Contents

Preface	xv
PROCESS-PRODUCT DESIGN AND INTEGRATION	
1. Explanatory and Predictive Analysis of Naphtha Splitter Products <i>Ahmet Can Serfidan, Metin Türkay</i>	1
2. Multi-objective optimization of the supply chain for the production of biofuels and high value-added products in Mexico: importance of the water footprint <i>Yulissa M. Espinoza-Vázquez, Fernando Israel Gómez-Castro, José María Ponce-Ortega</i>	7
3. Synthesis of Combined Heat and Mass Exchange Networks Via a Trust Region Filter Optimisation Algorithm Including Detailed Unit Designs <i>Saif R. Kazi, Michael Short, Lorenz T. Biegler</i>	13
4. Computer-Aided Refrigerant Design: New Developments <i>Nichakorn Kuprasertwong, Orakotch Padungwatanaroj, Arisa Robin, Kornkanok Udomwong, Anjan Kumar Tula, Lingyu Zhu, Liyang Zhou, Binhui Wang, Shuhua Wang, Rafiqul Gani</i>	19
5. Comparative assessment of black liquor upgraded gasification in integrated kraft pulp, methanol and dimethyl ether production plants <i>Meire Ellen Gorete Ribeiro Domingos, Daniel Flórez-Orrego, Moisés Teles dos Santos, Silvio de Oliveira Junior</i>	25
6. Sustainable Process Design and Synthesis for HDPE Recycling <i>Xiang Zhao, Fengqi You</i>	31
7. A Novel Process Design for Waste Respirator Processing <i>Xiang Zhao, Fengqi You</i>	37
8. Design and optimization of a shell-and-tube heat exchanger using the univariate marginal distribution algorithm <i>Oscar D. Lara Montaña, Fernando I. Gómez-Castro, Claudia Gutierrez- Antonio</i>	43
9. Synthesis of Microgels with Minimal Final Concentration of Initiator <i>Falco Jung, Johannes M. M. Faust, Adel Mhamdi, Andrij Pich, Alexander Mitsos</i>	51
10. Novel Dual Reactive Distillation Process for Eco-efficient Lactic Acid Recovery and Purification from Fermentation Broth <i>Isabel Pazmiño Mayorga, A.A. Kiss, M. Jobson</i>	57

11. Exergy Analysis of Vacuum Distillation Unit <i>Sena Kurban, Gizem Kuşoğlu Kaya, Serdar Yaman</i>	63
12. Computer-Aided Solvent Design Integrated with a Machine Learning-based Atom Contribution Method <i>Qilei Liu, Lei Zhang, Jian Du, Rafiqul Gani</i>	69
13. A versatile modelling system for integrated chemical product design problems <i>Shiyang Chai, Lei Zhang, Jian Du, Anjan K Tula, Rafiqul Gani, Mario R Eden</i>	75
14. An integrated system of multi effect distillation and wind power system - Evaluation of total energy saving <i>O.M.A. Al-hotmani, Mudhar. A. Al-Obaidi, Y. M. John, Raj. Patel, Iqbal M. Mujtaba</i>	81
15. Modelling and Performance evaluation of the air heated and water heated Humidification-Dehumidification desalination process using solar thermal energy <i>Damson Kaunga, Raj Patel, Iqbal M Mujtaba</i>	87
16. Enhancement of energy saving of reverse osmosis system of Arab Potash Company via a wind energy system <i>Alanood A. Alsarayreh, Mudhar. A. Al-Obaidi, Raj. Patel, Iqbal M. Mujtaba</i>	95
17. Multi-objective optimization for the incorporation of safety and reliability considerations in process design <i>Andrea P. Ortiz-Espinoza, Yixin Ye, Ignacio E. Grossmann, Arturo Jiménez-Gutiérrez</i>	101
18. Integrating Reliability and Uncertainty in Process Synthesis <i>Ying Chen, Yixin Ye, Ignacio E. Grossmann, Bingzhen Chen</i>	107
19. Optimization of Graded Bed Reactors for Syngas to Olefin (STO) Processes <i>Can Ekici, Lorenz T. Biegler, Christopher Ho, Joseph F. DeWilde, Dylan Kipp, Paul M. Witt</i>	115
20. Gas Lift Optimization for Optimum Oil Production from a Well Platform <i>Rahul Sudhanshu, Nitin Dutt Chaturvedi</i>	123
21. Techno-economic evaluation of sorption enhanced steam gasification of PKS system for syngas using CaO for CO₂ capture <i>Muhammad Shahbaz, Ahmed AlNouss, Suzana Yusup, Gordon Mckay, Tareq-Al Ansari</i>	129
22. A Robust Optimization Approach for Hydrogen Allocation Network with Parametric Uncertainties <i>Gaurav Shukla, Nitin Dutt Chaturvedi</i>	135

23. Process Design and Techno-economic analysis of Hydrogen Production using Green Ammonia Imported from Australia- A Korea Case Study	
<i>Malik Sajawal Akhtar, Jay Liu</i>	141
24. Life Cycle Assessment of Hydrogen Production from Imported Green Ammonia: A Korea Case Study	
<i>Malik Sajawal Akhtar, Jay Liu</i>	147
25. Optimal Design of Distillation Columns Using a Combined Optimisation Approach	
<i>Dian Ning Chia, Fanyi Duanmu, Eva Sorensen</i>	153
26. Process and product design for the simultaneous synthesis of xylitol and sorbitol from biomass	
<i>Guillermo Galán, Mariano Martín, Ignacio E. Grossmann</i>	159
27. An approach for simultaneous computer-aided solvent design and process design for CO₂ chemical absorption process	
<i>Ye Seol Lee, Amparo Galindo, George Jackson, Claire S. Adjiman</i>	167
28. Simulation-based Derivative-free Optimization for Hybrid Separation Design	
<i>Shuang Xu, Selen Cremaschi, Mario R. Eden, Anjan K. Tula</i>	173
29. Material Screening for Thermochemical Energy Storage in Solar Power Systems	
<i>Ishan Baja, Xinyue Peng, Christos T. Maravelias</i>	179
30. Network design optimization of waste management systems: the case of plastics	
<i>Rafael Castro-Amoedo, Alina Dahmen, Ana Barbosa-Povoa, Francois Maréchal</i>	185
31. Rational Design of Ionic Liquid Phase-Change Material for Efficient Thermal Energy Storage	
<i>Teng Zhou, Huaiwei Shi, Kai Sundmacher</i>	191
32. Tailor-made solvents by integrated design of molecules and CO₂ absorption processes	
<i>Johannes Schilling, Madlen Hopp, Joachim Gross, André Bardow</i>	197
33. Small-scale GTL Applications with Heat Integration in Reforming and Fischer-Tropsch Stages	
<i>Lígia B. Dias, Frederico S. Coelho, Fernando G. Martins, José Carlos B. Lopes, Mariana G. Domingos</i>	203
34. Automated Process Synthesis Using Reinforcement Learning	
<i>Quirin Göttl, Dominik Grimm, Jakob Burger</i>	209

35. **Operational Analysis of a Proton-Conducting Solid Oxide Electrolysis Cell for Synthetic Fuel Production**
Jinjutha Bhichaiphab, Dang Saebea, Amornchai Arpornwichanop, Yaneeporn Patcharavorachot 215
36. **Octane Optimization with a Combined Machine Learning and Optimization Approach**
Ahmet Can Serfidan, Metin Türkay 221
37. **A Platform of Machine Learning-Based Next-Generation Property Estimation Methods for CAMD**
Abdulelah S. Alshehri, Anjan K. Tula, Lei Zhang, Rafiqul Gani, Fengqi You 227
38. **Machine Learning Analysis of the Feed Water Parameters Affecting Reverse Osmosis Membrane Operation**
Çağla Odabaşı, Pelin Döloğlu, Fatih Gülmez, Gizem Kuşoğlu, Ömer Çağlar 235
39. **Novel technologies for low-quality natural gas purification**
Giorgia De Guido, Matteo Gilardi, Laura A. Pellegrini 241
40. **The Influence of Cuttings Polydispersity on Wellbore Cleaning Operations using the Kinetic Theory of Granular Flow and the Dense Discrete Phase Model**
Emmanuel I. Epelle, Dimitrios I. Gerogiorgis 247
41. **A Digital Twin for Process Optimisation in Pharmaceutical Manufacturing**
Dimitrios I. Gerogiorgis, Daniel Castro-Rodriguez 253
42. **Development of Hybrid RTO approaches in the absence of a rigorous dynamic model by the use of Hammerstein model structures**
Pedro de A. Delou, Rodrigo Curvelo, Maurício B. de Souza Jr., Argimiro R. Secchi 259
43. **Study of alternative configurations for methanol purification**
Stefania Moioli, Laura A. Pellegrini 267
44. **Power-to-OME1 via Direct Oxidation of Methanol: Process Design and Global Flowsheet Optimization**
Dominik Bongartz, Jannik Burre, Anita L. Ziegler, Alexander Mitsos 273
45. **A Machine Learning Approach for Device Design from Materials and Operation Data**
Luis A. Briceno-Mena, Gokul Venugopalan, Christopher C. Arges, Jose A. Romagnoli 279
46. **A Computer-Aided Platform for Simultaneous Process Synthesis and Intensification**
Mohammed Sadaf Monjur, Salih Emre Demirel, Jianping Li, M. M. Faruque Hasan 287

47. **Studying the effect of solvent properties in treatment design within CO₂ Integration Networks**
Dhabia Al-Mohannadi, Sabla Y. Alnouri 295
48. **A Multi-generation system in Sabkha-Tah operating with nanofluids and a novel RO unit.**
Yasser M. Abdellatif, Eric C. Okonkwo Yusuf Bicer Tareq AlAnsari 301
49. **A POD-ROM Methodology for Optimal Structuring of a Non-isothermal Fixed-bed Reactor for Process Integration**
Katarzyna Bizon, Gaetano Continillo, Enrico A. Cuttillo, Alfonso D'Onofrio 307
50. **Effect of Pseudo-Homogeneous Concentration Based Kinetics on Hybrid Reactive Distillation Columns for Selectivity Engineering**
Deepshikha Singh, Rajdeep Mukherjee, Harinder Singh, Ankur Gaur, Shabih Ul Hasan 313
51. **An MILP model of post-combustion carbon capture based on detailed process simulation**
Lukas Weimann, Guus Dubbink, Louis van der Ham, Gert Jan Kramer, and Matteo Gazzani 319
52. **Numerical study of fertilizer granules dynamics within rotary drum granulator**
Safae Elmisaoui, Lhachmi Khamar, Saad Benjelloun, Mohamed Khamar, Jean-Michel Ghidaglia 327
53. **Application of PharmaPy in the digital design of the manufacturing process of an active pharmaceutical ingredient**
Daniel Casas-Orozco, Daniel Laky, Vivian Wang, Mesfin Abdi, Xin Feng, Erin Wood, Gintaras V. Reklaitis, Carl Laird, Zoltan K. Nagy 333
54. **Computer-Aided Screening of Deep Eutectic Solvent Systems for the Associative Extraction of α -Tocopherol from Deodorizer Distillate**
Zhen Song, Teng Zhou, Zhiwen Qi, Kai Sundmacher 341
55. **Investigating critical design criteria for photo-electrochemical reactors**
Mohammed Al-Breiki, Yusuf Bicer 347
56. **Advanced exergoeconomic analysis of a double effect evaporation process in an instant coffee plant**
Tinoco-Cacedo D.L., Feijoó-Villa E., Calle-Murillo J., Lozano-Medina A., Blanco-Marigorta A.M. 353
57. **Energy-efficient membrane cascades for industrial separations**
Jose Adrian Chavez Velasco, Zewei Chen, Radhakrishna Tumbalam Gooty, Mohit Tawarmalani and Rakesh Agrawal 359

58.	Techno-economic evaluation of Carbfix technology for carbon storage in the US <i>María Paz Etcheverry, Haoshui Yu, Emre Gençer</i>	365
59.	Computational Exploration of Adsorption Enhanced Haber-Bosch using MOFs and Ionic Liquid/MOFs <i>Amro M. O. Mohamed, Yusuf Bicer</i>	373
60.	Optimization of a Continuous Fluidized Bed Process for the Separation of Enantiomers by Preferential Crystallization <i>Nadiia Huskova, Michael Mangold, Andreas Seidel-Morgenstern</i>	381
61.	Methanol and power production from waste tyres: a process synthesis approach <i>Athi-enkosi Mavukwana, Ephraim Llane, James Fox, Baraka Celestin Sempuga</i>	387
62.	Analysing the robustness of multi-stage bioseparations to measurement errors <i>Robert Milton, Emma Chandler, Solomon F. Brown</i>	393
63.	Improvements in Methyl Ethyl Ketone Production Through Intensified Processes <i>Eduardo Sanchez-Ramirez, Heriberto Alcocer-Garcia, Ana Gabriela Romero-Garcia, Gabriel Contreras-Zarazua, Juan Gabriel Segovia-Hernandez</i>	399
64.	Flexibility Assessment of Spirits Distillation Processes: Focus on the Armagnac Distillation <i>Alessandro Di Pretoro, Michel Meyer, Marie-Claude Segur, Xavier Joulia</i>	407
DATA ANALYTICS, MODELING, OPTIMIZATION AND SIMULATION		
65.	OUTDOOR – An open-source superstructure construction and optimization tool <i>Philipp Kenkel, Timo Wassermann, Celina Rose, Edwin Zondervan</i>	413
66.	Probabilistic Modeling for Optimization of Bioreactors using Reinforcement Learning with Active Inference <i>Ernesto C. Martínez, Jong Woo Kim, Tilman Barz, Mariano N. Cruz Bournazou</i>	419
67.	SPH Simulation of the Rising of a Kerosene Bubble in a Water Column: Effect of the Injection Condition <i>M. Robles-Santacruz, C. E. Alvarado-Rodríguez, F.I. Gómez-Castro, A. R. Uribe-Ramírez</i>	425
68.	Novel method for properties prediction of pure organic compounds using machine learning <i>Nattasinee Chorbngam, Rathachai Chawuthai, Amata Anantpinijwatna</i>	431
69.	Self-learning surrogate models in superstructure optimization <i>Julia Granacher, Ivan Daniel Kantor, Michel Lopez, Francois Maréchal</i>	439

70.	Data-driven Modeling of an Industrial Ethylene Oxide Plant: Superstructure-based Optimal Design for Artificial Neural Networks	
	<i>Hasan Sildir, Sahin Sarrafi, Erdal Aydin</i>	445
71.	Novel Tool for Selecting Surrogate Modeling Techniques for Surface Approximation	
	<i>Bianca Williams, Selen Cremaschi</i>	451
72.	ProREFD: Tool for Automated Computer-Aided Refrigerant Design, Analysis, and Verification	
	<i>Kornkanok Udomwong, Arisa Robin, Nichakorn Kuprasertwong, Orakotch Padungwatanaroj, Anjan Kumar Tula, Lingyu Zhu, Liyang Zhou, Binhui Wange, Shuhua Wang, Rafiqul Gani</i>	457
73.	Event driven analysis to enhance model calibration of experiments with high offline sampling rates	
	<i>M. Adnan JOUNED, Julian KAGER, Christoph HERWIG, Tilman BARZ</i>	463
74.	Process System Engineering Tool Integration in the Context of Industry 4.0	
	<i>Manuel Rodríguez Hernández, Ismael Díaz Moreno</i>	469
75.	Benchmarking of Surrogate Models for the Conceptual Process Design of Biorefineries	
	<i>Nikolaus I. Vollmer, Resul Al, Gürkan Sin</i>	475
76.	Predicting the Estrogen Receptor Activity of Environmental Chemicals by Single-Cell Image Analysis and Data-driven Modeling	
	<i>Hari S. Ganesh, Burcu Beykal, Adam T. Szafran, Fabio Stossi, Lan Zhou, Michael A. Mancini, Efstratios N. Pistikopoulos</i>	481
77.	Data-driven prognostics for Lithium-ion battery health monitoring	
	<i>Sukanya G, Resmi Suresh, Raghunathan Rengaswamy</i>	487
78.	The Adaptive Radial Basis Method (ARBM): An application to the hydrodynamics of liquid-liquid dispersions	
	<i>Samer Alzyod</i>	493
79.	Process modeling and multi-criteria optimization of an industrial phosphoric acid wet-process	
	<i>Ilias Bouchkira, Abderrazak M. Latifi, Lhachmi Khamar, Saad Benjelloun</i>	499
80.	Towards Automated HAZOPs	
	<i>Calum Robinson, Solomon Brown, Joan Cordiner</i>	505
81.	Multi-objective optimization of co-processing of algae hydrothermal liquefaction oil and vacuum gas oil: a survey of algal oil co-processing ratio and gasoline selling price	
	<i>Shuai Zhang, Qingyu Lei, Le Wu, Yuqi Wang, Lan Zheng</i>	511

82. Modeling of a software for sizing a wastewater treatment plant <i>Anass Qoutbane, Btissam Khmajer, Essediya Cherkaoui, Mohamed Khamar, Abderrahman Nounah</i>	517
83. Joint Chance Constraint Approach based on Data-Driven Models for Optimization Under Uncertainty applied to the Williams-Otto Process <i>Byungjun You, Erik Esche, Joris Weigert, Jens-Uwe Repke</i>	523
84. CFD Simulations of High Efficiency Gas Cyclones: An Influence of Dustbin Geometry <i>Pitiwat Pechmanee, Apinan Namkanisorn, Santi Wattananusorn, Eakarach Bumrunghthaichaichan</i>	529
85. InvQMOM: A Simple Inversion Method that Works <i>Menwer Attarakih, Armin Fricke, Hans-Jörg Bart</i>	535
86. A Dual-Layer Attention-Based LSTM Network for Fed-batch Fermentation Process Modelling <i>Kai Liu, Jie Zhang</i>	541
87. Resilience and Survivability-aware Optimal Design and Operation of Interconnected Supply Chains <i>Spyridon D. Tsolas, M. M. Faruque Hasan</i>	549
88. A Hybrid Modeling Approach for Liquid Entrainment Fraction Predictions <i>Yushi Deng, Selen Cremaschi, Mario R. Eden, Carlos Avila, Haijing Gao, Ivan Mantilla</i>	555
89. Rethinking Balance Models Applied to Pfrs And Extracting New Insights <i>João Manzi</i>	561
90. Digital Twin Model Development for Chemical Plants Using Multiple Time-Steps Prediction Data-Driven Model and Rolling Training <i>Jia-Lin Kang, Somayeh Mirzaei, Yao-Chen Lee, Yao-Cheng Chuang, Marvin Frias, Cheng-Huang Chou, San-Jang Wang, David Shan Hill Wong, Shi-Shang Jang</i>	567
91. Parameter estimation and sensitivity analysis for a diesel hydro-processing model <i>Esin Iplik, Panagiotis Tsirikoglou, Ioanna Aslanidou, Konstantinos Kyprianidis</i>	573
92. Model Development of Amine Regeneration Process with Electrodialysis Reclamation Unit <i>Jonghun Lim, Jesung Lee, Hyungtae Cho, Junghwan Kim</i>	579
93. CO₂ methanation: Reactor modelling and parametric analysis <i>Erasmus Mancusi, Piero Bareschino, Annunziata Forgione, Claudio Tregambi, Francesco Pepe</i>	585

94. **An uncertainty-aware hybrid modelling approach using probabilistic machine learning**
Rasmus Fjordbak Nielsen, Nima Nazemzadeh, Martin Peter Andersson, Krist V. Gernaey, Seyed Soheil Mansouri 591
95. **Modelling and Dynamic Optimization of beer fermentation towards optimal flavor and operation**
Carina L. Gargalo, Alex Matesanz Salvadó, Ulrich Krühne, Krist V. Gernaey 599
96. **On the fitting of bathtub-shaped failure models to lifetime data for selective maintenance optimization**
Teemu J. Ikonen, Iiro Harjunkoski 605
97. **Sampling Space Reduction for Data-driven Modelling of Batch Distillation - Introducing Expert Process Knowledge through Operation Recipes**
Gerardo Brand-Rihm, Erik Esche, Jens-Uwe Repke 611
98. **On the acceleration of global optimization algorithms using a cutting plane decomposition and machine learning**
Asimina Marousi, Antonis Kokossis 617
99. **Towards a Digital Twin: A validated Digital Model of a Pilot Scale Bioreactor producing Green Fluorescent Protein (GFP)**
Ole Laustsen Lave, Carina L. Gargalo, Ryan Barton, Christoph Bayer, Isuru A. Udugama, Krist V. Gernaey 625
100. **Automated Box-Jenkins Methodology to Forecast the Prices of Crude Oil and Its Derivatives**
Ahmet Can Serfidan, Gurkan Ozkan, Metin Türkay 631
101. **Systematic Modelling of Transport Processes across Interfaces**
Robert Pujan, Heinz A. Preisig 637
102. **An identification approach to a reaction network for an ABE catalytic upgrade**
Elham Ketabchi, Tomas Ramirez Reina, Bogdan Dorneanu, Harvey Arellano-Garcia 643
103. **MOSKopt: A simulation-based data-driven digital twin optimizer with embedded uncertainty quantification**
Resul Al, Gürkan Sin 649
104. **Global Optimization of Mixed-Integer Polynomial Programs via Quadratic Reformulation**
Tanuj Karia, Claire S. Adjiman, Benoît Chachuat 655
105. **A data-based approach for the development of asynchronous and distributed optimization algorithms in complex engineering applications**
Ioannis Geroulis, Georgios Panayiotou, Antonis C. Kokossis 663

Preface

This book contains papers presented at the 31st European Symposium of Computer Aided Process Engineering (ESCAPE-31), held in Istanbul, Turkey, from June 6-9, 2021. The ESCAPE series started in 1992 at Elsinore, Denmark, on a strong foundation of 23 events of the European Federation of Chemical Engineers (EFCE) Working Party on Computer Aided Process Engineering (CAPE). The most recent symposia were organised in Eindhoven, The Netherlands 2019 (ESCAPE-29), and Milano, Italy 2020 (ESCAPE-30).

The ESCAPE series serves as a forum to bring together scientists, researchers, managers, engineers, and students from academia and industry, who are interested in CAPE and Process Systems Engineering (PSE). The scientific aim of the symposium is to present and review the latest developments in CAPE and/or PSE. This research area bridges fundamental chemical and biological sciences with various aspects of process and product engineering. The objective of ESCAPE-31 is to promote the use of a systems approach, highlighting the traditional CAPE-PSE topics as well as the emerging CAPE-PSE topics of current interest and future significance.

The main focus for ESCAPE-31 is on the methodical approaches in process systems engineering with emphasis on circular engineering economy, and sustainable product and/or process development. The papers at ESCAPE-31 are arranged in terms of the following themes: Process-product synthesis, design and integration; Methods, models and computational tools for PSE; Process control and operations; CAPE/PSE in energy/water/food nexus and sustainability; Process operations and supply chains; PSE in biological systems and processes; Education in CAPE/PSE & knowledge transfer.

A total of 320 contributed 6-pages papers are included in this book. All the papers have been reviewed and we thank the members of the international scientific committee for their evaluations, comments and recommendations. It was a very difficult task since we started with more than 452 submitted abstracts. The selection process involved review of abstracts, review of manuscripts and final selection of the revised manuscript.

We hope that this book will serve as a valuable reference document to the scientific and industrial community and that it will contribute to the progress in computer aided process and product engineering.

Explanatory and Predictive Analysis of Naphtha Splitter Products

Ahmet Can Serfidan,^{a,b} Metin Türkay,^b

^a*TUPRAS, Address, Petrol Cd. No:25 D:No:25, Turkey*

^b*Koc University, Rumelifeneri, Sariyer Rumeli Feneri Yolu*

Abstract

Refinery operations are always prone to optimization, and due to the increasingly adverse effects of COVID-19 on energy sectors, its importance increased significantly. This work aims to predict the naphtha column KPI parameters with high accuracy so that operators make corrective actions efficiently. Although linear regression provides acceptable results for prediction, this is not the case for top and bottom product C7 and C6 prediction in the central Naphtha Splitter column. First, we did gather all the available data to overcome this problem, which can affect the top and bottom products. Including upstream units that feed the column. Instead of one common technique (linear regression), we used five additional machine learning methods: Adaboost, support vectors, kNN, random forest, XGboosting. Since there are many measurements, however, very few samples need to reduce dimensions before modeling. We used BorutaSharp to select the essential features. We also use classification machine learning methods to categorize bottom products since there is no need to predict the value instead of whether the value is higher or lower than a constant. Overall, we achieved 30% higher accuracy than the traditional ways for the top product, and we reached to predict C6 content in the bottom with higher accuracy than 80%. Xgboost provides the best regression model, and stochastic gradient boosting yields the best classification model. After our implementation, the energy consumption is decreased significantly, and 100k\$/month is saved since we can monitor top and bottom products simultaneously.

Keywords: naphtha splitter column, quality estimator, soft sensor.

1. Introduction

In the era of COVID-19, some of the most negatively affected sectors are petrochemical, refining, energy, etc., due to the most significant demand destruction events the world has seen. The refining companies experienced a sharp drop in margins and experienced substantial financial losses. This time optimization, whether it is minimizing the product giveaway, maximizing the energy utilities, becomes the most critical topic.

Naphtha Splitter (NS) columns are used to separate light naphtha from heavy naphtha. The naphtha splitter column's key performance indicator is the qualities of the bottom and top products. Namely, the top product is light naphtha, and its quality indicator is hydrocarbon content, which is measured by ASTM D5134 method. This method provides with C1%, C2%, C3%, C4%, C5%, C6%, C7%, C7+%, where, for example, C4% means percent of C4 hydrocarbons, mainly 1,3-butadiene, 2-methylpropene, butanes and butanes. The most important measure is the C7% content in the top product since beyond a threshold value of C7%, profit decreases drastically. The bottom product is heavy

naphtha, and its quality indicator again hydrocarbon content. The most important quality parameter is the C6% content since a higher C6 fraction will strongly affect the downstream of the naphtha splitter column (catalytic cracking units), resulting in benzene more than regulation limits. The process operators control the unit by monitoring C6 and C7 compositions in the bottom and top products. However, the samples are only taken twice a week, so an operator's general tendency is to keep the column condition the same as before. And this yields to stay in the over-safe zone for the unit. In other words, the product gives away. This work aims to predict the KPI parameters with high accuracy to make corrective actions efficiently.

2. Methodology

Optimization of NS depends on the refinery configuration and operating characteristics of refineries. Despite the differences, the main aim is to find the best conditions to minimize product losses. There are many obstacles in optimizing primary NS columns. One of them is the uncertainty in-feed content. They generally have a very complex feed network. Some of the feed flows are usually unknown since the flow meter is placed before the pipeline junction. For example, the bottom product of the debutanizer in the hydrocracker unit can go either LSRN tank or unifier feed (cannot feed them simultaneously). Although feed flow rate is known, there is no direct data that indicates which unit is feed by that flow.

Also, there is no measurement for the tank, and the main NS operation cannot know which type of feed they are operating until they see the effect (temperature, liquid level changes, etc.)

Other than feed conditions, there are disturbances to columns like weather conditions. For example, in the summer, the operation conditions have to change to keep the pressure stable. Based on the disturbances above, even if there is no other change in the main NS column, its product quality will change significantly. You will see the last two years' C7 and C6 results of the main NS column below.

Figure 1 Bottom C6 Content

Figure 2 Top C7 Content

Here are our aims: (i) There is a hard process limit on C6, 1. As long as C6 content does not exceed this limit, there is no problem. Otherwise, the subsequent unit will have a benzene problem. This will yield to the environmental problem, which is unacceptable. (ii) There is no limit on C7. However, since it is impure to the isomerization reactor, the aim is to send it low as much as possible. Otherwise, the temperature needed to compensate for the impurity will increase, yielding enormous economic loss. As seen in the above graph, operations are carried out such that C7 content is 2.0 on average. As we decrease the C6 at the bottom, we will increase the C7 on top and vice versa. Since the acceptable limit is 1 for C6, the optimum condition for main NS: (i) Lower the energy given the column as long as C6 does not exceed the threshold, (ii) Keep C7 minimum as much as possible. Currently, there is no inferential for C6, and C7 inferential mean absolute error is around 1.5

Since there is no way to exceed the C6 limit, they try to give more energy columns more than necessary. As you see, there is almost no exceeding limit but also many zeros. This is mainly because they want to stay in a safe zone as much as they can.

In this project, I aim to predict C6 and C7 with great accuracy so that the main NS column will be operated optimally. And as previously discussed, it is needed to infer the tank's content. However, this requires the following preparations: (i) LSRN T95 inferential of each unit sent to the tank or main NS column (ii) Heuristic solution for which units sent their LSRN to the tank.

Five different units can feed the main NS column. Each has different operating conditions, different lsrn specifications, and different constraints. But all of them are binary distillation columns. To infer LSRN, I took those as possible candidates: input flow rates, input temperature, all column temperatures, all column pressures, tray temperature controller, steam feed flows, reflux flow rates, bottom flow rate, distillate flow rate. Also, I generated these features: reflux overfeed, temperature differences between bottom and top of the columns, distillate over the bottom. We were able to get 200-400 rows of data for each unit.

I used BarutoSharp to select the most important features. It is a wrapper feature selection method that uses both the Boruta feature selection algorithm with Shapley values. It successfully reduces the column number from 30 to 5-10[1]

After that, I used linear regression to predict LSRN T95. However, I want to keep minimum columns while minimizing the mean. Here is the algorithm for selecting the best features to minimize error with the minimum number of features.

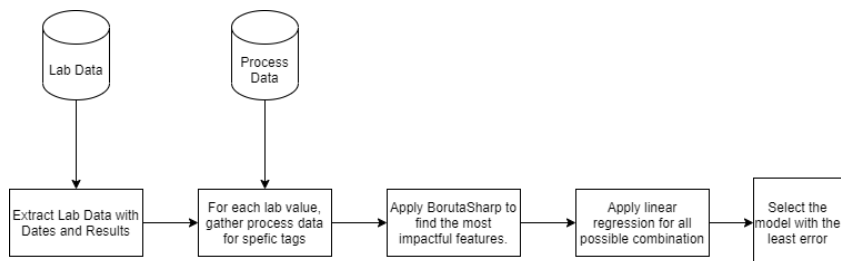

Figure 3 The algorithm for feed content prediction

The missing or misleading measurements are no surprise in refineries. In this optimization study, I have to also deal with this problem. Data by itself does not indicate whether the

flow is sent to the tank or some other unit. Here is the more detailed version of the feed network and all possible injections:

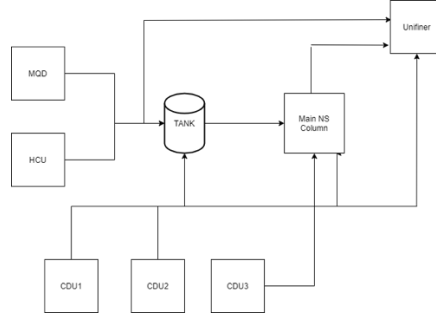

Figure 4 Feed Network

The heuristic optimization to find which feed goes to which unit is:

$$\begin{aligned} \text{minimize } F_{out} - (F_0 + \sum_{i=1}^n F_i * X_i) \\ X_i \in \{0,1\} \end{aligned}$$

Where F 's flows and X 's are binary variables indicating whether the flow is present or not.

After finding heuristic values for those unknowns and this data preparation process, we finally have the most important parameters that can affect top C7 content and bottom C6 content. Namely, the feed content and column operations. There might be other factors that can affect the target, like weather conditions. However, those disturbances will also change the column measurements. Thereby, even if we do not involve outlet temperature directly, we will know its change by one of the temperature/pressure measurements in the top part of the column.

To predict C7 and C6 content, I follow a very similar approach to the above methodology. But this time, in addition to linear regression [2], I make use of other powerful machine learning algorithms, specifically: Random Forest [3], AdaBoost, XGBoost [4], KNN, SVR[5]. Again, BorutaSharp is used to select the most important features, and then for each algorithm, I give all the important elements to the machine learning algorithm. Finally, this time, instead of trying all possible combinations of features, I tried different range of hyperparameters.

For the bottom content prediction, we followed a different approach. The main aim is not to exceed the process high limit. Since we will decrease the energy input to column bottom product quality impurity will get higher. We keep lowering the reboiler feed until we are close to the limit. So, instead of a regression problem, this becomes a classification one. To predict whether it is higher than the limit or lower, we used the following algorithms: Logistic Regression, kNN, Random Forest, SVM.

3. Results and Discussion

All of the algorithms are applied using python programming language between 2018 and 2020 of data gathered and implemented by our algorithms. The number of rows

As shown from the above table, all modeling algorithms yield almost the same result. However, explaining and updating Linear Regression is more accessible than the others in refinery conditions. Since lab results are taken daily, we can update the bias term if there is a significant process change.

And for the C6 prediction:

Table 3 C6 Classification Performance

Model	Accuracy
LogisticRegression	0.67
KNN	0.75
RF	0.78
SVM	0.80

4. Conclusions

Optimization in refinery has become one of the most important topics, and its importance is rapidly increasing due to the adverse effect of COVID-19 on the energy sector. We achieved this work to optimize column conditions by predicting the top and bottom product qualities with machine learning techniques. The winner algorithm in our case is Xgboost. And for C6 classification, it is SVM. Predicting the top and bottom content simultaneously gave us the leverage of optimizing the column operation without exceeding the process limits. In the previous case, since the column operations are at the safe-zone limits, we achieved 100k\$/month by lowering the energy cost.

Abstract

Mexico is a country with a wide agricultural production, which implies a high production of lignocellulosic residues. Those residues are potential raw materials to produce biofuels as bioethanol and biobutanol, similarly, such residues can be used to produce high value added bioproducts, as furfural, levulinic acid, among others. The use of biomass to produce only biofuels is not economically feasible; therefore, the use of a fraction of biomass to obtain bioproducts with high-added value may enhance the economy in the biofuels industry. To ensure obtaining as much profit as possible, a proper supply chain must be determined. Nevertheless, when considering biomass utilisation, the use of water must be taken into account, since these processes involve a large amount of that resource. Moreover, the availability of water is uncertain, thus this issue must be included in the decision-making process for such supply chain. For this reason, in this work a mathematical model representing the supply chain of the production of biofuels/bioproducts is proposed, considering economic and water footprint aspects. The model is relaxed to a MILP equivalent and solved using the software GAMS, aiming to the maximization of the profit and minimizing the water footprint, while satisfying as much as possible of the gasoline demand in the country. The water impact is measured through the ratio between the amount of water required by the process and the amount of water available at the plant location. Pareto-optimal solutions were obtained using the ϵ -constraint method. According to the results obtained, the maximum profit is 572,360.7 thousand dollars per year, with a water footprint of 0.584. For that case, there are two plants: Guanajuato and Queretaro; which produce levulinic acid and bioethanol. On the other hand, the minimum for water footprint is 0.021. For this case, a single facility is located in Veracruz, where levulinic acid and bioethanol are produced.

Keywords: optimization, water footprint, supply chain, biofuels.

1. Introduction

The use of fossil fuels as energy source has had an enormous cost for humanity and the environment, from air and water pollution to global warming. That is a reason to resort to the concept of biofuels, which are obtained from renewable biomass (Dermibas, 2017) and are expected to show lower greenhouse gas emissions than fossil fuels. In Mexico, there is a high potential for the production of biofuels, mainly from residues of corn, sugar cane, sorghum, wheat and barley. More than 50% of the waste is used for soil protection, 27% is fed to livestock and 20% is burned (Damián-Huato et al., 2013). Therefore, there is a major interest in evaluating the energy potential of waste that has low food quality, which is mostly burned in the field. Examples of biofuels are bioethanol, which can be mixed up to 10% by volume with gasoline (Costagliola et al., 2016), and biobutanol, which can be used in blends of up to 16% by volume (Zhang et al., 2016). Industrial biofuel production is not economically competitive. Therefore, in addition to the production of biofuels, the generation of high value-added products is necessary to improve the economic potential of the biomass-based industry. Among the many potential high value-added products, levulinic acid can be mentioned, which is a great platform for a variety of products such as levulinate esters, etcetera (Pileidis and Titirici, 2016). Another product with high added value is furfural, which is a platform for other products of industrial importance, such as furfuryl alcohol, tetrahydrofuran, etcetera (Bhogeswararao and Srinivas, 2015). Among the different biofuels and bioproducts that can be obtained from lignocellulose biomass, a given combination of products should have the highest profitability, using the greatest amount of residues possible and satisfying part or all of the demand. Similarly, it is important to note that the production of biofuels requires a large amount of water, while the country has problems with water supply (Godínez Madrigal et al., 2018). Within the supply chains analyzed in the country, none of them includes the water aspect or high value-added products as potential derivatives from biomass (Rendon-Sagardi et al., 2014; Santibañez-Aguilar et al., 2014). Similarly, in the case of the work presented by Espinoza-Vázquez et al. (2020), only the profit was considered as objective function, leaving out a very important aspect in the biorefinery industry such as water. For this reason, this work proposes the optimization of the supply chain for the production of biofuels and high value-added products from lignocellulosic material, taking into account the economic and water-use aspects.

2. Case Study

The case study in this work is similar to the one presented in the previous report by Espinoza-Vázquez et al. (2020). The availability of agricultural residues in Mexico is determined for four main crops: corn, sorghum, wheat and barley. Data for the distribution of such crops in all the country, and their contribution to the production of lignocellulosic residues, has been collected from the Service of Agrifood and Fisheries Information (SIAP, 2020). These raw materials are proposed to be used for the production of bioethanol and/or biobutanol, as biofuel alternatives, and levulinic acid and furfural as high-value added products. For the potential location of the facilities, the states with the highest industrial infrastructure have been selected. Finally, the production of each potential product is constrained by its national demand.

3. Mathematical Model

This model is based on the use of four raw materials (i) from the 32 states in Mexico (j). Raw materials from any state are transported to one of the five states with the highest industrial infrastructure (k), where the facilities will be located. On each facility, four products (m) can be obtained: bioethanol, biobutanol, levulinic acid and furfural. Finally, the products can be distributed to ten markets (n), selected among the 32 states because they are the locations with higher demand for gasoline. The mathematical model used in this work is as follows: the total demand of a product m in the market n , $TD(m,n)$, in mass units, is given by:

$$TD(m,n) = PD(m,n) \cdot \rho(m), \forall m, n \quad (1)$$

Where $PD(m,n)$ is the volumetric demand of the product m in the market n , and $\rho(m)$ is the density of the product m . The mass production of each product m in the k installation for each n market, $FP(m,k,n)$, should not be greater than the total demand for that product in that market:

$$\sum_k FP(m,k,n) \leq TD(m,n), \forall m, n \quad (2)$$

The amount of raw material i obtained from the source j that enters the biorefinery k to produce m , $RMAF(i,j,k,m)$, cannot be greater than the availability of raw material i in the state j , $RMA(i,j)$. This is represented as follows:

$$\sum_k \sum_m RMAF(i,j,k,m) \leq RMA(i,j), \forall i, j \quad (3)$$

The cost of transporting the biomass i from the source j to the plant k , $TSP(i,j,k)$, is represented as:

$$TSP(i,j,k) = \sum_m RMAF(i,j,k,m) \cdot D_1(i,j,k) \cdot TCSB, \forall i, j, k \quad (4)$$

$TCSB$ is the cost of transporting lignocellulosic biomass, while $D_1(i,j,k)$ is the distance of biomass i from state j to biorefinery k . In this work, $TCSB$ is taken as 0.00508 kUSD/km·kt, according to the data reported for the transport of solid biomass (OAS, 1999). The cost of transporting the product m from the installation to the market n , $CTP(m,k,n)$, is given by:

$$CTP(m,k,n) = FP(m,k,n) \cdot D_2(k,n) \cdot TCLP, \forall m, k, n \quad (5)$$

where $D_2(k,n)$ is the distance from the facility k to the market n , and $TCLP$ is the transport cost of the liquid product. In this work, $TCLP$ is taken as 0.00671 kUSD/km·kt, according to the data reported for the transportation of liquid products (OAS, 1999). A logical variable $Y(k)$ is assigned to each facility; if the variable $Y(k)$ is true, then the biorefinery must be built at location k . Similarly, a logical variable $S(m,k)$ is assigned to each product, indicating if it is produced or not. The disjunction is represented as follows:

$$\left[\begin{array}{l} Y(k) \\ TCP(k) = \sum_m \sum_n FP(m,k,n) \cdot CP(m) \\ TCRM(k) = \sum_m \sum_n \frac{FP(m,k,n)}{Yld(i,m)} \cdot RMUC(i) \\ TCL(k) = \sum_m \sum_n \frac{FP(m,k,n)}{\rho(m)} \cdot LS(m,k) \cdot LC \\ \left[\begin{array}{l} S(m,k) \\ \sum_n FP(m,k,n) = A \end{array} \right] \vee \left[\begin{array}{l} \neg S(m,k) \\ \sum_n FP(m,k,n) = 0 \end{array} \right] \end{array} \right] \vee \left[\begin{array}{l} \neg Y(k) \\ TCP(k) = 0 \\ TCRM(k) = 0 \\ TCL(k) = 0 \end{array} \right], \forall k \quad (6)$$

Where:

$$A = RMAF(i, j, k, m) \cdot Yld(i, m) \quad (7)$$

$TCP(k)$ is the total production cost of the biorefinery k , $CP(m)$ is the unit production cost for the product m , $TCRM(k)$ is the cost due to the raw material entering the facility k , $Yld(i, m)$ is the product yield obtained from the raw material i , $RMUC(i)$ is the unit cost of raw material i , $TCL(k)$ is the cost of land acquisition for installation k , $LS(m, k)$ is the required land area per liter of product, LC is the cost of land per square meter. In this work, $RMUC(i)$ has been taken as 87.5 kUSD/kt, which is an estimated selling price for agricultural residues for animal feed (Mercado Libre, 2020). LC is taken as 0.4048 kUSD/m² while $LS(m, k)$ is defined as 0.66 m²/L. The values of LC and $LS(m, k)$ are estimated from the production cost, surface and land reported for the “Francisco I. Madero” refinery, located in Ciudad Madero, Tamaulipas, Mexico (El Informador, 2019). The multi-objective optimization problem is represented as:

$$FOBJ = \min(-GN, AH) \quad (8)$$

Where the profit GN , is given by:

$$GN = \sum_m \sum_k \sum_n FP(m, k, n) \cdot SP(m) - \sum_k TCRM(k) - \sum_k TCP(k) - \sum_k TCL(k) - \sum_i \sum_j \sum_k TSP(i, j, k) - \sum_m \sum_k \sum_n CTP(m, k, n) \quad (9)$$

where $SP(m)$ is the selling price of the product m . While the water footprint AH is given by:

$$AH = \sum_m \sum_k \frac{FP(m, k, n) \cdot AW(m)}{WAP(k)} \quad (10)$$

Where $WAP(k)$ is the amount of water available for industrial processes at the facility k (Comisión Nacional del Agua, 2018). This value was obtained from the amount of water destined for industrial use in each state. On the other hand, the parameter $AW(m)$ is the amount of water required to process the product m . The minimal production of bioethanol is fixed as 10%, forced to be satisfied. The disjunctions represented by equation 6 are relaxed using the Big-M approach (TresPalacios and Grossmann, 2015) and the model was coded in the GAMS software. The resulting MILP problem consists of 887 equalities and 456 inequalities. The model has been optimized with the solver BARON, in a HP computer with a Inter Core i5-8300H CPU, 12.00 GB of RAM.

4. Results

Table 1. Limits of objective functions.

Objective	Profit	Water Footprint
Max GN	572,360.7	0.58
Min AH	0	0.02

The two previously established objectives were taken into account, generating the Pareto fronts for their analysis, forcing the code to satisfy 10% of the bioethanol demand. As a first step, the limits of the objective functions were established through their individual solution, as shown in the Table 1. Subsequently, the ϵ -constraint method is used, generating the Pareto front with about 50 points with the Hammersley technique for a

complete visualization of the data (Fu and Diwekar, 2004). It is important to mention that each point of the Pareto front-end involved 2 minutes of computing time, for a total of 100 minutes for the entire Pareto front.

Analyzing the results shown in the Figure 1, it is observed that minimizing the water footprint completely comes at the expense of a drop in supply chain profitability. While increasing the profit in very small fractions, it leads to an increase in the water footprint. Therefore, it is observed that the objective functions are competing, since the benefit of an objective function, compromises the other. It is important to mention, that the minimum water footprint is not shown, because the corresponding profit is 0, since only bioethanol is produced, and the other of the graph tend

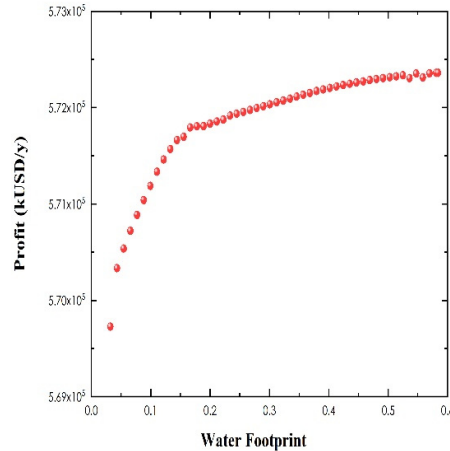

Figure 1. Pareto front: Profit Vs. Water Footprint.

to be lost due to the scale used. On the other hand, it can be seen that after the water footprint reaches a value of 0.15, the slope on the Pareto curve decreases, reducing the growing rate of the profit as the water footprint increases. Thus, a higher profit of the supply chain could be achieved if there were no restrictions on the use of water. It can be observed that the profitability tends to stabilize between $5.71 \cdot 10^5$ and $5.73 \cdot 10^5$, satisfying the required percentage of bioethanol demand and producing levulinic acid, without considerably increasing the water footprint. In terms of the supply chain, having the maximum profit, it is suggested the existence of a plant in Guanajuato, which produces bioethanol and levulinic acid, as well as a second facility located in Queretaro to produce levulinic acid. These plants fully satisfy the demand for the high value-added product and the 10% bioethanol restriction. This amount of bioethanol is only distributed to the same state where the plants are located, that is, Guanajuato and Queretaro. Finally, a greater quantity of corn waste from Aguascalientes and Jalisco is used, due to its high availability and proximity to the plants. On the other hand, the middle point, which satisfies both aspects, raises the existence of the four facilities, except Baja California. All four facilities produce bioethanol, while only Coahuila, Guanajuato and Veracruz produce levulinic acid, satisfying all the demand for the acid. As there are more plants, the amount of water available has lower impact, since as the production is distributed, it is not used in an excessive quantity. Similarly, there is a more specific distribution to the markets, for example, bioethanol produced by Coahuila goes to Nuevo Leon, while the product from Veracruz is sent the market in Puebla, and so on. This is due to the proximity of the plants to the market. In terms of the use of raw material, corn is still the most used waste, in this case obtained from Coahuila, Durango and Jalisco, distributed to the closest facilities.

5. Conclusions

A mathematical model has been developed to determine the optimal supply chain in terms of profit and water footprint for the use of lignocellulosic biomass to potentially obtain a

variety of renewable products in Mexico. This study concludes that solutions can be found that satisfy the economic and environmental aspect, producing bioethanol and levulinic acid from agricultural residues. Moreover, the facilities are located on states where the production of these biofuels and high value-added products do not have a negative impact on water use. This analysis gives us the opportunity to include more objectives within the supply chains, such as environmental and social aspects, all with the purpose of having a sustainable proposal in every aspect.

Abstract

Mass and heat integration are important to achieving economically and environmentally sustainable processes through increased efficiency. Typically, heat and mass exchange networks are solved separately using process integration techniques such as pinch technology or formulating nonconvex mixed-integer nonlinear programming (MINLP) problems, which are challenging to solve. To simplify the MINLP, shortcut models are employed, which can result in under/overestimation of the real network, leading to suboptimal or infeasible designs. We introduce a new optimisation algorithm for combined heat and mass exchanger network synthesis (CHAMENS), including detailed design models. The method uses shortcut models in an MINLP to find network topology, followed by a nonlinear programming (NLP) suboptimisation. The NLP allows non-isothermal and non-isocompositional mixing, uses detailed unit models of packed columns based on orthogonal collocation on finite elements (OCFE), and detailed shell and tube heat exchanger designs. We incorporate a differential-algebraic equation (DAE) based shell and tube heat exchanger design model via surrogates in a trust region filter (TRF) framework, guaranteeing optimal solutions for the detailed exchanger models are found by the surrogate models. We demonstrate the proposed approach on a case study, showcasing its performance and the need to incorporate detailed unit models in topology optimisation to find practical optimal designs.

Keywords: heat exchanger networks, mass exchanger networks, optimisation, mixed-integer nonlinear programming, process integration.

1. Introduction

Mass and heat integration increase process efficiency by reducing external heating and cooling utilities and mass separating agents (MSAs), thus maximising heat and mass recovery within the process. To solve the problem using mathematical programming techniques, mass exchanger networks (MENS) and heat exchanger networks (HENS) are commonly formulated as separate MINLPs using superstructure-based approaches such as the stage-wise superstructure (SWS) for HENS proposed by Yee and Grossmann (1990), or the approach of El-Halwagi and Manousiouthakis (1990a) for MENS. These require nonconvex MINLP formulations, which are difficult to solve, and therefore unit representations are simplified, with heat exchanger area and mass exchanger height used as sizing parameters and heat and mass transfer coefficients fixed. Despite abundant literature on solving these problems separately, mass and heat transfer coefficients are related to temperatures and velocities and therefore there is a need to integrate these

problems in combined heat and mass exchanger networks (CHAMENs). This is especially important in gas-liquid absorption, where there are benefits in operating absorption at low temperature and MSA regeneration at higher temperatures.

Srinivas and El-Halwagi (1994) formulated CHAMENs problems for the first time, using a two-step procedure, where an MINLP is first used to obtain the MEN with lowest MSA costs, followed by a HEN synthesis step. Liu et al. (2015) also solved the two networks separately using the SWS MINLP formulation to solve for network topologies before formulating an NLP to combine the models and optimise interactions between them. Recently, Kim et al. (2020) developed combined model for solving large MINLPs with MENs, HENs, and a newly developed regeneration exchanger network (REN), which incorporates different regeneration options. All these approaches, however, only use simplified representations for the unit operations and design models.

