, CO_2 efficiency assessment.

1. Introduction

We are regularly reminded of the need to radically cut emissions of CO_2 and other greenhouse gases (in this paper, collectively called "carbon" as a shortcut). Whether the cost of carbon externalities is better included through a carbon tax on products and services, or a regulatory framework with permits allocation and trading is hotly debated. Whatever the solution, the amount of carbon emitted will need to be counted and

attributed, so that individuals and organisations may be held accountable for their contribution. This is more easily said than done, as most products and services involve multiple materials, parts, suppliers, distributors and end users in highly complex supply chains, across intersecting geographical, national, regulatory, business entity and legal boundaries, to name a few. To properly allocate carbon origination, use, transfer and cost requires agreed, transparent and easily applied carbon accounting mechanisms. While this seems like a daunting problem, it has been addressed and solved in other areas. In particular, most governments have found ways to tax whatever we, as individuals or corporates, produce, earn, trade, spend, or consume (with exclusions, allowances, progressive or regressive rates, etc.) in ways that are (broadly) socially accepted. One such mechanism taxes the "value added" in each step by each entity.

Conventional material and energy balances over a set system boundary and temporal timeframe define their accrual or depletion within the system (Fig. 1, left). The financial state of a system is similarly defined by a set of money balances, done according to conventional principles or rules, and incorporated in three key documents, a Balance Sheet (assets and liabilities at a given time), Profit and Loss (flows in/out from activities between balance sheets) and Cash Flow (covering the same time frame as the P&L but for cash only). Their relationship is schematically shown in Fig. 1, right. Three similar balances and documents were developed to account for carbon assets (value held) or liabilities (value due), flows and cost over defined physical, organisational and temporal boundaries. The value of carbon added (VCA) by a material flow or process, the overall total embodied carbon, EC (sum of all VCAs contributions up to a given time and carried forward) and the overall life cycle impact, LCC of a product or service (adding up all contributions from cradle to grave) are defined. The latter is similar to the values produced by a life cycle analysis, LCA. Entries from single activities or flows are aggregated into the carbon accounting reports (balance sheet, P&L).
Figure 1. Flows over a physical boundary (e.g. a building), left. Relationship between key financial accounting reports over organisation (e.g. a company) and temporal boundaries (e.g. 1 year), right.

1.1. Carbon accounting and buildings

Half of humanity lives in cities. In the UK, the built environment contributes up to 50% of carbon emissions. The UK construction industry consumes over 420 Mt of materials, 8Mt of oil and releases over 29 Mt of carbon dioxide annually, including a significant quantity of new materials disposed as waste (Hammond and Jones, 2008). Capital cost, not just economic but also in terms of the carbon embodied in materials and construction costs ("carbon capital") required to achieve such objectives is also important. Some estimate suggest that the embodied energy in domestic buildings might be ten times the annual operating energy requirements and in commercial

buildings the ratio could be as high as 30:1 (Rawlinson and Weight, 2007). Most buildings' analyses and construction regulations focus on the "carbon running cost" of buildings rather than the "carbon capital cost" and do not take into account a building lifespan, which our method proposes to do. Finally, building design, construction, and use involve many entities, each of which will likely be required in the future to produce detailed, non-overlapping, mutually consistent carbon accounting reports. Counting and attributing carbon assets and liabilities is particularly challenging.

Traditional Life Cycle Analysis (LCA) does not account for temporal information and assumes a fixed horizon, often 100 years, with results sensitive to the chosen horizon. More recent advances addressed this aspect. Levasseur et al., 2010 proposed a Dynamic LCA (DLCA), of which there are versions related to the timing of processes, other to the proximity to the time horizon in the study scope. Collinge et al., 2018 applied two static and four time-resolved DLCA models to the analysis of two energy efficient buildings, however only to the buildings operating (use) phase. Pan et al., 2018 proposed a fundamental rethinking of system boundaries for the carbon emissions of buildings to include temporal, spatial, functional and methodological dimensions based on 12 variables. In spite of progress, a recent review of methodologies and applications for the carbon footprint of buildings (Fenner et al., 2018) concluded that there is no internationally accepted method for measuring, reporting, and verifying GHG emissions from existing buildings in a consistent and comparable way and indicated the need for a clear, accessible and consistent method.

Given the long lifetime of a building, financial concepts such as discounting (for future events) and depreciation (for past events) must be considered. A discount factor implicitly values carbon emitted in the future at lower price than emitted now. For example, the future cost of permits in a trading scheme, or the future cost of abatement technologies may decrease. As this is controversial and impossible to estimate on a long timescale (and arguably it is immoral to discount current liabilities to future generations), no discounting was applied. Depreciation is a measure of cost or value of an asset that has been consumed during a period. For carbon accounting purposes, assets should be written down at the faster of a model that estimates the decay of CO_2 in the atmosphere (such as the Bern model used in IPCC reports, Schimel et al., 1997) or the straight line that takes its value to zero at the end of its life, while liabilities should be depreciated over the lifetime of a product. Here, assets and liabilities were aggregated into net assets, depreciated at the shorter of the Bern rule or the lifetime of the building.

For all materials we used the ICE (Inventory of Carbon and Energy) database (Hammond and Jones, 2008). Together with relevant properties (e.g. thermal conductivity, density, specific heat) ICE gives the embodied energy and carbon of construction materials, by main groups, for Typical, Primary and Recycled material, with ranges and accuracy estimates. Values are qualified as being cradle to (factory) gate, to (building) site or to grave. At the project time, ICE1.5a contained records for 1400 construction materials, of which 22 (main materials only) were used (and cross checked against other sources). For each material the embodied carbon in ICE does not include an initial asset contribution, so an adjustment was made for biomass based materials. For example, manufacturing of softwood timber takes ~0.47KgCO$_2$/Kg, but assuming ~50%$_w$ of Primary wood is carbon drawn from the atmosphere, the initial carbon asset of softwood timber becomes -1.354KgCO$_2$/Kg. All timber products end up with a negative initial embodied carbon value.

2. Case study: Carbon accounting for buildings with different lifetime

The UK National Energy Foundation (NEF) was set up in 1990 to "provide help to improve energy efficiency in residential buildings". In addition to providing advice to companies and large corporations, they prepare inspectors for statutory home energy efficiency assessment and the UK National Home Energy Rating scheme. NEF is housed in two main buildings (Fig. 3), built to demonstrate energy efficiency practices. The Phase 1 building with ~1,000m^2 net floor area, finished in 1999, was designed based on a High Thermal Mass concept (to store heat and maintain the building's temperature) using conventional materials, with a lifespan of 150 years. It features amongst other devices a steel frame with brick outer skin, insulated cavity and poured concrete inner skin, a high thermal mass insulated roof, massive concrete highly insulated raft floor, internal light shelves to boost daylight and a 500W PV array. The Phase 2 building with ~450m^2 net floor area, finished in 2004, was designed based on a Lightweight Building concept using a timber frame and minimal use of concrete, with a lifespan of 50 years. It features amongst other devices a Ground Source Heat Pump (GSHP) driven by mains electricity feeding a 3 zone underfloor heating systems, solar hot water, eight Sunpipes to boost daylight and a 6.5kW rooftop PV array.

Figure 3. NEF Buildings Phase 1 and 2.

2.1. Carbon analysis

A carbon balance sheet was calculated for the two buildings, comprising carbon "capital" assets (carbon embedded in the building materials, positive or negative, discounted over the expected lifetime of the building) and annual carbon contributions from "operating" costs. As the two buildings are rather different, for ease of comparison calculations were also done for a notional building of the same dimension and plans as the Phase 2 building, but built with the more durable construction materials of Phase 1. This is denoted as Phase 2.1 building. The net carbon assets in each structure, based on detailed construction plans, drawings, records and material samples provided by NEF, are summarised in Fig. 4 by main type of materials used (left) and construction element (right). Some numerical values are shown in Table 1 (left). The embodied carbon in Phase1 Building is rather evenly distributed between foundations, floors, roofs and walls, while in the Phase 2 building over 95% is in foundations and floors, with the lightweight walls and roof hardly contributing. "Operating" carbon was calculated from a detailed analysis of energy suppliers and use in the buildings (Fig. 5). Table 1(right) summarises the buildings capital, operating and total discounted annual carbon.

3. Conclusions

The Phase 1 energy efficient building, built with traditional materials, embodied ~290 tonnes of "capital" CO2 (with an estimated error of 52 tonnes), vs 71 tonnes (+/- 23 tonnes) for the Phase 2 building and 190 tonnes (+/- 32) for the notional 2.1 building. The lightweight, 50-year lifetime Phase 2 building was found to be the most carbon efficient even when carbon embodied in the longer lasting building was discounted over a much longer period. The carbon Capex of all buildings being low relative to their carbon operating costs, the impact of depreciation over longer or shorter building lifetimes was limited. However, it increased from 5% to 11% of discounted annual costs from Phase 1 to Phase 2. As buildings become more efficient, carbon capital cost becomes more important. Further details of method and case study are in Veys (2008).

The proposed (financial-inspired) carbon accounting method enables the assessment of carbon investments with distinct lifetimes. It also enables the attribution, holding and transfer of arising carbon assets/liabilities to multiple agents in a complex supply chain over distinct temporal, spatial and business boundaries. As for VAT tax accounting, it is sufficient for each organisation, product or service to include in its carbon balance sheet just the net liabilities arising between accounting periods from its carbon P&L flows.

Fouling and Cleaning of Plate Heat Exchangers for Milk Pasteurisation: A Moving Boundary Model

Abhishek Sharma and Sandro Macchietto

Department of Chemical Engineering, Imperial College London

South Kensington Campus, London SW7 2AZ, UK

s.macchietto@imperial.ac.uk

Abstract

Plate heat exchangers (PHEs), widely used in the food industries, use large amounts of energy. Fouling reduces their thermal and hydrodynamic performance, and requires periodic cleaning (often after few hours), with productivity losses. Cleaning uses large amounts of water and produces wastes. Improving productivity, minimising energy, water and wastes, while ensuring effective pasteurization is of high interest and can be supported by simulation models. Current models describing the dynamic behaviour of PHEs with fouling typically rely on simplified assumptions, with limited predictive ability. More detailed models based on Computational Fluid Dynamics (CFD) are very computationally expensive for complete PHEs, not always better at fitting experimental data, and practically infeasible to use for operations optimisation and control.

A 2D distributed, dynamic model described by Guan and Macchietto (2018) for a single PHE channel, is extended to enable the modelling of full PHEs with multiple plates arranged in any design configuration (e.g. with parallel, countercurrent, mixed parallel-countercurrent flow). The model is validated here for two such arrangements (A1 and A2) against experimental results. Four milk fouling models are assessed: two deposition mechanism (due to aggregate or denatured proteins), each with/without deposit re-entrainment. No single model was found capable of describing both arrangements. A1 was predicted best by models with aggregate proteins deposition, A2 with fouling by denatured proteins.

A dynamic model for cleaning of fouled surfaces was integrated with the moving boundary model and validated against experimental data. This enabled for the first time in the literature the simulation of Cleaning-in-Place (CIP) procedures, establishing the duration of cleanings, and the seamless simulation of entire single and multiple heating-CIP cycles, with either pre-set or condition-based termination conditions for each phase. It is shown there is large scope for optimising the performance and productivity of overall heating-CIP cycles, and an optimal operation is demonstrated for arrangement A1.

Keywords: energy recovery, plate heat exchanger, fouling, cleaning, dairy processes, dynamic model

1. Introduction

PHEs, widely used in milk production, suffer from rapid fouling, requiring frequent cleaning (every 5-10 hr) of the equipment to recover thermal and hydraulic performance. A PHE productivity (kg milk processed/day) clearly depends on the time out for cleaning. Modelling provides a way to predict the extent of fouling and optimise the operation of

exchangers individually and in networks, aiming at more efficient processes. Many studies have dealt with modelling of PHEs for milk pasteurisation. Some used a set of differential and algebraic equation models developed from mechanistic mass, energy and reaction balances to capture the fouling dynamics (e.g. Georgiadis et al., 1998a, Jun and Puri, 2006), others used a Computational Fluid Dynamics (CFD) approach. The former is faster but typically needs simplifying assumptions associated with lack of detailed knowledge of underlying phenomena, leading to poor predictive ability. CFD incorporates better the effects of detailed geometry on fluid dynamics, but is computationally very expensive (often days of CPU), even when (other) simplifying assumptions are made, e.g. by focusing on a single channel, fixing temperatures (thus decoupling thermal and hydraulic aspects), or decoupling hot and cold sides (e.g. Bouvier et al. 2014). Cleaning has been much less investigated, and complete detailed models for simulation, monitoring, control and optimisation of full heating and cleaning cycles for PHEs are still not available.

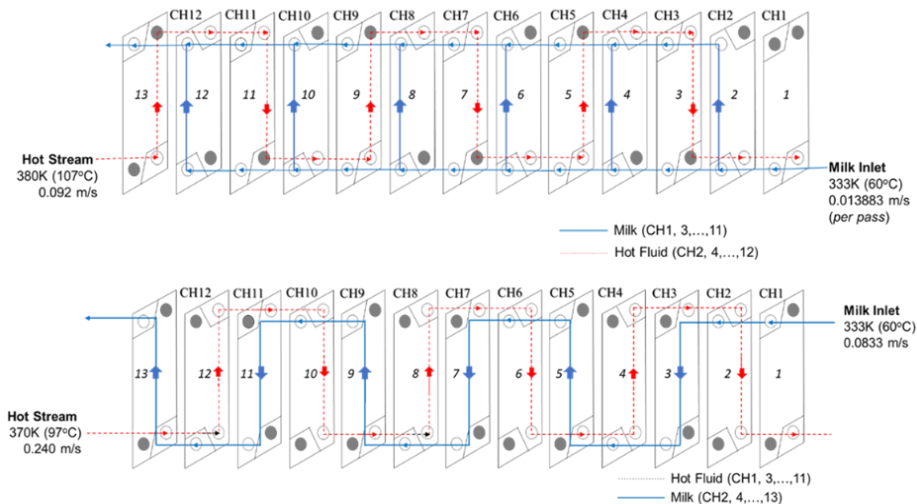
Guan and Macchietto (2018) proposed an advanced dynamic, moving boundary deposition model for a single PHE channel, building on Shell and Tube exchangers work (e.g. Georgiadis et al., 1998b, Diaz Bejarano et al., 2016). The model includes spatially varying, temperature dependent fluid properties, a detailed description of deposition rates over time, and thermal and hydraulic behaviour coupled to deposit layer formation. The result is a more predictive model which is computationally rather inexpensive. However, the Guam and Macchietto (2018) model only describes a single channel, not a complete PHE. A complete PHE model is developed here, with multiple models for aggregation and deposition of milk, and is validated against experimental data for the heating phase, for two quite different PHE design and flow arrangements (Fig.1). A dynamic model of cleaning of a fouled PHE was also integrated and validated. The overall model is then used to simulate and optimise for the first time full Heating and Cleaning in Place (CIP) cycles. Details of the work in this paper are given in Sharma (2018).


Figure 1. PHE arrangements A1 (top) and A2 (bottom). (Guan & Macchietto, 2018)

2. Models of PHE, Fouling and Cleaning

The thermo-hydraulic model of a single PHE channel (dynamic, 2D-distributed, characterising deposit growth at any point on plates using a moving boundary) detailed in Guan & Macchietto (2018) was used, with a few changes. Temperature dependent physical properties were modified for both heating and milk fluids (De-Jong, 1997, Gut and Pinto, 2003). A correlation between Nusselt, Reynolds and Prandtl numbers, Eq. 1, that better fits the conditions in the PHEs studied (Cavero, 2013) was used.

$$Nu(x) = 0.0902\, Re(x)^{0.663} Pr(x)^{0.333} \qquad \forall\, i = L, R \qquad (1)$$

Milk fouling depends on denaturation and/or aggregation of the β-lactoglobulin protein but the exact kinetics is uncertain. Four different literature fouling models, differing in respect of source (aggregated or denatured proteins) and re-entrainment, were used here: i) Fouling with aggregate proteins (Model A); ii) with aggregate proteins and entrainment (Model AE); iii) with denatured proteins (Model D) and iv) with denatured proteins and entrainment (Model DE). All are represented by Eq. (2), but with different parameters:

$$\frac{d\delta}{dt} = \beta \frac{\lambda_d}{h_f^0} k_d C^n - k_\tau \delta \qquad (2)$$

δ is the deposit thickness, λ_d its thermal conductivity, h_f^0 the heat transfer coefficient in clean conditions, k_d the deposition rate constant, k_τ the re-entrainment rate constant, and β an adjustable constant. k_d is represented in the Arrhenius form. C is the aggregate protein concentration in models A, AE, and the denatured protein concentration in models D, DE. Models A and D parameters are taken from Georgiadis & Macchietto (2000) and De-Jong (1997), respectively. $k_\tau = 0$ in models A, D and $k_\tau = 1.3\ 10^{-3}$ /s in models AE, DE (Fryer & Slater, 1985). The proportionality constant β is fitted to data in each case, as it depends on geometry (e.g. plate corrugations) and operating conditions.

For extension to a whole PHE, a hierarchical model structure was used (Fig. 2). Each channel inherits the single channel fouling model. Channels are linked in a parent PHE model according to its specific arrangement configuration. Connectivity conditions ensure proper connection of temperature, heat flux and flow between adjacent channels. Adiabatic heat flux boundary condition were used for the end plates. A Heating phase is considered, followed by a CIP comprising three phases (Washing with water, Cleaning with hot detergent solution, and Rinsing with water). Heating (the fouling producing phase) is modelled as described above. Mechanical displacement from Washing and Rinsing is very difficult to capture, so a fixed time duration was assumed, with no effects on the deposit. Cleaning was implemented by integrating the model of Bird & Fryer (1992) into the moving boundary model (with deposit removal at each point of a plate as in Eq.2) and validated (Sharma, 2018). We can then simulate a single Heating-CIP cycle, multiple cycles or other operation sequences. The termination of each phase may be based on fixed elapsed time, or some other conditions being achieved (condition-based).

The final DAE system (comprising 16, 15 and 7 equations for the thermal, fouling and CIP models, respectively) was implemented in gPROMS (2018). Differential equations were discretised with a second order backward difference for flow in positive x-direction, second order forward difference for flow in negative x-direction, and a central second order scheme in the y-direction (across deposit), with 20 and 8 differential elements in the x- and y-directions, based on mesh independency tests. For a full Heating-CIP cycle this results after discretisation in 43,485 equations (33,523 for the model + 9,962 initial conditions), with computing times for simulation of ~ 5 minutes.
Figure 2. Hierarchical decomposition of solution models. Equipment topology is set in "PHE"

3. Results, Validation and Discussion

Arrangements A1 and A2 were simulated with geometry and operating conditions in Georgiadis & Macchietto (2000), starting from a clean PHE. Figure 3 shows the deposit distribution for A1 after 6.7 hrs of heating. The deposit depth increases along the channel length and is asymmetrical for plates at either side of a channel, due to different plate temperatures. The deposition profiles reflect the calculated bulk protein concentration profiles (not shown). Model responses were validated against experimental fouling data (collected deposit mass in each channel) reported in Georgiadis & Macchietto (2000), with good results. Errors are mostly under 10% for A1 (Fig. 4) and 20% for A2 (not shown). Errors in the initial channels are larger as there is little deposit there due to the low temperatures. There is a very small drop in milk exit temperature by the end of the heating phase (0.1 °C). For A1 (parallel channels), ΔP in a single channel (11) rises from 3.98 kPa when clean to 4.11 kPa. For A2 (parallel-countercurrent channels), ΔP across the PHE goes from 26.6 kPa to 29 kPa. The deposited mass for A1 are better predicted by fouling models A, AE, those for A2 by fouling models D, DE, maybe due to different dependence of deposition on protein aggregation and denaturation with geometry, flow and temperature. The large range in β, used as a fitting parameter by all authors in Fig. 4, confirms that the milk fouling kinetics in the literature warrants further investigation.

A complete Heating-CIP procedure is defined, with a Heating phase with termination condition based on reaching an overall critical deposit mass of 16 g/m^2 (Georgiadis and Macchietto, 2000), followed by Washing for 3 minutes, then Cleaning until < 0.01 g deposit is on each plate, with a final Rinse phase of 3 minutes. Fig. 5 shows the evolution of deposited mass over two cycles operated according to this procedure, for A2 with fouling model D. After Heating, the deposit mass of 3-6 g on each plate is effectively reduced by CIP to the set low level, the bottleneck being the plate with highest deposit. With a looser termination criterion of 0.1 g of deposit per plate, cleaning times are almost halved (from 0.31h to 0.15h for A1 and 0.30h to 0.15h for A2), decreasing the cycle time and increasing productivity (cycles/day). Care must be taken to ensure this is still safe and acceptable in terms of the milk product quality. With the Cleaning termination condition at the lower, safer level, the Heating time was varied, while maintaining the deposited mass under the critical mass specified. A plot (Fig. 6) of cleaning costs and throughput vs cycle time for arrangement A1 (here with fouling model A, to demonstrate the framework flexibility) shows that the largest productivity is obtained with the longest possible cycle time (7.2 h), as more fouling in the Heating phase is not offset by the longer time required for Cleaning dirtier plates.
Figure 3. Deposit thickness distribution on A1 plates along channel length after 6.7h of heating
Figure 4. Error in deposited mass in each channel for four milk fouling models (arrangement A1)
Figure 5. Evolution of deposited mass over two Heating-CIP cycles (A2, fouling model D)
Figure 6. Cost of cleaning and throughput for various cycle times (A1, fouling model A)

4. Conclusions

The novel method presented allows us to easily and flexibly model PHEs of different configurations (e.g. with parallel, countercurrent, mixed parallel-countercurrent flow) and with various fouling, re-entrainement and cleaning models. This was demonstrated for two configurations which were implemented and validated. As far as we are aware, this is the first model describing in detail both fouling deposition and removal in PHEs. Results show that a good match to experimental data is achieved for two PHEs used for milk pasteurisation, in low computation time. It was demonstrated that the model may be used to study and optimise the dynamic operation of a complete PHE, including typical heating and cleaning policies. Its ability to predict deposit distribution on the plates will be also useful for monitoring and control.

Abstract

In this work, a model of a 218 L scale pharmaceutical antisolvent crystallization process was developed. The model is based on a hybrid method of computational fluid dynamics (CFD) and compartmental modeling. In the model, the mixing behaviour of the bulk fluid at two different impeller speeds was obtained from CFD simulations. The compartmental map of the crystallizer was extracted from CFD results based on a hypothesis driven compartmentalization approach. A novel dynamic compartment model was developed to capture the fluid dynamics during the feeding of the antisolvent into the crystallizer and implemented in MATLAB/Simulink environment. Developed model takes into account the changes in compartmental volume, solvent concentrations and density and it assumes a dynamic flow between compartments during the filling. Dynamic compartment model can be also applied in other areas of modeling practices in chemical engineering instead of steady-state compartment models such as fed batch fermentation.

Keywords: Pharmaceutical crystallization, dynamic compartmental modeling, scale-up, computational fluid dynamics (CFD)

1. Introduction

The performance of crystallization process changes significantly dependent on the scale. Upon scale-up, the influence of the fluid dynamics and mixing on the process kinetics becomes important and variations in the crystal size distribution (CSD), purity and morphology often occur and that impacts the product quality and the performance of further downstream processes (Wei, 2010). Several experimental studies on the antisolvent crystallization system demonstrated the strong dependency of obtained CSD on the operation conditions such as crystallizer scale, impeller speed (mixing intensity), antisolvent addition rate and mode of addition such as direct or reverse. Often variations in these operating conditions directly effects the mixing of the solvent with antisolvent, so called the composition of the solvent mixtures (Woo et al., 2006). Homogeneous mixing in a short time is difficult to achieve in the large-scale crystallizer by making no concessions to the cost of the operation or product stability e.g. high impeller speed to promote mixing increases power input and leads to crystal attrition. When the mixing is inhomogeneous, it leads to local variations of important process variables such as solute

and antisolvent concentration, supersaturation, particle concentration in the large scale geometry (Woo et al., 2006, Green, 2002). Since the crystallization kinetics such as nucleation and growth are strongly influenced by those process variables, the crystallization occurs at different kinetic rates in the vessel depending on the local variation profile. Many published studies that focused on aiding the optimization and control of crystallization processes are based on a well-mixed assumption (Nagy et al., 2008). Even though an optimum operation condition is determined after several experiments at well-mixed laboratory scale, this might not be valid for the scaled-up system, since the mixing behaviour and related local variation can be significantly different. Therefore, understanding and predicting the mixing behaviour in the large scale crystallizers is an effective strategy and crucial for the improvement of the process performance. Fluid dynamics of the large scale and related limitations of the chemical system should be always taken into account in tandem with the interactions of thermodynamics and kinetics between solute-solvent system in modeling of large-scale crystallizers, in order to support reliable design, optimization and control.

This study presents an approach to develop a predictive model for an antisolvent crystallization process scale-up of an active pharmaceutical ingredient (API) that is based on a hybrid method of computational fluid dynamics (CFD) and dynamic compartment modeling. Reliable and detailed mixing information of the fluid system obtained from non-reactive CFD simulations is used as a guidance to build up compartments. The mixing dynamics of the antisolvent addition into the solution is modelled with a dynamic compartment model in which the volumes of the compartments and fluxes in-between changes over time. The compartmental model, where crystallization kinetics are coupled with fluid dynamics, is implemented in MATLAB/Simulink. While compartmental modeling is a well applied technique in many areas of modeling practices in chemical engineering, there is no known application on the pharmaceutical antisolvent crystallization process. Besides, developed compartmental models in the literature always assume the volume of the compartments as constant, which is not the reality during addition of a second liquid into the solution as in the antisolvent crystallization. Therefore, this work presents also a pioneer approach for the dynamic compartmentalization method based on author's knowledge. Additionally, developed model can be applied to other processes where the volume changes can not be ignored e.g. fed batch fermentation.

2. Hybrid Model Development

2.1. Crystallizer geometry

A 218 L crystallizer vessel from a previous work was used for the model development of the large scale antisolvent crystallization system. The vessel has 0.640 m of internal diameter and 0.740 m height. A three-blade marine type impeller of 0.300 m diameter is placed in the vessel with a 0.270 m clearance from the vessel bottom. The diameter of the impeller shaft is 0.040 m. Four baffles are located with 0.009 m distance from the vessel wall (Öner et al., 2018). The initial liquid height in the crystallizer before antisolvent addition is 0.455 m, which equals to 126.1 L of the liquid volume.

2.2. Mixing characterization via CFD simulations

The mixing behaviour of the single-phase liquid in the crystallizer was predicted by solving the representative Navier-Stokes equations through transient CFD simulations

performed with a commercial CFD software ANSYS CFX release 17.1. A turbulent fluid flow in the crystallizer was created by the impeller rotation at a speed of 40 rpm and 100 rpm. The standard k-ε turbulence model was used. The crystallizer volume was divided into two domains: a rotating domain and a stationary domain. The rotating domain is a cylindrical zone with 0.330 m diameter and 0.100 m height that contains the impeller and rotates at the impeller speed. The stationary domain contains the remaining zone. The frozen rotor approach was chosen to model the rotation of the impeller in terms of frame change model between the intersections of the two domains. The rotating and the stationary domains were discretized into 118,895 elements of tetrahedron mesh and 1,037,970 elements of hexahedron mesh, respectively (Öner et al., 2018). Several monitor points at different locations in the crystallizer were placed to monitor the time evolution of the fluid velocity. When the fluid velocity remained constant at all these monitor points (reached the steady state), the simulation was ended and the transient average value of the flow velocity components was used in further compartmentalization procedure.

2.3. Compartmentalization

The aim of the compartmentalization approach is to describe the imperfect mixing by defining the large scale fluid system as a network of finite-number interconnected ideally-mixed sub-volumes that contain no or negligible gradients (Wells and Ray, 2006, Nauha et al., 2018). The compartmental zones can be decided based on several criteria such as flow pattern, gradients of temperature and concentration, solid distribution or local energy dissipation (Kougoulos et al., 2006). In the last decade, CFD has been immensely utilized as a standard tool to study the mixing behaviour and its limitations on the chemical systems in detail. A coarser mesh of CFD cells can be created through compartmental models that facilitates the prediction of fluid dynamics and can be coupled with complex reaction kinetics in a simplified simulation environment in a computational cost efficient manner (Nauha et al., 2018, Nørregaard et al., 2018). The compartmental zones can be identified by processing the fluid dynamics information obtained from CFD simulations using a manual or automatic zoning technique (Bezzo and Macchietto, 2004). In this work, the mixing behavior in the crystallizer volume was firstly predicted by means of CFD simulations. The compartmental zones were identified based on a novel hypothesis-driven compartmental model approach that includes the analyzing of axial and radial bulk flow velocities at different locations in the crystallizer. The boundaries of the compartments were defined at the locations, where there is a change in the flow direction in radial and axial components of the velocity. A unidirectional flow was considered for each surface of compartments (Nørregaard et al., 2018).

2.4. Modeling and simulation of antisolvent crystallization process

Antisolvent crystallization of acetylsalicylic acid (aspirin) from ethanol (solvent) and water (antisolvent) was chosen as a case study. Previously published solubility and kinetic data in the literature were used (Lindenberg et al., 2009). The initial solution in the crystallizer has a volume of 126.1 L and contains the weight fraction of 0.25 w/w water and 0.75 w/w ethanol at 35 °C. The initial supersaturation was 1.05. After addition of the seed, the crystallization started with feeding the antisolvent, water into the solution at a rate of $2.3 \cdot 10^{-5}$ m^3/s for 4000 s. When the antisolvent addition is completed, the final volume in the crystallizer is 218 L and contains 0.60 w/w water. The density change of the liquid mixture upon addition of the antisolvent was also taken into account and dynamically calculated during the simulation.

3. Results and Discussion

3.1. Mixing simulation via CFD and compartmentalization

The mixing characteristics of 218 L liquid flow at two different impeller speeds of 40 rpm and 100 rpm were studied with CFD simulations and is shown in Figure 1 (right). The obtained results show that there is much higher liquid flow circulation around the impeller region and the bottom of the vessel compared to top region in the vessel. After analyzing the three components of the bulk flow velocities at different locations in the vessel, total six compartments were detected and the compartmental map is illustrated in Figure 1 (left). The volume of each compartments (at $t = t_{final}$) and the volumetric flow rate between compartments (at $t = t_{final}$) are listed in Table 1. It should be noted that at the beginning of the antisolvent crystallization, while compartment 5 and 6 were completely full, compartment 3 and 4 were empty, and compartment 1 and 2 contained some amount of liquid. As the antisolvent was added to the vessel, firstly the empty volumes were filled in time. During the filling. It was assumed that the volumetric flow rate between compartment 1 and compartment 2 was constant until the compartments were full with liquid, then it started to increase dynamically up to final volumetric flow rate, during the filling of the compartment 3 and compartment 4, since additional flow, $Q_{4\rightarrow1}(t)$ entered to the system. The volumetric flow rates between empty compartments were activated after the volume of the compartments below was full. The volumetric flowrate between compartment 3 and 4, $Q_{3\rightarrow4}(t)$ as well as between compartment 2 and 3, $Q_{2\rightarrow3}(t)$ was also increased dynamically as filling of top zones started. These fluid data were used as input in the compartmental modeling of the antisolvent crystallization in the next section.

3.2. Compartmental model simulation

Antisolvent crystallization kinetics coupled with the fluid dynamics was simulated by means of compartmental modeling. The dynamics of the compartment volumes and accumulated antisolvent amounts in each compartment during the addition of antisolvent into the crystallizer at an impeller speed of 40 rpm are illustrated in Fig. 2 (top). During the antisolvent addition, it was assumed that antisolvent feed was entered from top of the vessel into both compartment 1 and compartment 2 with a volumetric flow rate proportional to their volumes, since the compartments are open volume systems and added liquid will increase the the liquid height at the same amount.

Table 1. Volumetric flow rates between compartments and the volume of the compartments.

Impeller speed	Volumetric Flow Rate [m³/s]						
	$Q_{1\rightarrow2}$	$Q_{2\rightarrow3}$	$Q_{3\rightarrow4}$	$Q_{4\rightarrow1}$	$Q_{2\rightarrow5}$	$Q_{5\rightarrow6}$	$Q_{6\rightarrow1}$
40 rpm							
$t = t_0$	0.0101	0	0	0	0.0101	0.0101	0.0101
$t = t_{final}$	0.0127	0.0026	0.0026	0.0026	0.0101	0.0101	0.0101
100 rpm							
$t = t_0$	0.0326	0	0	0	0.0326	0.0326	0.0326
$t = t_{final}$	0.0400	0.0074	0.0074	0.0074	0.0326	0.0326	0.0326
	Volume [m³]						
Time	C1	C2	C3	C4	C5	C6	
$t = t_0$	0.0351	0.0270	0	0	0.0200	0.0440	
$t = t_{final}$	0.0560	0.0430	0.0240	0.0310	0.0200	0.0440	

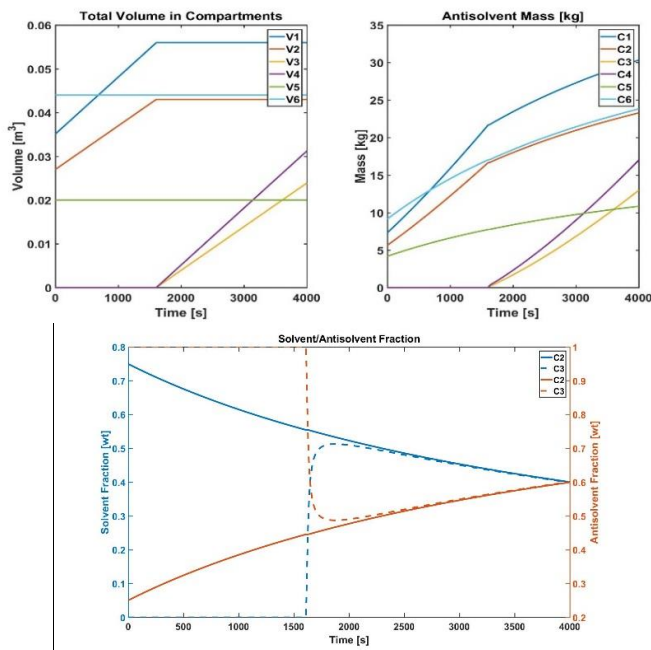
When these compartments were filled, the antisolvent was fed into the top compartments of 3 and 4. However, the filling of compartment 3 and 4 introduced the new flow from compartment 4 into 1, and increased flow ware between the compartment 1 and 2 that explains the increasing mass of antisolvent as illustrated in the Fig. 2 (top). Local variations of the antisolvent fraction shown in Fig. 2 (bottom) affect locally the crystallization growth and nucleation kinetics due to the differences in the supersaturation profiles.
Figure 1. Flow velocity and the mixing behavior at different impeller speed (left) and compartmental map (right).


Figure 2. Compartment volumes (top-left), accumulated antisolvent amounts (top-right) and solvent fractions (bottom) during addition of antisolvent into the crystallizer.

4. Conclusions

A model of a large scale pharmaceutical antisolvent crystallization process was developed based on a hybrid approach of computational fluid dynamics and compartmental modeling. Fluid dynamics of bulk fluid mixing at two different impeller speeds were studied via CFD simulations. Compartmental zones were determined based on the flow velocities obtained from CFD simulation through a hypothesis driven compartmentalization approach. A dynamic model was incorporated for predicting the volume changes of the compartments and dynamic exchange flows in-between. The crystallization of aspirin from ethanol (solvent) and water (antisolvent) was simulated for each compartment that interchanges liquid flows and related properties such as density, solvent/antisolvent weight fraction as well as particles. Future work will focus on the refinement of the compartmental map in two ways. First, analyzing the third component of flow velocity in circumferential direction will enable the addition of the antisolvent from a more specific feed point. Second, CFD simulations with different bulk fluid volumes will be performed in order to study the fluid dynamics of antisolvent addition and evolution of the compartmental map in more detail.

Abstract

In this study, the integration of renewable energy resources (RES) with reverse osmosis (RO) system is investigated to examine optimal design and operation of integrated water and power system over a planning time horizon. The supplied power from RES is assumed to be consumed by RO system for water production. Normally, model parameters vary over time such as water salinity, temperature, wind speed, solar radiation. Therefore, the proposed optimization problem is based on a multiperiod mixed integer nonlinear programming (MINLP) model. The MINLP model features two design and operation layers. The first layer includes design variables and constraints which are independent of time. These variables provide the capital investment requirements, and feasibility boundaries for the operation layer. The second layer involves time dependent variables and constraints to provide optimal operation and cost for the integrated system. The optimal results from the MINLP model will provide optimal system configuration and equipment size for the integrated system. Furthermore, the results will give optimal operation for the integrated system over the planning time horizon. A case study for seawater RO desalination system integrated with wind technology will be analyzed to show the application for the MINLP model.

Keywords: Renewable energy, reverse osmosis, water and power cogeneration, MINLP, multiepriod model.

1. Introduction

Water scarcity is a serious future challenge for sustainable development. Projection of water demand exhibits increasing trends due to global population growth accompanied with industrial expansions. The global water desalination market was valued at US$ 13.31 billion in 2016 and is expected to register robust growth reaching US$ 26.81 billion by 2025 (Hexa Research, 2017). Reverse osmosis (RO) is expected to witness the fastest growth because of its lower energy consumption rate. Growing demand for pure water is projected to boost the market for RO technology, and it is estimated to be worth US$ 15.43 billion by 2025. Nowadays, the generation of clean power from renewable energy sources (RES) is practical such as using wind, solar radiation, hydropower, and others (Ellabban et al., 2014). RES are abundant, moderately inexpensive, and without negative environmental impact compared to traditional fossil

fuels. The application of RES as power sources for desalination technologies have witnessed considerable increase from 2% in 1998 to 23% in 2016 (REN21, 2016).

Several techno-economic studies presented research problems which examined the feasibility of RES technologies as clean energy sources for RO desalination operation. A study investigated the possible integration of photovoltaic solar technology for RO desalination operation (Monnot et al., 2018). The study showed the positive effect of RO configuration selection on the overall optimal cost. Nafey and Sharaf (2010) analyzed different solar Rankine cycle with different working fluids to find minimum treatment desalination cost by RO technology. Gökçek and Gökçek (2016) presented techno-economic study for small scale seawater RO desalination driven by wind turbines in Turkey. The aim from the study is to find the best capacity of wind turbines for reduced cost of power and water production, and reduced emission compared with grid connected system. Gökçek (2018) examined a hybrid energy system (e.g., wind, solar, diesel engine) for small scale seawater desalination in Turkey. The study results showed that a hybrid energy system provides the lowest energy and water cost.

RO desalination network has been studied extensively by many researchers to find the optimal RO configuration in desalination applications (Saif et al., 2008; Sassi and Mujtaba, 2011; Saif et al., 2014). To the best of our knowledge, the integration of RES with RO design and operation through multiperiod optimization model is not available in the literature. Therefore, the main contribution of this work is the development of integrated model for the design and operation of RES and RO integerated system for water and power production in order to satisfy water demand. The proposed optimization model is a multiperiod mixed integer nonlinear program (MINLP). The optimization model is composed by two layers. The design layer is independent of time, and it reflects the required capacities of the process equipment and capital cost. The second operation layer gives decision variables which represent the required operation of process equipment under different time periods with different values of the model parameters. In addition, the operation decision variables are constrained by the selected values for the design variables, and provide the required operation cost. In the following section, the research methodology is briefly described. The third section describes the MINLP formulation. The fourth section presents the results for seawater desalination case study integrated with wind technology. In the last section, the conclusions from this research study are detailed.

2. Methodology

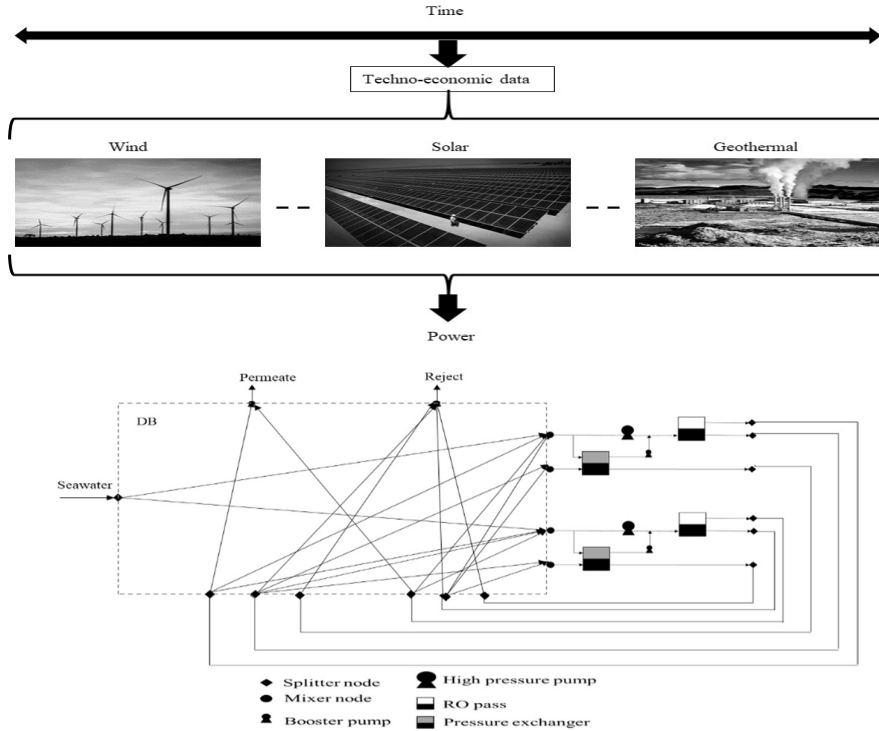
Figure 1 shows the energy and water sections for the proposed research problem. It is assumed that a planning time horizon (T) is given with discrete time intervals. Within these intervals, economic and technical data for the integrated system is available. The objective is to find optimal size of power and RO equipment, and equipment operation to satisfy water demand in every time periods while minimizing total annual cost. The results from the mathematical programming formulation provide optimal RO network configuration (e.g., number of RO passes, pressure vessels, and RO modules), auxiliary equipment (e.g., high pressure (HPP) and booster (BP) pumps, pressure exchangers (PE)), stream assignments within the network, and operation over time for water section. In addition, the results provide optimal selection of RES equipment and their operation over time under minimum total annualized cost. The following section provides the mathematical programming formulation.


Figure 1. RES-RO integrated system representation under time variant input parameters.

3. MINLP model

The objective function of the MINLP model is to minimize the total annual cost (TAC) which is composed of the annualized capital and operation cost. The annualized capital cost (cc) of equipment (Q) represents the RO passes with their auxiliary equipment, and the RES equipment, and op represents the operation cost for the process equipment over the planning time horizon. Eq. (1) gives the total annual cost.

$$TAC = \sum^{Q} cc_Q + \sum^{Q,T} op_{Q,T} \tag{1}$$

The higher layer design variables (xe) are assumed to be independent of time. These design variables give operation limit for the lower operation variables (xo) as given by Eq.(2). Examples of design variables are surface area, flow, pressure, temperature, etc.

$$xp_{Q,T} \leq xe_Q \quad \forall Q,T \tag{2}$$

Every RO pass produces water (wp). Water production is related to the selected number of RO modules (mr), RO pressure vessels (pr), applied pressure (p), and osmotic pressure difference (opd) between the reject and permeate side, and the pressure drop (drop) as given by Eq.(3). Water permeability is represented by the decision variable

wpr which is a function of reject side physical properties (e.g., salinity, temperature, viscosity, etc.). It should worth pointing out that concentration polarization effects are considered in the MINLP formulation to give better estimation of total dissolved solid (TDS) concentration at the membrane wall. In the water section (Fig. 1), there are stream splitting and mixing in the distribution box (DB). Therefore, total water and TDS balance are required over time for the splitter and mixer nodes which give nonconvex terms.

$$wp_{RO,T} = wpr_{RO,T} mr_{RO} pr_{RO} \left(p_{RO,T} - drop_{RO,T} - opd_{RO,T} \right) \quad \forall RO,T \tag{3}$$

The energy system involves several RES. These RES have different sources of energy for power production. The power production (pwp) from RES are related to the selected number (NU) and size (SZ) of a given technology and the power that can be produced from a single unit (Q) as given by Eq. (4). Examples of power production models from single RES equipment can be found elsewhere (Maleki, 2018). The design variable is a binary variable (y) which indicates existence of a given technology and size. In addition, another binary variable is given in Eq.(4) which indicates if an RES is under operation at time interval T. Therefore, the total energy production from all RES is assumed to be consumed by RO auxiliary equipment for water demand constraint at every time period. The following section provides results for the RO seawater desalination integrated with wind technology in Tunisia.

$$pwp_{RES,NU,SZ,T} = y_{RES,NU,SZ,T} y_{RES,NU,SZ} Q_{RES,T} \quad \forall RES,NU,SZ,T \tag{4}$$

4. Case Study

Table 1 shows input data for the MINLP model to represent a case study of Tunisia (Cherif and Belhadj, 2011). The planning time is assumed to be one year with monthly discrete values. In addition, this case study represents a small scale design problem for power and water cogeneration. Table 2 shows RO membrane properties (e.g., FilmTec SW30HR-380 from Dow chemical company), and Table 3 shows different small scale wind turbines (e.g., from AEOLOS manufacturer).

Table 1. Water demand, seawater properties, and air conditions over year.

Periods, month	T1	T2	T3	T4	T5	T6	T7	T8	T9	T10	T11	T12
TDS, ppt	21	33	34	35	36	36	36	36	38	35	35	35
Seawater temp, °C	12.9	13	17	19	20.6	25.1	28	34	30	23	19	16
Air temp, °C	12	13.4	15.7	18.0	21	25	27.6	28.6	26.9	23.3	18.5	14.3
Wind speed, m/s	7.9	8	8.3	8.4	8.4	8.4	7.8	7.6	7.9	7.6	7.8	8.4
Water demand, kg/s	0.69	0.87	0.98	1.13	1.15	1.2	1.2	1.23	1.13	0.93	0.75	0.67

The optimal solution for the energy section show TAC of US\$ 6504. Furthermore, the optimal selected capacity for the wind turbine is four wind turbines of 5 kW capacity. The total generated power is 94.7 kW for seawater desalination every year. This power

is consumed for seawater desalination in order to satisfy water demand over the year. The TAC for the RO section is US\$ 5681. Therefore, the combined water and energy TAC is US\$ 12,185.

Table 2. RO module specifications

Active area (m^2)	35.3
Module length (m)	1.016
Feed space (mm)	0.737

Water permeability (kg/m^2 s MPa)	2.7×10^{-3}
TDS permeability (kg/m^2 s)	2.3×10^{-5}
Module cost (\$)	1000

Table 3. Wind turbine specifications.

	Wind turbine 1 (WT1)	Wind turbine 2 (WT2)
Maximum power (kW)	2.6	7
Rated power (kW)	2	5
Cut in speed (m/s)	2	2.5
Rated wind speed (m/s)	10	10
Survival wind speed (m/s)	50	55
Generator efficiency (%)	96	96
Rotor height (m)	2.8	5.3
Cost (\$)	5605	14309
Figure 2. Optimal configuration for the RO plant.

Figure 2 shows the optimal configuration for the RO plant. It features two RO passes with permeate recycling. The recycled permeate stream is periodic when it is necessary to dilute the seawater feed stream. The mixed stream is divided into two streams for pressurization in the HPP and the PE units. Then theses streams are processed in the first RO pass with two pressure vessels and single RO module. The reject from the first RO pass flows through the second RO pass with one pressure vessel and dual RO modules to increase water recovery. The permeate streams from the first and second RO passes are combined to satisfy water demand.

5. Conclusions

This study presented a multiperiod MINLP for water and power production by RO and RES technologies. The model formulation is composed of two layers which represent the design and operation of the integrated system. The first layer provides optimal

solution for the RO network configuration, optimal selection of RES equipment sizes, and capital cost. The second layer provides the required operation for the integrated system to satisfy water demand by RO technology, power production by RES technologies, and the required operation cost for the integrated system. A case study in Tunisia was analysed to show the application of the optimization model. Future work will be focused on integrating more RES technologies for improvement of the power cost and production, and examining membrane fouling effects on the desalination energy requirement.

Abstract

The complex interactions between the turbulent flow field, bubble size distribution, mass transfer and chemical reactions make the design of bubble column reactors a challenging task. Especially at broad bubble size distributions the commonly used QMOM is not able to track the different velocities of small and large bubbles, while the classes methods are limited due to a high computational load. In this work, we extended our CFD-Sectional QMOM (SQMOM) (Drumm et al., 2008) to model and simulate bubbly gas flow in a rectangular column. For this purpose, we established a setup to measure, in 18 different zones of a rectangular bubble column, the bubble size distribution, the bubble velocity and bubble orientation. The coalescence and breakage model parameters are extracted in a parameter study using the software Dakota for a single case. A satisfactory agreement between local values of three experimentally investigated flow rates and simulations are found without further adjustment of the parameters. This work enables therefore a characterization of heterogeneous bubbly regimes including breakage and coalescence as found in industrial reactive bubble columns.

Keywords: Bubble movement, Local bubble size distribution, Sectional Quadrature Method of Moments, Population balance equation

1. Introduction

In many process engineering fields, dispersed systems are used to enhance momentum, heat and mass transport in either liquid-liquid, gas-liquid, solid-liquid or solid-gas phases. The generation of mono or multivariate size distributions depends not only on the particle generation and the internals of the apparatus, but also on the operational conditions. These include throughput and energy input. Among these multiphase apparatuses is the bubble column reactor, which is used in chemical and biochemical processes to bring a gas phase in contact with a fluid phase to enhance mass transfer and chemical reactions through maximizing the available interfacial area concentration. The complex interactions between the turbulent flow field, bubble size distribution, mass transfer and chemical reactions make the design of the reactors a challenging task (Hlawitschka et al., 2016). In this regard, population balance models coupled to computational fluid dynamics (CFD) have become a suitable tool to investigate bubbly gas flows where the evolution of full bubble size distribution can be modelled. This is because the experimental evidence shows

that broad distributions developed along bubble column reactors due to bubble breakage, coalescence and growth which could not be ignored (Hlawitschka et al., 2016). Unfortunately, the main population balance CFD modelling tools are based, on the one hand, on the Quadrature Method Of Moments (QMOM) which fail to predict the bubble column hydrodynamics due to averaging the whole distribution. On the other hand, classes methods which can follow the full bubble size distribution are inaccurate, especially when a small number of classes are used to reduce the expensive computer computational cost. For this reason, the Sectional Quadrature Method of Moments (SQMOM) (Attarakih et al., 2009) is used, which is a combination of both approaches (discrete and moment methods) to overcome these drawbacks and enable the simulation of BSD with difficult shapes, like a bimodal distribution.

1.1. Numerical framework

The SQMOM is implemented to the multiphaseEulerFoam solver of the toolbox Open-FOAM (version 4.1). The solver is an Euler-Euler multiphase approach and treats each phase as interpenetrating continua. The multiphase approach enables a direct implementation of the primary and the secondary particle concept of the SQMOM, where the primary particles represent the discrete sections and the secondary particles are responsible to account for the interactions between the sections.

The hydrodynamics inside the bubble column is basically simulated using the Navier-Stokes equations for each phase:

$$\frac{\partial \alpha_n}{\partial t} + \vec{u}_n \cdot \nabla \alpha_n + \nabla \cdot (\vec{u}_{comp}(1 - \alpha_n)) = \alpha_n S_\alpha \tag{1}$$

$$\frac{\partial}{\partial t}(\alpha_n \rho_n \vec{u}_n) + \nabla \cdot (\rho_n \alpha_n \vec{u}_n \vec{u}_n) = -\alpha_n \nabla p - \nabla \cdot (\alpha_n \tau_n) + \alpha_n \rho_n \vec{g} + \vec{F}_{D,n} + \vec{F}_{VM,n} \tag{2}$$

The phase fraction of a phase n is denoted by α, the density of each phase by ρ, and the velocity $\vec{u}$. In addition, the solver multiphaseEulerFoam includes an interface sharpening term, which includes the interface compression velocity:

$$\vec{u}_{comp} = C_\alpha |\vec{u}| \frac{\nabla \alpha}{|\nabla \alpha|} \tag{3}$$

A value of C_α enables the reconstruction of the interface of large bubbles. However, the dynamic switching between particles accounted by PBM and resolved particles is not resolved until now and we apply a value of $C_\alpha = 0$.

The hydrodynamic interactions between the phases like drag, lift, virtual mass, etc. are accounted by the respective forces. The drag force $F_{D,n}$ is determined by the equation of Tomiyama et al. (1998):

$$C_D = max\left(min\left(\frac{16}{Re}(1 + 0.15Re^{0.687}), \frac{48}{Re} \right), \frac{8}{3} \frac{Eo}{(Eo + 4)} \right) \tag{4}$$

The Reynolds number *Re* and the Eötvos number *Eo* are calculated by:

$$Re = \frac{\rho_c d_{32} |\vec{u}_c - \vec{u}_d|}{\mu_c} \text{ and } Eo = \frac{g(\rho_c - \rho_d)d_{32}^2}{\sigma_c} \tag{5}$$

The virtual mass force $\vec{F}_{VM,n}$ uses a constant value of $C_{VM} = 0$:

$$\vec{F}_{VM,n} = \alpha_{n^*} \rho_n C_{VM} \left(\frac{Du_n^*}{Dt} - \frac{Du_n}{Dt} \right) \tag{6}$$

The superscript $*$ describes the interacting other phase.

As turbulence model, the model Smagorinsky turbulence model is applied. For the calculation of the energy dissipation, the following equation is applied:

$$\varepsilon = \frac{\mu_{eff,c}^3}{\rho_c^3 (C_S \Delta)^4} \tag{7}$$

C_S is a model constant with a value of 0.167. The cubic root of the cell volume is Δ.

1.1.1. SQMOM

The Sectional Quadrature Method of Moments (SQMOM) and its variants was introduced by Attarakih et al. (2009). The SQMOM calculates the change of the moments using the primary and secondary particle based concept. The primary particles correspond to the classes of a distribution, the secondary particles involve the interactions such as coalescence and breakage, based on the Quadrature Method of Moments concept. The moment of order k of the primary particle i, falling in the bubble size interval $[L_{i-1/2}, L_{i+1/2}]$, can be calculated as follows:

$$m_k i = \int_{L_{i-1/2}}^{L_{i+1/2}} (L_i)^k n(L, x, t) dL \approx \sum_{j=1}^{N_s p} (w_{ji}(x,t) L_{ji}^k(x,t)) \tag{8}$$

Four moments are sufficient to represent each section. Thereby, each section moves with its own velocity. The two equal weights and abscissas can be calculated by the moments m_0, m_1 and m_3:

$$L_{1,2} = m_1 \pm \frac{1}{\sqrt{3}} \sqrt{\frac{m_3}{m_1} - m_1^2} \tag{9}$$

$$w_{1,2} = \frac{1}{2} m_0 \tag{10}$$

The transport equation for each section can therefore be calculated as:

$$\frac{\partial}{\partial t} (\alpha_i \rho_i m_k^{<i>}) + \nabla \cdot (\alpha_i \rho_i m_k^{<i>} \vec{u}_i) = \alpha_i \rho_i S_k^{<i>} \tag{11}$$

The source terms *S* for breakage and coalescence are described in Drumm et al. (2008). In this work, the breakage from Alopaeus et al. (2002) and coelescence from Coulaloglou

and Tavlarides (1977) and Prince and Blanch (1990) are applied. The breakage frequency is:

$$g(L) = C_1 \varepsilon^{1/3} erfc \left(\left[C_2 \frac{\sigma}{\rho_c \varepsilon^{2/3} L^{5/3}} + C_3 \frac{\mu_d}{(\rho_d \rho_c)^{1/2} \varepsilon^{1/3} L^{4/3}} \right]^{1/2} \right) \tag{12}$$

and the coalescence frequency is given by:

$$a(L, L^*) = C_4 \varepsilon^{1/3} (L + L^*)^2 (L^{2/3} + L^{*2/3})^{1/2} \eta(L, L^*) \tag{13}$$

The coalescence efficiency is:

$$\eta(L, L^*) = exp \left(-C_5 \frac{\mu_c \rho_c \varepsilon}{\sigma_c^2} \left(\frac{LL^*}{L + L^*} \right) \right) \tag{14}$$

The parameters described in literature are $C_1 = 6$, $C_2 = 0.04$ and $C_3 = 0.01$, $C_4 = 0.88$ and $C_5 = 6 \cdot 10^9$ (Buffo et al., 2013). There every system shows slight influences to coalescence and breakage, the model parameters were optimized using the optimization toolbox Dakota.

2. Experimental and numerical setup

A pseudo rectangular bubble column with a dimension of 0.18x0.04x1 m is filled with water up to a level of 0.6 *m*. Gas is introduced at the center of the column through a needle sparger with 5 needles in a row. The pitch of each needle is 1.5 *cm* and needle inner diameter is 1 *mm*. The gas superficial velocity was adjusted to 6 and 10 *mm/s*. A high speed camera (Imaging Solutions, IDT NX-8 S2) was placed in front of the column to track the bubbles in 18 sections of the column. Images were taken at a frame rate of 500 images per second, which in general allows a detection of bubble movement. The images were automatically analysed in regard to bubble size, bubble shape and orientation using the Opencv toolbox. The inlet diameter was determined from these experiments, by determine the diameter distribution close to the inlet. For the case of 6 *mm/s*, the inlet diameter was 6.7 *mm/s* in average and for the case of 10 *mm/s*, the inlet diameter is 6.3 *mm*. The numerical representation of the bubble column (1) consists of a hexahedral mesh with 28x5x120 cells. The dispersers is simplified by a planar surface with an area of 50 *mm* x 6 *mm*. Also in the simulation, the air phase above the water level is accounted for.

3. Results

For the case the superficial velocity of 6 *mm/s*, the model parameters were optimized to obtain a good fit of the bubble size distributions (Figure 2), while for symmetry reasons, only the left zones and middle zones of the bubble column are presented. The optimization resulted in parameters for $C_1 = 2$ and $C_4 = 0.1$. The other parameters were kept equal to the values, described in the numerical framework section. The average diameter obtained from experiments is 6.0 *mm* and the simulation results in an average diameter of 6.0 *mm*. The bubble regime is breakage dominated. In a second step, we applied the parameters to the case of higher superficial velocity of 10 *mm/s*. It can be seen, that the simulation fits well to the experimental results (Figure 3). The bubble size changes from 6.3 *mm* to
Figure 1: Numerical representation of the experimental setup with the 18 measurement zone for the bubble size detection (left) and example of the bubble size detecion (right).

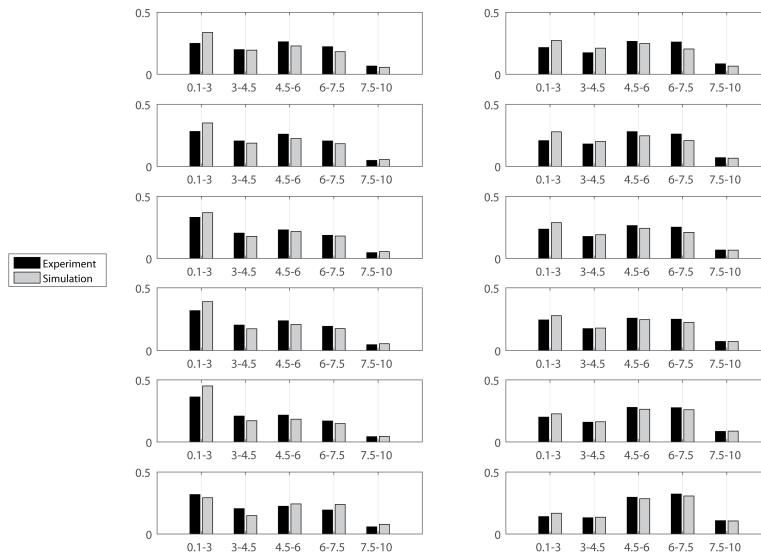
5.7 *mm* in average. The simulation predicts a diameter of 5.9 *mm* in average. A clear shift to smaller bubble sizes can be seen from the sections. Especially close to the wall, the smaller sized bubbles dominate the flow regime, while in the center of the column, larger bubbles can be seen. This effect is enhanced at higher velocities.


Figure 2: Bubble size distribution in each section at a superficial velocity of 6 *mm/s*.
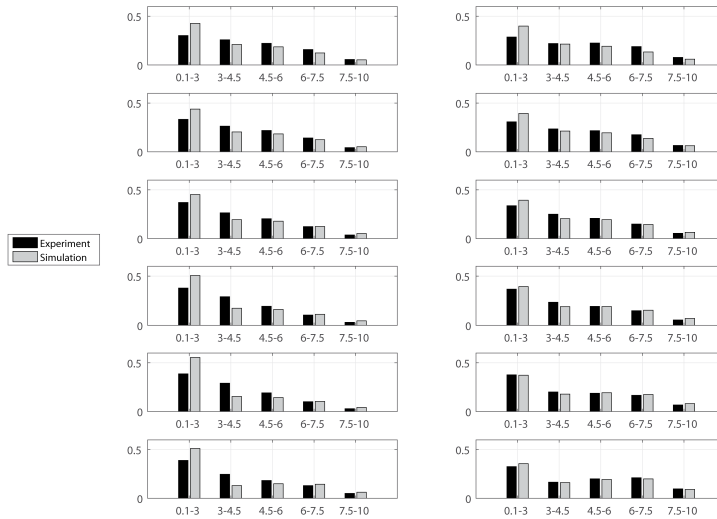

Figure 3: Bubble size distribution in each section at a superficial velocity of 10 mm/s.

4. Conclusion

In this work, we presented a method to model polydisperse systems coupled with an open source toolbox (OpenFOAM) to predict the local size distribution in a pseudo rectangular bubble column. We validated the SQMOM population balance solver to experimental data obtained by a high speed camera and automated data processing. The SQMOM is able to track the bubble size distribution by combining the advantages of the classes method with the ones of the quadrature method of moments. For the still inevitable calibration of the coalescence and breakage parameters, the toolbox Dakota was successfully applied. The computational performance can be flexibly adapted by adding or removing primary particles, leading in the second case to a reduced order model (OPOSPM).

Abstract

The Python Module Coupler (PyMoC) is a tool for co-simulation of Aspen Plus Dynamics modules that together make up an overall process flowsheet. The tool requires only user input in the form of file paths to Aspen Plus Dynamics modules, and it is able to automatically make the required connections there between, and keep track of the simulation whilst updating the streams regularly. This contribution briefly discusses the implementation and mechanisms of PyMoC, and then applies it to a multi-module, single-shooting constrained optimization problem, where an industrial set-up consisting of an evaporator system coupled to a distillation column is studied. This serves as a showcase of PyMoC's functionality and usability, as well as its potential in serving as a helpful tool for practitioners of model-based studies who could benefit from modularizing their models. Utilizing PyMoC for this purpose, the optimization results indicate that the operating costs induced from the steam consumption can be reduced by 54% compared to a nominal operating case, but a holistic, full-process study is necessary to understand the full set of possibilities, causes, and effects.

Keywords: Python, Aspen Plus Dynamics, co-simulation, optimization, PyMoC

1. Introduction

Model-based studies have a wide range of important uses, and can help practitioners save both time and money, whilst improving quality and safety of a process (Oppelt et al., 2015). Especially dynamic model-based studies have many different applications due to their capabilities of investigating not only steady-state conditions but also transient patterns (Skorych et al., 2017). Thus, performing such studies, e.g. single-shooting optimization, plays an important role in improving production processes in order to satisfy demands regarding e.g. environmental aspects whilst increasing production capacity.

When modeling and simulating large, complex flowsheets, there are advantages to be found in dividing the overall model into smaller sub-modules (i.e. modularization), such as simplifying the addition of complementing models and opening up possibilities for parallel work-flows (Felippa et al., 2001). It also makes overview easier if the models would follow existing P&IDs. Modularization is furthermore a solution to convergence issues that large-scale complex process flowsheet models may suffer from (Lin et al., 2017), which would otherwise obstruct model-based studies.

However, modularization comes with its own challenges, as there will thus be a need to connect and co-simulate the modules, which poses a challenge in itself (Andersson, 2016). Doing so manually is obviously not feasible considering the sheer number of spatial and temporal connections necessary for continuous simulation. Commercially available tools such as the AspenTech Operator Training Simulator (OTS) could be used, but the lack of publications utilizing the OTS for model-based studies (Ahmad et al., 2016) supports the conclusion that this tool may not be appropriate to use for such studies. To this end, a tool called the Python Module Coupler (PyMoC) has been developed to help practitioners with co-simulation of modules developed in Aspen Plus Dynamics (APD), utilizing the process flowsheeting software as the engine for calculations. The Python implementation of PyMoC allows for advanced model-based studies by automating connections and data transfer through the application of a naming convention and a zero-order hold analogy (ZOHA), respectively.

In this contribution, PyMoC has been used to optimize a multi-module model of an oscillating polyalcohol separation process, consisting of a two-stage evaporator system and a methanol distillation column. PyMoC will first be introduced briefly, before the modules and the optimization problem is presented, followed by results and conclusions.

2. The Python Module Coupler - PyMoC

PyMoC is based on the COM enabled interface first presented in Nolin et al. (2017), and works by taking as input the paths of the APD files that are to be co-simulated, and then automatically connects these and co-simulates them. The nature of its Python implementation further simplifies customizing model-based studies and applying useful 3rd party software. In this section, two of the main mechanisms behind the function of PyMoC are briefly explained; (i) the naming convention, and (ii) how the transfer of data between modules is performed during runtime.

2.1. The naming convention

In order to minimize the amount of work required by the user, connections between modules are made automatically. This is based on a naming convention, i.e. streams with identical stream names are connected. PyMoC automatically recognizes which stream is the source and the destination, based on the 'Fixed'/'Free' stream variable property used within APD. This means that the user only needs to make sure that the streams to be connected are named identically during modeling.See figure 1 for an illustrative, where the streams 'FEED' will be connected with the algorithm recognizing that the Module A stream is the source to the destination in Module B. The naming convention is also used for deciding which results that are to be presented. The user may provide an *interesting stream-name prefix*, which the algorithm will use to recognize for which streams the user wants results. This is practical especially for large systems, as the user can name the interesting streams with that prefix instead of naming specific streams, and the stream results will be extracted automatically for all interesting streams. Using figure 1 as an example again with e.g. "I-" as the prefix, streams I-IN, I-V, and I-L will have their results extracted automatically.
Figure 1: An illustrative example for the naming convention.

2.2. Data transfer using zero-order hold

A zero-order hold (ZOH) strategy, which has recently been successfully applied for the control of chromatographic separation (Sellberg et al., 2017), is utilized to transfer data between modules, and is essentially a piece-wise constant method. It works by taking the output of the source stream and setting that as the input of a destination stream, keeping this constant over a simulation time horizon, τ. The length of the simulation time horizon is chosen by the user, who should consider the trade-off between accuracy and speed - a smaller τ gives more frequently updated modules, increased accuracy since modules can work with fresher data, as well as longer run-times. The main advantage is the simple implementation, and the main disadvantage is that the sudden step-changes to a variable may introduce discontinuities, something of which the user needs to be aware.

3. Optimization of a modularized model using PyMoC

The problem entails optimizing the two parts of the polyalcohol separation system modeled in two independent flowsheets in order to grant the aforementioned advantages of modularization. The modules are described here, followed by the formulation of the optimization problem.

3.1. The models

The modularized process is presented schematically in figure 2. The evaporator system module has been presented in Nolin et al. (2018). The methanol distillation column was modeled using standard blocks of *RADFRAC*, *MHEX*, and *FLASH*2 in Aspen Plus and then converted to Aspen Plus Dynamics, since the evaporator system was oscillating with propagations into the distillation system. The default controllers added during the conversion to an APD model were kept. An important aspect to note of both processes is that the separation was driven by steam at different pressures, inducing different process costs. Furthermore, of special interest are the streams named PROD and MEOH in figure 2, representing the target product stream of the main component in each module.

The distillation module shares four connections with the evaporator module, all of which drawn from the top of process units in the evaporator module, thus containing the most volatile components at each instance. These streams are passed through a 'translation module' (TM in figure 2) since the evaporation and distillation modules do not share identical Aspen Property Definition files. The difference there-between, c.p., is that formaldehyde was excluded from the distillation module component/property sets during modeling (and subsequently also the Maurer reactions (Hasse and Maurer, 1991) of the evaporator system), as its presence was assumed to be negligible. Essentially, this means that the distillation module cannot handle formaldehyde since its component/property sets do not contain the component. The translation module makes sure that formaldehyde is bypassed, but that the rest of the stream states (in terms of temperatures, pressures, mass flows, and compositions) are transferred from the evaporation to the distillation module. The translation module consists of one *SEP* block per stream, with the singular task of separating formaldehyde into a bypass stream, available for use if necessary later on.

3.2. The optimization problem

The steam consumption was one of the major cost-drivers in a nominal operating case of the overall, oscillating process. Thus, the goal of the optimization was to minimize the steam consumption cost incurred during daily operation while managing process and product demands (which are averaged due to the process oscillations captured in the modules). These demands entail the evaporation module product stream (PROD in figure 2) purity and mass flow, as well as the mass flow and methanol concentration in the top stream of the distillation column (MEOH in figure 2). In

addition to these constraints, another constraint on the minimum mass flow rate from the top of the distillation column was set at half of the nominal run mean value, to keep the column from running dry. This gives a total of five inequality constraint functions. Furthermore, each simulation included a pre-processing simulation period of 12 simulation hours to have any potential (cyclic) steady-state established before the optimization run. The problem was approached by employing a single-shooting strategy with $\tau = 0.1h$, and formulated as unbounded optimization subject to non-linear constraints:

$$\underset{u}{\text{minimize}} \quad \phi(u) = \sum_{i=1}^{2} \frac{c_i}{u_{i,nom}} \cdot u_i$$

$$\text{w.r.t.} \quad u_1 = w_{steam,\ evap} \in \mathbb{R}$$
$$u_2 = w_{steam,\ dist} \in \mathbb{R}$$

s.t. Modularized flowsheet model

$$C_1 = \overline{w}_{PROD} - C_{w_{PROD}} \geq 0 \qquad\qquad C_2 = \overline{P}_{PROD} - C_{P_{PROD}} \geq 0$$
$$C_3 = \overline{w}_{MEOH} - C_{w_{MEOH}} \geq 0 \qquad\qquad C_4 = \overline{P}_{MEOH} - C_{P_{MEOH}} \geq 0$$
$$C_5 = w_{MEOH,\ min} - C_{w_{MEOH,\ min}} \geq 0$$

where w is mass flow rate, P is purity, $\overline{x}$ denotes the average of a variable over the time period, subscripts *PROD* and *MEOH* refer to the streams thus named (figure 2) $u_{i,nom}$ is the decision variable values , and c_i is a price factor relating the mass flow of steam to the incurred cost thereof; $c_1 = 1$ and $c_2 = 0.7$, reflecting the cost ratio between the two steam pressure levels. C_{ij}, $i = (w, P)$, $j = (PROD, MEOH)$ denote the respective values of the *mean constraints*, while $C_{w_{MEOH,\ min}}$ denotes the constraint value for the minimum flow rate in the MEOH stream. The problem was solved by utilizing the scientific computing package *SciPy*'s implementation of the optimization algorithm Constrained Optimization By Linear Approximation (COBYLA), using the nominal point of the simulation as initial values for the decision variables, and running the model as part of the constraint function rather than the objective function.

4. Results and discussion

The objective value for the nominal run, $\phi(u_{nom}) = 1.7$, represents a normalized hourly steam consumption cost. By reducing u_1 by 69% and u_2 by 33%, the optimization was able to reduce the objective value by 54% to $\phi(u_{opt}) = 0.78$, whilst successfully satisfying the constraints. The
Figure 2: A schematic of the modularized process model, marked by the dashed box; the evaporator system ("Evap.") is described in Nolin et al. (2018), whilst the translation module ("TM") and the distillation column ("Dist.") are introduced in this contribution. Note the target product streams PROD and MEOH. The decision variables, i.e. the steam streams, are fully embedded in each module.

latter can be seen in figures 3 and 4, as the mean of variables in the optimal run is greater than the respective mean constraint; the same is true for the minimum flow constraint regarding $\overline{w}_{MEOH}$.

To gain insight into the dynamic behavior of the process, the PROD and MEOH stream results (i.e. w and P) of the nominal run as well as the optimal run are presented together with their mean values and the relevant constraints in figures 3 and 4, respectively. The results have been scaled to be centered around the mean constraint for each variable, rendering the results as dimensionless quantities. Neither graph show sudden, discontinuous responses at the start/end of the simulation time horizons, suggesting that the ZOHA strategy has not created any significant discontinuities.

As can be seen in figure 3, the mass flow and purity for the product stream vary somewhat during the nominal run, as previously reported in Nolin et al. (2018), and such is still the case for the optimal run. The size (i.e. difference between minumum and maximum) of the oscillations in the mass flow have been reduced by 27%, which should lead to simplified control and mitigated effects downstream. Furthermore, the optimal solution will effectively lower the purity by almost 2 percentage units. Together, the increased production rate as measured by w_{prod} and the decreased purity as measured by P_{prod} indicate that the optimal solution essentially produces more of a less concentrated product stream. It is therefore possible that increased costs will be incurred downstream to evaporate any excess water. Exactly how these interact with each other and how they in combination will affect downstream processes may require further studies.
Figure 3: The PROD stream results from the nominal and optimal runs.

The mass flow results for the MEOH stream presented in figure 4 show that the optimal run yields massive oscillations over cycles, with a "jittery" model response, the latter of which presumably caused by the fast dynamics of a pressure controller at the top of the distillation column. The content of this stream is primarily used as fuel for the process, and the effects of propagations here will thus presumably not propagate to the same extent as will oscillations in the PROD stream, even though they are relatively large. Furthermore, the purity of the MEOH was increased significantly in the optimal run. This, combined with the reduced steam consumption for both modules, is further support for the natural conclusion that less water is evaporated in the evaporator module, and subsequently less water is passed on to the distillation column via the top-drawn streams.

5. Conclusions

The optimization shows that it is possible to reduce steam costs by 54 % compared to the nominal case whilst adhering to process demands. However, this may be a globally suboptimal solution
Figure 4: The MEOH stream results from the nominal and optimal runs; note the additional constraint regarding minimal mass flow rate.

when looking at the full process, since less water is evaporated in the investigated modules. This leads to as of now uncertain consequences downstream, but it is possible that the savings in the evaporator and distillation modules presented in the current work may be negated by increased costs downstream. As such, it is imperative to perform a holistic investigation of the full process to prepare for improved decision-making. However, the current work shows that, for the investigated systems, reducing the steam consumption whilst still adhering to production and product demands is indeed possible. Furthermore, oscillatory propagations from any module to other parts of the process need to be studied further. Negative effects thereof are especially necessary to study, and these can potentially be mitigated through an optimal control trajectory optimization possibly combined with improved tuning of the relevant controllers. PyMoC should be a useful tool to use for the former, due to the nature of its Python implementation as well as the implementation of the ZOHA strategy for data transfer.

Abstract

The aim of this work is to develop suitable process dynamic analysis and control strategies for implementing cogeneration unit (COGEN) as a flare utilization alternative to handle unexpected disturbances from unknown and uncertain flare sources. The developed steady state and dynamic simulations using Aspen Plus and Aspen Plus Dynamics allow the design of pressure and temperature controllers that demonstrate good performance. The simulation software and its built-in controller tuning option are used to create the dynamic modelling framework, and to perform controller installation and design. Finally, the proposed process dynamic analysis and control strategies are evaluated using an illustrative regulatory case study. It included disturbance rejection capability assessment in the presence of unexpected pressure load disturbances as well as temperature excursions from desirable operating conditions. The simple designed controller and its automated monitoring systems offered means of evaluating COGEN as a flare utilization alternative, while providing insights in to the techno-economic performance of the system.

Keywords: COGEN systems, Flare utilization, Dynamic process analysis, Simulation and control.

1. Introduction

Emissions from industrial flaring contribute to the accumulation of GHG in the environment and consequently to global warming. Thus, there is a need to develop an effective flare mitigation strategy and operational implementation plan that could reliably contribute to a systematic reduction of flare emissions while at the same time allow a further usage of otherwise unutilized flared streams as potentially valuable energy sources. Previous experience and research findings have demonstrated the utility of systematic process systems engineering (PSE) approaches for recovering and utilizing hydrocarbon streams typically flared during abnormal process operations (Kamrava et al., 2015, Kazi et al., 2018). These approaches have shown promising results and opportunities for substantial emissions reduction, enhanced energy recovery and cost-effective performance through the use of modular systems, such as cogeneration (COGEN) unit and thermal membrane distillation (TMD) systems (Elsayed et al., 2014, Kazi et al., 2016).

However, the prevailing design philosophy and most of the associated mathematical models for flare recovery/utilization in the pertinent literature rely on a set of design steady state conditions. Therefore, PSE research studies for flare recovery system analysis and control purposes conducted with the aid of a comprehensive, insightful and computationally tractable dynamic process modelling framework remain relatively limited and deserve further attention (Dinh et al., 2016, Eljack et al., 2014, Wang et al., 2016).

It should be pointed out, that abnormal situations encountered in process industries represent major sources of flaring when the process of interest deviates significantly from what is deemed the normal and acceptable operating conditions range. Consequently, these process deviations from the desirable performance profile are quite concerning since they often lead to financial losses as well as poor environmental records. The key challenge in abnormal situation management is to provide the operating team with tools that will enable them to avoid or minimize the impact of abnormal conditions. At the same time, if some portion of the unburned hydrocarbon streams is recovered and utilized under stable and robust conditions, significant techno-economic-environmental benefits could emerge by appropriately minimizing the associated waste streams. In this regard, the employment of classical yet comprehensive process control strategies could offer a potentially interesting solution option since satisfactory performance characteristics can be complemented by insightful cost-effective practical implementation strategies. Indeed, such strategies tend to be well received by plant personnel and engineering management teams resulting in greater plant operational efficiency through robust abnormal situation management approaches.

Based on preliminary results reported in Kazi et al. (2016), the present research work considers a COGEN unit as a flare mitigation alternative technology where by the dual process requirement of power and heating can be satisfied using a mixture of fresh fuel (natural gas) and unburned hydrocarbon streams. In particular, a systematic dynamic modelling approach is followed that leads to the development of a process analysis framework and control strategies focusing on the flare utilization section/component of the COGEN unit and the partial replacement of fresh fuel feed in order to enhance process system overall techno-economic-environmental performance. The primary objective of the proposed control strategies is the design, tuning and use of PI and PID controllers for a standard regulation problem, namely for smoothly driving key pressure and temperature variables in the combustion unit of the flare utilization section to desirable set-point values in the presence of various unexpectedly occurring disturbances that cause excursion patterns from operationally desirable steady states in flare systems. Therefore, within such a context, the COGEN unit can be used to recover some of the unburned hydrocarbon streams and utilize them to produce some value added products thus enhancing overall environmental and economic performance.

2. Methodology

The Aspen Plus V9 and Aspen Plus Dynamics software packages have been used for the development of a dynamic modelling framework focusing on the behaviour of the whole COGEN unit that encompasses the flare utilization section/component. First, open-loop (manual mode) tune-up is introduced based on an appropriately validated First Order Plus Dead Time (FOPDT) dynamic process modelling framework. Then, comprehensive closed-loop dynamic response tests are carried out for controller tuning and stability characterization purposes. The required steps for controller installation and controller design have been performed using the same software and its built-in controller tuning option. A succinct step-by-step graphic depiction of the methodology followed in this manuscript is presented in Fig.1.

Step 1: Dynamic Simulation
A pressure driven dynamic simulation of flare utilization section has been developed

Step 2: Controller Installation
Vulnerable unit (e.g., combustion reactor) has been identified
Required pressure controller (PC) and temperature controller (TC) have been installed

Step 3: FOPDT Modelling
Open-loop test has been carried out to find the parameters (open loop gain, time constant and dead time) for FOPDT modelling

Step 4: Controller Tuning
Closed-loop response test has been performed to tune and update the Controller parameters (Gain, integral time and derivative time)

Step 5: Performance Test
Disturbance rejection tests have been done for both pressure and temperature controller to evaluate the performance of the developed controllers

Figure 1. Methodology to develop PC and TC strategies using Aspen Plus Dynamics

3. Development of steady state and dynamic models

In this work, functional baseline steady state and dynamic models have been developed for the entire COGEN unit (see Fig. 2). Special focus was placed on the development of a pressure driven dynamic model for the flare utilization section in order to identify the vulnerable unit and the requisite action plan for reliable pressure or temperature monitoring (see dashed box in Fig. 2). Here, in the pressure controller case the pressure of the combustion reactor (CR) represents the process variable (PV), the set point value is set at 50 bar while the operating variable (OP) is the pressure maintained by the combustion stream valve (CSV). In the temperature controller case, PV is the temperature of CR, the set point value is the steady state temperature 2104 $^\circ$C and the OP variable is the flow of the cooling medium.

4. Controller design and performance

4.1. Open-loop (manual mode) tune up for FOPDT dynamic modelling

A rather standard open-loop test has been performed to identify and quantitatively capture key unknown complex process dynamics through a first-order plus dead time model-postulate. The response profile of the main process variables is used to estimate meaningful open-loop gain (K_P), time constant (τ_P), and dead time (θ_P) values for the given process. The estimated model parameter values of the installed pressure and temperature controllers are shown in Fig. 3. Specifically, a step up by 5% of the output range method has been used which is a built-in method/feature in Aspen Plus Dynamics software.

4.2. Closed-loop dynamic response tests and controller tuning

The closed-loop Auto Tuning Variation (ATV) test better describes the controlled process and offers more reliable estimates of the tuned-up controller parameters (Kamal et al., 2016). In the present work, using the "Tyreus–Luyben" tuning rule (Luyben et al., 1997), a set of controller parameter values: K_C =6.71, τ_I =1.98 min, and τ_D =0.0 min were calculated for a "PI"-type pressure controller. Furthermore, using the "Ziegler–Nichols" tuning rule, the following set of controller parameter values: K_C =1586.209, τ_I =3.75 min, and τ_D =0.6 min were calculated for a "PID"-type temperature controller. It should be noted that temperature control loops within the specific controlled process system's structure typically generate oscillatory behaviour. Therefore, different controller tuning methods were tested to induce

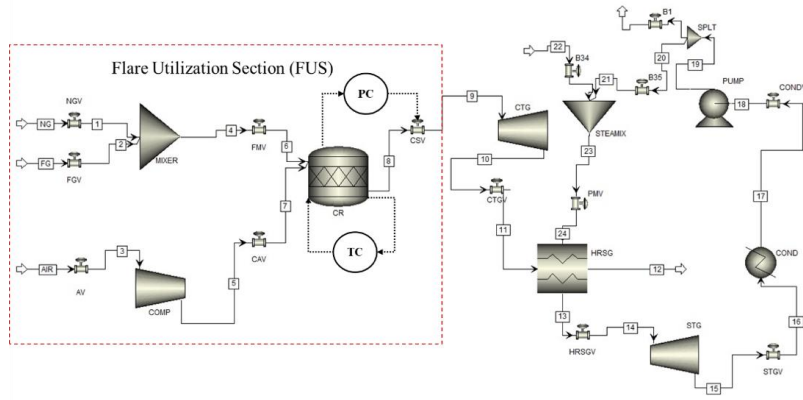
stable responses and appealing controlled process economic and environmental performance profiles. Moreover, temperature measurements can be noisy and the derivative action can lead to a deterioration of the noise-to-signal ratio and process control quality. To remedy this situation, a filtered PID controller or cascade control loop option is advisable.


Figure 2. Developed process flow diagram of COGEN unit and its flare utilization section
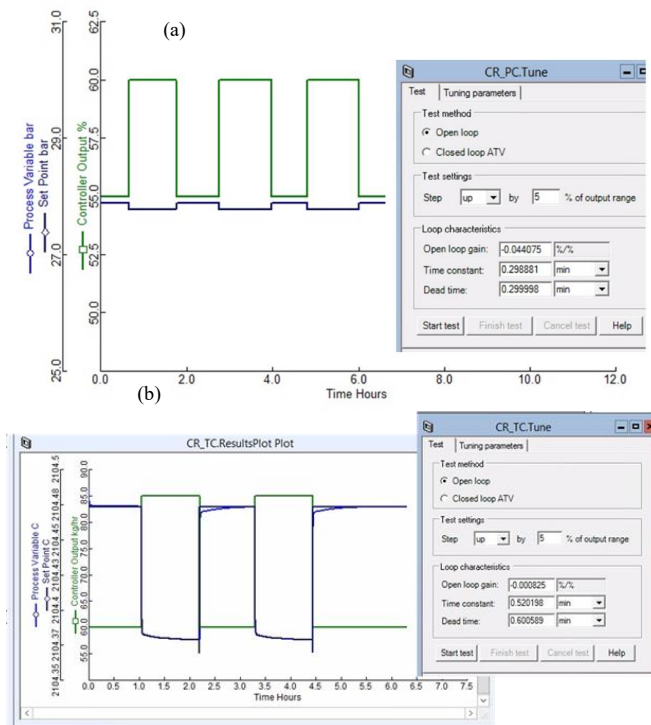

Figure 3. Open-loop response test for FOPDT modelling: (a) PC and (b) TC
Figure 4. Closed-loop profiles under disturbance rejection (process regulation) test: (a) PC
response and (b) TC response

4.3. Regulation Problem: Disturbance rejection test and controller performance evaluation

The regulatory capabilities of the aforementioned pressure and temperature controllers were
tested under various disturbances in an effort to evaluate their respective performance during
abnormal process operations and upsets. For testing the PI pressure controller, pressure has
been changed deliberately from 50 bar to 60 bar, 75 bar and 90 bar at certain time instants to
generate a pattern of unexpected occurring output disturbances. From Fig. 4a, it can be inferred
that the PI controller successfully brought the pressure variable to its set point value in an
offset-less, smooth and stable manner thus rejecting the disturbance effect while inducing
desirable dynamic characteristics in the closed-loop response profile. Please note that
unfiltered strong fluctuation behavior was observed in the beginning as the controller was not
activated during that period. These fluctuations may have occurred due to coupling effects of
the installed controllers, an issue which was later adequately addressed by the specific
controller's action. Similar satisfactory behavior was observed in the PID temperature
controller case where the cooling fluid flow rates were varied to create a pattern of occurrence
of sudden disturbances, suggesting that each time the proposed PID controller was able to
mitigate the disturbance effect and accomplish the primary regulatory objectives as delineated
in the previous case (see Fig. 4b).

5. Techno-economic-environmental performance analysis

Within the context of the present study and the steady state process simulation framework, standard heat/energy integration allows the calculation of the heating utility of the COGEN system which was found to be 52.18 MW as well as power utility that was found to be 105.50 MW. Furthermore techno-economic-environmental performance assessment for the designed COGEN unit with the proposed controllers installed was conducted within the framework presented in (Kazi et al., 2016) where the optimal sizing of the COGEN as a flare mitigation alternative was also pursued. It was found that the proposed configuration of the COGEN unit can lead to savings of 0.18 million USD annually realized by the associated carbon tax savings and can also generate 0.25 million USD annual income from power/heat generation by utilizing the flare during process upsets.

6. Conclusion

A dynamic modelling framework for the flare utilization component of a COGEN system was first developed on the basis of which process dynamic analysis, techno-economic-environmental performance assessment as well as controller design and tuning were also pursued. Simple and practical control strategies were proposed capable of successfully regulating pressure and temperature in the presence of various disturbances as well as inducing appealing performance characteristics for the controlled process. Finally, within the above context, it was demonstrated that there is indeed ample scope to use COGEN as a potentially viable flare mitigation technique by utilizing unburned hydrocarbon streams while generating heat (52.18 MW), power (105.50 MW) as well as annual tax savings (0.18 million USD).

talansari@hbku.edu.qa

Abstract

The global population has quadrupled over the last century. This has increased the global food demand and water sector. In the state of Qatar, the annual freshwater extraction from aquifers is four times the rate of natural recharge, and the depletion is driven by agriculture which represents only 1.6% of the total land area of Qatar, providing approximately 8-10% of domestic food consumption and contributing 0.1% to the domestic GDP. Considering the need for the sustainable intensification of food production systems, satellite technology has the ability to provide a frequent monitoring mechanism enabling the availability of physically-based spatial information useful for reliable environmental monitoring studies. The objective of this research paper is to assess the demand side water footprint of crops using satellite-driven technology in order to optimise the supply side irrigation requirements. The key vegetation indices, such as Normalized Difference Vegetation Index (NDVI) and Normalized Difference Water Index (NDWI) estimated from the remotely acquired information from the Landsat satellite is used for the water footprint assessment. Finally, the water resources demand in agriculture is met by optimising the water supplied from the various decentralized treated sewage effluent plants (TSE). A mixed integer non- linear programming (MINLP) formulation was used to model the spatially-dependent demands, and the TSE plants allocated 80% and 20% of their capacity to fields 1 and 2 respectively. The findings of this paper are promising and a high correlation of -0.93 is found between NDVI and crop water demand, demonstrating that satellite images can be used to monitor the crop vegetation development. vegetation stress can be differentiated using NDVI, thereby demonstrating its applicability for agricultural and water sectors.

Keywords: Crop water footprint, NDVI, NDWI, Satellite remote sensing.

1. Introduction

It is expected that global food production will need to increase to meet the demands of a growing population. Going forward, it is important increase global food produciton within a sustainable development framework which optimises the use of resources and in consideration of the relationship between energy, water and food (EWF) resources (Al-Ansari et al. 2016). Considering food security, and the need to enhance agriculture production, many countries within the Middle East are facing challenges related to the sustainable provision of water required for enhanced agriculture products. Agricultural production is heavily reliant on available water resources, of which excessive exploitation has contributed towards the depletion of groundwater and salt intrusion. The majority of

farms in the Arabian Peninsula which is characterised by a hyper arid climate depend on irrigation rather than rain fed Haddadin (2002). Considering water scarcity, there is a need to develop methods like water footprint to adequately monitor water consumption. The water footprint (WF) of a crop is defined as the amount of water consumed for crop production, where blue and green water footprint represents irrigation and rain water usage respectively Moreover, the WF concept can be used to understand international trading of water known as virtual water (Romaguera et al. 2010). Remote sensing has been used within agriculture and hydrology studies to monitor environment conditions. In this study, remote sensing data is used for the assessment of water footprint of crops in a Qatar case study, as an extension of the work previously conducted by the authors (Woldesellasse et al., 2018). It focuses on developing a neural network model which predicts water demand of alfalfa crops over a period of one year. The novelty is demonstrated using macro-scale water demand estimations from satellite imagery as inputs for optimising water supply in the field, linking irrigation systems and decentralized treated sewage effluent (TSE) plants. The study details the location of the plants, the crop water demand (m^3/ha) and the total amount of water is calculated by multiplying the area of the fields with the crop water demand.

2. Vegetation indices for water footprint estimation

The WF is defined as the sum of the volume of fresh water (blue, green and grey) used to produce the product along its supply chain (Hoekstra et al. 2009). A global study conducted between 1995 – 1999 determined the WF of crops based on crop yields and crop water requirement per country (Allen et al. 1998), Hoekstra and Hung (2005). The model assumes an ideal crop condition such as, optimal soil moisture conditions, disease free, single cropping pattern, well-fertilized and grown in large fields with 100% coverage. In a similar study, Liu et al., 2009 provided the blue and green components of water use for different agricultural crops during the period between 1998-2002 and at a spatial resolution of 30 arc minutes. The input datasets for their model includes, maps of harvested area, climatic data from CRU, soil parameters, and crop fertilizer application obtained from statistical reports. The limitations of the study include coarse data resolution, and an optimum ideal soil water conditions is considered in the study.

Remote sensing techniques can be a useful tool to overcome these limitations by providing high spatial, temporal and spectral resolution data using advanced image classification methods. A global assessment of crop WF using remote sensing techniques was conducted by (Romaguera et al. 2010). The study proposed an approach driven by remote sensing techniques for retrieving the global actual irrigation using evapotranspiration, precipitation, and surface runoff as an input dataset. The Satellite instruments used for estimating these parameters include Meteosat and Climatic Prediction Center Morphing Technique (CMORPH) simultaneously. In agriculture, spectral information is used to characterise the biophysical features of plants using vegetation indices. Vegetation indices are a unitless radiometric measures which are calculated by using two or more bands in the wavelength range of VIS, NIR and SWIR. (Rouse et al., 1974) proposed the most commonly used index known as Normalized Difference Vegetation Index (NDVI). It is calculated as the ratio of the reflectance difference and sum of the NIR and Red bands. Green plants strongly absorb the blue and red bands because of the chlorophyll and simultaneously exhibited a strong reflectance in the NIR region. The value of NDVI ranges between -1 to 1, where below zero values

indicate clouds and water, the positive values close to zero indicate bare soil, and higher positive values indicate vegetation. Sparse vegetation ranges from 0.1 to 0.5, and dense vegetation is illustrated by the value starting 0.6 and above (Stancalie et al. 2014).

The NDVI index is used for the application of many vegetative studies, including crop yield estimation, drought monitoring, monitoring of crop conditions, their developmental stage and biomass estimation (Stancalie et al. 2014). Thus, the information provided by different satellite instruments contribute to effective monitoring and management of agriculture, grasslands, forestry and above all help to understand the way the ecosystem works and its interactions with the atmosphere and human activities. Similarly, Normalized Difference Water Index (NDWI) can be used to provide an indication of the water content in leaves, through monitoring the humidity of the vegetation cover. The value of NDWI ranges from -1 to 1, with the green vegetation lies in the range of -0.1 to 0.4 (Gu et al. 2007). In retrieving the vegetation water content information, the combination of the two spectral bands eliminates the variation in information due to the leaf internal structure and dry matter content.

3. Methodology

The first part of the methodology consists of analysing satellite images acquired from Landsat 7 for the year 2002. NDVI and NDWI are calculated to assess the crop vegetation and water stress of crop over the given time period. NDVI is calculated using the Red and Near Infrared channels, which are Band 3 and 4 respectively using the GIS tool. The vegetation phase displays a seasonal pattern in terms of WF which depends on its water intake and temperature. Under ideal condition, where there is an abundance of water available within minimal evapotranspiration (ET), crops display green vegetation characteristics. Therefore, NDVI and NDWI are high because the corresponding water content of the crop is high. Alternatively, high temperature increases the ET and crop water stress, thereby lowering the NDVI and NDWI. The correlation of NDVI with crop water demand (m^3/ha) and temperature is also assessed to check the interaction between them. The total water demand of the fields, *D*, is then calculated by multiplying the crop water demand by the area of the fields. This study considers the optimisation of water supplied from the treated sewage effluent (TSE) plants to meet the water demand of the alfalfa fields, D, considered in (Woldesellasse, Govindan and Al-Ansari 2018). The water is pumped from the TSE plants and is stored at optimum locations (x,y) prior to its distribution to the alfalfa fields. The objective of the nonlinear optimisation is to minimize the cost of water distribution. The Non-Linear Programming sequence used to allocate the water irrigated to the fields is detailed below:

Constraint:
$q_{11} + q_{12} = 1$
$q_{21} + q_{22} = 1$
$C_1.q_{11} + C_2.q_{21} \geq D_1$
$C_1.q_{12} + C_2.q_{22} \geq D_2$
$q_{11}, q_{12}, q_{21}, q_{22} \geq 0$

Objectives - Minimise:
$(C_1.q_{11}.r_{11}.Cost_{11} + C_2.q_{21}.r_{21}.Cost_{21} + C_1.q_{12}.r_{12}.Cost_{12} + C_2.q_{22}.r_{22}.Cost_{22})$

Where , C_i is the capacity of the two TSE, D_i is the demand of the two fields, q_{ij} indicates the fraction of water transported from source plants to alfalfa fields, $Cost_{ij}$ is the cost of water distribution, and r_{ij} is the length of transportation from the TSE to the alfalfa fields.

4. Results and Discussion

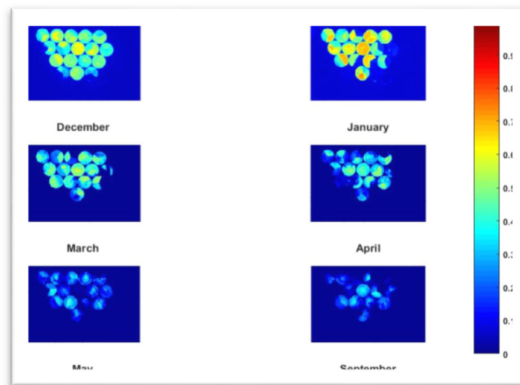
The state of a crop is monitored using a timeseries measurement of NDVI. Figure 2 illustrates the change in colour of the circular fields throughout the year, whilst surrounding areas remain almost constant. The values range from 0 to 1, indicated by the colour bar ranging from dark blue to red. Winter is the period where the temperature is cool in arid regions such as Qatar, and harvesting is most of the time during this period. Generally, the winter months demonstrate a high NDVI compared to the summer months. The highest NDVI recorded is 0.646 in January and lowest 0.194 in June.


Figure 2. Normalized Difference Vegetation Index (NDVI).

Furthermore, the field images illustrated in Figure 2 can be better interpreted through a comparison with Figure 3, where the NDVI is plotted against temperature and crop water demand. The objective is to ascertain the correlation between vegetation indices and the crop water demand, and to ultimately utilise satellite information to allocate water to agricultural fields. In Figure's 3a and 2b, NDVI displays an inverse relationship with temperature and crop water demand. This is due to the fact that the greenness of a crop is affected by its water stress. Since precipitation is sporadic in arid regions, agricultural fields are irrigated using water from underground or TSE. The analysis clearly illustrates the effect of hot temperature and low precipitation on agriculture, in which the NDVI fluctuates between high to low scores during the low and high temperature respectively. However, it should be noted that a low NDVI does not always imply water stress, as the field can also be a just harvested bare ground. NDWI is an indicator of the water content in the leaves of crops. During dry season, the vegetation state is affected due to water stress, and vegetation index, i.e. NDWI contributes towards monitoring of droughts as the two bands used for calculation are responsive to changes in water content. In this study the NDWI is calculated for the same area using the data acquired from Landsat satellite. The result is illustrated in Figure 4, where NDWI behaves similar to NDVI as it is

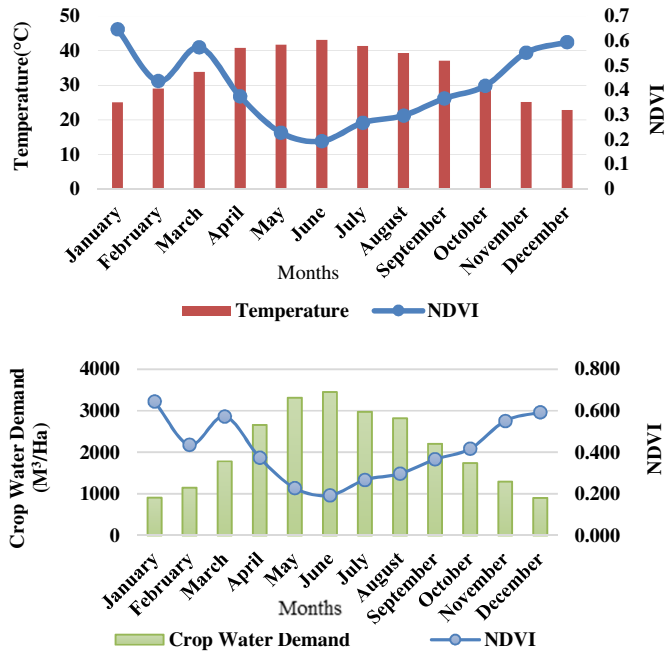
responsive to the crop water demand and temperature, and thereby can be used as a good indicator of water footprint.


Figure 3. Comparison of (a) NDVI and temperature, b) NDVI and Crop Water Demand.

In general NDWI is high throughout the year except, during the winter-summer transition months or summer months where temperature is very high, and where ET exceeds the normal range. Therefore, during these periods, NDWI falls below 0.2 as illustrated in Figure 4. Overall, the results demonstrate consistency with the previous study done. A high correlation of -0.93 is determined between NDVI and the crop water demand, from which it can be concluded that remote sensing instruments can be used for agricultural applications, including for the assessment of the crop water demand. Considering the optimisation framework applied in this study, the TSE plants (Doha West and Doha South) with a capacity of 7.37×10^6 m^3 and 7.20×10^6 m^3 respectively. Outcomes of the study conclude that 80% of the water production in each plant is distributed to field 1, the remaining 20% of the water capacity in each plant is distributed to field 2.
Figure 4. Comparison of NDVI and NDWI.

5. Conclusions

In this study, the correlation between vegetation indices and crop WF is assessed and an inverse relationship is found. This is a good indicator of vegetation phase. The results are further confirmed by considering both the NDVI and NDWI, and their interactions with temperature and ultimately the WF. Finally, the study concludes that satellite images can be used as input data to allocate water irrigated to agricultural fields.

Abstract

The distillation based separation can be extremely complex if highly non-ideal mixtures are to be separated. In spite of different successfully applied unit operations there is always a possible way to improve the distillation technique and widen its toolbar. A novel improvement in this area is the development of the extractive heterogeneous-azeotropic distillation (EHAD). For the sake of the demonstration of the efficient use of EHAD in Dividing wall columns (DWC), two quaternary mixtures are selected for separation: Water – Ethanol – Ethyl acetate – Acetone and Water – Ethanol – Ethyl acetate – Ethylene glycol. There are real waste mixtures from pharmaceutical industry. It must be mentioned, extractive heterogeneous-azeotropic distillation method has never been investigated in dividing wall columns.

Conventional distillation column sequences and dividing wall columns are selected for comparison. Rigorous steady-state simulations are carried out using ChemCAD flowsheet simulation software. Number of trays, heat duties and Total Annual Cost (TAC) of the systems are optimized. It can be concluded, the application of the EHAD in DWCs allows also the simplification of the separation schemes and the separation reduces the energy requirements of the distillation and opens new horizons for the separation of non-ideal mixtures saving energy, money and natural resources. Using DWCs the reboiler duties can be reduced with 20% and the appropriate separation can be reached with one less column.

Keywords: extractive heterogeneous-azeotropic distillation, dividing wall column, non-ideal mixtures, flowsheet simulator

1. Introduction

The highly non-ideal mixtures can be quite often found in fine chemical industries, where the separation of the usually azeotropic mixtures are complicated with the high product purity descriptions. Szanyi et al. (2004a, b) introduced a novel kind of distillation, the extractive heterogeneous-azeotropic distillation (EHAD) that has been proved as a powerful and efficient separation method for the separation of highly non-ideal liquid mixtures. The recovery of solvents from industrial aqueous solutions has particular

interest and moreover the water can be also recycled (Szabados et al., 2018). The EHAD combines the advantages of the heterogeneous-azeotropic and extractive distillations (see Fig.1). Heteroazeotropic distillation exploits the differences in volatility and liquid-liquid phase split by linking a distillation column and a phase separator. Therefore, it may also be interpreted as hybrid separation process. The heterogeneous-azeotropic option assumes that water is present in the mixture and limited immiscibility exists (Toth et al., 2016).
Fig. 1 The extractive heterogeneous-azeotropic distillation (EHAD) (Toth et al., 2016)

The EHAD differs from the heteroextractive distillation since no new azeotrope is formed, namely the extractive agent/entrainer is water and this component is already present in the mixtures to be separated (Toth et al., 2017). Moreover, the extractive and relative volatility changing effect of the autoentrainer/extractive agent is fully utilized and therefore the extractive effect takes place in the whole column (Szanyi et al., 2004b).

Dividing wall columns (DWCs) are todays alternative of sustainable distillation technology. Using DWCs in a distillation sequence significantly increases the number of possible arrangements. These options are worth to be considered as DWCs proved to be attractive in terms of energy consumption. Favourable energy consumption of DWCs is caused by the energy integration technique, thermal coupling (Tarjani et al., 2018). There are numerous feasible partition constructions of a DWC in the literature, but it is a common trend to investigate the properties of the original structure introduced by Asprion and Kaibel (2010) with the partition in the middle. As a systematic approach (Rong, 2011) suggests a strong connection between the conventional sequences and the DWCs with upper (DWCU) and lower (DWCL) partitions (see Fig. 2). DWCU can be considered as an alternative of the conventional direct sequence and DWLC as an alternative of the conventional indirect sequence.
Fig. 2 DWC with Upper partition (DWCU, left) and DWC with Lower partition (DWCL, right) (Tarjani et al., 2018)

The most significant advantage of a DWC is the potential cost saving. Using a DWC can lead to cost savings up to 30% (Sangal et al., 2012) as it only requires one distillation column instead of two ones considering the separation of a three component mixture. On the other hand, thermodynamic efficiency can be increased by avoiding the remixing effect (Kiss et al., 2012). In such a way both investment and operational costs can be reduced compared to the conventional sequences (Tarjani et al., 2018).

Recent studies investigate these complex arrangements and the interest in DWCs begins to increase. Several design methods (Ramírez-Corona et al., 2015; Van Duc Long and Lee, 2012) and applications for azeotropic, extractive and reactive distillation are also developed (Yildirim et al., 2011). It has to be mentioned, EHAD has never been examined in DWC. Therefore, the aim of this work is to investigate the applicability of DWC construction in the case of extractive heterogeneous-azeotropic distillation method considering the separation of quaternary mixtures.

2. Material and methods

Two quaternary mixtures are selected for comparison: Water (Component 1) – Ethanol (2) – Ethyl acetate (3) – Acetone (4) as Mixture I and Water (1) – Ethanol (2) – Ethyl acetate (3) – Ethylene glycol (4) as Mixture II. Table 1 shows the binary and ternary azeotropes of the selected mixtures. The target of this study to create a separation process based on extractive heterogeneous-azeotropic distillation to split the compounds of these mixtures. The limit value for the composition is determined, which is min. 99.5 m/m%, except Ethanol (96 m/m%) and Ethyl acetate (96 m/m%).

Table 1 Binary and ternary azeotropes of the investigated mixtures (Szanyi, 2005)

Azeotrope type	Mixture I	Mixture II	Boil. T [°C]	Azeotropic composition [m/m%]
Binary		(1) - (2)	78	4-96
		(1) - (3)	71.3	8.3-91.7
		(2) - (3)	71.5	29.6-70.4
Ternary		(1) - (2) - (3)	70.3	8.0-8.7-83.3

ChemCAD flowsheet operator program is applied for comparison of column types. Trayed SCDS columns and UNIQUAC method is used for the calculation of the vapor-liquid equilibrium (VLE) as an equilibrium model. The optimal number of trays and heating requirements can be determined (Toth et al., 2017). First, the optimal number of trays are calculated in conventional case and then this value is used in simulation of DWC case.