In MENS, without accounting for detailed aspects of the unit designs, the simplified formulations may result in sub-optimal or practically infeasible network designs with flooding, low mass transfer coefficients or strange column features, such as implausible L/D ratios. Isafiade and Short (2016) incorporated additional details of packed column unit design into the MINLP, such as column diameter, mass transfer coefficients, velocities, and noticed vastly different designs; however, the MINLP was difficult to converge due to the increased nonconvexity of the formulation. Short et al. (2018) developed detailed packed column models based on discretisation of the differential equations by OCFE to formulate a DAE model that can be solved via NLP. These models solve reliably, allowing for consideration of optimal diameters, heights, packing size, etc, while considering practical aspects such as column flooding. The authors then incorporated these into the MEN SWS model via a two-step optimisation algorithm, based on the work of Short et al. (2016), by using correction factors to ensure convergence of the MINLP shortcut models to the solutions of the detailed designs.

Recently, Kazi et al. (2020a) developed a shell and tube heat exchanger design optimisation model that uses efficient enumeration to determine discrete decisions on baffles, number of shells, tube passes, fluid allocation, etc., followed by a detailed DAE model. The model solves quickly and makes fewer assumptions than those based on the log mean temperature difference (LMTD). These models were incorporated into HENS, allowing for designs to incorporate detailed exchangers, including pressure drops, multiple shells, etc. (Kazi et al., 2020b). More recently, Kazi et al. (2020c) developed a novel algorithm for including these models into HENS as surrogates via a TRF algorithm from Yoshio and Biegler (2020).

In this work, we propose a two-stage approach where, in the first stage, an MINLP superstructure-based optimisation is used with simplified, shortcut unit models to find topologies for the CHAMEN. Next, an NLP is formulated with detailed optimisation unit models for the packed bed absorption columns, based on OCFE (Short et al., 2018). These models are directly incorporated in the NLP. Detailed shell-and-tube heat exchanger design models, from Kazi et al. (2020a), are incorporated into the flowsheet via a TRF algorithm. The algorithm allows for optimisation of a detailed flowsheet with first-principles models, and with superstructure decisions decided via a simultaneous optimisation procedure. The method does not increase the complexity of traditional MINLP process integration models, while providing a method of incorporating detailed unit designs. The algorithm and its application to CHAMENs demonstrates the power of the approach, highlighting the need for detailed unit models in superstructure-based process synthesis, and proposes a potential framework for future process synthesis.

2. Modelling framework

2.1. Topology optimisation

We present a modelling framework for CHAMENS that begins with solving the MEN, HEN, and REN separately as MINLPs to obtain initialisations for the full problem. Note that these formulations are very similar to common SWS approaches mentioned earlier, with a REN model following similar formulation to Kim et al. (2021). Following this, the problems are integrated through linking variables, with temperatures and flowrates of MSAs, in order to solve the combined problem as a large MINLP. These models assume constant heat and mass transfer coefficients, isothermal and isocompositional mixing, and use shortcut formulations to represent units. The shortcut heat exchanger models use areas as costing variables for the heat exchangers, ignoring the number of shells and pressure drops associated with them. Similarly, for the packed bed mass exchangers, only height is considered as a capital costing variable, with diameters and their effects on potential flooding, capital cost and mass transfer coefficients, considered constant. By doing this, we can maintain the model formulation as mostly convex and reduce complexity for the large MINLP formulation, which is challenging to solve. Parameters, along with the assumptions above, are selected to ensure that the MINLP problem underestimates the objective function, thus ensuring that this can act as a lower bound to the overall minimisation problem. If a global solution is found to the MINLP problem, this is a rigorous lower bound. However, in practice this cannot be guaranteed due to the size and non-convexity of the formulation.

2.2. Detailed network optimisation

The topology obtained from the shortcut model MINLP is used to construct an NLP, consisting of 3 linked submodels, solved simultaneously, for the REN, MEN, and HEN. The MEN and REN are formulated using the NLP optimisation model proposed by Short et al. (2018), where each selected mass exchanger is solved as a DAE model of a packed column using OCFE. This formulation allows simultaneous optimisation of the column diameters, heights, and packing sizes, using Onda's correlation for mass transfer coefficients. In Short et al. (2018), the mass balances over each column were fixed to that of the solution from the MINLP, however in our formulation, we allow for inlet and outlet concentrations of lean and rich streams to be optimised, along with column designs, providing the NLP with significant freedom. Furthermore, the model allows for non-isocompositional mixing of split streams and temperature-dependent mass transfer coefficients, linked via the Henry's Law coefficient. The MEN and REN submodels are connected via the variable flowrates for the MSAs that are regenerated.

The HEN NLP consists of the energy balance equations from the MINLP, with fixed topology via the binary variables and non-isothermal mixing. Shell and tube heat exchanger design variables that affect the overall objective function, such as number of shells, pressure drops, and areas, are included in the model via reduced order models (ROMs). These ROMs are updated at each iteration of the TRF algorithm to ensure that they are accurate within a small trust region around the previous solution, obtained from the running the detailed discretised DAE model of Kazi et al. (2020a). This strategy allows us to ensure that the solutions for the ROMs are the same as those of the rigorous models obtained from the DAE model, while also guaranteeing that we are at a stationary point for both. For more details on the TRF strategy, see the work of Yoshio and Biegler (2020). The NLP is solved at each iteration of the TRF, including all NLP subproblems, with the HEN NLP linked to the MEN and REN NLPs via temperatures and flowrates of the lean streams in the MEN, which are also the flowrates of the rich streams in the REN.

2.3. Integer-cut algorithm and implementation

Once the NLP TRF algorithm terminates, the solution includes optimal flowrates of utilities and detailed designs of individual units. These designs include optimal pressure drops, tube and shell passes, areas, fluid allocation and tube lengths for the shell and tube heat exchangers, and the optimal packing size, column heights, diameters, velocities, and stream splits for the packed columns in the MEN and REN. Additionally, the optimal temperatures for mass exchange are obtained. This solution acts as an upper bound to the overall algorithm. Integer cuts can then be generated to exclude the previously obtained topology from future iterations of the MINLP, allowing other topologies to be evaluated. Once the lower bound exceeds the upper bound, the algorithm terminates, with the upper bound solution as optimal. A graphic depiction of the algorithm is shown in Figure 1. The full strategy is implemented in Python, using Pyomo (Hart et al., 2017), with NLP problems being solved with IPOPT 3.13.3 (Wächter and Biegler, 2006) and MINLP problems solved using BARON (Tawarmalani and Sahinidis, 2005). Note that due to the size and nonconvexity of the MINLP, on certain iterations it may be necessary to relax tolerances in BARON to find feasible topologies for subsequent iterations.

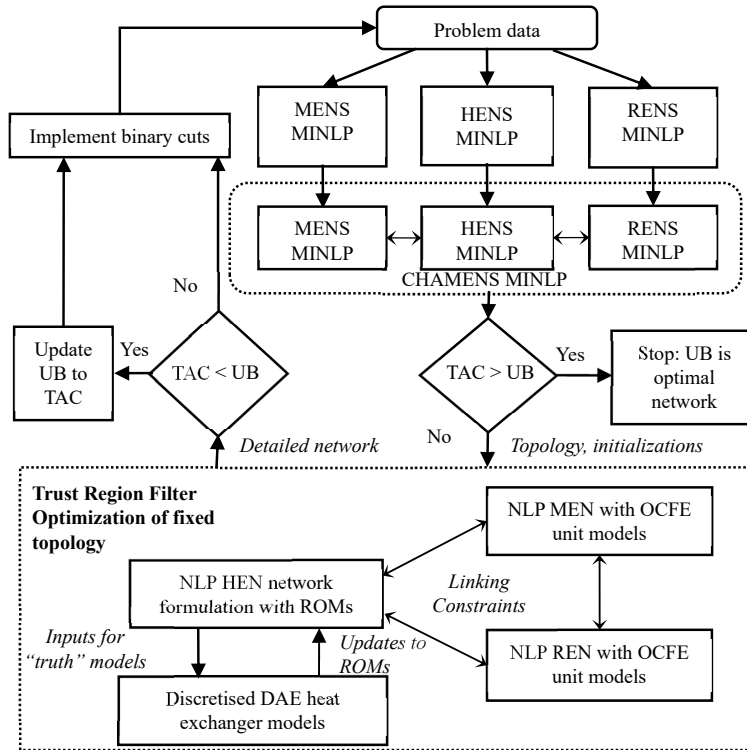

Figure 1: Overall solution algorithm

3. Case Study

We formulate an H₂S removal process, where coke-oven gas (COG) is sweetened. The problem has two rich streams, COG (R1) and tail-gas from a Claus unit (R2), both rich in H₂S, potentially absorbed by three lean streams: aqueous ammonia (L1), a process MSA,

and external MSAs (L2) 15 wt% methyl diethanolamine (MDEA), and (L3) chilled methanol regenerated via low pressure or medium pressure steam. For brevity, detailed problem data and model formulations are omitted, with results shown to demonstrate the algorithm. We use stream parameters from Kim et al. (2020), with flowrates multiplied by 10 and model formulations from aforementioned studies. For the purposes of this example we consider the temperature of L2 and flowrates of L2 and L3 as linking variables. The optimal design is shown in Figure 2. The MINLP consists of 460 constraints, 455 continuous variables and 64 discrete variables (TAC: \$26,209,870), and the NLP model consists of 11,199 constraints and 11,095 continuous variables (TAC: \$26,634,598). The full algorithm solves in 5 CPU min, with most computational effort spent in the TRF algorithm. Interestingly, the result finds that L2 and low-pressure steam are not needed in the optimal network. There are significant discrepancies in the area of the heat exchanger and column designs between the NLP and MINLP solution, showing the need for detailed designs. Interesting solution characteristics include that packed column designs are constrained by flooding, with velocities and packing sizes to ensure that each column is operating at maximum velocity to ensure high mass transfer without flooding. This generally results in smaller columns than the MINLP shortcut models, as diameters are available for optimisation. Interestingly, the NLP also redistributes mass load between the first 2 exchangers on R1 in a different way to the MINLP, using a far larger first column on R1, possibly due to the addition of mixing constraints in the NLP. This results in a slight decrease (0.02 kg/s) in methanol use and subsequent reduced costs.

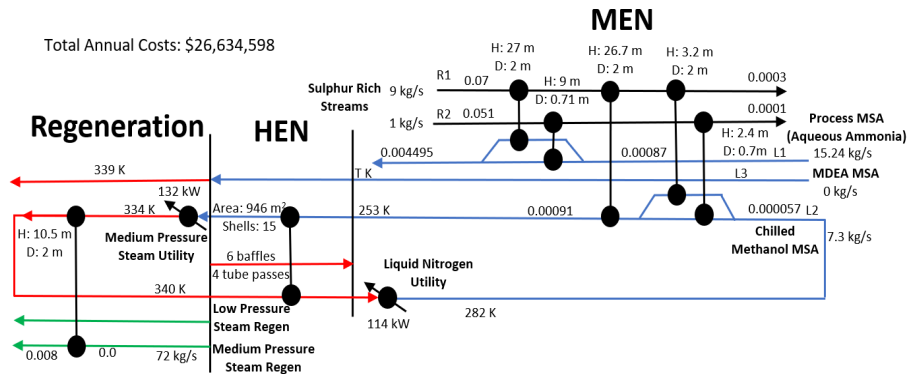

Figure 2: Optimal network identified for the Case Study

The shell and tube heat exchanger design requires many shells and high pressure drop and thus the NLP optimisation attempts to reduce the area of this exchanger, particularly since a fixed cost is introduced for numbers of shells and pressure drop is included in the objective function. The shortcut model in the MINLP underestimates the impact of this exchanger on the overall network costs without these considerations. On the second iteration of the algorithm, after the integer cut, only utilities and no process-process heat exchangers are selected and the new TAC is significantly worse due to high cooling costs.

4. Conclusions

We develop a new algorithm for solving CHAMENS that is the first to include detailed unit models as part of the optimisation formulation. The algorithm uses a MINLP model formulation with shortcut models to represent units to solve the large, nonconvex combinatorial problem first with parameters chosen to ensure an underestimation of the

objective function. This solution serves as the topology for the subsequent algorithmic steps. With topology fixed, an NLP model is then formulated. The NLP includes detailed mass exchanger designs, non-isothermal/non-isocompositional mixing constraints, and the mass and energy balances. Shell and tube heat exchangers are incorporated via surrogate models, generated from a detailed heat exchanger design algorithm, within a TRF optimisation algorithm, which guarantees that optimal solutions for the detailed exchanger models are found by the surrogate models. We demonstrate the technique on a case study involving the removal of H₂S from gaseous waste streams and find interesting designs that are different from those obtained using MINLPs alone. We present detailed heat exchanger designs and packed column designs, solving the large NLP quickly to show that the approach can be easily extended. Future work will focus on developing detailed regeneration models and including different column types that are common in MENs, in addition to a planned release of the code as an open-source heat and mass integration package. The flexible approach may also be modified to multi-component and reactive MENs in future work.

Abstract

Refrigerants are chemical compounds with specific thermodynamic properties that affect the performance of refrigeration processes. Consequently, the properties of refrigerants play a key role in the design and/or selection of refrigerants, as well as in the improvement of refrigeration systems with respect to their operational efficiencies as well as environmental impacts. In this paper, a version of the computer-aided molecular design technique, especially adjusted for application to refrigeration selection and/or design and verification is presented. The novel features of this technique are especially developed property models suitable for the small molecules that are commonly employed as refrigerants, a database of generated small molecules and a suite of computational tools that are needed at various steps of refrigerant design and verification. Based on the new property models, databases, and process models, methods for refrigerant design (single molecules or mixtures), selection and verification have been developed. Application examples highlighting the importance of the new methods and tools are also presented.

Keywords: CAMD, Computer-aided refrigerant design, Mixture design, Refrigerant.

1. Introduction

Refrigeration systems are an essential process in industry and home applications as they perform cooling or maintain room temperature at a desired value. A cycle of refrigeration consists of heat exchange, compression and expansion with a refrigerant flowing through the units within the cycle. The refrigerants are chemical compounds having thermodynamic properties that are especially suited for a refrigeration cycle operation. They are usually small molecules having lower normal boiling points (usually less than 273 K). However, other properties related to safety (such as flammability or auto-ignition temperature) and environmental impact (such as ozone depletion or global warming) also effect their selection. Also, a set of process related properties (such as phase equilibrium properties, phase enthalpies and heats of vaporization) effect the operational performance (such as the Coefficient of Performance, COP). Therefore, properties of a refrigerant need to be considered not only for its selection and/or design, but also related to environmental-health-safety (EHS) issues as well as process performance related issues. Consequently, these problems have attracted much attention as they are ideally suited for application of

the computer aided molecular design (CAMD) technique (Churi and Achenie, 1996; Sahinidis et al., 2003; Gani et al 2017; to name a few). However, after an examination of measured data (see section 2.1) of small molecules typically used as refrigerants, the group contribution (GC) methods (for example, Marrero and Gani, 2001) that have been employed in CAMD techniques for refrigerant design and/or selection, have been found to be of questionable accuracy for some of the important design related properties (see section 3.1). Even though these GC methods give acceptable predictions for larger molecules such as solvents, their prediction errors for smaller molecules have been found to be too large for reliable design of refrigerant systems. For a more reliable design of refrigerant systems, a new set of more accurate property models, together with appropriate databases integrated with the CAMD technique is necessary.

This paper presents an especially developed database of small molecules that can be considered as a refrigerant together with their collected data. Using the available measured data, new GC models are developed for three of the important properties normal boiling point (T_b), critical temperature (T_c) and critical pressure (P_c) that define the phase behavior and related refrigerant functions. Using these GC models as a basis, the applicability of other process related property models (such as equations of state) is also verified. As the models for EHS properties are already based on small molecules, only their prediction accuracies are checked. Using the new set of property models and the associated data, methods for selection and/or design of refrigerants are adopted. The CAMD technique used in this paper is of the “generate and test” type, where, candidates are selected (or designed) and then tested for process performance through appropriate process models (for refrigeration cycle simulation). To aid in the generate and test steps, computational tools for calculating thermodynamic diagrams for refrigerants and sensitivity analysis are also employed (not shown in this paper).

Results related to property model prediction accuracy, refrigerant substitution as an example of refrigeration design, and various aspects of the refrigeration cycle operation are highlighted in this paper. More details of the databases, the developed property models, the process models, the refrigeration selection method and a special software tool can be found as an extended version of this paper in Kuprasertwong et al., (2021).

2. Methods and tools for refrigerant selection and design

2.1. Database and property models

Databases of compounds that may be suitable as refrigerants have been created with Database-1 (pure component properties), Database-2 (Vapor-Liquid Equilibrium data) and Database-3 (Binary Azeotropic data). In Database-1, the collected pure component properties are divided into 3 main sections, which are Basic Properties (such as Molecular Formula, Normal boiling point, Critical properties, etc.), Chemical Properties (GWP, ODP, LD50, etc.), Temperature Dependent Properties (density, specific heat, heat of vaporization, etc.). A total of 60-different types of properties have been collected in terms of measured and estimated data. There are a total of 1766 compounds out of which 306 are known refrigerants listed in ASHRAE (Wilson et al., 2013), NIST (NIST, 2018). The compounds are classified into different types: (hydrocarbons - paraffins, -olefins, -alkynes, -cyclohexyl, -side-chains; chlorinated; fluorinated; non-condensable gases; etc.). New GC models has been developed using measured data for T_b , T_c and P_c considering compounds with 1-7 carbon atoms. Using a new set of functional groups (considering the C-atom and its bonds with other atoms) and including an atom contribution term. The new GC model expression is similar to the MG-method (Marrero & Gani, 2001):

$$f(x) = \sum_i N_i C_i + \sum_j M_j D_j + \sum_k O_k E_k \quad (1)$$

Where $f(x)$ is a function of the property x to be predicted. C_i is the contribution of the atoms of type- i that occurs N_i times in a compound. D_j is the bond-contribution of the atom j that occurs M_j times and E_k is the contribution of the second and third order groups of type- k that occurs O_k times in a compound.

Measured data for 1016 small molecules having 1-7 Carbon atoms are used for regression of the model parameters for T_b , T_c , and P_c . Since there are more measured data for T_b than T_c or P_c , a correlation is also developed to predict T_c from measured T_b values. The molecular structures of each compound are represented in terms of atoms, bonds and functional groups; the contributions C_i , D_j and E_k are regressed through measured data. Table 1 gives partial model correlation results for C1-C4 compounds. For reliable refrigerant design, prediction errors should be less than 5%, but less than 1% is preferred.

Table 1: The distribution of percentage of errors for C1-C4 of estimated normal boiling point temperatures compared with measured data from regression of parameters.

Carbon Number	Percentage of compounds having			Highest %Error	Number of Compounds
	<1% error	<5% error	<10% error		
C1	85.0	100.0	100.0	1.4	20
C2	44.2	87.5	100.0	8.0	104
C3	30.3	90.3	98.7	11.1	238
C4	40.3	90.8	100.0	8.4	119
Total C1-C4	36.0	89.8	99.3	11.1	481
Total C1-C7	40.4	91.8	99.3	13.9	1016

According to the results given in Table 1, the T_b of each compound are calculated with the regressed parameters and compared with measured data. 85% of C1 compounds have less than 1 % error (relative), while the largest percentage errors for C1, C2, C3 and C4 atoms are 1.4%, 8.0%, 11.1 % and 8.4%, respectively. The model performance for T_c (correlated as a function of T_b) and P_c (GC model) are shown in Figure 1 in terms of plots of estimated property values versus measured property values together with R^2 statistics, which shows very good model accuracy.

Figure 1: Plots of experimental versus estimated values for T_c (left) and P_c (right)

VLE data have been found for 214 compounds, while, binary azeotropes have been found for 258 compounds. The VLE phase equilibrium are predicted with cubic equations of state and with the PC-SAFT equation of state. The temperature and/or pressure dependent properties are calculated with in-house correlations, and/or equations of state.

2.2. Method for refrigerant selection and design

The selection method paradigm is as follows: define target properties and/or functions; find candidates that match the targets; verify selected candidates through simulation of process performance. The target properties for a refrigerant to be selected and/or designed are divided into two sets: Set-1 consists of T_b , T_c and P_c (these properties influence the phase equilibrium of the pure compound and/or mixture); Set-2 consists properties such as heat of vaporization, specific heat, density, GWP, ODP, etc. (these properties influence

the performance, sizing etc. of the process). In the selection method employed, Set-1 properties are matched as close as possible for the single refrigerant and exactly matched for mixed refrigerants. Set-2 properties are given in terms of upper and/or lower bounds and the candidate properties must be within the bounds. The operating conditions of a refrigeration process need to be consistent with the properties of a refrigerant and these are checked through the following consistency rules: T_b of the refrigerant must be lower than the room temperature (T_{room}); the maximum condenser temperature must be less than 0.9 of refrigerant T_c . Feasible candidates found through database search or CAMD are evaluated through refrigerant process simulation in terms of their performance.

Refrigerant selection - Pure molecules: It is unlikely that all target properties can be exactly matched through the properties of a single molecule. Therefore, in this case, upper and/or lower bounds for the target properties are given to find compounds that have properties within the bounds. Built-in search options in the database help to identify the candidates. Note that a database of small molecules (real and generated) has been created a priori and so new refrigerant molecules are not designed but retrieved from the database.

Refrigerant selection – mixtures: Unlike the single refrigerant molecule, mixtures can be tailored to exactly match the target values from 1 to 3 properties belonging to Set-1, while the rest of the properties (Set-2) are matched within the specified bounds. For example, as given in Table 2, the binary mixture composition is adjusted to match exactly the target T_{bT} ; ternary mixture compositions are adjusted to match exactly T_{bT} and one of T_{cT} or P_{cT} ; quaternary mixture, compositions are adjusted to match T_{bT} , T_{cT} and P_{cT} . Note that successful mixture design requires that at least one compound has a value lower than the target and one compound has a value higher than the target. The use of linear mixing rules for T_c and P_c is justified as these are also used by the cubic equations of state through which the phase equilibria are calculated. T_b is a result of the phase equilibrium at a specified pressure and thus fixes the operating condition. The value of T_b from the ideal mixing rule is used as an estimate of the operating temperature. The exact values from the phase equilibrium calculations are used later to adjust the operating temperature.

Table 2: Target properties versus compositions for refrigerant mixture design

Binary mixture	Ternary mixture	Quaternary mixture
$T_{bT} = x_1 T_{b1} + (1-x_2) T_{b2}$ (2)	$T_{bT} = x_1 T_{b1} + x_2 T_{b2} + (1-x_1-x_2) T_{b3}$ (3) $T_{cT} = x_1 T_{c1} + x_2 T_{c2} + (1-x_1-x_2) T_{c3}$ (4) Or $P_{cT} = x_1 P_{c1} + x_2 P_{c2} + (1-x_1-x_2) P_{c3}$ (5)	Match T_{bT} , T_{cT} and P_{cT} by adjusting x_1 , x_2 and x_3

2.3. Method for refrigeration cycle simulation

Refrigerators are cyclic devices where heat transfers take place from a low-temperature region to a high-temperature region and vice versa. The operations for one refrigeration cycle are shown in Figure 2 and a corresponding process model has been developed.

Figure 2: One cycle refrigeration process

The evaporator duty, compressor work, and condenser duty, are calculated at specified conditions of operation (defined by temperature and pressure) by using the following equations.

$$\text{Evaporator duty: } Q_{\text{evp}} = m_f(h_1 - h_4) \quad (6)$$

$$\text{Compressor Work: } W_{\text{cmp}} = m_f(h_2 - h_1) \quad (7)$$

$$\text{Condenser Duty: } Q_{\text{cnd}} = m_f(h_3 - h_2) \quad (8)$$

The performances of different refrigeration processes are compared in terms of COP:

$$\text{COP} = \frac{Q_{\text{evp}}}{W_{\text{cmp}}} = \frac{m_f(h_1 - h_4)}{m_f(h_2 - h_1)} \quad (9)$$

Note: In Eqs. 6-9, Q_{evp} is evaporator duty, W_{cmp} is isenthalpic work consumed by compressor, Q_{cnd} is condenser duty, m_r is refrigerant mass flow rate, and h_j is specific enthalpy at point j .

3. Application Examples

3.1. Consistency of data, models and CAMD solutions

To highlight the need for more accurate property models together with a need to use measured data for target properties in refrigerant selection, examples of reported feasible candidate molecules are given in Table 2 together with the target they are supposed to match as well as measured (if available) and estimated values. Only a small selection of compounds is being highlighted here (a comprehensive list can be obtained from the corresponding author). If single molecular replacements are being sought, deviations of more than 10 K from the target value may result in infeasible refrigeration cycle operation. However, if mixtures are being sought, then the target temperature can be matched exactly but the mixture compositions would not be consistent.

Table 3: Consistency check of measured-estimated property values versus target values

Compound (chemical formula)	Measured T_b (K)	Estimated T_b (K) with reported model ¹	Target value (K)
C2H6	184	GC-method not applicable	232-242
FNO	200	390	232-242
CHClO		329	242
C3H6O		316	242
C2H3FO	293	298	225
C3H4	238	260	232-242

1: Several GC-models available to the authors and including Marerro and Gani (2001)

3.2 Replacement and evaluation of R-134a

Table 4 lists selected alternative refrigerants for R-134a in terms of single, binary and ternary mixtures. The computed COP (not optimized) for the alternatives are compared with R-134a. The computations are done with the ProREFD software (Udomwong et al., 2021), where the developed property models, databases, refrigerant design and refrigeration process simulation models have been implemented.

3.3 Replacement of R-12

Another case study (Sahinidis et al., 2003) considered the replacement of R-12. A search of the database available in ProREFD (Udomwong et al., 2021) with respect to measured T_b to within 10 K of the reference gave the candidates listed in Table 5. In this problem, only compounds with at least one Carbon-atom have been considered. For each alternative, the corresponding refrigeration process has also been simulated to compute the COP at the conditions given in Sahinidis et al., (2003).

Table 4: Example of alternatives for R-134a refrigerant

Component (%wt)	Properties			Refrigeration process simulation results			
	T_b (K)	T_c (K)	P_c (bar)	Q_{evp} (kJ/h)	W_{cmp} (kJ/h)	Q_{cnd} (kJ/h)	COP
R-134a (Reference)	246.60	374.30	40.64	22,205	6,228	-28,434	3.57
Alternative of single refrigerant							
R-E170	248.35	400.10	53.70	52,624	13,695	-66,320	3.84
R-40	249.15	416.25	66.80	54,989	13,668	-68,657	4.02
Alternative of binary refrigerant							
R-12/40 (43.9/56.1)	246.60	402.49	55.57	38,710	9,911	-48,622	3.91
R-1216/E170 (36.5/63.5)	246.60	388.40	44.70	36,722	9,552	-46,275	3.84
R-1113/40 (67.1/32.9)	246.60	391.35	49.17	30,776	7,953	-38,730	3.87
Alternative of ternary refrigerant

4. Conclusions

Refrigerant design and/or selection together with refrigeration process performance can be performed reliably and efficiently through the CAMD technique. However, the property models typically used for molecules that are larger than the small refrigerant molecules have been found to give unacceptable prediction errors. Therefore, a new class of GC models suitable for refrigerant molecules have been developed and validated with measured data. Another issue is the size of the database. The number of small molecules that maybe suitable for application as refrigerant and for which measured target property values are available, is not very high. This means that the number of candidates within certain ranges of temperature, for example, lower than 250 K, is not very high. To overcome this problem, CAMD has been used to generate compounds with 1-6 Carbon atoms, resulting in around 3000 additional molecules that have been found but their properties have not yet been measured. Also, structures for another 8000 molecules have been generated that do not currently exist. Truly innovative and novel refrigerants most likely will come from this list. However, novel refrigerant mixtures satisfying target properties that a single molecule cannot satisfy may also result in novel refrigerants. Much work, however, is needed to predict and validate the newly generated molecules. It should be noted that the scope and significance of methods like CAMD depends on the application range of the property models. Inclusion of data analytics and machine learning based modelling are also likely to help advance the current state of the art.

Abstract

The conventional application of a pulp and paper mill, in which black liquor is typically concentrated and burnt, is compared with the upgrading gasification route for methanol (MeOH) and dimethyl ether (DME) co-production. This comparison is made in terms of exergy efficiency and environmental impact indicators, under different utilities supply scenarios. The combined energy integration and exergy analysis is used to identify the potential improvements related to the decarbonization and mitigation of the process irreversibility. The exergy efficiencies of the conventional scenario and the integrated plants average 40% and 45%, respectively, while the overall emission balances vary from 1.97 to -0.07 tCO₂/tPulp, respectively. These results reinforce the relevance of the electricity import from the Brazilian mix for pushing upwards the share of renewable energy resources in the production of traditionally fossil-based chemicals and fuels, which could be an important decision variable in favor of the exploration of forest-based integrated biorefineries.

Keywords: Black liquor, Kraft process, Gasification, Methanol, Dimethyl ether.

1. Introduction

The pulp and paper sector is classified as an energy intensive activity, accounting for about 5.6% of the total energy consumed by the industrial sector (IEA, 2017). It is also responsible for about 2% of the total yearly CO₂ emission of the industrial sectors worldwide (Leeson et al., 2017). The black liquor (BL) is a byproduct of the kraft pulping process, which contains more than half of the exergy content in the total woody biomass fed to the digester. The pressurized entrained-flow, high temperature black liquor gasification (PEHT-BLG) technology has been envisaged as a promising process to improve the energy performance in the pulp industry. The syngas produced from the gasification process of BL can be used either to generate electricity or produce chemicals and biofuels, expanding the products portfolio and matching the modern biorefinery concept. In this work, the conventional scenario of the black liquor use (i.e. concentration and combustion) is compared with the black liquor upgrading gasification process for methanol (MeOH) and dimethyl ether (DME) production, which are extensively studied as potential low carbon fuels (Fernández-Dacosta et al., 2019). The exergy destruction and the cumulative CO₂ emissions were considered as criteria for assessing the sustainability of the energy conversion systems involved.

2. Methods

2.1. Process modeling

An alternative approach to the conventional black liquor evaporation unit is adopted, namely, a mechanical vapor recompression (MVR) system. The gasification is modeled as a pressurized entrained-flow, high temperature black liquor gasification (PEHT-BLG). The produced syngas is used to produce either methanol or dimethyl ether (Figure 1). A detailed description of the kraft pulp mill, MVR and PEHT-BLG, and the syngas treatment and purification processes, as well as the data of the ultimate and proximate composition (mass basis) for BL and other industrial substances of interest, used to calculate the specific chemical exergy and lower heating value thereof, have been presented in (Domingos et al., 2021).

The methanol synthesis process is modeled using the LHHW (Langmuir-Hinshelwood Hougen-Watson) kinetic model developed by (Graaf et al., 1988). Before entering the methanol synthesis loop, the purified syngas is compressed to 90 bar. In the loop, the syngas is firstly heated up in a feed-effluent heat-exchanger (FEHE) by the reactor outlet stream. Then, the syngas is fed to a tubular plug-flow reactor (PFR) operated isothermally at 90 bar and 210°C. The reactor outlet comprises a gaseous mixture containing methanol, water and unconverted reactants (CO_x and hydrogen). This mixture is cooled and flashed twice, first to 30°C and 45 bar, and then to 30°C and 3.5 bar, in order to separate the condensable products and the non-condensable reactants (Kiss et al., 2016). The condensed stream continues to a distillation column operating at atmospheric pressure, where methanol with purity over 99% wt. is produced. The non-condensable stream is partially purged to avoid the built up of inerts, and the other part is recycled back to the methanol synthesis loop.

The DME synthesis occurs via the indirect route, i.e. via methanol dehydration over an acid zeolite catalyst. The purified syngas initially passes through the same processes described previously for methanol synthesis. Syngas is firstly compressed up to 90 bar and converted to methanol. Then, it continues to the DME synthesis loop, wherein an adiabatic DME reactor is used. The kinetic is given by (Bandiera and Naccache, 1991). The outlet stream of the reactor is a mixture of water, DME and methanol, which is fed to a first distillation column (DC), which removes DME as the distillate with purity over 98.5% wt. The bottoms stream is a mixture of water and methanol that is subsequently fed to a second DC. The methanol that exits the second column as the distillate is recycled back to the reactor, while the water exits from the bottom.

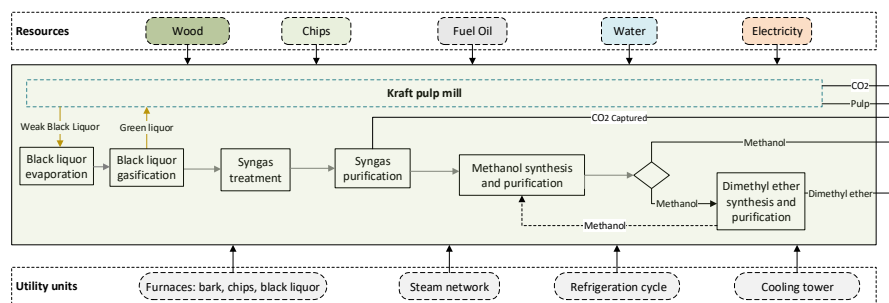

Figure 1. Integrated model used for assessing the production of methanol or dimethyl ether from black liquor upgrading gasification process.

The thermodynamic properties of the flows, the mass, energy and exergy balances of each process unit are evaluated using Aspen Plus® v8.8 software and the Peng-Robinson equation of state with Boston-Mathias modifications.

2.2. Exergy analysis indicators

Three conceptual processes are evaluated, namely (i) the standalone kraft pulp mill, based on the conventional recovery boiler, and two configurations proposed, based on the integration of black liquor gasification process for either methanol or dimethyl ether production. In turn, the two integrated chemical plants may consume either electricity from the grid (mixed mode) or only biomass as fuel import (autonomous mode).

In order to compare those configurations, two performance indicators are proposed. The rational exergy efficiency and the relative exergy efficiency. The former considers that the sum of the exergy of the two chemical products (MeOH or DME, and cellulose) and by-products (CO₂, purge gas, power) corresponds to the useful output of the chemical plant; the later compares the minimum theoretical work required to bring about only the two main chemical products of the integrated chemical plants to the overall exergy consumption in the actual production processes. The physical and chemical exergies, as well as the efficiencies are assessed using Excel add-ins embedded in Aspen Plus®.

2.3. CO₂ emissions

Two CO₂ emissions balances were performed: the overall CO₂ emissions and the net one. The overall CO₂ balance considers overall CO₂ emitted (either fossil or biogenic) minus CO₂ captured by the gas purification unit, whereas the net value subtracts the amount of CO₂ embodied by the crops, assumed as circular emissions. The indirect fossil CO₂ emitted considers the indirect emissions due to the upstream supply chains of electricity (62.09 g_{CO2}/kWh), wood (0.0043 g_{CO2}/kJ_{Wood}) and oil (0.0029 g_{CO2}/kJ_{Oil}) (Flórez-Orrego et al., 2015) The biogenic emissions comprise the emissions related to the combustion of woody components (bark and chips), based on the carbon content of the biomass.

2.4. Optimization framework and problem definition

Inasmuch as electricity can be imported from the grid, a trade-off is expected between additional fuel consumption for in-plant cogeneration and the extent of grid electricity purchase. This circumstance requires a complete redesign of the energy integration approach between the chemical units and the utility systems, so that the power and steam requirements remain satisfied.

The determination of the minimum energy requirements (MER) and the solution of the energy integration problem is handled by the OS MOSE Lua platform, developed by the IPESE group at EPFL, in Switzerland (Yoo et al., 2015). This framework allows to determine the most suitable utility systems and their operating conditions that lead to the lowest resources consumption and optimal operating cost (Maréchal and Kalitventzeff, 1998). The computational framework manages the data transfer with ASPEN Plus® software and builds the mixed integer linear programming (MILP) problem that minimizes the operating cost of the chemical plant. The utility units are modeled via equation-oriented subroutines written in Lua programming language. To this end, the additional equations required for the mass and energy balances of those units rely on the concept of layer (water, natural gas, biomass, syngas, methanol, dimethyl ether, power, carbon dioxide, heat, etc.). Finally, representative market cost for the wood (0.013 euro/kWh), chips (0.016 euro/kWh), oil (0.018 euro/kWh) and electricity (0.06 euro/kWh) consumed, as well as the selling prices of pulp (0.144 euro/kWh), methanol (0.065 euro/kWh), dimethyl ether (0.07015 euro/kWh), and CO₂ (0.0084 euro/kg) produced are taken from literature.

3. Results and Discussion

The overall exergy consumption in the conventional case achieves 42.20 GJ/tpulp, whereas for the integrated processes this value has an increment of over 14% for the mixed mode setups and of 38% for the autonomous mode configurations (Figure 2), respectively. This increase is explained by a larger amount of biomass and electricity required to drive the compressors and other ancillary equipment of the integrated chemicals production plants. The opportunity for importing ‘greener’ Brazilian electricity (i.e. in mixed mode designs) leads to a strikingly lower overall exergy consumption for MeOH and DME production compared to the autonomous cases.

The exergy efficiencies of the conventional and integrated cases for MeOH and DME, average 40%, 45% and 45%, respectively (Table 1). Thus, the integrated cases presented higher exergy efficiency in comparison to the conventional case. These results are strongly in agreement with those reported by Van Rens et al. (2011), who performed an exergetic analysis for production of MeOH and DME using wood as feedstock for gasification.

The mixed modes present the highest values of exergy efficiency (approx. 49.3% for MeOH and 48.6% for DME), whereas the autonomous cases averages 41.2% for MeOH and 40.9% DME (Table 1). This fact reinforces the idea that the electricity import, whether available, may help reducing the irreversibility in the manufacturing of bioproducts. All in all, there exists a large underexploited biomass potential that may contribute to develop new business opportunities from fuels to chemicals production. Moreover, despite the fact that an intensive industrial utilization of the Brazilian electricity mix may bringing some challenges to generation companies and other economic sectors, the advantages of the electricity import in the integrated biorefineries has been demonstrated in light of the reduction of the overall process irreversibilities.

The *Extended Exergy Consumption*, shown in Table 1, takes into account the exergy efficiency of the upstream feedstock supply chains, which ends up impairing the performance of the extended pulp and bioproducts manufacturing processes. Actually, in the case of the integrated chemical plants, when an extended control volume is observed, there is a significant increase in the exergy consumption (13.7-17.0%) compared to the exergy input to the control volume of the sole chemical plant. Although these results may not be immediately interesting for pulp and bioproducts manufacturers when evaluating the performance of the chemical plant itself, those features are certainly useful to public policies and decision-makers in environmental and benchmarking frameworks, as they permit a holistic comparison of the impact of the bioproducts sector with other industrial sectors based on other supply chains.

Figure 2. Plantwide and extended exergy consumption for the conventional and the integrated chemical plants (pulp and bioproducts co-production).

Table 1. Exergy destruction and efficiencies for the three studied scenarios.

Chemical plant	Conventional mill		Integrated chemical plants		
	Only pulp	Pulp + Methanol	Pulp + Dimethyl ether		
Operation mode	BL combustion	Mixed ²	Auto ³	Mixed	Auto
Rational exergy efficiency (%)	42.5	55.0	45.1	54.0	44.7
Extended rational exergy efficiency (%) ¹	36.7	45.7	38.9	45.0	38.6
Relative exergy efficiency (%)	42.3	52.8	43.3	52.0	43.0
Extended relative exergy efficiency (%) ¹	36.5	43.9	37.4	43.3	37.1
Exergy destruction (GJ/t _{Pulp})	24.3	21.5	32.0	22.2	32.3
Extended exergy destruction (GJ/t _{Pulp}) ¹	30.9	31.2	41.2	31.9	41.6

1. Overall exergy consumption increases if the cumulative efficiency of the electricity generation (55.68%), as well as of the oil (95.20%) and biomass (86.13%) supply chains are considered (Flórez-Orrego et al., 2015); 2. Mixed mode implies partial import of electricity to make up the overall power consumption in the integrated chemical plants; 3. In auto mode, in-plant cogeneration of the overall power and heat required relies only on the biomass fuel input and the steam network.

Figure 3 presents the overall and detailed CO₂ emission balance. The overall emission balances achieve 1.97 t_{CO2}/t_{Pulp} in the conventional mill; -0.07 t_{CO2}/t_{Pulp} in the combined pulp and MeOH plant, and -0.02 t_{CO2}/t_{Pulp} in the pulp and DME plant. The negative values indicate a net positive impact towards the depletion of the CO₂ present in the atmosphere. As a result, the indirect emissions from the biomass utilization are not only offset by the captured biogenic emissions, but also the import of ‘greener’ Brazilian electricity leads to a mitigation of CO₂ emissions.

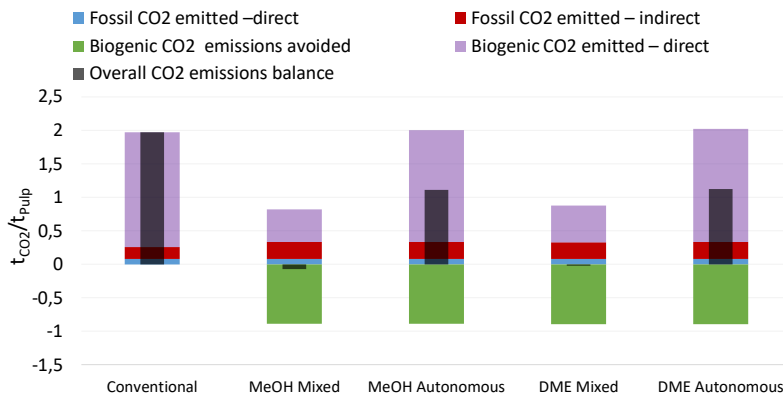

Figure 3. Overall and detailed (biogenic and fossil, directly and indirectly emitted, and avoided) CO₂ emissions for the conventional mill and the integrated kraft pulp and bioproducts manufacturing plants.

Table 2 evidences that all the integrated pulp and bioproduct production processes (mixed and autonomous) have higher operating revenues (increment between 12-15%), due to the complementary value-added CO₂ and bioproduct, not produced in the conventional kraft pulp process. These revenues, however, can be directly influenced by market prices fluctuations.

Table 2. Operating incomes, cost and revenues for the three studied scenarios.

Chemical plant	Conventional mill	Integrated chemical plants			
	Only pulp	Pulp + Methanol		Pulp + Dimethyl ether	
Operation mode	BL combustion	Mixed	Auto	Mixed	Auto
Operating Incomes (euro/ t _{pulp})	714.61	854.12	854.12	863.07	863.07
Operating Costs (euro/t _{pulp})	-153.49	-218.72	-224.89	-219.69	-225.62
Operating Revenues (euro/t _{pulp}) ¹	561.12	635.40	629.24	643.37	637.45

¹Operating revenues calculated as the difference between the gross operating incomes minus the operating cost.

4. Conclusions

The combined energy integration and exergy analyses performed allowed spotlighting the best alternatives of utility systems that ensure a competitive performance, while maximizing the recovery of the available waste heat exergy. As a result, the exergy efficiencies of the conventional and integrated cases average 40% and 45%, respectively, whereas the overall emission balance varies from 1.97 to -0.07 tCO₂/t_{pulp}, respectively. These negative values point towards the environmental benefits brought about by the production of chemicals through the use of alternative energy sources, such as biomass and electricity, in integrated chemical plants. Other environmental impacts should be also investigated.

Sustainable Process Design and Synthesis for HDPE Recycling

Xiang Zhao, Fengqi You

Cornell University, Ithaca, New York 14853, USA

xz643@cornell.edu

Abstract

Plastic pollution is an ongoing problem in the U.S. This work focuses on the sustainable process design and synthesis of waste high-density polyethylene (HDPE) recycling systems to mitigate plastic pollution. A superstructure that can be implemented to manufacture various chemical products is proposed. We formulate the following superstructure optimization problem as a multi-objective mixed-integer nonlinear fractional programming (MINFP) problem, which is efficiently solved by a tailored global optimization algorithm that integrates parametric algorithm and branch-and-refine algorithm. Results reveal the economic profitability via displaying unit NPVs of optimal solutions (\$107.2 to \$151.3 per ton HDPE treated), while the unit GHG emissions of the good-choice optimal design are 0.44 ton CO₂-eq/ton HDPE treated.

Keywords: waste HDPE, superstructure optimization, global optimization algorithm

1. Introduction

Plastic pollution is still an ongoing problem around the U.S. Over the country, 76% of waste plastics, which is mainly generated by the households, go to landfill, while only 8% of the plastics are effectively recycled (EPA, 2019). Landfilled plastics damage the bio-system via being decomposed into toxic chemicals or through watering into microplastics that can be accumulated in the eco-system (Heward, 2018). In this regard, closed-loop and open-loop recycling processes are implemented into recycling these waste plastics (Williamsa and Williamsb, 1997). The closed-loop process can manufacture recovered plastics with high capital cost, while the open-loop process can be implemented into producing various useful chemicals rather than original plastics, which improves the economic viability and environmental sustainability for processing waste plastics (Fivga and Dimitriou, 2018). Although various researchers have paid their main attention to improving the economic and environmental performances for processing waste HDPE by using the open-loop recycling process, the issue of the sustainable design and synthesis of HDPE recycling process systems is still a knowledge gap.

In this work, we address this knowledge gap by introducing the sustainable design and synthesis approach to determine optimal economic and environmental performances (Gong et al. 2015). We develop by far the first superstructure that aims to convert waste HDPE into various chemicals, namely monomers, aromatic mixtures, and fuels, so that plastic pollution can be effectively alleviated. The following superstructure optimization problem is then formulated by the life cycle optimization approach to optimize the unit NPV and unit life cycle environmental impacts simultaneously. Life cycle assessment (LCA) and techno-economic analysis (TEA) are performed to provide environmental and economic parameters, respectively, and thus the superstructure optimization problem can

be formulated as a multi-objective mixed-integer fractional programming (MINFP) problem. To tackle the computational challenge caused by the combinatorial nature and the pseudo-convexity shown in fractional objective functions, we apply a tailored global optimization algorithm that integrates the inexact parametric algorithm with the branch-and-refine algorithm. The proposed framework is implemented to design an HDPE recycling processing system that can treat 295,000 ton HDPE/year in maximum in the U.S., corresponding to the estimated annual landfill amount of waste HDPE in New York State (EPA, 2019).

2. Superstructure Description of Waste HDPE Recycling

In this work, we develop by far the first superstructure of waste HDPE recycling process systems. As shown in Figure 1, the superstructure includes 1,728 processing pathways and nine sections. The corresponding flowsheet accounts for various unit processes and technologies, which are corresponding to the technology options shown in Figure 1. Only one technology or unit process can be selected for each processing pathway.

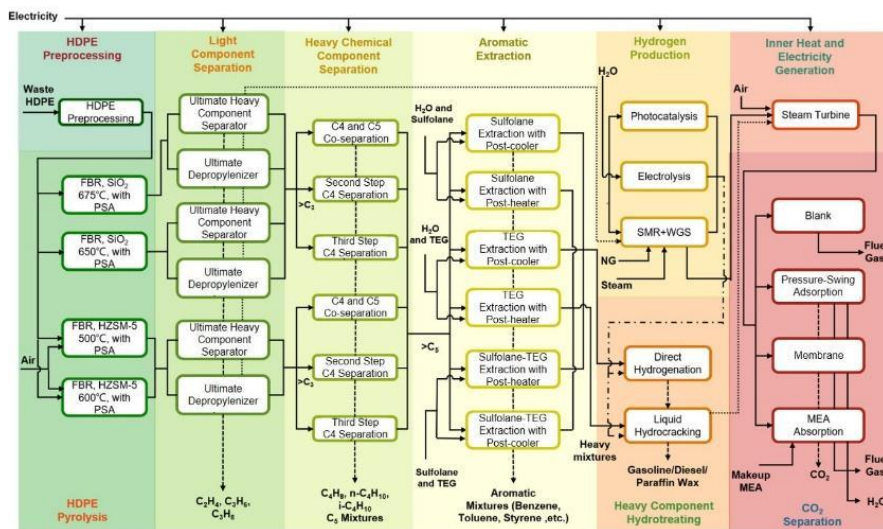

Figure 1. Overview of the proposed superstructure of Waste HDPE Recycling.

The whole superstructure starts with the HDPE preprocessing section, where the transported waste HDPE is shredded and transported to the HDPE pyrolysis section. The HDPE particles are thermally cracked into various hydrocarbon chemicals in a fluidized bed pyrolyzer (Hernández et al., 2007), where the nitrogen gas is an inert fluidized gas and circulated in the HDPE pyrolysis section. The streams with gaseous products are separated, cooled, and split into light and heavy components. In the light hydrocarbon separation section, all the technology options are considered for producing ethylene, propane, and propylene from the light hydrocarbon stream. The heavy streams from the light hydrocarbon separation and HDPE pyrolysis sections are mixed and fed into the heavy chemical component separation section, where three technologies configurations, namely second C4 separation, third C4 separation, and C4 and C5 co-separation, are considered (Yang and You, 2017). The mixture of heavy streams is split into n-butane, i-butane, butene mixture, and C5 mixture, which are important components in organic solvent and naphtha (Buekens and Froment, 1968).

The stream with heavy liquid (>C6) from the heavy chemical component separation section is sent to the aromatic extraction section to produce aromatic mixtures that are vital to produce benzene and toluene (He and You, 2014). Notably, sulfolane is selected as a solvent due to its wide usage in the typical UOP extraction process (Mayers, 2004), while the TEG is chosen because of its high selectivity to aromatics and miscibility in water (Wang et al., 1998). The raffinate from this section is directly fed into the heavy component hydrotreating section to be hydrogenated or hydrocracked. The raffinate is converted into gasoline, diesel, and wax (>C16 components), while the hydrocracking section produces fuel gas, gasoline, and diesel. The fuel gas stream is sent to the inner heat and electricity generation section to produce electricity and heat.