3. Results and discussion

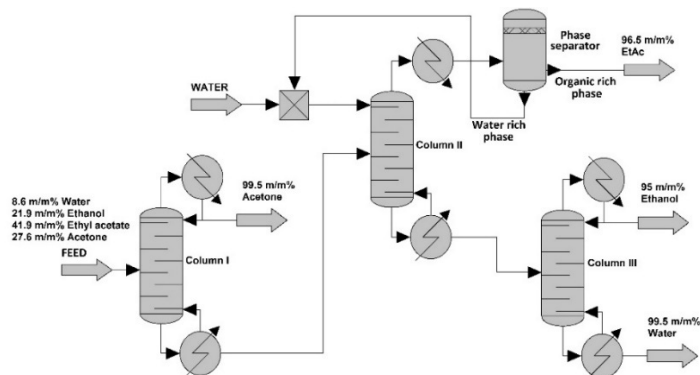
Fig. 3 and Fig. 4 show the separation alternatives of Mixture I. The separation of Mixture II in conventional and in dividing wall columns can be compared in the case of Fig. 5 and Fig. 6. The achieved product purities can be seen in flowsheet figures. First column can separate the non-azeotropic compounds of the mixtures (Acetone or Ethylene glycol) and the EHAD separation is carried out in the second column in conventional column cases. It can be seen DWCL construction is used in non-conventional case. Column II, III and IV symbolize the DWC construction in Fig. 4 and Fig. 6.


Fig. 3 Separation of Mixture I in conventional column
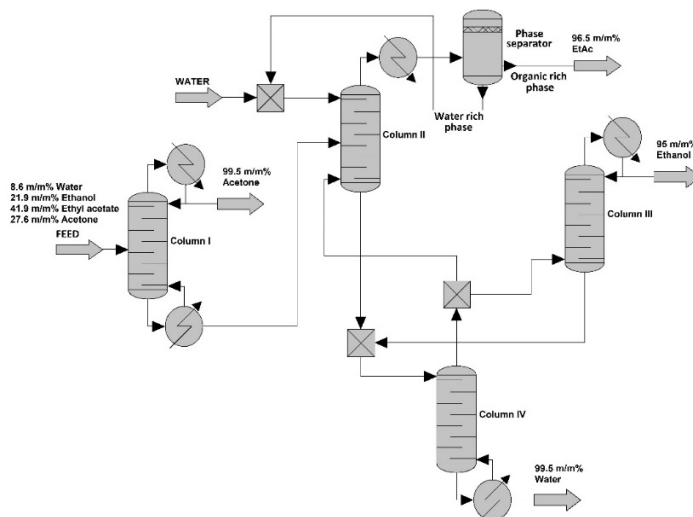

Fig. 4 Separation of Mixture I in dividing wall column (CII, CIII, CIV)
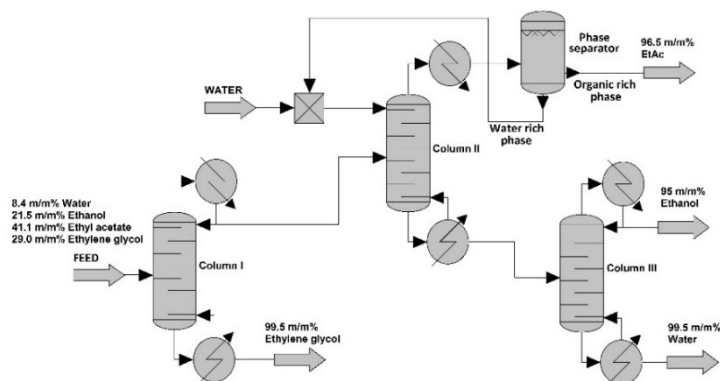

Fig. 5 Separation of Mixture II in conventional column
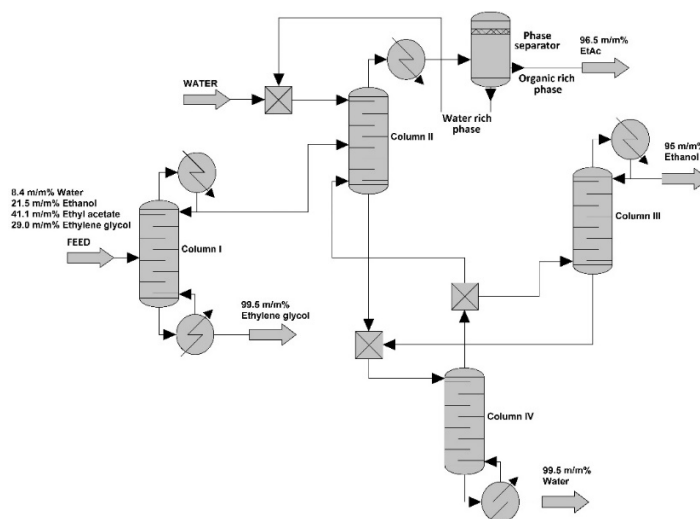

Fig. 6 Separation of Mixture II in dividing wall column (CII, CIII, CIV)

Total Annual Cost (TAC) of the optimized process is calculated according to the cost correlations of Douglas (1988) with current M&S index (1605). Investment costs of the distillation depend on different parameters, for e.g.: heat duty, the sizes of the column, and purity of the products. The operating costs contain the annual costs of the steam and water consumption. 8000 hours/year continuous operation is selected for the calculation of the operating cost. 10-year amortization of capital cost is assumed for the total cost estimation. The mixtures are selected for the comparison for 1000 kg/h feed stream. Valve trays are used in flowsheet simulator (Toth et al., 2017). Table 2 shows the comparison of two column constructions.

Table 2 Comparison of column constructions

	Mixture I		Mixture II	
	Conv.	DWC	Conv.	DWC
Feed water [kg/h]	600		800	
Total number of trays [-]	70		80	
Reboiler duty [MJ/h]	3343	2740	3837	3252
Total Annual Cost (TAC)	3206	2565	3540	2761

It can be seen the reboiler duty values are in accuracy with TAC and the DWC constructions have lower heat duties.

4. Conclusions

The applicability of extractive heterogeneous-azeotropic distillation is tested on two non-ideal mixtures in flowsheet simulator environment. Two column constructions are investigated and compared: (i) conventional columns, (ii) dividing wall column. It can be concluded both structures are capable for separation of quaternary mixtures. The application of dividing wall column results in cheaper solutions and less energy consumption then conventional column case, which means that DWC can be efficacious

tool for separation of highly non-ideal mixtures. Average 17% reduction can be reached in reboiler duty values and the Total Annual Cost can be reduced by up to 21%.

Abstract

Onshore oil and gas exploitation areas are usually composed of a numerous set of wells geographically distributed. The extraction of oil and gas requires complex and expensive equipment, including production devices and surface facilities. To keep efficiency sufficiently high, wells need regular maintenance. In this work, we address the scheduling of maintenance tasks on oil and gas wells and surface facilities. The main challenge is to determine the assignment and sequencing of operations combined with vehicle routing decisions, also accounting for preemption and precedence constraints. The goal is to maximize the use of available resources and also minimize both the production loss and the risk of failure in every well, using a mixed integer linear programming (MILP) formulation. We solve three case studies with increasing complexity to finally assess the model performance in real-size problems of the Argentine oil and gas industry.

Keywords: oil and gas wells, maintenance tasks, optimization, scheduling.

1. Introduction

Maintenance operations over oil and gas fields are usually performed by a specialized fleet of heterogeneous vehicles and crews. These activities comprise safety, environmental protection and regulatory tasks; as well as preventive, predictive and corrective maintenance. Sometimes, depending on the task to be performed, the production of the well needs to be interrupted yielding losses of profits. In practice, tasks are grouped into workorders, and there are many costs associated to the length of an order, related to the production loss and the risk of failure of the well. The more extended the order over the time horizon, the higher the costs of this order. Also, delays on the start time of interventions may cause substantial production losses.

The challenge of this problem is twofold. On the one hand, maintenance tasks should be assigned to crews, each of them having its own capabilities. A task can only be performed by certain crews, and the shifts of the crews widely vary, requiring time coordination. Crews have to travel from well to well and sometimes this time can be relevant (e.g., hours). On the other hand, every task should be precisely scheduled to account for precedence constraints, over a short-term time horizon. A task does not need to be scheduled immediately after the preceding one, but it certainly cannot be

scheduled earlier. There are also both preemptive and non-preemptive tasks. A preemptive task can be interrupted once the shift is over and be continued later. In contrast, a non-preemptive task must necessarily be started and completed within the same day. Complex tasks usually do not allow for interruptions.

To the best of our knowledge, very few works in the literature have focused on the optimal operation of onshore oil and gas wells using multiple heterogeneous resources. Several works have tackled the maintenance planning problem, but most of them are just focused on the most expensive resource: the workover rig (Aloise et al., 2006; Duhamel et al., 2012; Fernández Pérez et al., 2018). The rig planning problem can be seen as the scheduling of jobs (workovers) on parallel heterogeneous machines (rigs), including routing decisions to move the equipment from well to well. However, these problems do not address the whole set of operations, nor preemption and precedence constraints. On the other hand, continuous-time and precedence-based models have proved to be an effective choice when sequence-dependent changeovers are to be considered (Méndez et al., 2006; Castro et al., 2018). However, they would present severe difficulties to manage crews with different shifts. As a result, we propose a discrete-time formulation (Kondili et al., 1993) distinguishing between active and idle periods for every crew. The main contribution of this work is the development of an efficient discrete-time formulation that is able to manage: a) oil and gas well maintenance tasks; b) heterogeneous resources; c) different work shifts; d) preemptive and non-preemptive tasks; e) precedence constraints; f) risk of failure and production losses; and g) crew's travelling time.

2. Problem Statement and Mathematical Model

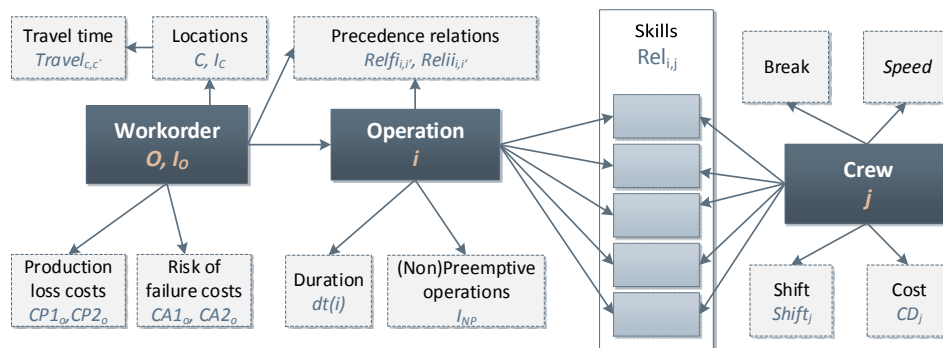
Our mathematical formulation is based on Kondili's discrete-time approach with predefined fix-size time periods. We introduce six major sets, being I: operations, O: orders, J: crews, T: time periods, D: days and C: locations. The model solution generates a maintenance schedule for every active crew over the planning horizon minimizing operating costs. Figure 1 summarizes the main components of the model and their features.


Figure 1: Graphical description of the model

As seen in Figure 1, a maintenance workorder o consists on the set of operations i included in the subset I_o. Each operation $i \in I_o$ requires specific skills and equipment, thus being necessary to assign a crew that is capable of performing that task. Crews are heterogeneous: their specific skills are derived from matching technical capabilities of

the crew and technical requirements of the operations. We define the subset $Crew_i$ to represent the crews with the skills to perform operation i ($j \in Crew_i \subset J$) and the subset $Task_j$ for the operations that can be performed by crew j ($i \in Task_j \subset I$). The binary parameter $Rel_{i,j}$ is equal to one if $j \in Crew_i$, and zero otherwise. Additionally, the subset $Shift_j$ includes the periods within the work shift of crew j ($t \in Shift_j \subset T$). Crews have different work shifts and breaks. Shifts are difficult to manage because they widely vary for every crew (not only the start and end times but also the number of working days per week).

The binary variable $W_{i,j,t}$ takes value 1 if operation i is assigned to crew j and starts on time period t. Eq. (1) states that every task should be accomplished by a single crew over the time horizon.

$$\sum_{j \in Crew_i} \sum_{t \in Shift_j} W_{i,j,t} = 1 \quad \forall i \in I \tag{1}$$

In turn, no operation can start until the assigned crew has finished its previous task. This implies that, if the crew starts performing a given operation i at period $t'<t$, the start time of any other operation is forbidden in any time t for at least dt units of time after the start of the task i. This requirement is expressed by Eq. (2).

$$\sum_{\substack{i \in Task_j}} \sum_{\substack{t'=t-dt_i+1 \\ t' \in Shift_j}}^{t} W_{i,j,t'} \leq 1 \quad \forall j \in J, t \in Shift_j \tag{2}$$

Note that constraint (2) is only binding for operations assigned to the same crew j and evaluates just the active periods of that crew, i.e. $\{t-dt_i+1, t-dt_i+2,\dots, t\} \in Shift_j$.

Moreover, Eq. (3) determines the value of variable $WF_{i,j,t}$, stating that the end of the operation i occurs just when the time given by its length (dt_i) has gone, that is dt_i-1 periods after it has started. Note that no operation can be completed after the end of the time horizon.

$$W_{i,j,t} = WF_{i,j,t+dt_i-1} \quad \forall i \in I, j \in Crew_i, t \in Shift_j, t \leq |T| - dt_i + 1 \tag{3}$$

Precedence and concurrence constraints determine that a task cannot start until the previous one has finished (end-start relation), or that a task cannot start until the previous one has started (start-start relation). These relations are represented using two binary matrices $Relfi_{i,i'}$ and $Relii_{i,i'}$, respectively. Their elements are equal to one in case the relationship between i and i' is enforced. Eq. (4) accounts for such relations, usually by linking tasks within the same order.

$$TI_{i'} \geq TF_i \quad \forall (i,i') | Relfi_{i,i'} = 1 \qquad TI_{i'} \geq TI_i \quad \forall (i,i') | Relii_{i,i'} = 1 \tag{4}$$

$$TI_i = \sum_{j \in Crew_i} \sum_{t \in Shift_j} W_{i,j,t} * (t-1) * slot \qquad TF_i = \sum_{j \in Crew_i} \sum_{t \in Shift_i} WF_{i,j,t} * t * slot$$

Finally, we introduce the notion of preemptive tasks within the equations developed by Kondili et al. (1993). Preemption allows for task splitting when there is a break. Castro et al. (2018) and Peteghem et al. (2010) introduced this concept into their model formulations by making modifications in some constraints. Instead, we propose to simply reduce the time domain to a subset, which only includes the available periods for

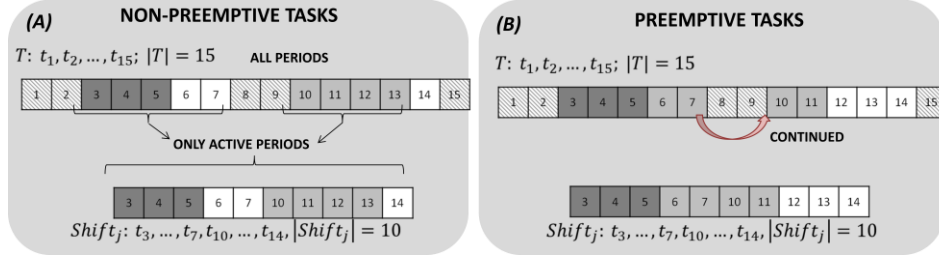
each crew, as shown in Figure 2. In this figure, each cell is a time period. Striped cells are unavailable periods, grey cells represent ongoing operations, and white cells are idle periods.


Figure 2: Shifts, preemptive and non-preemptive tasks definition.

As mentioned in the introduction section, non-preemptive constraints enforce that a task must start and end within the same day, mainly due to safety issues. I_{NP} represents the subset of non-preemptive operations. Variables $X_{i,j,d}$ and $XF_{i,j,d}$ in Eq. (5) are equivalent to $W_{i,j,t}$ and $WF_{i,j,t}$ but considering days instead of single time periods.

$$X_{i,j,d} = XF_{i,j,d} \quad \forall\, i \in I_{NP}, j \in Crew_i, d \in D \tag{5}$$

Following the changeover time concept introduced by Kondili et al. (1993), a travelling matrix is here proposed. We assume that the operations set I can be partitioned into disjoint sets I_c according to the locations c where each task is to be performed. The travelling time between location c and c' is represented by the parameter $travel_{c,c'}$. Thus we introduce a mathematical constraint stating that if two operations i' and i located in different sites c' and c are assigned to the same crew in the same day, and i' is scheduled earlier than i, then the end of operation i' cannot be distanced from the start of i less than $travel_{c',c}$ periods. This can be written in terms of the following linear inequality (6).

$$W_{i,j,t} + \sum_{\substack{t'=t-travel_{c',c} \\ t' \in Shift_j \,\cup\, T_d}}^{t-1} WF_{i',j,t'} \le 1 \tag{6}$$

$$\forall j \in J, d \in D, t \in Shift_j \cup T_d, c \neq c', (i \neq i') \in Task_j, i \in I_c, i$$

The MILP problem goal is given by Eq. (7), where important cost components are to be minimized. Variable MK is the completion time of the last task over the planning horizon, CD_j is the hourly fixed cost for crew j, $CP1_o$ and $CP2_o$ are production losses, $CA1_o$ and $CA2_o$ are risks-of-failure costs (in USD per hour), while $TIOT_o$ and $TFOT_o$ are the initial and completion times of order o. Note that the crew cost CD_j is paid even if the crew is not used by the scheduler. Since crews are outsourced, these costs must be paid until the end of the last operation.

$$Min \quad z = MK \sum_{j \in J} CD_j + \sum_{o \in O} CA1_o * TIOT_o + \sum_{o \in O} CA2_o * (TFOT_o - TIOT_o)$$

$$+ \sum_{o \in O} CP1_o * TFOT_o + \sum_{o \in O} CP2_o * (TFOT_o - TIOT_o) \tag{7}$$

3. Case Studies and Results

To evaluate the computational performance of the proposed model we solve three real-world case studies with increasing complexity from the Argentine oil and gas industry. Table 1 summarizes the model size and total operating cost in the solution of every case study. The MILP is implemented in GAMS using the solver CPLEX 24.6.1, on an Intel® XEON® CPU.

Table 1: Model size and optimization results for every case study

Case Study	$|I|$	$|O|$	$|J|$	$|T|$	CPU time (s)	Makespan (h)	Total Cost (USD)
1	28	4	24	96	1.8	33.5	102,939.3
2	45	6	24	96	4.8	34.5	109,936.5
3	73	19	34	96	16.6	42.0	154,947.0

The three cases comprise the same exploitation area and a planning horizon of two days. Note that the first example involves a total of 28 tasks (4 orders) and 24 crews, and takes less than 2 CPU seconds to be solved. The second example includes 45 tasks (6 orders) with the same number of crews, and is solved to optimality in less than 5 CPU seconds. Finally, the third case study comprises 73 tasks (19 orders) taking more than 3 times the CPU time consumed by the second case study. Figure 3 depicts the Gantt chart of the optimal solution to Case Study 1, in which tasks within the same order have the same colour. It comprises 4 workorders for repairing leaks in aqueducts and pipelines. For this purpose, specialized crews with skills to dig and weld, among other more general tasks, are needed. We can easily observe precedence and concurrence relations such as in the workorder o_3 starting with task i_{15}, assigned to crew j_{19}. Tasks i_{16} and i_{17} have end-start relations with task i_{15}, and a start-start relation among themselves. At noon, crews stop for lunch break. In fact, tasks i_4, i_{23} and i_{24} are interrupted for lunch and resumed later. After lunch, crew j_{11} starts performing task i_{18} (end-start relation with i_{17}) and when i_{18} is completed, i_{19} and i_{20} can also be executed. Once crew j_9 completes task i_{20}, crew j_{18} can perform task i_{21}. Furthermore, workorder o_2 (starting with task i_8) is the only one associated to production losses since the beginning of the time horizon. For that reason, task i_8 starts as soon as possible. In contrast, workorder o_1 (starting with i_1) yields production losses while it is being executed. Hence, once started, it is forced to end as soon as possible. Note that tasks i_{28} and i_7 must be performed during the second day, by crews j_{18} and j_{19}, respectively. Finally, i_8, i_{18} and i_{25} are non-preemptive tasks.

4. Conclusion

A novel discrete-time MILP model for planning general maintenance tasks on oil and gas wells and surface facilities has been proposed to simultaneously optimize scheduling and routing decisions. The main contribution of our work is the inclusion of travelling times, precedence and concurrence relations, preemptive and non-preemptive operations, different work shifts and heterogeneous crews. Real-world case studies from the Argentine oil and gas industry have been efficiently solved in reasonable computational times. The optimal solutions yield the allocation of up to 34 resources to 73 operations, in less than 20 seconds. Future work will focus on the development of solution strategies to manage the exponential complexity of larger size problems, including more tasks, crews and locations, over longer time horizons.

Abstract

Despite there are many studies regarding optimization of biorefineries in the literature, most of them modelled the hydrolysis reactor as a stoichiometric reactor with a predetermined conversion. This simplification implies loss of accuracy and lack of prediction capability, because it does not account for the dependency of hydrolysis yield with important parameters such as enzyme load, solids fraction and reaction time. In this work a kinetic model of the hydrolysis reactor is combined within the whole integrated biorefinery simulation to address this gap. The process modelling and simulation was made in EMSO. Two configurations of the second-generation ethanol (E2G) production process were simulated: the first one considering the xylose biodigestion and the second one implementing the xylose fermentation. The optimization problems involved the maximization of the Net Present Value, taking four key parameters of E2G process as decision variables. The ethanol production increase was incorporated as a constraint of the optimization problem, which was varied in a range of values to obtain optimal configurations for different scenarios. No configuration was economically feasible for the realistic economic scenario considered in the studies. However, the xylose fermentation configuration presented better economic performance than the xylose biodigestion as overall.

Keywords: Sugarcane biorefinery, Modelling and optimization, Economic feasibility.

1. Introduction

The increasing energy demands and the public pressure to decrease greenhouse gas emissions, linked to the governments concern about energy security, are shifting the global energy matrix towards renewable energy technologies (Longati et al., 2018). In this sense, sugarcane biorefineries play an important role producing both biofuel and bioelectricity. Despite the several researches and industry efforts to turn second-generation ethanol production process feasible, this technology is still not consolidated and requires studies to be more sustainable and profitable (Junqueira et al., 2017).

There are many studies regarding optimization of biorefineries in the literature. For a summary of relevant works, we recommend the review of Bechara et al. (2018). However, most of them modelled the hydrolysis reactor as a stoichiometric reactor with a predetermined conversion. This simplification implies loss of accuracy and lack of

prediction capability, because it does not account for the dependency of hydrolysis yield with important parameters such as enzyme load, solids fraction and reaction time. In this work we combined a kinetic model of the hydrolysis reactor within the whole integrated biorefinery simulation to address this gap.

2. Methodology

2.1. Process modelling and simulation

The biorefinery was modelled based on a standard autonomous Brazilian distillery, with a process capacity of 500 t/h of sugarcane (Costa et al., 2016). 35 t/h of sugarcane straw are brought from the field to be burnt in the boiler. The sugarcane and sugarcane straw compositions were in correspondence to Longati et al. (2018). The modelled biorefinery can produce first-generation ethanol (E1G) from sugarcane juice, second-generation ethanol (E2G) from bagasse, and electricity in an integrated process. Two different configurations of the biorefinery were modelled: (1) considering the xylose biodigestion and (2) executing the xylose fermentation. The main data used in the simulation of the biorefinery are shown in Table 1. An overall description of the process follows.

Table 1. Main data used in the biorefinery simulation (TC: ton of sugarcane).

Parameter	Value	Reference
Cleaning energy demand (kWh/TC)	5	Furlan et al. (2013)

Turbines isentropic efficiency (%)	80	Oliveira et al. (2018)
Electric generator efficiency (%)	95.8	Oliveira et al. (2018)
Biodigester COD removal (%)	74	Ribeiro et al. (2017)
Methane production (L/kg-COD-removed)	290	Ribeiro et al. (2017)

The bagasse obtained after milling is divided in two fractions. The first one is fed in the boiler and the second one is used for E2G production. The bagasse diverted to E2G production undergoes a liquid hot water pre-treatment. After that, the liquid fraction, rich in xylose is separated from the solid fraction containing the cellulose. The xylose liquor could be used in biogas production by biodigestion or in ethanol production by fermentation. On the other hand, the solid fraction containing cellulose is fed to the

enzymatic hydrolysis. The kinetic model of hydrolysis reactor proposed by Angarita et al. (2015) was used to access the dependency of hydrolysis yield on enzyme load, solid fraction and reaction time. The coupling of this kinetic model into the whole steady state simulation was made as described in Carpio et al. (2018a).

After hydrolysis reaction, the remained solid fraction (mostly lignin) is sent to the boiler and the liquid fraction (glycose liquor) is mixed to the 1G treated juice and undergoes the traditional stages of E1G. The cogeneration system includes a boiler, a back-pressure turbine and a condensing one, and produces steam and electricity to supply process demands. The electricity surplus is sold to the grid. EMSO software (Soares and Secchi, 2003) was used to perform the modelling and simulation of the biorefinery. The components and thermodynamic packages used in this work were the same of Longati et al. (2018).

2.2. Economic analysis

The economic analysis was also implemented in EMSO, coupled to the process model. This allows instant calculation of economic indexes for any feasible operational condition simulated, without requiring external or auxiliary sheet calculations. The main economic premises considered in this study are shown in Table 2.

Table 2. Main premises considered in the economic analysis.

Parameter	Value	Reference
Ethanol selling price (US$/m^3)	584.61	MAPA (2018)
Electricity selling price (US$/MWh)	71.19	CCEE (2018)
Sugarcane costs (US$/t)	22.15	UDOP (2018)
Straw cost (US$/t)	15	Bechara et al. (2016)
Enzyme cost (US$/t)	1250	Bechara et al. (2016)
Fresh water cost (US$/t)	0.06	Bechara et al. (2016)
Refrigeration cost (US$/kW)	0.04	Bechara et al. (2016)
Operation time (h/year)	42000	Furlan et al. (2013)
Project life time (years)	25	Longati et al. (2018)
Construction period (years)	1	Furlan et al. (2013)
Tax Rate (%)	34	Longati et al. (2018)
Discount rate (%)	10	Bechara et al. (2016)
Depreciation strategy (%/year)	10	Longati et al. (2018)

The capital cost (CAPEX), operating costs (OPEX), cash flows (CF) and net present value (NPV) were calculated based on the methodology of Peters et al. (2003). The main equipment purchase costs were estimated from the literature (Humbird et al., 2011) and were updated and scaled according to Peters et al. (2003). The minimum ethanol selling price (MESP) corresponds to the ethanol selling price that makes NPV equal to zero.

2.3. Process optimization

The objective function of the optimization problems was the maximization of the NPV. Some key parameters of hydrolysis were selected as decision variables: hydrolysed bagasse fraction, enzyme loading, solids loading and residence time. The increasing on total ethanol production due to E2G was incorporated as an inequality constrain. The Surrogate Assisted Optimization (SAO) framework proposed by Carpio et al. (2018b)

was applied for estimating an initial global solution of the optimization problems. After that, the Sequential Quadratic Programming (SQP) algorithm was used for refining the solution.

3. Results and discussion

Figure 1 shows the resulting Pareto set of NPV and MESP for different values of the constraint. The economic indexes of both configurations become worse when increasing the constraint value. It means that the additional income obtained by a larger ethanol production does not compensate the investment and operational cost involved in the E2G production process for the realistic economic scenario. This finding is in agreement with the results achieved by Bechara et al. (2016), Junqueira et al. (2017) and Longati et al. (2018).
Figure 1. Pareto curve of NPV and MESP for ethanol production increase.

As overall, the economic indexes of the xylose fermentation case are better than the xylose biodigestion case. In addition, the sensitivity of the Pareto curve for xylose fermentation case is lower than for the xylose biodigestion case. It is worth mentioning the existence of knee points, for which NPV and MESP witness a greater change, at the higher values of the constraint. This behaviour is better understood by analysing the optimal values of decision variables shown in Figure 2.

The hydrolysed bagasse fraction (Fig. 2A) rises almost linearly with the constraint increase until approximately 19 %. After that value, this variable rises more gradually because it is close to the maximum value of bagasse that can be diverted to E2G without affecting the steam requirements of the biorefinery. In the case of enzyme loading (Fig. 2B), the optimal values are between 12 and 16 FPU/g. Notice that for constraint values higher than 21 % the enzyme loading rise abruptly. This behaviour is due to the impossibility of an additional increase on the hydrolysed bagasse fraction for that condition. Consequently, it is necessary to increase the enzyme loading for producing more ethanol and meet the constraint.

The optimal values for solids loading (Fig. 2C) of both configurations are mostly above 15 %. For the xylose fermentation case there is a clear tendency of increasing the solids loading as the constraint increases as well. This behaviour is justified by the higher steam demand of this configuration. Therefore, it is necessary to increase the solids loading for decreasing the steam demand and allowing a higher hydrolysed bagasse

Optimization of an Integrated First- and Second- Generation Ethanol
Production Plant with Focus on Hydrolysis Parameters
551

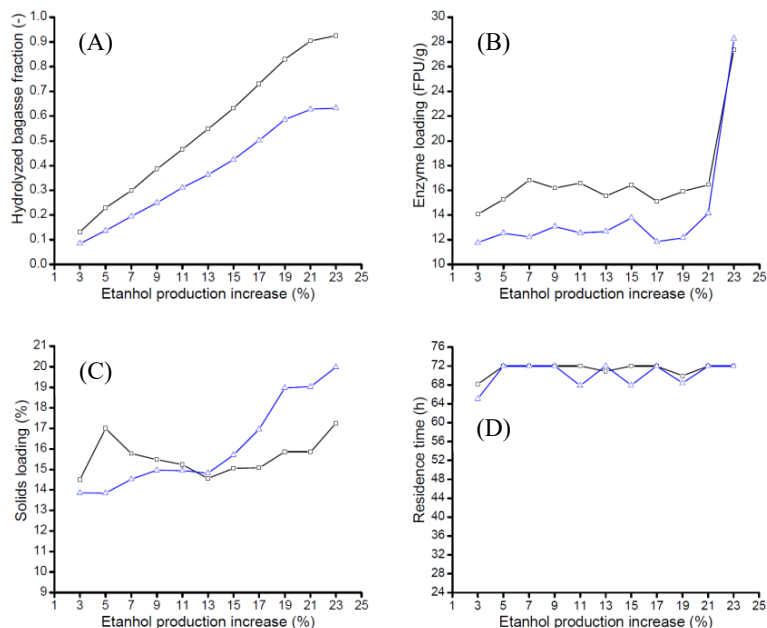
fraction. Optimal values for residence times (Fig. 2D) were mostly between 68 and 72 hours. The oscillatory behaviour of the residence time is due to the cost of hydrolysis reactors being a discrete variable that changes in steps, because the total required volume is attained by adding fixed-volume hydrolysis reactors. Consequently, there are some operating conditions where the additional ethanol produced by increasing the residence time does not compensate the cost of a new hydrolysis reactor, leading to optimal resident times below 72 hours.


Figure 2. Optimal values of decision variables for: □ xylose biodigestion and △ xylose fermentation.

4. Conclusions

No configuration was economically feasible for the realistic economic scenario considered in this study. However, the xylose fermentation case presented better economic performance than the xylose biodigestion as overall, and particularly for high cellulosic ethanol rates. It is possible to increase the ethanol production up to 23 % in both configurations due to E2G process. However, ethanol production increase greater than 21 % leads to significant deterioration of economic indexes. Most of the optimal configurations were achieved for enzyme loading between 12 and 16 FPU/g, solids loading in the range of 14 and 17 % and residence times above 68 hours.

Optimization of seaweed-based biorefinery with zero carbon emissions potential

Rofice Dickson,[a] Jay Liu[a,*]

[a]Department of Chemical Egnieering, Pukyong Nationl Univresity, Busan, 48547, Korea

jayliu@pknu.ac.kr

Abstract

The superstructure-based optimization was proposed to determine optimal pathway of biorefinery, producing bioethanol. In general, the bioethanol process produces a large number of waste streams such as carbon dioxide, wastewater, and residual solid from fermentation. To utilize the aforementioned waste streams, processes such as succinic acid (SA), microalgae (MA), wastewater treatment (WWT) networks, and solid processing were integrated with bioethanol process. Based on the superstructure, technoeconomic and environmental mixed integer non-linear model was formulated and implemented in GAMS (25.0.2). The aim of the present contribution was to determine a more economically and environmentally viable process design than a standalone process. These goals were achieved by two objective functions; maximize net present (NPV) value and minimize carbon dioxide emissions (CE). To account uncertainties in process parameters, sensitivity analysis was also performed. The result indicated minimum ethanol selling price (MESP) of integrated design is about 34% lower than that of a standalone bioethanol process with more than 90% reduction in CE.

Keywords: Superstructure optimization, process synthesis, biofuels, macroalgae

1. Introduction

Development of biofuel production from renewable sources like biomass has gained significant attention due to growing energy demand, depleting fossil fuel reserves, and increasing environmental concerns such as greenhouse gas emissions. Among various biomass feedstocks, brown algae, as a 3rd generation feedstock, is considered as a promising candidate due to its sustainable cultivation, high sequestration efficiency, and absence of ethical issues such as food competition. Furthermore, brown algae contain high carbohydrates contents, at 32-60%, dry weight, and lack of lignin (Roesijadi et al., 2010). Taking into consideration the benefits of brown algae and its versatile chemical composition, this study will focus on biofuel production from brown alga *Saccharina japonica* (SJ) as a potential feedstock.

In the literature, serval bench-scale experimental studies were conducted to produce biofuels from the carbohydrates of SJ via fermentation pathway. Reith et al. (2009) utilized the carbohydrate contents of SJ and obtained ethanol yields of 0.254 kg ethanol/ kg of dry feed. Based on this yield, Fasahati et al. (2015) determined the economic viability of bioethanol production from SJ and calculated MESP of 2.39 $/gal at 80,000 t/y plant capacity. Recently, Dickson et al. (2018) conducted an optimal design of SJ-based biorefinery by using a superstructure approach to report the values of the MESP and the maximum seaweed price (MSP).

Despite the promising yields and economics, bioethanol processing produces numerous waste streams and byproducts, and is water intensive. It is reported that medium-sized biorefinery, processing 2 to 3.5 mt/y sugarcane produces 110 to 193 kt/y of CE during fermentation (Bonfim-Rocha et al., 2018). Similarly, stillage from the distillation column has high values of chemical oxygen demand, biochemical oxygen demand, and minerals. Water consumption in bioethanol plants ranges from 3 to 15 gal of water per gal of ethanol. Disposal of these waste streams without treatment can cause severe environmental issues such as contribution to global warming, deoxygenation of water reservoirs, discoloration, odors, eutrophication, acidification, and other problems. In the literature, however, little attention has been paid to simultaneously reduce all waste streams from bioethanol processing.

Based on the presented challenges and research gap, this study is the first to simultaneously integrate processes such as SA, MA, unreacted solid processing, and WWT networks with bioethanol processing. The goal of this study is to utilize all waste components from SJ biorefinery by designing an economical and environmentally friendly process by taking a superstructure approach. To achieve these goals, two objective functions were employed in the optimization: NPV and CE. The novelty of this work includes a large number of process alternatives to find the optimal design under different objective functions.

2. Methodology

2.1. Problem statement

The optimization problem is defined as determining the optimal design for macroalgae-based biorefinery, which has maximum process economics as well as minimum detrimental effects on the environment.

2.2. Superstructure development

To design an environmentally friendly biorefinery, a superstructure is developed by adding large number of design alternatives into the conventional bioethanol process. The superstructure given in Figure 1 is capable of utilizing all components of seaweed and waste streams from the bioethanol process. Seven major sections are included in the superstructure: feed pre-treatment, enzymatic hydrolysis and fermentation, enzyme production, CO_2 utilization, harvesting, purification, and WWT.

The biorefinery process starts with the feed pre-treatment. The Feed can either be pre-treated with acid thermal hydrolysis (ATH) or hot water wash (HWW). The resulting treated feed then sent to the enzymatic hydrolysis and fermentation section, where carbohydrates are converted into glucose and ultimately to ethanol. There are two alternatives for obtaining enzymes for saccharification and fermentation. Enzymes can be manufactured on-site or they can be purchased. The outlet streams from the saccharification and fermentation section consist of the gaseous, liquid, and solid product stream. The gaseous products primarily consist of CO_2 and sent to CO_2 utilization section. Two design alternatives considered for CO_2 utilization are MA production and SA production. Based on the work of Bai et al. (2015), SA production from SJ is promising and can occur by consuming glucose and CO_2 in the presence of *E. Coli*. Glucose required for the SA fermentation is provided from the saccharification and fermentation section by splitting a part of glucose to CO_2 utilization section. As glucose split for the SA production will decrease the bioethanol production, therefore,

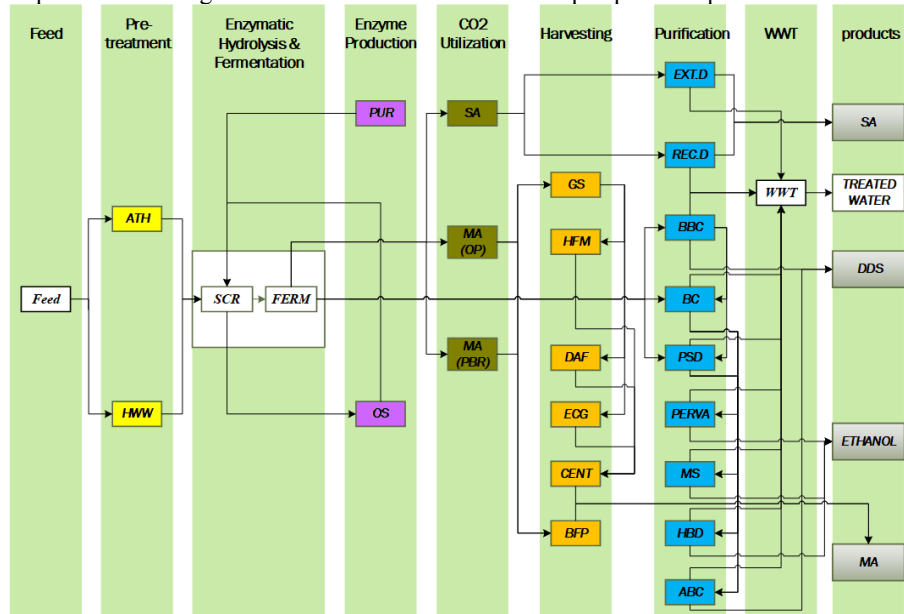
upper bound on SA production is applied. In an alternative method, CO_2 can be utilized to produce microalgae. MA can be cultivated either in open ponds or photobioreactors.


Figure 1. Superstructure for *Saccharina japonica* based biorefinery.

In harvesting section, five design alternatives are considered for MA harvesting and dewatering. The MA are harvested in gravity settler, which can be dewatered either by hallow filter membranes, diffused air flocculation, or electrocoagulation followed by centrifugation. Alternatively, belt filter press can be implemented at the outlet stream of gravity settler. The final concentration of MA from all dewatering alternative is 20 wt.%. The operating data considered for MA production is based on the work of Davis et al. (2011). In the purification section, various streams coming from the fermentation and CO_2 utilization section are processed to their desired level of purity. For example, SA can be purified either by extractive distillation or reactive distillation processes. Unreacted solids from the fermenter can be processed either before the beer column or after the beer column. Furthermore, solid processing can be performed either by centrifuge or belt filter press. As ethanol purification is an energy-intensive process, therefore, multiple design alternatives are considered in superstructure to select optimal topology for its purification. In general, two pathways included in the superstructure are conventional unit operations and novel technologies such as hybrid distillation (HD). The conventional unit operations consist of beer column, rectification column, and molecular sieves (zeolite beds) or pervaporation membranes (cross-linked vinyl alcohol). However, HD includes the combination of distillation columns and pervaporators in series. Furthermore, ethanol purification in the beer column is energy intensive. Therefore, to reduce the energy consumption, the beer column has two design alternatives: a single distillation column and pressure swing distillation (PSD). To reduce freshwater consumption, a complete WWT network incorporated into the superstructure that will treat and recycle wastewater from various process units. Process wastewater is treated using anaerobic digestion, aerobic digestion, and reverse osmosis. The treated water is assumed to be pure and is recycled to the process.

2.3. Objective function and assumptions

The objective function used for this optimization problem are maximization of the net present value (NPV) and minimization of CE, and are defined by:

$$NPV = \sum_{n=0}^{20} \frac{NCF_n}{(1+r)^n},$$ (1)

$$CE = \sum_{k} F_{k,CO2},$$ (2)

where NCF_n is non-discounted cash flow for the year n, and r is the discount rate. $F_{k,CO2}$ is the mass flow rate of CO_2 in the outlet stream k. Various assumptions considered in techno-economic analysis include 20 years project life, 10% discount rate, straight-line depreciation method over 7 years, 30% tax rate, and two-year construction time. The chemical composition of SJ reported by Roesijadi et al. (2010) was used in this work.

2.4. Optimization scenarios

Four optimization scenarios were studied to determine a sustainable biorefinery design. The scenario-1 is a base case design, which consists of traditional bioethanol process. In this scenario, all alternatives related with the utilization of CO_2 were excluded, and the optimization problem was solved with respect to maximizing NPV. The results obtained from this scenario will set targets for further improvements in the process. In scenario-2, all alternatives related to CO_2 utilization were activated and the problem was solved by maximizing the NPV. In addition, there was a restriction that only alternative can be selected for the utilization of CE. In scenario-3, all conditions were similar to that for scenario-2 except objective function which was the minimization of CE. In scenario-4, the synergistic effect of both CO_2 utilization processes was studied by removing the restriction to select only one alternative. The objective function was the maximization of NPV, whereas the second objective function was applied as a constraint in which net CE obtained from the scenario-3 was applied as an upper bound.

3. Results and discussion

The optimal topology obtained for bioethanol production and solid processing in scenario-1 consist of HWW, on-site enzyme production, ethanol purification by PSD and HD, and solid purification after the beer column. The same pathway was obtained in the rest of the scenarios for bioethanol production and solid processing. The products obtained in this scenario are bioethanol and DDS, and their production are presented in Table 1. Results indicated that NPV of this scenario is $38 MM.

Table 1. Mass balance summary.

Scenario	Ethanol yield (gal/t)	Ethanol (Mgal/y)	DDS (kton/y)	MA (kt/y)	SA (kt/y)	CO2 Produced (kt/y)	Net CE (kt/y)
1	83.94	51.37	314.80	0	0	148.7	148.7
2	73.51	44.99	275.67	0	15.30	129.6	121.8
3	83.94	51.37	314.80	62.13	0	148.7	14.9
4	73.51	44.99	275.67	50.91	15.30	129.6	12.9

In scenario-2, SA production was selected to utilize CE. The products obtained in this scenario are bioethanol, DDS, and SA, and their production are presented in Table 1. Only 6% of CO_2 is utilized in this scenario due to the upper bound on the SA

production. The NPV of this scenario is $134 MM. This improvement is attributed to the high selling price of SA, which is almost 5.5 times higher than the current wholesale price of ethanol.

In scenario-3, MA production was selected as an optimal process for the utilization of CO_2. The production rate of products obtained in this scenario are shown in Table 1. Results indicated that ~90% of CO_2 is utilized. The NPV of this scenario is $101 MM.

In scenario-4, both SA and MA production were selected for the utilization of CO_2. The production levels of products obtained in this scenario are given in Table 1. Results indicated that ~90% of CO_2 is utilized. The NPV of this scenario is $180 MM.

3.1. Optimal design

The comparison of all scenarios highlights that process topology obtained in the scenario-4 is both economically and environmentally superior, and therefore, selected as an optimal design. The optimal design shown in the Figure 2 has water consumption of 6.31 gal/gal of ethanol. The total capital investment, total manufacturing cost, and utility cost of optimal design are $377 MM, $153 MM, and $25 MM, respectively. The total capital investment of optimal design is 55% more than that for a standalone process.

3.2. Minimum and maximum selling price of products and seaweed

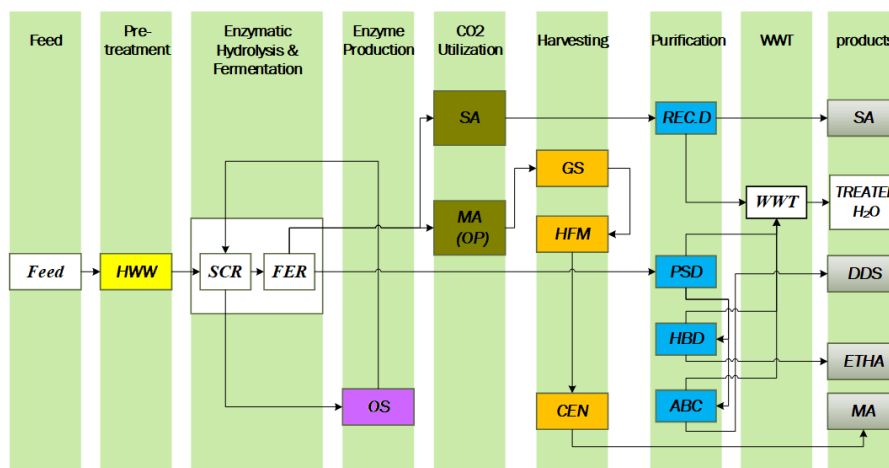
The estimated MESP of optimal design is 1.31 $/gal, which is ~34 times lower than that of scenario-1. Similarly, minimum selling price of DDS, SA, MA are 0.002 $/kg, 1.52 $/kg and 0.256 $/kg. The calculated MSP is 0.127 $/kg.


Figure 2. Optimal structure for bioethanol process

3.3. Sensitivity analysis

Sensitivity analysis was performed to evaluate the impact of key model parameters on MESP. Results presented in Figure 3 indicated that total capital investment, product selling prices, seaweed price, and IRR are the most dominant parameters that effect MESP.
Figure 3. Sensitivity tornado chart for MESP.

4. Conclusion

A process synthesis framework for the optimization of the bioethanol process as well as optimization of CE was proposed. Multiple scenarios were studied based on different optimization criteria to determine the optimal topology. The result indicated that biofuel production from SJ is viable, at MESP of 1.31 $/gal. The proposed framework is an important decision tool for systematically analysing optimal structure for bioethanol process and reducing various pollutants.

Abstract

A novel superstructure is developed for the biochemical conversion of macroalgae to mixed alcohols (MAs). With reference to environmental sustainability of manufacturing process, microalgae production processes are integrated to utilize CO_2 into useful products. Wastewater treatment network was modelled in the process synthesis framework to reduce freshwater consumption. Based on the superstructure, techno-economic mixed integer linear programming model was formulated. The objective function was maximization of the net present value (NPV). The results indicated that biofuel production from macroalgae is economically viable. The minimum selling price of ethanol, heavier alcohols, dry distillery solids, and microalgae are calculated to be 1.26 \$/gal, 2.3 \$/gal, 0.05 \$/kg, and 0.114 \$/kg, respectively. The maximum seaweed purchasing price is calculated to be 113 \$/ton. Furthermore, optimal design has achieved 90% reduction in CO_2 emissions (CE). Sensitivity analysis showed that the selling price of heavier alcohols and purchasing price of macroalgae are the most sensitive parameters to minimum ethanol selling price (MESP).

Keywords: Superstructure optimization, process synthesis, biofuels, macroalgae, volatile fatty acids

1. Introduction

Increasingly high energy prices, volatility of the global oil market, and consistent pressure to reduce greenhouse gases are major challenges within the transportation sector. To address these challenges, energy policies and goals are set by The United States and European Union, which have stimulated global interest in finding sustainable alternatives for replacing crude-oil derivatives (Zittel and Schindler, 2007).

Macroalgae, more specifically brown algae, as the third-generation biomass, are promising feedstock candidates for the biofuel production. Cultivation of macroalgae is considered sustainable, as it requires no arable land, irrigation water, or fertilizer. Among brown alga species, *Saccharina japonica* is extensively studied due to its high carbohydrate content, lack of lignin, and extensively available feedstock (Jiang et al., 2016). Therefore, this study focuses on the biofuel production using *Saccharina japonica* as feedstock.

There are three general pathways to produce biofuels: biochemical, chemical, and thermochemical. With reference to *Saccharina japonica*, arguments supporting

biochemical conversion are the most favourable due to its ability to process feedstock with high moisture content and mild operating conditions in comparison to the alternative pathways. In general, biochemical pathway can produce MAs including ethanol, butanol, and propanol. The biochemical pathway is divided into two alternative pathways: volatile fatty acid platform (VFAP) and sugar platform (SP). In the former, volatile fatty acids (VFAs) are produced by using anaerobic digestion (AD) of the feed using a mixed culture bacterial ecosystem, which can be further processed to produce MAs. In the latter, only bioethanol is produced by extracting sugars from the biomass. Dickson et al. (2018) used a superstructure-based approach to evaluate the economics of bioethanol production from *Saccharina japonica* through SP. They estimated the MESP of 1.97 \$/gal at a plant scale of 612,000 t/y. On the other hand, techno-economic evaluation of biofuel production from VFAP at industrial scale is still limited and should be systematically evaluated in order to determine an optimal biochemical pathway.

In the literature, various bench scale experimental studies demonstrated that VFAP has higher carbon yield (g MAs/g dry feed) than the SP (Pham et al., 2012). This high yield is mainly due to the ability of mixed anaerobic bacteria to utilize all components of the biomass, including carbohydrates, proteins, and lipids, whereas in the case of SP merely carbohydrates contents of biomass are converted to bioethanol (Fasahati and Liu, 2015). Despite the promising yields, the effective and economically viable separation technologies for dehydration of the aqueous VFAs are a major obstacle to industrial scale application of VFAP. This is mainly due to the close boiling point of water and acetic acid, which makes their separation difficult as well as energy intensive by distillation. Another challenge associated with biochemical route is the massive production of CO_2 during fermentation of biomass. A potential method to mitigate direct CE from VFAP is microalgae-based biological utilization. According to Davis et al. (2016), one kilogram of microalgae consumes 1.93 kg of CO_2, which make it a suitable candidate to reduce CE from MAs production.

Based on the presented arguments, this study introduces an optimization-based process synthesis framework for MAs processes that will directly analyse the techno-economic, and environmental trade-offs using a large-scale mixed-integer linear programming model. The proposed framework simultaneously optimizes the topology of MAs manufacturing process as well as determine the optimal strategy to utilize CE produced during fermentation.

2. Methodology

2.1. Problem statement

The optimization problem is defined as determining the optimal design for MAs production process from the given set of alternatives, which has maximum process economics as well as minimum detrimental effects on the environment.

2.2. Overall process description

MAs production process starts with the partial AD of brown algae in the presence of iodoform inhibitor, at 30 PPM concentration (Granda et al., 2009). The operating conditions of AD are 5 days of retention time at 13 wt.% solid loading and 35 °C (Pham et al., 2012). The overall efficiency ranges from 0.307-0.412 g VFAs/ g dry feed. The outlet stream from the digester consists of solid, liquid, and gaseous products. Products

from the digester are sent to flash drum to separate light gases such as hydrogen and carbon dioxide from the solid and the liquid products. Light gases in the vapor stream of flash drum are then sent to pressure swing adsorption to separate hydrogen from carbon dioxide, the former can be utilized during hydrogenation of VFAs to MAs. Solids are then separated from the liquid products by using solid separation technologies such as mechanical separator followed by drying. About 20 wt.% of solids are sent back to digester as an inoculum and nutrient source, while remaining fraction can be sold as animal feed called dry distillery solids. Liquid stream from the solid separation area is sent to VFAs recovery section, where VFAs are recovered at 99.9 wt.% using extraction column, rectification column, decanter, and stripping column. The concentrated VFAs are then hydrogenated for the synthesis of mixed alcohols. The hydrogenation process is a gas phase process, which takes place at 290 °C and 60 bars in the presence of cobalt catalyst to give a high alcohol yield of 97 wt.%. The catalyst consumption as well as hydrogen requirement are 0.46 mg catalyst/ kg MAs, and molar ratio of 2.1:1 (H2/VFA), respectively. The hot effluent of the hydrogenation reactor is cooled and sent to the two flash drums operating in series to recover vapours, which are recycled to the hydrogenation reactor. The bottom stream of the final flash drum consists of 25 wt.% water, 42 wt.% ethanol, 19 wt.% propanol, and 12 wt.% butanol, and is sent to the alcohol recovery unit. Herein, MAs are dehydrated by the molecular sieves, and sent to the alcohol distillation column to separate ethanol from butanol and propanol. The 99.9 wt.% purity of ethanol is obtained in the overhead stream of distillation column. Propanol and butanol are obtained in the bottom stream of column and considered as co-products.

2.3. Superstructure development

Design alternatives are added in the previously mentioned baseline process to develop a superstructure. The superstructure is shown in Figure 1 and consists of six sections: (1) fermentation and solid processing, (2) volatile fatty acids recovery, (3) hydrogenation, (4) mixed alcohols recovery, (5) utilization of carbon dioxide, and (6) wastewater treatment. The proposed superstructure contains fourteen design alternatives at various processing stages. The general mathematical model is similar to one reported in our previous work (Dickson et al., 2018). The design alternatives for solid processing include mechanical separator and centrifuge. As dehydration is energy intensive, five design alternatives are considered for recovering VFAs and MAs. VFAs can be recovered either by classical extraction/distillation processes or hybrid pervaporation (PV). The classical methods for recovering VFAs are similar to that described in Section 2.2. In PV, pervaporator is integrated into the classical process, which increases the concentration of VFAs from 5 wt.% to 10 wt.% by removing ~50 wt.% of the total water flow. Removal of this large amount of water directly impacts the process economics. Likewise, MAs can be dehydrated by three design alternatives to achieve a desired level of purity for their applications as a fuel. Dehydration can be performed by either molecular sieves, pervaporator, or vapor permeation. In all design alternatives, the target purity of ethanol is 99.5 wt.%.

To reduce CE, seven design alternatives are considered for microalgae cultivation and harvesting. Microalgae can be cultivated either in open ponds or photobioreactors. For its harvesting and dewatering, five design alternatives are considered. The microalgae are harvested in gravity settler, which can be dewatered either by hallow filter membranes, diffused air flocculation, or electrocoagulation followed by centrifugation. Alternatively belt filter press can be implemented at the outlet stream of gravity settler. The final concentration of microalgae from all dewatering alternative is 20 wt.%. The

operating data and equipment costs considered for microalgae production are based on the work of (Davis et al., 2016).

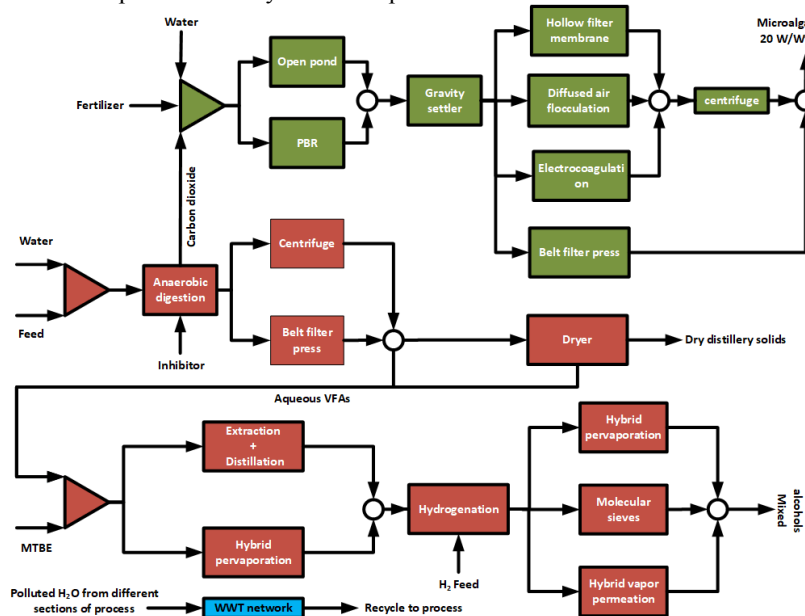
A complete wastewater treatment network is incorporated that will treat and recycle wastewater from various process units including distillation columns, blowdown from the cooling tower, and blowdown from the boilers. Process wastewater is treated using anaerobic digestion, aerobic digestion, and reverse osmosis. The treated water is assumed to be pure and is recycled to the process.


Figure 1. Superstructure for producing mixed alcohol from *Saccharina japonica*.

2.4. Objective function and assumptions

The objective function used for this optimization problem is maximization of the NPV and given in Eq. (1)

$$NPV = \sum_{n=0}^{20} \frac{NCF_n}{(1+r)^n},$$

(1)

where NCF_n is non-discounted cash flow for the year n, and r is the discount rate. Various assumptions considered in techno-economic analysis include: 20 years project life, 10% discount rate, straight line depreciation method over 7 years, 30% tax rate, and two-year construction time. The chemical composition of *Saccharina japonica* reported by Roesijadi et al. (2010) was used in the simulation. An efficiency of 0.35 g VFA/g of dry biomass is considered in AD. The selling prices of products such as ethanol, heavier alcohols, DDS, and microalgae considered in this study to calculate process revenue were 0.72 \$/kg, 1.13 \$/kg, 0.13\$/kg, and 0.5 \$/kg, respectively. Likewise, costs of raw materials such as brown algae, MTBE, cooling H_2O, chilled H_2O, H_2, LP steam, and electricity were 68 \$/t, 1100 \$/t, 0.013 \$/t, 1 \$/t, 1.5 \$/t, 12.68 \$/t, and 0.0622 \$/kWh, respectively.

3. Results and discussion

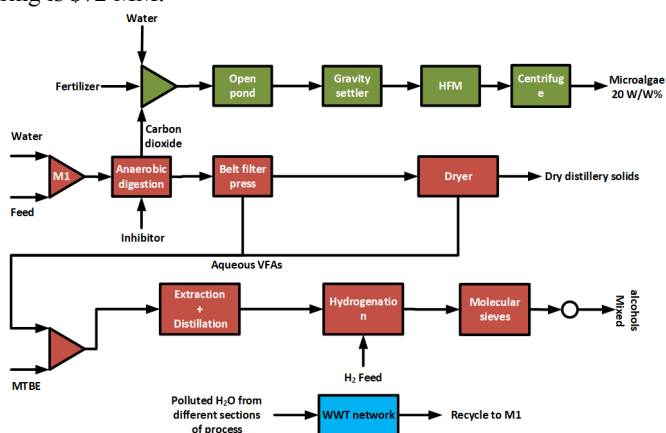
The proposed process synthesis framework was implemented in GAMS (25.0.2) to determine optimal process design for MAs production process and CE utilization. The digester receives 612,000 t/y dry feed for biofuel production. The optimal manufacturing process for MAs synthesis shown in Figure 2 consists of AD, solid separation by belt filter press and dryer, VFAs dehydration by the extraction followed by distillation, hydrogenation, and MAs dehydration by molecular sieves followed by distillation. For CO_2 utilization, microalgae cultivation in open pond, harvesting by gravity settler, and dewatering by hollow filter membranes followed by centrifugation were selected as an optimal strategy. The products obtained from the biorefinery are ethanol, butanol, propanol, DDS, and microalgae. Their production rates are 32 mgal/y, 8 mgal/y, 14 mgal/y, 258 kt/y, and 49 kt/t, respectively. The NPV, TCI, TCOM, and utilities costs are $124.7 MM, $328 MM, $31 MM, $141.7 MM, respectively. By integrating microalgae process to MAs manufacturing process, CE are decreased from 117 kt/y to 11kt/y. The cost of integration of microalgae process into the MAs manufacturing is $72 MM.


Figure 2. Optimal structure for mixed alcohol manufacturing process.

3.1. Minimum and maximum price of products and seaweed

The minimum selling price of products can be defined as the selling price of products that makes the NPV equal to zero. The estimated MESP of optimal design is 1.26 $/gal at the current whole sale price of all products. Similarly, minimum selling price of higher alcohols, DDS, and microalgae are 2.3 $/gal, 0.05 $/kg, and 0.114 $/kg.

The maximum seaweed price (MSP) can be defined as the purchasing price of seaweed that makes the NPV equal to zero. The estimated MSPP of optimal design is 111 $/ton, which is 1.63 times more than that of base case price.

3.2. Sensitivity analysis

Sensitivity analysis was performed to evaluate the effect of selling and purchasing prices of products and seaweed, respectively. Each sensitivity parameter was varied by ± 10% from the base value. The result of sensitivity analysis is presented as a tornado chars in Figure 3. Result indicated selling price of heavier alcohols and seaweed price are most dominant parameter that effect MESP.
Figure 3. Sensitivity tornado chart for MESP.

4. Conclusion

An optimization-based framework for the MAs process synthesis as well as optimization of CE was proposed in this study. A rigorous techno-economic objective function (NPV) was used to investigate various economic parameters such as minimum selling price of products and MSP. The result indicated that biofuel production by VFAs route is viable; however, some challenges such as biomass price and its availability should be addressed before implementation of such biorefineries.

Abstract

This paper presents a mathematical programming approach for the design of counter current gasketed plate heat exchangers. The objective function corresponds to the minimization of the heat transfer area and the set of constraints includes the thermofluid-dynamic equations for evaluation of film coefficients and pressure drops, the heat transfer rate equation, and bounds on velocities and pressure drops. We also consider discrete geometric options. The expressions of the objective function and constraints are reformulated into a linear form, without loss of rigor, i.e. the solution of the linear problem is exactly the same of the original one. Therefore, problems related to nonconvergence or multiple local optima with different values of objective function are avoided. An example of a typical design task is employed to illustrate the performance of the proposed approach.

Keywords: Optimization, Plate heat exchangers, Design

1. Introduction

Shell-and-tube heat exchangers are the main type of thermal equipment employed in chemical process plants. However, gasketed plate heat exchangers can be a better option in several thermal tasks. Despite its limitations for more severe operational conditions, plate heat exchangers present several advantages, e.g. film coefficients are higher, cleaning procedures are easier, they are less prone to fouling problems, etc. The design optimization problem seeks to identify the plate heat exchanger associated to the minimum area, according to the available pressure drops for both streams. In our case, the design variables are the number of plates and the plate size. There is no phase change along the heat transfer surface. The thermofluid-dynamic model is based on Kakaç et al.(2012), particularly employing the equations describe in Rao et al. (2005).

2. Problem Formulation

The heat exchanger model is composed of a set of nonlinear equations, encompassing the the heat transfer rate equation, correlations for the evaluation of the heat transfer coefficients and pressure drops, and performance constraints (in the presentation of the model here, the parameters are identified by a symbol ^ on top).

2.1. Heat transfer rate equation

The heat transfer rate equation is:

$$Q = UA_{req}\Delta\hat{T}_{lm}$$
(1)

where U is the overall heat transfer coefficient, A_{req} is the required area and $\Delta\hat{T}_{lm}$ is the logarithmic mean temperature difference. The expression of the overall heat transfer coefficient is:

$$U = \frac{1}{1/h_h + \hat{R}f_h + \hat{t}/\hat{k}w + \hat{R}f_c + 1/h_c}$$
(2)

where $\hat{R}f$ is the fouling factor, $\hat{t}$ is the plate thickness, $\hat{k}w$ is the thermal conductivity of the plate material.

2.2. Convective heat transfer coefficients

The Nusselt number can be evaluated from the Reynolds and Prandtl numbers through the following correlation, where the index *sSt* represents the hot and cold streams (*sSt* ∈ {*h,c*}:

$$Nu_{sSt} = \hat{C}Re_{sSt}^{\hat{a}}\hat{P}r_{sSt}^{\hat{b}}$$
(3)

where the Reynolds number is expressed in relation to the hydraulic diameter:

$$Re_{sSt} = G_{sSt}\,\hat{D}hyd/\hat{\mu}_{sSt}$$
(4)

The expressions of mass flux is:

$$G = \frac{\hat{m}_{sSt}/(Nch/2)}{\hat{b}\,Lw}$$
(5)

where $\hat{m}_{sSt}$ is the mass flow rate, *Nch* is the total number of channels, and $\hat{b}$ is the flow channel gap.

2.3. Pressure drops

The pressure drop encompasses the head loss in the flow channels and in the distribution plate orifice:

$$\Delta P_{sSt} = f_{sSt}\frac{(Lp+Dp)}{\hat{D}hyd}\frac{G_{sSt}^2}{2\hat{\rho}_{sSt}} + 1.4\frac{[\hat{m}_{sSt}/(\pi Dp^2/4)]^2}{2\hat{\rho}_{sSt}}$$
(6)

where *Dp* f_{sSt} is the Darcy friction factor:

$$f_{sSt} = \hat{K}Re_{sSt}^{-\hat{n}}$$
(7)

2.4. Performance constraints

The heat transfer area must be higher the required area according to a previously established "excess area" parameter:

$$A_{req} \leq A[100/(100+\hat{A}_{exc})] \tag{8}$$

where the heat transfer area depends on the plate features and the total number of plates:

$$A = \hat{\phi} Lw\,Lp(Nt-2) \tag{9}$$

where $\hat{\phi}$ is the enlargement factor of the plate. The pressure drop of both fluids and flow velocities must be bounded according to the available values for both streams:

$$\Delta P_{sSt} \leq \Delta \hat{P}_{sSt}^{max} \tag{10}$$

$$\hat{v}^{min} \leq G_{sSt}/\hat{\rho}_{sSt} \leq \hat{v}^{max} \tag{11}$$

2.5. Objective function

The heat transfer area must be higher the required area according to a previously The objective function corresponds to the minimization of the heat transfer area:

$$\min \quad A \tag{12}$$

3. Discrete Options

It is important to observe that the design variables are discrete; therefore, its representation in the model formulation is associated to a set of binary variables, as follows:

$$Nt = \sum_{snt=1}^{sntmax} p\hat{N}t_{snt}\,yNt_{snt} \tag{13}$$

$$Lp = \sum_{sp=1}^{spmax} p\hat{L}p_{sp}\,yP_{sp} \tag{14}$$

$$Lw = \sum_{sp=1}^{spmax} p\hat{L}w_{sp}\,yP_{sp} \tag{15}$$

where Nt is the total number of plates (discrete options $p\hat{N}t_{snt}$ associated to the binary variables yNt_{snt}), Lp and Lw are the plate effective length and width (discrete options $p\hat{L}p_{sp}$ and $p\hat{L}w_{sp}$ associated to the binary variables yP_{sp}). Since one of the options must be selected in the solution, these constraints are complemented by:

$$\sum_{snt=1}^{sntmax} yNt_{snt} = \sum_{sp=1}^{spmax} yP_{sp} = 1 \tag{16}$$

4. Problem Reformulation

The reformulation of the problem to a linear structure employs the procedure applied by Gonçalves et al. (2017) for the optimization shell-and-tube heat exchangers. This approach involves three steps: (i) Substitution of the binary representation of the discrete design variables (Eq. (13-16)) in the heat exchanger model equations and objective function (Eq. 1-12), (ii) Reorganization of the resultant mathematical expressions in a product of binaries, and (iii) Substitution of the product of binaries by a set of linear inequalities.

The procedure is illustrated here through the substitution of the design variables in Eq. (5) by their corresponding representation using binary variables as follows:

$$G_{sSt} = \frac{[2\hat{m}_{sSt} / \sum_{snt=1}^{sntmax} (p\hat{N}t_{snt} - 1)yNt_{snt}]}{(\hat{b} \sum_{sp=1}^{spmax} p\hat{L}w_{sp}yP_{sp})} \tag{17}$$

Due to the nature of the binary variables and the fact that only one option can be selected (Eq. (16)), this expression is equivalent to the following representation using product of binaries:

$$G_{sSt} = \frac{2\hat{m}_{sSt}}{\hat{b}} \sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} \frac{1}{p\hat{L}w_{sp}(p\hat{N}t_{snt} - 1)} yNt_{snt} yP_{sp} \tag{18}$$

Substituting the product of binaries by a continuous nonnegative variable $w_{snt,sp}$, together with the inclusion of a set of auxiliary inequalities, Eq. (18) can be substituted by the following set of linear relations:

$$G_{sSt} = \frac{2\hat{m}_{sSt}}{\hat{b}} \sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} \frac{1}{p\hat{L}w_{sp}(p\hat{N}t_{snt} - 1)} w_{snt,sp} \tag{19}$$

$$w_{snt,sp} \le yNt_{snt} \tag{20}$$

$$w_{snt,sp} \le yP_{sp} \tag{21}$$

$$w_{snt,sp} \ge yNt_{snt} + yP_{sp} - 1 \tag{22}$$

5. Mixed-Integer Linear Programming Formulation

The application of the procedure described above yields the following linear design problem (complemented by Eqs. (10,11, 16, 19-22)):

$$\min \sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} \hat{\phi} pNt_{snt} pLw_{sp} pLp_{sp} w_{snt,sp} \tag{23}$$

subject to:

$$\hat{Q}_c \left\{ \sum_{sSt} \sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} \left[\frac{\hat{D}hyd^{\hat{a}-1}}{\hat{C}\,\hat{k}_{sSt}\hat{P}r_{sSt}^{\hat{b}}} \left(\frac{\hat{b}\hat{\mu}_{sSt}}{2\hat{m}_{sSt}} \right)^{\hat{a}} p\hat{L}w_{sp}^{\hat{a}} (p\hat{N}t_{sNt}-1)^{\hat{a}} w_{snt,sp} + \hat{R}f_{sSt} \right] \right.$$

$$\left. + \frac{\hat{t}}{\hat{k}w} \right\} \leq \left(\sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} p\hat{N}t_{snt} p\hat{L}w_{sp} p\hat{L}p_{sp} w_{snt,sp} \right) \Delta\hat{T}_m \left(\frac{100}{100+\hat{A}_{exc}} \right)$$

$$\tag{24}$$

$$\Delta P_{sSt} = \left(\frac{\hat{K}}{2\hat{D}hyd\,\hat{\rho}_{sSt}} \right) \left(\frac{\hat{b}\,\hat{\mu}_{sSt}}{2\hat{m}_{sSt}\hat{D}hyd} \right)^{\hat{n}} \left(\frac{2\hat{m}_{sSt}}{\hat{b}} \right)^2 \sum_{snt=1}^{sntmax} \sum_{sp=1}^{spmax} \left[p\hat{L}w_{sp}(p\hat{N}t_{sNt}-1) \right]^{\hat{n}-2}$$

$$\left(p\hat{L}p_{sp} + p\hat{D}p_{sp} \right) w_{snt,sp} + \left(\frac{11.2\hat{m}_{sSt}^2}{\hat{\rho}_{sSt}\pi^2} \right) \sum_{sp=1}^{spmax} \left(\frac{1}{p\hat{D}p_{sp}^4} \right) yP_{sp}$$

$$\tag{25}$$

6. Numerical Results

The performance of the proposed approach is illustrated through the design of a plate heat exchanger for the thermal task described in Table 1, based on Kakaç and Liu (2002). The thermal conductivity of the plate material is 17.5 W/m°C) and the plate thickness is 0.6 mm. The hydraulic diameter associated to the heat exchanger is 4.8 mm, the enlargement factor of the area is 1.25 and the plate gap is 3 mm. The available pressure drop is 600 kPa for both streams. The fouling factor is $5\cdot10^{-5}$ m²K/W for the hot stream and it is null for the cold stream. The flow velocity must be between 0.4 m/s and 2.0 m/s for both streams. The minimum excess area is assumed equal to 10%.

The search space corresponds to 10 plate sizes with widths from 0.4 m to 1.3 m and lengths from 1.1 m to 2.0 m, associated to increments of 0.1 m. Additionally, an extra plate size is inserted in the search space based on a solution proposed by Kakaç et al. (2012) with width and length equal to 0.63 m and 1.35 m. The number of plates in the search space vary from 50 to 150 plates. The corresponding set of port diameters corresponds to an area of each port equivalent to 3% of the total area of the plate. The

parameters associated to the correlations employed from Rao et al. (2005) are $\hat{C} = 0.218$, $\hat{a} = 0.65$, $\hat{b} = 1/3$, $\hat{K} = 21.41$, $\hat{n} = 0.301$.

Table 1: Stream data for the optimization problem.

Stream	m (kg/s)	T_i (°C)	T_o (°C)	ρ (kg/m³)	Cp (J/kg°C)	μ (mPa·s)	k (W/mK)
Hot	140	65	45	985	4183	0.509	0.645
Cold	140	22	42	995	4178	0.766	0.617

The solution obtained using the proposed design optimization procedure is compared in Table 2 with the solution based on Kakaç et al. (2012) for the same task.

Table 2: Stream data for the optimization problem.

Solution	A (m^2)	Areq (m^2)	Nt	Lp (m)	Lw (m)	U (W/m^2°C)	ΔP hot (kPa)	ΔP cold (kPa)
Proposed solution	102.06	92.54	96	1.35	0.63	5503	490	546
Literature	111.63	95.54	105	1.35	0.63	5330	424	471

The results in Table 2 indicate that the optimization found a solution with a smaller area, associated to a reduction of 8.6% in relation to the solution found in the literature data. The plate size is identical in both solutions, but the solution obtained using the proposed procedure has a smaller number of plates (i.e. the solution from the literature has more plates than necessary for a given excess area of 10%).

7. Conclusions

This paper presented a mathematical programming formulation for the optimization of countercurrent plate heat exchangers. Starting from a set of nonlinear equations of the heat exchanger modelling, mathematical manipulations are applied to yield a mixed-integer linear programming problem. Therefore, the global optimum of the design solution can be found without any drawbacks associated to nonconvergence issues. Due to the flexibility of the proposed approach other thermal tasks could also be addressed using the same mathematical scheme (e.g. vaporization or condensation). Possible obstacles to extend the proposed approach would be presence of thermofluidynamic models based on mathematical relations with variables that cannot be explicitly represented in relation to the design variables.

Abstract

Multi-stage nonlinear model predictive control (msNMPC) is a robust control strategy based on the description of the uncertainty propagation through a dynamic system via a scenario tree and is one of the least conservative approaches to robust control. The computational complexity of the msNMPC, however, grows with respect to the number of uncertainties and with respect to the length of the prediction horizon. This paper presents a new approach, where the optimal cost-to-go function is approximated after a specific point in time, here in particular by neural networks, so the independent branches do not have to be optimized but are approximated. The optimization might be casted over the robust horizon only, which reduces the computational burden, but still guarantees robust satisfaction of the constraints. Moreover, this approach allows to consider any length of the prediction horizon for the same computational cost. The neural network models are trained offline using the optimal profiles in all branches of the scenario tree. The potential of the proposed approach is demonstrated by simulation studies on a semi-batch reactor.

Keywords: Nonlinear model predictive control, robust control, neural networks.

1. Introduction

Robust nonlinear model predictive control (NMPC) methods aim at overcoming the limitations of conventional NMPC w.r.t. the influence of model errors and presence of uncertainty. Very popular are min-max approaches (Witsenhausen, 1968) despite that these approaches are quite conservative because they ignore the fact that new measurements will be available in the future and that the future control actions can be adapted accordingly. Another possibility to formulate the NMPC controller within the framework of stochastic optimization. Such a formulation leads to a multi-stage NMPC (msNMPC) (Lucia et al., 2013), which has shown very promising results

for challenging nonlinear examples. Nevertheless, the main disadvantage of the msNMPC lies in solving a large-scale optimization problem. The size of the optimization problem grows exponentially with the length of the prediction horizon and with the number of uncertainties. To overcome this problem, deep neural networks (NNs) (LeCun et al., 2015) were proposed to approximate the NMPC policy (Lee and Lee, 2005) or the msNMPC policy (Karg and Lucia, 2018).

A neural networks-based (NN-based) msNMPC is investigated in this paper. The NNs are used to approximate the optimal cost-to-go functions of different scenarios. Then, after a specific point in time, the independent branches do not have to be optimized but are approximated using the NNs, which results in the reduction of the computational burden, that the approach retains the same robustness guarantees as the standard msNMPC. To demonstrate the potential of the proposed strategy, simulation tests are performed and the control performance of the approach is compared to standard NMPC and msNMPC approaches.

2. Multi-stage NMPC

Multi-stage NMPC is a robust NMPC strategy that is based on the description of the uncertainty propagation through a dynamic system by a tree of discrete scenarios (Lucia et al., 2013). Each branch of the tree represents an evolution of the system states under a certain realization of the uncertainty. The main advantage of this formulation is that the availability of information provided by the future measurements is taken into account, so that the future control inputs depend on the future knowledge and can be adapted w.r.t. the expected realizations of the uncertainty.

The optimization problem to be solved at each sampling instant using the msNMPC reads as:

$$
\min_{x_{k+1}^j, u_k^j, \forall (j,k) \in I_{N_p}} \sum_{i=1}^{N} \omega_i \overbrace{\left(\sum_{k=0}^{N_p-1} L(x_{k+1}^j, u_k^j) + \phi(x_{N_p}^j) \right)}^{J_i(x_0)}, \qquad \forall x_{k+1}^j, u_k^j \in S_i, \qquad (1a)
$$

$$
\text{s.t. } x_{k+1}^j = f(x_k^{p(j)}, u_k^j, d_k^{r(j)}), \qquad \forall (j, k+1) \in I_{N_p}, \qquad (1b)
$$

$$
g(x_{k+1}^j, u_k^j) \leq 0, \qquad \forall (j, k+1) \in I_{N_p}, \qquad (1c)
$$

$$
u_k^j = u_k^l \text{ if } x_k^{p(j)} = x_k^{p(l)}, \qquad \forall (j,k), (l,k) \in I_{N_p}, \qquad (1d)
$$

where, at stage $k+1$ and position in the tree j, the state vector x_{k+1}^j depends on $x_k^{p(j)}$, u_k^j and $d_k^{r(j)}$, i.e., the parent state vector, the vector of control inputs, and the realization of the uncertainty, respectively, via the system dynamics equations (1b). The scenario tree originates at the root node x_0 and is defined with the same number (s) of branches at each node, given by $d_k^{r(j)} \in \{d_k^1, d_k^2, \ldots, d_k^s\}$, and with the index set I_{N_p}. Constants N, N_p are the number of scenarios and the length of the prediction horizon, respectively. The functions $L(\cdot)$ and $\phi(\cdot)$ denote stage and terminal costs, respectively. The constraints on inputs and states are denoted by $g(\cdot)$. Parameter $\omega_i \geq 0$ is a weighting coefficient of the ith scenario (S_i) and is chosen based on the relative importance of the scenario while $\sum_{i=1}^{N} \omega_i = 1$. The constraints (1d) are non-anticipativity constraints, which denote that all the control inputs that branch at the same parent node must be equal. The branching of the tree stops at a certain point, which is denoted as the robust horizon of the length N_r, which can be set to 1 or 2 in practice (Lucia et al., 2013). Note that after N_r, all the scenarios become independent.

3. Neural networks-based multi-stage NMPC

The size of the optimization problem grows exponentially with the length of the prediction horizon and with the number of uncertainties. The main idea of this work is to use NNs (LeCun et al., 2015; Daosud et al., 2017; Kittisupakorn et al., 2017) to approximate the optimal cost-to-go

function of the individual scenarios such that the contribution of the independent scenarios can be approximated after the robust horizon when solving (1). This allows simultaneously for efficient real-time execution, for robust constraint satisfaction, and for an efficient training of NNs, since only an optimization over a single branch is needed therein. The NN is trained to give an approximate cost $\tilde{J}_i^*(x_{k,p}, W, b)$ of the scenario S_i, where $x_{k,p}$ is a training point for which (1) is solved. The optimal weights (W) and biases (b) for each neuron are found via

$$\min_{W,b} \sum_{p=1}^{N_t} (J_i^*(x_{k,p}) - \tilde{J}_i^*(x_{k,p}, W, b))^2, \tag{2}$$

where N_t is the number of data pairs $(J_i^*(x_{k,p}), x_{k,p})$.

The NN-based msNMPC then approximates the problem (1) as:

$$\min_{x_{k+1}^j, u_k^j, \forall (j,k) \in I_{N_c}} \sum_{i=1}^{N} \omega_i \left(\sum_{k=0}^{N_c-1} L(x_{k+1}^j, u_k^j) + \tilde{J}(x_{N_c}^j) \right), \qquad x_{k+1}^j, u_k^j \in S_i, \tag{3a}$$

$$\text{s.t. Eqs. (1b)--(1d)}, \qquad \forall (j, k+1) \in I_{N_c}, \tag{3b}$$

$$g_{SS}(x_{k+1}^j) \leq 0, \qquad \forall (j, k+1) \in I_{N_c}, \tag{3c}$$

where $N_c \in \{N_r, \ldots, N_p - 1\}$ is the length of the reduced prediction horizon and functions $g_{SS}(\cdot)$ represent the so-called safe sets (Rosolia and Borrelli, 2017), which constrain the states such that these are in the range of the data in the training set of the NNs. In practice, construction of suitable safe sets can be cumbersome, so one can then decide to drop the safe sets entirely from the formulation (3) or replace them with tightened $g(\cdot)$. This however requires tuning of N_c by increasing it to guarantee recursive feasibility of the problem. This path is examined in this study.

4. Case study

We use a challenging case study from the chemical engineering domain, i.e., a semi-batch reactor that is equipped with a cooling jacket, where the cooling jacket inlet temperature is controlled by a thermostat (Thangavel et al., 2015). An exothermic reaction of A and B produces C. The model includes mass balances for the reactor content (expressed through reactor volume V and species concentrations c_A, c_B, and c_C) and energy balances of the reaction mixture, the reactor jacket and the thermostat (expressed using the temperature of the reaction mixture T, cooling jacket T_J, and jacket inlet temperature $T_{J,in}$. The control inputs are the feed rate of the component B and the set point of jacket inlet temperature, summarized in $u = (\dot{V}_{in}, T_{J,in,set})^T$. The detailed mathematical model with all parameters and considered constraints can be found in Thangavel et al. (2015).

The control goal is to maximize the concentration of C in the fixed batch time $t_f = 1,800\,\mathrm{s}$. Thus, a shrinking-horizon strategy is used and the sampling time is taken as 120 s. The constraints on T and V must be respected despite a $\pm 30\%$ uncertainty in the reaction enthalpy H and in the reaction rate k, with nominal values $H_{nom} = -355\,\mathrm{kJ\,mol^{-1}}$ and $k_{nom} = 3.35 \times 10^{-7}\,\mathrm{m^3\,mol^{-1}\,s^{-1}}$.

5. Results

The dynamic optimization problems are solved using orthogonal collocation on finite elements using CasADi (Andersson et al., 2012). The nonlinear programs are solved via Ipopt (Wächter and Biegler, 2006). The plant response is simulated using a 4th-order Runge-Kutta scheme. All the results are obtained on a workstation with Intel i7 running at 2.4 GHz with 8 GB RAM.

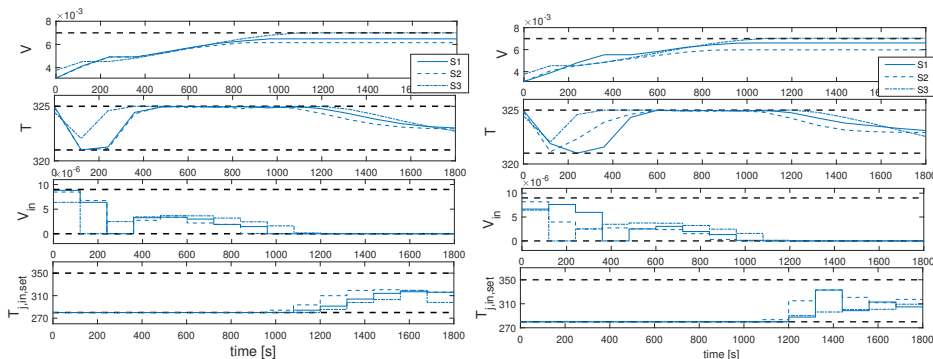
Neural networks with several hidden layers (deep NNs) are employed due to the theoretical evidence of outperforming the shallow NNs (Safran and Shamir, 2016). For the approximation of


Figure 1: Input/state trajectories for $[S_1, S_2, S_3]$; Left: standard NMPC, right: NNs-based NMPC.

Algorithm	$c_C(t_f) \, [\text{mol m}^{-3}]$	Cons. viol. $[\text{m}^3 \, \text{s}^{-1}]$	Cons. viol. $[\text{K s}^{-1}]$
standard NMPC	$[379.1, 470.8, 525.9]$	$[0, 0, 1.03] \times 10^{-6}$	$[0, 6.48, 0] \times 10^{-8}$
NNs-based NMPC	$[378.3, 470.0, 526.5]$	$[0, 0, 1.64] \times 10^{-5}$	$[0, 0, 9.39] \times 10^{-4}$

cost-to-go functions, a state vector $x = (V, c_A, T, T_j, T_{j,in}, t)^T$ is used as an input to the NN, which represents the minimal number of states (all other states can be obtained as combinations of these states) and the current time t is considered due to the problem nature (batch, shrinking horizon).

The NNs are trained with the data generated for 360 batches, where the initial conditions are randomly varied, w.r.t. the ones in Thangavel et al. (2015), between $\pm 5\,\text{K}$, $\pm 5 \times 10^{-4}\,\text{m}^3$, and $\pm 50°C\,\text{mol m}^{-3}$ for the temperatures, volume, and concentration of A, respectively. 75 % of the 34,560 data points is used for training and the remaining 25 % for testing. The structure of NN is selected based on the MSE criterion (Kittisupakorn et al., 2009). The activation function is the tanh function. The number of hidden nodes is varied between 2–34. The resulting structure of the NNs consists of 2 hidden layers with different number of nodes for different scenario (S_i).

We compare the performance of the standard NMPC and NNs-based NMPC for some selected scenarios. Figure 1 shows trajectories of constrained states and control inputs in $S_1 = (H_{min}, k_{min})$, $S_2 = (H_{nom}, k_{nom})$, and $S_3 = (H_{max}, k_{max})$. The optimal solution tries to feed B as much as possible at the beginning of the batch. Then the feed rate is adjusted to respect the temperature constraints. At these phases cooling is maximal. Towards the end of the batch, feeding is stopped since either maximal volume is reached or any further feeding only dilutes the reaction mixture and decreases the final concentration of C. At this phase, cooling is adjusted to respect the constraints on T. It can be seen that the use of the NNs-based NMPC results in similar state and input trajectories as the standard NMPC. Both control methods result in similar final concentrations of C (see Tab 1), while the constraint violations occur only marginally, due to numerical reasons. The average CPU times per sampling time are 0.35 s and 0.14 s for standard and NN-based NMPC, respectively.

For the msNMPC, we use $N_r = 1$. Nine scenarios are considered with all the combinations of extremal and nominal values of the uncertain parameters. As we do not use safe sets in this work, a tuning has to be done for the value of N_c. The tuning procedure is illustrated in Fig. 2, where state and input trajectories resulting from the use of NN-based msNMPC are shown for different values of N_c under the most extreme scenario (H_{min}, k_{max}), i.e., the most exothermic and the fastest reaction. As the NN-based msNMPC is myopic from its nature, large constraint violations can occur if N_c is too small. While the msNMPC would be initialized with $N_p = 15$, the NN-based
Figure 2: Input/state profiles using the NN-based msNMPC for (H_{min}, k_{max}) and different N_c.
Figure 3: Input/state profiles using the NN-based msNMPC for the 9 scenarios.

Table 2: Performance comparison msNMPC vs. NN-based msNMPC averaged over 9 scenarios.

Algorithm	$c_C(t_f)\,[\mathrm{mol\,m^{-3}}]$	Cons. viol. $[\mathrm{m^3\,s^{-1}}]$	Cons. viol. $[\mathrm{K\,s^{-1}}]$
msNMPC	354.4	3.72×10^{-10}	1.36×10^{-2}
NN-based msNMPC	371.5	3.50×10^{-4}	0

msNMPC is able to robustly satisfy the constraints with $N_c = 4$.

Figure 3 shows the state and input trajectories resulting from the use of the NN-based msNMPC in all 9 scenarios. The trajectories show great similarity with the trajectories obtained by msNMPC.

The performance comparison averaged over the 9 scenarios considered is shown in Tab. 2 for msN-MPC and NN-based msNMPC. Use of both algorithms results in certain minor constraint violations while the control performance is better when using NN-based msNMPC, which is attributed to slightly greater constraints violations. The optimization problems solved by the msNMPC have at most 5,686 optimization variables and are solved in average in 2.19 s, while NN-based msN-MPC requires 0.95 s of CPU time in average for solving optimization problems with at most 1,528 variables.

Figure 4 shows input and state trajectories obtained using NN-based msNMPC for 40 batches with different values of the uncertain parameters being randomly generated with uniform distribution ($\pm30\%$) around the nominal values. It can be seen that the performance is satisfactory for all batches and that the constraints are consistently respected, though with minor violations. The msNMPC and NN-based msNMPC achieve the maximum concentration of product C as $313.6\,\mathrm{mol\,m^{-3}}$ and $297.6\,\mathrm{mol\,m^{-3}}$, respectively. The 5 % performance loss of NN-based NMPC is attributed to the interpolation inaccuracy of the neural networks and represents the price to pay for the computational efficiency.
Figure 4: Input/state trajectories for 40 batches with random uncertainties (NN-based msNMPC).

The developed NN-based msNMPC scheme shows a great promise regarding an efficient implementation of the robust NMPC schemes. The results obtained on the challenging case study are encouraging, despite the fact that certain portion of performance must be given up for robust constraint satisfaction. This aspect can be further improved when safe sets are used. Another way of performance improvement, which we will concentrate on in our further studies, is the reduction of the sampling time. Our preliminary results show that using NN-based msNMPC and safe sets, one can reduce the sampling time up to 12 s and N_c to 1, while the CPU time reduces to 0.8 s in the worst case. Note that the use of msNMPC here requires 15 s for execution in the worst case.

6. Conclusions

Non-conservative robust NMPC control methods, such as msNMPC, are challenged by a large computation burden. To deal with this problem, an NN-based msNMPC is proposed. The idea pursued is to simplify the optimization problems of the msNMPC by approximating the cost-to-go functions of independent scenarios (after the robust horizon of the msNMPC). In this work, neural networks are used for this purpose. The results show that the proposed approach obtains similar results compared to the msNMPC, which is demonstrated on a challenging case study from chemical engineering domain. Most importantly, the NN-based msNMPC shows superior performance in terms of computational time. Thus the presented approach is a promising method of real-time implementation of msNMPC in case of complex control problems with long prediction horizons, large number of parametric uncertainties and short sampling times. Our future work will consist in improving the closed-loop performance of the proposed approach by the use of safe sets.

Abstract

High pressure process facilities like hydrocrackers and solvent deasphalting units in most cases are equipped with a system to quickly discharge the inventory in case of an emergency, and by doing so reduce the pressure to safe values in a short amount of time. Multi-stage depressurization is usually applied to cope with additional boundary conditions, such as high reliability and the limited capacity of the downstream flare system. In this paper, a design development is described using detailed dynamic simulation studies to come to an optimal design of such a system. The result of the work described is a structured design procedure for use on large scale design projects.

Keywords: depressurization, dynamic simulation, solvent deasphalting unit, hydrocracker

1. Introduction

Process facilities handling vapor or LPG at high pressures are in most cases equipped with a system to quickly discharge the inventory in case of an emergency in order to reduce the pressure and by doing so reducing the risk of fire and explosion and consequential damages.

Typical examples of this are: Hydrotreaters, Hydrocrackers and LPG plants.

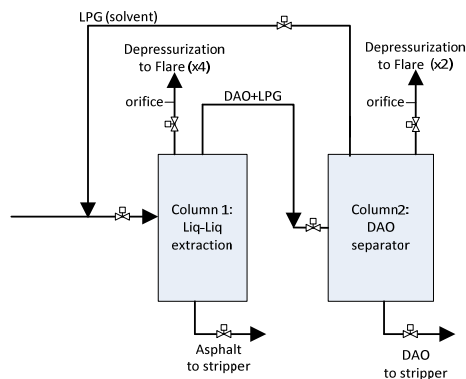
The example presented in this study is related to an Solvent Deasphalting Unit, which uses LPG as solvent for the liquid-liquid extraction of the asphalt components in the crude oil vacuum distillation residue. [Sattarin, 2006]


Figure 1: block flow diagram of SDA unit

The target of the system depressurization design is typically to reduce the pressure to 8 bar or 50% of the operating pressure, whichever lower in a period of 15 minutes time. [API, 2014]

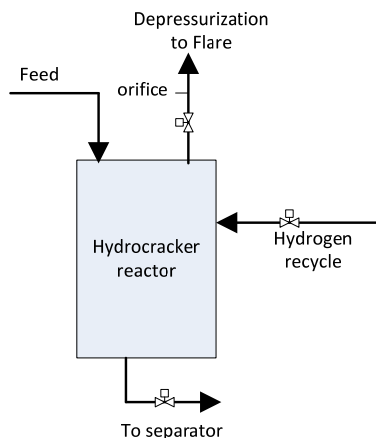
For some designs this can be solved with readily available tools like the Aspen HYSYS depressurization module, or the HYSYS blowdown module [AspenTech, 2018]. An example of this is the depressurization of a hydrocracker: for this unit the depressurization calculations can be solved in a relatively simple way by means of the standard utilities. A typical hydrocracker example is shown on figures 2A and 2B.


Figure 2A

Figure 2B

Figure 2A: the figure shows a typical block flow diagram of a Hydrocracker unit reactor Figure 2B: a typical depressurization curve for a hydrocracker reactor is shown. The fluid is depressurized from an initial pressure of 105 barg to a final pressure of 7 barg in 15 minutes. As can be observed, this can be achieved in one step, via a single valve. The calculation has been done with the HYSYS blowdown module.
The depressurization calculation of the system becomes more difficult when, as in the case of SDA process, dealing with liquid LPG at supercritical conditions, since a single valve design would imply a too high initial peak, which in turn would have a significant economic impact in the flare system design i.e. flare header and flare stack will increase in size. In the case of connecting to existing flares, it would imply to exceed the flare system capacity.

In order to cope with this constraint, multistage depressurization is applied.

2. A dynamic simulation study applied to a depressurization system

The design procedure of the SDA unit multistage depressurization system is discussed when using HYSYS dynamic simulation. Additionally, the benefits of this method compared with the standard HYSYS depressurizing utilities are highlighted.

2.1 Definition of the system

The evaluated system consists of two columns containing liquid LPG at high pressure (see Figure 1), which will be depressurised in parallel. In order to reduce the peak flowrate released to the flare, multiple valves are installed i.e. 4 on-off valves for the first column and 2 on-off valves for the second. The depressurized fluid is sent to flare via the flare header and knock out drum, which allows the liquid LPG collected during the depressurization case.

2.2 Staggered Depressurization Scenarios (multistage depressurization)

In industrial plants, the flare has a maximum capacity of gas that it can burn off. Exceeding this capacity can result in incomplete combustion and high pressure built-up exceeding the design conditions of the system. The soot produced in incomplete combustion could potentially block the flare. Hence, the flow of flammable gases to the flare needs to be limited below the maximum capacity.

In a standard depressurizing setup, peak flow is reached at the start, when the pressure is highest.

To reduce the peak flow, pressure is often relieved from a vessel stepwise: multiple valves, with smaller openings than the original single valve, are connected to the vessel. These valves are opened at different times. In this way, the initial peak flow that would be present in the original single valve setup, is distributed over several peaks. Consequently, the pressure can be decreased by the same amount in the same time as in the non-staggered case, without exceeding the maximum flare capacity. This is called staggered depressurization.

This method is also applied to plants with a high amount of equipment, where multiple units are usually connected to the same flare. This can create a high total flow to the flare. This total flow can be reduced by using a stepwise method, similar as described above for a single vessel. A staggered pressure relief scenario is created for the multiple vessel system by opening the valves of the several units at different times.

2.3 Sectionalizing

Sectionalizing is applied in order to limit the inventory release in the case of leakage, e.g. if only one column needs to be depressurized. This can reduce for some design cases the required capacity of the emergency depressurization system, considering that the case of all sections depressurizing at once is not a case for flare header sizing.

However, the study case is a particular case in which the flare capacity is limited since an existing flare is considered, and additionally the case of both sections depressurizing at the same time has to be considered.

One major drawback is the greatly increased number of valves required for this setup. More valves require higher investment cost, more maintenance and more chance of leakage to the flare. However, for this case increasing the amount of valves cannot be avoided, in order not to exceed the flare design limit constraint.

2.4 **Control valve versus restriction orifice**

There are typically two alternatives to control the emergency depressurization i.e. via a control valve or by means of a combination of on-off valve and a restriction orifice.

This study has been performed considering a combination of on-off valves and restriction orifices.

The benefit of this configuration is to avoid the risk of freezing because of low temperatures (as low as -40°C), caused by LPG depressurization. That may cause malfunctioning of closing the control valve that has been opened for depressurization.

With the proposed scheme the on-off valve will be able to close since the low temperatures will occur downstream the RO. The restriction orifice is installed at a safe distance downstream the on-off valve, so that the low temperature can dissipate without risk of freezing in the on-off valve.

2.5 **Computational setup**

This study is executed in Aspen HYSYS, using the full dynamic simulation capabilities. HYSYS also offers two other methods to simulate depressurization, the Depressuring Utility and the Blowdown Module, which are easier to use, but allow less detail in the model.

The thermodynamic model used in each depressuring case is the Peng-Robinson equation of state. Being HYSYS' most enhanced model, Peng-Robinson is especially suitable for the fluid considered in this study, with a wide range of T and P applicability and its extensive binary coefficents database.

For the modelling of the system, adiabatic vessels are considered.

2.6 **Valve characteristics and hydraulics**

2.6.1 **On-off valves**

On-off valves opening time is included in the simulation. A valve model was used with a cv-percentage opening characteristic taken from vendor information. For the actuator, a linear characteristic was taken with different values for the time to fully open the valve for individual valves. Note that in the HYSYS depressurization and blowdown utilities (and many other simplified calculation modules), on-off valves are considered instantaneously opened, which is a simplification of the method which leads to a higher peak than actual flow, and to a shorter depressurization time than actual.

2.6.2 **Flare system**

A level control was implemented for flare knock-out drum in the model. Having the level control keeps a low level to minimize evaporation in the KO vessel in the model. In reality, the KO vessel does not have a level control, but a quick evaporation is unlikely because of the limited surface area between gas and liquid. In the depressurization curves, the mass flow in and out of the KO vessel is shown.

Hydraulic restrictions were added to the system in order to model the hydraulics of the downstream system. The input to these restrictions was based on the detailed hydraulic calculations available for the existing system.

2.7 **Simulation results**

The main results of the depressurization study done with HYSYS dynamic simulation can be observed in Figure 3. In Figure 4, the results of the depressurizing tool are shown.
Figure 3: full dynamic simulation, pressure evolution and peak flowrate

As can be observed in the Figure 3, the C1 and C2 pressures are reduced to recommended levels while the depressurizing flowrate is within the capacity of the flare system.
Figure 4: simplified dynamic simulation using depressurization utility, pressure evolution and peak flowrate

Figure 4 shows that, when applying the depressuring utility, the design of the flare system is exceeded when the same orifice sizes and opening times are considered respect to the full dynamic simulation approach. The main reason for such a discrepancy is that depressurization utility does not take into account limitations like hydraulics, opening time of on-off valves and positive impact of a flare knock-out drum.

3. Conclusions

When dealing with complex depressurization systems with additional constraints respect to standard designs, a full dynamic simulation is a tool to be considered since, despite being more time consuming to build if compared with the HYSYS depressurization utility and blowdown module, its results are more accurate, take into account the influence of more parameters and can better represent the actual system behaviour, leading to an optimal design of the depressurization system.

Abstract

Reactive distillation (RD) technology offers key benefits in many chemical processes, including energy savings and costs reduction. Prior to its application in industry, screening, addressing technical feasibility and economic viability, must be performed at the conceptual design level. But these tasks can be challenging and time-consuming since detailed models are usually needed. To overcome this complexity, we provide a mapping method to quickly assess the applicability of RD. The mapping method overlays key parameters of a real system, i.e. relative volatilities (α) and chemical equilibrium constant (K_{eq}), onto pre-calculated graphs indicating the RD performance, i.e. the reflux ratio (RR) vs number of theoretical stages (NTS) based on generic cases. The mapping method focuses on quaternary systems ($A + B \rightleftharpoons C + D$). A case study (methyl lactate hydrolysis) is used to demonstrate the approach. Three scenarios are presented, applying different characteristic volatility values; each scenario gives rise to a different RD applicability map for equilibrium constants in the range 0.01 to 10. The findings are validated against results of rigorous process simulation and optimisation. The most accurate scenario is that in which α sets are calculated for mixtures with molar compositions 99% C / 1% A, 50% A / 50% B, 1% B / 99% D, respectively. The results show that the mapping approach allows the prediction of number of theoretical stages and reflux ratio to be estimated within 10% of the optimum values.

Keywords: reactive distillation, mapping method, applicability graph.

1. Introduction

Reactive distillation (RD) is an important intensification technology that offers multiple advantages: 1. an improved chemical process (i.e. higher conversion and selectivity), 2. energy savings, 3. costs reduction, and 4. inherently safer designs (Shah et al., 2012). This technology has received industrial interest for over 30 years; and for example the production of methyl acetate and ethers using RD is commercially well established (Stankiewicz, 2003). Within the same time frame, studies have been performed to intensify operation of a wider range of chemical processes, such as (trans-)esterification, hydrolysis, (de-)hydration and alkylation (Kiss, 2017).

In spite of the promising applications offered by RD, the complexity of designing RD columns has hindered industrial application of the technology. Simpler approaches are needed to guide design engineers and support design decision making as to whether RD

is an applicable unit (Segovia-Hernández et al., 2015). Recent work has aimed to provide such guidance, via a mapping approach that facilitates screening of RD application (Muthia, Reijneveld, et al., 2018). The method uses RD applicability graphs which plot reflux ratio (RR) vs number of theoretical stages (NTS) and aid go/no-go screening of proposed RD operations considering the maximum acceptable values for NTS and RR. The mapping method is currently limited to use in quaternary reactions (Muthia, van der Ham and Kiss, 2018). This paper presents an extended development of the method and highlights the importance of using appropriate characterisation of the relative volatilities in the column to predict RD applicability.

2. Mapping method

Figure 1 (left) shows the RD configuration used in this study. The column is assumed to operate at atmospheric pressure, with negligible pressure drop, and to achieve vapour-liquid and reaction equilibria at each stage. The reactive section is located between the inlets of the lighter and heavier reactants; reaction and separation occur simultaneously in this section. Further separation takes place in the rectifying and stripping sections, to achieve the targeted product purities. It is assumed that equal molar flows of the reactants are fed to the column as saturated liquids.

The RD column, with any configuration, is simulated using Aspen Plus v8.6. For a given NTS, a sensitivity analysis is carried out in which the number of stages in the rectifying, reactive and stripping sections is varied. A generic case is defined, in which the boiling order of the reactants and products and the type of reaction are defined (e.g. $A + B \rightleftharpoons C + D$). The method assumes that the generic cases have ideal vapour-liquid equilibrium behaviour (neither azeotropes formation nor liquid split) and constant key parameters, i.e. all relative volatilities (α) and chemical equilibrium constant (K_{eq}). The optimisation tool within Aspen Plus is used in order to minimize the reflux ratio, where the purity of both products is specified as a constraint. Multiple (flat) optimal solutions are obtained for each choice of NTS which correspond to multiple column designs that can meet the specifications. For a given number of theoretical stages, the lowest value of the reflux ratio defines a boundary to the region in which RD is feasible – this is known as the applicability area, as shown in Figure 1 (right).

Figure 1 (right) depicts the boundary lines of two RD applicability areas, corresponding to two different K_{eq}s. Only on and above each boundary line, the RD technology is applicable, i.e. the targeted product purities are achieved. The two dashed curves are the lower bounds belonging to two generic cases, i.e. with K_{eq}s equal to 1 and 2.
Figure 1. RD column configuration (left); RD boundary lines of generic and real systems (right)

The boundary lines of the generic cases are used to predict the RD applicability of a specific, real system. Firstly, key process parameters are calculated (a set of α values and the value of K_{eq}) for the real system. Then the user seeks the two boundary lines, one with a higher K_{eq} value and one with a lower K_{eq}. This allows the user to estimate the position of the boundary line for the real system. For example, for a real system with $1 < K_{eq} < 2$, its boundary line is predicted to lie between the two generic boundary lines, within the shaded area shown in Figure 1 (right). Later, rigorous simulations will be carried out to confirm that the actual boundary line of the real system – indicated by the solid line – is indeed well predicted by the neighbouring generic boundary lines.

In classic distillation, short-cut methods, such as the Fenske and Underwood methods, are used to estimate the minimum number of theoretical stages (NTS_{min}) and minimum reflux ratio (RR_{min}). The α value may be that of the feed or considered as an average α along the column based on the composition of the top and the bottom streams, and the results of the Fenske and Underwood design calculations can be relatively sensitive to which approach is adopted. The approximation quality is significantly affected by the nonideality of the mixtures involved. Greater errors are in general obtained in more nonideal systems (Smith, 2016). Therefore, it is crucial to use an appropriate representation of the set of α values in the column when applying simple distillation design methods. In the context of RD, this study evaluates different representations of α sets in the development of the mapping method. The work assumes that the characteristic value of the equilibrium constant, K_{eq}, should be calculated at the average boiling point (T_b) of the two reactants, as the temperature profile in the reactive section is typically confined to the within the range of the reactant boiling temperatures.

The generic boundaries are created by extensive series of calculations. The vast number of possible combinations of α sets and K_{eq} values implies that an infinite number of boundary lines for generic cases can be obtained. Therefore, the range of K_{eq} is limited to a pragmatic range from 0.01 to 10 (i.e. 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 2, 5, 10) that aims to cover the range of reactions with potential for practical RD application. In addition, the lower bound is chosen to the set of results corresponding to a number of theoretical stages that is twice the minimum ($NTS = 2 \cdot NTS_{min}$), in which the reflux ratio is up to 10% higher than the lowest reflux ratio on the boundary line. These choices are based on heuristics for estimating the optimal number of stages for classic distillation.

3. Case study

This study focuses on the quaternary reaction ($A + B \rightleftharpoons C + D$), where $T_{b,C} < T_{b,A} < T_{b,B} < T_{b,D}$), which has been explored widely for RD applications. Due to space limitations, only the case study of methyl lactate hydrolysis is presented, as shown in Eq. (1).

$$\text{Water (A)} + \text{Methyl lactate (B)} \rightleftharpoons \text{Methanol (C)} + \text{Lactic acid (D)} \tag{1}$$

T_b 100 °C   144.8 °C   64.7 °C   216.85 °C $\Delta H_r = +33.6 \text{ kJ.mol}^{-1}$
The activity coefficients are calculated by UNIFAC-HOC and a correlation between temperature and chemical equilibrium constant is shown in Eq. (2), where T is in K (Sanz et al., 2004). An azeotrope exists at 99.8°C with a molar composition of 97% water and 3% methyl lactate. In this study, the targeted purity of products $\geq$ 99 mol%.

$$\ln\left(K_{eq}\right) = 2.6 - (1954.2 / T) \tag{2}$$

4. Method development and validation

Table 1 presents three scenarios, applying different definitions for the characteristic α sets. For all scenarios, α_{AB} is for a 50/50 mol% mixture of the reactants, corresponding to the equimolar feed of reactants. In Scenario 1 (S1), α_{CA} and α_{BD} are calculated using the compositions of the top and the bottom streams, respectively. Scenario S2 aims to consider volatilities within the column, and not just at its extremities; therefore, the characteristic α_{CA} and α_{BD} are calculated 50/50 mol% binary mixtures. Scenario S3 calculates α_{CA} and α_{BD} at compositions (1/99% CA and 99/1% BD mixtures) that are only expected to occur if K_{eq} is very low, leading to very low conversion. In this case, a single RD column is unlikely to be appropriate.