To produce hydrogen for the hydrogenating or hydrocracking process, we consider three technology options in the hydrogenation section, namely photocatalysis, electrolysis, and steam-methane reforming are considered. In the steam-methane reforming section, the methane stream from the light component separation section is mixed with steam and converted into hydrogen, with carbon dioxide, carbon monoxide, and unconverted methane as byproducts, which are sent to the onsite combustion section. In the onsite combustion section, all overhead gas flows are mixed and ignited in the furnace to exchange heat in selected technologies options and evaporate the precooled water into steam, which can push the steam-turbine to do the work and thus be converted into electricity in a turbine generator. The flue gas from the onsite combustion section is sent to the CO₂ separation section to split and liquefy the CO₂ for storage.

3. LCA and TEA Methodology

3.1. LCA Methodology

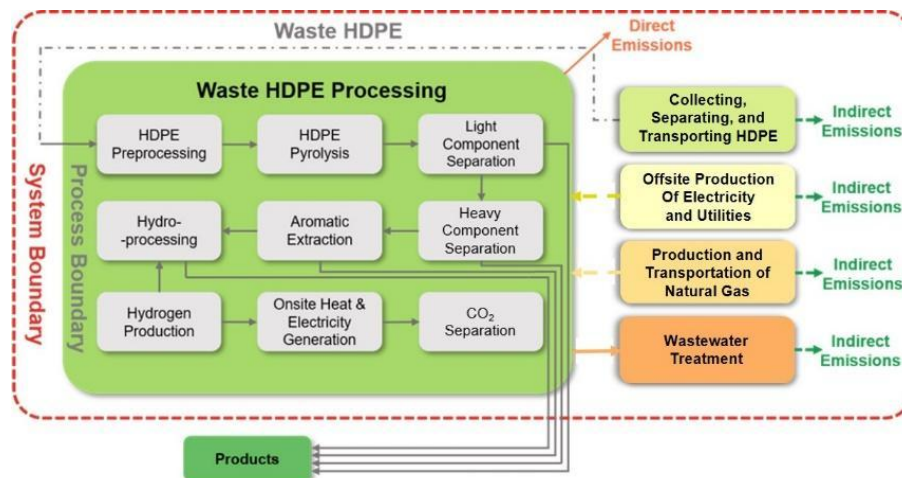

Figure 2. System boundary of a cradle-to-gate LCA for waste HDPE recycling process systems.

The LCA methodology is used for systematically quantifying the environmental impacts so that the environmental parameters can be provided to the corresponding superstructure optimization problem. The goal of this LCA is to quantify the life cycle environmental impacts from waste HDPE recycling process systems. Five life cycle stages, namely collecting, separating, and transporting HDPE, offsite production of electricity and utilities, waste HDPE processing, production and transportation of natural gas, and

wastewater treatment, are confined by the system boundary from cradle-to-gate, as shown in Figure 2. We choose the functional unit as one ton of waste HDPE processed within the waste HDPE processing system. We compile the detailed life cycle inventories (LCIs) of such five pre-defined life cycle stages based on their mass and energy balances, of which data are extracted from high-fidelity Aspen-Plus-based process simulations and the Ecoinvent V3.6 database. Notably, we extract the chemical composition of pyrolysis products from the experimental data of pyrolyzing waste HDPE. The global warming potential (GWP100) can be implemented into evaluating the greenhouse impacts over the course of 100 years relative to that of CO₂ (Hartmann et al., 2013). The GHG emissions of each life cycle stage are quantified and inputted as environmental parameters to the superstructure optimization problem. The environmental results are shown in the Pareto-optimal curve and GHG emissions breakdowns (Guillén-Gosálbez et al., 2019).

3.2. TEA Methodology

We consider the capital expenditure (CAPEX) and operating expenditure (OPEX) to provide the economic parameters to the superstructure optimization problem. The direct, indirect, and working capitals of all equipment units, as well as the land cost are accounted for calculating the CAPEX, while the OPEX includes the transportation, feedstock, utility, operations and maintenance (O&M) costs, as well as the property tax and insurance (PT&I), sales expense, and income tax. Notably, the net present value (NPV) is calculated via subtracting the CAPEX from the summation of annualized cash flow in each operating year.

4. Model Formulation

$$\begin{aligned} \max \quad & OBJ_{economic} = \frac{NPV}{HDPE \cdot yr} \\ \min \quad & GWP = \frac{(EECST + EEH + EEE + EEW + EED + EEN)_{GWP}}{HDPE} \\ \text{s.t.} \quad & \text{Mass balance constraints} \\ & \text{Energy balance constraints} \\ & \text{Environmental impacts assessment constraints} \\ & \text{Techno-economic evaluation constraints} \\ & \text{Superstructure network configuration constraints} \end{aligned}$$

The superstructure optimization problem is formulated as a multi-objective model that aims to maximize unit NPV ($OBJ_{economic}$) and minimize life cycle GHG emissions (GWP) (Thomassen et al., 2019). Notably, the model is a nonconvex MINFP problem. We introduce nonlinear terms in power functions to calculate capital costs, which are formulated as separable concave terms in the fractional objective functions. The combinatorial nature, pseudo-convexity, and separable concave terms in fractional objectives provide computational challenges for general-purpose global optimizers. Thus, a tailored global optimization algorithm that integrates inexact parametric algorithm (Zhong et al., 2014) with the branch-and-refine algorithm (You and Grossmann, 2011) is applied to tackle this computational challenge.

5. Results and Discussion

5.1. Results of the Superstructure Optimization

As shown in Figure 3, the maximum NPV is \$151.38/ton HDPE treated (corresponding NPV: \$3.4 billion) at point C, which improves by about 25% compared to that from

relevant literature. This improvement is contributed by the versatility of manufacturing multiple products from waste HDPE, heat integration, and the on-site production of high-temperature energy and electricity to reduce the cost of purchasing electricity and natural gas. However, the unit GHG emissions of solution A is 0.4 ton CO₂-eq/ton HDPE treated, which is 57% compared to that of point C. Comparatively, the good-choice solution B reveals minimum unit life cycle GHG emissions (0.44 ton CO₂-eq/ton HDPE treated), which are just 10% higher than that at point A, and a pronounced economic performance (unit NPV: \$142.9/ton HDPE treated, corresponding NPV: \$3.2 billion). The corresponding optimal HDPE recycling process selects MEA absorption as the CO₂ separation process so that more than 85% of GHGs can be removed from the flue gas, which greatly decreases the direct emissions compared to the most economically competitive design of solution C.

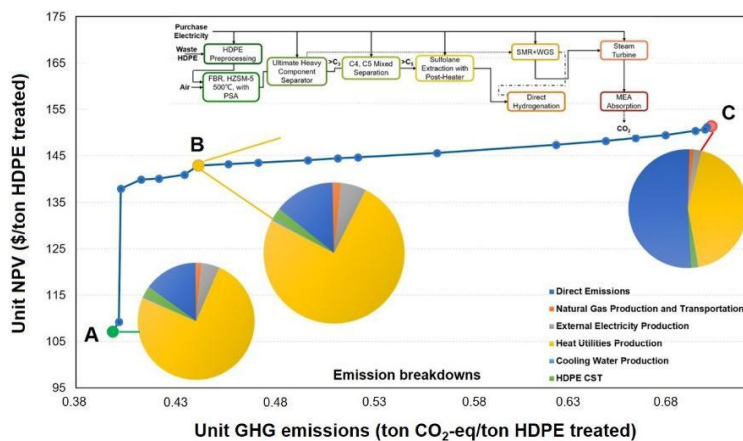

Figure 3. Pareto-optimal curve reveals the trade-offs between the unit NPV and unit life cycle GHG emissions.

5.2. Computational Performance

The superstructure optimization problem includes 104 integer variables, 63,906 continuous variables, and 67,743 constraints. A tailored global optimization algorithm is used for effectively solving this nonconvex problem. We perform the computational experiment on DELL OPTIPLEX 7040 desktop with Intel(R) Core (TM) i7-6700 CPU @ 3.40GHz and 32 GB RAM. The mathematical model and corresponding solution process are coded in GAMS 24.8.3. For all three cases corresponding to optimal solutions A to C, BARON 17.1 fails to find a global optimal solution within 44,000 seconds. Moreover, SCIP 3.2 also fails to find a global optimal solution due to the combinatorial nature and nonconvexity shown in fractional objective functions. Comparatively, all three instances are effectively solved by the tailored global optimization algorithm, which tackles the aforementioned computational challenges, within a few CPU seconds.

6. Conclusion

In this work, the sustainable design and synthesis of waste HDPE recycling process systems were addressed with optimal economic and environmental performances. We developed by far the first superstructure to convert waste HDPE into various chemicals. A tailored global optimization algorithm was applied for the effective solution of the

corresponding superstructure optimization problem. Results showed that the unit NPV of the good choice solution was \$142.9/ton, while its unit life cycle GHG emissions were 0.44 ton CO₂-eq/ton HDPE treated, which was contributed by the integration of MEA absorption. The computational results revealed the advantage of the tailored global optimization algorithm over general-purpose global optimizers.

A Novel Process Design for Waste Respirator Processing

Xiang Zhao, Fengqi You

Cornell University, Ithaca, New York 14853, USA

xz643@cornell.edu

Abstract

The ongoing COVID-19 pandemic increases the consumption of respirators. In this work, we propose a novel and effective waste respirator processing system that aims to protect public health and mitigate climate change. Respirator sterilization and pre-processing technologies are incorporated simultaneously to resist viral infection and facilitate unit processes for manufacturing and separating products, so the greenhouse gas (GHG) emission can be reduced via carbon reallocation from CO₂ to downstream products. High-fidelity process simulations are performed to extract detailed life cycle inventories used for evaluating environmental performance. Results reveal the economic viability in terms of the payback time (seven years) and the internal rate of return (21.5%). The proposed waste respirator processing system reduces GHG emissions by 59.08% compared to incineration, which reflects the potential of climate change mitigation.

Keywords: waste respirator processing, COVID-19, process design and integration.

1. Introduction

The U.S. has been trapped in the COVID-19 pandemic with no shutdown in sight. During the COVID-19 pandemic, people consume massive respirators to stem coronavirus infection, which substantially triggers the usage and disposal of respirators across the U.S (Bartoszek et al., 2020). Notably, the virus will transmit among the public if massive discarded respirators are mismanaged. In this regard, we apply the incineration process to treat these waste respirators in typical medical waste disposal sites (Nzediegwu and Chang, 2020). However, a large amount of greenhouse gases (GHGs) are emitted when incinerating respirators, which give rise to serious climate change (Klemeš et al., 2020). Even worse, the mixed-plastic component within discarded respirators can be decomposed into toxic chemicals (Bora et al., 2020), which are then digested by organics and accumulated in the food-web (Heward, 2018). In these regards, we currently call for a novel and effective waste respirator processing system to reduce the risk of viral infection and GHG emissions when fighting for the COVID-19 pandemic.

To fill in this current knowledge gap, we develop and propose a waste respirator processing system, which incorporates respirator sterilization and pre-processing technology to protect the public health and for manufacturing and separating products, so the greenhouse gas (GHG) emission can be reduced via carbon reallocation from CO₂ to downstream products. We consider seven sections in the processing system, namely respirator preprocessing, pyrolysis, light hydrocarbon separation, CO₂ separation, hydrogenation, hydrogen production, and onsite combustion. A commercially available sterilization process, which can shred, sterilize, and dehydrate the waste N95 respirators, is included in this system to disinfect respirators and triggers the thermal-cracking process

in the pyrolysis section (Nutsch and Spire, 2004) similar to plastics processing (Zhao and You, 2021). We apply a detailed life cycle assessment (LCA) approach to systematically quantify the GHG emissions from cradle-to-gate so that the potential in mitigating climate change can be evaluated. Specifically, high-fidelity process simulations of the waste respirator processing system integrated with the data from Ecoinvent V3.6 are used for extracting the detailed life cycle inventory. Techno-economic analysis (TEA) is also conducted to evaluate the economic viability by calculating the capital and operating expenses. We demonstrate the economic feasibility of establishing respirator processing systems and their potential for climate change mitigation through evaluating a proposed respirator processing system, which aims to treat 582 million waste N95 respirators that are corresponding to the HHS's recommended annual production amount in eight northeastern states in the U.S. (NY Times, 2020), namely New York, New Jersey, Pennsylvania, Massachusetts, New Hampshire, Vermont, Rhode Island, and Connecticut.

2. Process Description for the Waste Respirator Processing System

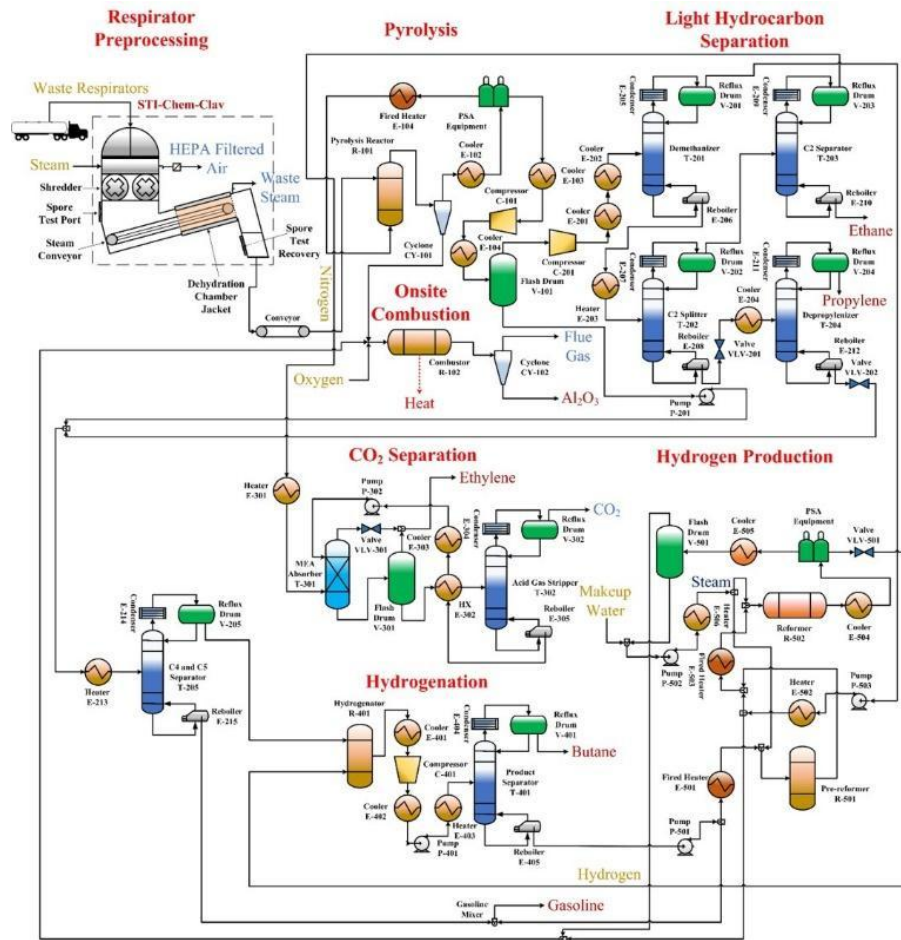

Figure 1. Process flowsheet of the proposed waste respirator processing system.

In this work, we develop and propose a novel and effective waste respirator processing system. As shown in Figure 1, the processing system integrates seven sections, namely respirator preprocessing, pyrolysis, light hydrocarbon separation, CO₂ separation, hydrogenation, hydrogen production, and onsite combustion. Detailed description of the whole processing system is shown as follows.

The whole process starts with the respirator preprocessing section, where the transported waste respirator can be shredded, sterilized, and dehydrated by steam (147.7°C, 44.61 bar) simultaneously. Notably, this section can effectively deactivate the coronavirus under the sterilization condition (95–120°C) (Nutsch and Spire, 2004). With the usage of nitrogen gas as the inert fluidized gas, the disinfected respirator particles are then thermally cracked into various inorganic and hydrocarbon chemicals in a fluidized bed pyrolyzer. The nitrogen gas is split by a pressure-swing adsorption (PSA) unit and circulated in this section. The volatile stream is then split into streams with light and heavy components in a flash tank, while the stream with char is sent to the onsite combustion section to generate high-temperature heating energy. In the light hydrocarbon separation section, the stream with light components is split into methane, ethane, ethylene, and propylene products. Notably, the methane stream is directly sent to hydrogen production or onsite combustion sections (Yang et al., 2018), while the stream with ethylene is fed into the CO₂ separation section to separate CO₂ from ethylene products. In the C₄ and C₅ Separator (He et al., 2015), the overhead liquid with C₄ components is sent to the hydrogenation section to produce butane product, while the raffinate is fed into a gasoline mixer or used for producing hydrogen (Gong et al., 2017).

Specifically, we apply NiMo catalyst (Swanson et al., 2010) in the hydrogenator to convert C₄ components into butane in the hydrogenation section. To satisfy the usage of hydrogen in this section, a hydrogen production section is implemented within the waste respirator processing system. Notably, the partial raffinate stream from the hydrogenation section is mixed with steam and produces lighter components in the pre-reformer to trigger the steam-methane reforming reaction in the downstream reformer. In the reformer, the steam is mixed with streams of methane and CO from the light hydrocarbon separation section and the mixture is converted into hydrogen following the kinetic of steam-methane reforming reaction (He et al., 2016). The hydrogen stream is separated from the PSA unit and sent to the hydrogenation section, while the steam is regenerated via pressurizing and heating the mixture of the makeup water stream and pre-cooled water stream from the flash tank. The remaining gaseous stream from the flash tank is mixed with oxygen, char, and gaseous chemical components, such as methane, and sent to the combustor to be ignited under 1000°C. The high-temperature heating energy is released from the combustor, while the solid stream (mainly Al₂O₃) is sold.

3. LCA and TEA Methodology

3.1. LCA Methodology

In this work, we apply the LCA methodology to systematically evaluate the potential of climate change mitigation via quantifying the GHG emissions from the waste respirator processing system, so the goal of this LCA is defined. Five life cycle stages, namely waste respirator transportation, waste respirator processing, offsite heating utilities production, offsite electricity production, and offsite production for inlet material, are confined by the system boundary from cradle-to-gate, as shown in Figure 2. We choose the functional unit as one thousand respirators treated within the waste HDPE processing system.

We compile the detailed life cycle inventories (LCIs) based on the mass and energy balances throughout these five life-cycle stages, of which data are extracted with the help of combining high-fidelity Aspen-Plus-based process simulations and Ecoinvent V3.6 Database. In the process simulation, we assume the chemical composition of pyrolysis products as the weighted average of chemical composition for pyrolyzing each single plastic compound (Westerhout et al., 1998).

We apply the global warming potential over the course of 100 years (GWP_{100}) to quantify the greenhouse impacts relative to that of CO_2 and thus evaluate the potential of climate change mitigation. Specifically, the GWP_{100} of methane is 28 due to the same greenhouse impacts of emitting 1 kg of methane and those of 28 kg CO_2 over the course of 100 years (Hartmann et al., 2003). The GHG emissions of each life cycle stage are quantified in this work and the results are shown as GHG emissions breakdowns.

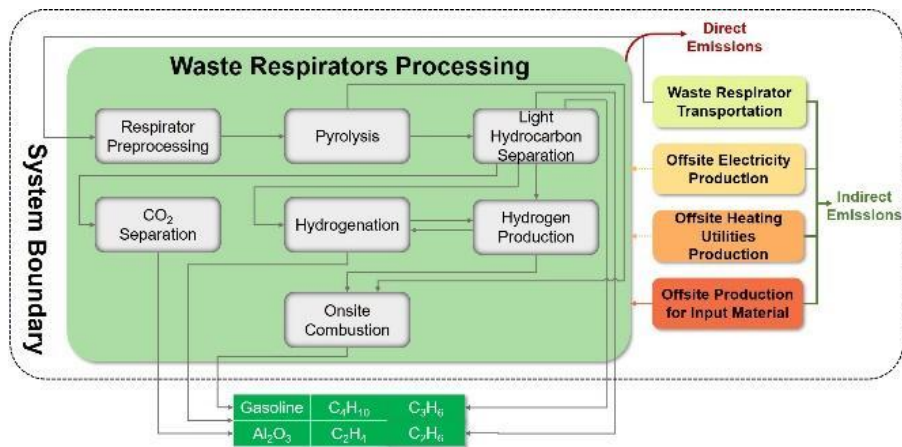

Figure 2. System boundary of a cradle-to-gate LCA for the waste respirator processing system.

3.2. TEA Methodology

We consider the capital expenditure (CAPEX) and operating expenditure (OPEX) to evaluate the economic viability of establishing the respirator processing system in terms of the net present value (NPV), payback year, and internal rate of return (IRR). CAPEX includes the direct capital, indirect capital, working capital of all equipment units, and the land cost used for setting up the processing system (Gong and You, 2018). OPEX includes the cost of transporting waste respirators, feedstock cost, utility cost, cost of operations and maintenance (O&M), property tax and insurance (PT&I), general expense, and income tax. The linear depreciation method is adopted to calculate the depreciation cost. Notably, the net present value (NPV) is calculated via subtracting the CAPEX from the summation of annualized cash flow in each operating year. The direct capital costs are extracted from Aspen-Plus Capital Cost Estimator.

4. Results and Discussion

4.1. TEA Results of the Waste Respirator Processing System

We present the breakdowns of CAPEX and OPEX of establishing the waste respirator processing system (near Citiwaste Medical Waste Disposal) in Figure 3. Notably, the total capital investment (\$16.31 million) is the major contributor to the total expenses, which

is further broken down into four categories, namely the total installation cost, total indirect capital, land cost, and working capital. The income tax is another major contributor (\$14.14 million), so that the high profitability of the waste respirator processing system is demonstrated. Specifically, the high indirect capital (\$5.82 million) is owing to the high costs for the procurement and installation of various equipment units and reactors (\$9.71 million). Owing to various distillation units and the refrigeration cycle to maintain cryogenic conditions when separating methane, the installed cost of the light hydrocarbon separation section (\$3.21 million) mainly contributes to the total installation cost, as shown in Figure 3. The installed costs for other sections are also shown in Figure 3.

The feasibility of establishing the waste respirator processing system can be illustrated in terms of the payback time of seven years, and an IRR of 21.5%. This high economic performance is mainly contributed by the various products converted from waste respirators, as well as the heat integration that minimizes the utility usage.

Figure 3. CAPEX, OPEX, and installed cost breakdowns.

4.2. LCA Results of the Waste Respirator Processing System

The direct emissions from the offsite combustion section and indirect emissions share 56% and 44% of total emissions, respectively. The indirect emissions can be further broken down and the major contributor to the indirect emissions is from the offsite production for inlet material (56% of indirect emissions). Moreover, GHG emissions from the offsite production of steam contribute most emissions (91.11%) among the offsite production for inlet materials, which due to the massive usage of steam in the sterilization system. Specifically, the unit GHG emissions of the respirator processing system is 12.93 kg CO₂-eq/thousand respirators, which reduces by 59.08% compared to the incineration-based system (31.60 kg CO₂-eq per thousand respirators). Hence, it is viable to establish a respirator processing system with high economic profitability and the potential to mitigate climate change.

5. Conclusion

In this work, we developed and proposed a novel and effective waste respirator processing system to protect public health and mitigate climate change. The waste respirator processing system included seven sections to convert waste respirators into various products. TEA results deciphered the economic viability for setting up the waste respirator processing system in terms of the payback time of seven years with an IRR of

21.5%. LCA results illustrated the potential of climate change mitigation by showing a reduction of GHG emissions by 59.08% compared to the incineration-based system.

Abstract

Estimation of Distribution Algorithms (EDAs) are interesting evolutionary methods; they have the characteristic of using an explicit distribution model, instead of mutation and crossover operators. In particular, Univariate Marginal Distribution Algorithms (UMDA) are some of the simplest distribution-based methods. In this work UMDA is used to design and optimize a shell-and-tube heat exchanger. To model the heat exchanger, Kern method and the Bell-Delaware method are employed. It has been found that UMDA has an inferior performance when compared with other metaheuristic algorithms. Nevertheless, other EDAs may lead to better results, which is part of future research.

Keywords: Heat exchanger, optimization, metaheuristic, estimation of distribution algorithm, Bell-Delaware.

1. Introduction

Heat exchangers are auxiliary process equipment that are necessary in almost every industry. Its main purpose is to recover energy from a process stream. Among the different available heat exchanger technologies, the shell-and-tube heat exchanger (STHE) is the most commonly used by industry. STHEs have some advantages, such as standardized design and building procedures, good heat transfer area/equipment volume ratio, and enough robustness to support high operational temperatures and pressures. Different methodologies to design STHEs can be found in open literature. Some of the most widely used are the Kern's and the Bell-Delaware methods. For both methods, many different STHEs designs can be calculated to satisfy the same energetic criteria. Therefore, it is necessary to perform an optimization routine to identify the best possible design according to an objective function.

The optimization of a STHE is not a trivial problem. Both design models contain non-convex, non-continuous, non-differentiable functions. In addition, they depend on continuous and discrete design variables. This results in a mixed-integer non-linear problem, where many local optima could exist. Deterministic procedures have been used to find optimal designs for this kind of equipment, as done by Yang et al. (2020), where a disjunctive mathematical model is proposed and considers five different heat transfer enhancement techniques. Recently, Kazi et al. (2021) developed a discretized differential algebraic equation model that can be combined with logarithmic mean temperature difference model to produce optimal STHes. Other reliable alternative is the use of evolutionary strategies to obtain optimal designs; such metaheuristic techniques does not require model adequation. Evolutionary Algorithms (EAs) are a class of optimization methods inspired in the Darwinian theory of survival of the fittest. These methods employ operators such as selection, crossover, and mutation. The different parameters of the operators must be tuned before solving an optimization problem; this represents an optimization problem in itself. To avoid the tuning procedure, EDAs were proposed as an alternative by Larrañaga (2002). In EDAs, there are neither crossover nor mutation operators. Instead, the new population (solutions) are created from an explicit probability distribution, that is built from a set of selected individuals of the previous generation. In EDAs, the interrelations of the design variables are expressed through the joint probability distribution. UMDA is a type of EDA that uses the simplest model to calculate the joint probability distribution; this model does not consider the interdependence between variables. It is reported that UMDA do not has a good performance working with non-linear problems and with problems with significant dependencies. In this work it is used as a starting point to be further compared with more complex EDAs that could work better to solve heat transfer problems.

Some works have used evolutionary strategies to optimize STHes; for example the proposal by Ponce et al. (2006) where genetic algorithms (GAs) were used, or the approach of Xiao et al. (2019) where the simultaneous design of a heat exchanger network and STHes are performed using a hybrid genetic algorithm/simulation annealing method. To the author's knowledge, distribution-based algorithms have not been used to optimize STHes. Thus, in this work a STHE is designed and optimized for a case study. Kern's and the Bell-Delaware methods are used to model the heat exchanger. As an optimization algorithm UMDA is selected, and its performance is compared with other metaheuristic methods previously used.

2. Shell-and-tube heat exchanger models

The Kern and the Bell-Delaware methods are widely used to design STHes. Kern's method gives good predictions of heat-transfer coefficients for standard designs. The prediction of the pressure drop is less accurate, because this variable is more affected by shell-side leakages, and the method does not consider it (Sinnott, 2005). On the other hand, the Bell-Delaware methodology provides a better prediction of all variables. In this method, multiple geometrical variables are calculated creating a highly non-linear search space. Also, five parameters are used to calculate the shell-side heat transfer, h_s , according to equation 1.

$$h_s = h_{id} J_c J_l J_b J_s J_r \quad (1)$$

where h_{id} is the ideal heat-transfer coefficient. J_c is the correction factor for baffle configuration. J_l is the correction factor for baffle leakage. J_b is the correction factor for bundle and pass partition bypass streams. J_s is the correction factor for baffle spacing at inlet and outlet. Finally, J_r is the correction factor for adverse temperature gradient in laminar flows.

The area of the heat exchanger is calculated for both models with equation 2. Q is the heat transfer rate, T_{LMTD} is the logarithmic mean temperature difference, F is a correction factor for T_{LMTD} , and U is the overall heat transfer coefficient computed with equation 3.

$$A = \frac{Q}{UFT_{LMTD}} \quad (2)$$

$$U = \frac{1}{\frac{1}{h_s} + R_{fs} + \frac{d_o \ln \left(\frac{d_o}{d_i} \right)}{2k_w} + R_{ft} \frac{d_o}{d_i} + \frac{1}{h_t} \frac{d_o}{d_i}} \quad (3)$$

Additionally, h_t is the tube-side heat transfer coefficient, d_i is the tube internal diameter, d_o is the tube outer diameter, R_{fs} and R_{ft} are the fouling factors for shell and tubes, respectively. Kern's method can be found in Flynn et al. (2019), and the Bell-Delaware methodology is reported by Shah and Sekulic (2003).

Commonly, the total annual cost (TAC) is used as an optimization criteria, and it depends on multiple variables and parameters as shown in equation 4 (Smith, 2005). TAC is calculated with the fixed cost, C_f , and operational cost, C_{op} , which are computed with equations 5 and 6, respectively. Also, C_p is the purchase cost of the STHE, f_m , f_p and f_c are factors to consider the construction material, operating pressure and operating temperature, respectively.

$$TAC = C_f \frac{r(1+r)^n}{(1+r)^n - 1} + C_{op} \quad (4)$$

$$C_f = C_p f_m f_p f_c \quad (5)$$

$$C_{op} = \frac{(E_s + E_t) Ec H_r}{1000} \quad (6)$$

E_s and E_t are the required pumping power (W) for shell and tube side. Ec , is the cost of the energy required for pumping. H_r is the number of operational hours per year, n is the projected lifetime, and r is the interest rate.

3. Univariate Marginal Distribution Algorithm

UMDA is a population-based evolutionary algorithm for optimization. It belongs to EDAs, which do not use operators such as mutation nor crossover to diversify the population and better explore the search space; instead, it uses an explicit model to estimate the joint probability distribution. The joint probability distribution is factored as a product of independent univariate marginal distribution, as shown in equation 7. p is the joint probability distribution, p_i is the univariate marginal frequency (Larrañaga, 2002).

$$p(X) = \prod_{i=1}^n p_i(x_i) \quad (7)$$

The selection of the sampled individuals is a very important part of this algorithm; for this work truncation is used. UMDA begins with a random population, which is ranked according to the values obtained from the objective function evaluation. Then, the best half of the population is used to build the distribution model; the population of the next generation is obtained from this model.

4. STHE optimization

The case study has been taken from Wildi-Tremblay and Gosselin (2007). It is required to design a STHE with a flow rate of 18.8 kg/s of cooling water. The inlet temperature is 33 °C and the outlet temperature is 37.2 °C. The hot fluid is naphtha with an inlet temperature of 114 °C, and 40 °C for the outlet temperature. Water is placed in tube-side because of its greater fouling resistance. The construction material for tube and shell side is stainless steel and carbon steel, respectively. Constraints are applied according to equations 8, 9 and 10, where ΔP_s and ΔP_t are the pressure drop in shell and tube side, respectively. v_t is the fluid velocity in tube-side, L is the heat exchanger length, and D_s is the diameter of the heat exchanger.

$$\Delta P_s, \Delta P_t \leq 70,000 \text{ Pa} \quad (8)$$

$$1 \text{ m/s} \leq v_t \leq 3 \text{ m/s} \quad (9)$$

$$L/D_s < 15 \quad (10)$$

The Bell-Delaware methodology depends on 11 design variables, while Kern's method on 7. Table 1 shows the established boundaries for each continuous variable. In Table 2 the allowed values for discrete variables can be found. The possibility of designs with multiple shells is not considered at this stage of the study.

Table 1. Limits of continuous design variables.

Design variable		Lower bound	Upper bound
Diameter of shell	D_s	300 mm	1,000 mm
Outer diameter of tube	d_o	15.87 mm	63.5 mm
Baffle spacing at center	L_{bc}	$0.2D_s$	0.55 mm
Baffle spacing at the inlet and outlet	L_{bo}, L_{bi}	L_{bc}	$1.6L_{bc}$
Tube-to-baffle diametrical clearance	δ_{tb}	$0.01d_o$	$0.1d_o$
Diametrical clearance of shell-to-baffle	δ_{sb}	$0.01D_s$	$0.1D_s$
Outer diameter of tube bundle	D_{otl}	0.8 ($D_s - d_{sb}$)	0.95 ($D_s - d_{sb}$)

Table 2. Allowed values used in discrete design variables.

Design variables	Allowed values
Tube pitch	P_t [1.25 d_o , 1.5 d_o]
Tube layout angle	TL [30°, 45°, 90°]
Baffle cut	B_c [25%, 30%, 40%, 45%]
Number of tube passes	s [1, 2, 4]

The equations 11 and 12 show the objective function for each method.

$$\min TAC = f(D_s, d_o, P_t, TL, N_p, B_c, L_{bc}, L_{bo}, d_{sb}, d_{tb}, D_{otl}) \quad \text{Bell-Delaware} \quad (11)$$

$$\min TAC = f(D_s, d_o, TL, N_p, L_{bc}, d_{sb}, D_{otl}) \quad \text{Kern's method} \quad (12)$$

If constraints are not satisfied a penalty is applied to the TAC; the penalized objective function is shown in equation 13. r_1, r_2, r_3 and r_4 are the penalty values, and ΔP_a is the maximum allowed pressure drop (70,000 Pa). To estimate the cost, 5,000 operational hours were assumed, an interest rate of 5%, a projected lifetime of 20 years, a pump efficiency equal to 0.85, and an electricity cost of 0.1 USD/kWh (Wildi-Tremblay and Gosselin, 2007).

$$\begin{aligned} \text{fobj} = \text{TAC} + r_1 \max[(\Delta P_s - \Delta P_a), 0] + r_2 \max[(\Delta P_t - \Delta P_a), 0] & \quad (13) \\ + r_3 [\max\{(1 - v_t)\} + \max\{(3 - v_t)\}, 0] \\ + r_4 \max[(L/D_s - 15), 0] \end{aligned}$$

5. Results

Fluid properties were computed at average temperature. For the UMDA, 50 individuals and 50 iterations were considered. The selection operator uses truncation with 50% of the total population. 30 experiments were done to obtain basic statistical information as the average and the standard deviation of the TAC. The required time to conduct one experiment for the Bell-Delaware and Kern’s method are 3.95 s and 4.01 s, respectively.

When Bell-Delaware methodology is used, the best design has a TAC of 4,093.96 USD/year, the C_{op} is 156.73 USD/year and the C_f is 3,937.23 USD/year. The TAC of the best design when Kern’s method is used is 3,613.88 USD/year, C_{op} and C_f are 286.46 USD/year and 3,327.41 USD/year, respectively. Table 3 reports the results of some important variables for both models, and its comparison with the results reported in a previous work (Lara-Montaña et al., 2020) where particle swarm optimization (PSO) and grey wolf optimization (GWO) were used. From this comparison it is evident that for both STHes models UMDA has a poor performance with respect to other metaheuristic algorithms. The optimization algorithms used in the referenced work have a better capability to avoid local optima. This can be inferred from the average TAC value that is 4,234.35 USD/year for PSO and 4,074.93 USD/year for GWO.

Table 3. Best design found and comparison with other methods (Lara-Montaña et al., 2020).

Parameter	D_s	d_o	N_t	A	L	P_t	TL	s	L_{bc}
Units	mm	mm		m^2	m	mm	°		mm
Bell-Delaware (this work)	311.83	15.87	149	34.23	4.60	19.83	90	1	79.65
Kern’s method (this work)	300.00	15.87	195	25.76	2.80	18.75	30	1	87.79
Bell-Delaware (PSO)	302.40	15.87	144	32.56	4.56	-	-	-	-
Bell-Delaware (GWO)	302.40	15.87	144	32.56	4.56	-	-	-	-
Kern’s method (PSO)	314.10	15.00	672	25.95	2.55	-	-	-	-
Kern’s method (GWO)	314.80	15.00	672	26.03	2.54	-	-	-	-

Parameter	L_{bo}	B_c	δ_{tb}	δ_{sb}	D_{atl}	C_{op}	C_f	TAC
Units	mm	%	mm	mm	mm	USD/year	USD/year	USD/year
Bell-Delaware (this work)	120.65	15	0.18	3.11	289.48	156.73	3,937.23	4,093.96
Kern’s method (this work)	-	-	-	-	239.22	286.46	3,327.41	3,613.88
Bell-Delaware (PSO)	-	-	-	-	-	160.51	3,865.99	3,966.50
Bell-Delaware (GWO)	-	-	-	-	-	160.51	3,806.01	3,966.53
Kern’s method (PSO)	-	-	-	-	-	263.34	3,262.45	3,525.80
Kern’s method (GWO)	-	-	-	-	-	257.76	3,275.97	3,525.73

After 30 experiments, an average TAC of 4,674.12 USD/year and a standard deviation of 296.68 USD/year is calculated when the Bell-Delaware model is employed with the UMDA. From these results, it can be inferred that the optimization algorithm has a poor capability to avoid local optima. The value of the standard deviation is moderate, but the difference between the best TAC and the average TAC is large. This indicates that in most of the experiments the algorithm converges in a solution far from the global

optima. Only for one of the experiments the minimum reported value of TAC was reached. For Kern's method, the average TAC and standard deviation are 3,701.81 USD/year and 44.72 USD/year, respectively. The performance of the optimization algorithm is better when Kern's method is used due its lower non-linearity and the lower number of design variables implied, compared with the Bell-Delaware method. Figure 1 shows the behavior of the TAC in each iteration for both design methods. It is evident that for Kern's method the optimization algorithm converges in less than 10 iterations. When the Bell-Delaware method is employed the UMDA method rapidly find better solutions in the first iterations, but after 25 iterations the convergence slows down, being unable to find the best design in 50 iterations.

Figure 1. Behavior of the TAC for both design methods

6. Conclusion

This work explores the viability of using EDAs to solve heat transfer problems. From the results obtained it is clear that UMDA is not a good option to optimize STHes, due its poor capacity to work with non-linear models. This optimization method uses a joint probability that does not take into account dependencies between variables. Better results could be found if a more complex joint probability were employed. It is clear that the difference in the complexity of the design methods impacts on the efficiency of the optimization algorithm. When Kern's method is used, the average TAC is closer to the best TAC. This does not occur for the Bell-Delaware method that is more complex and depends on more design variables. Although the results reported in this work demonstrate that UMDA is not capable of optimizing STHes efficiently, other EDAs could have better performance by using a joint probability distribution that consider dependencies between variables.

Abstract

Microgels are functional polymers with diverse applications synthesized by free radical polymerization using an initiator, monomers, and cross-linker as reactants. While monomers and cross-linker are incorporated into the microgel during the synthesis, initiator is left in the reactor due to its slow decomposition rate. The removal of unreacted initiator is a challenging and time-consuming post-synthesis procedure. Therefore, we use model-based dynamic optimization to determine synthesis procedures that reduce in the final concentration of unreacted initiator. The dynamic optimization requires a mechanistic model of the microgel synthesis, that needs to consider the inhibition of residual oxygen in the reactor at the beginning of the synthesis. Residual oxygen might inhibit the initiation of the synthesis when initiator concentrations are sufficiently low. We extend our existing model with the effect of an initial oxygen inhibition. We then use dynamic optimization to minimize the initial initiator concentration, while maintaining process and quality constraints. The considered product quality constraint is the hydrodynamic radius of the microgel, which must not change by more than 5 %. The determined synthesis procedure shows a 76 % reduction in the final concentration of unreacted initiator in comparison to the reference case, while maintaining the reference microgel hydrodynamic radius. The synthesis time, however, is 48 % longer than the synthesis time of the reference case. Hence, there is a trade-off between the final initiator concentration and the duration of the microgel synthesis demonstrating the value of dynamic optimization for the determination of optimal synthesis conditions valuable.

Keywords: microgels, initiator, dynamic optimization, model-based synthesis

1. Introduction

Microgel syntheses involve initiator, various monomers, cross-linker and other additives like surfactant (Pich and Richtering, 2011). Syntheses are separated in the stages of reactant preparation, the polymerization reaction, and purification of the microgel products that includes the removal of unreacted reactants in the reactor. Low amounts of unreacted monomer and cross-linker are left in the reactor after polymerization, as their

conversion is typically high (Jung et al., 2019a). The conversion of the initiator, however, is low due to high initial initiator concentrations in the reactor that are commonly used in experiments (Wu et al., 1994; Virtanen and Richtering, 2014; Ksiazkiewicz et al. 2020). The unreacted initiator has to be removed from the reactor after the reaction. The removal causes lengthy purification processes. With the perspective of producing microgels on a larger industrial scale, the surplus in initiator also causes significant costs for the large amounts of initiator used. Hence, it is desirable to determine the minimum amount of initiator required for the microgel synthesis. We propose here to use model-based dynamic optimization to determine a synthesis procedure that ensures high monomer and initiator conversion at the end of the synthesis. To analyze the effects, we define a reference experiment, which is a batch microgel syntheses based on 2,2'-Azobis(2-methylpropionamide) dihydrochloride (AMPA) as initiator ($c_i(t_0) = 1.23 \text{ mol m}^{-3}$), *N*-vinylcaprolactam (VCL) as monomer ($c_{VCL}(t_0) = 106.1 \text{ mol m}^{-3}$), and *N,N'*-Methylenebisacrylamide (BIS) as cross-linker ($c_{BIS}(t_0) = 2.59 \text{ mol m}^{-3}$), at 70 °C (Janssen et al., 2018).

Models of microgel syntheses have been previously investigated by multiple authors, e.g., Hoare and McLean (2006), Hoare and Pelton (2007), Janssen et al. (2018), Jung et al. (2019a,b). However, these models do not take the inhibition caused by residual oxygen (Bhanu and Kishore, 1991) in the reactor into account, which may become relevant at low initial initiator concentrations. The effect of oxygen on radical polymerization reactions has been studied in the past. Two theories towards the mechanism behind oxygen inhibition have mostly been proposed: (A) oxygen terminates active radicals directly, or (B) oxygen polymerizes as co-polymer into the polymer chains and the rates of propagation and termination reactions cause the inhibition of the polymerization reaction (Schulz and Henrici, 1956; Henrici-Olivé and Olivé, 1957; Mayo, 1958; Garton and George, 1973; Bhanu and Kishore, 1991).

For microgels, only few experimental results on the effects of oxygen on the microgel synthesis have been reported. The online calorimetric and Raman spectroscopy measurements conducted by Janssen et al. (2018) reveal an inhibition phase or induction period at the beginning of the synthesis between the addition of the initiator and the onset of the polymerization reaction. They postulate that residual oxygen causes the induction period at the beginning of the synthesis. For the estimation of model parameters based on these measurements, they remove the induction period, as the mechanistic model does not include the oxygen inhibition.

Here, we include the oxygen inhibition into our previously published microgel synthesis models (Jung et al., 2019a,b). Following, we present the results of a dynamic optimization with the aim of obtaining low final concentration of unreacted initiator.

2. Model of the microgel synthesis including oxygen inhibition

We extend the previously published reaction kinetics (Jung et al., 2019a) and microgel size modeling (Jung et al., 2019b) by the oxygen inhibition. We assume that oxygen terminates active radical chains and thereby inhibits the polymerization reaction. The only reaction that is added is the termination of active radical chains with oxygen, which terminate active polymer chains and make them inactive towards propagation reactions

where k_{t,O_2} is the rate constant of the termination reaction with oxygen and r_{t,O_2} is the relative rate constant of the termination reaction with oxygen $r_{t,O_2} = \frac{k_{t,O_2}}{k_{p11}}$. Hence, we only require one kinetic rate constant to be estimated with the assumption that the rate of termination with oxygen is independent of the end group of the active radical chain.

For high values of r_{t,O_2} , an induction period develops at the beginning of the synthesis. For values above $r_{t,O_2} = 10^3$ the induction period does not change considerably, as the inhibition reaction is then limited by the number of active radical chains available; the inhibition period is much faster than the polymerization reactions. For values of r_{t,O_2} between 1 and 10^3 the inhibition reaction has approximately the same order of magnitude as the polymerization reactions. Hence, both reactions occur simultaneously causing the shape of the flow of reaction enthalpy to change. For values below $r_{t,O_2} = 10^{-1}$ no effect of the inhibiting oxygen shows in the simulation, the polymerization reactions are faster than the inhibition reaction. Hence, we set the value of the inhibition for the following simulations that the parameter is equal to $r_{t,O_2} = 10^4$.

3. Dynamic optimization

Our main aim in performing dynamic optimizations is to determine synthesis conditions that allow for low final concentration of unreacted initiator at the end of the reaction. However, we also investigate the effect of the changes in the synthesis conditions on the microgel hydrodynamic radius and the synthesis duration.

The optimization problem to be solved is

$$\min_{t_{end}, T_R(t), c_I(t_0)} c_I(t_{end}) \quad (2a)$$

$$\text{s. t. model equations, initial conditions} \quad (2b)$$

$$10^{-5} \text{ mol m}^{-3} \leq c_I(t_0) \leq 2 \text{ mol m}^{-3} \quad (2c)$$

$$60 \text{ }^\circ\text{C} \leq T_R(t) \leq 80 \text{ }^\circ\text{C}, t \in \Gamma \quad (2d)$$

$$98 \% \leq \xi_M(t_{end}) \leq 99 \% \quad (2e)$$

$$\frac{R_{\text{gel}}(t_{end}) - R_{\text{gel,ref}}}{R_{\text{gel,ref}}} \leq 0.05 \quad (2f)$$

$$500 \text{ s} \leq t_{end} \leq 10^4 \text{ s} \quad (2g)$$

Equation (2a) is the minimization of the concentration of initiator at the end of the synthesis. Equations (2b) are the modeling equations and initial conditions of the state variables that are not degrees of freedom to the optimization problem. Equations (2c) – (2d) bound the controls (degrees of freedom). The initial initiator concentration commonly used in laboratory experiments is on the order of 1 mol m^{-3} ; hence, we allow this order of magnitude and values that are up to five orders of magnitude lower, as we expect the initial initiator concentration to decrease to allow for full conversion of the initiator. Equations (2e) – (2f) are the constraints to the reactant conversions. The conversion of the monomer is set to be between 98 % and 99 % to ensure that a high conversion of monomer is achieved. Constraint (2f) forces the hydrodynamic microgel

radius to be within a range of $\pm 5\%$ around the reference value. Constraint (2g) ensures that the duration of the synthesis is between 500 s and 10^4 s.

The dynamic optimization problems are implemented and solved with the open-source software DyOS (Caspari et al., 2019). The model is integrated using the solver NIXE with absolute and relative tolerances set to 10^{-10} . The dynamic optimization problem is solved using the solver SNOPT with optimization tolerances set to 10^{-6} and feasibility tolerances set to 10^{-4} .

4. Results and discussion

To check the validity of the model extension, we compare simulation results with experimental data of microgel synthesis at two different temperatures and two different initiator concentrations (Janssen et al., 2019). The induction period for experiments run at low temperature are considerably longer than induction periods for experiments run at higher temperatures. The induction period increases for lower initiator concentrations. The agreement between model simulation and experimental data is good; especially the transition from the induction period to the polymerization is in good agreement between model and data.

We minimize the final initiator concentration; the obtained value is 0.216 mol m^{-3} . The determined initial concentration of initiator is equal to 0.283 mol m^{-3} , which translates to a final conversion of 23.9 %. Hence, the final concentration is higher, and the final conversion is lower than the values achieved in the previously presented optimization cases. The reason for this is the constraint on the microgel hydrodynamic radius. The determined synthesis procedure yields microgels with a hydrodynamic radius that is within 5 % of the hydrodynamic radius of the microgel synthesized in the reference case. The final obtained radius is at 179 nm, which is just 5 % larger than the microgels obtained in the reference case. Hence, to obtain microgels with an hydrodynamic radius that is in the same range as in the reference case, The final initiator concentration is considerably lower than the reference case. However, the synthesis duration increased considerably to 1140 s in comparison to the reference case due to the lower concentration of initiator.

Figure 1 presents selected state variables over the synthesis time. The oxygen inhibition causes the monomer conversion to increase only after an induction period of approximately 550 s. The induction period can also be observed in the simulation of the microgel radius, as the microgel radius only starts to increase considerably after the induction period has passed. The reactor temperature is kept at the lower bond of 60 °C until all oxygen has reacted with active radical chains. Then the reactor temperature is raised to the upper bond of 80 °C for the rest of the synthesis. Comparing these results to the reference case, we find that we determined a synthesis procedure that yields microgels with the same hydrodynamic radius, while we reduced the concentration of remaining initiator at the end of the synthesis from 0.93 mol m^{-3} in the reference case to 0.216 mol m^{-3} in the determined optimal synthesis, which corresponds to a 76.8 % reduction. The synthesis time, however, increases from 770 s to 1140 s, which corresponds to a 48.1 % increase in comparison to the reference case. We expect, however, that the reductions in cost due to the lower amounts of initiator used and the expected simplified purification of microgels at the end of the synthesis makes up for the

increase in synthesis time in comparison to the reference case. An additional decrease of the synthesis duration may be achievable by reducing the concentration of residual oxygen at the beginning of the synthesis. Currently, almost half of the synthesis time is used to deplete the residual oxygen in the reactor. An additional optimization showed that tightening of the constraints on the hydrodynamic microgel radius causes the initial initiator concentration to be higher and the reactor temperature to increase earlier.