Table 1. Characterisation of α sets

| Scenario | Representation of α set | | |
	α_{CA}	α_{AB}	α_{BD}
S1	2.5 (99/1 mol%)		6.5 (1/99 mol%)
S2	3.6 (50/50 mol%)	5.5 (50/50 mol%)	11.7 (50/50 mol%)
S3	7.5 (1/99 mol%)		14 (99/1 mol%)

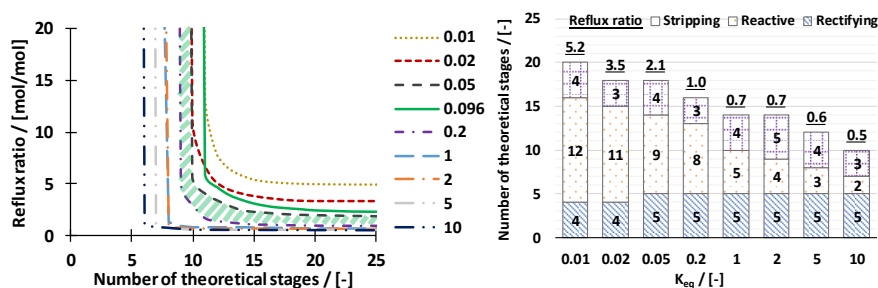
The dashed boundary lines in Figure 2, Figure 3 and Figure 4 (left) represent generic cases for S1, S2 and S3, respectively. Note that the solid line in each graph, which is the actual boundary line for the case study, is added later, after performing rigorous simulation for validation purposes.
Figure 2. RD applicability areas (left); their RD configurations at NTS=2·NTS$_{min}$ (right) for S1


Figure 3. RD applicability areas (left); their RD configurations at NTS=2·NTS$_{min}$ (right) for S2
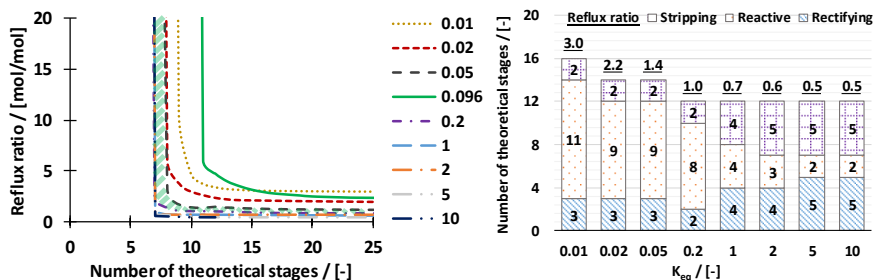

Figure 4. RD applicability areas (left); their RD configurations at NTS=2·NTS$_{min}$ (right) for S3

The size of RD applicability areas of the generic cases increases from S1, S2, to S3, respectively: the increasing ease of separation between reactants and products (shown in Table 1), leads to lower reflux ratios for any number of stages. This observation is in agreement with the resulting RD configurations, presented in Figures 2, 3 and 4 (right). In each system, fewer reactive stages are needed for higher K$_{eq}$ values, since the reaction performance is improved. Conversely, more separation stages are needed because fewer reactive stages achieve less simultaneous separation.

For the particular conditions of the case study, K$_{eq}$ is 0.096, calculated using Eq. (2). A premise of the mapping method is that the actual boundary line will lie between neighbouring generic boundary lines, i.e. within the shaded areas in Figure 2, Figure 3 and Figure 4 (left). Rigorous simulations of the case study provide the actual boundary line, indicated by the solid line. It may be seen that the generic boundary lines predict its location well only in S1, i.e. the effectiveness of the mapping method is sensitive to the approach used to characterise volatilities in the column.

Figure 5 (left) illustrates how the generic results can be used to design a particular RD column using linear interpolation to estimate number of theoretical stages and reflux ratio, for K$_{eq}$ = 0.096. The number of rectifying, reactive and stripping sections can be estimated using the same approach. Multiple designs configurations exist; two RD configurations of neighbouring generic cases (with K$_{eq}$ values close to the actual value) are considered, i.e. K$_{eq}$ values of 0.05 and 0.2. Figure 5 (right) shows the actual (simulated) RD configuration and configurations predicted using linear interpolation for S1, S2 and S3. Table 2 quantifies the goodness of fit in terms of the differences in NTS and RR, relative to that of the actual case. S1 is in good agreement with the generic results, with deviations below 10%.
Figure 5. NTS and RR predictions for S1 (left); Predicted and actual RD configurations (right)

Table 2. Comparison of linearly interpolated and actual NTS and RR values

Scenario	NTS			RR		
	Actual	Predicted	Deviation	Actual	Predicted	Deviation
S1	20	21	5%	2.7	2.5	8%
S2	20	17	15%	2.7	1.8	33%
S3	20	13	35%	2.7	1.4	48%

5. Conclusions

The mapping method aims to help engineers to carry out relatively quick initial evaluation of potential RD applications. The approach uses characteristic relative volatilities and chemical equilibrium constant of a real system to screen the RD designs based on generic RD applicability graphs. This study highlights the importance of having the appropriate characterisation of relative volatilities sets to predict the RD applicability and validates the approach by comparing predictions to rigorous simulation results. The relative volatilities sets should be calculated for total feed, top product and bottom product conditions. The approach enabled prediction of NTS and RR for the case study with deviations of less than 10%.

Filter-based Constraints to Easier Plant Feasibility in Modifier Adaptation Schemes

A. Papasavvas[a] and G. Francois[a]

[a]*School of Engineering, Institute for Material and Processes, The University of Edinburgh, Edinburgh EH93FB*
A.Papasavvas@sms.ed.ac.uk

Abstract

Output modifier adaptation (MAy) is an iterative model-based real-time optimization (RTO) method with the proven ability to reach, upon converge, the unknown plant optimal steady-state operating conditions despite structural and parametric plant-model mismatch and disturbances. However, as such, feasibility of the iterates cannot be guaranteed before convergence is achieved. This issue can be mitigated with additional modelling and/or experimental efforts, which is costly and sometimes cannot be envisaged, especially for large-scale systems. In this article, MAy is compared to one of its most recent extensions, namely "KMAy", which is shown to have more favorable sufficient conditions for feasibility of the iterates. A simulation study, performed on the Williams-Otto reactor – a standard benchmark case study for RTO algorithms – illustrates that KMAy is safer for practical applications.

Keywords: Real-time optimization, modifier adaptation, feasibility.

1. Introduction

Plant operators often manipulate the degrees of freedom of industrial processes to maximize performances, while trying to enforce the satisfaction of safety and quality constraints. However, such experience-based decision methods often lead to sub-optimal operations. Real-time optimization (RTO) methods use both the available model and measurements in the decision-making process. Output modifier-adaptation (MAy-Marchetti et al. (2016), Papasavvas et al. (2019)) has been recently proposed as an extension of Modifier Adaptation (MA) schemes (Marchetti et al., 2016). Basically, MAy uses all real-time plant measurements to implement input-affine corrections on the modelled input-output mapping to improve the prediction of the cost and constraints, while preserving the proven ability of MA schemes to reach upon convergence the true plant optimal inputs.

One challenge to push MAy further is to provide, at least, the same level of feasibility guarantees as experience-based decision methods. Indeed, forcing the satisfaction of the plant constraints typically requires global knowledge of the plant behaviour (Bunin et al., 2013; Marchetti et al., 2017), which is unfortunately rarely the case. In this paper, the focus is on a recent extension of MAy, i.e. "KMAy' '(Papasavvas and François, 2019). This method is shown to offer better feasibility guarantees than other MA algorithms without requiring more data or knowledge. On the basis of this study, a simple method for improving most MA algorithms is proposed.

The paper is organized as follows. After a brief review of MAy and KMAy in Section 2, these schemes are compared in Section 3 w.r.t. their ability to enforce plant feasibility. These results are illustrated by means of simulated chemical reactor in Section 4, and Section 5 concludes the paper.

2. Real-Time Optimization via Modifier Adaptation

Plant optimal operating conditions $\boldsymbol{u}_p^\star \in \mathbb{R}^{n_u}$ are such that they minimize the operating cost $\phi(\boldsymbol{u}, \boldsymbol{y}_p(\boldsymbol{u})) \in \mathbb{R}$ while satisfying the constraints $\boldsymbol{G}(\boldsymbol{u}, \boldsymbol{y}_p(\boldsymbol{u})) \leq \boldsymbol{0} \in \mathbb{R}^{n_g}$, where $\boldsymbol{y}_p(\boldsymbol{u}) \in \mathbb{R}^{n_y}$ is the input-output mapping of the plant, i.e. the relationship between the operating conditions and the steady-state measured outputs of the plant. Finding $\boldsymbol{u}_p^\star$ when only an approximate model of the plant $\boldsymbol{y}(\boldsymbol{u})$ is available, is generally not possible with standard model-based optimization methods but becomes handy with RTO algorithms like MAy. The main idea behind MAy is to use plant measurements to iteratively modify the model-based optimization problem so that its first order conditions of optimality match those of the plant optimization problem at each operating point $\boldsymbol{u}_k$. It is proven that the true plant optimum is the only possible fixed point of MAy despite structural plant-model mismatch (Papasavvas et al., 2019). MAy can be summarized as follows:

Output Modifier Adaptation (MAy): At the kth iteration, $\boldsymbol{u}_k$ is applied to the plant until steady state is reached, and the modified input-output mapping is modified: $y_{i,m,k}(\boldsymbol{u}) := y_i(\boldsymbol{u}) + \varepsilon_k^{y_i} + (\boldsymbol{\lambda}_k^{y_i})^\mathsf{T}(\boldsymbol{u} - \boldsymbol{u}_k)$, where $\varepsilon_k^{y_i} := y_{i,p}(\boldsymbol{u}_k) - y_i(\boldsymbol{u}_k)$ and $\boldsymbol{\lambda}_k^{y_i} := \nabla_{\boldsymbol{u}} y_{i,p}\big|_{\boldsymbol{u}_k} - \nabla_{\boldsymbol{u}} y_i\big|_{\boldsymbol{u}_k}$ are the 0th- and 1st-order modifiers, respectively, and $\nabla_{\boldsymbol{u}}(\cdot)$ is the gradient operator w.r.t. $\boldsymbol{u}$. Then, the following optimization problem is solved to derive the model-based optimal inputs $\boldsymbol{u}_{k+1}^\star$:

$$\boldsymbol{u}_{k+1}^\star := \quad \arg\min_{\boldsymbol{u}} \quad \Phi_{\text{MAy},k}(\boldsymbol{u}) := \phi(\boldsymbol{u}, \boldsymbol{y}_{m,k}(\boldsymbol{u})) \tag{2.1}$$

$$\text{s.t.} \quad \boldsymbol{G}_{\text{MAy},k}(\boldsymbol{u}) := \boldsymbol{g}(\boldsymbol{u}, \boldsymbol{y}_{m,k}(\boldsymbol{u})) \leq \boldsymbol{0}, \tag{2.2}$$

The next iterate $\boldsymbol{u}_{k+1}$ is obtained by applying the following filter:

$$\boldsymbol{u}_{k+1} := \quad \boldsymbol{u}_k + \boldsymbol{K}(\boldsymbol{u}_{k+1}^\star - \boldsymbol{u}_k), \tag{2.3}$$

with $\boldsymbol{K} \in \mathbb{R}^{n_u \times n_u}$ a filter gain matrix, typically diagonal with $K_{i,i} \in (0,1], \forall i \in [1, n_g]$.

The filter of (2.3) is used here to enable asymptotic stability and to avoid excessive corrections (Marchetti et al. (2016)) but its implementation is indeed risky: *Figure 1 illustrates that this filter can lead MAy to generate the next inputs where the model predicts infeasibility! This is due to the fact that the filter of (2.3) picks $\boldsymbol{u}_{k+1}$ in the segment $[\boldsymbol{u}_k, \boldsymbol{u}_{k+1}^\star]$, while the model predicts that the constraint is not satisfied in the red-shaded area. Of note is that this is a major common weakness to standard MA algorithms using a similar filter.* To avoid this, the following extension of MAy can be used:

Output Modifier Adaptation Extension (KMAy): Apply MAy until equation (2.1), and solve the following problem instead of (2.1)-(2.3):

$$\boldsymbol{u}_{k+1} := \quad \arg\min_{\boldsymbol{u}} \quad \Phi_{\text{KMAy},k}(\boldsymbol{u}) := \Phi_{\text{MAy},k}(\boldsymbol{v}_k(\boldsymbol{u})) \tag{2.4}$$

$$\text{s.t.} \quad \boldsymbol{G}_{\text{KMAy},k}(\boldsymbol{u}) := \left[\boldsymbol{G}_{\text{MAy},k}(\boldsymbol{v}_k(\boldsymbol{u}))^\mathsf{T}, \boldsymbol{G}_{\text{MAy},k}(\boldsymbol{u})^\mathsf{T} \right]^\mathsf{T} \leq \boldsymbol{0}, \tag{2.5}$$

$$\boldsymbol{v}_k(\boldsymbol{u}) := \boldsymbol{K}^{-1}(\boldsymbol{u} - \boldsymbol{u}_k) + \boldsymbol{u}_k. \tag{2.6}$$

As seen in (2.5), KMAy duplicates the model-based constraints, which are in turn also

checked at what would be the next iterate as the filter (2.3) is here implemented by means of equation (2.6). Note that loss of constraint qualification upon convergence could be expected with the duplication of the constraints, but it has been recently shown that if linear constraint qualification holds for MAy, then Mangasarian Fromowitz qualification holds for KMAy, while KMAy also leads to model adequacy conditions that are less difficult to satisfy compared to MAy (Papasavvas and François, 2019). Since model-based feasibility is checked at both at $v_k(u_{k+1})$ and u_{k+1}, KMAy will generate a u_{k+1} where modelled constraints are satisfied, while MAy will not, as illustrated in Figure 1. Selecting u_{k+1} such that the modified model predicts feasibility also at the next iterate does not guarantee, per se, plant feasibility. However, KMAy should outperform MAy in most cases, especially when the model provides a reasonable prediction of the plant contraints.
Figure 1: A 2D optimization problem solved with MAy and KMAy.

3. Comparison between MAy and KMAy from a Feasibility Perspective

In this section, we compare the ability of MAy and KMAy to generate feasible iterates or sequences of feasible iterates. To do so, the following definitions are required:

Definitions:
• $\mathcal{U} \subseteq \mathbb{R}^{n_u}$ is the set of feasible inputs for the subset of known constraints (i.e., not subject to modelling errors). The *known* constraints functions only depend of u, e.g., input bounds: $u^L \leq u \leq u^U$. $\mathcal{F}_p \subseteq \mathcal{U}$ denotes the set of feasible inputs for the plant.
• A *model* is an object m in the universe of models $\mathcal{M}$: $m \in \mathcal{M}$.
• $\forall k$, $\mathcal{C}^k_{\text{KMAy}}$ denotes the set of inputs that satisfy the constraints (2.5) and $\mathcal{C}^k_{\text{MAy}}$ denotes the set of inputs generated by the application of the filter of (2.3) to any input satisfying the constraint (2.2). This can be rewritten as: $\mathcal{C}^k_{\text{KMAy}} := \{u \in \mathbb{R}^{n_u} | G_{\text{KMAy},k}(u) \leq 0\}$ and $\mathcal{C}^k_{\text{MAy}} := \{u \in \mathbb{R}^{n_u} | G_{\text{MAy},k}(K^{-1}(u - u_k) + u_k) \leq 0\}$, respectively. In other words, $\mathcal{C}^k_X$ are the sets of candidate inputs u_{k+1} that can be generated by MAy or KMAy for $X \in \{\text{MAy}, \text{KMAy}\}$.
• $\forall k$ and for each $X \in \{\text{MAy}, \text{KMAy}\}$, $\mathcal{S}^k_X \subseteq \mathcal{M}$ are the sets of models m such that the candidate inputs u_{k+1} are feasible for the plant, i.e., $\mathcal{S}^k_X := \{m \in \mathcal{M} | \mathcal{C}^k_X \subseteq \mathcal{F}_p\}$. From the definition of $\mathcal{S}^k_X$, it is clear that $m \in \mathcal{S}^k_X$ is a *sufficient condition for the plant feasibility at the next iterate*.

For any given $u_k \in \mathcal{F}_p$ and given a model $m \in \mathcal{M}$, the following proposition states that KMAy is more likely to lead to $u_{k+1} \in \mathcal{F}_p$ than MAy:

Proposition 1 $\forall k$, *the set of models satisfying the sufficient condition for plant feasibility at $k+1$ with MAy is a subset of the set of models satisfying it with KMAy, i.e.,* $\mathcal{S}^k_{\text{MAy}} \subseteq \mathcal{S}^k_{\text{KMAy}}$.

Proof. u_{k+1} (generated by $X \in \{\text{MAy}, \text{KMAy}\}$) is in $\mathcal{C}^k_X$ and is feasible for the plant

when $m \in \mathcal{S}_X^k$, since, as said before, $m \in \mathcal{S}_X^k$ is a sufficient condition for plant feasibility at the next iterate. Since KMAy includes the same constraints as MAy *together with additional constraints*, $\mathcal{C}_{\mathrm{KMAy}}^k \subseteq \mathcal{C}_{\mathrm{MAy}}^k$. In other words, the duplication of the constraints with KMAy shrinks the set of candidate inputs $\boldsymbol{u}_{k+1}$ compared to MAy. Finally, $\mathcal{C}_{\mathrm{MAy}}^k \subseteq \mathcal{F}_p \Rightarrow \mathcal{C}_{\mathrm{KMAy}}^k \subseteq \mathcal{F}_p$ while $\mathcal{C}_{\mathrm{KMAy}}^k \subseteq \mathcal{F}_p \nRightarrow \mathcal{C}_{\mathrm{MAy}}^k \subseteq \mathcal{F}_p$. Thus, $\mathcal{S}_{\mathrm{MAy}}^k \subseteq \mathcal{S}_{\mathrm{KMAy}}^k$. $\qquad\square$

Indeed, Proposition 1 implies that any model satisfying the aforementioned sufficient condition for feasibility with MAy also satisfies it for KMAy, while the opposite does not hold. Thus, from the point of view of the feasibility of the iterates, KMAy should be preferred to MAy, since the chances that $\boldsymbol{u}_{k+1}$ is in $\mathcal{F}_p$ are higher.

Next, we go one step further and show that $\mathcal{C}_{\mathrm{KMAy}}^k$ can be manipulated through the filter gain K in a way that plant feasibility of $\boldsymbol{u}_{k+1}$ is guaranteed if a *local assumptions* about the model m holds. The observation that a reduction of the value of K leads to the aforementioned shrinkage of $\mathcal{C}_{\mathrm{KMAy}}^k$ on $\boldsymbol{u}_k$ is key to this result.

Assumption 1: Assume that at iteration k, there exists a subset $\mathcal{D}_k$ of $\mathcal{U}$, i.e., $\mathcal{D}_k \subseteq \mathcal{U}$, in which the modified model provides pessimistic predictions of the plant feasibility, i.e., the constraints of the modified model upper-bound the constraints of the plant: $\mathcal{D}_k := \left\{ \boldsymbol{u} \in \mathcal{U} | G_{i,\mathrm{MAy},k}(\boldsymbol{u}) \geq G_{i,p}(\boldsymbol{u}), \forall i \in [1, n_g] \right\}$. Assume that $\boldsymbol{u}_k \in \mathcal{D}_k^o$ the interior of $\mathcal{D}_k$.

These assumptions are likely to hold since at $\boldsymbol{u}_k$ the modified-model and the plant have identical local first-order properties thanks to the affine corrections of the model. Note that one way to enforce the satisfaction of this assumption over a larger area around $\boldsymbol{u}_k$ would be to amend the model so that the modelled constraints are local upper bounds of the plant constraints, similarly to what has been proposed in Marchetti et al. (2017). Contrary to what is suggested in (Marchetti et al., 2017), such modifications would only be performed here at a *local* level and will not necessitate more than the available measurements. Pessimistic predictions of the plant constraints should always be a favorable case, since pessimistic predictions are such that $G_{i,\mathrm{MAy},k}(\boldsymbol{u}) \geq G_{i,p}(\boldsymbol{u})$, while the optimization problems aims at enforcing $G_{i,\mathrm{MAy},k}(\boldsymbol{u}) \leq 0$, but it is shown hereafter that only KMAy can take advantage of this situation.

Theorem 1 *If (i) Assumption 1 holds, and (ii) $\mathcal{U}$ is bounded, then there exist diagonal filters $\boldsymbol{K} = K\boldsymbol{I}_{n_u}$ such that $\mathcal{C}_{\mathrm{KMAy}}^k \subseteq \mathcal{F}_p$ and, in turn, such that $\boldsymbol{u}_{k+1} \in \mathcal{F}_p$.*

Proof. Assumption 1 allows to define the biggest ball $\mathcal{B}(\boldsymbol{u}_k, r) \subseteq \mathcal{D}_k$, centered at $\boldsymbol{u}_k$ of radius r. Notice that $r > 0$ because $\boldsymbol{u}_k \in \mathcal{D}_k^o$. Now we show that the distance $||\boldsymbol{u}_{k+1} - \boldsymbol{u}_k||_2$ can be manipulated through K such that $\boldsymbol{u}_{k+1} \in \mathcal{B}(\boldsymbol{u}_k, r)$. By definition, $\boldsymbol{u}_{k+1} \in \mathcal{U}$, $\boldsymbol{v}_k(\boldsymbol{u}_{k+1}) \in \mathcal{U}$, and $||\boldsymbol{u}_{k+1} - \boldsymbol{u}_k||_2 := ||\boldsymbol{u}_k + K(\boldsymbol{v}_k(\boldsymbol{u}_{k+1}) - \boldsymbol{u}_k) - \boldsymbol{u}_k||_2 = K||\boldsymbol{v}_k(\boldsymbol{u}_{k+1}) - \boldsymbol{u}_k||_2 \leq K \max_{\boldsymbol{u} \in \mathcal{U}}\{||\boldsymbol{u} - \boldsymbol{u}_k||_2\}$. According to (ii) $\mathcal{U}$ is bounded, so $\max_{\boldsymbol{u} \in \mathcal{U}}\{||\boldsymbol{u} - \boldsymbol{u}_k||_2\} \in \mathbb{R}$. Therefore, $\forall K$ such that $K \leq r/(\max_{\boldsymbol{u} \in \mathcal{U}}\{||\boldsymbol{u} - \boldsymbol{u}_k||_2\})^*$, the inequality $||\boldsymbol{u}_{k+1} - \boldsymbol{u}_k||_2 \leq r$ holds, and $\boldsymbol{u}_{k+1} \in \mathcal{B}(\boldsymbol{u}_k, r) \subseteq \mathcal{D}_k$. Given that the feasibility is checked[**] at $\boldsymbol{u}_{k+1} \in \mathcal{D}_k$ and that the model provides pessimistic predictions of the plant constraints in $\mathcal{D}_k$, it follows that $\boldsymbol{u}_{k+1} \in \mathcal{F}_p$. $\qquad\square$

Despite the fact that the set $\mathcal{D}_k$ is unknown in practice, Theorem 1 shows that reducing K in KMAy is a very simple way to increase the chances to have $\boldsymbol{u}_{k+1} \in \mathcal{D}_k$ and, thus,

---

[*] Since $r > 0$, satisfying this inequality does not requires to have $K \to 0$.

[**] This difference between MAy and KMAy is the reason why a similar theorem can not be stated for MAy.

to make RTO iterations safer. Interesting enough is that in (Papasavvas and François, 2019), it is shown that *reducing K* is also the way to relax the model adequacy condition for KMAy. Also, it has to be noticed that a similar result cannot be obtained from MAy, mainly because model-based feasibility is not checked at the filtered inputs. In fact, when the conditions (i) and (ii) hold, the iterate $\boldsymbol{u}_{k+1}$ can be brought arbitrarily close to $\boldsymbol{u}_k$ if K is taken small enough. However, with MAy, the feasibility being not checked at $\boldsymbol{u}_{k+1}$, the fact that the model is pessimistic in $\mathcal{D}_k$ is ignored and changing K so that $\boldsymbol{u}_{k+1} \in \mathcal{D}_k$ is not helpful for feasibility with MAy. As illustrated on Figure 1, reducing K with MAy would also bring $\boldsymbol{u}_{k+1}$ closer to $\boldsymbol{u}_k$, but on the segment $[\boldsymbol{u}_{k+1}^\star, \boldsymbol{u}_k]$, while it is ignored that this segment lies in set the of infeasible inputs (red-shaded area) for the modified-model.

4. Case study

Williams-Otto Reactor: The continuous stirred-tank reactor described in (Williams and Otto, 1960) is considered. 3 reactions take place in reality: (i) $A + B \rightarrow C$, (ii) $C + B \rightarrow P + E$, and (iii) $P + C \rightarrow G$; but the models only considers two (different) reactions (Marchetti et al., 2017; Forbes et al., 1994). So there is structural plant-model mismatch.

A and B are fed separately, with mass flowrates of F_A and F_B ([kg/s]), respectively. P and E are the desired products, C is an intermediate product and G is an undesired by-product. The reactor is operated isothermally at T_R ([^oC]). Steady-state mass balances can be found in Zhang and Forbes (2000). The model-based optimization problem of (Marchetti et al., 2017) is considered, where $\boldsymbol{u} = [F_A, F_B, T_R]^\mathsf{T}$ and $\boldsymbol{y} = [X_E, X_P, X_G]^\mathsf{T}$ are the inputs and outputs, respectively, and X_i denotes the concentration of species i. The goal is to maximize profit at steady state, and both inputs and X_G are constrained:

$$\max_{\boldsymbol{u}} \quad \phi(\boldsymbol{u}, \boldsymbol{y}) = (1143.38 X_P + 25.92 X_E)(F_A + F_B) - 76.23 \alpha F_A - 114.34 \beta F_B \quad (4.1)$$

$$\text{s.t.} \quad g(\boldsymbol{y}) = X_G - 0.08 \leq 0, \quad F_A \in [3, 4.5], \quad F_B \in [6, 11], \quad T_R \in [80, 105]. \quad (4.2)$$

The two parameters $\alpha \in \mathbb{R}$ and $\beta \in \mathbb{R}$ are used to simulate market fluctuations. Also, note that $g(\boldsymbol{y})$ is a concave constraint (Marchetti et al., 2017).

Three different market regimes are considered: mode 1: (1.1, 1.1), mode 2: (0.85, 1), and mode 3: (1, 0.9), with different pairs of α and β values (in brackets). For the two mode transitions mode 1 $\rightarrow$ mode 2 and mode 2 $\rightarrow$ mode 3, MAy and KMAy have been applied and constraints violations have been analyzed for different filter values of the diagonal filter $\boldsymbol{K} = K\boldsymbol{I}_{n_u}$. Other transitions have been simulated with similar conclusions.

Simulation Results: Note that the optimal operating conditions activating the concave constraint (4.2) for each mode, the segment that joins the optimal operating points of two different modes always lies in the infeasible part with MAy. Therefore, constraint violations will clearly be likely to occur with MAy similarly to what is illustrated in Figure 1. Both problems are indeed comparable, i.e., "sliding around a concave constraint" with KMAy or going potentially through it with MAy. Figures 2 and 3 show a large difference between the maximal constraint violations observed with MAy and KMAy for different K values. As expected, using KMAy always leads to less violations.

5. Conclusion

In this article, a weakness that is common to all MA-inspired RTO algorithms using a filter has been identified. Two recent MA extensions are compared and it is argued that KMAy
Figure 2: Maximal constraint violations with MAy and KMAy, for two different market variations.
Figure 3: Simulation results for $K = 0.5$.

is safer than MAy, in the sense that less, or smaller, constraints violations can be expected. Sufficient conditions for plant feasibility have been compared for the two algorithms and it has been shown that they are in favor of KMAy. It has been proven that, under certain conditions, a filter value can always be found such that plant feasibility can be enforced at the next iteration with KMAy, while this is not the case with MAy and it indeed appears that most MA algorithms would benefit from a formal implementation of the filter at the level of the optimization problem. Future research could include an analysis of the potential effects of such an integration to most MA-inspired RTO methods. Also, the conditions for the existence of $\mathcal{D}_k$ in Assumption 1, though beyond the scope of this article, should be investigated. Finally, the main benefit of the integration of the filter into the KMAy formulation (with the relaxation of model adequacy conditions, (Papasavvas and François, 2019)) being to prevent the generation of operating conditions where the modified model predicts infeasibility, future research should investigate how this double model-based feasibility check could, in practice, enforce plant feasibility under moderate assumptions about the nature of plant-model mismatch.

Abstract

Design of biorefineries has been often addressed by process flowsheet optimization tools without adequately considering the relevant supply chain network. In this work, an integrated optimization algorithm including the biorefinery process flowsheet structure and biobased supply chain network was developed. A superstructure of different process pathways for a biorefinery co-producing ethanol, ethyl levulinate and electricity is built on the base of up-to-date technologies. The bio-based supply chain model was implemented to address the transportation, the inventory management and the size of the biorefinery. Mixed Integer Linear Programming (MILP) was used as a modeling approach. The efficiency of the algorithm was demonstrated by applying it to a case study consisting of a wheat straw supply chain network for bioproducts demand in Germany. The algorithm reached convergence after three iterations providing a final optimal number of biorefineries distributed in different regions of the country corresponding to a maximum Net Present Value.

Keywords: biorefinery, superstructure, bio-based supply chain, optimization, MILP

1. Introduction

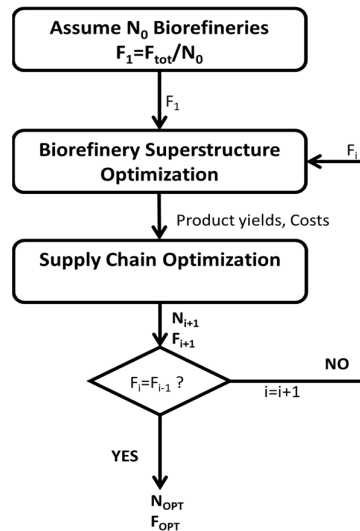
A biorefinery is an industrial facility that is capable of producing multiple products from a wide variety of biomass sources. Decision-making tools and tailor-made approaches allow the appropriate exploitation of the potential of each type of biomass in power generation, heat and cooling application and as a transportation fuel (Laínez-Aguirre et al., 2015). Design of biorefineries has been often addressed by process flowsheet optimization tools without adequately considering the relevant supply chain network (Belletante et al., 2016). In particular, the optimal plant size does not depend simply on the economies of scale, but also on the biomass feedstock availability and the topology of the territory affecting logistics (transportation and storage) costs (Giuliano et al., 2018). On the other hand, works aiming at the supply chain level consider literature data or approximate correlations to estimate biorefinery technical performance, capital and operating expenditure (Galanopoulos et al., 2017). In this work, an integrated optimization algorithm including the biorefinery process flowsheet structure and the biomass and bioproduct supply chain network is developed. An original superstructure of alternative process pathways for a biorefinery co-producing biofuels and fuel addivives like ethanol "EtOH", ethyl levulinate "EL" (from levulinic acid and ethanol) and electricity is built on the basis of more recent technologies from literature.


Figure 1: Graphical representation of the integrated optimization algorithm.

The bio-based supply chain model is implemented to address the logistics network, the transportation, the inventory management. The aim of the work was concentrated also on the optimal size of each biorefinery to build in a Germany region.

2. Methodology

The algorithm used to optimize the biorefinery system is presented in Figure 1. Assuming N_0 biorefineries of the same size F_1 initially, where F_1 is obtained dividing the total available biomass by N_0, the process optimization model for a single biorefinery fed by F_1 is used to optimize the flowsheet by maximizing the Net Present Value (NPV) of the single biorefinery by a MILP approach (Giuliano et al., 2015). Product flowrates, capital costs, operating costs of the single biorefinery are obtained and these data are used as input to the supply chain optimization model by Galanopoulos et al. (2018). The total system of biorefineries is then optimized by maximizing the total NPV including the supply chain costs. As a result, an updated N_i value and a new set of F_i values are obtained removing the constraints of biorefineries with equal size. The new F_i is then used for the process optimization model applied to each biorefinery of different size. In this way, the relevant process flowsheets, product flowrates, capital costs and operating costs are updated. Optimal biomass allocation, product flowrates, costs are obtained in order to design the biobased system. Convergence is achieved when the number of biorefineries and all the flowrates of feedstock for each biorefinery are the same as those obtained from the previous iteration. Finally, N_{opt} and F_{opt} are obtained.

2.1. Process Optimization Modelling

The process optimization model is based on a multiproduct lignocellulosic biorefinery superstructure. The model is obtained by Mixed Integer Linear Programming and it consists in the mathematical description of all biorefinery processes (Giuliano et al.,

2016). The original optimization mathematical model is a MINLP with integer variables for the selection of alternative technologies, after a discretization method for each non-linear variable, the model is rearranged as a MILP, in order to find the global optimal solution (Giuliano et al., 2014).

2.2. Supply Chain Modelling

Biomass is cultivated and collected at the harvesting site of each district. Then, it is either stored or transported to a biorefinery of a region where the conversion to products takes place. Similarly, the bioproducts are then transported to the demand sites to satisfy the demand. The goal is to develop a piece-wise linear model that includes the capital costs of the biorefineries. A detailed description of the supply chain network can be found in Galanopoulos et al. (2018).

3. Case study description

In Germany, the creation of a supply chain network based on cereal straw seems profitable. According to S2Biom report on cost supply (S2Biom, 2017), Germany is the second country in Europe with the highest production of cereal straw (22 Mt_{DRY}/y). The country is divided into 16 regions to quantify the distances in a cereal straw supply chain network in Germany. The distance between each region is evaluated using Google Maps. For the distance inside one region, the Manhattan Distance calculation ($8r/3\pi$) is used by considering that the regions are circles. To have a sustainable supply chain, 30% of all cereal straw produced in each region is assumed to be used for biorefinery purposes. Moreover, a seasonality similar to the growth of wheat is assumed. The products of the cereal straw biorefinery are bioethanol, ethyl levulinate and excess electricity. According to Wang et al. (2012), bioethanol and ethyl levulinate can be used as biofuel and fuel additive respectively for diesel/biodiesel. Ethyl levulinate was obtained by levulinic acid and ethanol equimolar reaction (Nandiwale et al., 2014), while the percentage of demand covered by the ethyl levulinate was set lower than the demand covered by the biofuel ethanol in order to obtain a similar covered demand for both products. The produced electricity can be sold to the grid. The demand of biofuel and of fuel additive is assumed equal to 10 % of the diesel demand for both products.

Table 1: Economic parameters used in the model.

Economic parameter	Value
Wheat straw cost (€/t)	100
Ethyl levulinate price (€/kg)	3.73
Ethanol price (€/kg)	0.694
Electricity price (€/MWhe)	145
Biomass transportation cost (fix €/t) + (variable €/t km)	2.64 + 0.15
Bioproduct transportation cost (fix €/t) + (variable €/t km)	2.4 + 0.17

4. Results

To develop the biomass supply chain model and process optimization model, the Advanced Interactive Multidimensional Modelling (AIMMS) software, version

4.21.5.583 64-bit, was used. CPU time to solve the supply chain model was equal to about 1 hour, for the process optimization was equal to about 30 minutes. For the process optimization the model got linear about 200 nonlinear variables. Data collected from the topology of Germany were used to find the total available wheat straw (WS). The initial number of biorefineries was assumed equal to three, because, by previous studies (Galanopoulos et al., 2018), Germany could contain about three biorefineries, considering the territory topology and availability of wheat straw in full Germany. Consequently, three biorefineries fed with 2,203,200 t/y of biomass were initially considered in the process optimization. The results of the iterative calculations are reported in Table 2. The two models converge after three iterations of the algorithm. The results show that the optimal solution is a decentralized production by means of nine biorefineries, eight with a capacity of 698,400 t/y of biomass and only one with a capacity of 871'200 t/y. Yields to products were constant for all iterations and all the biorefineries with different sizes because of constraints on covered product demands. The optimal number of biorefineries derived from a trade off between capital costs and transportation costs.

Biorefinery Operating Costs (M€/y)	1'162	1'149	1'149
Capital Costs (M€)	4'418	4'167	4'167
Wheat straw production cost (M€/y)	845	800	800
Wheat straw & products transportation costs (M€/y)	341	337	337
NPV (M€)	30	43	43

Table 3: Biorefinery size (Mt/y of feedstock) distribution for each iteration of process optimization. Iterat. = iteration.

Iterat.	Number of biorefineries												
	1	2	3	4	5	6	7	8	9	10	11	12	13
I	2.20	2.20	2.20	-	-	-	-	-	-	-	-	-	-
II	0.94	0.87	0.81	0.78	0.70	0.53	0.52	0.44	0.36	0.30	0.23	0.09	0.05
III	0.87	0.70	0.70	0.70	0.70	0.70	0.70	0.70	0.70	-	-	-	-

In particular, the first iteration assuming only three biorefineries implied high transportation costs for the wheat straw. Therefore, next the supply chain optimization provided a result consisting in a decentralized production with 13 biorefineries with feedstock rate spanning between 0.05 and 0.94 Mt/y (Table 3). More accurate evaluation of the capital costs of smaller biorefineries, by process optimization of single plants, determined that the four smallest biorefineries, processing less than 0.3Mt/y, were deleted in the next iteration of the supply chain optimization. The straw production costs are lower in the second and third iteration compared to the first one because only 98% of available wheat straw is used as feedstock. Moreover, the transportation costs in the first iteration are almost the same with the ones in the second and third iteration as more wheat straw is used. The final result shows an increase of NPV up to 43 M€. Figure 2 shows the localization of the final biorefineries in the Germany's territory. The largest biorefinery (871'200 t/y) resulted in Rhineland-Palatinate region (dashed line in Figure 2) because WS is harvested in North West and West of Germany and from the topology results since there are no biorefineries in all its neighbour regions.

Figure 2: Biorefineries location in the map from the final iteration of the algorithm.

5. Conclusions

In this work, an integrated methodology to consider both the supply chain optimization and the process optimization was proposed. The developed MILP algorithm was tested on a biobased system transforming cereal straw into biofuels, ethanol and ethyl levulinate, in Germany. The algorithm efficiency was successfully demonstrated. In fact, three iterations were sufficient to reach the convergence of the algorithm to the optimal solution consisting in nine biorefineries located in different regions of Germany. This decentralized production resulted from a trade off between capital costs and transportation costs in a big territory. In fact, by increasing the number of biorefineries capital costs increase while biomass and bioproducts transportation costs decrease. The optimal solution derived from the maximization of the NPV.

Abstract

We propose smart liquid-liquid extraction columns of biopharmaceuticals using deep Q-learning algorithm. In this contribution, we demonstrated the application of the tool for design of liquid-liquid extraction process for concentration of API from fermentation broth. To this end, we present the following;1) development of property model to describe solubility of API in different solvents using the nonrandom two-liquid segment activity coefficient model, 2) design the liquid-liquid extraction process for different solvent candidates commonly used in pharma industries, 3) application of deep Q-learning algorithm to optimize liquid-liquid extraction control, and 4) perform sensitivity analysis to study effect of feed fraction of API on the performance. We have validated the developed property process modelling by comparing the existing experimental data and the characteristics of diverse solvents and using sensitivity analysis. We expect that the results from this study would contribute to further development the general framework of downstream separation for the future by extending to more downstream separation processes.

Keywords: Property process modelling, liquid-liquid extraction, deep Q-learning, control, biopharmaceuticals.

1. Introduction

The global pharmaceuticals industry enjoyed years of favorable growth –total revenues generated in 2011 were in excess of $698 billion representing an annual growth rate of 6.7% between 2007 and 2011. The industry now finds itself facing a number of challenges including a changing health care landscape, expiring patents and generic competition, pricing pressures, and a persistent economic slowdown (Fernandes 2015). One of the feasible solutions to overcome the current situation is to develop a smart modelling tool for design and synthesis of downstream separation for biopharmaceuticals. Liquid-liquid extraction (LLE), which is also called solvent extraction, is the main process that is much employed during the downstream separation. In LLE process, a liquid feed of two or more components is faced with a second liquid phase containing solvent (Seader, Henley et al. 1998). Therefore, the use of proper solvents is an inevitably important issue to obtain high yield of active

pharmaceutical ingredients (APIs) and achieve great crystalline form from the product performance's point of view. The property process modelling such as the solubility, which is a chemical property referring to the ability for a given substance called solute to dissolve in solvents, can explicitly affect the general feasibility of the LLE process. As part of development of a general framework of a smart modelling tool for downstream separation process for biopharmaceuticals, this study aims to develop the property process modelling and design one of the commonly used separation step for concentration of API by using an in-silico tool and reinforcement learning. In the reinforcement learning section, a deep Q-learning algorithm to control the LLE process considering Markov decision process and deep neural networks has been investigated (Henderson, Islam et al. 2018). Sensitivity analysis of API has been simulated and the general framework of a smart LLE column for downstream separation has been proposed.

2. Problem statement

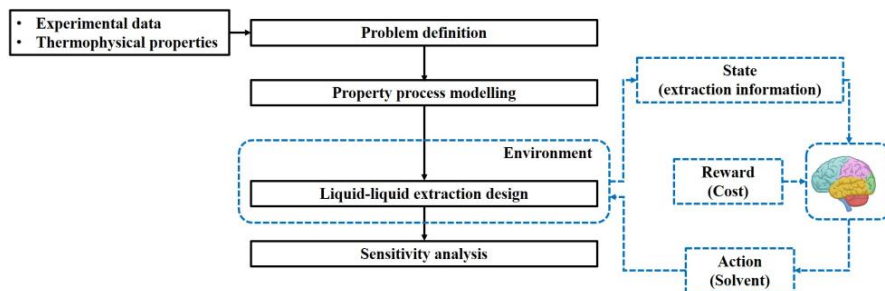
Figure 1 illustrates the overall framework of this study. Property process modelling based on thermodynamic model is developed and the LLE process is designed using the results from the property process modelling. The property process modelling is able to be constructed by either conducting experiments or applying thermodynamic models. However, the research on the property process modelling of various compounds via thermodynamic models have been actively studied because the experiments costs time and resources. Nonrandom two-liquid segment activity coefficient (NRTL-SAC) model was selected for the purpose of solubility modeling and Aspen Properties was employed to regress segment parameters. Reinforcement leaning was applied to conduct process operation optimization in the LLE process to optimize process operation.


Figure 1. Overall framework of a smart liquid-liquid extraction process for downstream separation of biopharmaceuticals.

Deep Q-learning algorithm, which is one of the most dominant reinforcement learning tools, was employed to implement to design optimal control strategies (Mnih, Kavukcuoglu et al. 2015, Gu, Lillicrap et al. 2016). The LLE process corresponds to the environment and discloses LLE column information towards a deep Q-learning agent. The main role of the deep Q-learning agent optimizes parameters of the value function, which is taken into account as deep neural networks, to obtain the reward as much as

possible that is the operating cost in this research. The deep Q-learning agent makes an action to manipulate information of solvents and finally the environment is newly characterized by the action. Sensitivity analysis of APIs with distinct solvents that were selected by the property process modelling has been performed.

3. Property process modelling and the LLE column design

Aforementioned thermodynamic models such as universal functional activity coefficient (UNIFAC), conductor-like screening model for real solvent (COSMO-RS), conductor-like screening model-segment activity coefficient (COSMO-SAC), NRTL-SAC correspond to liquid-phase non-ideality of organic nonelectrolytes (Chen and Crafts 2006). In this study, the NRTL-SAC model has been selected and utilized to construct the property process modelling. General mathematical expression at stages in the LLE process consists of differential equations. Solute concentrations in the raffinate phase (x_i) and the extract phase (y_i) are derived by the raffinate flowrate (R), the extract flowrate (E), backmixing coefficients (α and β), mass transfer (Q_{x_i}), and fractional holdup (h_{x_i} and h_{y_i}) and mass transfer is determined by mass transfer coefficient (K_{x_i}), interfacial area coefficient (a_i), and equilibrium concentration (x_i^*) (Eqs. (3) and (4)) (Mjalli 2005).

$$\frac{dx_i}{dt} = \frac{\left[(1+\alpha)R_{i+1}x_{i+1} + \alpha R_{i-1}x_{i-1} - (1+2\alpha)R_i x_i - Q_{x_i} \right]}{h_{x_i}} \tag{1}$$

$$\frac{dy_i}{dt} = \frac{\left[\beta E_{i+1}y_{i+1} + (1+\beta)E_{i-1}y_{i-1} - (1+2\beta)E_i y_i + Q_{x_i} \right]}{h_{y_i}} \tag{2}$$

$$Q_{x_i} = K_{x_i} a_i V (x_i - x_i^*) \tag{3}$$

The equilibrium concentration of solute is numerically connected with the mole fraction of the solute (x^{SAT}), which is able to be calculated by the entropy of fusion of the solute ($\Delta_{fus}S$), the activity coefficient of the solute (γ^{SAT}), and the melting point (T_m) (Eq. (4)) (Chen and Song 2004) .

$$\ln x^{SAT} = \frac{\Delta_{fus}S}{R} \left(1 - \frac{T_m}{T} \right) - \ln \gamma^{SAT} \tag{4}$$

The LLE process can be designed with inherent input data. In this LLE process, we mainly assume that the number of stages is 10, the system temperature is the room temperature, the reactor is adiabatic, and liquid-liquid coefficient form is calculated by the defined property method. As the feed composition, we have considered a stream after solid-liquid removal of the fermentation broth which results in a water rich (rather

dilute) stream containing API with typical concentration levels. For confidentiality purposes, the identity of the API cannot be disclosed.

4. Off-policy control with deep Q-Learning

General reinforcement learning includes five components, each of which is state, state transition probability matrix, action, reward, and discount factor. State illustrates the current environment and the transition from the previous state to the next state depends on actions from the agent. All the actions are based on a policy contained in the agent and the ultimate goal of reinforcement learning is to figure out the optimal policy to maximize rewards during both exploration and exploitation. In the case of off-policy learning, experience generated from old policies can be reused and the agent learns about multiple policies while following one policy. Off-policy Q-learning converges to the optimal action-value function, and provides the optimal control solution. The general definition of the action-value function ($Q(S,A)$) is the expected return obtained by starting from the current state (S), taking an action (A), and then following the current policy (π) (Eq. (5)). Reward (R) and another state (S') are observed by taking action from the existing state using policy derived from the existing action-value function. Then, the current action-value function is updated toward a better action-value function (Eq. (6)).

$$Q_\pi(s,a) = \mathrm{E}_\pi[G_t \mid S_t = s, A_t = a] \tag{5}$$

$$Q(S,A) \leftarrow Q(S,A) + \alpha \left(R + \gamma \max_{a'} Q(S',a') - Q(S,A) \right) \tag{6}$$

Action-value functions in this study were considered by deep neural network and the concept of experience replay was taken into account to enhance the performance of training agent. Extraction information such as flowrates of materials, molar ratio, operating temperature, and pressure represents the state of the environment and the deep Q-learning agent exports actions such as solvent flowrate to control the LLE extraction. The LLE process operation method under the optimal control strategies can be suggested with the minimization of the operating costs.

5. Results and discussion

Validation of the property process modelling and sensitivity analysis of the API mole fraction with the amounts of solvents have been performed. Figure 3 describes the predicted solubility of API with various single solvents and one binary solvents. Acetone, acetonitrile, 1-butanol, methyl tert-butyl ether (MTBE), 1,4-dioxane, ethanol, ethyl acetate, n-heptane, methyl isobutyl ketone (MIBK), isobutanol, isopropyl alcohol (IPA), and methanol were used as single solvent and the predicted mole fraction of API dissolved in those solvents shows a considerably linearity with the experimental solubility (Figure 2(A)). In the case of the binary solvents, the patterns between the predicted and the experimental values are alike but there exist visually differences until 20% of water in the binary solvents because the experiment had been conducted over the unsteady room temperature (Figure 2(B)).

The deep Q-learning algorithm has been performed to conduct process operation optimization. Designed LLE process as the environment in the deep Q-learning world

manifests a total of 5 characteristics in a state which are flowrates, molar ratio, operating temperature, and pressure in the LLE process. The deep Q-learning agent has received state information and been trained via deep neural networks. In this research, two deep neural networks have been used in order to account for behaviour action-value function and target action-value function. We assumed that the internal structure of those deep neural networks are identical, with three hidden layers. The behaviour action-value function is related to an exploring policy able to extend the range of control optimality. The target action-value function is associated with the optimal policy which should be finally determined with maximizing rewards, in other words, minimizing the operating costs of the LLE process. The action of the deep Q-learning agent has been assumed as solvent information and the total of 20,000 episodes for training have been executed. The total operating costs were approximately reduced by 4.66% compared to the existing LLE process. The more real data, the better robustness and feasibility would be anticipated.

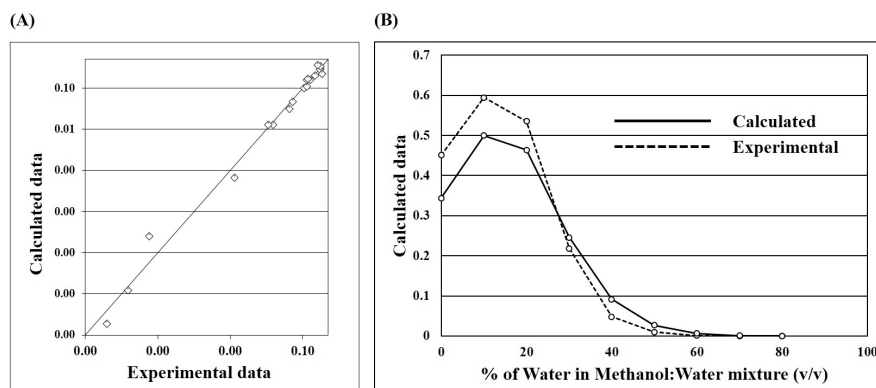
Sensitivity analysis using Aspen Plus indicates that the types of solvents play an important role in the LLE process. 94%(w/w) water in the feed stream and the room temperature in the system were assumed in the sensitivity analysis. The range between the minimum value and the maximum value of the API mole fraction in the extract stream of the LLE process is infinitesimal because used solvents (acetone, acetonitrile, 1,4-dioxane, ethanol, and methanol) are miscible with water. The API mole fraction exponentially decreases according to an increase of the quantity of solvents because used solvents (1-butanol, MTBE, ethyl acetate, MIBK, and isobutanol) are immiscible with water. Changing the number of stages in the LLE process, adding different solvents or replacing single solvents with binary solvents would be implemented with respect to sensitivity analysis.


Figure 2. Solubility results from the property process modelling using thermodynamic model. (A): Solubility of API in single solvents. (B): Solubility of API in different volume fraction of water in methanol/water solvents.

6. Conclusions

An in-silico tool for the property process modelling and the LLE process has been studied and developed by using simulation tools and artificial intelligence software. We have demonstrated the application for a fermentation broth containing an API with

dilute concentration (<5% wt). The main conclusions of this study are as follows: 1) NRTL-SAC model and parametric regression in Aspen Properties are able to describe solubility of API in different solvents quite satisfactorily, 2) the LLE process has been designed considering a class of solvents commonly used in pharmaceutical industry which enabled fast screening of LLE design candidates, 3) reinforcement learning such as deep Q-learning in this study has been conducted to implement the LLE process operation optimization, and 4) sensitivity analysis has been performed to clarify the connection and impact between solvents and API. Future works will extend the analysis of LLE design under uncertainty of experimental data in particular property measurements and modelling to enable robust design and solvent screening (Frutiger, Jones et al. 2018). Moreover, the LLE column design technique implemented in this study would be applied for the development of a general downstream separation framework tool able to be extend to other relevant downstream separation steps including crystallization process and chromatographic separation to offer a complete design of biopharmaceutical separation.

Abstract

Pineapple surplus in the region of Choco-Colombia, the selection process that involves its commercialization and being a rapidly perishable fruit, causes serious losses for farmers. Due to the high content of sugars, it is anticipated that discarded fruit juice can be used as a substrate for the development of bioprocesses to obtain value-added products on an industrial scale. A new model for a 1600 ton / year pineapple wine production plant has been developed with Aspen Plus® v10.0 (Aspentech, Cambridge, MA). It is observed that the cost of the raw material and the fixed manufacturing costs have the greatest impact on the operating cost with 29 and 28% respectively, the capital cost are estimated in US\$ 15.52 million, on the other hand the plant generates 2210 tons of pineapple bagasse as solid waste and emits of 162.3 tons of CO_2 per year.

Keywords: modeling, simulation, techno-economic analysis, pineapple wine

1. Introduction

About 4 thousand tons of pineapple are wasted every year in the Choco region [1]. Thanks to governmental programs that have encouraged the cultivation of this fruit, in recent years the production of pineapple in the region went from 2,737 tons in 2007 to more than 8,000 tons in 2015[2]. However, such an increase in pineapple production leads to a simultaneous increase in waste generation due to the selection and elimination of components during processing. Most pineapples are eaten fresh; nevertheless, only the first-quality fruit is selected for later distribution to the markets. Therefore, fruit that does not comply with these characteristics is left to rot on farms or is sold at very low prices [1]. Although some alternatives to fresh consumption (jams, concentrates, nectars, purées, etc.) are being implemented, a high percentage of the production is still left in the fields as a waste[3]. These practices create both an ecological and an economic problem, because large amounts of organic matter have to be recycled and money must be spent on agrochemicals, labour, and machinery for both the fruit that is consumed and the fruit that is disposed of, but all the costs are borne by the fruit that is consumed. Thus, higher prices and environmental contamination result from fruit surplus[4].

Several alternatives have been proposed and implemented in some countries, mainly transformations by fermentation, with wine, vinegar and other compounds as value-added products. Despite several laboratory-scale experimental investigations of pineapple wine

production, little information is available on the economics of semi-industrial or industrial production [1, 5-7]. In this work, both modeling and simulation are used to evaluate the process of transformation of pineapple juice into wine. To the best of author's knowledge, a techno-economic evaluation to the transformation of pineapple juice into wine under the context of Choco-Colombia region has not been reported so far. Aspen Plus® v10.0 was used to model and simulate the process, then the model was used to estimate the capital and operating costs, as well as the emissions of the plant.

2. Model description

Using the Aspen Plus® software a process flowsheet is presented in Fig. 1. The diagram shows the fundamental operations of the plant: the extraction of the juice, the clarification, fermentation, ageing, filtration and bottling, the process is simulated and the material and energy flows of each operation and the sizing of the equipment can be determined. Based on these values, the purchase costs of the equipment are estimated and with data from the literature assume the values corresponding to the operating costs of each unit. Currently such models (of non-conventional operations) and the related data for evaluation are not at hand. In this work we offer this valuable information. From the design and simulation, the economic analysis of the plant is presented.
Figure 1. Aspen Plus® process flowsheet of the pineapple wine manufacturing plant

3. Outline of Process Technology

Pineapples are mechanically peeled, cored and crushed for juice extraction. The ripeness of the pineapple is judged from the sugar content in the juice; it is assumed that the pineapple juice has a 22°Brix index. Pineapple pomace is considered as a waste and the cost for its final disposal is included in the value of the raw material. Fermentation tanks made of stainless steel are used and the fermentation time is set at 15 days. Pineapple juice of a 22°Brix index when fully fermented with yeast will produce wine with an ethanol percentage of 11.5% at a rate of 1L of wine/kg of juice [8]. The fermentation is an exothermic process and the temperature in the fermentation tank must be maintained below 30°C. Therefore, cooling is required. The storage of pineapple wine results in biochemical- and physicochemical reactions that improve organoleptic characteristics and facilitate its clarification. In this case, the pineapple wine is aged for 6 months, before being bottled. Pineapple wine is stored in stainless steel tanks of 150ton capacity at 20°C, which requires cooling. Then, pineapple wine is filtered to remove all suspended particles before bottling. A suitable technology is a cross flow microfiltration. The aged and clarified pineapple wine is packaged in 0.75 L capacity glass bottles, using a high speed bottling machine at a speed of up to 5000 bottles/h.

4. Economic assessment

The economic assessment includes the purchase prices of the raw material, labor cost, industrial services, capital costs and the tentative value of sale of the finished product, the

economic analysis of the production plant. Additionally, a plant lifetime of 27 years is considered, three years lower compare with a similar project using grapes, due to immediate pineapple availability. It is assumed that 50% of the required capital is covered by a loan with interest of 8% for 15 years, with a discount rate of 4%. The annual depreciation is estimated from the modified accelerated cost recovery system (MACRS) method described in Maroulis and Saravacos [9], in which, the machinery depreciates in 7 years. It assumes a production capacity equal to the installed capacity during the life time of the project. Finally, a 35% tax rate on profits is considered.

5. Results and Discussion

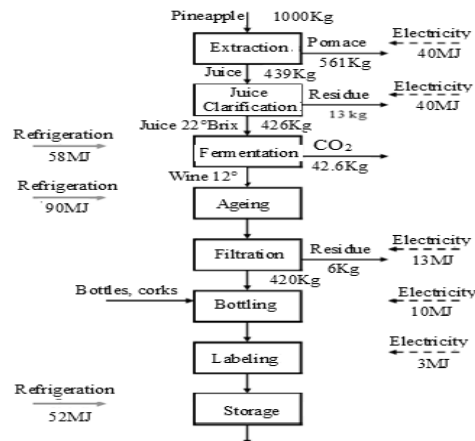
A flow chart of the process including the unit operations considered during the transformation of pineapple juice into wine is shown in Fig. 2. The values are based on 1000 kg of raw material. In the same diagram the requirements of the industrial services are presented in MJ. Also, Table 1 lists the material and energy requirements of the wine manufacturing plant, based on the material and energy diagram in Figure 2. The annual data corresponds to 320h/y. Labour refers only to production workers that is obtained by the counting method, both supervision and technical support are obtained by the factorial method both methods described in Maroulis and Saravacos [9].


Figure 2. Material and energy balances of the pineapple wine manufacturing plant

In the extraction of the juice, pineapple peel and core are considered as residue, and the yield of this operation is taken from the literature with a value close to 44% of pulp juice per each kilogram of pineapple. In this operation, 13kg of waste is generated for each ton of pineapple, which means that from 1 ton of pineapple that enters the process only 426kg reaches the fermenter, which generates a loss of raw material close to 60%. Therefore, a strategy that generates value to these lignocellulosic wastes using superstructure optimization approach, which will be addressed in future work[10, 11].
Based on the juice input flows it the size of the fermenters should be 40 m^3 of stainless steel capacity. The pineapple juice of 22 ° Brix index was inoculated with activated dry yeast (ADY) at the rate of 0.15kg / ton, and was transformed into pineapple wine with

approximately 12% ethanol with a yield close to 1L of wine / kg of juice. The carbon dioxide generated during the reaction at a rate of 0.1kg CO_2 / L juice of 22 ° Brix.

On the other hand, as can be seen in Figure 1, 0MJ of electricity is required for each ton of pineapples for juice extraction, 40MJ for clarification, 13 MJ for filtration, 10 MJ for bottling and 3MJ in the labelling. While the refrigeration requirements are made in the stages of fermentation with 58MJ, aging with 90MJ and storage with 52MJ. It should be noted that water consumption is not considered during the cleaning of both the raw material and the equipment, nor the sterilization process.

Table 1. Material and Energy Requirements of the Pineapple Wine Manufacturing Plant

		Per product		**Hourly basis**		**Annual**	
Product							
Pineapple wine		1.00	kg/kg	5.00	t/h	1 600	t/y
Raw material							
Pineapples	Fr.	2.38	kg/kg	11.9	t/h	3 810	t/y
Bottles	Fg.	0.75	kg/p	6667	p/h	2. 133 333	p/y
Utilities							
Electricity	Fe.	0.05	kWh/kg	0.26	MW	82	MWh/y
Refrigeration	Fz.	0.13	kWh/kg	0.66	MW	212	MWh/y
Labour							
Manpower	M.	6.4	h/t	32.0	p	10 240	h/y

Capital costs and operating costs calculations are based on the short methods detailed in Maroulis and Saravacos [9], the size and cost of the equipment are estimated and the results are summarized in Table 2. The required capitals along with the appropriate assumptions are presented in Table 3.

Table 2. Equipment Cost Estimation of the Pineapple Wine Manufacturing Plant

Equipment	Qty	Size unit	Cost, Thousands US$
1. Fermentation tanks	20	40 ton	1000
2. Storage tanks	10	150 ton	1000
3. Crusher	1	5 ton/h	150
4. Screw press	1	5 ton/h	150
5. Heat exchanger	1	5 ton	150
6. Microfiltration	1	1 ton/h	150
7. Bottling machine	1	5 ton/h	400
			3000

It should be noted that for the economic analysis the purchase price of equipment had to be considered, these prices were updated taking by assuming a Lang factor of 4.5 because it is a new construction for food processing and to be located in an area with difficult access conditions. Although a centralized plant is considered in this work to reduce the cost of transporting the raw material, since more than 60% of the pineapple transported does not end up in the final product local storing might reduce costs significantly. In addition, it is assumed that the plant is close to the fields, the maximum distance is assumed to be 50km. In addition, losses are not considered due to the manipulation of the raw materials.

For the costs calculations the following assumptions are made: the annual operating time is 4 weeks per year, 5 days per week, 2 shifts per day and 8 hours per shift, product rate 4 ton/h, a labour cost of US $ 2.5 / h was assumed, which is representative of the unskilled

Process design and techno-economic analysis of a pineapple wine
production plant under the context of the Choco-Colombia region

workers in the Colombian context, raw material US$0.3/kg, a value three times higher than the price farmers normally receive when selling second and third quality pineapples, packaging material US$ 0.3/p, electricity cost US$ 0.11/kWh, cooling water cost US$ 0.01/kWh. and the results are presented in Figure 3. From figure 3, it is observed that the cost of the raw material is the one that has the greatest impact on the cost analysis, so if the farmers are directly involved in the pineapple wine production the cost of the raw material could decreased and the profitability of the plant could be higher.

Tabla 2. Capital Cost Estimation of the Pineapple Wine Manufacturing Plant

Purchased Equipment Cost	Ceq	3.00	M$
Lang Factor	fL	4.50	-
Fixed Capital Cost	CF	13.50	
Working Capital Cost	CW	2.02	
Total Capital Cost	CT	15.52	M$

The estimated profitability data is shown in Table 4. An internal rate of return of 23% is attractive for this type of investment. In that sense, this model can be the first step of a tool for helping processing decisions in the pineapple wine production sector. Although first result look promising, further research is needed to determine for example the amount of pineapple wine that can be diverted for the production of vinegar or premium-quality brandy.
Figure 3. Operating cost estimation of the wine manufacturing plant per unit of product.

Table 4. Profitability of the Pineapple Wine Manufacturing Plant.

Profitability			
Sales Income	S	6.73	M$/y
Manufacturing Cost	CM	3.81	M$/y
Gross Profit	Pg	2.92	M$/y
Net Present Value	VPN	19.23	M$
Own Capital Cost	Co	7.59	M$
Capital Return Ratio	CRR	2.53	-
Internal Rate of Return	IRR	0.23	-

6. Conclusions

A techno-economic analysis of a plant that transforms pineapple juice into wine as the main product was carried out. The higher capital costs are related to the size of the

fermentation and aging tanks, and the bottling machine. The emissions are primarily the residue or bagasse of the pineapple, which can be arranged in the field or be processed to obtain other products of interest. Moreover, this model can be the first step of a tool for helping processing decisions, making possible to vary the amount of raw material that can be transformed into pineapple wine, giving the flexible enterprise the advantage to better adapt to changes in demands that occur in the market. We are aware that this result may be significantly affected by the size of the plant, raw materials and products prices, or the volume of production and deserves a sensitivity analysis, which will be addressed in future work.

Abstract

Directed self-assembly of colloidal particles is a promising route for the fabrication of advanced materials with novel properties. However, the formation of defect-free non-periodic structures is difficult to achieve without active control. Dynamic models can determine optimal input trajectories of manipulated variables during directed self-assembly. This paper presents a dynamic model for the simulation of particle trajectories in a microfluidic device in the presence of an electric field with time-varying properties, which can be used to predict the dynamic development of the particle density distribution. The model is based on first principles and has been experimentally validated at low particle densities. It has great promise to be used for model-based control of directed self-assembly of colloidal particles.

Keywords: Directed self-assembly, Model-based control, dynamic modelling, dielectrophoresis

1. Introduction

Self-assembly is defined as the spontaneous and reversible association of molecules or particles into organized structures (Whitesides and Grzybowski, 2002). The self-assembly of desired structures can be directed by external fields such as flow, magnetic or electric fields. Such directed self-assembly provides a promising bottoms-up route for the fabrication of advanced materials with micro- and nanoscale structures that may unlock novel optical, mechanical and electrical properties. The control of particle densities is necessary for the formation of defect-free non-periodic structures when specific features need to be self-assembled (Solis et al., 2010). However, controlling a local density of colloidal particles is challenging due to the stochastic nature of the particles, potential lack of local actuation and the highly nonlinear process behaviour. Controls based on free energy landscapes (Tang et al., 2016) and model-free feedback control have been implemented for the electric field assisted crystallization of colloidal particles (Jurez and Bevan, 2012) and for the defect-free alignment of colloidal particles (Gao and Lakerveld, 2018). The use of dynamic models in an open-loop or closed-loop model-based control framework offers the potential to better control the local colloidal particle density, which can ultimately minimize the occurrence of defects for non-periodic structures. However, the development and experimental validation of dynamic models that are favourable for online implementation for control of local particle density within a directed self-assembly process are in their infancy.

Directed self-assembly of micro and nano-sized particles are inherently stochastic even in the absence of measurement noise and unknown perturbations (Ulissi et al., 2013), therefore the dynamics of directed self-assembly processes are typically described with probabilistic models such as the Fokker-Planck equation (Komaee and Barton, 2016) for systems with continuous states or

master equations (Lakerveld et al., 2012) for discrete-state continuous-time Markov processes. The use of master equations is limited to systems with a relatively low number of states. The full set of master equations may become computationally intractable if all states are considered due to the curse of dimensionality. In addition to the computational challenges, experimental validation of probabilistic models is difficult. Therefore, the utilization of existing dynamic models for automated control of directed self-assembly processes remains challenging.

The objective of this work is to develop and validate a dynamic model that describes the dynamic development of the particle density distribution within a microfluidic device in the presence of electric fields that can be used for control purposes. The model is deterministic and describes the prevailing dielectrophoretic and drag forces based on first principles. The model is validated with experiments. In future work, the proposed dynamic model can be extended to include noise from Brownian motion. This model can be a suitable basis for the development of novel open and closed-loop model-based control approaches for directed self-assembly of colloidal particles in microfluidic devices.

2. Approach

2.1. Microfluidic device and self-assembly system

The colloidal particles (silica, diameter of 2 μm) are suspended in DI water. The suspension is contained in a microfluidic device, which consists of two transparent electrodes (one patterned with photoresist and the other unpatterned) arranged in a parallel-plate configuration (see Fig. 1). The patterned electrode (2 cm x 2cm) is fabricated by spin-coating a 25-45 nm thick indium-tin oxide (ITO) coated glass with positive photoresist (400 nm) through standard photolithographic techniques. The two electrodes are separated by a 750 μm thick silicone rubber spacer (Grace Bio-Labs Bend, Oregon). About 23 μL suspension of silica particles is pipetted into a hole that is punched in the silicone double-adhesive rubber spacer. Electric wire leads are connected to the top and bottom electrodes. AC electric fields with a frequency between 300 kHz and 1 MHz and a peak-to-peak voltage between 2V and 10V are applied to the electrodes via a function generator (33500B, Keysight Technologies). Particles are allowed to settle in the device for about 10 minutes at the beginning of each experiment so that the effect of gravity on particle motion can be neglected. The particle assembly in the cell is continuously observed with an optical microscope (Nikon Ni-U) equipped with a digital camera (Nikon Digital Sight Qi2). Images captured by the CCD camera at a rate of 2 frame/s are analysed using image processing functions in MATLAB 2017a to obtain particle positions as a function of time in an automated fashion.

When non-uniform AC fields are applied to the microfluidic device, the particles and medium experience forces of electrical origin including dielectrophoresis (DEP) and AC electro-osmosis (ACEO). DEP is the electrically induced movement of uncharged dielectric particles in the presence of a non-uniform electric field. For two electrodes separated at a certain distance, the minimum electric field occurs at an equidistance to both electrodes which coincides with the center of the photoresist layer in our experimental setup. The maximum electric field occurs at the edges of the photoresist (Gao and Lakerveld, 2018). The direction of the particle motion is determined by the relative polarizability of the particles and the suspending medium. Particles that are more polarizable than the medium are drawn towards regions of electric field maxima (pDEP). Alternatively, particles with lower polarizability compared with the medium are directed to regions of lower electric field (nDEP). ACEO on the other hand, arises from the interaction of ions in the electrical double layer formed close to the surface of the electrodes and the tangential component of the applied electric fields. At the high AC frequencies applied in our experiments, there is insufficient time for the double layer to form, thus there is no resultant fluid flow to drive the particles (Squires and Bazant, 2004). Therefore only DEP is considered in our model development.
Figure 1: Schematic drawing of the microfluidic device

2.2. Model development

The dynamic trajectories of the colloidal particles in the microfluidic device in the presence of electric fields is described by a force balance over the individual particles. The translational motion of a colloidal particle in a fixed frame of reference is governed by the momentum equation:

$$m\frac{d\vec{v}}{dt} = -6\pi\eta a \vec{v} + \pi a^3 \varepsilon_m Re\left(f_{CM}\right)\bigtriangledown|E|^2. \tag{1}$$

The first term on the right-hand side of Eq. (1) is the Stokes drag force acting on the particles where $\vec{v}$ is the velocity of the particle at any given instant of time. The directed self-assembly of the colloidal particles is carried out at a frequency above the charge relaxation frequency of the ions in the electrical double layer; therefore, ACEO effects are assumed negligible. Since ACEO is not considered, the fluid velocity is assumed to be zero, a is the radius of the particle, η denotes the dynamic viscosity of the medium, m represents the mass of the particle. The effects of Brownian motion and particle-particle interactions are not considered in the model and are subject of future work.

The second term on the right-hand side of Eq. (1) is the dielectrophoretic force (Bakewell and Morgan, 2001) acting on the colloidal particles in nonuniform AC fields. The DEP force depends on the gradient of the electric field, $\bigtriangledown|E|^2$, the permittivity of the medium, ε_m and the real part of the Clausius-Mossotti function, $Re\left(f_{CM}\right)$. The Clausius-Mossotti function is defined in Eq. (2) with respect to the complex permittivity of the medium, ε_m^* and particles, ε_p^*;

$$f_{CM} = \left(\frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*}\right). \tag{2}$$

The complex permittivity is defined as $\varepsilon^* = \varepsilon - \left(j\sigma/\omega\right)$, where σ represents the electrical conductivity of the medium and particles, ω is the angular frequency of the electric field applied. The Clausius-Mossotti function is frequency-dependent and dictates the direction of the DEP force. For example, when the particles are more polarizable than the medium, the real part of the Clausius-Mossotti function is positive and the colloidal particles experience pDEP. Parameter values used in the simulations are obtained from literature (Yeh and Juang, 2017) and are shown in Table 1. The gradient of the electric field is obtained from the Laplace equation for electric potential, ϕ according to Eq. (3).

$$\bigtriangledown^2\phi = 0, E = -\bigtriangledown\phi. \tag{3}$$

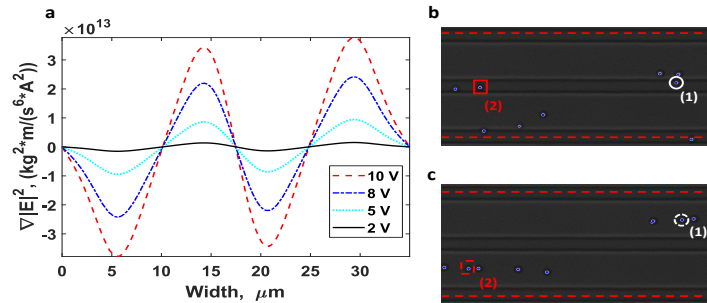
The Laplace equation is a mixed boundary problem which involves a boundary condition for the applied voltage on the electrode surface and a zero-flux condition in the direction normal to the electrode plane. The solution of the mixed boundary Laplace equation is computed by the finite element method using COMSOL Multiphysics to obtain the gradient of the electric field norm as function of position in the microfluidic device as shown in Fig. 2a, which completes the dynamic model.


Figure 2: (a) FEM simulation of the gradient of electric field norm squared at different voltages (b) Initial positions of particles for an experiment at low particle density. (c) Particle positions after a step change from no electric field to an AC field of 1 MHz and 10 V for 32.5 s.

Table 1. Parameter values used in simulations

Parameter	ε_p	ε_m	σ_p	σ_m
Value	$3.363 \times 10^{-11} F/m$	$6.947 \times 10^{-10} F/m$	$2.56 \times 10^{-3} S/m$	$1.23 \times 10^{-2} S/m$

The model is used to simulate the dynamics of the colloidal particles in the microfluidic device with results for a step change in frequency and voltage (from 0 to 1 MHz and 0 to 10V, respectively) shown in the following section.

3. Results and Discussion

3.1. Simulation and validation of particle trajectories for a low particle density

In order to validate the predictive capabilities of the dynamic model, the model is first used to predict the trajectories of single particles in an experimental system with low particle density (see Fig. 2b), which facilitates easy particle tracking. Simulations of the single particle trajectories are performed using the initial particle positions obtained from the experiment. Under the experimental conditions, the electric-field minima for the system are located in the middle of the photoresist layer while the center of the ITO layer forms (indicated with red dashed lines in Fig. 2b and 2c) a potential barrier to particle motion. The predicted trajectories of two selected particles (indicated with circles and squares as particle (1) and (2), respectively, in Fig. 2b and 2c) obtained from simulation are shown in Fig. 3. Furthermore, the experimentally obtained particle trajectories are shown for comparison. The predicted particle trajectories from simulation are generally consistent with the experimental particle trajectories. The model slightly overestimates the response time when a step change in AC frequency and voltage is applied compared to the experimental trajectories. Nevertheless, the model predictions are satisfactory when considering that no fitting parameters have been used and the effects of Brownian motion have been neglected.

The performance of the model under pDEP conditions has also been tested, which is not shown here due to space limitations. The predicted particle trajectories when pDEP is the dominant electrokinetic phenomenon are also consistent with the experimentally observed particle trajectories. Therefore, it is concluded that the model can predict individual particles trajectories well at least in dilute systems when either nDEP or pDEP is the dominant electrokinetic phenomenon.

3.2. Simulation and validation of particle density distribution

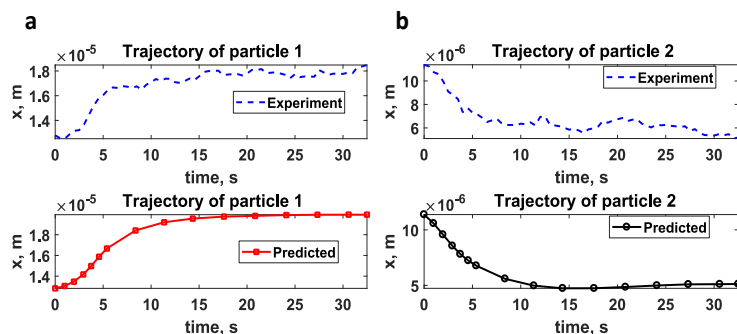
The performance of the dynamic model at high overall particle density is investigated in this section. The particles are initially randomly distributed (see Fig. 4a) but are directed towards the


Figure 3: Experimental and predicted trajectories of particles (1) and (2) in Fig. 2b and 2c
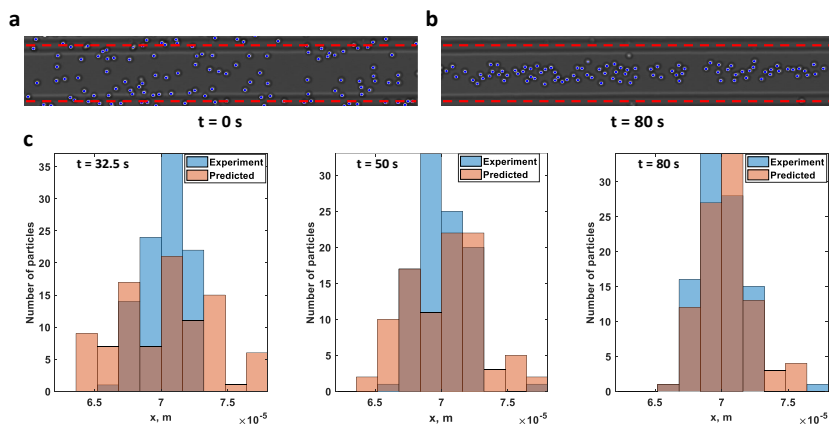

Figure 4: Particle density (a) at the start of experiment (b) when AC fields of 10 V at 1 MHz are applied for 80 s. (c) experimental and predicted particle distribution in the microfluidic device at 32.5 s, 50 s and 80 s respectively.

middle of the photoresist layer by an nDEP force acting on the particles as shown in Fig. 4b. Simulations of the particle density distribution are based on the initial particle positions of Fig. 4a. The experimental and predicted density distributions at different times are shown in Fig. 4c for comparison. It can be seen that the density distributions of the experimental system show less variation with time compared to the distributions obtained from the model. In addition, the dynamics of the model seem slower in comparison with experiments. It can also be observed that the accuracy of the model initially increases with time. However, simulations at longer times for which experimental results are not available indicate that all the particles accumulate in the center of the photoresist layer after about 400 s which is physically not possible in the experimental system because of the high overall density. The error between the model predictions and experiments may be the result of particle-particle interactions. Particle-particle interactions would have to be added to the model to predict such long-term behaviour more accurately.

4. Conclusion

A dynamic model based on the dielectrophoretic and drag forces acting on colloidal particles is presented to predict the dynamic trajectories of particles during directed self-assembly in a mi-

crofluidic device. The combined trajectories of all particles in a system can predict the dynamic development of the particle density distribution, which is of practical importance for assembling defect-free small-scale structures. The model predictions of the particle trajectories at low particle densities are in good agreement with experiments. The model is based on first principles and is computationally tractable for online implementation to develop novel control approaches for directed self-assembly. The model can be extended in future work by considering Brownian motion and particle-particle interactions from induced dipole forces (Mittal et al., 2008) and electrostatic forces that result from the particles acquiring a negative surface charge density in water. The electrostatic forces between the colloidal particles can be obtained from the DLVO theory.

Abstract

Quality by Design (QbD) is the concept of designing a process by gathered knowledge to fulfill desired quality of the product. This requires monitoring and controlling product quality throughout process development. In biotherapeutics production, glycosylation is one of the major quality attributes. In general, the glycoform generated by the cell glycosylation machinery is highly dependent on the cell performance and the variations in its surrounding. Mathematical modelling of this machinery can facilitate process understanding, describe the complexity of different layers of cellular metabolism and enable model-based optimization of product formation.

In this work, we investigate possible feeding scenarios utilizing a calibrated model to help understanding the possible effects of process changes in the paradigm of QbD for biotherapeutics. Our QbD objective is to maximize product yield while satisfying product quality given by criteria on the protein glycosylation pattern. For this we use a mechanistic model comprised of three major layers (scales) including bioreactor dynamics, intracellular reaction network and kinetic reactions inside Golgi apparatus. We apply design of experiments method followed by *in silico* experiments using the mechanistic model to identify optimal feeding profiles and evaluate the respective formed glycopatterns. In a future step, these predictions can be experimentally tested. Thereby, in a series of steps, a model can be developed to be used for model-based optimization.

Keywords: Biotherapeutics, Quality by Design, Mathematical Modelling, Optimization

1. Introduction

Variations in product quality are generally caused by changes in the production process. In order to be able to ensure that the product quality variations lie within pre-defined ranges, a systematic approach is needed. This approach should be able to incorporate knowledge of the process and effects of critical factors on product quality. This is called QbD, where the key elements are the critical process parameters (CPPs), the critical quality attributes (CQAs), the design space, and the quality target product profile (QTPP) (ICH Q8). The implementation of QbD needs, first, a definition of the intended

product properties to define QTPP. Through process knowledge, regulatory guidelines and literature, CQAs can be identified. To identify the sensitive parameters (i.e. CPPs) affecting the QTPP, often an initial experimental design for screening is conducted in the wet-lab. The CPPs should be monitored and controlled to ensure the process produces the desired quality.

In biotherapeutics production considered in this work, bioactivity, stability and *in vivo* circulatory half-life are examples for QTPP. One of the most important CQAs is the protein glycosylation pattern, since it highly affects the respective QTPPs. Human-like glycosylation is important for correct functionality of glycoproteins. Usually, well known CPPs for mAb CQAs include cultivation parameters (e.g., pH, dissolved oxygen, temperature) and medium composition (e.g., carbon and nitrogen sources, vitamins, trace elements).

An important step in the QbD process is to determine the design space for the CPPs. The design space as defined in (ICH Q8) is "*the multidimensional combination and interaction of input variables and process parameters that have been demonstrated to provide assurance of quality. Working within the design space is not considered as a change. Movement out of the design space is considered to be a change and would normally initiate a regulatory post-approval change process*". Description of the design space provides flexibility of the manufacturing process in the defined ranges.

To determine the design space, additional experiments are needed within the boundaries of the CPPs. Statistical design of experiments (DoE) helps in a systematic planning of such experiments in order to identify the effects of variations of CPPs on CQAs. In the paradigm of QbD, the traditional one-factor-at-a-time designs are no longer efficient since a holistic understanding of the system at hand is aimed for.

Combination of DoE methods for process development and model-based simulations within the QbD context can provide an estimate of the critical QbD elements before running time consuming and cost intensive experiments. In addition, it can help in assessing the points in parameter boundaries where performing real experiments face limitations.

As pursued in this work, model-based optimization for QbD in biotherapeutics production, the optimization of the cell culture process in regard to product quality requires systematic analysis of the glycosylation throughout the cell line and process development. The biosynthesis of glycans is a result of a complex network of metabolic and enzymatic reactions that are influenced by many factors, including the host cell line as well as the upstream and downstream bioprocesses (Sha et al. 2016). Mathematical modelling of the system provides better understanding on the product quality variations. Initial computational models (Umana and Baily 1997) approximated the Golgi apparatus as a series of continuously stirred tank reactors where reactions generate potential glycan structures. Hossler et al. (2007) started to adopt the Golgi maturation model and used plug flow reactors in series to mimic the change in enzyme concentrations along the Golgi apparatus. Follow-up models were developed to simulate antibody glycosylation specifically, and particular attention was paid to the nucleotide sugar donor level to link glycosylation to cellular metabolism (Jedrzejewski et al. 2014). The mechanistic models which link glycosylation to cellular metabolism are state of the art (Jedrzejewski et al. 2014, Sou et al., 2017).

In this work, we utilize the current state-of-the-art modelling approach in combination with DoE methods to assess and understand the process response. This is done as a first step towards a model-based approach of a QbD workflow. Before performing the experiments in wet-lab, the resulting responses are checked against observations taken from literature. The results of these *in silico* studies give first insights about the system`s outcome and need to be later tested experimentally. Finally, the predictive nature of mechanistic models can be used for control of the glycosylation process and pave the way towards quality-based optimization of therapeutic production bioprocesses.

2. Modelling and Identification Approach

2.1. Mathematical Model of Cell Culture and Protein Glycosylation

We use our previous mechanistic model (Ehsani et al. 2017). It includes three layers (i) extracellular, (ii) intracellular dynamics coupled with (iii) glycosylation reactions inside Golgi apparatus. The model equations are solved using ODE15s in MATLAB R2017b. We perform a global sensitivity analysis (Wang et al. 2003) by evaluating 105 samples in the range of 50%-200% of the nominal values of the parameters nominal values. By calculating first order global sensitivity indices, we can fix 97 parameters, out of 133, to their nominal values. We use a scatter search optimization algorithm (Egea et al. 2009) to estimate the remaining parameter values and fit model outputs with experimental data of hybridoma batch culture taken from Jedrzejewski et al. (2014).

2.2. Design of Experiments

We conduct two rounds of design of experiments using Box-Behnken design (MATLAB Statistics Toolbox) as a response surface method, each one followed by *in silico* experiments. The design goals are, first, finding the strategy to maximize protein titer and second taking this strategy as starting point to adjust glycosylation pattern.

In the first DoE round, three factors (decision variables), namely glucose and glutamine feeding concentrations and the number of feed boluses are incorporated. Three levels of each factor are considered, which corresponds to low, middle, and high for the concentrations and one, two or three number of boluses. The boundaries of 5-15 mM and 2-6 mM are used for glucose (Glc) and glutamine (Gln) respectively, according to the feeding strategies reported for hybridoma cell by Pörtner et al. (2004). With this input, a set of 15 experiments are designed that are then performed *in silico* to examine the effects of different feeding strategies on process performance.

The values for the fed-batch process that results in the maximum value of response (protein titer) are selected as starting point to perform the second round of DoE. In this case, four factors, namely N-acetylglucosamine, fucose, galactose and sialic acid, in three levels within the boundaries of 1-10 mM, 1-8 mM, 5-20 mM and 1-5 mM are assessed using Box-Behnken design followed again by *in silico* experiments.

2.3. Identify Feeding Strategies by Optimization of Response Surface Function

We use the outcomes of the designed set of experiments in previous section to fit a second-order function as response surface (R). This function (Eq. (1)) is composed of

intercept (β_0), linear terms (β_1, β_2, β_3), cross product terms (β_{12}, β_{13}, β_{23}) and squared terms (β_{11}, β_{22}, β_{33}).

$$R = \beta_0 + \sum \beta_1 Glc + \sum \beta_2 Gln + \sum \beta_3 No.Feed\ \beta_3 + \sum \beta_{12} Glc\ Gln + \sum \beta_{13} Glc\ No.Feed +$$
$$\sum \beta_{23} Gln\ No.Feed + \sum \beta_{11} Glc^2 + \sum \beta_{22} Gln^2 + \sum \beta_{33} No.Feed^2 \tag{1}$$

We use numerical optimization function *fmincon* (MATLAB Optimization Toolbox) to calculate the optimum point of the response function (Eq. 1) within the boundaries of its variables as mentioned in previous section.

After performing two DoE rounds and *in silico* experiments, we find the optimal values for supplementation of both nucleotide sugars and nutrients for maximizing the response function. This approach can be extended in our future research using dynamic optimization in the whole space of decision variables.

3. Results and Discussion

In this section, we briefly present the results obtained in the considered case study.
Figure 1. The projection of the response function (protein titer) with respect to the different levels of glucose and glutamine concentration and number of bolus feeds. Dashed lines show the protein titer in min/max levels; solid line shows the protein for medium values of the other factors.

We show the changes in response function (protein titer) in different levels of decision variables from the first DoE round in Figure 1. The toxic effect of ammonia in the culture is assumed to be the limiting factor when overfeeding occurs. In order to avoid overfeeding, the simulated culture stops, when ammonia accumulation reaches 4 mM.
Figure 2. Batch (dashed line) and fed-batch (solid line) simulation results of (A) cell density, (B) glucose and (C) glutamine dynamics and (D) protein titer. Experimental data are shown with solid circles.

As shown in Figure 1 the optimum feeding strategy is two feeds with 13.4 mM glucose and 3.9 mM glutamine concentration. This fed-batch strategy results in a maximum cell density of 2e+6 cells/ml and 218.6 mg/L protein titer. Supplementing cell culture media by glucose and glutamine provides major nutrients and energy sources for growth and

protein production. We show in Figure 2 the dynamics of cell density and the concentrations of glucose, glutamine and protein in batch and the selected fed-batch process with maximum protein titer in first round of *in silico* experiments.

Coupling glycosylation to the metabolic model provides the opportunity to assess the effects of supplementation on product quality and helps in making further improvements in the process. Figure 3 shows the differences between eight important glycosylation patterns in batch and fed-batch processes. Generally, there is a shift from accumulation of unmatured early structures (high mannoses like M5) to more complex structures: The glycosylation pattern of batch culture shows the presence of more than 10% Mannose-5 glycans which in monoclonal antibodies should be normally less than 10% (Blondeel and Aucoin, 2018).

In the fed-batch culture providing enough glucose and glutamine caused conversion of this early structure to more complex glycans. M3Gn2F is the most popular structure in monoclonal antibodies with around 40% (Blondeel and Aucoin, 2018). The fraction of this structure in fed-batch compared to batch culture is about 2.5 fold higher. This results in improved quality, albeit not sufficiently. Further quality improvement could be achieved possibly through supplementing N-Acetylglucosamine. In average, the amount of galactosylation is between 10-40% depending on the glycoprotein (Blondeel and Aucoin, 2018). As shown in Figure 3 the galactosylated (M3Gn2FG /M3Gn2FG2) content is also increased in fed batch but not in the same rate as M3Gn2F increased. This arises from the fact that the cell is producing more glycosylated protein having enough glucose available, while the intracellular biosynthesis rate of galactose is limited by the cell`s capacity. Therefore, Galactose supplementation can increase the galactosylated content.

In the second DoE round, we assessed further supplementation of nucleotide sugars using Box-Behnken design in 46 *in silico* experiments. According to the results the optimum glycosylation pattern can be achieved by adding 15 mM Galactose and 6 mM N-acetylglucosamine in 3 boluses. These predictions are in well agreement with literature reports where the most effective and popular supplementation strategy to increase galactosylated content is to feed N- acetylglucosamine 7-10 mM and galactose 10-20 mM (Blondeel and Aucoin, 2018). This feeding strategy also increased the sialylated content to about 2% which improves plasma half-life of the glycoprotein (Sha et al., 2016).
Figure 3. Batch (dashed line), fed-batch with (dark solid line)/ without (light solid line) nucleotide sugars supplementation, simulated dynamics of eight important glycan structures. M: mannose, Gn: N-acetylglucosamine, F: fucose, G: galactose, S: N-acetylsialic

4. Conclusions

Implementation of QbD requires detailed characterization of the process and thorough exploration of the various conditions that can affect the quality. In this work, we use a mechanistic model of cell culture and glycosylation to identify biological meaningful feeding strategies and pave the way towards quality-based optimization of glycoforms. We proposed adjustment of CQA (glycosylation) by supplementing nutrients (nucleotide sugars) and the qualitative behavior of our model showed agreement with reported literature data.

Abstract

In this paper, a mathematical model is developed for microalgae filtration by applying Population Balance Equation. The main objective is to investigate the impacts of cell size distribution and filter average pore size on filtration efficiency and their interrelationships. The results of using standard filters with different pore sizes are compared and discussed. Experiments of microalgae filtration on Chlorella cells are performed to provide size distribution information of the cell cultures to validate the model. Behaviours of cells at different sizes during the harvesting process are examined and the obtained data is combined with the mathematical model to evaluate the harvesting efficiency along with operation time and filter depth. The model could be extended to predict the size specific filtration efficiency of microalgae under different operation conditions, which potentially helps determine the process parameters for optimization purposes.

Keywords: Microalgae harvesting, Filtration, Population Balance Equation

1. Introduction

Biofuel, as a renewable energy, is an alternative to the traditional fossil fuel. One of its bio-resources is microalgae, which is regarded to be promising with high lipid content and high photosynthetic efficiency. Microalgae harvesting has been the bottleneck of the whole microalgae production process since it accounts for 20-30 % of the cost (Danquah et al., 2009). Therefore, maximizing the harvesting efficiency as well as capacity and meanwhile minimizing the cost are of critical importance to the development of a scale-up process for industrial purposes.

Filtration is a commonly employed harvesting method for microalgae because of its high efficiency as well as stable operation conditions without using chemicals. Although research efforts have been dedicated to investigate the efficiency of microalgae filtration, few modelling works have been done to understand the relationships between different physical parameters. Previous studies usually consider the algal culture, which contains different cell sizes, as a whole for performance evaluations (Wicaksana et al., 2012; Zhao et al., 2017). However, not many concerns have been raised towards the interdependence of cell size distribution and the corresponding cell recovery although size distribution is a critical factor of the filtration process.

The main objective of this study is to apply Population Balance Equation (PBE) to simulate the microalgae filtration process. This equation has been commonly used in chemical engineering processes to describe evolutions of particle populations. There are few studies employing PBE for modelling microalgae growth (Pahija et al., 2017) and harvesting processes of sedimentation and centrifugation (Lee et al., 2018). So far there is no significant research contribution to the application of PBE to model the microalgae filtration process and to study the impact of cell size distributions or characteristics. In this study, a PBE model is proposed for investigating microalgae filtration efficiency, which derives additional size specific information of the cells during the process.

2. Methodology

Applying Population Balance Equation to microalgae filtration, a model is proposed with the aim to study size dependent recovery and filtration coefficient of the process. Experimental data is used to evaluate the process efficiency and to validate the mathematical model.

2.1. Population Balance Equation model

One of the simplified forms of PBE for studying particle size distributions commonly includes two terms as follow:

$$\frac{\partial n(t,d)}{\partial t} + \frac{\partial[G \cdot n(t,d)]}{\partial d} = 0 \tag{1}$$

The first term on the left side denotes changes in particle number density with time, while the second term represents the change with particle size, in which n is number density, t is time and G is particle growth rate. To model the microalgae filtration process, Eq. (1) is modified into the following form in this study:

$$\frac{\partial n(t,h,d)}{\partial t} + v\frac{\partial\big[[1-\phi(h,d)] \cdot n(t,h,d)\big]}{\partial h} = 0 \tag{2}$$

The first term is similar to that in Eq. (1), while the second term is revised to be the cell number density change with h, which denotes traveling distance of cells inside the filter medium. ϕ is defined as filtration coefficient, so that the fluid velocity v times $[1-\phi(h,d)]$ together gives the cell velocity inside the filter medium. The larger the coefficient, the smaller the cell velocity compared to fluid velocity, resulting in higher harvesting efficiency of microalgae. First order upwind discretization scheme is used to generate numerical solutions for Eq. (2).

Since the model parameters i.e. cell number density, cell size, time, filter depth and flux can be easily measured, the filtration coefficient can be back-calculated for evaluations of the process efficiency. In addition, the main purpose of the model application in this paper is to compare and study the impacts of different filter mediums on cell size distributions during microalgae filtration.

2.2. Experiments

Chlorella is a common green spherical microalgae species and the cell size ranges from 3 um to 9 um. In this study, an experimental setup of dead end vacuum filter with filter diameter of 50 mm is used to separate the cells from the cultivation medium. To

evaluate the impacts of filter pore size on the harvesting process, standard polypropylene filters with different average pore sizes of 6, 8, 10, 15 and 20 um are used. Each run of the experiment filters 10 mL microalgae solution for 1 min and the filtrate's optical density (OD) as well as size distribution are measured. In every sampling, 1.5 mL filtrate is transferred by an electronic pipette to a photospectrometer for OD measurement to obtain the solution concentration. Meanwhile, a micropipette is used to take10 uL filtrate for imaging under a microscope and the images are processed and analysed by a computer software to give cell size distribution information. A calibration curve of the relationship between cell concentrations and OD is experimentally attained prior to conducting the filtration experiments.

3. Result

Performances of filtration is commonly evaluated by the change in liquid concentration after the process. In this study, the filtration efficiency is defined as the percentage change in optical density, which is proportional to the cell number density, from the original algal solution to the collected filtrate. The overall filtration efficiency represents the percentage change in cell number density of the solution as a whole without taking the specific change of cells at each size into consideration. After the experiments and data analysis, the overall filtration efficiencies of microalgae filtrations with different filter mediums are obtained. With the previously mentioned calibration curve, the cell number densities of the filtrate samples can be derived from the OD measurements. By fitting the cell size distribution results into the proposed PBE model, the filtration coefficient ϕ defined in the model can be derived.

As shown in Figure 1, the filtration efficiency is inversely proportional to pore size as expected and the relationship is observed to be almost linear. Although the pore size of from 15 to 50 um are obviously larger than the cell size range of 3 to 9 um, considerable amounts of cells are captured. Therefore, concerns are raised towards size selectivity of the microalgae filtration process and the mechanisms behind. With an original mean cell size of 5.381 um, Figure 2 shows the mean filtrate cell size, which drops with decreasing filter pore size. From the pore size of 6 um to 15 um, it is observed that smaller mean pore size filters can effectively capture smaller size cells since the cells cannot penetrate through the narrow pores. However, a drop of mean captured cell size is observed at 20 um pore size, implying that an increasing number of small cells are captured even though the pores become larger. This data briefly indicates the tendencies of the filters to capture cells at different sizes.
Figure 1. Impact of filter pore size on the overall cell harvesting efficiency
Figure 2. Impact of filter pore size on the mean filtrate cell size

Analysing size distributions of the captured cells can give additional information of microalgae filtration for studying the changes in mean cell size during the process. Figure 3 presents the size distributions of captured cells after the filtration experiments. It agrees with the previous findings that the number density of microalgae in the filtrate generally decreases when a filter with smaller pores is used. Applying Population Balance Equation to simulate the filtration process, the harvesting efficiencies of microalgae cells at each size changing along with time and travelling distance throughout the process are investigated. After numerical simulations of the developed PBE model with size distribution data from the experiments, the size specific filtration coefficients of microalgae filtered by medium of different pore sizes are obtained as shown in Figure 4.
Figure 3. Size distributions of captured cells with different mean filter pore sizes
Figure 4. Derived size specific filtration coefficients of microalgae from the PBE model

Two different patterns are observed for smaller pore sizes (6, 8 and 10 um) and larger pore sizes (15 and 20 um). For small pore sizes of 6, 8 and 10 um, the coefficient increases with cell size, indicating that larger cells are more favourable to be captured. Among the three curves, the 6um pore size curve has the steepest slope, which means it is more sensitive to cell size and its selectivity for large cells is higher. For large pore sizes of 15 and 20 um, convex curves are observed, indicating that both large and small cells are more favourable to be captured. The 20 um pore size curve is comparatively

steeper, such that the filter captures small and large cells better but oppositely it captures middle size cells worse than 15 um pore size filter.

4. Discussion

Comparing the overall filtration efficiencies of the tested standard filters, the filters with smaller pore size are generally more effective in capturing the microalgae cells. Studying the pattern of the derived size specific filtration coefficients gives additional insights of the process size selectivity as well as the filtration mechanisms behind. It is shown in Figure 4 that 6, 8 and 10 um filters demonstrate similar size selectivity patterns, which the direct interception mechanism is essentially dominant. 6 um filter gives the best overall filtration efficiency, but its performances for capturing 3 and 3.5 um cells are the worst. For 15 and 20 um filters, although their resulted changes in mean captured cell size are different, their derived filtration coefficients give similar patterns. The capture of more large cells can again be explained by the direct interception mechanism. Meanwhile, the tendency of capturing more small cells by larger pore filters shows that other mechanisms which are selective towards small cells are dominant. Particularly, the mechanism of electrostatic effect favours the capture of small cells since microalgae cell surface is known to be negatively charged and it is enhanced with increasing charge intensities of the cells. The convex pattern implies that in addition to direct interception, electrostatic effect is also affecting the process size selectivity. This is in alignment with the literature finding of a minimum filtration efficiency at a certain particle size in micron scale when the pore size to particle size ratio becomes large (O'Melia and Ali, 1978; Yao et al., 1971), confirming the results of this study.

With the PBE model, the actual size selectivity of the filters are derived. If only the overall filtration efficiency or mean cell size is considered, a very brief conclusion of the filters' capturing tendencies may be drawn. For example, although 15 um filter apparently tends to capture more large cells than small cells as shown in Figure 2, it actually tends to capture both small and large cells as shown in Figure 4. Its size selectivity pattern is also quite different from those of 6, 8 and 10 um filters, which this information is obtained by the model simulation. The new modelling approach to examine the size specific performance of microalgae harvesting derives additional information of the process size selectivity. This is useful for understanding the interrelationship between process parameters and cell characteristics, including cell size and surface charge.

5. Conclusion

A Population Balance Equation model is developed for modelling microalgae filtration, which is a common harvesting process in microalgae production. The model effectively describes changes in cell number densities with cell size, filter pore size, filtration time together with filter depth during the process. Filtration experiments are carried out on Chlorella cells by using filters different pore sizes. Experimental data, including the overall filtration efficiency, mean filtrate cell size and size distribution, are processed and analysed from a size specific approach. The results are combined with the developed mathematical model to study the impacts of cell size distribution and filter pore size on the filtration performance as well as their interrelationships. Furthermore,

size specific capturing of the cells is investigated for a clearer picture of the process size selectivity.

The derived size specific filtration coefficient provides insights to anticipate the effectiveness of different filter mediums for the filtration process. Instead of analysing the cell culture as a whole, this model focuses on size selective properties of microalgae filtration. The PBE model can also be extended to study and predict microalgae size distributions throughout the filtration process with different parameters or set ups. Meanwhile, it is beneficial for the determination of process parameters, such as filter pore size, material, thickness and filtration time for specific size selective separation purposes as well as process optimization.

Optimisation of Aqueous Two-Phase Systems

Emma Chandler[a], Robert Falconer [a] and Solomon Brown[a,*]

[a]*Department of Chemical and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, United Kingdom*
s.f.brown@sheffield.ac.uk

Abstract

Aqueous two-phase extraction (ATPE) is a liquid-liquid extraction (LLE) technique which is viable as a continuous protein purification unit operation for the manufacture of therapeutic proteins. A shift from batch to continuous manufacturing in this industry has been encouraged by regulatory bodies, including the Food and Drug Administration (FDA), as it is expected to increase the quality and consistency of the product and decrease manufacturing costs.

For ATPE to compete with current batch protein purification procedures, a multi-stage operation can be used to achieve a high purity and yield. However, there is a lack of reliable modelling techniques in the design of multi-stage ATPE; as a result, its design and operation is often reliant on both individual expertise and trial and error. To reduce this, there is a need to develop modelling techniques to aid in system design. In this study we present a modified equilibrium binary separation method to predict an optimal number of stages in a multi-stage system. The model is validated against data, for both traditional LLE and ATPE, in a counter-current multi-stage operation [Rosa et al., 2009a, Warade et al., 2011]. The model is then applied to a case study separation of phycocyanin from lysozyme using PEG-phosphate ATPE. The model is successfully used to predict a suitable design of a counter-current multistage system to optimise purity and yield of the target protein. The approach provides the basis with which to design general ATPE-based continuous downstream processes incorporating extraction, back-extraction and washing steps.

Keywords: Aqueous two-phase extraction, equilibrium binary separations, multi-stage optimisation.

1. Introduction

Aqueous two-phase extraction (ATPE) has been demonstrated to be capable of being a valuable alternative protein purification technique to chromatography [Rosa et al., 2010]. The unit operation is cheap relative to chromatography and, unlike chromatography, it is geared towards continuous manufacturing. Continuous manufacturing, as opposed to the traditional batch manufacturing techniques used in biomanufacturing, has been encouraged by regulatory bodies such as the FDA as it is seen as a way to reduce costs, increase manufacturing capacity and increase the consistency of the product quality [Konstantinov and Cooney, 2014]. A move to continuous manufacturing will require either a rethinking or replacement of the current downstream purification operations. However, these new manufacturing techniques still need to compete with the current manufacturing techniques as well as meet the high purity standards required of the regulatory bodies of this industry [Azevedo et al., 2009].

Currently, there are two major drawbacks to ATPE as a unit operation: the low purity / yield achieved in a single stage operation, and the lack of understanding of the phase forming mechanisms [Rito-Palomares, 2004, Ruiz-Ruiz et al., 2012]. The number of different parameters which

control the phase separation and protein partitioning mean that the process optimisation is achieved through trial and error, which is both time consuming and expensive. Modelling strategies have been employed to identify key performance parameters, such as the concentration of the phase forming material (polymer(s) and salt(s)) used, and reduce the experimental workload [Rosa et al., 2007, Mao et al., 2010, Patel et al., 2018]. However, the specifics of optimising system selection still requires extensive experimental work and experience. Multi-stage techniques have been used extensively in the process industries when a separation technique is simple and cost effective but provides low purity and / or yield. In PEG-Salt ATPE the economics of the process can be further improved through using the multistage technique of back extracting the target protein into the less expensive salt rich phase, so that the more expensive polymer rich phase can be recycled [Rosa et al., 2013].

A common method for the stage-wise optimisation of equilibrium binary separations is McCabe Thiele. It was originally used to determine the number of stages for binary distillation and is still widely used in this application [Richardson et al., 2002]. The method has been demonstrated to be suitable for traditional liquid-liquid extraction (LLE) by Warade et al. [2011]. In this study a single operating line was used to optimise the number of stages for a specified purity in multi-stage counter current systems. The method was also demonstrated to be suitable for ATPS when it was applied by Rosa et al. [2009b,a], who also used a single operating line to optimise the number of stages for a required yield in ATPE. They also utilised equilibrium curves of different fractions of Chinese Hamster Ovary (CHO) cell media to predict the success of their extraction from Immunoglobulin G (IgG) [Rosa et al., 2009b]; however, the number of stages for extraction was not determined. In both cases, a single component is considered in the model the target component. In terms of traditional LLE, there are often only two components and by considering one, the other component can be inferred as one phase forming component is the target compound and the other is the contaminant. However, in ATPE, the phases are formed by the phase forming components (i.e. polymer(s), salt(s) and water) and the partitioning of the contaminants (protein, cells and solutes) is determined by the phase forming components and the environmental conditions. As such by considering only the target protein, the contaminants cannot be inferred in ATPE, and only the yield of the system can be evaluated.

This paper uses equilibrium binary separations to evaluate and optimise multi-stage ATPE. The model is validated using the experimental data in Warade et al. [2011], (counter-current multi-stage traditional LLE) and in Rosa et al. [2009a], (counter-current multi-stage ATPE). In this paper the models in Rosa et al. [2009a] and Warade et al. [2011] are interpreted for a counter-current multi-stage ATPE to evaluate both contaminants and target protein in a model separation of phycocyanin from lysozyme using a PEG phosphate ATPE. Equilibrium curves were constructed for both the target protein, phycocyanin, and the contaminant. The required number of stages to achieve the desired purity and yield were predicted using the model. Through alteration of the operating line, the system could be evaluated in other operational configurations, for instance co-current, cross-current, etc.

The work is structured as follows, Section 2 presents the model formulation developed, Section 3 presents the results from validating the model followed by the results from the model separation of phycocyanin from lysozyme and Section 4 discusses the conclusions from this work.

2. Model Formulation

In this work, we present a model for the multi-stage ATPE which incorporates the separation behaviour in each stage and that may then be used as a basis for optimisation. The model firstly assumes that while the phases are semi-miscible, the phases are treated as immiscible; this is a common assumption for ATPE. The process is isothermal so an energy balance is not used [Mistry et al., 1996, Rosa et al., 2009b,a]. It was assumed that perfect mixing was achieved

at each stage and the phases are operated in equilibrium. In ATPE, several components must be considered and can be divided into the phase forming materials (polymer(s), salt(s) and water), and the protein / particulates / cells which are to be partitioned (the contaminants and target protein /cells / particulates). The partitioning of the protein is assumed to be a result of the phase forming materials. The concentration of the phase forming components and the phase volumes are assumed to be constant across the system [Rosa et al., 2009b,a]. The binary separation evaluated is the target protein from the contaminants.