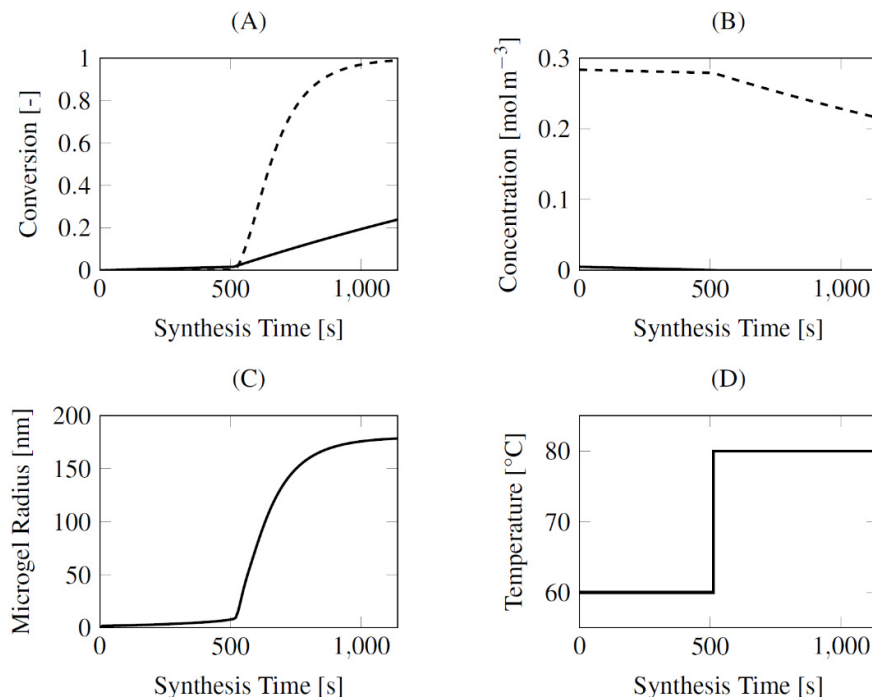

Figure 1: Dynamic optimization results considering oxygen inhibition. (A) Conversion of initiator (solid) and monomer (dashed); (B) Oxygen concentration (solid) and initiator concentration (dashed) in the reactor; (C) Hydrodynamic microgel radius; (D) Reactor temperature.

5. Conclusions

We propose to use the dynamic optimization for microgel synthesis with the aim of achieving a low concentration of unreacted initiator at the end of the reaction. In the optimization, we also consider the induction periods at the beginning of the syntheses caused by oxygen inhibition. Therefore, we extended the previously presented model of the microgel synthesis with reaction kinetics of the oxygen inhibition. We achieved good agreement with the induction periods observed in experiments run at different reactor temperatures. We minimize the final concentration of initiator in the reactor, while constraining the hydrodynamic microgel radius to be within range of the reference

synthesis. The result is a synthesis procedure that allows a 76.8 % reduction in the final concentration of initiator, while maintaining the microgel size. However, the reaction time is increased to 1140 s.

Even though the predictions of the used mechanistic model have been validated in by us for various synthesis conditions in other publications, we advise to again validate the results of the optimizations presented here. Of special interest in the experimental validation is whether the final initiator concentration is in agreement with model simulation results and whether the predicted hydrodynamic microgel radius is met.

Abstract

Process intensification (PI) is a major area of interest for downstream processing in biorefineries, where dilute aqueous streams must be processed to separate and purify valuable components. For example, lactic acid (LA) purification faces these challenges as the feed consists of a dilute aqueous mixture of LA and other organic acids as impurities. These characteristics result in high energy requirements, large equipment, and multiple operations when considering conventional technologies. The combination of otherwise individual processing tasks is enabled by exploiting synergies following PI principles, which improves energy efficiency and reduces the processing equipment's size. This study presents a new conceptual design of an intensified dual reactive dividing wall column (R-DWC), applied to lactic acid purification. This CAPE study is the first to investigate the effect of impurities that disrupt the reaction and the separation. The approach taken in this study is a mixed methodology based on a decomposition approach, shortcut calculations, and rigorous process simulation in Aspen Plus. The intensification and the heat integration of this new realistic process led to a more eco-efficient operation in terms of material intensity (over 50 % reduction), water consumption (35 % reduction) and energy intensity (25 % reduction) compared to a 4-column flowsheet that does not account for reactive impurities and additional azeotropes. The recovery (>95 %) and purity (88 % w/w LA) targets were successfully achieved, and the acid impurity was effectively removed.

Keywords: process intensification, reactive distillation, process simulation, lactic acid

1. Introduction

Process intensification (PI) is a discipline within chemical engineering that addresses improvements in functional / phenomena / unit levels, occurring at various stages to improve process performance. For example, major enhancements have been shown by applying PI technologies to the downstream processing in biorefineries using reactive distillation (RD) (Kiss et al., 2016). Further intensification of RD attempts to overcome its inherent limitations, such as a restricted range of operating conditions and complex scaling-up. To overcome RD's limitations, exploiting additional driving forces can expand its applicability to systems that cannot be handled by RD only (Kiss et al., 2019). Therefore, the design of further intensified technologies to promote better utilization of resources (e.g. energy, water, raw materials) improves the process' eco-efficiency and reduces the equipment size, while maintaining the targets of purity and recovery, which encourages the investigation of intensified processes (Keil, 2018).

The synergy between reaction and separation in RD can be exploited by adding extra intensification features. For example, a reactive dividing wall column (R-DWC) reaches the second level of intensification by combining two already intensified technologies: DWC and RD (Weinfeld et al., 2018). R-DWC offers benefits such as increased energy efficiency, reduced number of vessels, handling of multiple outlet streams and feasible operation via decentralized control (Egger and Fieg, 2019; Mueller and Kenig, 2007). These attributes have been widely studied in academia, and the research outputs suggest that R-DWC can improve chemical processing (Kiss et al., 2019).

This paper develops the conceptual design of a novel dual R-DWC based on a decomposition approach, applied to a case study to recover and purify LA from a fermentation broth. The dual R-DWC features the esterification of the acids with methanol to facilitate the separation of esters, and the hydrolysis to recover the purified LA. For this study, a diluted mixture containing water, LA, and succinic acid was used to demonstrate the novel configuration in a flowsheet context. The kinetic data for the esterification of LA with methanol was taken from the study of Sanz et al. (2004). Also, the esterification of succinic acid with methanol and LA oligomerization were considered (Asthana et al., 2006). Amberlyst 36 ($T_{\max} = 150\text{ }^{\circ}\text{C}$) catalyst was selected for this study as previous studies indicated that Amberlyst 15 ($T_{\max} = 120\text{ }^{\circ}\text{C}$) limited the operating windows for RD (Su et al., 2013).

2. Problem statement

A primary concern of the downstream processing in biorefineries is handling large volumes of liquid containing mostly water and the target component. In addition, the removal of impurities in low concentrations requires energy-intensive processes consisting of various devices, usually of large size (Kiss et al., 2016). From the process design point of view, the development of efficient flowsheets has overseen the effects of impurities in the process performance, as process simulation research to date has not yet considered the effect of reactive impurities in the concentration of LA (Cho et al., 2008; Kim et al., 2017; Su et al., 2013). Experimental laboratory and pilot-scale studies have proven the simultaneous occurrence of the reactions of the target component and the impurities in the purification of organic acids. The evidence from these studies suggests that the impurity reaction can affect the heating and cooling needs due to the extra heat of reaction, introduce new azeotropes, require makeup of reactants, and promote operational issues such as blockage of outlet lines. To address this problem, this CAPE study is the first to investigate the effect of reactive impurities that disrupt the reaction in a novel dual R-DWC applied to purify bio-produced LA.

3. Conceptual design approach

The steps followed for the conceptual design of a novel dual R-DWC is depicted in Figure 1, and the procedure consists of a decomposition approach, shortcut models, and implementation of rigorous models.

3.1. Decomposition approach

A decomposition approach was applied to design an intensified unit that features three outlet streams (impurity, product, and excess water / methanol), and two different reactions (esterification and hydrolysis).

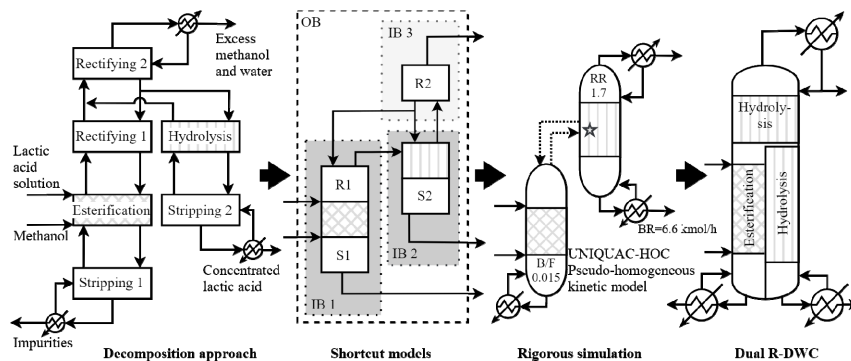

Figure 1: Methodological approach for the conceptual design of a dual R-DWC (OB: outer boundary, IN: inner boundary, B/F: bottom to feed ratio, RR: reflux ratio, BR: bottom rate)

First, the tasks and internal connections were identified: the esterification converts the organic acids into esters that are easier to separate, and the hydrolysis of the purified methyl lactate allows obtaining LA on specification. The rectifying and stripping sections remove excess compounds and reaction products to adjust the final product's composition and drive higher conversion in the reactive sections. For this case study, the heaviest cut was removed first, so the indirect sequence led to a side-stripper configuration. As the configuration proposed in this work includes two reactions, the returning stream's composition exiting the hydrolysis section depended on the vapor-liquid equilibrium (VLE) and the reaction rates. This consideration applied to the decomposition approach of dual-reactive systems differs from the one used for DWC and R-DWC, where only VLE data provides the composition of the returning stream.

3.2. Shortcut models

The tasks and interconnection identified were analyzed by defining system boundaries around the whole arrangement and grouping tasks to obtain initialization values. The grouping allowed evaluating a sub-system that contained one reaction only or a critical task that entailed a degree of freedom. For this arrangement, two inner boundaries included the esterification and hydrolysis reactions, and the top rectifying section contained the liquid split ratio. The mass balance calculations for each boundary allowed computing the interconnecting streams' values and defining operating variables such as liquid to feed ratio or reflux ratio to initialize a rigorous simulation.

3.3. Implementation of rigorous models

The simulation of the dual R-DWC was implemented in Aspen Plus v8.8 using two RadFrac modules in a thermally coupled indirect sequence leading to a partitioned side-stripper configuration. The values obtained from the shortcut calculations were used to set up the RadFrac modules separately. The observation of composition, temperature, and generation rate profiles combined with an update of the initial mass balances, accelerated a trial-and-error method to determine the initial number of reactive and non-reactive stages, location of the inlet and side-draw streams and catalyst holdup. Then, the interconnecting streams between the two RadFrac modules were implemented after updating the flowrates and compositions between iterations until reaching a match. A full flowsheet, including a preconcentrator unit and a methanol recovery column, was implemented in Aspen Plus, and the results provided key performance indicators.

4. Results and discussion

4.1. Conceptual design of a dual reactive dividing wall column

A sequential approach was used to implement the rigorous models in Aspen Plus, first building the esterification column, then implementing the hydrolysis column, and finally integrating the two with a thermally coupled arrangement.

The esterification column was initialized with the values gathered from the shortcut calculations. The base case was defined after varying variables such as the catalyst holdup, number of reactive and non-reactive stages, and feed location, so that a robust converged simulation accomplishes the performance indicators set for the esterification column: 99 % conversion of LA, low LA oligomers production, and near-to-sharp split between methyl lactate and dimethyl succinate.

The hydrolysis column was set up using the feed stream values from the simulated esterification column and the shortcut calculations' operating parameters. The number of reactive and non-reactive stages, the location of the inlet and side streams, and catalyst holdup were varied by tracking the performance indicators established for the hydrolysis section: methyl lactate conversion higher than 80 %, low methyl lactate loss in the top and bottom streams and the product specification (88 % w/w LA).

Figure 2 presents the concentration profiles in the liquid phase and the generation rates in the hydrolysis column. Figure 2a shows the initial configuration where the inlet stream entered the first top reactive stage. The liquid phase composition indicated that the upper rectifying stages were still rich in the reactants: water and methyl lactate. Then, by systematically changing the feed stream's location and observing the methyl lactate content in the top and bottom streams, Figure 2b clearly shows how the methyl lactate concentration in the liquid phase reduces towards the top and bottom ends. Figure 2c shows the generation rate profiles for lactic acid and methyl lactate with two different inlet stream locations. The most interesting aspect of this graph is how the feed stream's location can be facilitated by inspecting the column profiles.

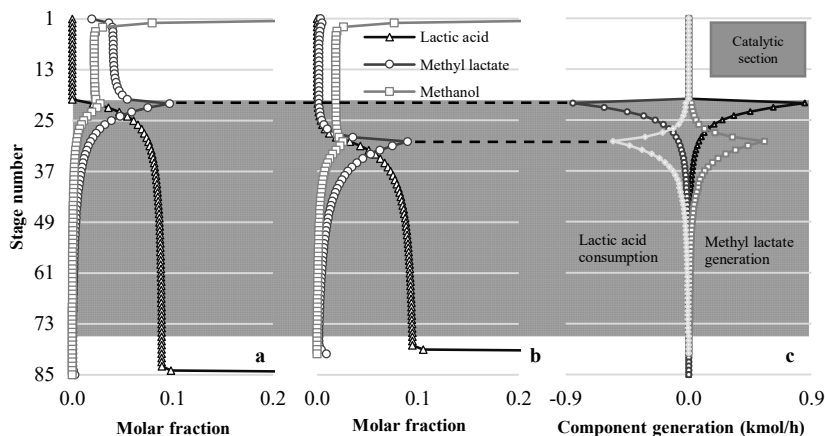

Figure 2: Liquid composition and component generation profiles in the hydrolysis column a) feed on the 1st reactive stage b) feed on the 10th reactive stage c) generation rate profiles

Figure 3: Process flowsheet for the pre-concentration and purification of lactic acid

An iterative procedure to match the vapor stream's composition exiting the esterification column and the returning liquid side stream into the esterification column was necessary to couple the two RadFrac modules. To facilitate a good convergence of the simulation, we generated the estimates of temperature, flowrate, and composition in the RadFrac modules, i.e., values of a previously converged simulation were used as starting values for a new run after a significant modification.

A pre-concentration operation in a flash vessel and a methanol recovery column were included to compare the novel configuration's performance with existing benchmark processes, as depicted in the flowsheet of Figure 3.

4.2. Key performance indicators

The performance of the flowsheet, including the novel dual R-DWC, was compared against two benchmark configurations that consist of a sequence of two reactive and two conventional distillation columns, and of one conventional, one reactive and one fully thermally coupled column between the hydrolysis and recovery sections (Kim et al., 2017; Su et al., 2013). The comparison is not straightforward because of the introduction of a more realistic approach by considering the esterification of succinic acid (in addition to LA) and the exploitation of additional heat recovery opportunities.

Table 1 presents the key performance indicators to evaluate the novel configuration's efficiency. Regarding the use of raw materials, considering the esterification of succinic acid resulted in an increase of the methanol makeup compared to the benchmark studies. However, the observed decrease in the methanol/LA feed molar ratio could be attributed to the solid catalyst that withstands higher temperatures, so less methanol is required to produce a quenching effect in the reactive section resulting in less methanol recirculating in the system. Also, the two benchmark studies introduced an additional water stream for the hydrolysis reaction. In contrast, the process developed in this study used the water produced in the first reaction by appropriately locating the vapor stream exiting the esterification column into the hydrolysis section, which resulted in a decrease in water consumption and material intensity. This process also achieved a higher LA recovery as milder temperatures in the hydrolysis section reduced oligomerization reactions. The direct heat integration in the dual R-DWC and the process-to-process heat recovery implemented in this study reduced the energy intensity in 25 % and 10 % compared to the benchmark technologies, respectively.

Table 1: Key performance indicators of the novel process and two benchmark processes

Parameter	Su et al. (2013)	Kim et al. (2017)	This work
Methanol makeup (kmol/h)	0.2	0.2	0.8
Water flowrate for hydrolysis (kmol/h)	14	14	0
Methanol/lactic acid feed molar ratio	4	4	3.3
Lactic acid recovery (%)	91.8	94.2	95.7
Material intensity ($\text{kg}_{\text{waste}}/\text{kg LA}$)	0.178	0.194	0.089
Water consumption ($\text{m}^3/\text{kg LA}$)	0.051	0.043	0.033
Energy intensity ($\text{MJ}/\text{kg LA}$)	14.9	12.6	11.2

5. Conclusions

This research provided insights for the conceptual design of a dual R-DWC using a combination of a decomposition approach, shortcut models, and rigorous simulations. The intensified dual R-DWC unit was successfully evaluated in a flowsheet for the pre-concentration and purification of lactic acid, including a more realistic approach by considering side reactions. The most interesting findings of this study were the effective removal of the impurity, the elimination of extra water for the hydrolysis reaction, and a more eco-efficient performance in terms of material, water and energy use.

Abstract

Energy efficiency studies have an important role in the petroleum industry in terms of environmental impacts and cost. In this context, distillation units are important process units in the refinery. Osuolale and Zhang (2018) pointed out they cause about 35 % of energy consumption. Energy analysis studies are useful in energy efficiency but remain incapable in some areas. Besides energy analysis in other words exergy analysis, which is related to the second law of thermodynamic, is a very powerful tool for detecting losses.

In this study, an exergy analysis study was carried out on the vacuum distillation unit located in TUPRAS Izmit Refinery. Vacuum distillation unit (VDU) processes heavy petroleum products from atmospheric distillation column. Heavy, medium, and light gas oil and vacuum residue are the products of VDU.

Vacuum distillation column was simulated in ASPEN HYSYS V10 in this study by using operational data and equipment information for exergy analysis. Energy and exergy analysis calculations were completed and case studies were carried out to examine the effect of various operational conditions on the exergy efficiency of the column in the ASPEN HYSYS. In order to see the effects of different operational conditions such as pump-around (PA) flowrate and return temperature for exergy efficiency on online platform, data was created by using of Aspen Simulation environment and an exergy prediction model was developed with machine learning models in R-Studio. Thus, support on exergy efficiency was provided with successful prediction models.

Keywords: exergy analysis, thermodynamics, vacuum distillation unit, modelling, machine learning model

1. Introduction

Energy efficiency is among the most focused topics in the industry recently. Feyzi and Beheshti (2017) stated that distillation columns, which are commonly used in chemical industry, are an energy intensive separation units. For instance, the USA alone has about 40,000 distillation columns, which consume about 6 % of the total US energy and they accounts for 40 - 60 % of the total energy use in chemical industry (Osuolale and Zhang, 2014). Therefore, designing energy efficient distillation systems and determining operational parameters that affect energy efficiency are important to minimize the energy consumption.

Rivero (2002) stated some questions such as how and where energy is degraded and how to reduce energy consumption need to be answered in order to clarify energy efficiency. To overcome this, thermodynamic analysis brings an analytic approach to the topic of energy efficiency. The First Law of Thermodynamics (FLT) is known as the law of the conservation of energy. This means that energy can be transformed, but it can be neither

created nor destroyed. The Second Law of Thermodynamics (SLT) state that the entropy of the system increases whenever any energy conversion or transfer occurs within a closed system. When comparing these laws, the first law has no knowledge of the thermodynamic process, which is related to its inability to completely convert heat to mechanical work. At this point, the concept of exergy emerges in relation to SLT and entropy (Dincer and Rosen, 2013).

Many researches focused on exergy analysis of distillation columns. Waheed and Oni (2015) improved the energy performance of crude oil distillation unit with using simulation of process techniques. As a result of these developments, both the energy and exergy efficiency of the column are increased by 4.0 and 1.6 %, respectively. Al-Muslim et al. (2003) conducted exergy analysis of single and two-stage crude oil distillation units for determining exergy losses and efficiencies. Overall exergy efficiencies of single and two-stage distillation units were found 14.0 and 31.5 %, respectively. Tarighaleslami et al. (2011) studied an atmospheric distillation unit based on the exergy analysis by changing streams and new configurations.

Simulation of process is an important tool for exergy analysis in terms of process analysis and design. The objective of this study is to present exergy analysis of vacuum distillation column in both current situation and various situation with changing operational conditions. Also, exergy analysis is supported neural network models to enhance model accuracy and reliability.

2. Exergy Analysis

The exergy of the system is described as the quantity of the ability to do work that is composed of mass, heat, work flows transfer to the system at a specified reference temperature. Exergy analysis determines the locations of the system's inefficiencies and exergy loss of system is reduced by improvements. Numerous engineers and researches prefer exergy analysis on the ground that it is an effective tool for analyzing, designing and developing processes and systems (Izyan and Shuhaimi, 2014).

The total exergy is obtained with the sum of physical and chemical exergy in Eq. (1). The physical exergy is related to difference of actual and reference conditions of enthalpy and entropy as Eq. (2).

$$Ex_{Total} = Ex_{physic} + Ex_{Chemical} \quad (1)$$

$$Ex_{physic} = (h - h_0) - T_0 \cdot (s - s_0) \quad (2)$$

Where the subscript "0" indicates the ambient conditions that are 25 °C and 101.325 kPa. Exergy efficiency in Eq. (3) gives information about the measure of approaching the ideal.

$$\psi = \frac{\sum Ex_{out}}{\sum Ex_{in}} = \frac{\text{Exergy in product outputs}}{\text{Exergy in inputs}} \quad (3)$$

3. Case Study

3.1. Process Description and Simulation

The aim of the vacuum distillation column of TUPRAS Izmit Refinery is to separate the atmospheric residue by three main streams. These are light vacuum gasoil (LVGO), a mixture of medium and heavy vacuum gas oil (MHVGO) and vacuum residue (VR).

A summary day that has exact laboratory data is chosen for the simulation. Unit operation values of summary day and equipment data sheets were used for performing the simulation. Figure 1 shows the computer-aided simulation of vacuum distillation column.

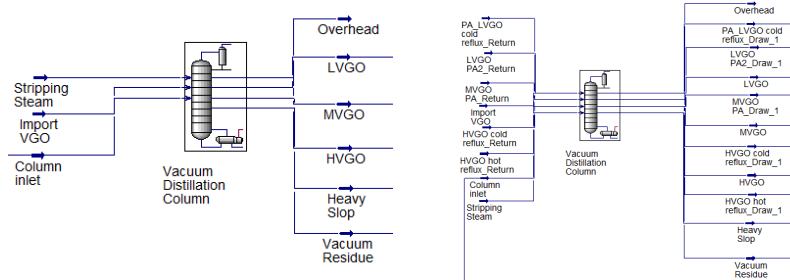

Figure 1: (a) Basic simulation of VDU; (b) Simulation of VDU with Pump-Arounds

3.2. Computer Aided Exergy Analysis

Exergy calculations were done via ASPEN HYSYS V10. The spreadsheets were created for exergy calculations in connection with the process simulation. In this study, the spreadsheets were prepared using the formula in Eq. (2) and exergy, which is directly calculated by ASPEN HYSYS. Moreover, the effect of operating parameters on exergy efficiency was examined by using “Case Studies” in ASPEN HYSYS. Lower and upper process control limit values like those given in Table 2 were entered in this case study to see the changing the exergy efficiency.

4. Machine Learning Model

Exergy efficiencies can be predicted by using the machine learning models without the need for complex exergy analysis calculations. Also, the effect of operating parameters on exergy efficiency for vacuum distillation column can be determined by means of these predictive models. Firstly, the parameters that affect exergy efficiency were determined to predict exergy efficiencies in “Case Study” of ASPEN HYSYS. Synthetic data was produced by using these parameters that input the model. In this study, Bootstrap aggregating (Bagging) and Random Forest models were used to predict exergy efficiencies in R-Studio. “Ipred” and “randomForest” packages of R-Studio were used to develop model for Bagging and Random Forest respectively. The data for both models were divided into training data (50 %), testing data (30 %) and unseen validation data (20 %). The machine learning model for exergy efficiency is of the following form:

$$\varphi = f(x_1, x_2, x_3)$$

Where φ is exergy efficiency, x_1 , x_2 , and x_3 are model inputs which are furnace exit temperature, MVGO PA temperature and HVGO cold PA temperature.

5. Results and Discussion

Exergy analysis results of VDU are summarized in Table 1. Results of Eq. (2) and exergy which is directly given by ASPEN was the same. Exergy efficiency was found to be 0.67 in current situation by the ratio of total output exergy to input exergy by using Eq. (3).

Table 1: Inlet and outlet streams exergy of vacuum distillation unit

	Stream	Mass flow rate (kg/s)	Specific exergy (kJ/kg)	Exergy rate (kJ/s)	Σ Exergy (kJ/s)
Inlet streams	Column inlet	108.944	356.442	38,832.357	
	Import VGO	25.655	34.514	885.456	39,717.814
	Stripping	0.000	1,002.207	0.000	
Outlet streams	Overhead	1.230	-8.903	-10.950	
	LVGO	10.832	23.709	256.821	
	MVGO	36.112	126.999	4,586.153	26,850.608
	HVGO	26.397	202.965	5,357.767	
	Heavy slop	13.222	263.466	3,483.599	
	Vacuum residue	46.806	281.531	13,177.218	

Table 2 shows the effect of operating parameters on exergy change between lower and upper bound. The first three parameters that affect the exergy most are shown in Table 2 are furnace exit temperature, MVGO PA temperature, HVGO cold PA temperature, respectively. These parameters were used to model input. Essentially, the change in operating PA parameters did not significantly affect the exergy efficiency. Also, Dincer and Rosen (2007) have reported that the change of temperature profile, which is controlled by the PA did not cause a significant change in exergy efficiency.

Table 2: The effect of operating parameters on exergy and energy efficiency change

Operating parameters	Lower-upper bound	Exergy efficiency change	% Absolute exergy change	Energy efficiency change	% Absolute exergy change
HVGO cold PA flow (t/h)	320-360	0.6555-0.6599	0.671	1.133-1.131	0.177
HVGO hot PA flow (t/h)	90-115	0.6560-0.6556	0.061	1.133-1.133	0.000
LVGO hot PA flow (t/h)	6.9-14.9	0.6560-0.6560	0.000	1.133-1.133	0.000
LVGO PA2 flow (t/h)	110-128	0.6552-0.6567	0.229	1.133-1.132	0.088
LVGO cold PA flow (t/h)	29.5-65.5	0.6499-0.6576	1.185	1.138-1.131	0.615
MVGO PA flow (t/h)	348-432	0.6565-0.6536	0.442	1.133-1.134	0.088
LVGO PA2 temperature (°C)	50-60	0.6570-0.6560	0.152	1.132-1.133	0.088
MVGO PA temperature (°C)	190-212	0.6431-0.6560	2.006	1.138-1.133	0.439
HVGO cold PA temperature (°C)	267-277	0.6571-0.6442	1.963	1.132-1.138	0.530
HVGO hot PA temperature (°C)	280-296	0.6529-0.6560	0.475	1.134-1.133	0.088
Furnace exit temperature (°C)	395-410	0.6655-0.6290	5.485	1.124-1.157	2.936

Figures 2 and 3 show the model performances in predicting the exergy efficiency of the vacuum distillation unit on the training, testing and unseen validation data. The sample numbers at Figures 2 and 3 consist of the case study of three parameters mentioned in the fourth section. Due to the temperature increase of the furnace output, which is one of these parameters, the exergy of column inlet stream increases depending on the increase enthalpy. Thus, the trend of the exergy efficiency in the Figures 2 and 3 decreases while the column input exergy increases considering Eq. (3).

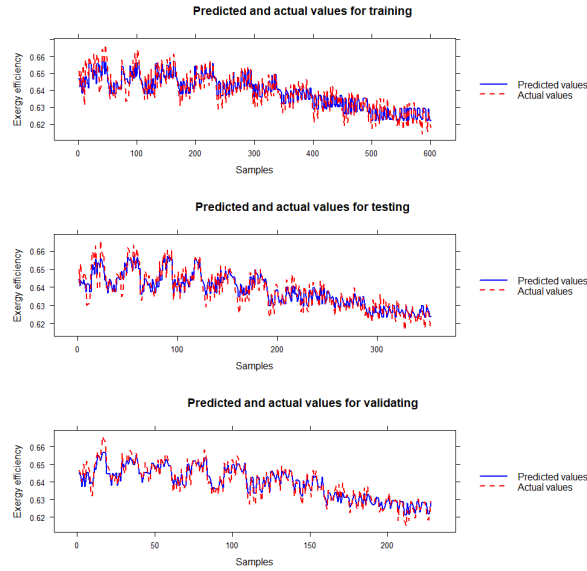

Figure 2: Actual and Bagging model predicted exergy efficiency for VDU

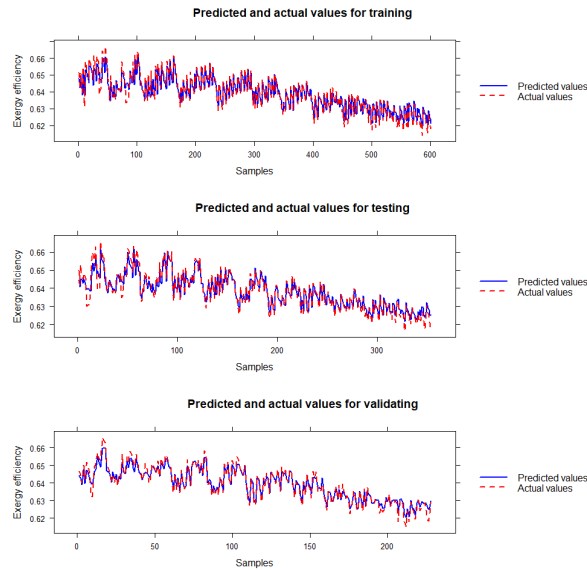

Figure 3: Actual and Random Forest model predicted exergy efficiency for VDU

The mean squared error of models can be seen in Table 3. The results in Figures 2 and 3 and Table 3 show that the machine learning models give good prediction performance, but the Random Forest model seems to give better results than the Bagging model. These models can be used to determine the exergy efficiencies for the most affecting operating parameters.

Table 3. Mean Squared Error of Models

	Training	Testing	Validation
Bagging model	0.0000126	0.0000132	0.0000080
Random forest model	0.0000060	0.0000064	0.0000047

6. Conclusions

Vacuum distillation column in TUPRAS Izmit Refinery was evaluated for exergy analysis by using parameter values under nominal conditions. Thus, an exergy analysis was made about the inefficient use of energy at which points of the process. The aim of the project is to create a machine learning model to see the effect of operational parameters on column exergy efficiency without the need for continuous running ASPEN HYSYS. The effect of various operation parameters on exergy efficiency has been examined by case studies in the ASPEN HYSYS simulation program. Changing the PA operating parameters did not lead to significant changes in exergy efficiencies. It has been seen that furnace exit temperature is the most important variables on exergy efficiency. In addition, machine learning models for exergy efficiency were improved using the process operation parameters which have the most effect on exergy efficiency. The results of two models indicated a successful performance on predicting exergy efficiency without the need for exergy-intensive calculations. From this study, we conclude that, it is necessary to prepare a substructure that requires the online working of ASPEN HYSYS continuously in order to ensure improvements through the exergy calculation. Instead of this, we obtained a model in R that can run in the online data integration tool, so we take the first step to working online platform. The reason why optimization is not considered in this study is that it is necessary to do a study for determining the optimum operating conditions by trying different values of each parameter, which is important in exergy analysis. Exergy analysis for optimization may be the subject of another study.

Abstract

Solvents are widely applied in chemical industries. The use of efficient model-based solvent selection techniques is an option worth considering for rapid identification of solvents with desired properties. In this paper, a Machine Learning-based Atom Contribution (MLAC) method is developed for fast predictions of molecular surface charge density profiles ($p(\sigma)$) using the three-dimensional atomic descriptors. Integrating the developed MLAC method and Computer-Aided Molecular Design (CAMD) techniques, an optimization-based MLAC-CAMD framework for solvent design is established by formulating and solving a Mixed-Integer Non-Linear Programming (MINLP) model, where model complexities are managed with a decomposition-based solution strategy. Finally, a case study involving crystallization is presented to highlight the effectiveness of the MLAC-CAMD framework.

Keywords: machine learning, computer-aided molecular design, atom contribution, surface charge density profiles, decomposition-based algorithm.

1. Introduction

The selection of solvents is of importance in the optimization of product yield and purity in chemical processes. However, it is practically impossible to perform thousands of time-consuming and extensive experiments for screening solvent candidates using a trial-and-error approach. As a result, it is worth employing efficient model-based methods that can help to focus the limited experimental resources on a few promising solvent candidates. CAMD techniques are efficient model-based methods for solvent design (Zhang et al., 2016). The success of CAMD depends very much on the reliability of property prediction models used, for example, the UNIFAC models. However, a large set of experimental data are required for regression of binary interaction parameters the models need, hindering thereby wide application of UNIFAC models (e.g., extractive distillation (Chen et al., 2005)).

To overcome the above-mentioned limitation of UNIFAC models, COSMO (COnductor like Screening MOdel)-based models are developed as potential alternatives due to their powerful ability to predict solvent properties with only a small set of group-independent model parameters (Hsieh et al., 2010). However, the computationally costly Density Functional Theory (DFT) calculations needed to obtain the molecular $p(\sigma)$ in the COSMO-SAC (Segment Activity Coefficient) model limit their application in CAMD

techniques for high-throughput solvent design. Scheffczyk et al., (2017) presented a COSMO-CAMD framework, where an optimization-based genetic algorithm LEA3D and a hierarchical approach consisting of two accuracy levels of DFT calculations are combined to reduce the computational cost of the DFT calculation for novel solvent design. Dong et al., (2018) proposed a COSMO-UNIFAC method for fast activity coefficient (γ) predictions of organic liquids. Their method takes the advantages of COSMO-based models (use of pseudo-experimental data for γ) and UNIFAC models (relatively accurate prediction) to bypass the DFT calculations. Mu et al., (2007) developed a GC-COSMO method for molecular $p(\sigma)$ predictions, where the $p(\sigma)$ values are estimated by the addition of group contributions to $p(\sigma)$ in milliseconds. Although their work offers an efficient molecular $p(\sigma)$ generation for the COSMO-RS (Real Solvents) model, one limitation cannot be ignored. It is known that $p(\sigma)$ is a charge-dependent molecular property. The simple scheme of group (or descriptor) additivity is unable to describe the complex interactions among functional groups, e.g., induction effect or conjugation effect, leading to poor prediction results.

In this paper, an optimization-based MLAC-CAMD framework is established for solvent design. In Section 2, the three-dimensional atomic descriptors, weighted Atom-Centered Symmetry Functions (wACSFs), are used to develop a MLAC method for fast and accurate predictions of molecular $p(\sigma)$ for the COSMO-SAC model (Hsieh et al., 2010). Then, the MLAC method is integrated with the CAMD problem, which is formulated as an MINLP model and solved by a decomposition-based solution algorithm. In Section 3, the proposed framework is evaluated with a case study involving solvent design for the improved crystallization operation.

2. MLAC-CAMD Framework for Solvent Design

2.1. The Development of MLAC Method

A database is created before developing the MLAC method, where 1120 solvents containing H, C, N, O elements with Chemical Abstracts Service (CAS) numbers are collected from the Virginia Tech database (Mullins et al., 2006), as these elements can be found in most of the commonly used organic solvents. The Isomeric SMILES (Simplified Molecular-Input Line-Entry System) of the 1120 solvents are then collected from the PubChem (<https://pubchem.ncbi.nlm.nih.gov/>) database using CAS numbers.

For the development of MLAC method, the SMILES representations of 1120 solvents are first converted to stereoscopic representations with cartesian coordinates using the OpenBabel tool (O'Boyle et al., 2011). Based on the stereoscopic solvents, the three-dimensional atomic descriptors, wACSFs (Gastegger et al., 2018), are calculated and selected as inputs for the establishment of High-Dimensional Neural Network (HDNN) model, which is an essential $p(\sigma)$ prediction model in the MLAC method. The wACSFs represent the local atomic environment of a centered atom i via the functions of radial (G_i^{rad}) and angular (G_i^{ang}) distributions of the surrounding atoms inside a cut-off sphere. More detailed information about the wACSFs can be found in Gastegger et al., (2018).

As the HDNN model needs atomic $p(\sigma)$ ($p_{atom}(\sigma)$) as outputs for model training, the $p_{atom}(\sigma)$ of 1120 solvents are prepared with the Gaussian 09W software (Frisch et al., 2016) and the COSMO-SAC model (Hsieh, et al., 2010). Finally, a database of $p_{atom}(\sigma)$ is established, where the number of samples for H, C, N, O atoms is 15535, 9108, 305 and 1215, respectively. With the obtained input (wACSFs) and output data ($p_{atom}(\sigma)$), the HDNN model is trained, which consists of four separate element-based (H, C, N, O) back propagation Artificial Neural Networks (ANNs). A diagrammatic sketch of HDNN model

is shown in Figure 1. For each element, atoms are randomly divided into the training, validation and test set with the ratio 6:1:1. In each ANN model, the optimizer, loss function, metrics function and activation function are selected as Adam (Kingma and Ba, 2014), Mean Squared Error (MSE), coefficient of determination R^2 and ReLU (Xavier et al., 2011), respectively. The metrics of training sample R_{train}^2 , validation sample R_{val}^2 and test sample R_{test}^2 are 0.964, 0.918, 0.907 for H element, 0.975, 0.931, 0.931 for C element, 0.950, 0.889, 0.865 for N element, 0.935, 0.867, 0.902 for O element. All these results satisfy the fitting criterion $\frac{R_{train}^2 - R_{test}^2}{R_{train}^2} < 0.1$ (note that $\frac{R_{train}^2 - R_{test}^2}{R_{train}^2} \geq 0.1$ indicates overfitting) (Zhao et al., 2020), indicating that the ANNs for H, C, N, O elements are reliable for $p_{atom}(\sigma)$ predictions.

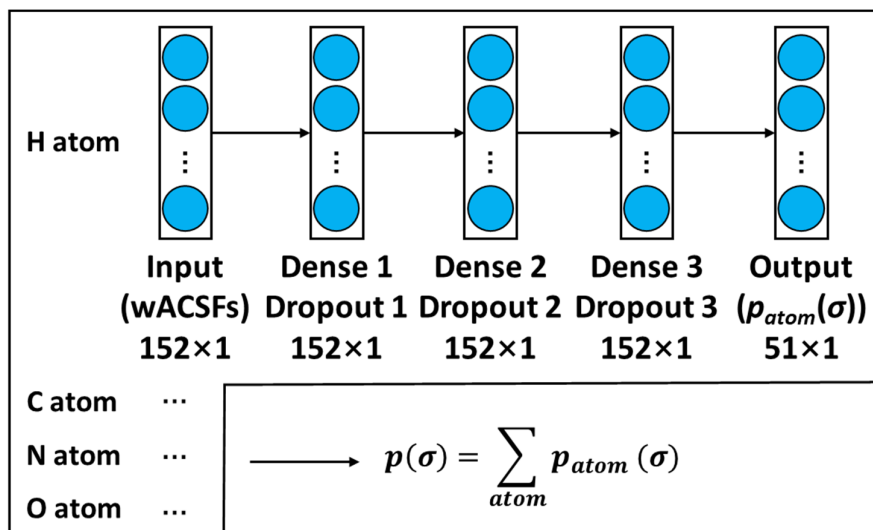

Figure 1. A diagrammatic sketch of HDNN model.

2.2. The Evaluation of MLAC Method

To further verify the feasibility and effectiveness of the HDNN model, the differences of predicted $p(\sigma)$ between the MLAC method and the DFT method (benchmark) are evaluated with the criterion R^2 . The R^2 results of the predicted $p(\sigma)$ for each discrete σ interval in the MLAC method are shown in Figure 2. Furthermore, the MLAC method is employed to determine $p(\sigma)$ for the predictions of infinite dilution activity coefficients $\gamma^\infty = f(p(\sigma), V_C)$ based on the COSMO-SAC model, where the molecular cavity volume V_C is predicted by the Group Contribution (GC) method using the MG group sets (Hukkerikar, et al., 2012) with a fitting quality of $R^2=0.9998$. The γ^∞ predictions of the MLAC method are compared with those predicted by the DFT calculated $p(\sigma)$ and V_C . Sixteen solutes (denoted as “c1~c16”) and 1120 solvents that composed of four H, C, N, O elements from the Virginia Tech database (solvents are classified in 13 categories and denoted as “s1~s13”) are selected for γ^∞ calculations. The Average Absolute Percent Error (AAPE) criterion is used to evaluate the differences of predicted γ^∞ between the DFT (benchmark) and MLAC method. Finally, the AAPEs for 16 types of solutes and 13 types of solvents using the MLAC method are shown in Figure 3.

Figure 2. The R^2 results of the predicted $p(\sigma)$ for each discrete σ interval in the MLAC method.

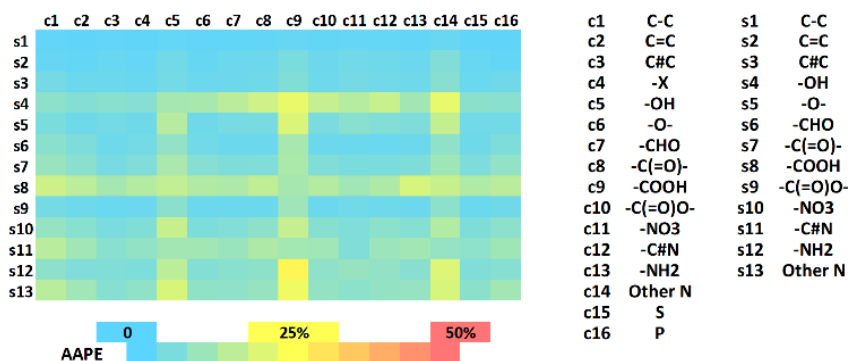

Figure 3. The heap map of AAPEs among 16 types of solutes and 13 types of solvents using the MLAC method.

It is noted that most of the AAPEs in Figure 3 are acceptable with minor prediction errors. Also, the overall AAPE for the total number of 17920 data points ($1120 \text{ solvents} \times 16 \text{ solutes}$) is calculated using the MLAC method and the result (AAPE = 6.6%) confirms that the developed MLAC method is feasible and sufficiently reliable to provide molecular $p(\sigma)$ (that is, a sum of $p_{atom}(\sigma)$ that are predicted by the HDNN model) to the COSMO-SAC model for the predictions of γ^∞ .

To highlight the computational efficiency of MLAC method, a molecule (SMILES: CCOC(C)CC(=O)OCOC(C)=O) is taken as an example for illustration. The MLAC method takes around 0.921 seconds to predict $p(\sigma)$ with SMILES on a PC laptop (Intel Core i5-8250U CPU @ 1.60 GHz), which is more efficient compared with the DFT calculation (around 51 minutes on the same laptop).

2.3. The Integration of MLAC Method and CAMD Technique

Based on the SMILES-based isomer generation algorithm (Liu et al., 2019) and GC-based property package, the ProCAPE tool (<https://www.pseforspeed.com/procape-computer-aided-property-estimation/>), the MLAC method is integrated with the CAMD technique for solvent design by formulating and solving an MINLP model through a decomposition-based algorithm (Karunanithi et al., 2005).

3. Case Study

The CAMD problem designing cooling crystallization solvents for Ibuprofen is considered. The following functional groups are selected: CH₃, CH₂, CH, C, OH, CH₃CO, CH₂CO, CHO, CH₃COO, CH₂COO, HCOO, CH₃O, CH₂O, CH-O, COOH, COO. The lower and upper bonds for structure and property constraints are given in Table 1. The objective for this case study is to design a crystallization solvent with the highest potential recovery *PR*%. More details about the objective function and constraints can be found in Karunanithi et al., (2006).

Table 1. List of structure and property constraints, as well as the top designed crystallization solvent for the Ibuprofen cooling crystallization process.

Property	Constraint	Property	Result
Number of groups	$2 \leq N_g \leq 8$	Molecule (SMILES)	CC(=O)OCC(=O)OCOCOC(C)C
Number of same groups	$N_s \leq 8$	Molecular structure	
Number of functional groups	$1 \leq N_F \leq 8$	<i>PR</i> %	95.91% (MLAC), 96.04%(DFT)
Hildebrand solubility parameter at 298 K	$17 \leq \delta \leq 19 \text{ MPa}^{1/2}$	δ (MPa ^{1/2})	18.470
Hydrogen bonding solubility parameter	$\delta_H \geq 8 \text{ MPa}^{1/2}$	δ_H (MPa ^{1/2})	11.018
Flash point	$T_f \geq 323 \text{ K}$	T_f (K)	400.172
Toxicity	$-\log(LC_{50})FM \leq 3.3 - \log(\text{mol/L})$	$-\log(LC_{50})FM$ ($-\log(\text{mol/L})$)	2.939
Normal melting point	$T_m \leq 270 \text{ K}$	T_m (K)	266.773
Normal boiling point	$T_b \geq 340 \text{ K}$	T_b (K)	523.919
Viscosity	$\mu \leq 1 \text{ cP}$	μ (cP)	0.577

Through using the decomposition-based algorithm, 272 feasible molecular candidates are designed at the first step with the constraints of molecular structures and linear properties (δ , δ_H , T_f , $-\log(LC_{50})FM$, T_m , T_b , μ), which are predicted by the GC methods (Hukkerikar, et al., 2012). Then, 6723 SMILES-based isomers are generated using the SMILES-based isomer generation algorithm. Afterwards, for the 6723 solvent candidates and solute Ibuprofen, *PR*% are individually calculated and arranged in descending order with the key property γ that is estimated by the integrated MLAC method - COSMO-SAC model. Finally, the top designed crystallization solvent is listed in Table 1. Although the DFT-based *PR*% of the top designed solvent in Table 1 (96.04%) has made a minor improvement compared with Karunanithi's solvent (94.95%), our best designed solvent is safer ($T_f = 400.172 \text{ K}$) and has lower toxicity measure ($-\log(LC_{50})FM = 2.939 - \log(\text{mol/L})$) than Karunanithi's ($T_f = 354.290 \text{ K}$ and $-\log(LC_{50})FM = 3.040 - \log(\text{mol/L})$). Further experimental verifications will be performed in the future to confirm the performance of the top designed solvent.

4. Conclusions

In this paper, an optimization-based MLAC-CAMD framework is established for solvent design, where the MLAC method is developed for fast predictions of $p(\sigma)$ using wACSFs descriptors through a HDNN model. Benefiting from the stereoscopic feature of the wACSFs descriptors and the powerful nonlinear fitting ability of the HDNN model, high prediction accuracy for $p(\sigma)$ is achieved with the MLAC method in terms of R^2 of $p(\sigma)$ and the overall AAPE of γ^∞ . A case study of designing crystallization solvents is performed, identifying a minor *PR*% improved solvent with the safer and lower toxic attributes compared with the previous work, which demonstrates the effectiveness of the MLAC-CAMD framework.

Abstract

Chemical products can be classified as single species, mixtures and/or blends, formulated and/or functional products and chemicals-based devices. Each product class can be represented by a suite of models representing different sub-classes depending on the product function and/or application. In this work, a versatile modelling system consisting of a collection of ten sub-models (molecular structure, property, process, costing, pricing, economic analysis, quality, sustainability, environmental impact, and performance) is presented. This modelling system has been incorporated into ProCAPD, which is a chemical product design software tool together with an extended database and a library of product design templates. Application of ProCAPD with the built-in versatile modelling system is highlighted through two cases: crystallization solvent design and reaction solvent design.

Keywords: chemical product design, versatile model, ProCAPD, decomposition-based algorithm.

1. Introduction

Chemical products are widely used in modern society. Chemical product design usually has hierarchical and multi-disciplinary features. As pointed out by Ng and Gani (2019), chemical products can be classified as single species, mixtures and/or blends, formulated and/or functional products and chemicals-based devices. Each product class contains sub-classes depending on the product function and/or application. One of the difficulties in computer-aided chemical product design is that each product class and sub-class are defined in terms of different sets of product attributes, which needs multi-discipline knowledge for the modeling of the design problems.

A variety of sub-models have already been used in different problem formulations of chemical product design. For example, in solvents for CO₂ capture, Pereira et al. (2011) have employed complex thermodynamic models for prediction of CO₂ solubility. Chai et al. (2020) combined COSMO-based solubility predictions in the design of solvents for crystallization. Zhang et al. (2018) proposed a multi-objective optimization framework for the influence of government policy and consumer preference on product design. Fung

et al. (2016) proposed the use of a grand product design model including costing, pricing, sustainability, etc., together with the more common product attributes related to properties and process. Subsequently, Ng and Gani (2019) identified the technical and non-technical issues and/or problems in integrated product and process design, the relationships among which are captured in a Grand Product Design Model. Many of these recent developments have been included in teaching product and process design to prepare the new generation of chemical engineers. However, the specific models presented in their work are mainly simplified correlations, and most of the sub-models presented are conceptual equations. Therefore, a versatile modeling framework is needed for wider applications of chemical product design problems from which the needed sub-models can be retrieved and combined easily for a specific chemical product design problem.

In this paper, a versatile modeling framework suitable for chemical product design has been developed and implemented in ProCAPD (Kalakul et al., 2018). In section 2, the versatile model is formulated as a collection of ten sub-models. In section 3, the new additions to ProCAPD software are presented. In section 4, two cases studies are given for highlighting the application of ProCAPD software in chemical product design.

2. Versatile Modeling Framework

The framework of the versatile mathematical model is shown in Figure 1.

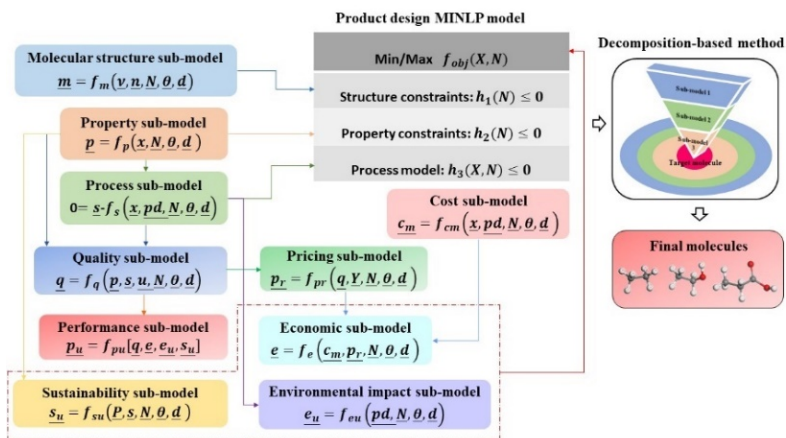

Figure 1. Versatile modelling framework for chemical product design

In Figure 1, molecular structure sub-model mainly represents the constraints related to molecular structure feasibility in terms of octet rule (v) (Odele and Macchietto, 1993) and the number of groups (n) representing the molecule. Here, N is the number of arguments, θ and d represent the supplied model parameters and specified variables, respectively. Property sub-model is used to predict the properties (p) of the compounds of the product (x). Process sub-model relates the product attributes (s) of each compound of the product (x) and process design variables (pd) through the process model equations based on conservation of mass and energy. The material properties (p), product structure attributes (s) and product use conditions (u) collectively determine the product quality (q), which is determined through the product quality sub-model. Pricing sub-model is to determine product price (p_r) and market share (Y) under the condition of given market model. Market

share (Y), in turn, affects the amount of production and the required capital investment and operating costs. Cost sub-model related to product manufacturing mainly includes the capital cost and production cost used to produce the product. All of the above models lead to an economic sub-model, which is used to evaluate the financial performance of the product being designed. There are many indicators that can be used for economic analysis, such as net present value (NPV), internal rate of return (IRR), and return on investment (ROI). For the analysis of the commercial value of products, the environmental sub-model needs to be considered in the production process, mainly due to the harmful substances generated during the production process. It is necessary to consider the recovery and treatment of these substances. So, it is necessary to consider the sustainability sub-model. Performance sub-model refers to the performance indicators in the product design process. These indicators include product quality (q), economy (e), environmental (e_u) and sustainability issues (s_u), which can be formulated as a single or multiple objective problem.

In Figure 1, each sub-model is not only a conceptual single function equation but a more detailed set of model equations. The model equations and parameters can be obtained through literature, experiment or machine learning. For each sub-model, it can be further decomposed according to its type. For example, the property sub-model can be divided into primary pure component properties, secondary pure component properties and phase equilibrium related properties. In addition, the modelling framework is continuously extended through the addition of new models in different categories. Each class of sub-models has its corresponding interface for data transfer. Also, together with an associated database and a model generation sub-system, new models can be created through data regression and machine learning based modeling. The developed modelling framework has been incorporated into a chemical product design software tool ProCAPD, which provides the software new features such as use of machine learning based models and the associated problem solution strategy.

3. Multipurpose Tool for Product design

The above versatile model is integrated into ProCAPD. The architecture of the ProCAPD tool is shown in Figure 2. It includes several other features, such as design templates for guiding the user through established workflows for specific product design problems; solution approach where different solution strategies can be applied by different problems. The aim of ProCAPD is an integrated tools which contain a suite of computer-aided tools that helps with the problem formulation, database search, properties prediction and model development.

The solution of a chemical product design problem using any model-based system requires the retrieval, calculation, use and management of a wide range of models and methods, as well as very large amounts of data. For this reason, ProCAPD is integrated with different in-house tools that are necessary to provide more efficient and flexible options for chemical product design and analysis.

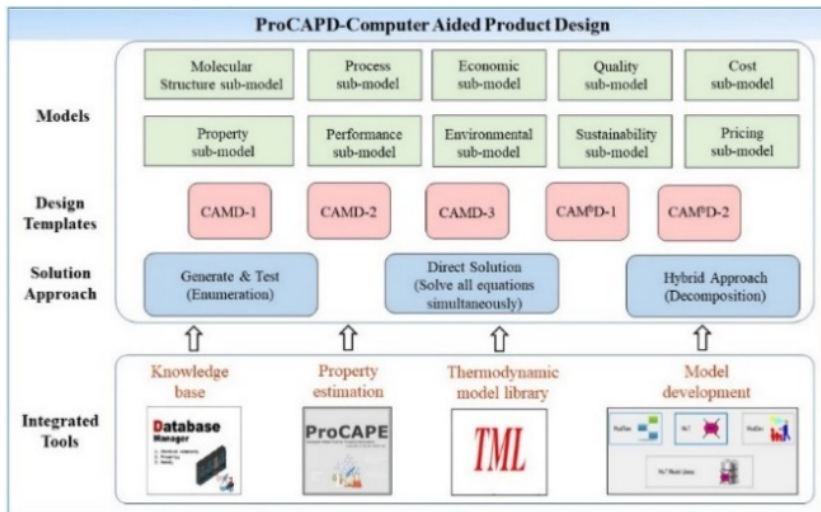

Figure 2. ProCAPD architecture for solving different product design problems

4. Case study

4.1. Crystallization solvent design

This case study is taken from Chai et al. (2020). 2-Mercaptobenzothiazole (MBT) is an important vulcanization accelerator using in the rubber industry. In the solvent-based method, it is important to select a suitable crystallization solvent to ensure the refined MBT meets the industry requirements.

In this case study, CH₃, CH₂, CH, C, aC-CH₃, aCH, aC-Cl, OH, CHCOO groups are selected. The lower and upper bonds for structure and property constraints and the optimal solvents are shown in Table 1. (A is the designed solvent that need to be kept confidential). The decomposition-based strategy (Karunanithi et al., 2005) is employed to solve the MINLP model.

Table 1. The lower and upper bonds for structure and property constraints and the candidate solvents

Objective function: $\text{Max } PR\% = \frac{1}{0.88(1-w_1)} (1 - \frac{w_2}{w_2}) \times 100\%$					
Properties	Lower bound	Upper bound	No	Name	PR%
N_G	3	8	1	Methyl lactate	97.34
N_C	-	7	2	n-Heptanol	94.61

Note: The process sub-model also includes the COSMO-SAC model equations for activity coefficients (Chen et al., 2016), which are not listed in the table

From Table 1, the product yields (PR%) of the candidate solvents are increased to above 90%, which meet the industrial needs.

4.2. Reaction solvent design

This case study is taken from Zhang et al. (2020). TMQ is an important antioxidant and is widely used in rubber production technology. In order to further improve the quality of TMQ products, it is necessary to find a more suitable reaction solvent.

The groups (building blocks) selected in this case include CH₃, CH₂, CH, C, CH₂=CH, CH=CH, CH₂=C, CH-C, C=C, CH₃CO, CH₂CO, CH₃COO, CH₂COO, CH₃O, CH₂O, aCH, aC, aC-CH₃, aC-CH₂, aC-CH, CH₂(cyc), CH(cyc), C=C(cyc). The lower and upper bonds for structure and property constraints and the optimal solvents are shown in Table 2.

Table 2. The lower and upper bonds for structure and property constraints

Objective function: maximizing the yield of dimer: $n_d^t = \int r_d^t dt$ minimizing the energy consumption: $Q = f_q(\Delta H_{vap,298K}^i, T, T_c^i, x_i, R, F_i, \varepsilon_i)$		
Properties	Lower bound	Upper bound

5. Conclusions

A versatile modeling framework suitable for chemical product design has been developed and implemented in ProCAPD, a chemical product design software tool together with an extended database and a library of solution approaches. New features such as machine learning based models developed in previous publications, have been highlighted in this

paper in terms of their incorporation in the product design problem and the associated problem solution strategy. These new features are highlighted by two application examples (crystallization solvent design and reaction solvent design).

Abstract

Due to depletion of freshwater resources in arid and semi-arid regions accompanied with an increase in water demand, the focus is on improving thermal desalination technologies such as multi effect distillation (MED) that are energy intensive. Undoubtedly, this technology plays an important role in generating high quantity of freshwater from saline water resources. To maintain a sustainable seawater desalination technology, this research suggests a new hybrid system of 10 effects of MED and a farm of 100 wind turbines to be installed in Al-Shuaibah Power Plant located 103 km south of Jeddah in the Kingdom of Saudi Arabia. To carry out this proposal, a generic model for MED developed by the same authors and a set of model equations of wind power turbine are embedded in a mathematical framework. The developed framework is then used to carry out a simulation for a given set of seawater characteristics, and input design parameters at different months of the year 2019. The study investigates the average monthly saving of power for the proposed hybrid system compared to a single MED system. It is revealed that the wind turbines can save around 43% of electrical power of MED system in June 2019 based on the mean monthly wind speed.

Keywords: Seawater desalination; Multi effect distillation; Hybrid system; Wind turbine; Energy saving.

1 Introduction

Despite the abundance of water around the globe, there is a clear challenge of delivering freshwater due to scarcity of freshwater resources accompanied with a rapid growth of population. Seawater desalination has confirmed its robustness to provide freshwater especially for those countries that have coastal areas with water shortage. However, desalination plants and especially thermal one requires a considerable amount of energy to produce freshwater from seawater resources. More specifically, multi effect distillation (MED) is one of the well-known thermal desalination technologies that has been extensively used in the Gulf countries including the United Kingdom of Saudi Arabia. The most part of consumed energy in the MED system is to provide the thermal energy required to evaporate the brine besides operating the pumps (electrical energy). Due to depleting petroleum reserves and the considerable CO₂ emissions associated with these

processes, there has been progressive interest to integrate thermal desalination with a renewable source of energy. However, harnessing wind as an alternative source of power is reliant on weather and location. Interestingly, the KSA has a consistent wind energy resource as confirmed by Salah et al. [1] who stated an average wind speed of 3.5 m/s in various areas of the KSA. Thus, it would be possible to exploit wind energy as a reliable source of energy to drive the MED desalination system. The design and efficacy of a hybrid system of renewable energies and MED has been discussed in the literature. Specifically, the familiar use of wind energy of a wind turbine in the seawater desalination systems is to employ the mechanical and electrical energies. For instance, Yilmaz and [2] presented the hybrid seawater desalination system of MED and flat-plate collector (solar) and wind turbine units. They proposed to instill the hybrid system at 18 stations located at on-shore regions of Turkey. The research stated the potential of renewable energy of each location and identified the required system size of each sub-system. Also, a high-capacity wind turbine was integrated to MED system by Khalilzadeh and Nezhad [3] to exploit the wasted heat of wind turbine to produce the necessary steam for MED system. The results affirmed the merits of the proposed technique which can work adequately without any limitations during variable temperatures.

This study focuses on exploring the feasibility of a proposed hybrid renewable energy system of 100 wind turbines (Dencon Tornado type) and 10 effects MED desalination system to be installed in the Al-Shuaibah Power Plant, located 103 km south of Jeddah in the Kingdom of Saudi Arabia. The simulation-based model built in gPROMS software is carried out at fixed seawater conditions to investigate the average monthly power saving throughout 2019 that can be achieved for the hybrid system.

2 Hybrid seawater desalination system of wind turbine and MED

The proposed hybrid system of forward feed MED of 10 effects coupled to thermal vapor compression (external steam provider) and a farm of 100 wind turbines is schematically presented in Fig. 1. The wind turbine type Dencon Tornado [4] is selected to be linked with the MED system. Each effect of MED comprises an evaporator of brine, spray nozzle, demister, and feed pre-heater. The characteristics of the associated MED and design parameters of wind turbine systems are illustrated in Table 1. The purpose of installing the wind turbine as a renewable source of energy is to generate the power required to produce fresh water from the MED system.

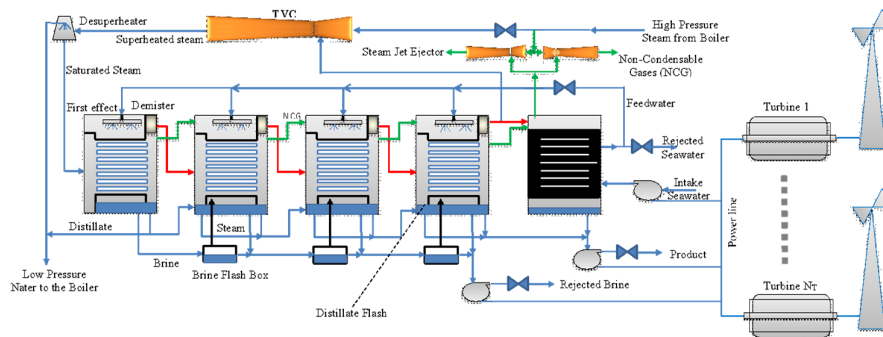

Fig. 1. Hybrid system of MED and wind turbine systems

3 Modelling of MED system

Filippini et al. [5] developed a successful model for the MED-TVC system. Some important equations of the model developed are shown in Table 2. The procedure of model developed and the associated assumptions for MED+TVC system and its validation can be found in more details in Filippini et al. [5].

Table 1. Characteristics of MED and wind turbine (Dencon Tornado) systems

Wind turbine system						
Parameter	Rated power, Pr (kW)	Height above the ground level, H (m)	Wind turbine cut-in speed, Ucut (m/s)	Wind turbine rated speed, Ur (m/s)	Wind turbine cut-off speed, Uf (m/s)	Shape parameter, k (m/s)
Value	200	32	3	12	25	2.5649
MED system						
Parameter				Unit		Value

Pressure at vapor temperature	$Pv = P_{crit} e^{\left(\frac{T_{crit} + 273.15}{Tv_n}\right)^{-1}} \cdot \sum_{j=1}^8 f_j$	Bar
Pressure at steam temperature	$Ps = P_{crit} e^{\left(\frac{T_{crit} + 273.15}{Ts}\right)^{-1}} \cdot \sum_{j=1}^8 f_j$	Bar
Compression ratio	$CR = \frac{Pv}{Ps}$	-
Entrainment ratio	$Ra = 0.296 \frac{Ps^{1.19} Pm^{0.015} PCF}{Pev^{1.04} Pev^{0.015} TCF}$	-
Motive steam flow rate	$Mm = Ms \frac{Ra}{1 + Ra}$	kg/s

4 Simulation of MED system

The simulation based the model developed was used to explore the required power to generate the fresh water from MED system. The simulation results based on the seawater conditions are depicted in Table 3.

5 Modelling of wind turbine energy

The generated power P_W (kW) of a single wind turbine can be calculated using the correlation of Eltamaly and Al-Shamma'a [6].

$$\begin{aligned}
 1 - P_W &= 0 && \text{if } U \leq U_{cut} \text{ and } U \geq U_f \\
 2 - P_W &= P_r \frac{U^k - U_{cut}^k}{U_r^k - U_{cut}^k} && \text{if } U_{cut} \leq U \leq U_r \\
 3 - P_W &= P_r && \text{if } U_r \leq U \leq U_f
 \end{aligned}$$

where P_r , is the rated power (kW), U the wind speed (m/s), U_{cut} the wind turbine cut-in (m/s), U_f the wind turbine cut-off (m/s), U_r the rated wind turbine (m/s) and k the rated wind and shape parameter (-), respectively.

Table 3. Seawater conditions and corresponding power of MED system

Seawater salinity	ppm	39000
Seawater temperature	°C	25
Specific energy consumption	kWhr/m ³	17.9885
Productivity	kg/s, m ³ /hr	68.327, 245.977
Power	kW	4424.760

6 Evaluation of wind turbine and MED systems at various wind speeds

The simulation of the MED system showed the productivity of about 245 m³/hr of fresh water for the design operations of the MED system and specified seawater conditions (reported in Table 3). This specifically requires generating 4424.760 kW as an average required power to produce fresh water from MED system. The variation of average monthly wind speed in the studied region (Al-Shuaibah Power Plant, Jedda in the KSA) for a period of 12 year of 2019 is shown in Table 4. Table 4 also shows the corresponding generated monthly power from a single wind turbine. The results confirmed a low generated power using only a single wind turbine system due to low average wind speed during the months of 2019 (Table 4). This in turn means the necessity of constructing a considerable number of turbines to be integrated with the MED system to generate the total required power of the MED system. However, this is not a feasible option due to a high capital cost. To solve this problem, this research proposed the deployment of a farm of 100 wind turbines to be integrated to the MED. In this respect, Table 4 provides the power saving values. Clearly, June of 2019 has the highest percentage of power saving of 42.81% compared to November 2019 of 6.67%. Also, it should be noted that the calculation of power saving is carried out based on the monthly average wind speed. Therefore, it is fair to expect a regular increase of generated power during the days that can increase the relevant energy saving. For example, 100 wind turbines and MED attains an energy saving of 63.64% at the maximum wind speed for June 2019. It is also fair to claim that the use of a larger scale of wind turbine (if it is existed) would reduce the total number of required turbines to be integrated to MED-TVC seawater desalination system. Due to the fact of variable wind speed at different time scale and the necessity of a constant source of energy to drive the desalination plant, this study therefore recommends the investigation of the integration of both solar (photovoltaic cells) and wind turbine (sources of energy) with the MED desalination system. Moreover, having a battery bank to save generated electricity from the wind turbine would be a possible solution during times of low power consumption in the plant. In this regard, the integration of solar energy to MED desalination plant (located in Aqaba, Jordan) has reduced the total thermal energy by 68% [7].

7 Conclusions

This paper has presented a proposed integrated system of wind turbine and MED thermal desalination plant to be instilled in in Al-Shuaibah Power Plant, Jedda, KSA. The simulation of the proposed hybrid system is carried out based on developed model of sub-systems. The simulation results confirmed the possibility of attaining a maximum electrical power saving of 42.81% in June 2019 based on the monthly mean wind speed for the proposed hybrid system of 10 effects MED and a farm of 100 wind turbines. The lowest energy saving was found to be in November 2019.

Table 4. Mean wind speed [8], generated electrical power, and energy saving

Month	Mean wind speed, U (m/s)	Generated power of a single wind turbine, Pw (kW)	Power saving of 100 wind turbines%

Abstract

The aim of this study was to deduce the most effective desalination process by comparing performance of the water heated with the air heated Humidification-Dehumidification desalination systems. The process model was developed by applying conservation of mass and energy across the processes' major components and simulated using gPROMS ModelBuilder platform. Simulation results shows that, the water heated HDH desalination process has higher fresh water productivity than the air heated process. At the maximum inlet temperature of 60 °C the water heated and air heated HDH desalination processes have the maximum productivity of 42 kg/h and 18 kg/h respectively.

Keywords: Humidification, Dehumidification, desalination, solar thermal energy.

1. Introduction

A rapid growth in population, industrialisation and urbanisation is causing shortage of fresh water in many areas around the globe. On the other hand, sea water or underground saline water is abundant in most areas that encounter the problem of fresh-water shortage. As demand for fresh water continually increases, it becomes necessary to develop cheap desalination technologies which are powered by renewable energy (Kucera, 2014).

Multistage humidification-dehumidification (HDH) desalination using solar energy is a viable process for remote and arid areas with severe shortage of fresh water. Humidification-dehumidification is a thermal desalination cycle that operates by heating saline water using solar thermal energy, evaporating the heated water using a humidifier and finally condensing the water vapor to form fresh water in the dehumidifier. The process is viable because of its' simplicity, abundance of solar energy and moderate operating costs compared to conventional desalination processes (Al-Enezi, et al., 2006).

Various researchers have used simulation models to investigate the key parameters affecting performance of the humidification-dehumidification desalination process. On

the one hand, there is a common agreement that high yield of fresh water is favoured by increasing temperature of streams entering the humidifier. On the other hand, there is still a debate whether the maximum yield is achieved by heating the water stream (Huifang, et al., 2014) or by heating the air stream (Mohamed & El-Minshawy, 2011) before passing into the humidifier. Therefore, the purpose of this study is to use simulation tools and mathematical models to explore the performance of an emerging HDH water desalination process. Specifically, these are used to compare performance of the water heated HDH desalination system with air heated HDH desalination system to deduce system with the maximum fresh-water productivity.

2. Description of the HDH desalination models

2.1. Water heated HDH desalination cycle

In this cycle, pumped saline water from a storage vessel enters the system at the dehumidifier. As it passes in the dehumidifier it cools and dehumidifies moist air stream that comes from the humidifier as shown in Figure 1a. The enthalpy of vaporization for this condensation process is transferred from the moist air to the saline water to warm the feed stream. The condensate is collected as fresh water at the bottom. Saline water is further heated by passing through a solar heater. The hot saline water is sprayed on top of the humidifier and flows downward while a cool air stream flowing in the opposite direction is blown at the bottom. The tiny water drop formed by spraying saline water maximizes the surface area for water-gas contact which improves the evaporation rate. The humidification process occurs by transfer of heat and mass (vapor) from the hot saline water stream to the cool air stream.

Figure 1: Schematic representation of the HDH desalination systems (a) Water heated HDH desalination cycle (b) Air heated HDH desalination cycle

2.2. Air heated HDH desalination cycle

Air heated HDH desalination cycle can be achieved by shifting the solar heater from water stream to the air stream as shown in Figure 1b. The flow of water and air through the humidifier and dehumidifier are exactly the same as described for water heated cycle, except that the heater is now placed to heat the air stream instead of heating water stream.

2.3. Modelling and simulation of the humidifier

Figure 1 shows the schematic diagram of water heated and air heated HDH desalination systems considered for developing the mathematical model in this study. They are assumed to operate at steady state. An air-water vapor mixture of known humidity ratio (ω) enters the humidifier through inlet 3 at a known pressure (p) and temperature (T). As the mixture passes through the humidifier, it comes into contact with a stream of water. If the entering mixture is not saturated, some of the water would evaporate. The pressure of the mixture is assumed to remain constant as it passes through the

humidifier. The humidity ratio ω_4 of the exiting moist air can be obtained by applying conservation of mass and conservation of energy to the humidifier of the system with an assumption that the moist air is an ideal gas mixture of dry air and water vapor. At the exit of the humidifier, air is assumed to be saturated. Moreover, the work, and changes in kinetic and potential energy are also ignored. The feed water salinity is less than 30 g/kg hence physical properties are similar to those of pure water. The enthalpy of the incoming saline water is evaluated as that of saturated liquid at the corresponding inlet temperature. Similarly, the specific enthalpy of the entering water vapor has been evaluated as that of saturated water vapor at the temperature of the incoming mixture (Moran, et al., 2011).

Conservation of mass (air and water) at steady state

$$\dot{m}_{a,3} = \dot{m}_{a,4} = \dot{m}_a \quad (1)$$

$$\dot{m}_2 = \dot{m}_1 + \dot{m}_a (\omega_3 - \omega_4) \quad (2)$$

At steady state an energy rate balance can be reduced to

$$\dot{m}_1 h_1 - \dot{m}_2 h_2 = \dot{m}_a \left((h_a + \omega h_g)_3 - (h_a + \omega h_g)_4 \right) \quad (3)$$

If enthalpy of water is approximated as $h^l \approx h^l(T^l)$, $h^g \approx h^g(T^g)$ then equation 2 and 3 can be combined and solved to get:

$$(\omega_3 - \omega_4) = \frac{\dot{m}_1 (h_f(T_1) - h_f(T_2)) + \dot{m}_a (h_{a3} - h_{a4}) + \dot{m}_a (\omega_3 h_{g3} - \omega_4 h_{g4})}{\dot{m}_a h_f(T_2)} \quad (4)$$

The dry air enthalpies of equation 4 can be calculated from the specific heat capacity and temperature of air as follows

$$h_{a3} - h_{a4} = C_{pa}(T_3 - T_4) \quad (5)$$

The evaporation rate of the system is given as:

$$\dot{m}_v = \dot{m}_a(\omega_4 - \omega_3) \quad (6)$$

The humidity ratio ω_3 at the entrance is calculated as

$$\omega_3 = 0.622 \frac{p_g(T_3)}{p - p_g(T_3)} \quad (7)$$

$$h(T) = \int_0^T C_p(T) dT \quad (8)$$

Heater energy balance equation (for both cycles) can be written as:

$$\dot{Q}_{in} = \dot{m}_f C_{p,f}(T_{f,out} - T_{f,in}) \quad (9)$$

$$\dot{Q}_{in} = \dot{m}_a C_{p,a}(T_{a,out} - T_{a,in}) \quad (10)$$

Table 1: Definition of symbols used for mathematical models

Symbols	Subscripts
C_p specific heat capacity ($\text{kJ kg}^{-1}\text{K}^{-1}$)	a air
h specific enthalpy (kJ kg^{-1})	$1,2,3,4$ inlet and exit points
\dot{m} mass flow rate (kg/s)	g,v water vapour
T temperature ($^{\circ}\text{C}$)	f liquid water
ω humidity ratio (kg_w/kg_a)	

Table 2: Parameters used for model simulation

Parameter	Value		Parameter	Value	
	System a	System b		System a	System b
C_p	1.006	1.006	hg_4	2583.2	2583.2
m_l	0.28	0.28	T_1	50	20
m_a	0.15	0.15	T_2	45	30
h_{f1}	209.33	83.96	T_3	20	50

3. Results and Discussion

In this study we used mathematical models to deduce the system with higher productivity by comparing performance of the water heated HDH desalination system to

the air heated HDH desalination system. These models were validated by comparing theoretical results obtained through model simulation with the corresponding experimental data which were previously reported by (Huifang, et al., 2014).

Figure 2: Comparison of the simulated and measured productivity of the system corresponding to various inlet temperature of saline water

As the base case, performance of the two HDH desalination systems were compared by changing the position of heater between the water and air streams. For water heated system the temperature of saline water and air at the inlet points of the humidifier was 50 °C and 20 °C respectively. For the air heated system the inlet air was heated to 50 °C while temperature for the inlet water was 20 °C. The flow rates for air and saline water were fixed at 0.15 kg/s and 0.28 kg/s respectively for both HDH systems. Other input parameters for both systems are shown in Table 2. The system’s mathematical model was simulated using gPROMS ModelBuilder platform for the conditions specified for both of the HDH systems. Simulations results shows that fresh water productivity for water heated system is 28 kg/h; higher than air heated system which was 15 kg/h (Figure 3).

The effect of temperature on system’s productivity is shown in Figure 3 for both water heated system and air heated system. The figure shows a significant increase of the fresh water productivity (i.e from 21 to 42 kg/h) with increase of the inlet water temperature for the water heated HDH system. On the other hand, the figure shows that, an increase of the air inlet temperature does not have significant influence on fresh water productivity. This difference of response can be attributed to the huge difference of water and air specific heat capacities which are 4.2 and 1.0 kJkg⁻¹K⁻¹ respectively. For the case of water heated system, temperature of the air stream rises as the air ascends the column. Previously, it was demonstrated by Bergman, et al (2011) that, for longer column the air temperature keeps on rising to approach the inlet water temperature. Consequently, the highest vapour carrying capacity (humidity ratio) is attained by the humid air exiting the humidifier. This is different for the air heated system whereby; the hot air stream is cooled rapidly on ascending the column. Since the heat capacity of water is 4 times higher than that of air, the water temperature is only slightly affected thus causing more condensation than evaporation as air approaches to the column’s exit

(Bergman, et al., 2011 and Sinnott, 2005). For this reason, the longer the column, the lower humidity ratio for air stream exiting the column.

Figure 3: The effect of temperature on productivity for the water heated system and air heated system

Therefore, as recommended by (Mistry, et al., 2011) the fresh water productivity for the water heated HDH system can be maximized by increasing length of the humidifier. For the air heated system (Sharqawy, et al., 2014) recommended to reduce the length of the humidifier and/or to increase the air flow rate in order to maximise the productivity.

4. Conclusions

In this study we have developed and simulated the mathematical model of the Humidification Dehumidification desalination process. The model was used to compare performance of the water heated with the air heated HDH desalination system. Simulations results shows that, the water heated system has higher fresh water productivity than the air heated system. It was also found that the increase of water inlet temperature for the water heated system is associated with a significant increase of the fresh water productivity. A varying inlet temperature from 48 °C to 60 °C corresponded with an increase of productivity from 21 kg/h to 42 kg/h. On the other hand, the increase of air inlet temperature does not have a significant influence on the fresh water productivity for the air heated system provided that other parameters of the system are not varied. For this system, the same temperature variation raised the water productivity from 15 kg/h to 18 kg/h. Finally, it is recommended to boost the productivity by increasing length of the humidifier for the water heated HDH system and by reducing length of the humidifier and/or to increase the air flow rate for the air heated system.

Abstract

The Reverse Osmosis (RO) system has confirmed its viability to produce high quality water from brackish water sources. However, the increase in water and electricity demands and has raised the necessity of a sustainable and integrated water treatment systems. Renewable sources of energy can be applied to reduce the environmental footprint and satisfy the energy demand. An integrated system of wind energy and large-scale RO system has been proposed in this paper to generate freshwater from brackish water. A generic model of the multistage multi pass RO system of Arab Potash Company (APC) was dedicated with a set of algebraic equations for wind turbine operation to form an accurate model to compute different performance indicators including total energy consumption. The energy analysis was carried out for each individual and the integrated systems and estimating the total generated power from the wind turbine for one year (July/2019 to July/2020). In this regard, the power for the high-pressure pumps of the RO system has been supplied from the grid and the wind energy system. The results show that the integrated wind – RO system attain a maximum energy saving during the windy months. Overall, the wind turbine system has enhanced the reduction of total required power of RO system compared to a grid powered RO system.

Keywords: Desalination; Brackish water; Reverse Osmosis; Wind turbine; Energy saving.

1 Introduction

In the last few years, membrane based separation technology has dominated the market, and consequently the Reverse Osmosis (RO) membrane technique has been increasingly implemented in industrial water treatment plants due to its better performance in terms of less energy consumption, higher water recovery, and low operational costs compared to thermal desalination processes (Qasim et al., 2019). However, several methods were implemented to reduce the energy consumption of RO process including the use of a high permeable membrane, energy recovery device, chemical demineralization, optimisation techniques, and renewable energy sources (Li, 2011).

Owing to the high prices of fossil fuel energy coupled with air pollution and global warming, it is necessary to supplement a non-renewable energy (NRE) sources (fossil fuel) with a renewable energy (RE) sources such as wind turbines and photovoltaic cells. (Nassrullah et al., 2020). Charcosset (2009) demonstrated the viability of wind turbine systems as a valuable and sustainable energy resource to be integrated with the RO process especially for coastal areas which have a high availability of wind. Wind energy offers many environmental benefits compared to conventional energy sources and a significant decrease of use of fossil fuels was noticed due to the employment of renewable energy systems. Several studies can be found in the literature that have investigated the efficiency of wind turbine in a hybrid of wind turbine and RO system. For example, Miranda and Infield (2003) tested a 2.2 kW small wind turbine to drive a RO desalination unit. A computer model was developed in order to find optimum wind turbine power that yields maximum fresh water production rate. The model has been verified and supported with experimental data. The results showed that increasing wind speed up to 11 m/s resulted in a higher water production rate. Moreover, the results showed that the specific energy consumption of RO desalination system decreased sharply as wind speed increased up to 6 m/s. Moreover, Forstmeier et al. (2007) studied a wind powered system with RO desalination system with an electrical grid connection. The results confirmed the feasibility of the hybrid system if some grid connection is available to supply energy at low specific energy consumption.

This study focuses on the development of a hybrid system of wind turbine and multistage multi-pass brackish water RO system of the APC located in Jordan. The viability of this hybrid system is tested for a selected set of inlet conditions of brackish water. To attain this goal, model simulations will be carried out to determine the total energy saving of the hybrid system. In this regard, the total number of wind turbines to appropriately provide the power of RO system will be studied for each month from July 2019 to July 2020.

2 Description of RO desalination plant powered by wind turbine system

Fig. 1 shows the layout of brackish water RO powered by wind energy system for the APC plant (capacity 1200 m³/day). It consists of two passes with permeate and retentate reprocessing designs. The 1st pass has two stages of pressure vessels arranged as (4:2). The 2nd pass has three stages of pressure vessels arranged as (2:1:1). The permeate of 1st pass is fed to the 2nd pass for further processing. The high-concentration stream of the 1st pass is sent to drain. However, the low-concentration streams of the 2nd pass are collected to constitute the high-quality water (salinity 2 ppm). The high-concentration stream of the 2nd pass is reprocessed back to the raw feed water of the 1st pass. Several wind turbines are integrated with RO system to supply the required amount of power to drive the pumps as shown in Fig. 1.

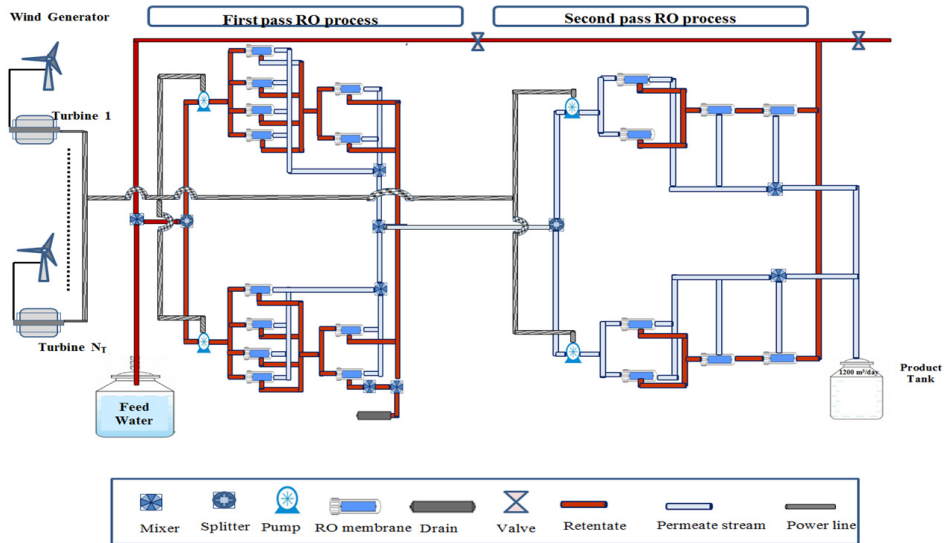

Fig. 1. Layout of brackish water RO plant of APC powered by wind turbine system

3 Modelling of RO system of APC

Al-Obaidi et al. (2018) established a steady-state model for a medium-scale brackish water RO desalination system of APC. The detailed model was validated against actual data collected from the APC and then used to study the plant performance with variable operating conditions. The mathematical model parameters and equations of RO system of APC are shown in Table 1. Recently, this model was upgraded by including a specific sub model to measure the power generated from the wind turbine as depicted in the next section.

Table 1. Mathematical model of RO system of APC

No	Model equations	Specifications
1	$Q_p = A_{w(T)} N D P_{fb} A_m$	Total water flux (m ³ /s)
2	$A_{w(T)} = A_{w(25\text{ }^\circ\text{C})} T C F_p F_f$	Water permeability constant at 25 °C (m/s atm)
3	$T C F_p = \exp \exp [0.0343 (T - 25)] < 25\text{ }^\circ\text{C}$ $T C F_p = \exp \exp [0.0307 (T - 25)] > 25\text{ }^\circ\text{C}$	Temperature correction factor of permeate
4	$N D P_{fb} = P_{fb} - P_p - \pi_b + \pi_p$	The driving pressure (atm)
5	$P_{fb} = P_f - \frac{\Delta P_{drop,E}}{2}$	The feed brine pressure (atm)
6	$\Delta P_{drop,E} = \frac{9.8692 \times 10^{-6} A^* \rho_b U_b^2 L}{2 d_h Re_b^n}$	The pressure drop along the membrane element (atm)
7	$\pi_b = 0.7994 C_b [1 + 0.003 (T - 25)]$ $\pi_p = 0.7994 C_p [1 + 0.003 (T - 25)]$	The bulk and permeate osmotic pressure (atm)
8	$C_b = \frac{C_f + C_r}{2}$	The bulk salinity (kg/m ³)
9	$Q_s = B_{s(T)} (C_w - C_p)$	The solute flux through the membrane (kg/m ² s)
10	$B_{s(T)} = B_{s(25\text{ }^\circ\text{C})} T C F_s$	The solute transport parameter at operating temperature (m/s)
11	$C_w = C_p + \left(\frac{C_f + C_r}{2} - C_p \right) \exp \exp \left(\frac{Q_p / A_m}{k} \right)$	The concentration at the membrane surface (kg/m ³)
12	$k = 0.664 k_{dc} Re_b^{0.5} Sc^{0.33} \left(\frac{D_b}{d_h} \right) \left(\frac{2 d_h}{L_f} \right)^{0.5}$	Mass transfer coefficient (dimensionless)
13	$Sc = \frac{\mu_b}{\rho_b D_b}$	Schmidt number (dimensionless)
14	$Re = \frac{\rho d_e J_w}{\mu}$	Reynolds number (dimensionless)
15	$Rec = \frac{Q_p}{Q_f} = \frac{(C_r - C_f)}{(C_r - C_p)}$	Total recovery (dimensionless)
16	$Rej = \frac{C_f - C_p}{C_f}$	Observed rejection (dimensionless)
17	$J_w = \frac{B_{s(T)} Rej_{real}}{(1 - Rej)}$	The water flux (m/s)
18	$C_p = \frac{C_f}{Rec} [1 - (1 - Rec)]^{(1 - Rej)}$	The average permeate salinity at the permeate channel (kg/m ³)
19	$C_r = C_f [1 - Rec]^{-Rej}$	The average retentate salinity at the permeate channel (kg/m ³)
20	$E1 = \frac{P_f(in)(plant) * 101325 * Q_f(Raw\ water)}{Q_p(plant) * \epsilon * p_{unp}} + \frac{P_f(Block\ 3) * 101325 * Q_f(Block\ 3)}{Q_p(plant) * \epsilon * p_{unp}}$ $\frac{36 \times 10^5}{36 \times 10^5}$	The total plant energy consumption (kWh/m ³)

4 Modelling of wind turbine system

The power generated from the wind turbine, measured in kW and based on the value of wind speed, can be calculated by the following equations;

$$Power_g(u) = 0 \quad u \leq u_c \text{ and } u \geq u_f \quad (21)$$

$$Power_g(u) = P_{rated} \left(\frac{u^k - u_c^k}{u_r^k - u_c^k} \right) \quad u_c \leq u \leq u_r \quad (22)$$

$$Power_g(u) = P_{rated} \quad u_r \leq u \leq u_f \quad (23)$$

Where P_{rated} is the rated wind turbine power (kW), u the wind speed (m/s), u_c the wind turbine cut-in (m/s), u_r the wind turbine rated (m/s), and u_f the wind turbine cut-off speed (m/s).

5 Evaluation of a hybrid system of RO and wind turbine

This section focuses on evaluating the feasibility of wind energy system to be integrated with the RO desalination system. In this regard, the necessary power to drive the pumps that satisfies the production of freshwater at a specified set of feed conditions will be outlined. More importantly, this research will determine the precise number of turbines required to supply the necessary power of the RO system. The feed characteristics of RO plant are 1098.62 ppm, 74 m³/h, 25 °C and 9.22 atm of feed water.

The simulation-based model developed by Al-Obaidi et al. (2018) based on the selected feed conditions showed that the total energy consumption of their RO system was 0.8371 kWh/m³ for water productivity rate of 48.6 m³/h. Therefore, the power required to operate the RO plant is 40.7 kW. Here, the Hummer H25 wind turbine is selected to be integrated with the RO system. Table 2 shows the features of wind turbine.

The speed values for one year (July/2019 to July/2020) of the specified location of RO system of APC were evaluated and presented in Table 3 with the associated power generated from a single wind turbine. This in turn aids to determine the number of turbines needed to run the RO plant of APC. The total numbers of turbines wind are determined through numerical simulation technique by using the gPROMS software.

Table 2. The wind turbine data (Matysik, 2020)

Type of wind turbine	Rated Power (kW)	u_c (m/s)	u_r (m/s)	u_f (m/s)	K
Hummer H25	100	2.5	10	20	2.5649

Table 3. Simulation results of RO system powered by wind energy system

Month	Mean wind speed (m/s)	Power generated from a single wind turbine (kW)	Number of wind turbines
July/2019	2.744	0.793	51
August/2019	3.187	2.541	16
September/2019	3.125	2.271	17
October/2019	3.126	2.275	18
November/2019	3.426	3.657	11
December/2019	8.822	71.699	1
January/2020	7.88	52.931	1
February/2020	6.852	36.097	1
March/2020	5.61	20.432	2
April/2020	4.4535	9.988	4
May/2020	4.197	8.163	5
June/2020	4.282	8.749	5
July/2020	3.083	2.093	19

The simulation results of Table 3 show that the highest number of turbines required to power the RO desalination plant of APC is 51 in July /2019 at the lowest wind speed of

2.744 m/s. It should be noted that this number of turbines is determined based on the power generated from a single wind turbine. Therefore, it is important to construct a farm of 51 wind turbines to satisfy the requirements of energy. However, only one wind turbine is required for the windy winter season. Thus, the excess electrical power of windy season can be used to feed the internal grid and provides a sustainable source of energy.

5 Conclusions

Nowadays, the use of wind turbine as an alternative source of energy in the RO desalination appears as a reasonable and technically mature option towards the reduction of the total required power. The feasibility of integrating the wind turbine with the RO desalination system of APC has been examined in this study. The study has confirmed the viability of this hybrid system as only one wind turbine is sufficient to provide the required power of RO desalination system of APC. However, a farm of 51 wind turbines is necessary to drive the RO system in low wind speed seasons.

Abstract

In the traditional process design approach, aspects such as safety and reliability are typically left for analysis once the design phase is completed. Recently, methods have been developed to include inherent safety in the early design stages. This approach allows the generation of inherently safer designs as part of the process synthesis task. The design of reliable chemical processing plants can be enhanced by adding back-up units to prevent shutting down the plant due to failure of units. In this work, we present a multi-objective optimization model for the design of chemical process systems accounting for safety, reliability, and economics. The model is formulated within a generalized disjunctive programming framework, which is then reformulated as a mixed-integer nonlinear programming model using the ϵ -constrained method to generate pareto curves. The model includes the selection of standby units to increase the system availability and provides the optimal structure of the process flowsheet and operating parameters. The model is applied to the design of a distillation system accounting for risks due to explosion, while rating the system reliability and the process economics. The results show that the proposed optimization model yields design alternatives with optimal trade-offs among safety, reliability, and economics.

Keywords: safety assessment, reliability, multi-objective optimization.

1. Introduction

In the conventional process design safety assessment is typically left for analysis once the design phase is completed. Recently, as part of the process synthesis task, safety has been considered with a focus on generating inherently safer designs. For example, Medina-Herrera et al. (2014) presented an approach for the design of inherently safer distillation systems. In that work, quantitative risk assessment (QRA) techniques were used to incorporate safety considerations in the design of different distillation schemes. Ortiz-Espinoza et al. (2017) proposed a multi-objective assessment approach to evaluate chemical processes accounting for safety, sustainability, and economics. Within this approach, modifications to the processes were considered to increase safety performance while evaluating their impact on the remaining objectives. Nemet et al. (2018) presented

a mixed-integer nonlinear programming (MINLP) model for the synthesis of a methanol production process considering risk assessment during the synthesis stage. These works showed the conflict that generally exists between safety and economics. In this regard, Guillen-Cuevas et al. (2018) introduced a metric to reconcile safety and sustainability with economic aspects using a weighted return on investment type of metric.

Another aspect that is important to consider during process design is that of reliability. The reliability of a chemical processing plant can be enhanced by adding back-up units to prevent shutting down of the plant due to the failure of units. Recent works have addressed this topic from different perspectives. For instance, Ye et al. (2018) proposed MINLP models to determine the selection of parallel units considering the trade-off between availability and cost. Ade et al. (2018) studied the effect of inherent safety principles on the reliability of process plants with a focus on risk migration. Moreno-Sader et al. (2019) proposed an approach to incorporate safety, sustainability, reliability, and resilience during conceptual design stages.

Although safety and reliability of chemical plants are closely related, models that explicitly capture the interactions of both aspects in process synthesis and optimization have not been formally addressed before. This work presents a multi-objective optimization model for the design of chemical processes accounting for safety, reliability, and economics. The proposed optimization model includes the selection of parallel standby units for critical process stages to increase the system availability, together with the computation of frequency and consequences of possible catastrophic events to estimate risk levels. The model also considers decisions regarding selecting the structure of the process flowsheet and operating parameters.

The trade-offs among the objectives arise as the selection of more standby units benefits the availability of the systems but increases investment costs. Regarding safety, the presence of more units may increase the exposure to the risk produced by the additional units; on the other hand, increasing availability reduces the risk due to transition states such as start-ups and shut-downs. Furthermore, the selection of the flowsheet structure and operating parameters is a factor in which risk and economics may be in conflict. While extreme operating conditions may favour the economics of the process, operating under such conditions increases the consequences of the outcomes of hazardous events. The purpose of the proposed multi-objective optimization model is to synthesize process alternatives with optimal trade-offs among safety, reliability, and economics.

2. Problem Statement

Given a superstructure for a production process/system, a multi-objective modelling framework is presented to account for safety, reliability, and economics. The purpose of the model is to evaluate design alternatives that minimize risk, maximize availability, and minimize cost. For modelling purposes, the process under study is divided into K stages (e.g., compression, heating, cooling, etc.) for which design parameters and operating conditions are to be determined. Also, for certain critical stages (K_{red}), the option to install standby units is considered. When the process under study considers the selection of different flowsheet alternatives, the model can be formulated as a Generalized Disjunctive Programming (GDP) model (Grossmann and Trespalacios, 2009) of the form shown in Eq. (MO-RAC) involving Boolean variables Y_k , 0-1 variables for selecting the units in the superstructure, 0-1 variables y for selecting back-up units, and continuous variables x , c for the state, design and cost variables of the corresponding flowsheet.

$$\begin{aligned}
 & \min_{x,y} \text{Risk} \\
 & \max_y \text{Availability} \\
 & \min_{x,y} \text{Cost} \\
 \text{s.t.} \quad & g(x) \leq 0 \\
 & \left[\begin{array}{c} Y_k \\ h_k(x) \leq 0 \\ c_k = \alpha_k \\ R_k = f_R(x) \end{array} \right] \vee \left[\begin{array}{c} \neg Y_k \\ B^k x = 0 \\ c_k = 0 \\ R_k = 0 \end{array} \right] \forall k \in K \setminus K_{red} \\
 & \left[\begin{array}{c} Y_k \\ h_k(x) \leq 0 \\ c_k = \alpha_k y \\ AV_k = f_A(y) \\ R_k = f_R(x, y) \end{array} \right] \vee \left[\begin{array}{c} \neg Y_k \\ B^k x = 0 \\ c_k = 0 \\ AV_k = 1 \\ R_k = 0 \end{array} \right] \forall k \in K_{red} \quad (\text{MO-RAC}) \\
 & \Omega(Y) = \text{True} \\
 & \text{Risk} = \sum_{k \in K} R_k \\
 & \text{Availability} = A = \prod_{k \in K_{red}} AV_k \\
 & \text{Cost} = \sum_{k \in K} c_k \\
 & x \in R^n, c \geq 0, Y \in \{\text{True}, \text{False}\}^m, y \in \{0,1\}
 \end{aligned}$$

In the next section we present the equations for evaluating the availability AV_k and risk R_k that pertain to the reliability and safety of the selected flowsheet at each stage k .

3. Model formulation for reliability and safety

To increase the reliability of the process, the GDP model considers the installation of a number of potential standby units (J) in certain stages (K_{red}). The evaluation of the availability of each stage is computed through the probabilities of each unit to be available (p) (Ye et al., 2018). Eq. (1) describes the selection of at least one unit per stage, Eq. (2) is a symmetry breaking constraint for stages with identical parallel units (K_{ide}), Eq. (3) evaluates the availability of stages with only identical standby units, while the evaluation of the availability of stages with nonidentical units (K_{non}) is shown in Eq. (4). The system availability is calculated using Eq. (5).

$$\sum_{j=1}^{n_k} y_{k,j} \geq 1, \quad \forall k \in K_{red} \quad (1)$$

$$y_{k,j+1} \leq y_{k,j}, \quad \forall j \in J_k, \forall k \in K_{ide} \quad (2)$$

$$P_k = p_k \sum_{j=1}^{n_k} y_{k,j} (1 - p_k)^{j-1}, \quad \forall k \in K_{ide} \quad (3)$$

$$P_k = 1 - \prod_{j \in J_k} (1 - p_{k,j} y_{k,j}), \quad \forall k \in K_{non} \quad (4)$$

$$A = \prod_{k \in K} P_k \quad (5)$$

The cost of the system is determined considering installation and repair costs. Eq. (6) and (7) represent the cost per stage and the total cost of the system.

$$C_k = \sum_{j=1}^{n_k} y_{k,j} (c_{k,j}^{inst} + c_{k,j}^{rep}), \quad \forall k \in K_{red} \quad (6)$$

$$Cost = \sum_{k \in K} C_k \quad (7)$$

The safety performance of the processes is evaluated using QRA techniques. Within this context, risk is defined as a function of the frequency (freq) and consequences (DR) of a hazardous event. Eq. (8) shows the calculation of risk for each unit j in a stage k . The frequency element considers the failure frequency for each unit j as well as the probability of a certain hazardous event to take place (p^{haz} , p^{exp}) as shown in Eq. (9) and (10). Risk is computed per stage as shown in Eq. (11), and the risk due to transient states is calculated in Eq. (12). Finally, Eq. (13) shows how to estimate the total risk in the plant.

$$Risk_{k,j}^{Exp} = freq_{k,j}^{Exp} DR_k^{Exp}, \quad \forall k \in K, \quad \forall j \in J_k \quad (8)$$

$$freq_{k,j}^{Exp} = \lambda_k p_k^{hazf} p^{Exp} y_{k,j} (1 - p_k^i)^{j-1}, \quad \forall k \in K_{ide}, \quad \forall j \in J_k \quad (9)$$

$$freq_{k,j}^{Exp} = \lambda_{k,j} p^{haz} p^{Exp} y_{k,j} \prod_{j=1}^{j-1} (1 - p_{k,j} y_{k,j}), \quad \forall k \in K_{non}, \quad \forall j \in J_k \quad (10)$$

$$Risk_k^{Exp} = \sum_{j \in J_k} Risk_{k,j}^{Exp}, \quad \forall k \in K \quad (11)$$

$$Risk_k^{ExpT} = (-\ln A) p^{haz} p^{exp} DR_k^{Exp} \quad (12)$$

$$Risk = \sum_{k \in K} (Risk_k^{Exp} + Risk_k^{ExpT}) \quad (13)$$

The estimation of consequences is measured in this work as the damage radius resulting from an explosion event (DR). Eq. (14) shows how such a radius depends on the hazardous potential of the explosion. This hazardous potential is estimated according to energy factors and penalties. For more details on the procedure to estimate the hazardous potential the reader is referred to Rathnayaka et al. (2014).

$$DR_k^{Exp} = 0.9 (HazPot_k^{Exp})^{\frac{1}{3}} \quad (14)$$

4. Case study

To illustrate the application of the proposed multiobjective GDP model (MO-RAC), a simplified case study is considered with fixed configuration of a distillation column to separate hexane and heptane. Figure 1 shows the distillation scheme, which is based on the case proposed in (CCPS, 2000). In this case study, the installation of standby units in the condenser and reflux pump stages is considered to increase the system availability. The safety assessment considers scenarios of continuous releases of flammable material, thus leading to potential explosion incidents. Table 1 shows the parameters used in the model for the stages with potential parallel standby units.