Assuming X is the phase which the component / solute should be removed from and Y is the target phase, the volumes of the phases are V_X and V_Y respectively. A mass balance across an entire counter-current process can be written as:

$$V_x X_0 + V_Y Y_{n+1} = V_x X_n + V_Y Y_1 \tag{1}$$

Likewise, material balances for stage i can be written as:

$$V_x X_{i-1} + V_Y Y_{i+1} = V_x X_i + V_Y Y_i \tag{2}$$

Using equations (1) and (2) we can pose the stage-wise optimisation of the multi-stage ATPE as follows:

$$\max X_N \le X_{Target} w \tag{3}$$

Where X_{Target} is the required concentration in phase X. If optimising for yield, X is the bottom phase and the solute / component to be considered is the target solute /component. If optimising for purity, X is the top phase and the solute / component to be considered is the contaminant solute / component. To determine the first step a mass balance across the entire system is used:

$$Y_1 = Y_{n+1} - \frac{V_X}{V_Y}(X_n - X_0) \tag{4}$$

Each stage is then evaluated as follows:

$$\left. \begin{aligned} X_i &= f(\text{equilibrium line}), \\ Y_{i+1} &= Y_i - \frac{V_X}{V_Y}(X_i - X_{i-1}), \end{aligned} \right\} \quad i = 1, \ldots, n \tag{5}$$

Where f is the function determined for the equilibrium line. The line is determined by piecewise linear function between the equilibrium points. To determine equilibrium points, a model separation of phycocyanin from lysozyme was carried out using a PEG-phosphate ATPE. Two equilibrium curves were generated; one for phycocyanin and one for lysozyme. Protein concentration was determined using ultraviolet visible spectroscopy.

Figure 1: Depiction of a multi-stage counter current operation.

(a)   (b)
Figure 2: (a) McCabe Thiele diagram generated from data in Warade et al. [2011]. (b) McCabe Thiele diagram generated from data from Rosa et al. [2009a]. The dotted lines represent the stage results from the original authors. The solid line shows the results from the model in this paper.

3. Case Study

Figure 1 shows a schematic representation of the multistage counter current system where Y_i is the concentration of the phase component / solute in the target phase (% w/w) or (mg /ml) of stage i, for stages 1 to n, and X_i is the concentration of the phase component / solute (% w/w) or (mg /ml) in the opposing phase of stage i, for stages 1 to n.

The model developed above is first applied to traditional LLE and ATPE. The fit is shown above, Figure 2 (a) shows a result for traditional LLE and (b) shows a result for ATPE. It should be noted that in this model, the stages were counted off from the feed as opposed to from the target composition and so the predicted compositions are slightly different; however, the results for the number of stages were the same as the original authors.

Figure 3 shows the McCabe Thiele diagram for achieving > 99 % yield of phycocyanin using a counter-current multi-stage PEG-phosphate system. It can be seen from Figure 3 that the equilib-
Figure 3: McCabe diagram for phycocyanin in the model PEG-phosphate ATPE.

Table 1: Stage results for lysozyme in the model PEG-phosphate ATPE.

Stage	Bottom phase (mg /ml)	Top phase (mg /ml)
1	8.91	0.503
2	0.161	0.00885

rium curve is a linear for phycocyanin before the concentration of 110 mg /ml. It is predicted that three stages were required to achieve a yield of > 99 % of phycocyanin.

Similarly, Table 1 shows the results for the concentration (mg /ml) of the contaminant, lysozyme, in each phase for each stage. The model was set up to remove > 99 % of lysozyme from the target phase using a counter-current multi-stage PEG-phosphate system, in this case two stages were required to achieve this.

4. Conclusion

In conclusion, ATPE is a developing, cheaper alternative protein purification technique which is disadvantaged by the low purity and yield achieved in a single step and the extensive experimental work required in system development and optimisation. Multi-stage operation can be used to achieve the high purities and yields required in the biopharmaceutical industry. The work has shown that the use of an equilibrium binary separation model is a viable technique in evaluating different multi-stage ATPE. The model was validated using experimental data in the literature and a case study on the purification of phycocyanin from lysozyme was carried out. It was shown that a yield of > 99 % and a purity of > 99 % could be achieved using three and two stages respectively in a counter current ATPS of PEG - phosphate. The work evaluates the different proteins separately in terms of protein concentration in each of the phases. This approach simplifies the model greatly and removes some of the complexity which is associated with ATPS, thereby further increasing the accessibility of the process.

In the future, the model could be used to optimise the stages for not only extraction protocols, but also back extraction and washing protocols as a repeating unit in a superstructure. In back extraction, conditions would be selected, usually through the addition of NaCl, to push the target protein into the salt phase. This is easier to deal with down-stream and allows the recycling of the more expensive polymer phase. For this, only a single equilibrium curve for the target protein under the new extraction protocols would be required. The washing protocol would also require a single equilibrium curve and would require looking at removal of any remaining contaminants in the salt phase, once the target protein has been extracted there, using a fresh polymer phase. Using this method, the model can be used to investigate and develop more complicated multi-stage operational techniques. Modification of the operation line can be used to investigate different multi-stage modes of operation i.e. cross current, co-current, counter-current procedures.

Abstract

The field of Process system engineering (PSE) is constantly developing with the availability of advanced computational resources. Since 1960s, process simulation has been one of the most successful story in using computer aided methods and tools in the field of chemical engineering. Nowadays, several software tools are available for process simulation, process optimization, process synthesis and design. However, the current software in PSE is mainly focussed on processes without consideration of controller design or validation. The gap between process design and controller design seems to be increasing, which may lead to suboptimal solutions especially for closed-loop systems. Therefore, there is always a demand for integrating the process design with consideration of the controller design; even though the development of such software tool has not been well addressed so far, or are industry specific. In this paper, a model-based integrated process and controller design software tool called ProCACD (computer aided controller design) is presented along with a case study to design controllers and optimize controller parameters for a system of three-tanks-in-series with recycle.
Keywords: computer aided controller design, process simulation, PID tuning.

1. Introduction

Nowadays sustainable and efficient processes are needed in chemical industry to address the grand challenges of resource depletion, energy consumption and environmental impacts (Roh et al., 2016). Therefore, identification, design and development of appropriate processes are important for the industry to remain competitive. During the last decades, many researchers have developed computer aided software tools to address different aspects of process development, including Aspen for process simulation and control, ProCAFD (Tula et al., 2017) for process synthesis, GAMS (Biegler, 2018) for process optimization, etc. However, it seems that not much work has been done in the area of software development of simultaneous process design and control, though a trend towards considering process design and control aspects simultaneously has been proposed. Several methodologies have been developed for addressing the interactions between process design and process control (Mansouri et al., 2015). At first, researchers focus on the controllability of process systems. Controllability metrics based on open and closed-loop stability analysis were developed (Yi & Luyben, 1997). However, controllability metrics are used mostly in either steady state or linear dynamic models, and the uncertain link between the value of the measure

and the plant design may cause trouble. Thus, methods to overcome the limitation of controllability metrics appeared. These methods can be classified into two types. One type is based on multi-objective optimization (Gebreslassie et al., 2012). The other type is based on dynamic optimization (Diangelakis et al., 2017). Lagging behind the advance of method development for integration of process design and control, the software development is quite scarce. The objective of process design is to identify the types of tasks/operations that need to be performed, the corresponding design of the operation/equipment, their configuration, mass/energy flows, etc. (Tula et al., 2015). And the main objective of process control is to design control system to achieve optimal closed-loop dynamic performance (Yuan et al., 2012). Solving these two problems independently may lead to suboptimal solutions. A key to integrating the process design and controller design is to model them in a unified structure. Embedded with the previously developed modelling tool-box MoT (Fedorova et al., 2015), an integrated controller design software tool, ProCACD, is proposed in this work.

2. Architecture of ProCACD

2.1. MoT based Model-objects

ProCACD is a c# based software tool developed in Visual Studio. The process and control models are generated in ProCACD through the modelling tool-box MoT, where model developers define equations and set necessary variable values. In this work, a generic model object approach is implemented where a unified model is used to represent both open-loop and closed-loop processes for all possible pairings and all controller types (P, PI, PID, etc). As shown in Figure 1, one model-object can have several different configurations in ProCACD. While using the model-objects, the user should select the manipulated variables (MVs) and controlled variables (CVs) according to the real process, and then select the controller type and pairing based on his system. 'MVi' and 'CVi' are used to name the ith selected MVs and CVs, respectively.
Figure 1: Different configurations of model-object

The controller equations part is the most essential part for model developers to establish a model-object with different kinds of controller configurations. Keywords '*ol*', '*clp*', '*clpi*', and '*clpid*' are kept to denote logic configurations of open-loop control, closed-loop P control, closed-loop PI control, and closed-loop PID control, respectively. Additionally, to denote the pairing between MVs and CVs, another keyword, "*Pair*m_n" is adopted to denote if a pairing exists between the mth MV and n^{th} CV. An example template is given as follows to describe the controller equations of a process containing two MVs and two CVs.

$$Error1 = CV1 - CV1SP \tag{1}$$
$$Error2 = CV2 - CV2SP \tag{2}$$

$$\frac{dAE1}{dt} = Error1 \tag{3}$$

$$\frac{dAE2}{dt} = Error2 \tag{4}$$

$$MV1 = MV1 * o\text{\small{\it{l}}}1 + \\ [(P1 * Error1 + MV1Star) * c\text{\small{\it{l}}}p1 + (P1 * Error1 + I1 * AE1 + MV1Star) * c\text{\small{\it{l}}}pi1] * Pair1\_1 \\ + [(P1 * Error2 + MV1Star) * c\text{\small{\it{l}}}p1 + (P1 * Error2 + I1 * AE2 + MV1Star) * c\text{\small{\it{l}}}pi1] * Pair1\_2 \tag{5}$$

$$MV2 = MV2 * o\text{\small{\it{l}}}2 + \\ [(P2 * Error1 + MV2Star) * c\text{\small{\it{l}}}p2 + (P2 * Error1 + I2 * AE1 + MV2Star) * c\text{\small{\it{l}}}pi2] * Pair2\_1 \\ + [(P2 * Error2 + MV2Star) * c\text{\small{\it{l}}}p2 + (P2 * Error2 + I2 * AE2 + MV2Star) * c\text{\small{\it{l}}}pi2] * Pair2\_2 \tag{6}$$

By properly setting the logic variables, this template can represent different controller type and the pairing structure between MVs and CVs. It should be noted that the need for process understanding is very essential for an efficient design. The process model together with the controller model template, called as MoT based model-object in this project, can be used to design, analyze and verify controller design and application.

2.2. Process Analysis and Controller Design

An overview of the 5-staged method is presented in Figure 2, which describes the main architecture of the ProCACD software as follows.

1.Problem Definition	2.View Model Variable	3.Open-Loop Run	4.Controller Configuration	5.Closed-Loop Run
Inputs: Generic MoT model-object *Outputs:* Configured process model	*Inputs:* Configured process model *Outputs:* Detailed variable information of the model	*Inputs:* Configured open-loop process model Data of initial variable values *Outputs:* Data of model simulation results	*Inputs:* Configured open-loop process model *Outputs:* Best pairing of the model Tuned Controller parameters results	*Inputs:* Tuned Controller parameters results *Outputs:* Data of configured closed-loop model simulation results

Figure 2: Process Analysis and Controller Design Method (in ProCACD)

<u>Problem Definition</u>: The main objective of this step is to define the configuration of the loaded generic MoT model-object. Configuration includes open-loop or closed-loop model, number of closed-loops as well as the pairing status and the selection of controller type (P, PI, or PID) for each loop.

<u>View Model Variable</u>: In this step, the configured process model defined in Problem Definition is elaborated through a table showing all the model variable details. If closed -loop option is chosen in Problem Definition step, an additional table showing the pairing of each loop is added.

<u>Open-Loop Run</u>: This step is used for the open-loop option in Problem Definition, where the configured open-loop process model variable details are listed in a table allowing users to set the initial input variable values so that open-loop simulations can be performed.

<u>Controller Configuration</u>: This is an essential step for finding the best pairing structure and tuning of the controller parameters for a closed loop process model. Here we connect Tai-ji PID tuning system through a web-API deployed in public cloud (www.taijipid.com). This web-based technology can conduct system identification and PID parameter tuning based on supplied simulation data. Additionally, the relative gain is calculated to find the best pairing by using the identified transfer function model. Once the best pairing is found, it is possible to tune the PID controller parameters. The related flow-diagram is shown in Figure 3. The MoT first generates open-loop data

through simulations. The generated simulation data is transformed to equal time interval data using the cubic spline interpolation algorithm embedded in ProCACD. Then the transformed simulation data is exported to Tai-ji PID tuning system, which analyses the process through transformed simulation data and conducts system identification as well as tuning of the controller parameters.

Closed-Loop Run: In this step, the tuned controller parameters are used for the configured close loop process model simulation. The software also allows the user to modify the controller parameters and add disturbances in this step. Eventually, the software provides a graph, in which, different closed-loop simulations are compared.

The integration of process and controller design is achieved through model analysis in terms of sensitivity of process variables to controller variables.
Figure 3: Flowsheet of Controller Tuning step

3. Case Study

The application of ProCACD is highlighted using a recycled three-tanks-in-series process model stored in a MoT-based model-object. The process is shown in Figure 4(a). Variables A1, A2 and A3 represent the cross-sectional area of the three tanks. Variables h1, h2 and h3 represent the liquid level of three tanks. Variables alpha1, alpha2 and alpha3 represent the valve opening values. Variables Fin, F1, F2 and Fout represent the inlet and outlet flowrate of the tanks. Variable purge represents the outlet flowrate of the whole system. The candidate control variables and manipulated variables are also marked in the figure with bracked CV and MV, respectively. ProCACD helps users to find the best pairing, design controllers for the process, and tune controller parameters.

In the first step, Problem Definition, a user starts from introducing the MoT model, followed by a selecting options between open-loop or closed-loop analysis. If open-loop option is choosen in Problem Definition step, then in step 2, View Model Variable, a table will be automatically generated to list all the variables in this model; there follows an Open-Loop Run step, where the user can conduct open-loop simulations through the tank model. While if the closed-loop option is choosen in Problem Definition, further an initial configuration among CVs and MVs and selection of controller type will be prompted. Then in the second step, View Model Variable, ProCACD automatically creates another table listing the user's configuration information. Afterwards, the Open-Loop Run step is skipped and ProCACD goes straight to the Controller Configuration option, where the best pairing between CVs and MVs is found and the controller parameters are tuned accordingly.

The recycled three-tanks-in-series process model consists of 3 CVs and 3 MVs. Thus, there is a total of 6 different pairings if a user wants to control all the three liquid levels. It also means that the model has 6 different closed-loop configurations. ProCACD can find the best configuration using relative gain method through three steps. First, transfer function matrix is obtained with the generated open-loop simulation data. Then, relative gain matrix is calculated according to the transfer function matrix. Last, the best pairing is obtained by analysing the relative gain matrix. In this case, the best configuration is

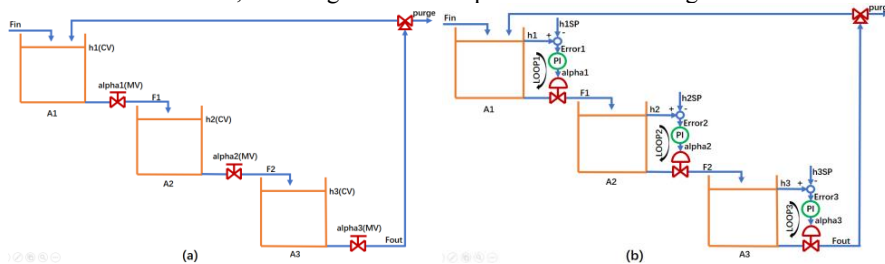
shown in Figure 4(b), where valve opening of the outlet stream of each tank is used to control each tank level, which agrees with the process understanding.


Figure 4: A case study of recycled three-tanks-in-series
(a) The original process flowsheet; (b) The process flowsheet with best pairing controller design.

Based on this closed-loop configuration, ProCACD further tunes the PID controller parameters in Controller Configuration step. After finishing Controller Configuration step, the data, including the tuned controller parameters, is stored and transferred to the Closed Loop Run step, where users can conduct closed-loop simulations. Figure 5 shows the comparison of the simulation results of CVs with the tuned controller parameters and the initial controller parameters which were obtained manually accodring to experiences. The simulation results indicate that the controllers perform well both in disturbance rejection and set point tracking using the tuned controller parameters. Here, the value of the integral time square error (ITSE) is used to quantitatively analyze control performance. At time 0, users give a set point step change of h1 from 1 to 2. The ITSE value of h1 using the tuned parameters is 0.31, much less than the ITSE value 0.62 using initial parameters. From the simulation result of h1, we can also see that the tuned parameters perform both less overshoot and less adjusting time, indicating a better set point tracking. As for h2 and h3, the step change of h1 could be regarded as a disturbance to them. The ITSE values of h2 and h3 using the tuned parameters are 0.19 and 0.23, respectively, less than the ITSE values of 0.26 and 0.33 with initial parameters. From the simulation results of h2 and h3, it can also be seen that the tuned parameters bring less oscillation amplitude and less adjusting time, thus a better disturbance rejection. At 10 second time, a disturbance step change of Fin from 0.1 to 0.2 is introduced. The ITSE values of h1, h2 and h3 using the tuned parameters are 0.15, 0.26 and 0.31, respectively, less than the ITSE values of 0.28, 0.31 and 0.37 with the initial parameters. As shown in Figure 5, the tuned parameters perform less oscillation amplitude and less adjusting time than the initial setting, which again demonstrates better disturbance rejection. Further integration of the process design and controller design can be achieved through analyzing the sensitivity of process variables to controller variables, e.g., how the recycle ratio from the final tank outlet to the first tank affects the process dynamics and what the optimal recycle ratio should be designed.

4. Conclusions

In this work, a computer-aided method and associated software is developed to integrate modelling-simulation tools with controller design, analysis and verification tools. Interfacing with the modelling toolbox MoT, ProCACD helps users to design controllers from an open-loop process model with designated candidate CVs and MVs. The best pairing among the CVs and MVs can be detected. PID controller parameters can be well tuned. Good performance in disturbance rejection and set point tracking is

demonstrated through a case study involving control of liquid levels of a recycled three-tanks-in-series process model. As a summary, the model-based analysis tool provides a good understanding of the process and through it, a good design of the controller configuration and the controller parameter tuning can be achieved. In the future, an extensive library of process models and control strategy such as model predictive control (MPC) will also be implemented. On the basis of this work, a simultaneous process and controller design will be developed.

Abstract

Sorption-enhanced water-gas shift (SEWGS) process is very attractive for an energy efficient pre-combustion CO_2 capture, as it enables direct conversion of syngas into separate streams of H_2 and CO_2 at high temperatures and pressures. Using advanced computational fluid dynamics (CFD) methods, quantitative performance differences were assessed for rectangular channel monolith structures versus regular packed-bed structures when used for pre-combustion CO_2 capture. Published data of breakthrough capacities at different pressures for CO_2 and H_2O were used to validate a multicomponent adsorption isotherm. A COMSOL 1D model was developed to describe CO_2 adsorption in a fixed-bed reactor, filled with adsorbent pellets, to confirm the accuracy of the results compared to the existing studies, after which a 2D model was built simulating the adsorption step of a SEWGS process inside of a monolith reactor channel. Model predictions display an increase in productivity of adsorption in the case of monolith structures versus conventional packed-bed columns. Results will be used to improve the performance of experimental monolith structures undergoing SEWGS.

Keywords: CFD, CO_2 adsorption, isotherm, SEWGS

1. Introduction

Developing energy efficient low carbon applications is of great importance today as an active way of combating the climate change (IPCC, 2014). Sorption-enhanced water-gas shift (SEWGS) is a pre-combustion carbon capture and storage (CCS) process which combines the water-gas shift (WGS) reaction (Eq. (1)) with in situ adsorption of CO_2 (Eq. (2)) at 300-500 °C and 10-40 bar. Steam can also be adsorbed (Eq. (3)).

$$CO + H_2O \leftrightarrow CO_2 + H_2 \tag{1}$$

$$CO_2 + \bullet \leftrightarrow CO_2 - \bullet \tag{2}$$

$$H_2O + \bullet \leftrightarrow H_2O - \bullet \tag{3}$$

A SEWGS process consists of a series of reactors capable of CO_2 adsorption, operated in pressure cycles, similar to the cycles of a PSA, as to enable the periodic loading and regeneration of the sorbent. By using multiple reactors, the process can be characterized as a continuous one, allowing the constant production of separate H_2 and CO_2 streams. In the adsorption step of the cycle, syngas is fed into a reactor where the CO and steam react to produce CO_2 and H_2. The sorbent material takes up the CO_2 and a hot high pressure, H_2 rich product stream is directly produced, ready to be used as gas turbine fuel for power generation. SEWGS enables a direct conversion of syngas into separate hot streams of H_2 at feed pressure and CO_2 at regeneration pressure, making the process attractive for pre-combustion CCS and reduction of GHG emissions (van Selow et al., 2009).

Hydrotalcite based adsorbents are valuable for SEWGS, as they demonstrate high thermal stability, fast sorption kinetics and high CO_2 selectivity. The clay layered structure collapses at high temperatures, transitioning to a well dispersed mixed metal oxide with a higher surface area because of porosity formation. The impregnation of the oxide with K_2CO_3 increases the sorbent's capability to adsorb basic species. The potassium-promoted hydrotalcite (K-HTC) has two roles in SEWGS, catalyzer for the WGS reaction and sorbent for reversibly adsorbing CO_2. After adsorption, during K-HTC regeneration, the CO_2 released is sufficiently pure to be stored (Sikander et al., 2017).

Traditionally, columns filled with granulated adsorbent pellets are used in a SEWGS process, however, in this work, the columns are replaced with innovative 3D printed monolith reactors built of K-HTC material, as packed-bed reactors show significant bottleneck due to the restrictions regarding flow-rate inside the reactor, pressure drops and adsorption kinetics (Govender and Friedrich, 2017). A graphical representation of a monolith structure with square channels is presented in Figure 1.
Figure 1. a – 3D schematic representation of a monolith reactor with square channels;
b – 2D representation of the channel geometry used in the monolith reactor model.

Models simulated in COMSOL Multiphysics are used in order to further add improvements to experimental monolith structures. If successful, a significant size reduction of SEWGS for syngas processing with CO_2 capture will be possible while maintaining the same productivity.

2. Model development

This paper is evaluating the high-temperature, high-pressure adsorption step of a SEWGS process in which the columns, normally filled with K-HTC pellets that act as sorbents, are replaced by monolith reactors that are made entirely of adsorbent K-HTC material. Using COMSOL Multiphysics, a 1D model was developed to simulate, in space and time, the adsorption process of CO_2 in a packed-bed reactor. A reactor model published by Reijers et al. (2009) was used for validation. Following, a 2D COMSOL Multiphysics model was developed to simulate the adsorption step of SEWGS for CO_2 inside a single rectangular channel of a monolith reactor.

2.1. Adsorption isotherms

Adsorption isotherms are used to describe the quantity of adsorbate on the surface as a function of its pressure at constant temperature. Boon et al. (2014) used experimentally obtained breakthrough data to fit a multicomponent adsorption isotherm for the system and obtained good results with two double isotherms, deriving a model that takes into account surface and nanopores contributions for the adsorption of CO_2 and H_2O at high pressures.

2.2. Model parameters and assumptions

For the 1D fixed-bed reactor model, process parameters are taken from literature (Reijers et al., 2009), so as to add validity to the predictions and enable proper comparison. Although the monolith structure contains around 500 channels, the 2D model simulates the adsorption of CO_2 inside a single rectangular channel, in order to reduce hardware computation requirements. The geometry of the model is seen in Figure 1b. The parameters for the fixed-bed reactor model and the rectangular channel reactor model are presented in Table 1.

Table 1. Model specific parameters

Parameter	Fixed-bed model	Monolith model	Parameter	Common values	
Length	0.2 m	0.1 m	Bed density	533	kg m^{-3}
Tube diameter	0.016 m	-	Particle density	922	kg m^{-3}
Bed height	0.02 m	-	Feed temperature	673.15	K
Width	-	1e-4 m	k_{LDF}	0.1	s^{-1}
Feed velocity	0.0056 m s^{-1}	0.035 m s^{-1}			
Feed pressure	101,325 Pa	25e5 Pa			
Porosity	0.4	0.44			

Simplifying assumptions are common for both models. These include a uniform distribution of sorbent activity, laminar fluid flow, dispersion does not occur, heat transfer is not considered and the LDF mass transfer coefficient is constant.

2.3. Process phenomena

For the fixed-bed model, the phenomena occurring are convection-diffusion of the bulk phase and diffusion-adsorption of CO_2, which are solved with a convection-diffusion equation (Eq. (5)) and a porous media transport equation (Eq. (6)).

$$\frac{\partial c_i}{\partial t} + \nabla \cdot (-D_i \nabla c_i) + u \cdot \nabla c_i = R_i \tag{5}$$

$$(\varepsilon_p + \rho k_{p,i}) \cdot \frac{\partial c_i}{\partial t} + \left(c_i - \frac{\rho}{(1 - \varepsilon_p)} \cdot c_{p,i} \right) \frac{\partial \varepsilon_p}{\partial t} + \nabla \cdot \Gamma_i + u \cdot \nabla c_i \tag{6}$$

For the 2D monolith reactor channel model, mass transport in the bulk is solved by using Eq. (5), while adsorption of CO_2 is solved through the material balance on the active surface of the walls inside the channel (Eq. (7)). The surface concentration of CO_2, c_s, is described using Eq. (8) with terms for the linear driving force mass transfer coefficient and adsorption isotherm. The way through which mass transport and surface adsorption are coupled is by setting the adsorption rate as an outward flux in the boundary condition for Eq. (5).

$$\frac{\partial c_s}{\partial t} + \nabla \cdot (-D_s \nabla c_s) = r_{ads} \tag{7}$$

$$\frac{\partial q_{CO_2}}{\partial t} = k_{LDF} \cdot \left(q_{CO_2}^* - q_{CO_2} \right) \tag{8}$$

3. Results and discussions

3.1. Breakthrough capacities for CO_2 and H_2O

For validation of the adsorption isotherms, published data (Boon et al., 2014) regarding breakthrough capacities for CO_2 and H_2O were plotted as a function of pressure, with pressure values of up to 24 bar. The data points in Figure 2 show pure component breakthrough capacities measured for CO_2, while Figure 3 shows the capacities for steam. The lines are drawn based on the isotherm developed from the full dataset and the symbols are the measured data.
Figure 2. CO_2 breakthrough capacities vs CO_2 partial pressure (diamonds), predicted capacity (line), surface contribution (dashed line), nanopore contribution (dotted line).
Figure 3. Pure H_2O breakthrough capacities versus H_2O partial pressure (circles), predicted capacity (line), surface contribution (dashed), nanopore contribution (dotted line).

The capacities for CO_2 seen in Figure 2 follow a two-step adsorption mechanism. The first step is due to surface sites and adds contribution up to 0.4 mol kg[-1], while the additional adsorption at partial pressures over 3 bar is attributed to nanopores. Steam behaves similarly to CO_2. In Figure 3, at partial pressures under 12 bar, the

CFD of Rectangular Channel Monolith Reactor vs. Packed-Bed
Column for SEWGS

647

experimental capacities show a surface contribution of about 0.3 mol kg^{-1}, while the point above 20 bar might indicate an additional nanopore adsorption mechanism.

3.2. Fixed-bed reactor model describing CO_2 adsorption

In regards to the validation of the fixed-bed reactor model, Figure 4 shows the breakthrough curve calculated by the COMSOL 1D model compared to existing published data (Reijers et al., 2009). The results seem to be in agreement with their predictions, as the breakthrough times are within close range and the curves present similar profiles for identical process parameters.
Figure 4. CO_2 mole fraction at the reactor outlet relative to CO_2 mole fraction of the feed gas calculated by the COMSOL 1D. a – breakthrough curve calculated by the COMSOL Multiphysics model; b – breakthrough curves calculated by the MATLAB model (line) and from the analytical solution (symbols) (Reijers et al., 2009).

3.3. Monolith reactor model describing CO_2 adsorption in a single rectangular channel

The breakthrough curve predicted by the 2D monolith reactor model, in which the adsorption of CO_2 takes places at the surface of the walls inside the rectangular channel, can be seen in Figure 5. Comparing the time of breakthrough and its profile with existing data predicted by fixed-bed reactor models, it can be assumed that a monolith reactor would provide a better adsorption of CO_2.
Figure 5. CO_2 mole fraction at the reactor outlet relative to CO_2 mole fraction of the feed gas calculated by the COMSOL 2D monolith reactor model.

Figure 6. CO_2 surface concentration at different times calculated by the COMSOL 2D monolith reactor model and surface velocity profile along the reactor.

4. Conclusions

Using the published data regarding breakthrough capacities of CO_2 and H_2O, a multicomponent adsorption isotherm has been successfully validated. The isotherm accounts for surface adsorption at lower partial pressures and nanopore contributions at higher values of partial pressures.

A 1D model of a fixed-bed reactor has been developed using COMSOL Multiphysics, with the purpose of validation based on published data. Using the multicomponent isotherm and the linear driving force approximation, the adsorption of CO_2 was successfully simulated, as breakthrough predictions agree with other predictions found in literature.

Finally, a 2D monolith reactor model describing adsorption of CO_2 occurring at the surface of a single channel's walls was developed. Although validation is not possible at the moment due to lack of experimental data, assessing the time of breakthrough and its profile leads to the conclusion that a monolith structure would provide better adsorption.

Review of override control methods

Jan Schuurmans[, a *]

j.schuurmans@dotxcontrol.com

Abstract

This paper focusses on potential issues with override control. We show that, in the presence of stochastic disturbances, the existing methods can fail due to frequent switching from one controller to the other. Based on the analysis of the cause of the problem, we propose a simple solution and demonstrate its applicability on a test setup involving a Siemens PLC and software.

Keywords: override control, PID, constrained output control, cascade control

1. Introduction

In some cases, the control must adjust a manipulated variable to control one process variable at setpoint while maintaining other process variable(s) within limits. In practice, this problem, sometimes referred to as the output constrained control problem, is often solved with the use of PID controllers. Scientific literature on this subject usually focusses on stability and performance in the presence of deterministic disturbances (Glattfelder 1988, Lopez 1996). To the knowledge of the author, the case of stochastic disturbances has not been considered so far. This paper analyses two common methods to handle output constraints and shows that they face potential problems in the presence of stochastic disturbances. Based on the analysis of the cause of the problem, we propose a simple solution and demonstrate its applicability on a test setup involving a standard Siemens PLC.

The paper is structured as follows. Section 2 defines the output constraint problem in full detail. Section 2 and 3 present two common solutions (override control and cascade control, respectively) to the output constraint problem, using PID controllers, and shows that these solutions may not work in the presence of stochastic disturbances. Section 4 analyses the problem and presents solutions. Finally, section 5 presents the conclusions.

2. Description of the output constraint problem

The main question of this paper, is: are the existing constraint handling methods (using PID controllers) capable of handling stochastic disturbances, and if not, can we fix the problem? This section describes this main question in more detail.

We assume that the process is described by the following model:

$$y_1 = G_1(s)\, m + d_1, \quad y_2 = G_2(s)\, m + d_2 \tag{1}$$

with m the manipulated variable, y_i (i = 1 or 2) process variable, d_i disturbance variable, $G_i(s)$ a transfer function as a function of the Laplace variable s.

This paper considers both deterministic and stochastic disturbances. The deterministic disturbances provide immediate insight in the dynamic behaviour, the stochastic disturbances are more common in practice.

The output constrained control challenge is defined in words as follows. Control y_1 as closely as possible to setpoint s_1, while the second process variable y_2 should not cross some limit (that we assume, without loss of generality, to be a high limit y_{2max}). When we are dealing with stochastic disturbances, it makes sense to try to ensure that the chance of exceeding the limit y_{2max} is less than some predefined percentage.

The controllers are assumed to be PID controllers equipped with a Tracking Mode option. Although the exact equations are usually not provided by commercial manufacturers, we shall assume, for clarity of the paper, that this means that the PID controllers can be represented by $m_i = C_i(s)e_i + b_i$, with $C_i(s)$ a PID controller in the Standard Form:

$$C_i(s) = K_{p,i}\left(1 + \frac{1}{T_{i,i}s} + T_{d,i}s\right)e_i \tag{2}$$

Furthermore, $e_i = s_i - y_i$, and b_i is a bias term, defined by $b_i = \frac{1}{T_t s}(m - m_i)$ with m the manipulated input. If the i-th PID is active, i.e. if $m = m_i$, the bias term disappears. Otherwise, in Tracking mode, the controller's output can be written as:

$$m_i = \frac{T_t s}{T_t s + 1}C_i(s)e + \frac{1}{T_t s + 1}m \tag{3}$$

and clearly, m_i tracks m for frequencies below $\omega < 1/T_t$

Basically, the Tracking mode ensures that the output of the controller that is not active 'tracks' the output of the controller that is active, to avoid a bump when switching. The exact equations for the Tracking mode method are not essential for the results in this paper.

In the next sections, we consider different control solutions. To simulate them, we shall simulate one specific process model, according to:

$$G_1(s) = \frac{1}{3s + 1}e^{-0.2s}, \qquad G_2(s) = \frac{2}{4s + 1}e^{-s}$$

The disturbances vary according to:

$$d_1(s) = w_1 + d_d, \qquad d_2(s) = w_2 + d_d$$

with w_1 and w_2 independent normally randomly distributed white noise, with variance 1, and d_d a deterministic disturbance component, starting at time t = 0.4 and changing stepwise to −2 at t = 100 s.

The setpoint for controller C_1 is s_1 = -0.1 and we assume that at t = 0, the system is in steady state. The maximum on output y_2 is $y_{2max} = 2$, and we wish to reduce the chance of y_2 exceeding y_{2max} to less than 2.5%. In order to allow comparison between different control options, we adopt the following control parameters for the controllers C_1 and C_2:

$$K_{p1} = 5.25, \quad T_{i1} = 1.6, \qquad T_{d1} = T_{d2} = 0, \qquad K_{p2} = 0.7, \; T_{i2} = 4$$

These settings were chosen based on the tuning rules as presented in (Skogestad 2001) and results in well damped and fast response under normal conditions (i.e. no switching between controllers). We have chosen not to use D-action for reasons of simplicity.

Given these control parameter settings, and the stochastic disturbance w_2 as defined above, the standard deviation (σ_2) of y_2 will be close to $\sigma_2 = 1$, if C_2 is either

active or not during the entire simulation period. This implies that if we choose the setpoint s_2 as 0 or slightly lower, we can expect that the output constraint on y_2 can be met in 'steady state conditions', i.e. at all times outside the transients caused by the deterministic variations in d_d. Therefore, we select setpoint $s_2 = y_{2max} - 2\sigma_2 = 2 - 2 = 0$, since the chance of exceeding $2\sigma_2$ is less than 2.5% for a normal distribution.

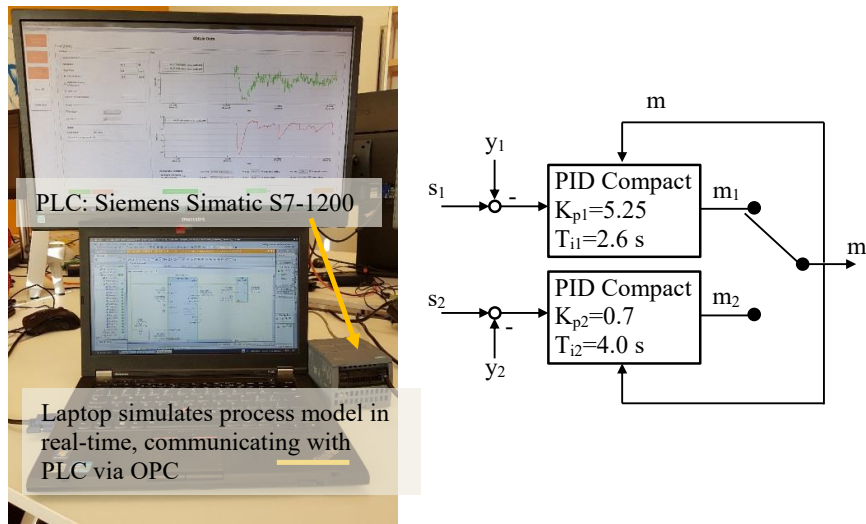
The override control solutions, as described in this paper, were tested on a hardware in the loop setup, as shown in Figure 1. In this setup, the process model was simulated using the PID Tuner software described in its manual (Schuurmans 2018). The control output (m) was calculated by the Siemens S7 1200 PLC, programmed with an override control solutions as described in the manual of the PLC (Simatic 2018). The controllers C_1 and C_2 were realised with the PID Compact blocks.


Figure 1   Photo of the Hardware in the Loop setup (left) and diagram of the control setup (right).

3. Override control

One method to handle the output constraint is Override control (Shinskey 2005) . In override control, the controller with minimal (or maximal) manipulated variable is selected, i.e. $m = \min(m_1, m_2)$. In other words, control switches to C_2 if (and only if) $m_2 < m_1$. For this method, it is clear how to set the control parameters. Indeed, the PID settings as presented in section 1 work well in the absence of stochastic disturbances, see Figure 2. This figure shows both the simulated response according to our assumed PID formulas (solid lines) and the actual PID Compact (dashed lines); the responses differ slightly, but in essence the behaviour agrees. Control switches correctly from C_1 to C_2 at t=100s.

However, in case of stochastic disturbances, frequent switching between controllers take place, and this results in a problematic performance (solid lines in Figure 3). The Mean Squared Error (MSE) of y_1, defined as $MSE_1 = \frac{1}{n}\sum_{i=0}^{n} e_1(t)^2$ increases to 9 (with n = number of samples), whereas MSE equals just 1.2 if C_1 is active all the time.

4. Cascade control

In case of cascade control, the PID controller C_1 adjusts the setpoint of the second PID controller (s_2). By constraining the setpoint of s_2, according to $s_2 \leq y_{2max}$, the output y_2 can be expected to satisfy the output constraint.

A disadvantage of this method is that the controller C_1 cannot be tuned optimally on the basis of the process model given by Eq. 1, but, instead, it must be tuned on the basis of the closed-loop dynamics given by $y_2 = \frac{G_2}{1 + C_2 G_2} s_2$. In many cases, these closed-loop dynamics are slower than the open-loop dynamics. This problem can be overcome using cleverly chosen filters, as was shown in (Lestage 1999). Nevertheless, this solution copes with the same issues as Override control, in the presence of stochastic noise, and similar results as shown in Figure 3 apply to this control solution.
Figure 2   Simulated (solid) and measured response of the PID Compact (dashed).

5. Analysis of the problem and solutions

Override control and (cleverly chosen) cascade control boil down to the same solution, where control switches from C_1 to C_2 or vice versa. In case of stochastic disturbances, the switching may occur too frequently, resulting in lousy performance. We can analyse the switching conditions more closely. The controller that is not active, is in tracking mode. Let us, for example, assume that C_1 is active and C_2 is in tracking mode. In that case, the switching condition can be written as $C_1 e_1 > C_2 e_2$. The same condition applies when the second controller is active. Hence, the condition for switching from one controller to the other can be expressed in terms of a condition on controller deviations (e_i), weighed by the controller transfer function. Similar switching conditions, but with different 'weighting transfer functions' can be derived for cascade control, and in case of different PID implementations (such as the PID in velocity form). In the presence of noisy control deviation signals (e_i) with mean values that differ less than the variations, frequent switching will take place.

To resolve this issue, we can change the switching conditions such that switching takes only takes place when meaningful. Changing the switching conditions does not alter the stability (proofs) of the control systems, see for instance the stability proofs as

presented in Glattfelder (1988, 2004) and Lopez (1996). We therefore defined a continuous 'switching' parameter α, according to

$$\frac{d\alpha}{dt} = K_{\alpha 1}(e_1 - e_2) - K_{\alpha 2}(\alpha - \alpha_c) \tag{4}$$

with $\alpha_c = \text{sat}(\alpha)$, i.e. $\alpha_c = \alpha$ if $\alpha_{min} < \alpha < \alpha_{max}$, $\alpha_c = \alpha_{min}$ if $\alpha \leq \alpha_{min}$ and $\alpha_c = \alpha_{max}$ if $\alpha \geq \alpha_{max}$.
Figure 3 Measured response with stochastic disturbances (solid lines) and without (dashed) when using the Siemens PID Compact. In the case of stochastic disturbances, control switches frequently.

The parameter α is driven to 'one side' as long as there is a difference between e_1 and e_2. Control switches to C_1 if $\alpha_c > 0.45$. Control switches to C_2 if $\alpha_c < -0.45$.
For sufficiently small gain $K_{\alpha 1}$, it will not switch too frequently. The gain $K_{\alpha 2}$ feeds back on saturations of α, and basically provides anti-windup. The parameters were chosen as $\alpha_{min} = -0.5, \alpha_{max} = 0.5, \ K_{\alpha 1} = 3, K_{\alpha 2} = -3$.
　　　Figure 4 shows the results when we changed the switching conditions in the PLC to the conditions depending on α_c described here. Clearly, control switches only when it makes sense, from controller C_1 to C_2 at t =100 seconds in the simulation. As a result, the MSE of the deviations of y_1 from setpoint have reduced from 9 to 1.76 (compared to the results shown in Figure 3), while the percentage of y_2 samples crossing the limit y_{2max} is within specifications at 1.9% (outside the transients due to the deterministic disturbance change at t = 100, so outside the time span t = 100 to 130 s).

6. Conclusions

Returning to the main question posed in this paper, if the existing constraint handling methods (using PID controllers) are capable of handling stochastic disturbances, and if not, if we can fix the problem, the answer to the first question is 'no'. This answer was based on an analysis of the existing methods, both on paper and in experiments. Analysis showed that the problem was due to too frequent switching from one controller to the other. By changing the switching conditions this problem can be overcome though.
Figure 4 Results with override control with adjusted switching conditions applied to the Siemens PID Compact. Now, control switches from C_1 to C_2 at t=100s only.

Abstract

Biofuels are a promissory alternative to satisfy the world energy demand, and its production can be performed in a biorefinery scheme; however, few researches have been reported under this concept. According to the open literature, the raw material used to obtain renewable fuels represents roughly 60-80% of total annual cost. Thereby, the exploitation of a low-price feedstock into a biorefinery scheme is a good strategy to improve the production cost of the renewable fuels, and mitigate the environmental impact related with the processing. In this work, a biorefinery scheme using waste cooking oil (WCO) is presented, aiming to obtain biodiesel and biojet fuel simultaneously as main products. The modelling of the biorefinery scheme is performed in the process simulator Aspen Plus. The biodiesel is obtained through esterification and transesterification with ethanol, adding the refining zone to recover the ethanol; biojet fuel is produced through the hydrotreating process. The biorefinery is evaluated in terms of economic and environmental indicators, whose are compared with previously reported assessments for the separate production processes. Reductions on the processing cost and CO_2 emissions are expected regarding each individual process.

Keywords: waste cooking oil, biorefinery scheme, biofuels

1. Introduction

The depletion of fossil resources is a huge economic and environmental issue concerning the modern society, due to population growth, and the increase of energy demand. Since last decade, scientific and technological efforts have been focused on the development of novel alternatives to take advantage of renewable resources. Second and third generation raw materials have been used to produce a broad range of renewable products, mainly biofuels. However, its processing cost is high along with the price of renewable fuels. Recent studies on alternative biofuels have reported the use of agricultural wastes and waste cooking oil as promising feedstock to produce renewable products, diminishing the processing cost (Dewan et al, 2013; Gasca-González et al, 2018). The production of biofuels can be performed in a biorefinery scheme, which is a processing plant wherein

biomass is converted into a broad range of renewable products; its processing routes are designed according to biomass nature and composition. Regarding petroleum refineries, a biorefinery splits the raw material in useful fractions, which are taken as internal raw material to generate the desired products (Sadhukhan et al, 2014). Therefore, due to integral and multiple use of the feedstock selected, the price of the obtained renewable products could be competitive with its fossil counterparts. On the other hand, in the transport sector the demand of diesel and jet fuel has expanded significantly, and so its environmental impact (Grote et al, 2014). Thus, the use of biodiesel and biojet fuel has been recognized as a promising strategy to diminish the generated environmental impact and partially cover the demand. Regarding biodiesel production, several techniques have been proposed to diminish its energy consumption, related costs, and improve the biodiesel yield (Hajjari et al, 2017). However, conventional processing route through esterification and transesterification reactions is commonly chosen due to its low cost (Gasca-González et al, 2018). Furthermore, the biojet fuel is an emergent biofuel, which can be produced through few processing pathways that are certified by ASTM (Gutiérrez-Antonio et al, 2018); one of them is the hydrotreating process, which is the most mature technology due to similarity with the petro-refineries (Gutiérrez-Antonio et al, 2016). Recently, advances into process operation such as novel catalyst to improve biojet fuel yield and strategies of process intensification have been proposed. In this work, a biorefinery scheme using waste cooking oil (WCO) is presented, aiming to obtain biodiesel and biojet fuel as main products. The biorefinery scheme is modelled in the process simulator Aspen Plus. The biodiesel is obtained through esterification and transesterification with ethanol; while the biojet fuel is produced through the hydrotreating process, generating green diesel and naphtha as co-products. The economic and environmental indicators for the biorefinery process are calculated, and they are compared with the previously reported assessments for biodiesel and biojet fuel individual production processes. The main contribution of this work relies on the proposal and assessment of a biorefinery scheme to convert WCO into biofuels, employing both, conventional and intensified technologies, and establishing a base structure for future enhancements.

2. Process modelling

The WCO is classified as a hazardous waste, which has severe effects on urban waste water and, thus, on fresh water bodies, due to its inadequate disposal (Hajjari et al, 2017). In Mexico were recollected 5,596,032.97 L of WCO in 2015, in agreement with government data (SEMARNAT, 2004; SEDEMA, 2015). Thus, the proposed biorefinery scheme, showed in Figure 1, has been designed to process 5,596,032.97 L/year of WCO; moreover, the scheme considers two stages of heating at 65°C and impurities removal by sedimentation as pre-treatment for the WCO. At the end of these pre-treating stages, 20% of the total volume of WCO was removed as water and suspended solids. The average density for WCO was assumed as 0.91 g/ ml. Thus, 2,004.88 kg/h were processed through simulations in Aspen Plus V.8.0. The WCO composition has been considered as 94 wt% triglycerides and 6 wt% FFA; also, according to Gasca-González et al (2018) the FFA profile in wt% is: palmitic acid (12.3%), oleic acid (24%), linoleic acid (56.6%), and linolenic acid (7.1%). It is important to highlight that several efforts to recollect the WCO have been implemented in the country; however, a well-defined supply chain has not been established yet. In the biorefinery scheme, the total WCO recollected in 2015 is divided in half after pre-treatment in order to produce biodiesel and biojet fuel; this percentage

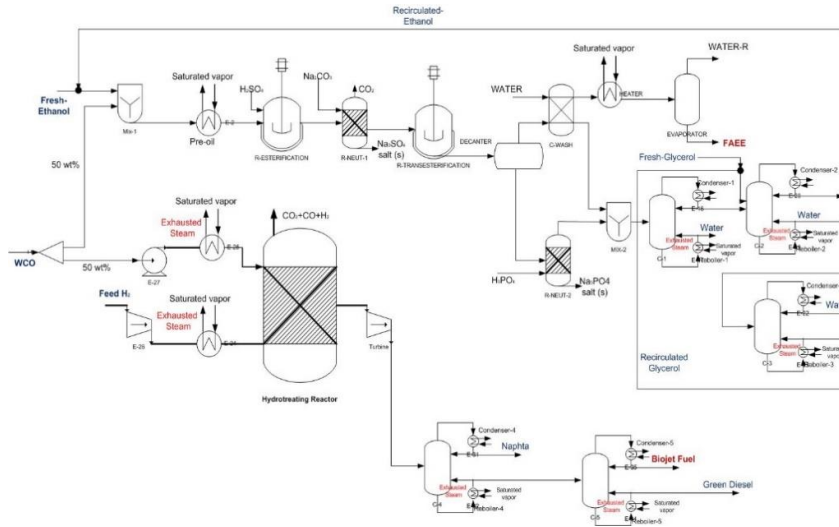
was chosen as the base scenario after a preliminary analysis to determine the proportion which allows the higher gross profit. The biodiesel process starts conditioning the WCO at 70°C, operation temperature for the esterification process. Ethanol is fed with molar ratio ethanol:oil, 6:1 and 1 wt% of sulfuric acid as catalyst; processed into a batch module. Next, the reaction products are fed to a neutralization reactor, wherein Na_2CO_3 was used to remove H_2SO_4 catalyst as Na_2SO_4 salt. The amount of Na_2CO_3 was stoichiometrically calculated regarding the H_2SO_4. The removal of Na_2CO_3 salt was realized by a filter. At once, the output stream is feeding to the transesterification reactor operated at 70°C, adding NaOH (1 wt%) as catalyst. Fresh ethanol is added to complete the 6:1, ethanol:oil molar ratio. The reaction is done into a batch module reactor. The stream leaving the transesterification reactor is feeding to decanter module, wherein two streams are splitting. In the first one, the separated biodiesel (FAEE) is fed to the washing column, operating with water (50 wt% regard FAEE); and then the excess of water is eliminated in an evaporator. The FAEE yield was 92.37%. The second stream leaving the decanter module is introduced to a neutralization reactor with H_3PO_4 (stoichiometrically calculated regarding NaOH). The Na_3PO_4 salt generated was removed by a filter. The stream leaving the neutralization reactor was rich in ethanol and water; this stream was feeding to distillation train, which includes 3 distillation columns to recover the ethanol. In the first one, the ethanol was concentrated near to the azeotropic point. In the second one, a glycerol stream was fed in 1.3:1 mass ratio, glycerol:mixture (ethanol + water). The azeotropic point was overcome and the ethanol mol purity was 99.76%. Finally, the last distillation column was used to separate water from glycerol; mole purity of 99.99% was reached for glycerol. The glycerol used to break the azeotropic point was generated as co-product in transesterification process; only 0.64% of fresh glycerol was purchased from external source to cover the glycerol/mixture ratio. The recovered ethanol and glycerol were cooled down to 25°C and recirculated to the process. It is worth to mention that the ethanol was used as alternative reactant to methanol, since it can be produced from renewable feedstock; also, is lower toxic than methanol. UNIQUAC was the thermodynamic method used to model the reaction and conditioning zones of the biodiesel process; also, the refining FAEE zone (distillation train) were modelled by NRTL method. The reaction kinetics for esterification and transesterification reactions were reported by Gasca-González et al (2018). Regarding the biojet fuel process, the WCO and hydrogen were conditioned at 380 °C and 30 bar, and fed into the hydrotreating reactor, which operates with NiMo/USY@Al-SBA-15 as catalyst. The volume ratio hydrogen:WCO was 500:1. The operation conditions, conversion, yield and distribution of products were reported by Zhang et al (2018). It is important to emphasise that the catalyst used is bifunctional, thus, the hydrotreating and hydrocracking /hydroisomerization reactions were carried out in the same equipment. Three products are obtained from the hydrotreating reactor: naphtha, biojet fuel and green diesel. A distillation train conformed by two distillation columns was designed to separate each product. The thermodynamic method used to model the conditioning of reactants and reactor zone was Peng-Robinson; while the distillation train was modelled using BK10 method. The naphtha selectivity was of 41%, biojet fuel 36% and green diesel of 84%. It is worth to mention that the biojet fuel is composed by 79.4 wt% of lineal paraffins, 1.9 wt% cycloparaffins, and 18.7 wt% aromatic compounds. Figures 2 and 3 show the biodiesel process from WCO and biojet fuel process from Jatropha curcas oil reported by Gasca-González et al (2018) and Gutiérrez-Antonio et al (2016), respectively. It is worth to mention that the processing structure for the biorefinery scheme has been constructed based on each individual process.


Figure 1. Proposed biorefinery scheme.
Figure 2. Biodiesel individual process extracted from Gasca-González et al (2018).
Figure 3. Biojet fuel individual process extracted from Gutiérrez-Antonio et al (2016).

3. Results

In this section, results for the proposed biorefinery scheme are presented. The TAC was obtained by Guthrie-Ulrich method (Turton et al, 2012), which take into account cost equipment, utilities cost (heating and cooling), raw materials (hydrogen and ethanol) and additional reagents (neutralisation reagents and glycerol). This estimation does not consider the cost of the heterogeneous catalyst for hydrotreating, filters cost and cost for removal equipment of CO_2-CO. Likewise, the biorefinery generates 20.4 kW of electricity; thus, its sale was considered, after covering the internal demand. In Table 1

the TAC and total CO_2 emissions per year are presented. The raw material cost represents 61.7% of TAC; also, the utilities cost is high. Regarding total CO_2 emissions, those related to the generation of vapor used in the process and those released by the hydrotreating reactor are considered. The CO_2 emissions by electricity are not considered, since the internal demand is covered by the energy produced in the biorefinery. Thus, the major CO_2 emissions are generated due to vapor production, considering a natural gas boiler with efficiency of 80%.

Table 1. TAC and total kg CO_2 emissions /year for proposed biorefinery scheme.

Utilities Cost ($USD/year)	Equipment Cost ($USD/year)	Raw Material Cost ($USD/year)	Electricity Sale Cost ($USD/year)	Total Annual Cost, TAC ($USD/year)
$1,158,967.54	$1,858,623.10	$4,826,117.42	$19,490.04	$7,824,218.02

Used vapor (kg CO_2/year)	CO_2 Release by hydrotreating process (kg CO_2/year)		Total Emissions (kg CO_2/year)
7,347,269,188.12	1,346,683.54		7,348,615,871.66

The comparison between the biorefinery and individual processes is made in terms of two economic indicators and two environmental indicators. The economic indicators are defined as TAC per mass unit and TAC per energy unit of main biofuel produced. The environmental indicators are defined as kg CO_2 per mass unit and kg CO_2 per energy unit of main biofuel produced. In the individual processes, the main products are biodiesel and biojet fuel, respectively; while in the biorefinery process, the sum of biodiesel and biojet fuel are considered as the main products. The proposed indicators show, in Table 2, that the biorefinery has a higher cost than biodiesel individual process, but lower than the biojet individual process. In addition, the minimum value of kg CO_2 is reached by the biorefinery scheme, regarding to each individual process; this reduction in CO_2 emissions and cost could be attributed to the use of the free-of-charge WCO, the use of bifunctional hydrotreating catalyst, and the biorefinery concept.