Figure 1. Distillation scheme

Table 1. Parameters for the case study

	Availability		Failure rate (fails/yr)	
	k=1	k=2	k=1	k=2
j=1	0.94	0.88	0.064	0.127
j=2	0.94	0.89	0.064	0.116
j=3	0.94	0.90	0.064	0.105
	Installation cost (k\$/yr)		Repair cost (k\$/yr)	
	k=1	k=2	k=1	k=2
j=1	$0.65(A)^{0.6}$	$26.0(\text{flow})^{0.54}$	2	3
j=2	$0.65(A)^{0.6}$	$26.8(\text{flow})^{0.54}$	2	4
j=3	$0.65(A)^{0.6}$	$27.3(\text{flow})^{0.54}$	2	5

As part of the design the model determines the reflux ratio, the pressure and temperature at the condenser, and the number of stages. The evaluation ranges of such variables are: 2 to 30 for the reflux ratio, 3 to 10 bar for pressure, 100 to 300 °C for temperatures, and 5 to 25 for number of stages.

5. Results

Figure 2 shows the Pareto curve for the multi-objective GDP optimization problem. Each point corresponds to one subproblem solved to minimize risk subject to a certain upper bound of total cost. The availability objective is implicitly considered in the optimization of risk as higher availability levels generally lead to lower risk levels (see Eq. (12)). The estimated availability for each point is shown in Figure 2. Figure 3 shows details for the following solutions: a) minimum risk (maximum cost and availability), b) maximum risk (minimum cost and availability), c) and d) intermediate scenarios. It is observed that the minimum risk solution operates at the lowest possible pressure with the installation of every possible standby unit. On the other hand, the minimum cost solution operates at the highest operating pressure considered for the column, with the installation of just one unit in each stage. The multiobjective GDP model was reformulated as an MINLP using the ϵ -constrained formulation to find the Pareto curve. The model was implemented in GAMS and solved using the commercial solver BARON requiring a total of 112.7 CPUs.

Figure 2. Pareto curve of cost vs risk for different levels of availability

6. Conclusions

A multi-objective GDP optimization model for the incorporation of safety and reliability in the design of chemical processes has been presented. The model considers the selection of standby units to increase the system availability and design decisions that impact safety performance. The application to the design of a binary distillation system showed how designs are obtained with optimal trade-offs among safety, reliability, and economics. Future work will report the application of the proposed model in the synthesis of a methanol process.

Abstract

Plant availability and operating uncertainties have been critical considerations for the design and operation of chemical processes as they directly impact service level and economic performance. This paper proposes a two-stage stochastic Generalized Disjunctive Programming (GDP) model with reliability constraints to deal with both the exogenous and endogenous uncertainties in process synthesis, where the reliability model is incorporated into the flowsheet superstructure optimization. The proposed stochastic programming model anticipates the market uncertainties through scenarios for selecting the optimal flowsheet topology, equipment sizes and operating conditions, while considering the impact of potential parallel units for improving plant availability. An improved logic-based outer-approximation algorithm is applied to solve the resulting large-scale GDP model, which effectively avoids numerical difficulties with zero flows and provides high quality design solutions. The applicability of the proposed modeling framework and the efficiency of solution strategy is illustrated with an industrial methanol synthesis process.

Keywords: reliability-based superstructure optimization, stochastic programming, endogenous and exogenous uncertainties, logic-based outer approximation algorithm

1. Introduction

Process synthesis is the assembly and interconnection of units into a process network, involving different physical and chemical phenomena to transform raw material and energy inputs into desired products with the goal of optimizing a given objective function (Chen and Grossmann, 2017). Generalized Disjunctive Programming (GDP) is a modeling framework to explicitly represent the relationship between algebraic descriptions and the logical structure of a design problem. It is therefore well-suited to problems involving selection among discrete process alternatives with nonlinear process models (Grossmann and Trespalacios, 2013). Synthesis of process flowsheets are subjected to uncertainties, which directly impact its service level and economic performance. There are two types of uncertainties in process synthesis: exogenous, where the true parameter values are revealed independently of decisions, and endogenous, where the parameter realizations are influenced by the decisions taken (Apap and Grossmann, 2016). Exogenous uncertainties correspond typically to market uncertainties, such as product demands, product prices and utility prices. For endogenous uncertainties, decisions can influence the parameter realizations by causing alteration of the probability

distribution, or affecting the time at which we observe these realizations. Reliability-based design optimization (RBDO) captures the endogenous uncertainties from equipment failures, where the selection of redundant equipment, maintenance policy and storage sizing affect the plant availability by altering the probability distributions (Ye et al., 2018). In previous work Straub et al. (1990) and Thomaidis et al. (1994) integrated flexibility (exogenous uncertainties) and reliability in a uniform framework. However, their work only considered a quantitative measure to evaluate the proposed design alternatives, and did not consider the selection of standby units in order to improve the system availability. The major goal of this paper is to propose a novel model that integrates both exogeneous uncertainty through stochastic programming, and endogenous uncertainty through RBDO, for the synthesis of process flowsheets, where the reliability model is incorporated into the superstructure optimization. Application of the proposed model is illustrated with an industrial methanol synthesis process.

2. General model formulation

We propose the following two-stage stochastic GDP model with reliability constraints to deal with the exogenous and endogenous uncertainties in process synthesis:

$$\begin{aligned}
 & Z = \sum_i c_i + A \sum_s p_s f(x_s) \\
 \text{s.t.} \quad & g(x_s) \leq 0, \forall s \in S \tag{1} \\
 & [Y_i h_i(y_i, x_s) \leq 0 \ c_i = c_i^{fix} + c_i^{var} \times y_i + c_i^{repa}] \vee [\neg Y_i \ B^i x_s = 0 \ c_i = 0], \ \forall s \in S, i \in I_R \\
 & \left[Y_i h_i(y_i, x_s) \leq 0 \ z_{i,r+1} \leq z_{i,r} \ c_i = (c_i^{fix} + c_i^{var} \times y_i + c_i^{repa}) \sum_{r=1}^{n_r} z_{i,r} \ A_i \right. \\
 & \quad \left. = p_i \sum_{r=1}^{n_r} z_{i,r} (1 - p_i)^{r-1} \right] \vee [\neg Y_i \ B^i x_s = 0 \ c_i = 0 \ A_i = 1], \ \forall s \in S, i \\
 & \quad \in I_{iden} \\
 & \left[Y_i h_i(y_i, x_s) \leq 0 \ c_i = \sum_{r=1}^{n_r} z_{i,r} (c_{i,r}^{fix} + c_{i,r}^{var} \times y_i + c_{i,r}^{repa}) \ A_i = 1 - \prod_r (1 - p_{i,r} z_{i,r}) \right] \\
 & \quad \vee [\neg Y_i \ B^i x_s = 0 \ c_i = 0 \ A_i = 1], \ \forall s \in S, i \in I_{non} \\
 & \quad Y_i = True, \quad \forall i \notin I^D \\
 & \quad \Omega(Y) = True \\
 & \quad A_{sys} = \prod_{i \in I_{iden} \cup I_{non}} A_i \\
 & \quad y \in R^m, \ c \geq 0, \ Y \in \{True, False\}^r, \ z \in \{0, 1\}^t \\
 & \quad x_s \in R^n, \ \forall s \in S
 \end{aligned}$$

In the two-stage stochastic programming model, the first-stage variables consist of three types of design variables, the Boolean variables Y_i which determine the selection among the different process alternatives, the binary variables $z_{i,r}$ to represent whether to choose

the redundant unit r for the certain equipment i , and the continuous variables y_i related to the equipment sizes, such as reactor volume, number of trays in column, and design capacity of heat exchanger or compressor. The second-stage decisions x_s are related to the operational variables which can be adjusted to different scenarios, such as flowrates, temperatures and pressures. The objective function is to minimize the total cost of the system, including the capital cost c_i and the expected operational expenditure $A \sum_s p_s f(x_s)$. Generalized Disjunctive Programming is applied to explicitly express the logic encapsulated in the superstructure. The reliability model is integrated within disjunctions that define the selection of the units, which in turn define the structure of the selected flowsheet. Single units are given fixed probabilities of being available, and Simple Bayes Rules are used to predict the system availability A_{sys} . If a unit exists, the constraints $h_i(y_i, x_s) \leq 0$ enforce the relevant mass and energy balances, and the constraints $c_i = c_i^{fix} + c_i^{par} \times y_i + c_i^{repa}$ calculates the total cost of the unit. Otherwise, constraints $B^i x_s = 0$ describe port variable relationships when the unit is absent, and the capital cost of the unit is set to 0. The proposed two-stage stochastic programming model anticipates the market uncertainties through scenarios for selecting the optimal flowsheet topology, equipment sizes and operating conditions, while considering the impact of additional redundant units for improving plant reliability.

3. Solution Method

In this work, we propose an improved logic-based outer-approximation (LOA) algorithm to solve the resulting large-scale GDP model. LOA allows the solution of reduced space subproblems, including only constraints in selected disjuncts rather than the full-space representation. Therefore, it can effectively avoid numerical difficulties with zero flows and provides high quality design solutions. It should be noted that, when we consider the reliability, binary variables are introduced to represent the selection of parallel units. Our model becomes a hybrid GDP formulation with implicit “nested disjunctions”, which not only contain the Boolean variables to select the flowsheet structure, but also includes binary variables to select the redundant units for improving reliability. Therefore, when considering the choices of the units in the superstructure (Boolean variables) in the master problem, the reduced space subproblems in the LOA become MINLP subproblems rather than only NLP subproblems. The advanced computational tool GDPopt, provides various implementations for solving GDP problems. As an open-source platform, it incorporates recent innovations in reformulation strategies and logic-based solution algorithms (Chen and Grossmann, 2019).

Figure 1. Improved logic-based outer approximation flow diagram for process synthesis considering reliability.

4. Industrial Case Study

In this section an industrial case study which converts syngas to methanol is presented to illustrate the application of the model (1). The methanol synthesis process was formulated by Türkay and Grossmann (1996) without reliability and uncertainty considerations. This includes the discrete decisions between two syngas feeds with different purity and cost, single and two-stage compression for both the feed and recycle streams, as well as the choice between a higher-conversion, higher-cost reactor and a cheaper variant. Our goal is to determine both design- and operational-level decisions in order to minimize the total cost of the system with both the exogenous uncertainties and plant availability taken into consideration. When considering reliability, parallel units are installed in the critical stages. The problem has four explicit disjunctions for the structural choices, involving implicit “nested disjunctions” for the selection of redundant units. The superstructure of methanol synthesis problem is shown in Figure 2.

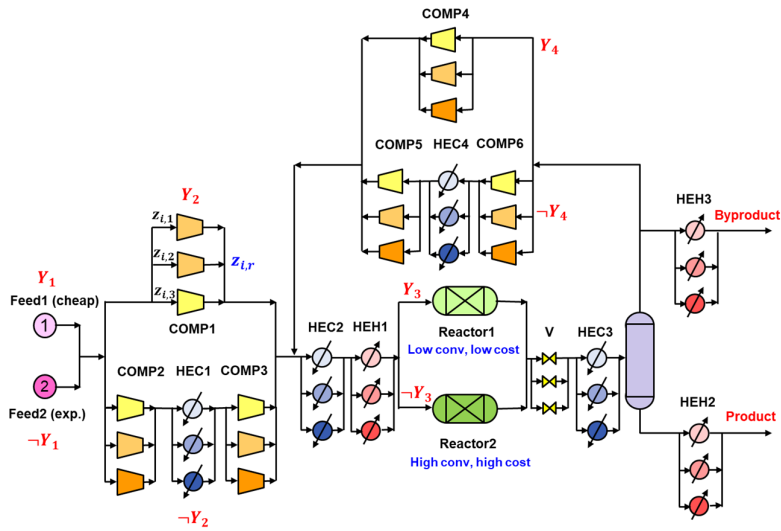

Figure 2. Superstructure of methanol synthesis problem.

The synthesis of the methanol process can be formulated as the two-stage stochastic programming problem. In the first stage the topology of network is selected, and in the second stage the process operation is selected out according to the realization of uncertain parameters. In terms of cost, the first-stage decisions represent the design decisions, including the feed selection, reactor selection, single-stage compression or two-stage compression selection, redundancy selection and design capacity of each unit, which are related to the capital expenditure; the second-stage decisions are the operational decisions, involving flowrates, temperature, pressure, and utility requirement that account for the operational expenditure. The methanol product demand and the electricity price are regarded as exogenous uncertainties. Each of them is modeled with 3 scenarios (low, medium, high) with certain discrete probability distribution, based on the historical data from the changing markets. Therefore, the two-stage stochastic programming has a total of 9 scenarios. Moreover, some critical units are given with fixed failure rates that can be regarded as endogenous uncertainties. The failure of any one of these processing stages

can result in the failure of the entire system, which will compromise its ability to meet customer demands. At each stage three potential back up units are considered.

5. Solution Results

Table 1. Solution results for different models.

Model	# of Cons	# of Cont. Vars	# of Bin. Vars	Strategy and Solver	Solution Time (s)	System Availability	Objective Profit
Deterministic Model	474	307	8	GLOA MILP-Gurobi NLP-Conopt4	35.2	0.9318	2009.16
Stochastic Programming	3986	2491	8	GLOA MILP-Gurobi NLP-Conopt4	322.8	0.9318	2156.04
Integrate Reliability and Uncertainty	4306	2537	58	GLOA MILP-Gurobi NLP-Conopt4 MINLP-Dicopt	446.1	0.9646	2174.96
VSS (\$)		146.88		VSS (%)		7.31 %	
VSS+VRS (\$)		165.80		VSS + VRS (%)		8.25 %	

To illustrate the advantages of the proposed modelling method, we compare the solution results from three different models, the deterministic model with exogenous uncertainties evaluated at their mean values, the stochastic programming model with 9 scenarios to account for exogenous uncertainties, and model (1) which integrates reliability and uncertainty to handle both exogenous and endogenous uncertainties. The first two models are standard GDP models while the last model is a hybrid GDP formulation with the introduction of binary variables to indicate the selection of the redundant units. These three models are coded in Pyomo. The logic-based outer approximation algorithm is applied to solve these three models, where GUROBI is used to solve the MILP master problems, CONOPT4 is used to solve the NLP subproblems and DICOPT is used to solve the MINLP subproblems when considering reliability. The value of stochastic solution is calculated to evaluate the profit that can be expected from implementing the stochastic solution instead of simply using the deterministic solution.

As seen in Table 1 the model that integrates reliability and uncertainty yields the best economic performance compared to the cases when either reliability is not considered, or when exogenous uncertainties are evaluated with mean values. The system availability is increased from 0.9381 to 0.9646 by adding back-up units, while the profit is increased by 8.25 % with improved operational flexibility and reliability. Figures 3-5 present the optimal designs of the corresponding process flowsheets obtained from these three models.

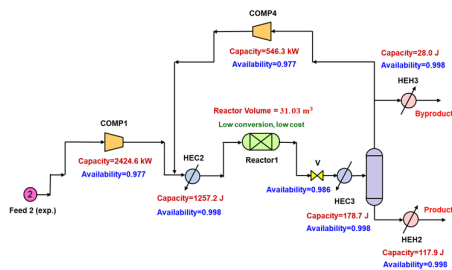

Figure 3. Deterministic Model.

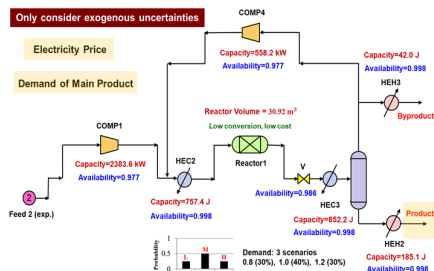

Figure 4. Stochastic Programming Model.

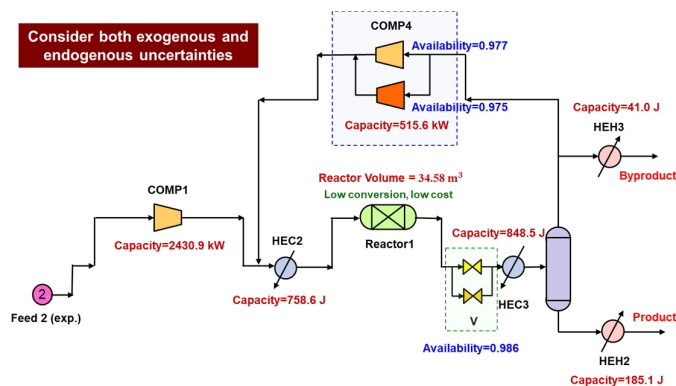

Figure 5. Integrating Reliability and Uncertainty Model.

6. Conclusions

In this paper, we have proposed a two-stage stochastic programming GDP model with reliability constraints to deal with both the exogenous and endogenous uncertainties in process synthesis. Simultaneous optimization of reliability and uncertainty in process design provides potential improvement for the operational flexibility and economic performance. An improved Logic-based Outer Approximation (LOA) algorithm was applied to the hybrid GDP model with implicit nested disjunctions, obtaining optimal solution by avoiding zero-flow singularities. The proposed methodology was illustrated with the synthesis of a methanol process to simultaneously optimize the process flowsheet and the number of stand-by units by considering exogenous uncertainties in product demand and electricity price, and endogenous uncertainties in equipment failures. It was

shown that the proposed design led to simultaneous improvement both in the profit and in the system availability.

Abstract

Reactor designs with mixed catalysts play an important role to transform a multiple reactor system to single-shot reactors. In addition to savings in capital and ease of implementation, single-shot reactors are useful to break equilibrium limitations, therefore increasing the yield and selectivity of desired product. However, the nonlinear, highly exothermic and poorly conditioned nature of mixed-catalyst systems makes it difficult for commercial process simulation and optimization tools to optimize these systems. This study describes the zone and partial moving finite element approaches and their applications to o-xylene oxidation and syngas to olefin (STO) processes. 35% and 5% increases are achieved in the product yield for o-xylene oxidation and STO problems, respectively. Shown with these two examples, this tool is very promising in process intensification for other reactive systems.

Keywords: process intensification, reaction, optimization

1. Motivation and Background Information

Lower olefins (C₂ – C₄) are traditionally produced from cracking of naphtha. However, high oil prices and environmental concerns have initiated research to find other alternatives for olefin production. The two-stage syngas to olefins process is a well-studied process, in which the synthesis gas, mixture of hydrogen and carbon monoxide, reacts to methanol as the first step. Then, methanol reacts to produce olefins. However, this process has equilibrium limitations. On the other hand, olefins can be directly made in one-shot reactors by mixing the catalysts from the two-stage process [1]. Single shot reactors can break the equilibrium limitations with reduced number of unit operations.

The mixed catalyst design of a single shot reactor can be found in other graded bed problems. The ultimate objective of the study is to optimize the catalyst mixing ratio along the reactor, which makes the problem a singular control problem, where control variables appear only linearly in differential algebraic equations. In this case, the optimal control cannot be derived from the stationary condition of Hamiltonian [2]. Numerical optimization methods fail to handle the singular arcs and lead to highly oscillatory profiles, especially when a finer mesh is introduced. There have been other methods to tackle the ill-conditioned nature of the problem, but these methods mostly need a known solution structure and an expression for the singular control profile, which are difficult to determine beforehand. Therefore, a partial moving grid method with direct optimization approach is selected to solve the singular control problems [3].

In this manuscript, the detailed STO reaction mechanism and models used for o-xylene oxidation and STO problems are defined. Two separate optimization approaches are explained and their implementation and results are presented. Conclusions are drawn and future work is proposed for modeling and optimization of STO reactors and other mixed-catalyst reactive systems.

2. Reactor Modeling

Two dimensional models provide accurate representations of heat and mass transfer phenomena for packed bed reactors. In a reactor with exothermic reactions, it is crucial to capture the radial temperature profile accurately. However, two dimensional models are computationally costly to solve, especially as optimization problems. Therefore, we consider the one dimensional alpha model, which can approximate the temperature profiles of a two dimensional model. The two dimensional steady state model of a packed bed reactor in pseudo-homogeneous form, for species j and reactions i , is given below:

$$Q \frac{\partial c_j}{\partial V} = \frac{D}{R} \frac{\partial}{\partial R} \left(R \frac{\partial c_j}{\partial R} \right) + \sum_i v_{ij} r_i$$

$$\sum_j f_j c_{pj} \frac{\partial T}{\partial V} = \frac{\Lambda}{R} \frac{\partial}{\partial R} \left(R \frac{\partial T}{\partial R} \right) + \sum_i (-\Delta H_i) r_i$$

Starting with the governing equations above, the radial concentration differences are neglected by assuming the timescale of reactant consumption is much slower than that of radial dispersion. On the other hand, the radial temperature profile is non-uniform due to constant heat removal through the reactor walls. Therefore, the radial temperature profile needs to be approximated.

The total heat release H is introduced as:

$$H(c, V) = \sum_i (-\Delta H_i) r_i(c, T)$$

and a Taylor series expansion is performed around the heat-averaged temperature, \underline{T}

$$H(c, V) = \sum_i (-\Delta H_i) r_i(c, \underline{T}) e^{A(T-\underline{T})+B(T-\underline{T})^2}$$

where A and B are evaluated at $T = \underline{T}$ as:

$$A = \frac{\partial \ln \ln H}{\partial T}, \quad B = \frac{1}{2} \frac{\partial^2 \ln \ln H}{\partial T^2}$$

Hagan et al. [4] show that the heat equation can be simplified to the equation below, where α is the dimensionless heat loss parameter.

$$\sum_j f_j c_{pj} \frac{\partial T}{\partial V} = -\frac{8\alpha\Lambda}{AR_t^2} + \sum_i (-\Delta H_i) r_i$$

Here, α can be calculated using the implicit equation:

$$\frac{4\alpha}{Bi} = A(\underline{T} - T^c) + \ln \ln(1 - \alpha) - \frac{B}{3A^2}(1 - \alpha)$$

The mass balance equations are constructed in terms of change in the molar flow rates of components, f_j .

3. Optimization Formulation and Solution Strategy

3.1. Zone Algorithm

In the zone approach, the differential and algebraic equations (DAEs) are discretized and converted to nonlinear equations via orthogonal collocation on finite elements. The number of zones along the reactor bed is selected before solving the problem. Each zone is equally divided into a fixed number of finite elements and each element has a fixed number of collocation points. Three collocation points per finite element are selected for every case in this study. The control variable, the catalyst mixing ratio, is constant in each zone and only changes from one zone to another. This is consistent with the implementation in practice, because mixed catalysts can be deployed in layers within tubular reactors.

Although the number of zones is fixed for the problem, the locations of these zones are variable. This formulation increases the size and the nonlinearity of the problem but provides a quick implementation and an approximate solution to the optimal control profile.

3.2. Partial Moving Finite Element Algorithm

Partial moving grid algorithm is a novel method developed by Chen et al. [3] to find the exact solutions to singular optimal control problems. The strength of this method comes from a systematic implementation of heuristics and addresses the critical issue of size and nonlinearity for singular control problems, while enforcing the variational optimality conditions for optimal control.

Because the solution structure of the control profile is unknown, it is not possible to guess the number and location of the singular arcs in the control profile. Therefore, the break points for the singular arcs have to be freely determined by the nonlinear solver, IPOPT in this case. For that purpose, all the finite elements have to be moving elements, so that they can move “freely” along the reactor and capture the break points, and the optimal profiles. The number of finite elements must be sufficiently large, so that the profiles do not lack accuracy.

However, a higher number of moving finite elements would lead to a large problem size and an increase in the nonlinearity, and more importantly to ill-conditioning in the problem, which could easily make the problem unsolvable. Thus, a judicious selection of moving elements is crucial, and this is why this algorithm is very effective.

The partial moving grids (PMG) approach can be summarized in three main stages: constructing a fixed grid; calculating the switching function; and inserting moving elements and detecting and deleting any spikes in the control profiles. Starting from an equally spaced coarse grid and calculating the errors on non-collocation points, fixed elements are introduced at points where error constraints are violated, and moving elements used to determine optimal breakpoint locations. Along the way, any spikes in the control profile are detected and eliminated, in order to ensure that the variational optimality conditions are satisfied.

4. Results

4.1. *O*-xylene Oxidation to Phthalic Anhydride

The *o*-xylene oxidation mechanism consists of three reactions. The desired reaction is the partial oxidation of *o*-xylene to phthalic anhydride. Remaining reactions, total oxidation of *o*-xylene and total oxidation of phthalic anhydride, are side reactions. The reactions are catalyzed by a vanadium pentoxide catalyst mixed with an inert powder, and the blue plots in Figure 1 show the fraction of the active (vanadium pentoxide) catalyst. This reaction system is modelled using the alpha model. The objective is to maximize the phthalic anhydride production. The problem is solved using the zone approach, for one, three, four and six zones.

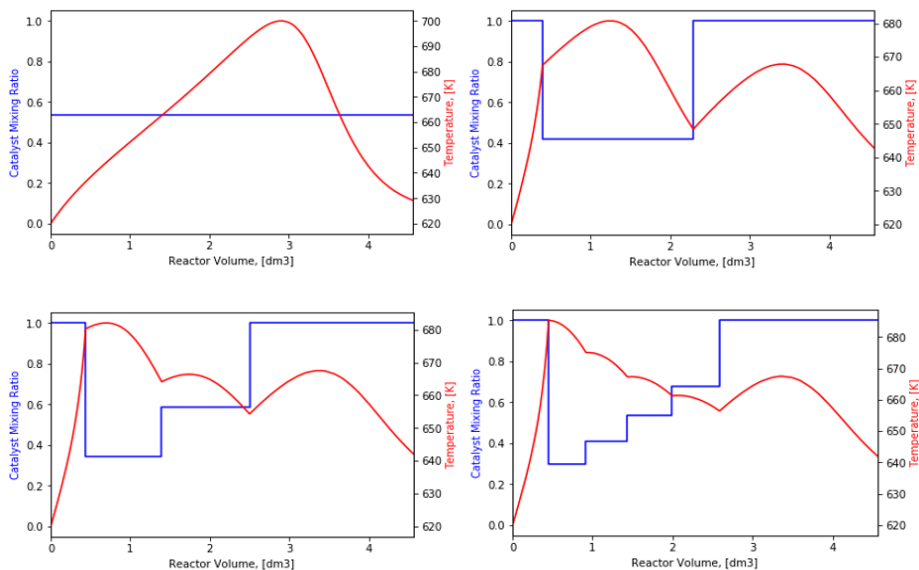

Figure 1 Control and Temperature Profiles for Alpha Model *O*-xylene Oxidation Problem with Different Number of Zones

A developing trend can be observed in the control profile as the number of zones increases. Higher phthalic anhydride production is achieved with an increasing number of catalyst zones. These results are in agreement with those of Nie et al. [5]

The same problem is then solved using the partial moving grids approach. Unlike the zone approach, where the solution depends on the number of zones selected, the partial moving grid approach can yield the exact solution to the infinite dimensional singular control problem. Compared to the solution graphs from the zone approach, both the stepwise control and kinked temperature graphs are smoothed as needed by partial moving grids and represent the exact variational solution. The NLPs for both methods have up to 15,000 variables and equations. These NLPs are solved for 1 to 6 zones using the zone approach and for the exact profiles using partial moving finite elements in under 30 CPU seconds.

Syngas to Olefin

The syngas to olefins reaction mechanism is a complex kinetic system, particularly when catalyzed by mixed catalysts. The olefin production starts with introduction of synthesis gas mixture into the reactor and CO and hydrogen react over Zn/Zr catalyst to yield methanol. Methanol reacts over SAPO catalyst to yield methanol. Moreover, as a result of Zn/Zr – SAPO catalyst mixture, the olefins can react to paraffins, which is an undesired reaction. [6]. The overall kinetic scheme is shown in the figure below.

The catalyst mixture breaks the equilibrium limitation during the methanol production step and enables higher rates, but it also promotes the hydrogenation of olefins, which is an irreversible reaction and results in loss of olefins.

Figure 3 STO Mechanism over Zn/Zr - SAPO Catalyst Mixture

STO optimization problem is solved to maximize the lower olefin ($C_2 - C_4$) yield at the reactor exit using the zone approach. The decision variables in the optimization formulation are inlet temperature, inlet feed ratio and catalyst mixing ratio. The blue plots in Figure 4 show the Zn/Zr catalyst fraction. A 5% increase in lower olefins yield is achieved switching from one zone to three zones.

5. Conclusions

Mixed catalyst problems are singular control problems which are usually ill-conditioned and cannot be dealt with commercial optimization tools. Two different optimization techniques, the zone approach and the partial moving finite element approach, are applied to *o*-xylene oxidation and STO problems, leading to 35% and 5% increases in the product yield in 3 zones for the two problems, respectively. The zone approach is easier to implement and its results are more practical to implement in industry. However, the result will always be suboptimal, and it is not possible to know how far the solution is from the exact solution. On the other hand, it is possible to get the exact solution to the same problem with the partial moving grids (PMG) approach, which is a more complex algorithm and more difficult to transfer to practice. Thus, applications of the two different optimization algorithms to the same problem are necessary for the completeness of the study.

Also, because of the exothermic nature of the STO mechanism, thermal runaways need to be considered for a safe operation and reactor design. In addition, part of our future work will consider optimization under uncertainty. These extended optimization formulations will be implemented to address uncertainties in the reaction parameters and catalyst deactivation, using a two-stage multi-scenario approach [7]. The aim would be to maximize product yield, while respecting the conversion and selectivity constraints and avoiding thermal runaways.

Abstract

The objective of gas-lift optimization is to allocate the available compressed gas to each well of the platform such that crude oil production is maximized from the group of wells. A wrong allocation of gas may lead to the de-optimization of those wells resulting in lesser production of fluid. Considering the cost and scarcity of compressed gas, allocating them to the group of wells in optimum quantity to enhance oil production becomes the job of utmost importance. In this paper, representative field data have been used to optimize the production using regression and mathematical linear programming. Results produced by this method have been tested at one of the well platforms of the Indian offshore oil field with satisfying outcomes.

Keywords: Artificial Lift, Gas Lift, Production Optimization, Regression, Oil and Gas

1. Introduction

As a routine practice, mostly one or two wells are put under testing and optimization thereafter to get the maximum production. On that very day, lift-gas is adjusted for production optimization to those tested wells accordingly. Since the quantity of lift-gas is not unlimited (and certainly not cheap) in the field, allocating it to all the individual wells for maximum production is even more important. Many thumb rules are being used in the field and different models have also been developed by researchers to optimize the oil production and lift-gas allocation. Posenato et al. (2012) used a Genetic Algorithm for gas lift optimization under lift-gas supply constraint due to limited compression facility. Dutta-Roy (1997) used sequential quadratic programming to study the gas lift allocation and interaction between wells flowing on a common gas lift supply header. Camponogara et al. (2006) used dynamic programming for addressing the problem of gas-lift optimization. Epelle et al (2019) optimized Net Present Value (NPV) of production system by determining lift gas allocation, well controls and other routing constraints, where NPV is combined effective value of revenue generated from oil and gas production and cost incurred on application of artificial lifts etc. Supplying an inadequate quantity of lift-gas may lead to liquid loading in the production tubing causing lesser production; on the other hand, more lift-gas into production tubing will not allow the oil to flow at the optimum rate. In this work, a simple methodology has been developed to allocate the right amount of lift gas among already tested and optimized wells for optimum production from the well platform which house group of wells.

2. Problem Statement

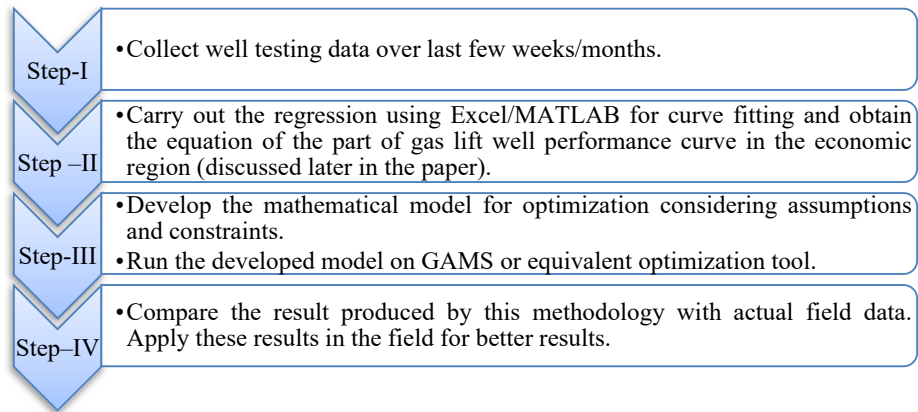

The lift-gas is being supplied to a particular well platform housing a set of wells from a common header/manifold and adjusting this lift gas to one particular well will affect the gas injection rate and pressure of other wells due to interaction among them (Dutta-Roy, 1997). Consequently, production from other wells gets de-optimized from their maximum value. Therefore, it becomes a matter of utmost importance to adjust lift-gas of all the wells such the maximum production is obtained not just from a few wells but from the entire well platform. The objective function problem can be expressed as in Eq. (1.0):

$$\text{Max } P = \sum_{i=1}^n (p_i) \quad (1.0)$$

Where, n is the set of n -number of wells designated as well- $i = \{i: i = 1, 2, \dots, n\}$, need gas injection at the rate of $q_i = \{i: i = 1, 2, \dots, n\}$ to produce liquid/oil at the rate of $p_i = \{i: i = 1, 2, \dots, n\}$.

3. Methodology

In this methodology, a simple procedure depicted in the flowchart has been followed:

Before going further following are the assumptions and declarations in this methodology of gas lift optimization:

- In this analysis, only the effect on the production due to the allocation of lift-gas to individual wells has been considered.
- the liquid produced is mostly oil (almost zero BSW), therefore, the effect of water-cut is not considered.
- Backpressure on well-head due to change in pressure in the group/common production manifold due to variation in production has been ignored.
- The effect of change in pressure at well-head due to change in lift gas rate and pressure has also been ignored.

3.1. Collect well testing data and understanding well performance curve

Figure 1 is a schematic diagram of a well testing facility in which total injection gas is coming to 6" common manifold from the gas compression facility, wherefrom it is distributed among wells. Quantity of produced oil and gas can be tested by diverting a particular well to the separator via 6" test header. The flow of oil from the well is a very complex mechanism and it depends on multiple factors like reservoir conditions, inflow

and outflow performance relationships, etc. Mayhill (1974) initially discussed the concept of gas lift performance curve (Figure 2), where point D indicates the maximum production of the well, and the line DE divides the entire plot into two areas, Area I and Area II.

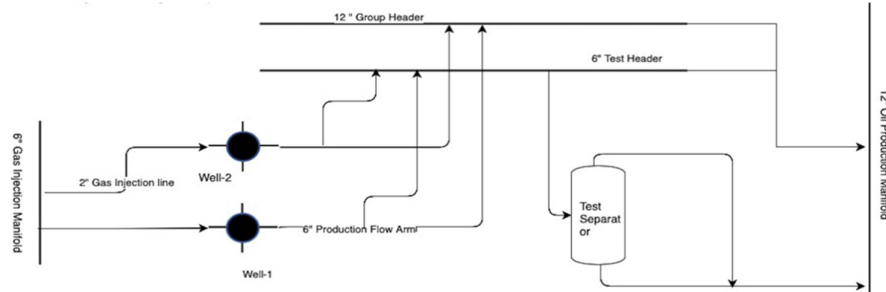

Figure 1: Well testing facility of well platform

Figure 2: Representative gas lift performance curve

Production of oil is increasing function of gas injection rate till point D and it starts decreasing afterward. Upon analysis, it can be observed that near the point of maxima gas injection rate increases significantly compared to the minor improvement in oil production. Point A to C is marked with a dotted ellipse and is the most economical region for production. It can also be observed that in this small region the curve is following an almost straight-line pattern (from point A to C).

3.2. Regression analysis

When the reservoir depletes and it does not have enough pressure to flow the well on self-mode, the role of an artificial lift to flow the fluid of the well to the separator becomes pertinent. The gas lift method is the preferred way to flow them at offshore installations. Further, the study and analysis of the gas lift performance curve which shows the relationship between the oil production rate (p_i) and gas lift injection rate (q_i) help a lot in optimizing the production and in lift-gas allocation. An n-th order polynomial has been provided to correlate the relationship between gas lift injection rate (q_i) and the oil production rate (p_i) (Sun-Young Jung et al., 2016):

$$p = a_0 + a_1 q_i + a_2 q_i^2 + \dots + a_n q_i^n = \sum_{j=0}^n (a_j q_i^j) \tag{2.0}$$

where p is the rate of production of oil, q is the gas lift injection rate for i-th well and a_0, a_1, a_2, a_n are coefficients generated by the least-squares method during regression analysis. To understand the relationship between oil production rate and gas lift injection rate, well testing data have been tried to fit into the polynomial of higher orders. Though they offer a better fit to the well test data, better understanding of the

function is not developed, neither it is a good predictor. Regression analysis has always been suggested to keep the order of polynomial as low as possible. In this study, the mathematical model is considered to be of the first order as in Eq. (3.0), around the economic region where most of the well testing and optimization data lie.

$$p_i = a_0 + a_1 q_i \quad (3.0)$$

3.3. Develop the mathematical model for optimization

For further simplification and calculation of mathematical model, a curve equivalent to equation (3.0) is plotted keeping p – Oil Production on x-axis and q – Gas Injection on y-axis represented by the equation (4.0):

$$q_i = m_i p_i + c_i \quad (4.0)$$

$$\text{Maximize} \quad P = \sum_{i=1}^n (p_i) \quad (5.0)$$

$$\text{Subject to:} \quad \sum_{i=1}^n (q_i) = \sum_{i=1}^n (c_i) + \sum_{i=1}^n (m_i) * p_i \leq Q \quad (5.1)$$

$$p_i' \leq p_i \leq p_i^* \quad (5.2)$$

$$q_i, p_i \geq 0 \quad (5.3)$$

Equation ((5.0) – (5.3)) is proposed mathematical model for optimization, where P is total production from the well platform (sum of production from all individual wells), Q is the maximum injection gas available for gas lift, q_i and p_i are quantity of lift-gas and production from well i , c_i and m_i are constants generated from linear regression. p_i' is the minimum acceptable production considering the short-term optimization case and p_i^* is the maximum production that can be drawn from i -th well in the economic region.

3.4. Implementation and results

Testing data [Table 2, Annexure A] from a set of five wells of a well platform is considered for optimization under this model. Regression analysis of the data of all the wells has been done on MATLAB_R2020a and part of the well performance curve of the first order is plotted (part of the curve near economic region/optimum region is depicted in Figure 3 for well-1).

Figure 3: Part of well performance curve for well-1

As discussed during the development of the mathematical model, an equivalent curve is also plotted keeping p – Oil Production on the x-axis and q – Gas Injection on the y-axis using linear regression and the new relation between oil production and gas injected have been generated for all the wells. Figure 4 shows this relation for well-1.

Figure 4: Relation between oil production and gas injection

Finally, the data have been fed to the mathematical model (from Eq. 5.0 to 5.3) and run on GAMS 32.1.0 with CPLEX solver. For different values of Q (190,500 – 201,500 SCMD at the interval of 500 SCMD) on each run, optimal values of variables P are generated. Figure 5 shows the relation between ‘optimized production’ vs ‘maximum gas consumed’. Equations generated by linear regression give values of q_i for all values of p_i and lift gas thus be allocated judiciously for the optimum production. Set of quantity of oil production p_i and corresponding allocated gas q_i , for maximum value of oil produced P and quantity of gas consumed Q at entire well platform is given in Table 3 [Annexure A]. Compared to the field data where oil production is in the range of (1450 – 1651) barrels of oil per day (BOPD) and total injection gas is in the range of (188,771 – 233,914) standard cubic meter per day (SCMD), this model gives the production in the range of 1780 BOPD upon the consumption of 200,000 SCMD of lift-gas from that well platform.

Figure 5: Optimized production Vs. Maximum gas consumed

4. Conclusion

It is obvious that result of this model is not just showing increase in oil production but approximately 30,000 SCMD of compressed gas are saved. This methodology provides wellhead engineers/managers relatively simple and quick approach to analyze and work on the available production data during field visit. Optimal lift-gas injection rate from other oil-fields can be further tested/implemented, on the wells of the field to verify actual improvement in oil production. Though results produced by this methodology will help oil field operators in day-to-day well optimization, additional constraints like impact of well head pressure upon variation in gas injection rates, changes in water cut (BSW) on oil production etc. will be considered in future work.

Abstract

Biomass Gasification is a viable process to convert biomass into valuable energy production. In this study, the techno-economic feasibility of a sorption enhanced steam gasification of palm oil waste for syngas production is developed using Aspen Plus. The sorption enhancement is achieved by utilising CaO as a medium to capture CO₂ and generate clean syngas. CaO has recently demonstrated the feasibility to capture CO₂ at reduced capital and operating investment costs compared to conventional capture processes. For this purpose, the flowsheet configuration and economic analysis has been carried out using Aspen plus. The results of the economic assessment demonstrate a total hydrogen production cost approximated at \$2.51 per kg for gasification system utilising CaO compared to \$2.57 for the base case without CO₂ capture. Moreover, a sensitivity analyses and a multi-objective optimisation has been carried out to maximise the hydrogen to carbon monoxide ratio and minimise the CO₂ emissions. The results demonstrate that by increasing the steam flowrate in the range of 500-2000 kg/h, the H₂/CO ratio, and the CO₂ emissions increase. This is mostly due to the acceleration of gasification reactions; mainly the methane reforming and water gas shift reactions. Similarly, increasing the CaO flowrates in the range of 500-2000 kg/h results in increasing the H₂/CO ratio significantly and reducing the CO₂ emissions rapidly. This CO₂ reduction with the use of CaO is experimentally validated in the literature mainly due to the carbonation reaction. Whereas, the variation of gasification temperature indicates a decreasing trend in the H₂/CO ratio and CO₂ emissions with the increase in temperature in the range of 600-800 °C. The Pareto curve generated from the multi-objective optimisation demonstrates an overall increasing trend of CO₂ emissions with the increase in the H₂/CO ratio in the produced syngas.

1. Introduction

Biomass is a leading source of alternative energy for fossil fuels as it offers promises advantages such as its low carbon footprint due to carbon neutrality (Shahbaz et al., 2017a), and it can be considered part of a renewable and sustainable supply chain due to its abundant availability (Inayat et al., 2020a). The conversion of biomass into energy is achieved through biological and thermochemical conversion processes (Zeng et al., 2016). Thermochemical conversion processes are advantageous over biological processes due to the conversion of biomass to all forms of energy, such as gaseous, solid, and liquid fuels, in addition to (Shahbaz et al., 2020). Incidentally, gasification is the preferred thermochemical conversion process in the production of a gaseous fuels such as H₂ and syngas (AlNouss et al., 2020a). Many researchers have experimentally investigated syngas production from palm oil waste through lab and pilot-scale processing (Chan et al., 2019), whilst simulation-based modelling is also useful to inform syngas production process (Inayat et al., 2020b). The H₂ rich syngas produced from the biomass processing depends on many factors such as biomass feed, gasification agent, and most importantly, the reduction of CO₂ in the product gas (Inayta et al., 2012). In this regard, CaO based sources, such as, dolomite and limestone are used for the reduction of CO₂ in the gasification of palm oil waste through modelling and experimentation (Shahbaz et al., 2017a).

Palm oil waste is a major waste available in South East Asia and has been investigated for energy production especially through gasification (Shahbaz et al., 2017b), for which techno-economic analysis is a very important activity for the commercialisation of any technology. A process developed for the steam-gasification of empty fruit bunches (EFB) based on kinetic parameters using MATLAB was developed by Inayat et al. (2012), and Aspen PLUS was used for equilibrium modelling of palm kernel shell (PKS) (Shahbaz et al., 2017a). From the above discussion, there is no study reported for the techno-economic analysis of PKS steam gasification using the CaO for CO₂ capture. As such, the main aim of this study is to perform a techno-economic feasibility study of sorption enhanced steam gasification of palm kernel shell using Aspen Process Economic Analyser (APEA) with adsorbent regeneration. In addition, the study investigates the impact of process parameter and optimises the parameters for low H₂/CO ratio to maximize the H₂ rich syngas production. Sensitivity and, and multi curve optimisation is also developed.

2. Methodology and Process Description

For several industrial processes, such as polymers, metals, biofuels, other chemicals, modelling and simulation of solid process steps is crucial. Aspen Plus advanced process simulation capabilities allow the integrated high-performance simulation of process steps for solids and fluids with stable physical properties. In this study, palm kernel shell (PKS) undergoes steam gasification process, which is simulated using Aspen Plus software, to yield synthesis gas. The process is simulated under the assumptions of steady-state and isothermal-operation, atmospheric pressure with no pressure gradient, neglected tar formation and char is carbon. The model begins with a decomposition unit operating at 40 °C and 1 bar to convert the PKS biomass to conventional components; the attributes are summarised in Table 1 (Shahbaz et al., 2017a). The decomposition unit is linked with a calculator block to calculate the yields of the conventional components as presented by (AlNouss et al., 2020b). The converted stream enters the fluidised bed gasification unit, modelled as a Gibbs free energy reactor, along with the superheated steam to yield syngas at 800 °C and 1 bar as illustrated in Figure 1. The effluent syngas is fed to the fixed bed

gasification unit where the CaO is used to capture the generated CO₂ and yield a solid CaCO₃. A solid separator is used to remove ash and the formed CaCO₃ and keep the syngas that is cooled to further purify it from water. The CaO is then regenerated from CaCO₃ using a regeneration reactor operating at 900 °C and 1 bar and a purification step to remove vent gases from the regenerated CaO.

Table 1. Proximate and ultimate analysis of Palm kernel shell (Shahbaz et al., 2017a)

Proximate analysis		Ultimate analysis (dry mass wt% basis)	
Moisture (wt%)	9.70	C	48.78
Dry mass wt% basis		H	5.70
Volatile matter	80.81	N	1.01
Fixed carbon	14.25	S	0.21
Ash content	4.94	O (by difference)	39.36

Figure 1. Process flow sheet for the sorption enhanced steam gasification of PKS.

The simulated model has then been utilised to perform a number of sensitivity cases to study the effect of changing steam flowrate, gasification temperature and CaO flowrate on the quality of syngas production. Moreover, the optimisation capabilities of Aspen Plus software has been utilised to perform singular and multi-objective optimisations to maximise the ratio on hydrogen to carbon monoxide and minimise the emissions of CO₂ in the produced syngas. Equations 1 and 2 summarise the formulation of the optimisation problem.

$$\text{Maximise} \quad \frac{y_{H_2} \cdot \text{Syngas}}{y_{CO} \cdot \text{Syngas}} \quad \text{eq. (1)}$$

$$\text{Minimise} \quad x_{CO_2} \cdot \text{Syngas} \quad \text{eq. (2)}$$

$$\text{Subject to} \quad 600^\circ\text{C} \leq T_{\text{gasification}} \leq 800^\circ\text{C} \quad \text{eq. (3)}$$

$$500 \text{ kg/h} \leq \dot{m}_{\text{Steam}} \leq 2000 \text{ kg/h} \quad \text{eq. (4)}$$

$$500 \text{ kg/h} \leq \dot{m}_{\text{CaO}} \leq 2000 \text{ kg/h} \quad \text{eq. (5)}$$

Where y_{H_2} and y_{CO} are the molar fractions of hydrogen and carbon monoxide, x_{CO_2} is the mass fraction of carbon dioxide, respectively, \dot{m} represents the mass flowrate of steam/CaO and syngas is the molar flowrate of the produced syngas. The use of CaO has also been validated by conducting a techno-economic-environmental evaluation using the built-in tools inside Aspen Plus® and utilising the equations presented earlier by (AlNouss et al., (2020c). In the study, the price of purified syngas is taken as \$24/km³.

3. Results and discussion

The results of the techno-economic-environmental evaluation based on the use of CaO to capture CO₂ demonstrates a huge decrease in CO₂ emissions compared to the base case without CO₂ capture as presented in Table 2. However, this decrease is associated with slightly higher capital and operating costs. This demonstrates the effectiveness of CaO utilisation in offsetting the high CO₂ emissions associated with the gasification process with only a slight increase in investment. Moreover, the higher hydrogen production in the CaO case has projected a lower cost of hydrogen production at \$2.51 per kg compared to \$2.57 for the base case. The process revenue for the case without CaO addition demonstrates slightly higher results approximated at \$3.772 million compared to \$3.769 for the case with CaO addition. This increase is mainly due to the increase in the CO content in the purified syngas. The addition of the regeneration unit has increased the capital and operating costs, although it resulted in an additional reduction in the CO₂ emissions, and a reduction in the costs associated with the raw material since CaO is regenerated internally. The cost of hydrogen production remained similar to the case of CaO utilisation without regeneration despite the slight increase in the total annualised cost.

Table 2: Techno-Economic analysis with and without CaO

Case	with CaO	without CaO	with CaO regeneration
Total Capital Cost [\$]	4,233,300	4,147,700	5,054,360
Total Operating Cost [\$/y]	1,427,190	1,413,370	1,435,570
Total Raw Materials Cost [\$/y]	525,600	350,400	350,400
Total Utilities Cost [\$/y]	143,318	138,912	5,054,360
Equipment Cost [\$]	207,500	159,100	259,900
Total Installed Cost [\$]	1,015,800	952,600	1,330,600
Total Annualised Cost [\$/y]	2,822,126	2,615,527	2,823,916
Revenue [\$/y]	3,769,178	3,772,167	3,769,178
H ₂ Production (kg/y)	1,123,514	1,019,029	1,123,514
(T = 700 °C, Steam = 1500 kg/h, CaO = 100 kg/h)			
Cost of H ₂ Production (\$/kg)	2.51	2.57	2.51
CO ₂ Emissions (kg CO ₂ -e/h)	535	1031	509

The results of the different analyses performed on the steam gasification of PKS are presented in terms of sensitivity relations, optimum objective functions and techno-economic comparison. Figure's 2 and 3 present the relationships between the molar compositions of the produced syngas and the changes in CaO flowrate, gasification temperature and steam flowrate, respectively. The change in CaO flowrate at constant gasification temperature of 700 °C and a constant steam flowrate of 1500 kg/h demonstrates an increase in hydrogen composition from 70% to 99% and a decrease in CO, CO₂ and CH₄ compositions from 13%, 17% and 0.27% to 1%, 1% and 0.05%, respectively. The decline in CO₂ with the addition of CaO is due to the carbonation reaction and was also reported by Shahbaz et al. (2017b).

The increase in gasification temperature at a constant CaO flowrate of 1000 kg/h and constant steam flowrate of 1500 kg/h demonstrates an increase in hydrogen and CO compositions from 76.3% and 6.5% to 77.8% and 12.3%, respectively, with the decrease in CO₂ and CH₄ compositions from 13.8% and 3.43% to 9.8% and 0.02%, respectively. The reason behind these trends is mainly due to the influence of higher temperatures on the gasification reactions leading more syngas products, where the reactions of steam-methane reforming, Boudouard and CO water shift are favoured (Shahbaz et al., 2017b).

Moreover, H₂ production trend indicates a peak at around 700 °C of temperature.

Figure 2. Impact of CaO flowrate and gasification temperature on syngas composition.

The change in steam flowrate at a constant gasification temperature of 700 °C and a constant CaO flowrate of 1000 kg/h demonstrates an increase in H₂ and CO₂ compositions from 70.5% to 78.6% and 3% to 13% respectively, with a decrease in CO and CH₄ compositions from 19% to 8% and 7.55% to 0.11%, respectively. These trends indicate an enhancement in steam-methane reforming and CO water gas shift reactions with the addition of steam, where more H atoms are converted to H₂ resulting in less CH₄ and more C atoms are converted to CO₂ resulting in less CO (Inayat et al., 2012).

Figure 3. Impact of steam flowrate on syngas composition.

Figure 4. Pareto-front curve

Furthermore, to analyse the optimal operating parameters that will achieve an increase in the production quality and reduction in CO₂ emissions, the singular and multi-objective optimisations have reported different parameters for steam and CaO flowrates and the gasification temperature. For the singular optimisation, the solution of Eq. (1) with the constraints in Eq. (3-5) indicates an overall objective function for the H₂/CO molar ratio approximated at 297 for gasification temperature of 600 °C and 2000 kg/h flowrate for steam and CaO, individually. Whereas, the singular optimisation of Eq. (2) with the constraints in Eq. (3-5) indicates an overall objective function for the CO₂ emissions below 0.07 kg CO₂-e/h for gasification temperature of 800 °C, the steam flowrate of 500 kg/h and CaO flowrate of 2000 kg/h. The multi-objective optimisation of both Eq. (1) and (2) with the constraints in Eq. (3-5) produces the illustrated Pareto-front curve in Figure 4. This curve indicates various optimal points for the decision-makers on CO₂ emissions and H₂/CO molar ratio of the steam gasification of PKS given various operating points.

4. Conclusions

The sorption enhanced steam gasification of PKS with the utilization of CaO for CO₂ capturing developed using Aspen PLUS[®]. The techno-economic analysis performed using the tool present in Aspen PLUS[®]. The cost of H₂ production is reduced from 2.57 to 2.51 \$/kg with the use of CaO. In addition, the CO₂ emissions were significantly decreased from 1031 to 535 (kg CO₂-e/h) with the application of CaO. The H₂ production increase with the increase of gasification temperature, steam, and CaO flow rate. A significant reduction of CO₂ is observed from 17 to 1 mol% with the increase of CaO flow rate from 500-2000 kg/hr, which shows the effectiveness of CaO for CO₂ capturing. The multi-curve optimisation made and a petro curve was generated for H₂/CO molar ratio and CO₂ emissions of the steam PKS gasification for different process parameters.

Abstract

Hydrogen is an important resource in chemical processes industries. As hydrogen demand in the refineries is increasing rapidly, hydrogen management strategies are of great interest to the refineries. Hydrogen management trades in with the optimal supply, routing, and flow allocation of hydrogen gas also called Hydrogen Allocation Network (HAN) within a refinery linking the source station to the demand station. Other than minimizing the fresh hydrogen requirement, it is extremely important to reduce the compression work, required in any HAN. In the real world, uncertainties in the parameters (e.g. flow, quality, pressure, etc.) may arise due to various reasons so that undermine the effectiveness of HAN. In this paper, to deal with these uncertainties, an optimization model based on robust linear programming formulation is proposed to minimize the compression work and fresh hydrogen as a resource within the HAN. The applicability of the robust model helps to optimize HAN with uncertain flows and quality for the application of individual sources station and demand station with the desired reliability. The resultant formulation preserves the linearity of the mathematical model and can control the degree of conservatism for every constraint. The applicability of the proposed methodology is demonstrated through an illustrative example.

Keywords: Hydrogen allocation network, Compression work, Robust Optimization, Optimization

1. Introduction

Hydrogen, a clean and efficient secondary energy source, is widely used in chemical industries to produce clean fuels. Petroleum refineries consist of many processes with complex reactions involving hydrogen consumption or production. In a hydrogen network, there are several compressor stations for supplying hydrogen producers to consumers. So hydrogen management is an important practical aspect of refineries. It aims to achieve the optimal hydrogen allocation network (HAN) of hydrogen resources to satisfy the demands of refinery processes (Brijandi et al. 2014). Operating variables play an important role in designing of HAN, such as the purity and flow rate of input and output for consumers. In the real world, uncertainties in the parameters (e.g. flow, quality pressure, etc.) may arise due to various reasons so that undermine the effectiveness of HAN (Al-Redhway et al. 2005). Therefore, the inlet or outlet variables are determined by any changing variable after optimization. Zhang et al. (2014) proposed a graphical method for targeting the minimum fresh resource consumption of hydrogen networks by considering the separation performance of purifiers. The method optimizes both the purity and the flow rates of feed and products for the purifier within a feasible operating range. Lou et al. (2015) introduced a framework to optimize the hydrogen network of refineries under uncertainty. This framework considers several scenarios representing possible future environments. Lima et al. (2018) proposed a

robust optimization model is developed to cope with the oil price and demand uncertainties in the tactical management of the downstream oil supply chain. Liu et al (2019) proposed a fuzzy optimization model for the design of a multi-component hydrogen network with parametric uncertainties is developed. A data-driven adaptive robust optimization approach is proposed by Zhao et al. (2019) to deal with the operational optimization problem of industrial steam systems under uncertainty. From the above literature review, it is found that minimizing the fresh hydrogen and compression work has rarely been studied together with the optimization of HAN. In this paper a mathematical formulation for calculating the robust target of minimizing the compression work and resource requirement in a HAN. The presented model utilizes the concept of robustness developed by Bertsimas and Sim (2004). The proposed model enables us to decide the robust targets of fresh hydrogen and compression work requirement based on budget parameters and uncertainty levels. The proposed model is explained via an illustrative example where the process data is represented through uncertain parameters. The solution set provides flexibility to the decision-maker to the trade-off between the uncertainty level with compression work or fresh hydrogen requirement.

2. Problem Definition and Mathematical Formulation

The HAN usually includes several compressor stations for supplying the hydrogen at several demand nodes at their required pressure. The problem of optimizing hydrogen allocation with uncertainty in any allocation network optimization in a plant can be stated as follows:

- A set of N_s internal sources is available with uncertain flow and quality in a bounded interval with a known deviation from its nominal value.
- A set of N_d internal demands to be satisfied are also known such that each demand accepts a flow with a quality that is less than a predetermined maximum quality.
- The unutilized flow from the internal sources is sent to an external demand, called waste, without any maximum quality or flow limits.

The objective of this study is to minimize the compression work for supplying the flow and also minimize resource requirement in a fixed desired reliability of each demand as well as each source. The model comprises of following constraints.

2.1. Flow Balance Constraints: Let f_{ij} and f_{rj} represent the flow from i^{th} source and resource to j^{th} demand. The flow balances for compressor station and demand station may be addressed as Eq. (1) and Eq. (2):

$$\sum_{j=1}^{N_d} f_{ij} + f_{iw} = F_{si} \quad \forall i \quad (1)$$

$$\sum_{j=1}^{N_s} f_{ij} + f_{rj} = F_{dj} \quad \forall j \quad (2)$$

2.2. Quality Constraints: Due to quality constraint at every demand, the hydrogen mass-load requirement for any internal demand may be mathematically expressed as follows: (Eq. 3)

$$\sum_{j=1}^{N_s} f_{ij} q_{si} + f_{rj} q_{jr} \leq F_{dj} q_{dj} \quad \forall j \quad (3)$$

Where q_{si} , q_{jr} , and q_{dj} are the quality of i^{th} source, resource, and j^{th} demand. The total fresh hydrogen requirement can be calculated using Eq. (4).

$$F_{fr} = \sum_{j=1}^{N_d} f_{frj} \tag{4}$$

2.3 Robust Mathematical Model for HAN

Adapting the robust formulation proposed by Bertsimas and Sim (2004) for dealing with uncertainty. The mathematical model can be modified as follows.

Flow uncertainty: Let us consider that the flow supply by each internal source is uncertain and can vary in the region. To include flow uncertainty Eq. (1) is modified as follows:

$$F_{st} - \sum_{j=1}^{N_d} f_{ij} - f_{iw} - \Gamma^f z^f - q^f = 0 \tag{5}$$

$$\Gamma^f - q^f \geq \hat{F}_{st} \tag{6}$$

$$\Gamma^f, q^f \geq 0 \tag{7}$$

The parameter Γ^f and q^f are introduced that controlled the degree of conservatism and budget of uncertainty in source flow. \hat{F}_{st} is the deviation magnitude of the flow.

It may be noted that after the fresh hydrogen requirement has been minimized, the fresh hydrogen source and waste flow can be treated as entities of the sources and demands sets without any loss of generality.

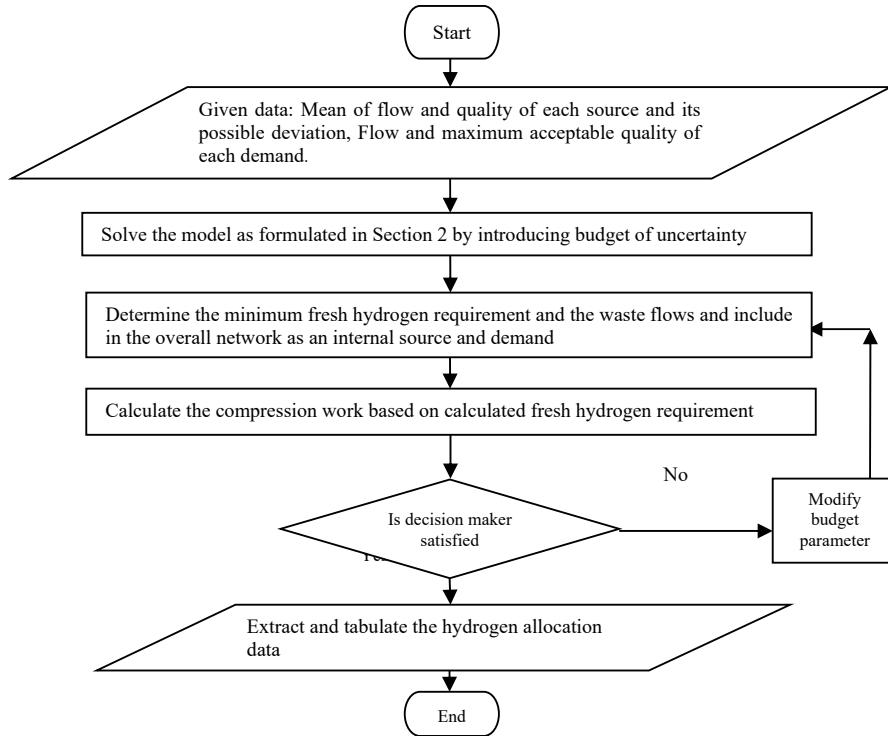

Figure 1: Flow chart showing the proposed algorithm

With these new modified sets of sources and demands with the inclusion of fresh resource and waste flows, the second part of the optimization problem is formulated. The compression work (W) required for a stream is governed by the initial (P_{in}) and final (P_{out}) states (volumetric flow (F_{in}) and pressure) as well as the process followed for compression. For isothermal compression, the work done can be expressed as Eq. (8).

$$W = P_{in} F_{in} \ln\left(\frac{P_{out}}{P_{in}}\right) \quad (8)$$

Applying the characteristic of an isothermal process;

$$PF = Const \quad (9)$$

The compression work requirement for supplying flows balance f_{ij} from various supply pressure levels (P_i) pressure level to demand at a pressure (P_j) pressure level ($P_j > P_i$) may be expressed as follows: (Shukla and Chaturvedi 2020)

$$E_j = \sum_{i=1}^{N_i} f_{ij} (\mu_j - \mu_i) \quad (10)$$

The quantity $(\mu_j - \mu_i)$ can be defined as the compression energy index.

It may be noted that supplying flow from a station having a higher pressure than the lower demand station pressure does not require any compression work. Further, it may be noted that demand pressure includes various pressure drops during flow transfer. Figure 1 shows the flow chart of the proposed algorithm.

3. Illustrative Example:

Applicability of the proposed methodology is demonstrated through illustrative examples. Data for the overall HAN from the work of Bandyopadyay et al. (2014) are given in Table 1. The source flow data are modified for illustrative purposes.

Table 1: Source and Demand Data for Illustrative Example

	Purity (%)	Quality (%)	Flow (Sm ³ /s)	Pressure (kPa)
S0 (resource)	99	1		11031.6
S1	91	9	114.7 ± 20	11031.6
S2	85	15	163.8 ± 20	16168.4
	Purity (%)	Quality (%)	Flow (Sm ³ /s)	Pressure (kPa)
D0 (waste)				
D1	92.8	7.2	131.1	10061.4
D2	87.5	12.5	196.6	15168.4

Table 1 represents the source and demand data for the example. From the deterministic approach, it is found that the minimum fresh hydrogen requirement and waste production are determined to be 58.99 and 9.79 Sm³/s, respectively and the is minimum compression power using isothermal process is found to be 1.37 MW. In the proposed example the flow is uncertain. In this case, bounded uncertainty of flow availability from the source side is given. The availability of flow parameters has ± 20 t/h variability levels for each flow. Here budget

parameter takes a value between [0, 1], its variation with objective value is calculated using the proposed methodology. The result is tabulated in Table 2.

Table 2: Solution data of example

Γ^f	0.0	0.	0.4	0.6	0.8	1.0
Fresh Hydrogen(Sm ³ /s)	58.99	60.70	65.2	73.2	81.2	89.2
Waste (Sm ³ /s)	9.79	3.506	0.363	0	0	0

It is found that for the worst case ($\Gamma^f=1$) the minimum fresh hydrogen requirement is 89.2 Sm³/s. In the presented example if it is solved considering all parameters to take their worst boundary values i.e. lower bound for flow rates using (Soyester, 1973), the resource requirement is calculated to be 89.2 Sm³/s, which increase the resource requirement by 51.21 % from the deterministic case and with maximum protection against uncertain.,This value can be considered as overestimated if the uncertainties in the parametric coefficients lie in the narrower range. Similarly, the unpredictability level in quality of each source can be included in the example and check the impact of the budget parameter in the requirement of fresh hydrogen. Next, based on the fresh hydrogen requirement and supply to demand compression station, the minimum compression work can be calculated using Eq. (10) and tabulated in Table 3.

Table 3: Minimum compression work data for an illustrative example

Γ^f	0.0	0.2	0.4	0.6	0.8	1.0
Fresh Hydrogen(Sm ³ /s)	58.99	60.70	65.2	73.2	81.2	89.2
Work (kJ/s)	1.37	1.30	1.31	1.44	1.570	1.71

The trade-off between the compression work and minimum fresh hydrogen (2 a) and uncertainty level and optimum value of compression work (2 b) is plotted.

Figure 2: Trade-off between minimum hydrogen and compression work (a), Impact on the compression work with variation in the budget parameter of (b)

The proposed methodology provides a feasible solution for a relative magnitude of uncertain data in a parameter which assists decision-maker via trade-off between the feasibility tolerance and a reliability level. The model is solved using the GAMS/ CPLEX solver on the computer (Intel(R) Core(TM) i5 (3 GHz) and 4 GB RAM

4. Conclusions

In the real world for designing any process industry, it is necessary to address different parametric uncertainties. In this paper, a methodology is presented to determine the minimum compressor work required in a HAN, while satisfying the minimum external hydrogen resource requirement including the parametric uncertainties. The proposed methodology is based on robust optimization which is capable of adjusting the level of risk (worst case scenario) is applied to derive a robust optimal solution for HAN. The main benefit of using robust optimization is that it provides the trade-off between uncertainty level and an upper probability of constraint violation which helps to choose suitable functional situations for decision-makers under uncertain conditions and to do the required planning accordingly and protected the process against uncertainties to satisfy demands. In future work, the model formulation may be readily expanded to incorporate other constraints such as carbon emission, pressure uncertainty along with economical aspects such as the annual electricity consumption of compressors and the annual revenue created by fuel gas to make the problem close to the real world.

Process Design and Techno-economic analysis of Hydrogen Production using Green Ammonia Imported from Australia- A Korea Case Study

Malik Sajawal Akhtar ^a, Jay Liu ^{*}

^{a,*} *Department of Chemical Engineering, Pukyong National University, Busan 48513, South Korea*

jayliu@pknu.ac.kr

Abstract

Hydrogen can be a potential solution to decarbonise the transportation sector since it has a very high energy content. Its separation from water by the process of electrolysis need a vast amount of electricity and renewable energy sources like solar PV and wind electricity can play a vital role in shifting towards hydrogen economy, if they are utilised effectively. Still the problem with the hydrogen economy is the massive investment in its large scale transportation and storage infrastructure as it has a low volumetric energy density, which creates significant challenges in transporting bulk volumes. One feasible and still optimistic approach is to use ammonia as a hydrogen carrier that can be transported globally with the existing infrastructure. South Korea is evaluating the possibilities of importing green ammonia and using it for hydrogen production to meet country hydrogen demands particularly related to transportation sector. This research work presents a process design and techno-economic analysis of importing green ammonia from Australia and using it for hydrogen production in Korea at the hour of need. Processes were simulated by using commercial process simulator Aspen Plus V11. The main contributors of the economic assessment are capital and operational expenditures of electrolyser and solar photovoltaic power plant. The levelised cost of green ammonia is 870 \$/ton while that of hydrogen is 8.90 \$/kg stating that it is a viable option to use imported green ammonia to meet country hydrogen demands. Future estimates from multiple studies show that by 2030 further cost declines are possible in electrolyser and solar panels capital expenditures resulting the green ammonia cost to \$350 per ton and making this case more economically viable to meet hydrogen demands.

Keywords: Process design, green ammonia, techno-economic analysis, green hydrogen.

1. Introduction

Decarbonisation of world's industrial processes specifically the energy production is a hotspot now a days due to declining fossil fuel resources, increasing oil prices and high energy demands. Electricity and heat production are the highest contributor in carbon emissions followed by transportation. The need of transportation will be increasing with the time and more efforts would be required to decarbonise the transportation sector. Clean and green fuel is a dire need of the time in order to minimize the carbon emissions related to transportation sector. Hydrogen having the high energy content can be a potential solution to this problem since it is available in abundant quantity in the form of

water and needs only electricity for production through the process of electrolysis. One of the major challenge in implementation of hydrogen economy is its transportation in bulk volumes due to its low energy density and massive investments. To address this issue, hydrogen carriers like ammonia is under consideration. Ammonia is a well-known chemical having large existing infrastructure for transportation. Million tons of ammonia is transported every year globally through ships. In ammonia production, hydrogen is produced by reforming of natural gas which is the major cause of high carbon emissions. If it is produced through water electrolysis by using power from renewable energy sources, then decarbonisation of ammonia industry is possible. This carbon free green ammonia can be transported globally and can be used in fertiliser sector and hydrogen production through its decomposition reaction generally known as cracking.

Australia is one of the major producer of renewable electricity which is not only cost-effective but also is being produced on larger scales. The world's largest renewable energy project 'Asian Renewable Energy Hub (AREH)' of 26 GW is planned in Pilbara region of Western Australia planning to start exporting green ammonia by 2028 according to ammonia energy association. According to Sichao Kan (2018), the H₂ demand for Korea by 2022 is estimated to be at 0.47 million tons, 1.94 million tons in 2030, and 5.26 million tons in 2040, so soon new H₂ supply sources will be required. To address this issue, importing Green Ammonia from Australia and using it for H₂ production is under consideration but detailed and rigorous techno-economic analysis is required for government and industry to make a final decision.

Therefore, in this research work a process design of 300 tons/day green ammonia production plant and economic assessment of hydrogen production through thermal catalytic cracking of ammonia is studied in detail. Imported ammonia will be transported through ships from Australia in refrigerated containers normally 30,000 tons per container and will be shifted to H₂ re-fuelling stations within Korea as per requirement. Ammonia cracking units will be installed beside the re-fuelling station to ensure continuous fuel supply and avoiding extra transportation of H₂. According to Hydrogen Europe, a normal H₂ re-fuelling station has H₂ production capacity of 300 Nm³/hr and contains storage tanks, high pressure compressors, and dispensing units.

2. Methods

2.1 Description of the green ammonia production plant

The production of green ammonia considered in this work constitutes an air separation plant, green hydrogen production plant (electrolysis powered by renewable energy), and an ammonia synthesis unit. The ammonia is being produced in Australia, after production it will be compressed and stored and then shipped to Busan, South Korea. Production capacity of the plant is 746 t/day and total power requirement is about 360 MW as adapted from Morgan et al (2017) in which 335 MW (93% of total power requirement) is only for electrolysis unit. Imported green ammonia will be cracked in a cracking unit installed besides the hydrogen re-fueling station to ensure continuous supply. Aspen plus V11 was used for process designing and simulation. The heat generated throughout the process is captured by EX to generate steam. This steam is then used to run a steam turbine operating at 90% polytropic efficiency, which in turn, aids in driving the compressors to increase overall efficiency of the process. Complete process flow diagram of aspen plus simulation is shown in Figure 1.

- Air Separation Unit (ASU).

Cryogenic distillation unit was modelled which constitute multi-stage compressor having inter-stage cooling, shell and tube heat exchangers, and distillation columns. Air is at atmospheric conditions and compressed in C1 to 7 bars followed by cooling near to its liquefaction temperature. This cooled air is then introduced into a high-pressure distillation column of 25 stages and operating at 7 bar. The top and bottom products from this column are introduced in low pressure column of 20 stages operating at 1.013 bar for further separation of nitrogen. The nitrogen obtained from the top at 26.260 MT/hr is 99.999% pure and fed to the ammonia synthesis loop for ammonia production. Total power consumption of this unit is 3.24 MW.

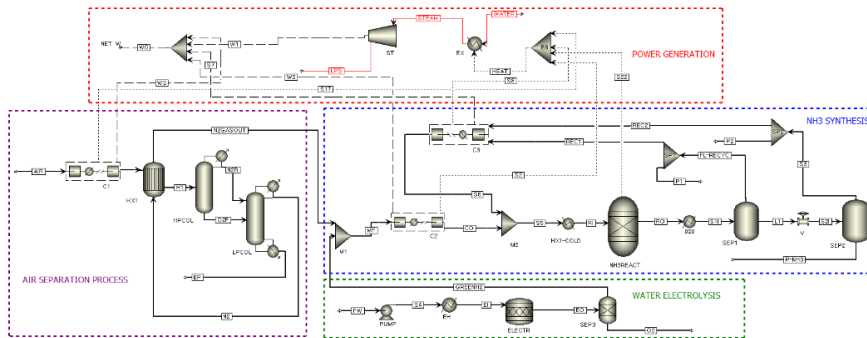

Figure 1: Aspen Plus-Process Flow Diagram (PFD) of Green Ammonia Synthesis

- Water Electrolysis.

After water purification, purified feed water is compressed in a centrifugal pump to 30 bar and heated in a heat exchanger to 80°C. Alkaline water electrolyser was modelled using RStoic reactor from model palette. Reactor outlet stream constitute 66.66% hydrogen and 33.33% oxygen, this stream was then introduced in a separator and hydrogen purity was set to 99.99% considering the purity from commercial electrolyser. Purified hydrogen gas at 5.66 MT/hr. is mixed with nitrogen and then fed to ammonia synthesis unit while total power consumption of this section is 335 MW.

- Ammonia Synthesis.

Nitrogen from air separation and hydrogen from electrolyser is first mixed adiabatically M1. This synthesis gas stream is then compressed using multi-stage (five) compressor to 150 bar pressure. This high-pressure stream is then heated to the required reaction temperature of 450°C. The reaction of ammonia synthesis is exothermic, so the heat generated during the reaction is captured by EX to generate steam which is used to power the compressors being used in the process. The reactor outlet stream is cooled to atmospheric temperature of 25°C and introduced to a flash separator Sep1 being operated adiabatically. The separator outlet stream L1 contains 97% pure ammonia, unreacted gases are recycled back to compressor train C3 and subsequently to mixer M2. Final product stream P-NH3 from Sep2 is at -18°C and 2 bar contains 99.99% pure ammonia. The power requirement for this ammonia synthesis unit is about 20 MW.

- Transportation.

In this project, transportation is considered from Dampier port of Pilbara region in Western Australia where the world biggest renewable energy project ‘Asian

Renewable Energy Hub (AREH)' is planned to Busan port, South Korea. The transport distance between the mentioned ports is 3867 nautical miles (7161 kilometre).

- Cracking Unit.

According to Hydrogen Europe, a normal hydrogen refuelling station (HRS) are operated at 300 Nm³/hr hydrogen flow rate. It is assumed that the imported ammonia from Australia is transported to hydrogen refuelling stations in Korea where cracking units are installed beside the fuelling station to ensure continuous supply. A process flow diagram of the unit is shown in Figure 2 Chung et al (2017) reported the performance of the decomposition reaction over Ru-based catalysts (Ru/La(x)-Al₂O₃) as more than 95% conversion. Reaction conditions were set at 400°C and 1.013 bar. Liquid ammonia pass through a heater to attain the reaction temperature. The outlet stream of the reactor was then introduced in pressure swing adsorption column, ultra-pure H₂ gas with 99.999% purity was collected from top while the bottom product was 99.82% pure N₂.

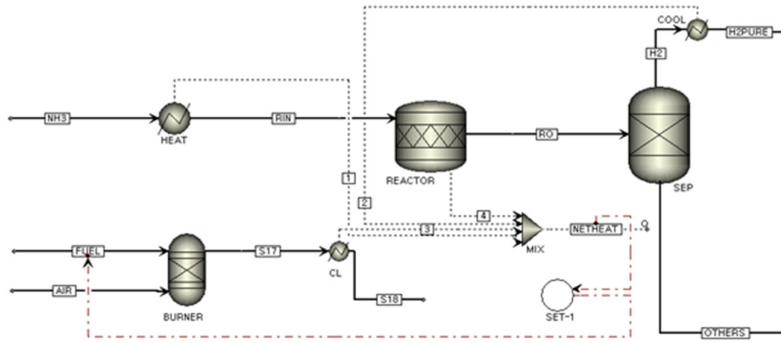

Figure 2: Aspen Plus-Process flow diagram (PFD) of Ammonia Decomposition

2.2 Economic Analysis

Lee et al (2019) compared a cracking unit for laboratory scale of 0.9 m³/hr. and for a small size refueling station of 30 Nm³/hr. Equipment cost was calculated using chemical engineering plant cost index (CEPCI) for 2020 and scaling factors obtained from Remer et al 1993 and Lee et al (2020). The capacity of our cracking unit is 300 Nm³/hr. Transportation and cost of green ammonia for Australia was obtained from Bruce et al (2018) and from green ammonia white paper by Argus media (2020). Details of cost calculations is shown in table 1 below. NREL's correlation as shown in Eq.1 was used for the calculation of levelised cost of hydrogen (LCOH) as mentioned by Short et al (1995), where TLCC is the total life cycle cost of plant including manufacturing cost, D is the discount rate, $NPV_{OTHER-PRODUCTS}$ is the net present value of the other products i.e. oxygen and nitrogen, $nH_{2_GENERATED}$ is the amount of hydrogen produced.

$$LCOH = \frac{TLCC - NPV_{OTHER-PRODUCTS}}{\sum_0^I \frac{nH_{2_GENERATED}}{(1+D)^n}} \quad (1)$$

Table 1: Economic Assessment for Cracking Unit

Parameter	Value	Reference
Assumptions for the analysis		
Depreciation year	7	-
Tax rate	30%	-
Internal Rate of Return	4.5%	-
Total Power requirement for green ammonia plant	360 MW	Morgan et al (2017)
Assessment results		
Solar PV Capex	902 \$/kwh	NREL (2019)
Green Ammonia Plant Total Cost	1.60 billion \$	-
Green Ammonia Cost (LCOA)	0.87 \$/kg	-
Ammonia required for H2	138.5 kg/hr.	-
Power requirement for cracking unit	300 KW	-
Ammonia shipping cost to Busan	0.052 \$/kg	Valentini (2020)
Cracking Catalyst cost	0.66 \$/kgH2	Lee et al (2019)
Cracking unit installed Cost	\$1,535,490	Jackson et al (2020)
Levelized Cost of Hydrogen	8.90 \$/kg	-

3. Results and discussion

The LCOH cost of hydrogen production from imported green ammonia resulted as \$ 9.12/kg. According to Jane et al (2020), the current LCOH of green hydrogen is estimated to range between \$ 2.50/kg and \$10/kg, which validate our results. So, the case of importing green ammonia from Australia for hydrogen production in Korea resulted to be a viable option. The cost of ammonia production is largely dependent on the cost of renewable electricity needed and the cost of electrolyzer. In the coming future, fall in electrolyser and renewable electricity prices is expected, so green hydrogen will be cheaper than today.

Table 2: Future estimated cost (\$/kg) of ammonia and hydrogen production

Year	2020	2025	2030	Reference
Solar PV Capex \$/kw	902	733	565	NREL (2019)
AWE Capex (including stack replacement)	1,061	849	707	Ju(2020), Matute et al., (2019)
LCOA	0.87	0.73	0.60	-
LCOH (after cracking)	8.90	8.30	7.75	-

Considering future cost reductions in capital expenditures of solar pv panels and electrolyser, we have done an analysis of future estimated prices of hydrogen production through cracking of imported ammonia excluding the expected reduction in electricity prices, as shown in table 2. Moreover, multiple research studies are also ongoing for increasing the activity and economic viability of catalysts for ammonia cracking. According to Argus media and Nayak et al (2020) estimates, by 2030 renewable electricity prices will drop to \$20-25 per MWh and LCOH of green hydrogen will eventually fall to \$2.30 to 2.40\$ per kg also the price of green ammonia will fall to \$ 310-350 per ton. Considering these future estimates, it will become more viable to import green ammonia and use it to fulfil hydrogen demands of the country and to decarbonize the ammonia and hydrogen industry. To have a fair comparison with imported case and

to reach at a point of some decision, there is also a need to do techno-economic assessment of domestic production of green hydrogen in Korea. So, our future work will consist of a comparative analysis of this case of importing green ammonia with domestic production of green hydrogen in Korea along with Monte-Carlo based sensitivity analysis.

Life Cycle Assessment of Hydrogen Production from Imported Green Ammonia: A Korea Case Study

Malik Sajawal Akhtar ^a, Jay Liu ^{*}

^{a,*} *Department of Chemical Engineering, Pukyong National University, Busan 48513, South Korea*

jayliu@pknu.ac.kr

Abstract

To decarbonise the transportation sector, South Korea is looking forward to evaluate possible cross-regional hydrogen supply pathways to meet the future hydrogen demand and reduce carbon emissions to ‘zero’ under Paris agreement by 2050. The use of ammonia as hydrogen carrier to meet hydrogen demands is under consideration and the goal of this paper is to evaluate environmental aspects of green hydrogen production from green ammonia imported from Australia. In the present work, a cradle to gate life cycle assessment of hydrogen production from imported green ammonia imported is carried out by using commercial life cycle assessment software Simapro. The scope of life cycle assessment includes; green ammonia production in Australia, shipping to South Korea, ammonia transportation from port to hydrogen refuelling stations in Korea, and hydrogen production through catalytic craking of ammonia. Mass and energy balance data obtained from process flow modelling are used as an input for life cycle assessment. In terms of energy consumption, hydrogen production through water electrolysis consume more than 90% of total power while ammonia synthesis only consume 5.5%. The results of life cycle assessment show that transportation of the green ammonia was the major contributor having 95% of total CO₂ emissions while hydrogen production through water electrolysis was producing about 4.5% of total carbon emissions. This study reveals that considering environmental sustainability, using imported green ammonia is not a viable option until transportation fuel is replaced with an environmental friendly fuel. However, if marine fuel is replaced by a green fuel it can further reduce the transport related emissions turning this case into a viable option to meet the hydrogen related demands.

Keywords: Life Cycle Assessment, Green Ammonia, Green Hydrogen

1. Introduction

The alarm of increasing global warming is shifting the world's focus towards clean and sustainable energy systems. The increasing concentration of greenhouse gases in the atmosphere is mainly due to the extensive burning of fossil fuels for energy generation. Energy demand is growing quickly with the rapid urbanization and industrialization of the world, and considering environmental sustainability; it is needed to offset the large dependency on fossil fuels. Renewable energy sources such as wind and solar are available in ample quantity in nature and can be used efficiently as a substitute for fossil fuels. Electricity and heat production are the highest contributors to carbon emissions, followed by transportation. Decarbonisation of the transportation and industrial sector is possible only by using clean and sustainable fuel instead of high carbon-emitting fossil

fuel. Hydrogen carrier like ammonia can be a potential candidate to solve the issue of infrastructure for the global transportation of hydrogen due to its low volumetric density. Ammonia production can be carbon-free if the hydrogen required for ammonia production is obtained from renewable energy sources through water electrolysis rather than that of the conventional process of steam methane reforming, emitting high carbon emissions. Energy hungry countries like Japan and Korea are thinking of importing green ammonia from countries like Australia to offset their large dependency on fossil fuels and meeting their hydrogen economy roadmaps. The decision to import green ammonia needs an intensive analysis on environmental sustainability assessment considering the transportation from Australia to Korea.

Currently, according to Philibert (2017), global ammonia production contributes to 1.3% of total carbon dioxide emissions, along with about 420 million tons of CO₂ being emitted into the atmosphere. Globally, ammonia production relies on fossil fuels both as an energy source and feedstock, specifically for hydrogen. The ammonia industry's decarbonisation is possible only if the source of energy and hydrogen feedstock is replaced by fossil fuel with greener and sustainable sources. Hydrogen production through water electrolysis needs electricity, and if this electricity is from renewable energy sources such as wind and solar, the produced hydrogen and then ammonia can be termed as green and sustainable. Life cycle assessment (LCA) is a well-known methodology to assess the environmental impacts associated with a product or process at each stage of its life cycle like raw materials extraction, product manufacturing, services, and final disposal. The assessment of green ammonia production's environmental impacts will give a brief insight into the process's sustainability aspects and economic indicators.

Therefore, this study presents a cradle to gate environmental assessment of hydrogen production from imported green ammonia. This assessment's system boundary includes; raw materials required for manufacturing the product, infrastructure for green ammonia production, including construction and manufacturing of electrolyzer, and transportation from Australia to Busan. This work doesn't include the construction of renewable energy power plants, compression, and hydrogen storage since it is assumed that the hydrogen generation unit is onsite and construction of hydrogen refuelling stations. It is assumed that ammonia imported from Australia will be shifted to fuelling stations in Korea as per requirement, and cracking units will be installed beside the stations to avoid hydrogen transportation and ensure continuous fuel supply.

2. Methods

A block flow diagram is shown in Figure 1 for a brief overview of the process. This work was done in three stages; process designing and simulation of hydrogen and ammonia production processes, life cycle inventory and assessment, and interpretation of results. For process design and simulation, Aspen Plus V11 was used, mass and energy balance data from process design was used as an input for life cycle assessment. SimaPro 9.1.1.1 was used for life cycle assessment, and method CML-IA baseline V3.06 was selected for evaluation of economic indicators.

Figure 1: Block diagram of the case study

2.1 Process design and simulation

Ammonia here is produced by the combination of nitrogen (from air separation unit) and hydrogen (water electrolysis) at high temperatures (450°C) and pressure (150bar) in the presence of Fe_2O_3 as catalyst. Aspen plus process flow diagram of green ammonia synthesis is shown in Figure 2. Electricity from renewable energy sources is used as an input of power source of electrolyzer and production process of ammonia of 746 tons/day with 5.66 ton/hr. of hydrogen from electrolyzer and 26.260 ton/hr. nitrogen from air separation requires 360 MW in total, according to Morgan et al. (2017). Power consumption of each unit is; air separation 3.24 MW, ammonia synthesis unit about 20 MW, and water electrolysis about 335 MW. This green ammonia will then be shipped to Korea and then transported from port to hydrogen refuelling stations as per requirement. It is assumed that cracking units are installed beside the fuelling station for onsite production of hydrogen and to avoid hydrogen transportation. A process flow diagram of the unit is shown in Figure 3, reaction conditions were set at 400°C and 1.013 bar. Liquid ammonia pass through a heater to attain the reaction temperature. The outlet stream of the reactor was then introduced in pressure swing adsorption column, ultra-pure H_2 gas with 99.999% purity was collected from top while the bottom product was 99.82% pure N_2 . A normal hydrogen fuelling station operates at a 300 Nm^3/hr hydrogen flow rate. High-pressure compressors (750-1000 bar) are used for hydrogen at the fuelling station. However, hydrogen compression and storage is not considered in the environmental assessment.

Figure 2: Process flow diagram of green ammonia synthesis

Figure 3: Process flow diagram of cracking of green ammonia

2.2 Life Cycle Impact Assessment

Life cycle assessment is a universal and mature tool to assess the environmental impacts from manufacturing, packaging, storing, transportation, and final disposal. Life cycle inventory is calculated by using mass and energy balance data obtained from process design modelled in Aspen Plus V11. The system boundary for this assessment includes; raw materials required for manufacturing the product, infrastructure for green ammonia production which includes construction and manufacturing of electrolyser, and transportation from Australia to Busan. This work doesn't include construction of renewable energy power plants, hydrogen re-fuelling stations, and compression and storage of hydrogen since it is assumed that hydrogen generation unit is onsite. Australian energy statistics (2020) published by the department of industry, science, energy, and resources reported that electricity generation by renewable energy sources (wind, hydro, and solar) 21% in 2019 in which wind and solar contributed equally at 6%. Hydrogen production from electrolysis needs a huge amount of electricity, about 54.3 kwh per kg of hydrogen (Koj et al., 2017). So, it is the major source of carbon emissions in the green hydrogen production process. In contrast, the electrolyzer construction has very little contribution to the emissions, as shown in Figure 4 below.

Figure 4: LCA results of hydrogen production from electrolysis

The transportation from Australia to Korea emits high CO₂ and SO_x emission since no renewable fuel is used in marine transport now. These results are shown as relative contribution, since ammonia is being transported from Australia to Busan having distance of 7161 km so it is contributing maximum in the emissions. There is a probability of using green ammonia as a marine fuel, and if marine fuel is replaced with green energy, then the high emissions related to transport can also be mitigated. The results of environmental indicators after LCA of green ammonia production is shown in Figure 5. Following the ammonia transportation, hydrogen production presents the second highest emissions throughout the process. Hydrogen production through cracking of green ammonia has the lowest contribution since very less power, about 300 kwh for hydrogen production of 300 Nm³/hr. is required for the process.

2.3 Interpretation of results

The results of the complete life cycle assessment of the case study as shown in figure 5, reveal that more than 90% of GWP related emissions come from NH₃ shipping while

Figure 5: LCA results of hydrogen production from imported green ammonia

Figure 6: Comparison of LCA of ammonia production routes

hydrogen production by water electrolysis emits about 5% of total emissions. Ammonia synthesis unit results into only 0.12% while ammonia cracking process presents almost negligible amount of carbon related emissions as compared to other stages of process. Selected environmental indicators for life cycle impact assessment are explained below in table 1 along with the sources. Anthropogenic CO₂ emissions in global warming cause climate change, which in turn results in negative effects on human health and ecosystem quality. Similarly, other indicators such as the depletion of minerals and fossil fuels that come under abiotic depletion are also evaluated. Eutrophication, along with other economic indicators, was also evaluated in the analysis. CH₄-methane; CFC_s-chlorofluorocarbons; HCFC_s-hydro-chlorofluorocarbons; CH₃Br-bromomethane; PM10-particulate matter 10 μm; SO₂-sulphur dioxide; NMVOC-non-methane volatile organic compound.

3. Conclusion

Production of ammonia is a very mature process commercially, but source of hydrogen production is through steam reforming of natural gas (fossil fuel), which is a major source of high carbon emissions. We have compared our green ammonia production process with that of conventional ammonia production processes in Figure 6. According to Luke et al. (2020), ammonia production contributes to 1.3% of the world's total carbon dioxide emissions. Green ammonia production contributes only 4% of carbon dioxide emissions

as compared to conventional ammonia production routes and that 4% are due to the raw materials required for electricity production. Steam reforming uses natural gas route use natural gas and ammonia production as synthetic fuel by Fischer-Tropsch process use coal, so it has the highest contributions to the emissions. Results indicate that importing green ammonia for meeting hydrogen demands is not environment friendly now due to huge amount of emissions related to NH₃ shipping, but it can be viable in the coming future. If marine transportation is replaced by ammonia as fuel by using fuel cells or ammonia fuelled engines (2 stroke engines), which is also under research work (MAN 2019), then transportation of green ammonia will be more beneficial for the environment.

Table 1: Economic Indicators, definition, and contribution sources (Chisalita et al. 2020)

Impact Category (Units per kg emission)	Definition	Relevant LCI Data
Abiotic Depletion (ADP) (kg Sb eq.)	Collective quantification of the impact caused by extraction of minerals due to inputs in the system	Extraction of mineral resources
Abiotic Depletion (fossil fuels) (AFFDP)(MJ)	Surplus energy (lower heating value) per extracted MJ, kg, or m ³ fossil fuel, as a result of lower quality resources; unavailable for use by future generations	Extraction of fossil fuel resources
Global Warming (GWP 100a) (kg CO ₂ eq.)	GWP potential for time horizon 100 years: The impact caused by emissions of greenhouse gases	CO ₂ , NO ₂ , CH ₄ , CFCS, HCFCS, CH ₃ BR
Ozone Layer Depletion (ODP) (kg CFC-11 eq.)	Thinning of the stratospheric ozone layer due to anthropogenic emissions due to greenhouse gases	CFCS, HCFCS, CH ₃ BR, Halons
Human Toxicity (HTP) (1,4-dichlorobenzene eq.)	Potential impacts of toxic substances on human health present in the environment	Human toxic substances
Photochemical oxidation (kg C ₂ H ₄ eq.)	Formation of reactive chemical compounds like ozone, by the action of sunlight on emissions of air pollutants	PM ₁₀ , NH ₃ , SO ₂ , NO _x , and NMVOC
Acidification (kg SO ₂ eq.)	Formation of acidic compounds as a result of the manufacturing process	SO _x
Eutrophication (kg PO ₄ eq.)	Collective quantification of formation of phosphorus compounds	Nitrogen and Phosphorus compounds

Optimal Design of Distillation Columns Using a Combined Optimisation Approach

Dian Ning Chia^a, Fanyi Duanmu^a and Eva Sorensen^{a,*}

^a*Department of Chemical Engineering, UCL, Torrington Place, London WC1E 7JE, UK*
^{*}*e.sorensen@ucl.ac.uk*

Abstract

Distillation is the most important separation process in the chemical industry despite being very energy-intensive, hence any attempt to optimise its design may potentially have a significant impact. In this work, a combined optimisation strategy based on Genetic Algorithm (GA, stochastic method) and an outer approximation method (OAERAP, deterministic method) is proposed and demonstrated to reliably and efficiently optimise different distillation processes by achieving significant energy and/or capital savings. Three different case studies are presented to compare the combined strategy to the stand-alone GA and OAERAP methods. The combined optimisation strategy shows excellent results, with the total annualised costs obtained from the combined strategy being similar or better than for the stand-alone methods. More importantly, the combined strategy requires much shorter CPU time, as well as significantly less manual effort, thus greatly increasing the time efficiency when compared to the OAERAP method.

Keywords: Optimisation, Genetic Algorithm, Outer-approximation, Distillation

1. Introduction

The optimisation of many chemical processing units, including distillation columns, is a Mixed Integer Nonlinear Programming (MINLP) problem, as well as a highly non-convex problem, leading to the existence of potentially multiple local optima (Javaloyes-Antón et al., 2013). Current optimisation methods used to solve these problems can be categorised into deterministic and stochastic methods, where the former requires the translation of the problem into a convex model to find the global optimum (Grossmann et al., 2005), an approach that can be quite challenging (Bonami et al., 2008). Stochastic methods do not require the model to be transformed, but will instead typically require a long time to converge. In this work, a combined optimisation strategy is proposed that exploits the ability of the stochastic method to easily identify the proximity of the global optimum for a non-convex problem, and the quick convergence of the deterministic method once close to that optimum. Several case studies will be used to illustrate the strategy, including a two column sequence, a dividing wall column (DWC), and a hybrid separation process.

2. Methodology

The proposed strategy uses a stochastic method in the form of Genetic Algorithm (GA) to find an approximate, preliminary, optimal design in the first step. In the second step, and based on the preliminary design from the first step, a deterministic method based on outer approximation (OAERAP) is used to find the global optimum. For the combined

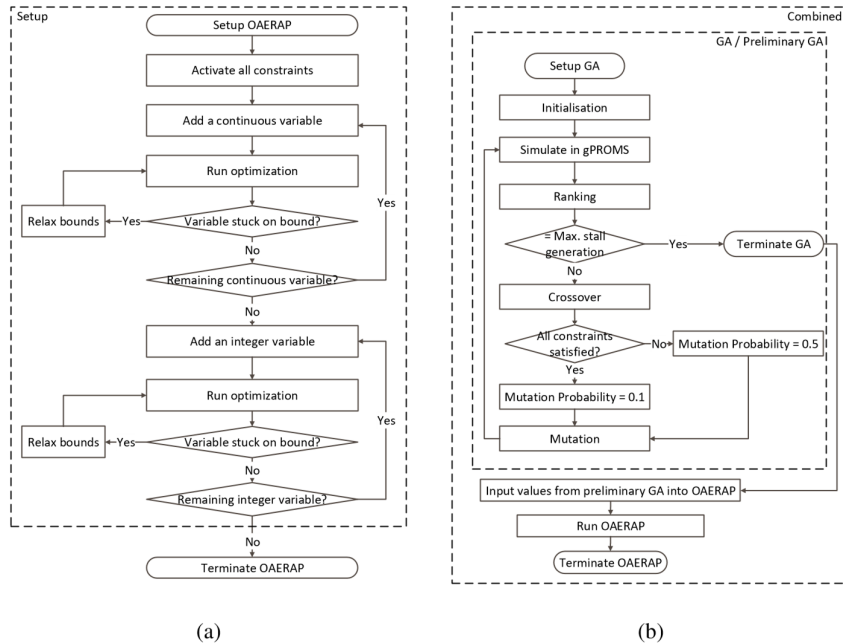

Figure 1. Flowcharts of (a) deterministic (OAERAP) method, (b) stochastic (GA) method and combined strategy.

approach, the values returned from the GA algorithm represent a valid solution to the model and the outer approximation initialisation is therefore non-problematic. All the case studies are performed in a process simulator, gPROMS ProcessBuilder, and the same distillation process model is used for all methods. gO:MATLAB is used to exchange data with MATLAB within which the external GA optimiser is implemented.

The OAERAP algorithm may easily fail to converge if the optimisation problem is highly non-convex and complex. Thus, a setup procedure as shown in Figure 1a is introduced to overcome the convergence issue of initialising the OAERAP algorithm. The OAERAP used in this work is built-in in gPROMS ProcessBuilder, and the procedure can be found in the gPROMS documentation (Process Systems Enterprise, 2020). The optimisation convergence is highly dependent on the variable bounds and the initial values provided, and the optimisation problem is therefore typically implemented in two stages. First, the continuous variables are added one-by-one and the optimisation problem is solved after each. Next, the integer/discrete variables are similarly included, and finally the whole problem optimised. It should be noted that for certain problems some of the variables may be linked, e.g. number of stages and feed locations for DWC, and these variables should then be added together. During optimisation, some of the variables may be stuck on bounds, which must then be relaxed and the problem re-optimised before adding another variable into the problem. To improve the convergence, the search space may subsequently be narrowed again before adding another variable. This manual procedure is clearly time consuming but unfortunately often necessary.

The procedure of the GA method is shown in the inner box in Figure 1b. In this work, the GA method was developed in MATLAB and was validated against several classical

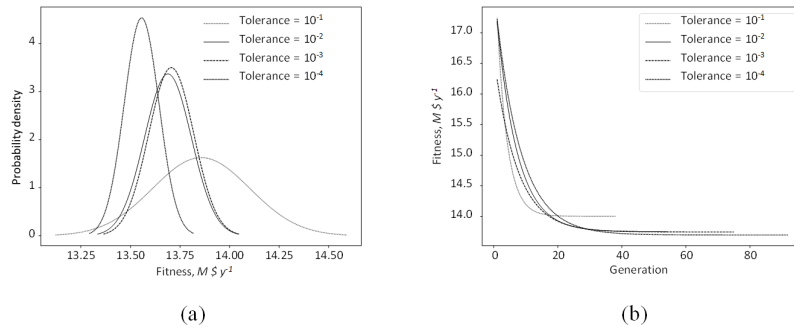

Figure 2. (a) Probability density function of fitness, and (b) Exponential regression for TAC-Generation, at different values of fitness tolerance (Case study 1).

mathematical functions (e.g. Schwefel function and constrained Rosenbrock function) and literature (Deep et al., 2009; Deb, 2000) (not shown). Based on this validation, the population size in this work is chosen as five times the number of optimisation variables, and the GA is stopped when the best fitness value remains constant (within the fitness tolerance) for 20 consecutive generations. The discrete crossover is used for all case studies (Umbarkar and Sheth, 2015). The top 50 % of the ranked chromosomes are chosen to participate in the crossover, and the elitism percentage is chosen as 10 %. To improve the performance of the GA, the mutation probability is set as 50 % initially and the value is changed to 10 % after a feasible (all constraints are met) design is found. Furthermore, the penalty function proposed by Deb (2000) is used to avoid guessing the R value. To improve the optimisation convergence, the following approaches were applied: 1) dynamic bounds were introduced for some variables (for example, the feed location should always be lower than the number of stages in a column, thus the upper bound of the feed location should be dynamically equal to the number of stages in its chromosome); and 2) the model was initialised using a feasible simulation with the number of stages close to the lower bound before each simulation. By applying these strategies, the percentage of infeasible simulation dropped from 90 % to 10 % in each generation.