Table 2. Proposed economic and environmental indicators.

Indicators		Biodiesel process (Gasca-González et al, 2018)	Biojet fuel process (Gutiérrez-Antonio et al, 2016)	Biorefinery (This work)
TAC/kg biofuel	(USD/kg)	0.7651	29.915	0.7471
TAC/kJ release	(USD/kJ)	0.0006	0.021	0.0005
kg CO_2/ kg biofuel	(kg CO_2/kg)	4.0828	1769.48	0.1294
kg CO_2/ kJ biofuel	(kg CO_2/ kJ)	0.0030	1237	0.0001

4. Conclusions

A biorefinery scheme to transform WCO into biodiesel and biojet fuel as main products has been presented. The total WCO recollected in Mexico for 2015 was the processing goal; 92.37 % yield to biodiesel and 36 % selectivity to biojet fuel were obtained in this scheme. The TAC per unit of mass or energy from biorefinery process was better than the

biojet fuel individual process reported; while, the total kg CO_2 emissions per mass or energy obtained were better than each individual process. Thus, the biorefinery scheme could be a promissory alternative to use WCO to produce biofuels.

Abstract

For chemical industry, safety is always primary. A safe and reliable systems are required to ensure the safety of chemical plants. Many data-driven process monitoring methods have been developed and successfully applied to various processes. Autoenocoder is an unsupervised learning algorithm, which can extract the features automatically from the unlabelled data. However, one limitation of autoencoder is that it does not consider any temporal dependency of the data. And autoencoder can not be ensured to get various meaningful features from the raw data. In this work, we proposed Feature Points Distance Dynamic Autoencoder (FPDDAE) to capture the temporal dependency and encourage the autoencoder to get meaningful features. The FPDDAE is constructed by the recurrent neural network (RNN), RNN can capture the time dependency of the process by adding a recurrent hidden state whose activation at each time is dependent on that of the previous time. To make the data points as near as possible in feature space, we define a penalty term $\mathcal{FPD}$ that measures the average distance between any two points in feature space. The penalty term $\mathcal{FPD}$ is a constraint to encourage the FPDDAE to learn meaningful features. A simple nonlinear simulation example is used to illustrate how the proposed method works. The proposed method is applied to the Tennessee Eastman process (TEP) to demonstrate its performance.

1. Introduction

For chemical industry, safety is always primary. Names like Bhopal or Piper Alpha, are well-known not only for causing a lot of death but also for the damage to the environment (Drysdale and Sylvester-Evans, 1998; Sen and Egelhoff, 1991). A safe and reliable systems are required to ensure the safety of chemical plants. With the wide application of distributed control system (DCS) and large number of variables are measured and stored, many data-driven process monitoring methods have been developed and successfully applied to various processes.

Data-driven process monitoring methods can be roughly divided into statistical methods and artificial intelligent methods, although there are many connections between them. Some typical statistical methods include principal component analysis (PCA) (Wise et al., 1990), partial least squares (PLS) (Kruger and Dimitriadis, 2008),independent component analysis (ICA) (Lee et al., 2004), Fisher discriminant analysis (FDA) (He et al., 2005), statistics pattern analysis (SPA) (He and Wang, 2011) and their variations. Due to the dynamics and nonlinearity of the chemical

process data, statistical methods have a lot of limitations when they are applied to the process monitoring.

For artificial intelligent based process monitoring methods, significant progress has been made in recent years, especially for the deep learning (DL) methods. DL methods were originally proposed as feature selection and classification methods. There is one limitation of most deep learning methods that they need large amount of labelled data and usually they do not perform well with limited data(Zhang and Zhao, 2017; Wu and Zhao, 2018). Autoenocoder is an unsupervised learning algorithm, which can extract the features automatically from the unlabelled data. However, one limitation of autoencoder is that it does not consider any temporal dependency of the data. And autoencoder can not be ensured to get various meaningful features from the raw data (Jia et al., 2018). The feature extraction process of an autoencoder can be regarded as the dot produce results between its weight matrix composed by a set of basis vectors and raw data. In this paper, we proposed Feature Points Distance Dynamic Autoencoder (FPDDAE) to solve the above problems. We use the recurrent neural network (RNN) to construct the autoencoder. RNN can capture the time dependency of the process by adding a recurrent hidden state whose activation at each time is dependent on that of the previous time. To make the data points as near as possible in feature space, we define a penalty term $\mathcal{FPD}$ that measures the average distance between any two points in feature space. The penalty term $\mathcal{FPD}$ is a constraint to encourage an autoencoder to learn meaningful features.

The remainder of the paper is organized as follows. In section 2, the autoencoder and RNN are briefly reviewed. Section 3 introduces the proposed FPDDAE method. In addition, a simple nonlinear simulation example is used to demonstrate how the proposed method work. In section 4, the proposed method is applied to the TEP model to demonstrate its performance. Conclusions are given in section 5.

2. Autoencoder and recurrent neural network

2.1. Autoencoder

An autoencoder consists of encoder and decoder. Given unlabeled data $\{\mathbf{x}_m\}_{m=1}^{M}$, the function $\mathbf{f}$ is called encoder and will calculate a feature vector $\mathbf{h}_m$ from $\mathbf{x}_m$:

$$\mathbf{h}_m = \mathbf{f}(\mathbf{x}_m) \tag{1}$$

The decoder reconstructs $\hat{\mathbf{x}}_m$ from the feature vector $\mathbf{h}_m$ by a mapping function $\mathbf{g}$:

$$\hat{\mathbf{x}}_m = \mathbf{g}(\mathbf{h}_m) \tag{2}$$

The set of parameter θ of the encoder and decoder are learned simultaneously on the task of reconstructing as well as possible the original input data. The aim of an autoencoder is to minimize the reconstruction error. This minimization is usually carried out by stochastic gradient descent in the training of Multi-Layer-Perceptrons (MLPs). The reconstruction error is as followed:

$$\mathcal{L}_{AE} = \frac{1}{2M} \sum_{m=1}^{M} ||\hat{\mathbf{x}}_m - \mathbf{x}_m||_2^2 \tag{3}$$

2.2. Recurrent neural network

A recurrent neural network (RNN) is an extension of a conventional feedforward neural network, which is able to handle a variable-length sequence input. The reason that RNN can handle time series is that RNN has a recurrent hidden state whose activation at each time is dependent on that of the previous time. Long short-term memory units (LSTMs) are one type of RNN, which make each recurrent unit to adaptively capture dependencies of different time scales. LSTMs have cell and forget gate to modulate the flow of information. The structure of LSTMs is showed in figure 1.
Figure 1: The structure of LSTMs.

3. Feature Points Distance Dynamic Autoencoder

We use $\mathbf{X}_t$ to denote a window (with window width w) of process measurements of n variables as below:

$$\mathbf{X}_t = [\mathbf{x}_{t-w+1}, \mathbf{x}_{t-w+2}, \cdots, \mathbf{x}_t]^T = \begin{bmatrix} x^{(1)}(t-w+1) & x^{(2)}(t-w+1) & \cdots & x^{(n)}(t-w+1) \\ x^{(1)}(t-w+2) & x^{(2)}(t-w+2) & \cdots & x^{(n)}(t-w+2) \\ \vdots & \vdots & \ddots & \vdots \\ x^{(1)}(t) & x^{(2)}(t) & \cdots & x^{(n)}(t) \end{bmatrix} \quad (4)$$

LSTMs are used as the neural network layers of FPDDAE to capture the time dependency among the process variables. The encoder $\mathbf{f_L}$ consists of two layers of LSTMs and calculates the feature vector $\mathbf{h}_t$ from $\mathbf{X}_t$:

$$\mathbf{h}_t = \mathbf{f_L}(\mathbf{X}_t) \quad (5)$$

The decoder reconstructs $\hat{\mathbf{X}}_t$ from the feature vector $\mathbf{h}_t$ by a mapping function $\mathbf{g_L}$:

$$\hat{\mathbf{X}}_t = \mathbf{g_L}(\mathbf{h}_t) \quad (6)$$

The penalty term $\mathcal{FPD}$ is the measure of the average distance between any two points in feature space. The historical data of normal operation is easily obtained in the industry. The process monitoring model is often built from the data at normal state. Therefore, it is meaningful to make points in feature space as near as possible when training the model. The penalty term $\mathcal{FPD}$ is defined as followed:

$$\mathcal{FPD} = \frac{1}{M-w} \sum_{i=1}^{M-w} \sum_{j=1}^{i} ||\mathbf{h}_i - \mathbf{h}_j||_2^2 \quad (7)$$

The cost function of FPDDAE is made up of reconstruction error and $\mathcal{FPD}$. The β regular parameter controlling the weight between the reconstruction error and the penalty term $\mathcal{FPD}$. The cost function is as followed:

$$\mathcal{L}_F = \frac{1}{2(M-w)} \sum_{t=1}^{M-w} ||\hat{\mathbf{X}}_t - \mathbf{X}_t||_2^2 + \beta \frac{1}{M-w} \sum_{i=1}^{M-w} \sum_{j=1}^{i} ||\mathbf{h}_i - \mathbf{h}_j||_2^2 \quad (8)$$

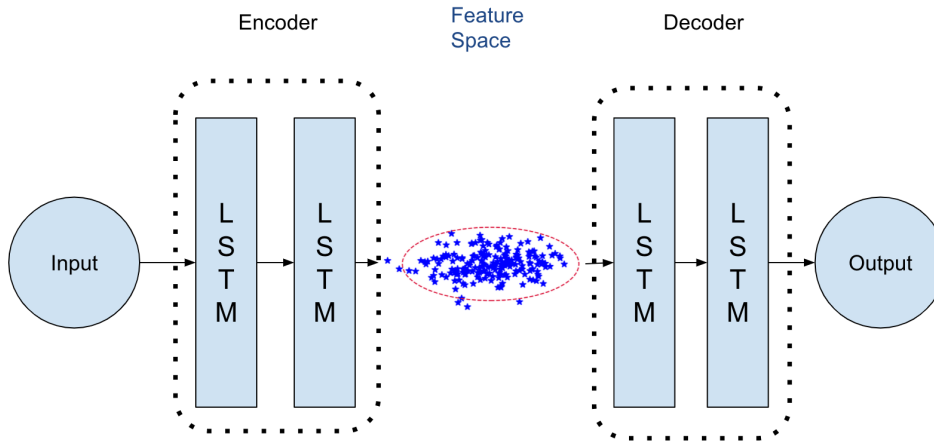
The FPDDAE is trained by minimizing the cost function $\mathcal{L}_F$. The structure of FPDDAE is showed at figure 2. The $\mathcal{L}_F$ is used as the monitoring scores. A threshold of monitoring scores is estimated by the empirical method. If test samples are faulty, when they are projected onto the FPDDAE model, which was trained using normal samples, the resulted monitoring scores would be higher than the threshold.


Figure 2: Structure of FPDDAE.

3.1. A simple nonlinear example

A simple nonlinear simulation example is as followed:

$$x_2 = x_1^2 + e \tag{9}$$

where x_1 is a random variable that follows a uniform distribution between [-0.5, 0.5], and e is a random variable that follows a normal distribution with variance 0.02. A total of 15000 normal samples is simulated with 10000 samples for training and 5000 samples for validation. Two groups of testing samples (faults A and B) are simulated, each group with 5000 samples. Figure 1 shows the scatter plot of the normal and faulty samples. Both auteoncoder and FPDDAE are trained by normal data. The results of autoencoder and FPDDAE at training process are compared in figure 3. From the figure 3 (b)-(d), the average distance of data points decreases in the FPDDAE method. The normal data and faulty data are clearly separated in the feature space. However, as showed at figure 3 (e)-(f), the normal data and faulty data can not be separated clearly by using an autoencoder. The proposed method FPDDAE can deal with the nonlinearity and capture the meaningful features.

4. Case study

In this section, the benchmark Tennessee Eastman model process simulator is used to demonstrate the performance of the proposed method. Compared with the small nonlinear simulation model in the previous section, the TEP is a much larger nonlinear system. The model consists of five major units: a reactor, condenser, compressor, separator, and stripper (Downs and Vogel, 1993). The process contains 12 manipulated variables and 41 measured variables. The measured variables contain 22 process variables sampled every 3min, and 19 quality variables sampled with dead time and time delays. In this case study, 22 process variables and 12 manipulated variables are used for the process monitoring. Here we compare PCA, DPCA, KPCA, autoencoder and FPDDAE. For all the methods, 960 samples of normal state is used as the training data set. The validation data set is made up of 480 samples of normal state. Each fault consists of 960 samples, and the fault is introduced at 161 samples. The upper control limits correspond to the 99% confidence level for all the methods.

(a) Raw data

(b) epoch = 20

(c) epoch = 30

(d) epoch = 40

(e) epoch = 20

(f) epoch = 30

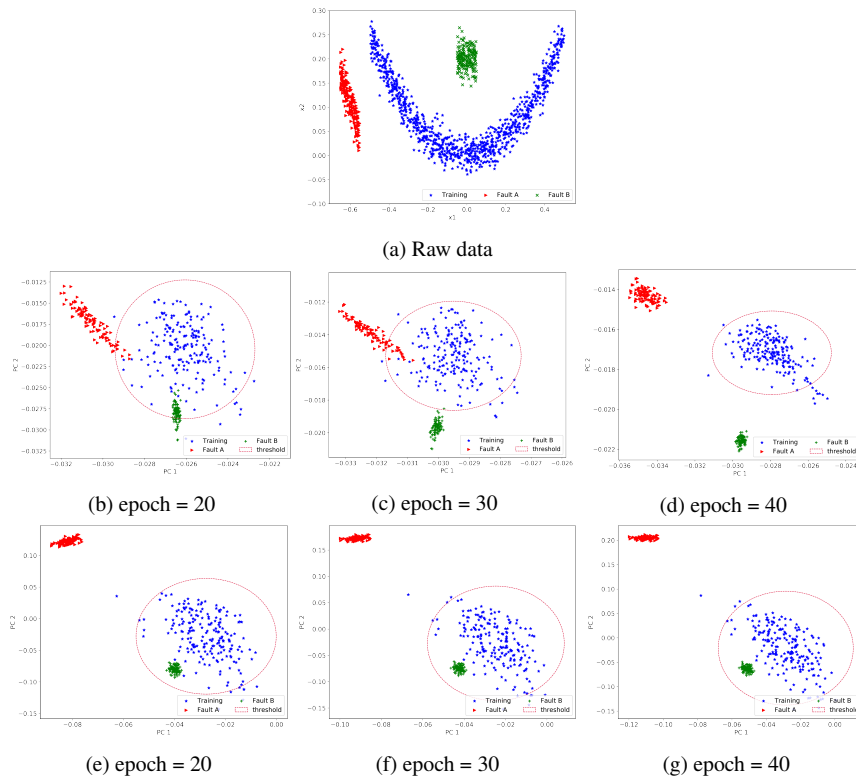
(g) epoch = 40


Figure 3: Scatter plot of normal and faulty data. Raw data: (a). FPDDAE: (b) , (c) , (d) . Autoencoder: (e) ,(f) , (g).

The fault detection rates of different methods for all faults are listed in Table 1. It is suggested that faults 3,9 and 15 are difficult to detect and may have been corrected by the control mechanism, so they are not consider here (Lee et al., 2006). In the case study, PCA, KPCA and DPCA don't perform well on six faults (Fault 5, 10, 16, 19, 20, 21). In comparison, the proposed FPDDAE method have a higher detection rate than other methods.

5. Conclusion

In this paper, we proposed a new cost function to make the points in the feature space as near as possible. Based on this new cost function, we proposed FPDDAE for the process monitoring. FPDDAE can capture the temporal dependency and encourage the autoencoder to get meaningful features. Compared with the traditional methods like PCA, FPDDAE can deal with nonlinearity and dynamics. The performance of the proposed FPDDAE is compared with other methods on a small nonlinear example and the benchmark Tennessee Eastman process. The results show that FPDDAE can detect the faults more efficiently than other methods. The temporal dependency is captured by the LSTMs.

This work highlights that the unsupervised deep learning methods can be adapted for process monitoring. Various meaningful features can be captured by using the different cost functions. For

Abstract

In this work, we present a systematic comparison of the performance of five mixed-integer non-linear programming (MINLP) multiobjective optimisation algorithms on a computer-aided solvent design problem. The five methods are designed to address the nonconvexity of the problem, with the aim of generating an accurate and complete approximation of the Pareto front. The approaches includes: a weighted sum approach with simulated annealing (SA), a weighted sum approach with multi level single linkage (MLSL), the sandwich algorithm with SA, the sandwich algorithm with MLSL and the non dominated sorting genetic algorithm-II. These five combinations of optimisation techniques are applied to the design of a solvent for chemical absorption of carbon dioxide (CO_2). The results shows that the sandwich algorithm with MLSL can efficiently generate diverse Pareto points leading to a construction of more complete Pareto front.

Keywords: multiobjective optimisation, CAMD, MINLP, global search

1. Introduction

Computer-Aided Molecular Design (CAMD) is a promising technique that can accelerate the discovery of new molecules, such as solvents, refrigerants, and pharmaceutical products, by making it possible to explore *in silico* a very large space of possibilities. In the field of CAMD, numerous mathematical methods have been developed to handle the complexities that arise from the large number of molecules that can be formed from the combination of a given set of atom groups and from the inherent non-linearity and non-convexity of structure-property and process models. Many of the methods proposed to date have been based on an optimisation framework and have made use of single objective Mixed-Integer Non-Linear Programming (MINLP) to achieve better economic criteria or property targets. However, in many cases, it is beneficial to consider multiple conflicting objectives that cannot easily be combined together in a single metric. Multi-Objective Optimisation (MOO) is thus receiving increasing attention in the CAMD area. Papadopoulos and Linke (2006) proposed a multi-objective molecular design technique linked with a process synthesis framework, extending it (Papadopoulos et al., 2013) to the design of binary working fluid mixtures in organic Rankine cycles and (Papadopoulos et al., 2016) to the design of solvent for CO_2 capture. Burger et al. (2014) adapted the sandwich algorithm to the design of a solvent for a CO_2 physical absorption process. Herring and Eden (2015) also successfully introduced MOO with a genetic algorithm to the

molecular design problem. Although the mixed-integer nature of molecular design MOO problems presents specific challenges, there has been no systematic analysis to compare the performance of MOO algorithms for CAMD applications.

In this work, we present a comparative analysis of the performance of three main MINLP MOO approaches, the weighted sum (WS), the sandwich algorithm (SD) (Rennen et al., 2011), and the non-dominated sorting algorithm-II (NSGA-II) (Deb et al., 2000). To increase the likelihood of identifying the globally optimal Pareto front, we make use of the simulated annealing version of WS (Marcoulaki and Kokossis, 2000), which has been previously applied to MOO CAMD (Papadopoulos et al., 2016). We also put forward a simulated annealing version of the sandwich algorithm, and multi-start approaches for the both WS and SD. This results in 5 combinations of algorithmic options, which are applied to the design of a solvent for the chemical absorption of CO_2. Algorithmic performance is compared based on reliability and efficiency criteria.

2. Optimisation methodology

In this section, we describe the methodologies for MINLP MOO that are used in this work. The WS and SD rely on on a scalarisation of the multiple objective functions as a single aggregated objective function. NSGA-II, on the other hand, falls into the category of 'evolutionary algorithms'. The NSGA-II can in principle solve a broader range of MOO problems as it is a derivative-free method, but the accuracy of the resulting approximation cannot be guaranteed.

2.1. Weighted sum method

WS is the most widely used scalarisation method in MOO . It is formulated as $\min \sum_{i=1}^{p} \lambda_i f_i$ (p : # of objectives) , where $\sum_{i=1}^{p} \lambda_i = 1$. The weights, λ_i are positive real values. The method is that it is easy to implement and the scalarised problem is of the same degree of difficulty as the original MOO problem. However, the weights have to be assigned beforehand and a large perturbation in weights does not always lead to a corresponding change in the objectives. As a result, the generated Pareto points are strongly dependent on expert knowledge and this might lead to points that are biased. Alternatively, weight vectors can be randomly generated to try and obtain a sufficient coverage of the Pareto front.

In our study, the weights are randomly chosen from the uniform distribution to achieve multiple search directions.

2.2. Sandwich algorithm

The basic idea behind the algorithm is that inner and outer approximations of the Pareto set are constructed iteratively until the difference (error) between the two approximations falls below a given tolerance. This approach can help to reduce the number of solutions of the scalarised problem that need to be obtained to construct a good approximation of the Pareto front (Rennen et al., 2011). In this study, the tolerance of error is taken as 10^{-3}.

2.3. Global phase for WS and SD

A challenge in applying WS and SD to nonconvex MOO problems is ensuring that the global solution of each scalarised problem is identified, as local solutions are dominated

solutions of the MOO rather than Pareto-optimal points. In this work, Multi-Level Single Linkage (MLSL) (Kucherenko and Sytsko, 2005) and Simulated Annealing (SA) (Marcoulaki and Kokossis, 2000) are used. The MLSL method is based on the simple idea of enumerating all the local minima by starting a local minimization procedure at a set of starting points generated by a Sobol' sequence, combined with a clustering method in which the local search procedure is applied to a sample point, only if there is no other sample point within some critical distance (R_k) which has a lower objective function value. In the SA algorithm, the analogy of the heating and slow cooling of a metal so that a uniform crystalline state can be achieved is adopted to guide the search for an optimal point. The key algorithmic feature of SA is that it encourages a more extensive exploration of the search space, thereby increasing likelihood of global solution. The parameters were carefully chosen based on the statistical experiment and the values are listed in Table 1.

2.4. Non-dominated Sorting Genetic Algorithm-II (NSGA-II)

The NSGA-II algorithm (Deb et al., 2000) is a particular form of genetic algorithm (GA) and is one of the most widely-used MOO evolutionary algorithms. NSGA-II is directly applicable to MOO as it uses an explicit diversity-preserving mechanism based on a crowding distance metric to generate uniformly distributed Pareto points. Furthermore, it makes use of elite-preserving operators to give "elite genes" an opportunity to survive in the next generation. To implement the NSGA-II into a solvent design, one needs to specify a suitable set of heuristic parameters. These parameters are specified in Table 1.

3. Comparative methodology

A CAMD application based on the design of a solvent for the chemical absorption CO_2 is introduced in Section 3.1 as an example that can be used to evaluate the performance of each method. The formulation is based on the recent work of Papadopoulos et al. (2016), who considered an extensive list of property criteria for MOO. The performance of the selected algorithms is analysed based on the criteria, as discussed in Section 3.2.

3.1. Objectives and constraints

Four of solvent properties considered by Papadopoulos et al. (2016) are selected as objective functions in this study, namely, liquid density (ρ), heat capacity (C_p), saturated vapour pressure (P_{vap}), and relative energy difference (*RED*). Several other performance criteria are considered as constraints: a) the normal melting point (T_m), to ensure that the solvent is in the liquid phase at the lowest process operating temperature, b) the normal

<table>
<tr><td colspan="2">Table 2: property constraints</td><td colspan="2">Table 3: Solvent design space</td></tr>
</table>

Physical properties, $\mathbf{g(n)}$	Bounds	Functional groups	Bounds
ρ (g/cm^3)	[0.6,1.5]	CH$_2$-N< ,-CH$_2$-N<,	
RED	(0, 6.5]	CH$_2$-NH-,-CH$_2$-NH-,	
T_b (K)	[393, 550]	>CH-NH-,-CH$_2$-NH$_2$,	$n_{total} = 13$
T_m (K)	[273,313]	>CH-NH$_2$,$\geq$C-NH$_2$,	$n_{tot,amine} = 5$
σ (dyn/cm) at 25°C	[25, 60]	CH$_3$-,-CH$_2$-,	
μ (cP) at 40°C	(0,60]	>CH-,> C< , -OH	

boiling point (T_b) to avoid excessive evaporation at absorber operating conditions, c) the viscosity (μ) to ensure ease of transport and d) the surface tension (σ), to promote mass transfer performance. The property targets and performance criteria are summarised in Table 2. The SAFT-γ Mie group contribution equation of state (Papaioannou et al., 2014) is used to predict ρ, C_p, P_{vap}, and T_b. The Group Contribution (GC) methods are used for T_m, σ, *RED* (Hukkerikar et al., 2012) and μ (Hsu et al., 2002). A set of 13 functional groups (n_i, i=1,...,N, N=13) shown in Table 3 including 8 amine molecular groups are selected as molecular building blocks based on the applicability of the in property prediction methods used and knowledge of the problem (Papadopoulos et al., 2016).The mathematical formulation of the solvent design problem for CO$_2$ capture by chemical absorption is described as follows:

$$\min_{\mathbf{n}} \quad C_p, P_{vap}, RED$$

$$\max_{\mathbf{n}} \quad \rho_{solvent}$$

$$\text{s.t.} \quad \mathbf{g(n)} \leq 0$$

$$\sum_{i=1}^{N} (2 - v_i)n_i - 2m = 0, \tag{1}$$

$$\sum_{j \in G_a}^{N} n_j - n_{tot,amine} \leq 0, \ (G_a : \text{amine groups}), \quad \sum_{i=1}^{N} n_i - n_{total} \leq 0$$

where $\mathbf{g(n)}$: inequality constraints of the physical properties, v_i: valence of each group, m: structural parameter (m=1 for acyclic)

3.2. Algorithmic performance measures

In this study, three measures for comparing the performance of the algorithms are used: 1) average CPU times (CPU$_{avg}$, seconds); 2) the number of Pareto points found (N$_{Pareto}$); 3) hypervolume indicator (HV) (Zitzler et al., 2003). The *CPU$_{avg}$* is calculated by averaging the time taken to generate one point on the Pareto front. An algorithm with a lower value of this criterion is preferable. The number of unique Pareto optimal solutions obtained by algorithm is also considered. The algorithm with the highest value of this metric provides a more complete and diverse representation of the Pareto front. The hypervolume indicator represents the volume in the objective space that is covered by a set of Pareto points and a corresponding reference point (Zitzler et al., 2003). The indicator can provide a measure of closeness to the real Pareto set as well as of the diversity of the points.

4. Results and Discussion

In this section, we compare the relative performance of five algorithms: the WS with MLSL (WSML), WS with SA (WSSA), SD with MLSL (SDML), SD with SA (SDSA), and non-dominated sorting genetic algorithm-II (NSGA-II). All algorithms under comparison were implemented in MATLAB 2017a and interfaced with gPROMS Model Builder, which provides a standard MINLP solver. All computations were run under 64-bit Windows 10 on a single Intel i7-6700 3.4GHz processor core and with 8 GB of memory.

Table 4 summarises the performance of the global search methods, SA and MLSL in combination with WS and SD method. WS combined with the local MINLP solver is are used as a base case. The simulation data correspond to a set of 100 different weight vectors: an identical set of weight vectors was assigned to each algorithmic options. The results in Table 4 demonstrate that the WSML outperforms the WSSA such that the higher hypervolume can be achieved within the same cost of CPU time. This clearly indicates that the MOO algorithm with MLSL is more efficient. However, for both WSML and WSSA, only a small number of chemical structures (Pareto points) has been identified. This confirms that different weight vectors do not always lead to different solutions. As can be seen in the results of SDML and SDSA, systematically assigned weights also cannot generates different Pareto points for each iteration although the methods result in a larger set of Pareto points than WS. This is mainly due to the fact that the mapping of the weights into objective space assume that the feasible region is continuous. As a result, the assigned weights may result in same Pareto point as the problem is MINLP.

Table 5 summarises simulation results under a fixed CPU time (48 h) with respect to the performance measures. In the comparison between five combinations of algorithmic options, SDML produces the best results for two criteria, hypervolume and the number of Pareto points. The reason is that the SDML can deterministically guide the direction of the weight vector in a sequence of iterations, which increases the possibility of finding different Pareto points. This results largely imply that more difference in molecular structures and physical properties can be seen in the Pareto optimal set generated by SDML. In Table 5, the NSGA-II exhibits a relatively lower hypervolume than other tested methods although it generated a larger number of Pareto points within the allowed CPU time. This implies the accuracy of the Pareto front generated is not satisfactory when using NSGA-II with the parameters in Table 1.

Table 4: Comparison of global search methods

Metric	Base	WSML	WSSA	SDML	SDSA
No. of iterations	100	100	100	100	100
N_{Pareto}	20	12	14	54	50
HV	3.436	3.689	3.539	4.891	4.724
CPU_{avg} (s)	23	809	22106	818	17837

Table 5: Comparison of WSML, SDML, and NSGA-II algorithms

Metric	WSML	SDML	NSGA-II
CPU time (fixed, h)	48	48	48
N_{Pareto}	26	74	100
HV	3.982	5.832	0.672

5. Conclusion

In this paper, five different MOO algorithms have been compared by assessing their specific performance on a solvent design problem. To increase the probability of finding the true Pareto front, two different global search algorithms were combined with two scalarisation based methods. The algorithms were tested using a solvent design problem with four objective functions. For the global search phase, comparative results have highlighted the efficiency of the MLSL algorithm. In comparison to WSML and NSGA-II, SDML been found to have the best performance as it can generate a better distributed Pareto fronts in a given time frame, as indicated by the number of Pareto points generated and the hypervolume achieved. In a future work, the application of the methodologies will be extended to different size of CAMD problems to generalised the performance of the methods beyond the solvent design for the CO_2 removal.

Abstract

The simultaneous control of crystal size and shape is particularly important in fine chemical and pharmaceutical crystallization. These two quantities influence the dissolution rate and bioavailability of final drug products, and also contribute to the manufacturability and efficiency of downstream operations. Numerous practical issues are associated with the implementation of an industrially relevant crystal size and shape control algorithm, such as the limited number of commercially available measurement devices and tight productivity constraints. Model-based control algorithm is required to address these problems, which, however, brings an additional challenge: the high computational demand of the applicable process simulation.

In this work we show that the model predictive control, relying on measurements coming from routinely applied, commercially available process analytical technology (PAT) tools may be feasible. The algorithm is based on GPU accelerated full 2D population balance model (PBM) solution, which does not require external computation units (i.e. cloud computing). The state estimation, which is a crucial part of any robust model-based control system, is carried out by fitting the model, through the re-adjustment of some model parameters, on the measured FBRM count, PVM based mean aspect ratio (AR) and solute concentration, in real time. Artificial neural network (ANN) based soft-sensor is employed to simulate the most likely mean AR of the bivariate crystal size distribution (2D CSD) calculated by the PBM, which is compared then to the mean AR measured by the *in-situ* imaging tool, as a part of real-time parameter re-adjustment.

Keywords: crystallization, model predictive control, real time control, crystal shape

1. Introduction

The size and shape of crystalline active pharmaceutical ingredients (APIs), in addition to the purity and polymorphic form, impact both the downstream operations (filtration, drying *etc*.) and some of physical properties (dissolution rate, flowability *etc*.). Consequently, simultaneous size and shape control of particles during solution crystallization has gained more attention from both academic and industrial perspectives (Nagy and Braatz, 2012). The size control in crystallization processes is a well-studied field, but simultaneous size and shape control has gained more attention only in the recent years, due to two major factors: (1) the lack of real-time crystal shape measurement tools and (2) limitations by computational power for the (often required) model-based control.

Numerous variables can be manipulated to control crystal shape, including the supersaturation (through temperature or antisolvent addition), facet-specific growth rate

inhibitor concentration, stirring power or internal/external milling (breakage). The most convenient is to manipulate supersaturation, which influences the crystal shape through the different supersaturation dependencies of facet-specific growth and dissolution rates. Although model free shape control was already successfully achieved by these simple principles, the productivity and yield is far under the industrially desired levels. Model-based shape control approaches, which can directly involve productivity and yield constraints, were not implemented so far, mainly due to the aforementioned limitations.

In this work we propose a real-time feasible nonlinear model predictive control (NMPC) algorithm, with growing horizon state estimator (GHE). The system is based on full 2D PBM (with nucleation, growth and dissolution) to describe the entire 2D CSD, not only its moments. ANN based soft-sensor model is applied to quickly approximate the most likely measurable AR distribution (ARD) in conjunction with a GPU accelerated bi-dimensional FVM solver, already presented in the literature (Szilágyi and Nagy, 2018). In this paper we show that the NMPC is real-time feasible and it has no practical limitations from the standpoint of measurement system, since it relies on routinely applied concentration, chord-length distribution (CLD) and ARD measurements, which is a significant novelty of this work. For brevity, we will analyse the performance and calculation time requirement of GHE and NMPC individually. In the feasibility analysis we assume 4 hours batch crystallization of rod-like crystals and 5 minutes sampling time. The timings were obtained on a Dell Alienware machine with Intel i7-7700 CPU, 2400 MHz main memory clock speed, and nVidia GeForce GTX 1060m GPU.

2. The process model and the soft-sensor

The process model and simulation procedure was described in details in the literature (Szilágyi and Nagy, 2018), thus here we give only a brief overview. Assuming that the crystals are characterized by the length (L_1) and width (L_2) size dimensions, denoted by the $(L_1, L_2) \rightarrow \mathbf{L}$ size vector, and the crystal population is described by the $n(\mathbf{L}, t)$ bivariate size density function, the 2D PBE governing the variation of 2D CSD is:

$$\frac{\partial n(\mathbf{L}, t)}{\partial t} + \sum_{i=1}^{2} G_i \frac{\partial n(\mathbf{L}, t)}{\partial L_i} = B\delta(\mathbf{L} - \mathbf{L}_n) \tag{1}$$

B is the nucleation rate, and G_i denotes the size-independent growth rates along the length and width axes. Eq.(1) has $n(\mathbf{L}, t=0) = n_0(\mathbf{L})$ initial and $n(\mathbf{L} = \infty, t) = 0$ boundary conditions. The initial condition is given by the seed distribution, whereas the boundary condition expresses that the crystals must have finite size. The first term in Eq. (1) describes the temporal evolution of the 2D CSD, the second term is for the growth. The right hand side is the nucleation term. The solute mass balance is written as:

$$\frac{dc}{dt} = -k_v \rho_c \left(\iint G_1 L_2^2 n(\mathbf{L}, t) d\mathbf{L} + 2 \iint G_2 L_1 L_2 n(\mathbf{L}, t) d\mathbf{L} \right) \tag{2}$$

with the $c(t=0) = c_0$ initial condition. Here, k_v is the volume shape factor, whereas ρ_c is the crystal density. Since the temperature is manipulated variable, energy balance is not required for model closure.

The applied kinetic rate equations are listed in Table 1. The equations were compiled based on the literature data for potassium dihydrogen phosphate (KDP) (Eisenschmidt et al., 2015; Gunawan et al., 2002). Since the activation energies and supersaturation exponents are from separate works, the rate constants were modified so to bring the growth and dissolution rates in reasonable domain. The nucleation parameters were modified to give reasonable nucleation rate with the applied growth rate expressions.

Table 1. Kinetic rate equations applied in this work. σ is the absolute supersaturation.

Mechanisms	Expression (for length)	Expression (for width)
Nucleation [#/m³s]	$B = 3 \cdot 10^{12}\sigma^{5.24}$	
Growth [μm/s]	$G_1 = 6.04 \cdot 10^6 \sigma^{1.74} \exp\left(-\dfrac{39100}{RT}\right)$	$G_2 = 2.42 \cdot 10^5 \sigma^{1.48} exp\left(-\dfrac{37100}{RT}\right)$
Dissolution [μm/s]	$D_1 = 2.72 \cdot 10^5 \sigma^1 \exp\left(-\dfrac{26800}{RT}\right)$	$D_2 = 8.18 \cdot 10^5 \sigma^1 exp\left(-\dfrac{29700}{RT}\right)$

The model equations were solved with a high-resolution finite volume method (HR-FVM) on non-uniform grid involving GPU acceleration. This allows up to two orders of magnitude speedup compared to a standard serial *C* implementation, which makes the simulation capable of real-time optimization (for timing details see the literature Szilágyi & Nagy, 2018). The advantage of the GPU acceleration, beyond enabling NMPC, is that it provides the computational power on site for low investment cost, eliminating the need for supercomputers or cloud-services, which are both undesired in industrial environment.

It is known that the *in-situ* imaging based shape measurement underestimates the real AR due to random spatial orientation of the crystals. To calculate the most likely measurable AR of a crystal, a geometrical model-based technique was proposed, that constructs the ARD of the single 2D crystal by mapping all possible two dimensional projections of the crystal. Then, using large number of *ARD = f(L)* pairs, an ANN is trained to give the most likely ARD of an arbitrary sized (*L*) crystal. The most likely ARD of the 2D CSD is then approximated in real time as a weighted sum of individual ARDs corresponding to the HR-FVM grid sizes, returned by the ANN, where the weighting factor is the $n(\mathbf{L}, t)$.

3. Growing horizon state estimator (GHE)

There are two major reasons that require the utilization of already available measurement data. Firstly, the system states (2D CSD and concentration) are required in NMPC optimization as initial condition of the simulation. While the concentration can be measured, the 2D CSD generally not. Therefore, the 2D CSD must be estimated from the available measurements, but for robustness (e.g. with respect to sensor communication errors), the concentration is often estimated, too. Secondly, there are often uncertainties related to seed loading, and the crystallization kinetics is known to be sensitive to process conditions (through disturbances from impurities, mixing energy *etc.*), which is a typical plant-model mismatches (PMMs) that leads to sub-optimal control.

The basic idea of the NMPC is that if the system states are accurate and the model describes well the process, the process output can be predicted, hence, optimized. Our GHE is based on the same principle: the parameters that capture the main sources of PMM are identified, then used as decision variables for fitting the model to the measured data in the estimation horizon (from zero to the actual process time) in real-time. Once the updated model parameters become available, process simulation is carried out from the initial time to the actual process time, which gives the system states.

In a batch crystallization process, the parameters related to nucleation and growth kinetics as well as the seed loading generally exhibit the most batch-to-batch variability, thus are ideal candidates for decision variables in the GHE optimization. Denoting the vector of model parameters by ψ, listed in Table 2, the following GHE objective is proposed:

$$O_{GHE}(\psi) = \sum_i \left(c_{m,i} - c_{s,i}\right)^2 + w\sum_i \left(AR_{m,i} - AR_{s,i}\right)^2 + u\sum_i \frac{\left(N_{m,i} - N_{s,i}\right)^2\left(N_{m,i}^2 + N_{s,i}^2\right)}{N_{m,i}^2 N_{s,i}^2} \quad (3)$$

Subscript "m" and "s" are for measured and simulated quantities, N_m is the FBRM count and N_s is the simulated number density normalized to $N_m(t = 0)$. The values w and u are weighting factors. The first part of the objective is for the fitting of concentrations, the second is for the ARs. It can be shown that the count term is considerably more sensitive to the correct capturing of the nucleation point than to the actual value of final count. This enables to reliably use the FBRM for nucleation detection.

Table 2. Initial values and bounds of decision variables of GHE optimization as well as the performance of state estimator in parameter re-adjustment

ψ_i	Seed v.f.	k_b*	b	$k_{g1}*$	g_1	$k_{g2}*$	g_2
Starting point	$1.21 \cdot 10^{-3}$	$3.0 \cdot 10^{12}$	5.24	$6.04 \cdot 10^6$	1.74	$2.42 \cdot 10^5$	1.48
Actual parameters	$1.43 \cdot 10^{-3}$	$1.1 \cdot 10^{12}$	5.30	$2.91 \cdot 10^6$	1.72	$1.38 \cdot 10^5$	1.44
Lower bound	$8.5 \cdot 10^{-4}$	$7.1 \cdot 10^{11}$	5.08	$2.72 \cdot 10^6$	1.68	$1.32 \cdot 10^5$	1.43
Upper bound	$1.6 \cdot 10^{-3}$	$1.2 \cdot 10^{13}$	5.40	$1.31 \cdot 10^7$	1.80	$4.49 \cdot 10^5$	1.52
Readjusted parameters	$1.38 \cdot 10^{-3}$	$7.8 \cdot 10^{11}$	5.15	$2.94 \cdot 10^6$	1.71	$1.38 \cdot 10^5$	1.44

*In the GHE the log(k) was readjusted rather than the nominal value, to improve the optimization performance

A recent study suggested that in such a GHE, the kinetic parameters move within the confidence intervals of the off-line parameter estimation (Szilágyi et al., 2018). Hence, the bounds for kinetic parameters are set to the 95 % confidence interval limits available from the off-line parameter estimation. The bounds of the seed loading may be chosen arbitrarily, based on the accuracy and precision of the balance, for instance. The nominal values of ψ, as well as the (assumed) bounds are listed in Table 2.

To improve the convergence, the decision variables were scaled ($\psi \rightarrow \psi_S$), using scale parameters (χ) that normalizes the initial values to 1. The ith element of vector χ is:

$$\chi_i = \frac{1}{\psi_i} \rightarrow \psi_{S,i} = \psi_i \times \chi_i \qquad (4)$$

The optimization was solved in Matlab using the interior-point algorithm (implemented in the *fmincon* inner optimization routine). The iteration limit was set to 13. It worth

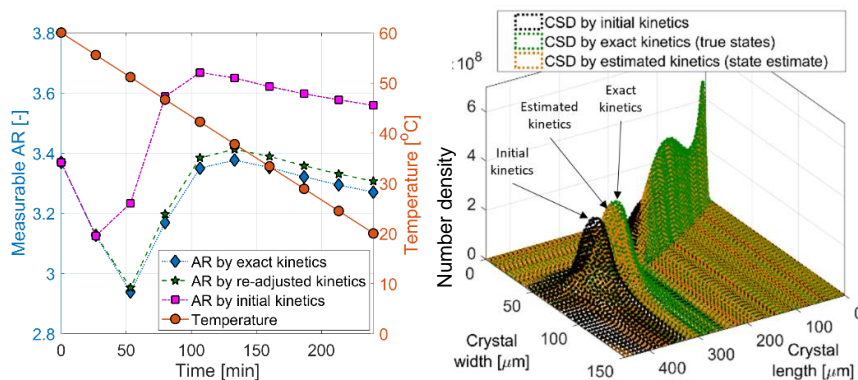

Figure 1. State estimator performance: fitting the model on measured ARs (the concentrations and counts are not plotted for brevity) as well as the estimated and exact 2D CSD. The calculation time was 115 s.

noticing that in the demonstration (Figure 1) we assumed that the estimation horizon is the same as the batch time. Therefore, this GHE operates on the longest possible time frame, so the 115 s timing gives the maximum calculation time requirement. According to Table 1 and Figure 1, the estimator readjusted successfully the model parameters, and was able to estimate the actual system states with acceptable accuracy.

4. The real time optimization problem and provisionally results

The NMPC is a repeated real-time optimization of the control signal in every sampling instance, using the estimated system states and the updated model parameters. Hence, the calculation time, i.e. the NMPC optimization and the state estimation time, must fit into the sampling time. The 5 minutes sampling time is a reasonable choice for the dynamics of a usual crystallization processes.

For the sake of simplicity, the batch NMPC problem is formulated as end-point (product property) optimization. The decision variables are the vector of temperatures in the control horizon, i.e. the current time to the final time, which time frame is shrinking as the batch evolves. We defined the temperature profiles by 12 discrete temperature points, which translates to 10 decision variables (the initial and final temperature are fixed).

$$O_{NMPC}(T) = w_1 AR_{prod.}^2 + w_2 F_{idx}^2 + w_3 \left(\frac{n_{t_{final}}}{n_{t_{initial}}}\right)^2 + w_4 \sum_i (t_{i+1} - t_i) \frac{(T_{i+1} - T_i)^2}{(t_{i+1} - t_i)^2} \tag{5}$$

The first term of objective function is to minimize the product AR, the second term minimizes the fine index (i.e. volume fraction of crystals under a threshold sphere-equivalent diameters, here set to L_f=100 μm), the third term is for the ratio of final to initial number density (zero moment), whereas the last term is to ensure smooth temperature profile. The values of weight factors (w_i, i=1,...,4) define the relative importance of sub-objectives. Setting all values to 0, except w_1, leads to pure AR minimization NMPC, w_2 controls minimization of fines in the product, whereas w_3 is for the nucleation minimization, or, indirectly crystal size maximization.
Figure 2. Optimal temperature profiles calculated for different objectives and the corresponding. All timing is an average of three run.

Although there is an AR term in the Eq.(5), the AR can be manipulated only within the attainable AR domain. The attainable size and shape domains are delimited by the crystallization kinetics and process parameters (temperature profile, seed properties *etc.*) (Vetter et al., 2014; Acevedo and Nagy).

In the optimization constraints are imposed on the heating and cooling rates (0.5 °C/min both) and for minimal and maximal temperatures (60 and 15 °C). The initial and final temperatures are fixed for yield to 60 and 20 °C. The optimization was solved using a sequential quadratic programming approach in the *fmincon* routine of Matlab. Provisional optimization results and timings are presented in Figure 2. The development of the NMPC control algorithm from its main components is associated with numerous challenges to ensure robustness and stability (Mayne et al., 2000).

5. Conclusions

In this paper a full 2D PBM based NMPC was presented for batch crystallization processes. In the study it was shown that the system is real-time feasible and implementable using commercially available monitoring systems and locally available, low cost GPUs as efficient accelerators for improved optimization times. Another enabling invention used in this work was the fast, approximate, ANN based soft-sensor, which takes the 2D CSD calculated by the PBM and transforms it to the most likely measurable ARD (mean AR), which is measured by the most common, commercially available imaging based PAT tools. Due to brevity, we analyzed separately the feasibility and performance of the NMPC and GHE optimizations only; both simulations revealed that, using the accelerated computation, fast soft-sensor and the search-space delimited by the constraints, all the calculations can be done within the 5 minutes sampling time on a standard computer, which is reasonable for many industrial crystallization processes.

Abstract

Directed self-assembly provides a novel processing route for the manufacture of structured materials. Future processes based on self-assembly will need to be equipped with suitable automated process controls for improving performance. Closed-loop control has been applied to directed self-assembly with one or two actuators when real-time and non-invasive observation is feasible. However, such observation may be challenging in practice. Furthermore, multiple actuators may have to be used for the self-assembly of complicated structures. In this work, an automated open-loop control method for directed self-assembly using multiple actuators is developed and tested experimentally. The method relies on a novel design of microelectrodes to assemble a specific number of particles in a desired area in a microfluidic device. An empirical model is developed to determine an optimal sequence of control actions. The experimental results show that the number of particles after the implementation of the open-loop control is close to the targeted number.

Keywords: directed self-assembly, open-loop control, modelling, electrokinetics

1. Introduction

Self-assembly is the spontaneous association of small molecules or particles into structures, which provides a novel processing route for the manufacture of materials with structures at the micro/nano-scale. Future manufacturing processes based on self-assembly will need to be equipped with suitable automated process controls to compensate for design uncertainty and to reject disturbances. Local actuation is required to fabricate specific structural features or to heal defects, which can be enabled by the introduction of external fields to direct the self-assembly (Ulissi et al., 2013; Paulson et al., 2015). Electric fields are of particular interest for local actuation due to their noninvasiveness and flexibility in manipulating particles according to a diverse set of electrokinetic phenomena that can be induced (Oh et al., 2009). Feedback control has been implemented for directed self-assembly to effectively assemble colloidal structures using one or two electrokinetic actuators when real-time observation is feasible (Juárez et al., 2012; Tang et al., 2016; Gao and Lakerveld, 2018). However, to enhance control performance or to assemble more complicated and possibly non-periodic structures, multiple actuators have to be used systematically to direct the self-assembly process. Such control is challenged by the stochastic nature of self-assembly, nonlinear process behavior and also by the design of the actuators. In case a system would not allow for real-time and non-invasive observation, an open-loop strategy has to be considered

based on a suitable mathematic model (Komaee and Barton, 2016). Model-based control methods are particularly interesting for nonlinear systems when multiple actuators are available. However, experimental studies on the performance of such control methods for directed self-assembly are limited.

In this work, a novel automated open-loop control method for directed self-assembly of colloidal particles using multiple actuators to induce various electrokinetic phenomena in a microfluidic device is developed and characterized experimentally. The control objective is to adjust the particle densities of two neighbouring regions. Firstly, a triple-parallel microelectrode is fabricated to provide multiple actuators in the microfluidic device for directing the self-assembly process over the two neighbouring regions. The multiple-electrode actuators can be manipulated flexibly to exhibit four types of system state. By engineering the different electrokinetic interactions within the four states, particles can either be transferred between two regions or be maintained in individual regions. Subsequently, an open-loop control strategy based on an input-output model is designed to transfer a specific number of particles from one region to the other. Finally, the open-loop control is implemented experimentally for performance assessment.

2. Microfluidic design and system characterization

The microfluidic cell and the microelectrode design are illustrated in Figure 1. A suspension of microspheres (radius 1μm) is placed between two transparent ITO-coated glass slides that act as electrodes. After approximately 20 minutes, the particles settle to form a two-dimensional system on the bottom electrode, where the ITO is patterned such that three actuators are available. The space between the adjacent actuators is defined as the density control area (see Figure 1B). Each actuator is connected independently to a channel of a function generator (33500B, Keysight Technologies) to apply AC electric fields. An optical microscope (Nikon, Ni-U) equipped with a digital camera (Nikon Digital Slight Qi2) and automated image analysis (Matlab, The Mathworks) are used to observe the positions of all particles in real time with a typical image processing time of 1s.

Four types of system state form the basis of the process model (see Figure 2), which can be realized with different combinations of the electric fields parameters (i.e. voltage v, frequency f) applied to the three actuators. These states are referred to as stabilization, shifting, collection and transfer. The transitions between the four states enable the transfer of particles between regions, which are dynamically modelled (Gao and Lakerveld, 2018). During the stabilization step (see Figure 1(A)), negative dielectrophoresis (nDEP) at a high field frequency is induced, which directs the particles towards an electric field minimum (Gao and Lakerveld, 2018). The particles cannot cross the middle actuator, which can be understood from a COMSOL simulation of the field strength distribution (see Figure 1(A)). The particles all accumulate near the field minimum, which allows for easier transfer in the next step, as the distance towards the middle actuator is similar for all particles. Note that the particles form chains due to their induced dipoles at this frequency. In the shifting step (Figure 1(B)), the voltage on the left actuator is increased and the voltage on the right actuator is decreased, which shifts the electric field minima.
Figure 1. (A) Schematic design of the microfluidic device. (B) Illustration of the bottom electrode including density control areas and multiple actuators.

The shift causes the particles in the left control area to move closer to the middle actuator while the particles in the right control area move further away. In the collection step (Figure 1(C)), electroosmotic flow (EOF) at a low frequency is generated using only the middle actuator. The induced flow carries the particles from the left control area towards the middle actuator. Finally, in the transfer step (Figure 1(D)), the nDEP is induced again to transfer the particles collected at the middle actuator to the right control area. The electric field strength has been shaped such that only the particles on the middle actuator will be transferred to the right control area. The electric field parameters for each step are summarized in Table 1.

Table 1. Electric field parameters for the four types of state in Figure 2

	Left actuator		Middle actuator		Right actuator	
	f/kHz	v/volt	f/kHz	v/volt	f/kHz	v/volt
Stabilization	100	5	100	1	100	5
Shifting	100	8	100	1	100	1
Collection	-	-	5	0.5	-	-
Transfer	100	8	100	1	100	1

3. Model development and open-loop control design

To design an open-loop control strategy for transferring a specific number of particles from the left to the right control area, the dynamics of the collection step has to be modelled. To describe the dynamics of the collection step, two sets of experiments involving all four steps were conducted and the location of all particles as function of time were documented using optical microscopy and automated image analysis. Figure 3(A)-(B) shows the change in the number of particles that are present in the left control area during the collection step as function of time. The dynamic evolution of the change in the number of particles in the left control area with time can be modelled empirically using a fifth-order polynomial for both experiments. By taking the average of the two fifth-order polynomial models, the empirical model for simulating the collection dynamics is constructed as follows:

$$n(t) = 0.0000049t^5 - 0.00054t^4 + 0.02t^3 - 0.23t^2 + 0.81t + 0.057 \qquad (1)$$

where n represents the change of particle number in the left control area and t represents the implementation time of the collection step. Based on the four-step control framework and the empirical model for simulating the dynamics of the collection step, automated

For each state, the top figure shows a schematic illustration of the locations of the particles. The middle figure shows the electric field strength distribution on the electrode surface from COMSOL simulation. The bottom figure shows a representative microscopy image.

open-loop control strategies can be designed to relocate a specific number of particles from the left density control area to the right density control area. The four steps are implemented sequentially and in an automated fashion using Matlab and an interface between Matlab and the function generator. To relocate a specific number of particles, the desired execution time for the collection step is estimated using the empirical model. Two open-loop strategies were designed and implemented for relocating 14 and 22 particles, corresponding to a transfer time of 21s and 25s, respectively.

4. Control strategy implementation and performance assessment

The dynamic development of the particle number on the middle actuator for the two experiments with open-loop control is illustrated in Figure 4. Note that the different steps from the four-step control framework are labelled differently. It can be seen that 11 and 21 particles are relocated from the left to the right control area, respectively, which are equal to number of particles collected on the middle actuator (see Figure 4). The relocated particle numbers are close to the intended number of particles to be transferred (14 and 22, respectively) set as objective for the open-loop control strategy, which demonstrates the effectiveness of the proposed open-loop control strategy. The small deviation in the number of relocated particles can be due to the stochastic nature of the self-assembly process, which cannot be avoided in this type of system, or due to the inaccuracy of the process model.