The procedure of the combined strategy proposed in this work is shown in the outer box in Figure 1b. First, the GA method with a looser tolerance, and thereby a faster convergence, is used to locate a preliminary global optimum design. Figure 2 (based on a minimisation problem) shows that with a tighter fitness tolerance, the fitness is better but more generations are required. By trading off between fitness and generations (CPU time), a tolerance of 10^{-2} is chosen as this value provides good results but needs only half the generations compared to a 10^{-4} tolerance, which is the default value normally used in OAERAP and GA. Apart from the change of fitness tolerance, all other GA settings are kept the same. Once the preliminary GA design is obtained, this design becomes the initial values in the OAERAP problem and the entire optimisation is solved in one step without applying the setup procedure for the OAERAP.

3. Case Studies

The optimisation strategy is illustrated using three case studies. For each case, several optimisations are performed for each optimisation methods with almost identical solutions. In the following, the solution with the most common fitness and CPU time (referring to the peak in the probability density function) is presented. All simulations

3.1. Description

Case study 1 is the separation of an equi-molar benzene/toluene/o-xylene mixture separated in a two-column direct sequence. The feed is a saturated liquid at 0.37 bar with flow rate of $500 kmol h^{-1}$. The column operates at 0.37 bar with no pressure drop, and is modelled in gPROMS ProcessBuilder using “Distillation_column_gML”, which is an equilibrium model. For case study 2, the same separation task takes place in a dividing wall column (DWC), with all other information remaining the same as for case study 1. As there is no library model for a dividing wall column (DWC), a thermodynamically equivalent Petlyuk structure is considered instead. Case study 3 is a hybrid distillation-*per*vaporation column separating an azeotropic water-ethanol mixture. The feed is an equi-molar saturated liquid at 1.1 bar with flow rate of $500 kmol h^{-1}$. The column pressure is 1.1 bar with no pressure drop. The membrane model is a user-defined model coded in gPROMS ProcessBuilder which was validated against the membrane model by Luyben (2009). For all case studies, UNIQUAC is the thermodynamic model.

The objective function is to minimise the total annualised cost (TAC), including capital and operating costs, with the assumption of 8 years of payback period with an annual operating hour of $8400 h y^{-1}$, and a membrane lifetime of 2 years. The column sizing equations are obtained from Seider et al. (2016) and the cost equations from Sinnott and Towler (2020).

3.2. Results and Discussion

To evaluate the performance of each optimisation method, TAC and CPU time is chosen as the main indicators. Tables 1 to 3 show all the optimised variables, TAC, and CPU time for each case study. The tables show that the preliminary design obtained from GA in the proposed combined strategy has a slightly higher TAC but much lower CPU time when compared to the stand-alone GA method. The final optimal designs for the combined optimisation strategy (preliminary GA + OAERAP), show better TAC (up to

Table 2. Case study 2 – Dividing Wall Column (DWC): Comparison between GA, OAERAP, and the combined strategy.

Total CPU time	13586	-	7419	-	s

2% reduction) compared to the stand-alone GA method. Due to the fast convergence speed of the single OAERAP optimisation in the second step, the total CPU time of the combined strategy can be reduced by 19-53 % depending on the complexity of the system.

In general, the optimal TAC obtained from the combined strategy is close to the TAC obtained from the OAERAP method. However, the CPU time of OAERAP within the combined strategy (labelled as “Final” in the tables) was greatly reduced (36-76 %) when using the preliminary GA design as initial values. It should be noted that the CPU time for the standard OAERAP method is misleading as this is only the solution time and therefore does *not* take into account the considerable time required to set up the problem, and the trial and error needed to adjust the bounds etc. This time is therefore highly dependent on other factors such as the optimisation experience of the user, initial guesses for the values, and/or short-cut design method used. In our experience, and especially for complex systems, the OAERAP optimisation often fails to converge, gives values stuck on bounds, runs “infinitely” (e.g. for DWC more than 30 hours without yielding any results) with poor initial values, etc., which lead to a much higher time consumption compared with the combined strategy. Most of the optimisation time in the combined strategy is used in the preliminary GA which is far more robust and unlikely to fail hence not needing constant monitoring.

4. Conclusion

A hybrid optimisation strategy combining Genetic Algorithm (stochastic method) and OAERAP (deterministic method) is proposed in this paper and illustrated using three distillation-based case studies. The case studies show that using only the deterministic method may yield an infeasible solution if the bounds of the optimisation variables are too wide, and that to narrow these bounds, significant manual trial and error is required. In addition, the optimisation variables must typically be added manually and gradually to achieve convergence. For the stochastic method, the GA can yield a preliminary optimal

Total CPU time	4291	-	3490	-	s

design in a moderate amount of time, however, significantly more time is needed to converge to the actual optimum. For all the case studies, the proposed combined strategy shows a greatly reduced overall optimisation time. Although the combined strategy requires more computational effort compared to the stand-alone GA and OAERAP, the significant saving in time and manual effort, especially for complex systems, overwhelms the limitation of the combined strategy. To conclude, the proposed combined strategy makes optimisation easier, requiring less manual effort, and can yield a better global optimum in a shorter time. The combined strategy can also be used for other types of optimisation problems, e.g. based on a superstructure.

Abstract

This work deals with the design of integrated facilities for the simultaneous production of xylitol and sorbitol from lignocellulosic biomass. A superstructure of alternatives is formulated. Different pretreatments, such as dilute acid or AFEX for the fractionation of the biomass are considered. Next, after hydrolysis, the C5 and C6 sugars are processed separately, for which either a catalytic or a fermentation stage are evaluated. Finally, the purification of any of the products is carried by crystallization in a multi-state evaporator system. Surrogate models based on experimental data for the different stages of the process including the pre-treatment and the synthesis and first principles models for crystallization are developed to formulate the superstructure MINLP optimization model. The optimal results suggest the use of dilute acid and the catalytic system, and a system of three crystallizers is selected. This optimal flowsheet is also used to evaluate the performance of different raw materials into the product portfolio as a function of the biomass composition as well as the design of the optimal biomass.

Keywords: Integrated processes, Biomass, added valued products, Optimization.

1. Introduction

The chemical industry is undergoing a transformation towards a more sustainable future starting from the use of renewable instead of fossil resources, which constitutes the 7th principle of green chemistry (Erythropel et al., 2018). Biomass has emerged as a rich raw material towards the production of energy and chemicals (Keshwani and Chen 2009). The diversification of the use of biomass results in the need to use it for products beyond fuels and energy. In particular xylitol and sorbitol are considered in the production of dietetic foods as well as in pharmaceutical applications (mainly as a carrier), cosmetics industry (as an emulsion stabilizer), moisturizer, texturizer and softener having being listed on the top 12 high value-added building block intermediate chemicals that can be produced from renewable biomass resources (Werpy et al., 2004). Xylitol can be obtained from xylose via fermentation or catalytic hydrogenation (Rafiqul and Sakinah, 2013). Sorbitol is obtained from glucose via catalytic hydrogenation or from fructose via fermentation (van Gorp et al., 1999; Chun and Rogers, 1988). Fructose can be obtained from glucose via

isomerization (Illanes et al., 1992). In spite of previous efforts in the design of production processes, no attempt has been made on the design of an integrated process for the simultaneous production of both from lignocellulosic biomass.

2. Process description

Biomass starts with a size reduction step before pretreatment. There are many alternative pretreatments (Sung and Cheng, 2002). However, among them the ones that have reached commercial exploitation are (1) dilute acid (H_2SO_4) pretreatment, and (2) ammonia fibre explosion (AFEX). Once the physical structure of the switchgrass is broken, we separate cellulose from hemicelluloses sugars. Cellulose is hydrolyzed at 45-50°C for 3 days to obtain glucose (Piccolo and Bezzo, 2009). Glucose can be isomerised into fructose for its fermentation into sorbitol or catalytically hydrogenated. Next, the sorbitol is recovered by crystallization in a three-effect evaporator. Xylose follows a similar path into xylitol. It can be either fermented or catalytically hydrogenated into it. The superstructure of alternatives is presented in Figure 1.

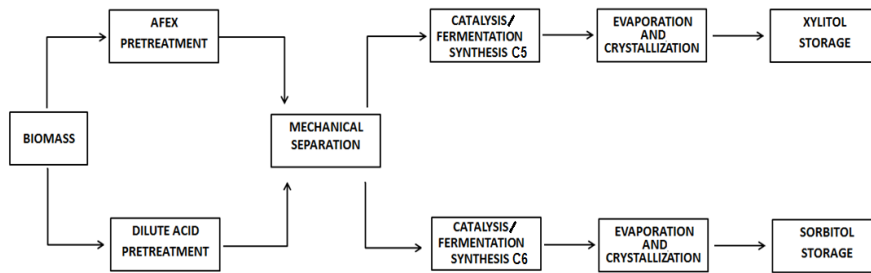

Figure 1.-Superstructure for the production of xylitol and sorbitol

3. Modelling approach

Surrogate models based on detailed simulations and/or experimental data are developed for particular units such as the pretreatments, the ammonia recovery column, and the crystallizers. The model for the superstructure is expressed in terms of total mass flows, component mass flows, component mass fractions, and temperatures of the streams in the network.

Pretreatment: Both pretreatments, AFEX and dilute acid, are modelled using response surface models developed experimental data from the literature to estimate the yield and process simulators for the recovery of ammonia. For the acid pre-treatment the yield is a function of the operating temperature, T , the acid concentration, %, the enzyme added, Enz , and the residence time (Shi et al., 2011).

$$Y_{cellu} = f(T, \%, Enz, t)$$

$$Y_{Hemi} = f(T, \%, Enz, t) \quad (1)$$

In the case of the AFEX, the yield to sugars depends on the water and ammonia added per kg of biomass, $NH_{3,added}$ or Wa_{added} , the residence time and the operating temperature, T (Garlock et al., 2012).

$$Y_{cellu} = f(T, NH_{3,added}, Wa_{added}, t) \quad (2)$$

A surrogate model is developed to evaluate the effect of the feed composition on the operating conditions of the column that recovers ammonia.

Xylitol production:

Via fermentation the reaction consumes ammonia and hydrogen as follows, operating at 30°C and 1 bar with a conversion of 92% (Mountraki et al., 2017).

The catalytic synthesis reaction takes place at 100-120 °C and 40-60 bar for 3-4 h. A model to estimate the conversion is developed from the kinetics results in the literature (Ngoc Pham et al., 2016).

Sorbitol production:

Via fermentation an additional step is required to isomerise the glucose into fructose

That is next fermented into sorbitol as follows:

Based on experimental data, the conversion of the fructose into sorbitol can be predicted by the following correlations

$$X_{(\text{fructose})} = -1.40 \cdot 10^{-6} (\text{concentration}(\text{g}\cdot\text{L}^{-1}))^2 + 8.700000 \cdot 10^{-4} (\text{concentration}(\text{g}\cdot\text{L}^{-1})) + 0.819 \quad (7)$$

The catalytic hydrogenation of glucose is carried out at 100-140 °C, 40-60 bar

Crystallization: Each crystallizer is modelled using mass and energy balances. Note that the pressure at the evaporation chamber will depend on the steam generated in the previous one and the composition of the mixture to concentrate. The solubility as a function of the temperature has been correlated from the literature data (Zambé et al, 2001) as well as the ebulloscopic effects. S represents steam, s condensed stream, F feed, E, evaporated water, L liquid product and C crystals.

$$F_j \cdot x_{j,f,i} = C_{j,i} + L_j x_{j,l,i} \quad \forall j \in \{\text{effects}\}, i \in \{X, S\}$$

$$H_s + H_f = H_s + H_e + H_l + H_c \quad (9)$$

$$H_i = \sum_i f_i \cdot \Delta h_{i,f} + F \int_{T_{ref}}^T c_p(X, T) dT$$

4. Optimization procedure

The superstructure is decomposed into four flowsheet alternatives: one per pretreatment and one for each of the synthetic routes, either fermentation or catalysis. An NLP problem is solved for each one where the objective function consists of a simplified production costs given by eq. (10)

$$Z = P_{Xylitol} m_{Xylitol} + P_{Sorbitol} m_{Sorbitol} - P_{Steam} \sum_i \frac{Q_i}{\lambda} - P_{H_2} \quad (10)$$

Subject to the models described in section 3. Each NLP consists of around 2700 eqs and 3800 variables and it was solved with GAMS requiring 12.5 s of CPU-time. After the optimization, a heat exchanger network is designed to reduce energy consumption. Finally, a detailed economic evaluation of the alternatives is performed to compute the

production and investment costs of the facility using the cost correlations in Martín and Grossmann, (2011) and the procedure described in that work.

5. Results

In this section the major operating results as well as the economics of the different alternatives are presented. In addition, a subsection commenting on biomass design has also been included.

5.1. Process analysis

The superstructure of alternatives has been decomposed to evaluate the performance of each of the alternative processes including two pre-treatments and two synthetic lines. Table 1 shows the major results of each of the optimized paths.

Table 1.- Major yields of the alternative production paths

	Dilute Acid Catalysis Hydrogenation	AFEX Catalysis Hydrogenation	Dilute Acid Fermentation	AFEX Fermentation
kg H ₂ / Kg Biomass	0.007	0.005	0.001	0.001
kg H ₂ SO ₄ / Kg Biomass	0.024	-	0.017	-
kg NH ₃ / Kg Biomass	-	1.052	-	1.052
kg Xylitol _{crystallized} / Kg Biomass	0.259	0.187	0.166	0.120
kg Sorbitol _{crystallized} / Kg Biomass	0.282	0.231	0.142	0.102
kg Steam/ Kg Biomass	0.505	0.587	2.013	1.374

Two main results can be highlighted. Dilute acid pretreatment and catalytic hydrogenation show the largest yield to products. In general, fermentation requires more energy than catalytic synthesis due to the diluted products and operating conditions, while dilute acid pretreatment consumes also more steam than AFEX, since it operates at milder temperature. Note that the isomerisation of the glucose is endothermic, increasing the need for utilities. The best objective function corresponds to the use of dilute acid pretreatment followed by catalytic hydrogenation. Even though further results of the four paths will be presented, the focus of the analysis will be that this best process. But for the case of the fermentation-based processes, three effect evaporation systems are used operating under vacuum.

5.2. Process economics

Table 2 shows the investment and production cost of the four alternatives. The fermentation-based processes require additional investment due to the need for isomerisation of the glucose and the high residence times in both the isomerisation and the fermentation itself, that doubles the one when catalytic hydrogenation is considered. In addition, the larger consumption of steam in the case of fermentation also increases the production costs which double the ones using catalytic synthesis. Figure 2 shows the detail of the breakdown for the production costs, Figure 2a, and investment costs, Figure 2b. With regards to production costs, 70% of them correspond to the raw material so that the more efficient process in using it will yield better economics. That is the reason for the catalytic hydrogenation to be the best synthetic path and the dilute acid the selected pretreatment. The best process reports an investment cost of 121 M € and a production cost of 18.74 M€/yr. In terms of investment, biomass pretreatment towards sugar production represents over 50% of the investment cost. That is the reason for biomass-

based processes to show a barrier to enter the market versus the more established use of fossil alternatives. The second major contribution corresponds to the heat exchanger network responsible for reducing steam use at the cost of the investment required in the network.

5.3. Biomass design

The inverse problem is solved here. Instead of using a fixed biomass composition, belonging to a lignocellulosic species such as switchgrass, the optimal flowsheet is used to determine the best composition within the typical ranges of hemicelluloses, cellulose and lignin for the simultaneous production. The resulting biomass composition corresponds to 15% water, 20% cellulose, 40% hemicellulose, 15% lignin and 5% ash. The higher cost of the xylitol results in a biomass with larger fraction of hemicelluloses. The cellulose represents a secondary role due to lower market price of the sorbitol and higher amount of steam used respect to xylitol production.

Table 2.- Summary of economic analysis

	Dilute Acid Catalysis Hydrogenation	AFEX Catalysis Hydrogenation	Dilute Acid Fermentation	AFEX Fermentation
Investment (MM€)	120.78	146.44	323.74	273.45
Production Cost (MM€)	18.74	22.94	45.80	37.80

Figure 2.- Breakdown of a) production costs b) investment cost.

Among typical biomasses such as wheat straw, corn stover, switchgrass, hybrid poplar, forest residues from pine, birch, spruce and sugarcane bagasse the one that fits the best is sargassum algae (*sargassaceae*) with a composition of 20.48% cellulose and 43.19% hemicellulose and similar lignin content as the optimization results (Rabemanolontsoa and Saka, 2013). Further sensitivity analysis on the effect of the product prices is to be carried out. Working with the optimal biomass the production cost and investment decrease almost 0.5 M€ each one but there is a reduction in the production cost of xylitol almost two times, from 0.59 €/kg to 0.37 €/kg. (Table 3)

Table 3.- Economic parameters comparison

	Investment (M€)	Production Cost (M€/yr)
Switchgrass	120.78	18.74
Best biomass	120.50	18.37

6. Conclusions

The best alternative obtained to produce xylitol and sorbitol from biomass is the catalytic synthesis process with a dilute acid pretreatment due to a highest $\text{kg}_{\text{xylitol}}/\text{kg}_{\text{biomass}}$ and $\text{kg}_{\text{sorbitol}}/\text{kg}_{\text{biomass}}$ and low use of steam, reaching the lowest production and investment cost. Following this optimization, the biomass design was made to determinate the better biomass composition, reaching a key percent of 40% hemicellulose and 20% cellulose, finding this composition in the sargassum algae (*sargassaceae*), highly available in almost of the world.

The use of the best biomass would yield a saving of around 0.5 M€ in the production and investment costs, and reduction of xylitol production cost from 0.59 €/kg to 0.37 €/kg.

Abstract

In the field of Computer-Aided Molecular and Process Design (CAMPD), a variety of solution methods have been developed to handle the complexities associated with the non-convexity and non-linearity of molecular structure-property and process models. However, most algorithms are prone to failing to generate feasible solutions when the integrated solvent-process model renders a significant portion of the search space infeasible. In this work, we propose a solution approach for the integrated design of an optimal chemical absorption process in which tailored feasibility tests are incorporated into a process optimisation problem. The solution approach allows the exploration of a design space without unnecessary difficulties by recognising infeasibilities. The effectiveness of the approach is demonstrated on an aqueous amine solvent-based CO₂ capture process.

Keywords: CAMPD, carbon dioxide capture, amine-based solvent, MINLP

1. Introduction

Amine-based chemical absorption processes are regarded as some of the most effective and mature technologies for post-combustion carbon dioxide (CO₂) removal from large point sources (Rochelle, 2009). The conventional solvents used for this chemical absorption are monoethanolamine (MEA) and methyldiethanolamine (MDEA). However, the use of such solvents requires high energy consumption for solvent regeneration, consequently introducing significant economic penalties that are a concern in many contexts such as flue gas cleaning in power plants (Lee et al., 2013). In order to overcome this adverse effect, substantial research efforts have been directed towards the development of novel solvents.

A promising research direction to accelerate the identification of new solvents is the development of Computer-Aided Molecular and Process Design (CAMPD) techniques. CAMPD offers a systematic methodology to explore a very large molecular domain in which the overall performance of a process is evaluated by capturing mutual interaction between molecular properties and process performance (Adjiman et al., 2014). While a variety of strategies for the solution of CAMPD have been developed, many algorithms resort to decomposition to overcome numerical challenges. These arise mainly because the integrated solvent-process model exhibits a number of infeasible regions, thereby making it challenging to generate a feasible solution with some solvent structures. This strategy may however result in convergence to a suboptimal solution. Thus, the development of robust algorithms that make it possible to avoid infeasibilities during the exploration of a large search space is an important enabling step for CAMPD.

In this work, a robust optimisation framework for the integrated design of an optimal aqueous solvent and the associated CO₂ chemical absorption process is presented. The focus is on enabling the solution of such problems when a large set of potential molecules is entailed. New feasibility tests are introduced as an extension of the approach proposed by (Gopinath et al., 2016) for physical absorption, to ensure applicability to the more complex setting of chemisorption. The design of the tailored feasibility tests is focused on the screening of infeasible solvent candidates and the identification of feasible ranges of process conditions by

investigating: 1) physicochemical properties of the solvent mixture; 2) environmental impact arising from solvent loss; and 3) thermodynamic feasibility of satisfying separation targets. The efficiency of the proposed algorithm is demonstrated on a case study.

2. Problem Formulation

2.1. Process and cost model

The integrated design of an aqueous solvent and a CO₂ chemical absorption process is considered to determine an optimal solvent structure and process conditions. This CAMPD problem is often posed as Mixed-Integer Nonlinear Programming (MINLP) problem. The generic mathematical formulation of the design problem can be defined by:

$$\begin{aligned}
 \min_{\mathbf{x}, \mathbf{n}} \quad & f(\mathbf{x}, \mathbf{n}), \\
 \text{s.t.} \quad & \mathbf{g}(\mathbf{x}, \mathbf{n}) \leq \mathbf{0} \\
 & \mathbf{h}(\mathbf{x}, \mathbf{n}) = \mathbf{0} \\
 & \mathbf{C}\mathbf{n} \leq \mathbf{d} \\
 & \mathbf{x} \in \mathbb{R}^n, \mathbf{n} \in \mathbb{N} \subset \mathbb{Z}^q
 \end{aligned} \tag{1}$$

where \mathbf{x} is a n -dimensional vector of continuous process variables, \mathbf{n} is a q -dimensional vector of integer variables that define the molecular design space, $\mathbf{g}(\mathbf{x}, \mathbf{n})$ is a vector of inequality constraints that represent design and feasibility constraints, $\mathbf{h}(\mathbf{x}, \mathbf{n})$ is a vector of equality constraints that include structure-property models and process models and a set of linear equations $\mathbf{C}\mathbf{n} \leq \mathbf{d}$ represents molecular feasibility constraints and bounds on vector \mathbf{n} .

A schematic of the process configuration considered is shown in Figure 1. The process and cost estimation models are based on Alhajaj et al. (2016), who adopted an equilibrium-stage model combined with a lumped hydrodynamic model for process optimisation. Total annualised cost (TAC) is selected as an objective function to measure the overall economic performance for given molecules. We consider three key process design variables: the temperature of the solvent entering the absorber (T_0), the lean solvent loading (θ_0) and the desorber pressure ($P_{N,d}$). For a detailed description of the modelling strategy and assumptions used, the reader is referred to Alhajaj et al. (2016).

2.2. Molecular design space

The molecular design space is constructed by selecting groups present in typical CO₂ capture solvents and taking into account the availability of group contribution values. It is generated from the following 13 functional groups: NH₂CH₂, NH₂CH, NH₂C, NHCH₃, NHCH₂, NHCH, NCH₃, NCH₂, CH₃, CH₂, CH, C, OH. The property prediction methods of Hukkerikar et al. (2012) are used for the normal melting temperature (T_{mp}), the auto-ignition temperature (T_{AIT}), the flash point (T_{fp}), and the LC50 toxicity ($LC_{50,mgL}$). The method of Hsu et al. (2002) is used to predict surface tension (σ) and viscosity (μ). The SAFT- γ Mie group contribution equation of state (Papaioannou et al., 2014; Perdomo et al., 2020) is used to predict the fluid-phase behaviour of water, solvent and CO₂ mixtures. To make use of this thermodynamic model, the original functional groups are translated into the following SAFT- γ Mie groups: NH₂, NH, N, CH₂, CH, C, CH₂OH. The total number of functional groups in the molecule is limited by bounds $[n_t^L, n_t^U] = [3, 12]$. The total number of groups with amine and hydroxyl functionality are constrained by $[n_a^L, n_a^U] = [1, 2]$ and $n_{OH}^U = 3$, respectively. Because the two sets of functional groups are not exactly equivalent, the set of potential molecule is defined by the intersection of the two sets. This means for instance, that OH can only appear in the designed solvent when connected to CH₂. An additional

Figure 1: Schematic of the CO₂ chemisorption process

constraint, $n_{\text{CH}_2} \geq n_{\text{OH}}$, is imposed to enforce this.

3. Feasibility Tests

In this section, we describe four feasibility tests that are applicable to CAMPD for chemical absorption, as described in section 2.

3.1. Test 1: Solvent property feasibility

Test 1 is employed to evaluate whether the properties of the pure candidate solvent or those of the aqueous solution are within suitable ranges. Test 1 is formulated with explicit constraints on eight essential properties that are independent of the optimal process conditions. These include T_{bp} , $LC_{50,\text{mgL}}$, T_{AIT} , T_{fp} , T_{mp} , μ at lowest possible solvent handling temperature and bubble point (T_{bb}) at atmospheric pressure. The resulting formulation is as follows:

$$\begin{aligned} T_{sh}^U - T_{\text{bp}}(P = 1\text{atm}, \mathbf{n}) &\leq 0 & T_{\text{mp}}(P = 1\text{atm}, \mathbf{z}(\mathbf{n})) - T_{sh}^L &\leq 0 \\ LC_{50,\text{mgL}}(\mathbf{n}) - LC_{50,\text{mgL}}^U &\leq 0 & \mu(T_{sh}^L, P = 1\text{atm}, \mathbf{z}(\mathbf{n})) - \mu^U &\leq 0 \\ T_{sh}^U - T_{\text{fp}}(P = 1\text{atm}, \mathbf{n}) &\leq 0 & T_{\text{bb}}(P = 1\text{atm}, \mathbf{z}(\mathbf{n})) - T_s^U &\leq 0 \\ T_{op}^U - T_{\text{AIT}}(P = 1\text{atm}, \mathbf{n}) &\leq 0 \end{aligned} \quad (2)$$

where $\mathbf{z}(\mathbf{n})$ is a composition of aqueous solvent mixture, T_{sh}^L and T_{sh}^U are lower and upper bounds on solvent handling temperature, and T_{op}^U is an upper bound on the process operating temperature to avoid potential risks of solvent degradation in the reboiler.

3.2. Test 2: Solvent phase stability

Biphasic solvents are receiving increasing attention as alternatives to conventional solvents. They undergo liquid-liquid separation upon heating or CO₂, and only the CO₂-rich phase is sent to the desorber for regeneration, thereby reducing energy requirements and equipment costs (Papadopoulos et al., 2020). However, it is necessary for the aqueous solvent to form a homogeneous liquid phase for the successful operation of the absorber. Test 2 is designed to examine whether the absorber can operate outside the liquid-liquid region across its operating temperature range with the selected solvent. This is done by identifying the highest solvent concentration (W_{solvent}^*) at which only one liquid phase can form, at conditions corresponding to the absorber pressure (P_{N_a}) and the maximum temperature of the solvent leaving the absorber ($T_{N_a}^U$). If the highest solvent concentration obtained is less than the upper bound on solvent concentration, i.e. $W_{\text{solvent}}^* < W_{\text{solvent}}^U$, the molecule is discarded from the search space. Here, the upper bound on the solvent concentration is set to 0.4 kg/kg to prevent corrosion and foaming.

3.3. Test 3: Absorption capacity feasibility

Test 3 is introduced to eliminate operating conditions or solvents that cannot achieve the required absorption capacity. Test 3 is used to determine an upper bound on the lean solvent loading (θ_0^U) based on thermodynamic feasibility on the bottom stage (N_a). A constraint proposed by Gopinath et al. (2016) is also included in the problem to guide the solution in the desired direction of separation:

$$\begin{aligned} \theta_0^U &= \max_{T_{N_a}, \mathbf{z}} \theta_0 \\ \text{s.t.} \quad & [\mathbf{y}_{N_a} \ \mathbf{x}_{N_a} \ \alpha \ \beta]^T = \mathbf{f}_{\text{ext}}(\mathbf{z}, T_{N_a}, P_{N_a}, \mathbf{n}) \\ & \alpha \geq \epsilon_{ph}, \quad \beta \geq \epsilon_{ph} \\ & x_{N_a, \text{CO}_2} - y_{N_a+1, \text{CO}_2} - \frac{(y_{N_a+1, \text{CO}_2} - x_{0, \text{CO}_2})}{(y_{N_a+1, N_2} - x_{0, N_2})} (x_{N_a, N_2} - y_{N_a+1, N_2}) > 0 \\ & x_{N_a, N_2} < y_{N_a+1, N_2}, \quad x_{0, \text{CO}_2} \leq x_{N_a, \text{CO}_2} \\ & W_{N_a, \text{solvent}} \leq W_{0, \text{solvent}} + \epsilon_s \\ & 0 < z_i < 1 \quad \forall i \in \mathcal{NC}, \quad \sum_{i \in \mathcal{NC}} z_i = 1 \\ & \max(T_{mp}(\mathbf{n}) + 10, T_0^L) \leq T_{N_a} \leq T_{op}^U \end{aligned} \quad (3)$$

where the subscript a denotes the absorber, the set $\mathcal{NC} = \{ \text{H}_2\text{O}, \text{solvent}, \text{CO}_2, \text{N}_2 \}$ and \mathbf{y}_{N_a} , \mathbf{x}_{N_a} are the compositions of the vapour and liquid phases at equilibrium, $W_{N_a, \text{solvent}}$ is liquid phase solvent concentration in weight fraction at the bottom stage of the absorber, $W_{0, \text{solvent}}$ is solvent concentration at the absorber inlet, α and β are the vapour and liquid phase fractions, fl_{ext} an isobaric-isothermal flash calculation, ϵ_{ph} is a positive value to ensure the coexistence of vapour and liquid phases at stage N_a and ϵ_s is a positive value to avoid the excessive loss of water in aqueous solvents. In this study, ϵ_{ph} is set to 10^{-3} and ϵ_s is set to 10^{-1} respectively.

Equivalently, a lower bound on the lean loading (θ_0^L) is obtained by investigating the minimum achievable loading on the bottom stage (N_d) of the desorber with respect to global composition \mathbf{z} and desorber operating temperature (T_{N_d}).

$$\begin{aligned}
 \theta_0^L = & \min_{\theta_0, T_{N_d}, \mathbf{z}} \theta_0 \\
 \text{s.t.} & [\mathbf{y}_{N_d} \ \mathbf{x}_{N_d} \ \alpha \ \beta]^T = fl_{ext}(\mathbf{z}, T_{N_d}, P_{N_d}, \mathbf{n}) \\
 & \alpha \geq \epsilon_{ph}, \quad \beta \geq \epsilon_{ph} \\
 & W_{N_d, \text{solvent}} \geq W_{0, \text{solvent}} - \epsilon_s \\
 & 0 < z_i < 1 \quad \forall i \in \mathcal{NC} \\
 & \sum_{i \in \mathcal{NC}} z_i = 1 \\
 & \max(T_{mp}(\mathbf{n}) + 10, T_{N_d}^L) \leq T_{N_d} \leq T_{op}^U \\
 & P_{N_d}^L \leq T_{N_d} \leq \min(P_b(\mathbf{n}), P_{N_d}^U)
 \end{aligned} \tag{4}$$

where subscript d denotes the desorber and $W_{N_d, \text{solvent}}$ is liquid phase solvent concentration in weight fraction at the bottom stage (N_d) of the desorber.

If the bounds on lean loading violate the condition $\theta_0^L \leq \theta_0^U$, the candidate solvent is discarded from the molecular design space.

3.4. Test 4: Operating pressure

Given the lean loading range $[\theta_0^L, \theta_0^U]$ generated from Test 3, Test 4 is designed to provide tighter pressure bounds on the desorber, $P_{N_d}^U$. This is done by finding the highest pressure at which: 1) a vapour-liquid phase split occurs in the bottom stage of the desorber; and 2) there exists a lean solvent composition that satisfies the target lean loading. An additional constraint on the solvent concentration is imposed in order to prevent the optimisation algorithm from converging to a trivial solution. The resulting formulation is as follows:

$$\begin{aligned}
 P_{N_d}^U = & \max_{P_{N_d}, T_{N_d}, \mathbf{z}} P_{N_d} \\
 \text{s.t.} & [\mathbf{y}_{N_d} \ \mathbf{x}_{N_d} \ \alpha \ \beta]^T = fl_{ext}(\mathbf{z}, T_{N_d}, P_{N_d}, \mathbf{n}) \\
 & \alpha \geq \epsilon_{ph}, \quad \beta \geq \epsilon_{ph} \\
 & 0 < z_i < 1 \quad \forall i \in \mathcal{NC} \\
 & \sum_{i \in \mathcal{NC}} z_i = 1 \\
 & P_{N_d}^L \leq P_{N_d} \leq P_{N_d}^U \\
 & \max(T_{mp}(\mathbf{n}) + 10, T_{N_d}^L) \leq T_{N_d} \leq T_{op}^U \\
 & W_{N_d, \text{solvent}} \geq W_{0, \text{solvent}} \\
 & \theta_0^L \leq \theta_0 \leq \theta_0^U
 \end{aligned} \tag{5}$$

Table 1: Key input parameters and specification of the CO₂ capture case study

Parameter	Symbol	Value	Parameter	Symbol	Value
Gas flow rate Nm ³ /s	m_f	5,000	Degree of CO ₂ captured, %	-	85
Gas temperature, K	T_f	323	Condenser temperature, K	$T_{N_d}^L$	333
Gas pressure, MPa	P_{N_a}	0.1	Min. temperature approach, K	ΔT_{min}	20
Gas molar composition of H ₂ O	y_{N_a+1, H_2O}	0.12	Bounds on desorber pressure, MPa	$[P_{N_d}^L, P_{N_d}^U]$	[0.1, 5]
Gas molar composition of CO ₂	y_{N_a+1, CO_2}	0.05	Bounds on handling temperature, K	$[T_{N_d}^L, T_{N_d}^U]$	[303, 333]
Gas molar composition of N ₂	y_{N_a+1, N_2}	0.73	Bounds on lean solvent temperature, K	$[T_0^L, T_0^U]$	[313, 353]
Max. operating temperature, K	T_{op}^U	413	Bounds on lean loading, mol/mol	$[\theta_0^L, \theta_0^U]$	[0, 2]

4. Case Study and Results

CO₂ capture from an exhaust gas from a 400 MW CCGT power plant (Alhajaj et al., 2016) is considered as a case study to assess the performance of the proposed feasibility tests. The key input parameters and the pre-specified bounds on the design variables are provided in Table 1. An automated implementation of the sequence of tests and solution of the primal problem (process optimisation with fixed solvent structure) is developed in C++. Individual tests and the primal problem are implemented in gPROMS ModelBuilder 6.0.2 with the gSAFT Foreign Object interface for the SAFT- γ -Mie calculations.

A set of 4,179 solvent candidates is generated in accordance with the molecular feasibility constraints described in section 2.2, and the investigation of the effectiveness of the feasibility tests is carried out over this entire molecular design space. The overall results of applying the feasibility tests to these alkanolamines and alkylamines are summarised in Table 2. Within the 4,179 candidate molecules, only 910 amine-based solvents pass all feasibility tests. As can be seen in Table 2, the majority of the alkylamines are found to be infeasible in Tests 1 and 2, mainly due to their low water miscibility as well as low safety and environmental performance. For example, the maximum solvent concentration (W_{solvent}^*) of trimethylamine (TMA) that can ensure a homogeneous liquid phase at absorber operating conditions is identified as 2×10^{-2} kg/kg. It indicates that the constraint $W_{\text{solvent}}^U \leq W_{\text{solvent}}^*$ is violated and TMA should be eliminated from the design space. The performance of Tests 3 and 4 is examined for the solvents that pass Tests 1 and 2. Tests 3 and 4 lead to the tighter bounds on the lean loading and desorber pressure and their average values are presented in the Table 2. For the case of MDEA, the minimum requirement on lean solvent purity, $\theta_0^L = 0.25$, is calculated as a result of Test 3. This implies that if the initial guess on the lean loading were set to be greater than 0.25, the initialisation step of the process model would lead to numerical failure, making it impossible to evaluate the performance of this solvent. Instead, the initial point can be chosen to be below 0.25 and the primal problem can be solved successfully.

To exemplify the solution of primal problems, the impact of the feasibility tests and updated bounds are investigated for MEA and 2-amino-2-methyl-1,3-propanediol (AMPD) and the results are summarised in Table 3 and Figure 2. The results are generated based on five runs using different initial guesses for each solvents. They highlight that the process optimisation problems converge successfully and the computational cost is reduced by 12.6% and 72.2% for MEA and AMPD, respectively, with the introduction of feasibility tests. Fewer search steps are taken during the course of the optimisation, mainly as a consequence of the reduction in the ranges of the design variables achieved in Tests 3 and 4. This robustness and efficiency are likely to be critically important in molecular and process design problems where many candidate solvents are infeasible or where the evaluation of the primal problems is computationally expensive.

5. Conclusions

In this paper, we have proposed a robust optimisation approach for the design of an optimal aqueous solvent and CO₂ chemical absorption processes. New feasibility tests have been combined with the primal problem to provide a reliable way to converge to an optimal so-

Table 2: Overall results of feasibility tests over the complete list of candidate molecules

	Single Amine		Diamine	
	Alkanolamine	Alkylamine	Alkanolamine	Akylamine
Number of molecules tested	765	416	1918	1080
Number of molecules screened by Test 1	194	198	463	262

Avg. CPU time with tests	s	551	696
Avg. CPU time without tests	s	631	2509

Figure 2: CO₂ partial pressure (P_{CO_2}) versus solvent loading (mol CO₂/mol solvent) for AMPD (---) and MEA (—) at the optimal process conditions

lution by removing infeasible process conditions and molecular structures from the search space. This has also led to a reduction in the computational cost by enabling the ranges of the operating conditions to be reduced automatically. The efficiency of the proposed algorithm has been highlighted through a case study on the design of solvents for CO₂ chemical absorption processes. Future work involves the full integration of the approach within a mixed-integer nonlinear optimisation algorithm in order to identify the best performing solvent and it could be directed at testing the performance of the feasibility tests on more case studies to access general conclusions of their performance on the design of optimal solvents and CO₂ chemical absorption processes.

Abstract

Distillation is the most widely applied separation technique in the chemical process industry. Due to its high energy consumption and low thermal efficiency, researchers have investigated several approaches to reduce utility requirements, such as hybrid separation and using intensified equipment. In most prior examples, hybrid separations have been studied to separate azeotropes and/or close boiling mixtures. In this work, two hybrid separation design strategies to replace any distillation separation task are developed. These strategies are shown to improve thermal efficiency and thus save energy in the range of 10-20%. Additionally, by implementing hybrid separation schemes, the throughput of the distillation process can be increased. In this paper, two solution strategies have been developed based on simulation-based derivative-free optimization (DFO) algorithms and rigorous mathematical optimization. Both methods are applied to a case study of methanol/water separation, and the results show that the proposed hybrid separation processes yield at least 20% energy reduction and 20% capacity improvement.

Keywords: Distillation, Hybrid Separation, Optimization.

1. Introduction

With the chemical process industry continuing to move in a more efficient and sustainable direction, researchers have investigated several approaches to reduce energy consumption, improve thermal efficiency and sustainability, including new methods for process synthesis, hybrid separation, and design of intensified equipment. Tula et al. (2017) pointed out that after applying hybrid distillation-membrane techniques, 15-20% energy reduction of the retrofitted process can be achieved without significant additional capital investment. In their approach, distillation was used to purify the distillate until a certain composition (switching composition) and then sent to a membrane system to reach the purification target. O'Connell et al. (2019) further evaluated the influence of the switching composition in hybrid distillation-membrane separations through case studies involving the separation of C6 isomers and ethylbenzene/styrene. Through these studies, O'Connell et al. (2019) established the strong causal relationship between switching composition and the economic feasibility of retrofitted processes. Figure 1 shows the relationship between normalized separation driving force as a function of feed concentration. The driving force is defined as the concentration difference between the two phases, thus representing the ease of separation. As the distillation/membrane maximum driving forces are located at different positions in the diagram/composition space, the separation can ideally be divided into two regions where Region I is more efficient for distillation, and Region II is more efficient for membrane separation.

Therefore, determining the location of these two regions and the corresponding operating/design parameters is an important problem to be solved. One feasible solution method is sensitivity analysis, which analyses the impact of different variables and then chooses the best combination. A more rigorous approach is to formulate an optimization problem and solve it mathematically. Caballero et al. (2009) presented an algorithm based on a shortcut/rigorous distillation model to identify the optimum hybrid separation configuration. In our work, a mathematical optimization model and a simulation-based derivative (DFO) free optimization model are developed to determine the hybrid distillation design/operating parameters.

Figure 1. Driving force for n-hexane/2,2-dimethylbutane (distillation and membrane separation).

2. Solution Strategies

2.1. Simulation-based Optimization

The simulation-based optimization approach uses DFO algorithms to select operating/design variables. This approach incorporates the inner process simulation results with an outer DFO algorithm. In the inner-loop, process simulations are performed, and the results are used to calculate the objective function corresponding to the design decisions. The results from the inner-loop (operating/sizing variables) are sent to the outer-loop, where a suitable solver based on a gradient-free optimization algorithm is employed to obtain new/improved values of the decision variables/design parameters. This iterative calculation continues until the maximum number of iterations is reached or the optimal solution is found. Simulation-based optimization takes advantage of the process simulator, which represents implicit equations, making the problem relatively easy to solve. In this study, three open-source DFO algorithms (RBFOpt, GPyOpt, ZOOpt) are applied to all the case studies. The algorithms are applied to find the optimum design and operating variables for methanol/water separation process using distillation-membrane and distillation-adsorption approaches. A generalized form of the optimization problem solved by the DFO algorithms is given in Equations (1)-(7).

$$\min: TAC = \frac{i(i+1)^n}{(i+1)^n - 1} \times IC + AUC \quad (1)$$

$$\text{st. } IC = \sum_j Cost_j(q_{s,j}) \quad (2)$$

$$AUC = 24 \times 300 \times \sum_j Utility_j(q_{o,j}) \quad (3)$$

$$q = \theta(x, z, p(x)) \quad (4)$$

$$\sum_j Utility_j \leq Utility_0 \quad (5)$$

$$x_{product} \geq purity \quad (6)$$

$$x \in X, \quad z \in Z \text{ integer} \quad (7)$$

In the model, TAC is the total annualized cost, IC is the investment cost, AUC is the annualized utility cost, i is interest, n is plant life, $Cost_j$ is the investment cost of equipment j (Turton et al., (2008)). $Utility_j$ is the utility cost of equipment j (Kalakul et al., (2014)). $Utility_0$ is the utility cost of the initial single distillation column, q_{sj} is the sizing variable for equipment j , q_{oj} is the operating variable for equipment j , $p(x)$ is the membrane estimation model (Sommer and Melin, (2005)). $\Theta(x, z, p(x))$ is the process simulation model, x is the switching composition, and z is the number of membrane/adsorption stages.

2.2. Mathematical Optimization

For mathematical optimization, the distillation-membrane separation problem is considered with only one membrane system following the distillation separation. Since the final purification is achieved by the membrane, the original distillation column will underperform at the new conditions. The objective is to validate if column capacity can be increased while maintaining operation at feasible normal conditions. The retrofitting distillation model and hydraulic analysis (Gadalla et al. (2003)) are included in the optimization. To investigate the relationship between capacity improvement and energy cost reduction, a generalized bi-objective nonlinear programming problem (NLP) is formulated, which is shown in Equations (8)-(13).

$$\min_{x,y} F_1 = f_1(x, y, q) \quad (8)$$

$$\max_{x,y} F_2 = f_2(x, y, q) \quad (9)$$

$$st. h(x, y, q) = 0 \quad (10)$$

$$g(x, y, q) \leq 0 \quad (11)$$

$$q = q(x, y) \quad (12)$$

$$x, y \in R^+ \quad (13)$$

Here, f_1 is the total annualized cost, f_2 is the profit, $h(x, y, q)$ is a simple regressed thermodynamic model and retrofitting distillation model, $g(x, y, q)$ is the hydraulic and purity constraints, $q(x, y)$ is the dependent variable, which is determined by three decision variables x (switching composition of the distillate and bottom) and y (feed flowrate).

3. Case Study

Both solution strategies are applied to a case study of methanol/water separation. The base case methanol/water distillation column has 32 stages with stage efficiency of 60%, and is fed to stage 12. The inlet conditions are: 2.5 atm, 107°C, 1342 kmol/h, 76.5 mol% water, 23.5 mol% methanol. The base case distillation column's reboiler duty is 36.9 GJ/h, and the product requires 99.9 mol% purity of both water and methanol.

3.1. Distillation-membrane (DFO)

Okamoto et al. (2001) proposed a Zeolite NaA vapor permeation membrane for methanol/water separation, which shows high selectivity for water permeation. Sommer and Melin (2005) developed a model to estimate the membrane permeability at different operating conditions. In our work, the hybrid distillation-membrane is considered, and the process scheme is shown in Figure 2. The binary mixture of water and methanol is first fed into a distillation column (B1) for separation (Region I). Then, the distillate stream passes through a membrane system (B4 and B7) for further purification (Region

II). To maintain the same outlet conditions of the products as the original distillation column, the permeate and retentate streams are heated/compressed. The top product is methanol, and the bottom is water. Membrane selectivity and permeability depend on the inlet stream conditions, thus the number of membrane stages should be determined. Here, the maximum number of membrane stages is two because of the high selectivity. In this problem, three decision variables: distillation top/bottom composition (switching composition) and the number of membrane stages, need to be determined. Note that the driving force of the membrane separation is the vapor pressure difference of the permeate compound between the permeate and feed side. In this membrane system, either a vacuum pump or sweeping gas is required to enhance the permeation. In our case, we specify the total pressure at the permeate side as near vacuum (2 kPa).

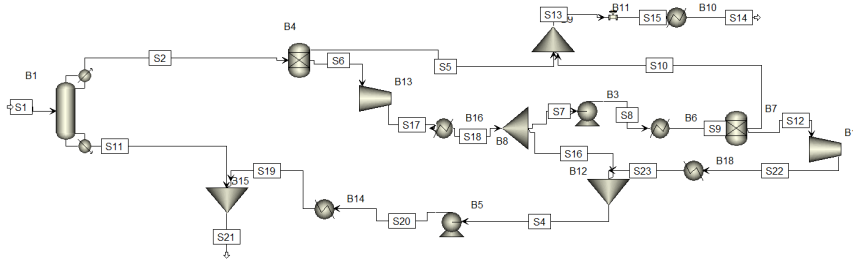

Figure 2. Process scheme of the distillation-membrane separation process.

All algorithms yield similar results (Table 1). The optimal top switching composition is 88 mol% of methanol, and the system requires one membrane stage after the distillation separation, resulting in 36.8% in energy savings and a payback time of three years.

Table 1. DFO results for distillation-membrane separation.

	RBFOpt	GPyOpt	ZOOpt
Top switching (methanol), mol%	88.4%	88.8%	88.3%
Bottom switching (water), mol%	99.90%	99.91%	99.94%
Stages	1	1	1
Annualized cost (\$)	1,950,848	1,952,675	1,952,774

Table 2. DFO results for distillation-adsorption separation at different selectivities.

	S = 1,000			S = 500		
	RBFOpt	GPyOpt	ZOOpt	RBFOpt	GPyOpt	ZOOpt
Top switching (methanol), mol%	96.68%	98.16%	98.22%	97.58%	97.78%	98.20%
Bottom switching (water), mol%	99.95%	99.94%	99.94%	99.91%	99.92%	99.90%
Stages		1			2	
Annualized cost (\$)	1,488,569	1,492,973	1,494,281	1,542,266	1,539,384	1,535,048
Energy savings		33%			31.5%	
Payback time (year)		0.3			0.4	

3.2. Distillation-adsorption (DFO)

In this case, the process scheme and DFO model are similar to the distillation-membrane system. The adsorption of water is a widely used technology, and Gabruš et al. (2015) proposed a Langmuir-Freundlich model for adsorption capacity estimation. In the process model, the membrane is replaced with an adsorption system that is integrated with distillation. An analogous set of three decision variables, as described above, are

identified for the distillation-adsorption process. Due to the lack of specific selectivity data for the adsorbent system, two different selectivities, 500 and 1,000, are used for optimization. The results are shown in Table 2. All three algorithms give similar results, with over 30% in energy savings. For the lower selectivity, two adsorption stages are required, compared to only one at the higher selectivity. To estimate the energy cost of the adsorption/desorption system, a constant desorption energy 45.95 kJ/mol is used in the calculations (Gabruś et al., 2015).

3.3. Mathematical Optimization

A schematic depiction of the distillation-membrane process is shown in Figure 3. The binary mixture is first fed into an existing distillation column for separation. Then, a membrane system is used to purify the distillate. In the process, a compressor is used to keep the product at the same conditions as the original distillation column.

Figure 3. Distillation-membrane process scheme for mathematical optimization.

The ϵ -Constraint method developed by Deb (2001) is used to solve the bi-objective problem. The resulting Pareto front is shown in Figure 4. The annualized cost and profit are varied along with switching composition and column capacity. The optimization results indicate that the objective function is very sensitive to column capacity only when the annualized cost is lower than \$3.2 million/year. However, when the annualized cost is higher than \$3.2 million/year, both switching composition and column capacity influence the objective function. The profit increases faster when the annualized cost is lower than \$3.2 million/year. That is because this region has higher energy efficiency, resulting in lower product cost, i.e. in this region, it is easier to improve the profit by varying the column capacity. A switching composition of 92.4 mol% is suggested for this hybrid operation, which can achieve 20% capacity improvement and energy savings.

Figure 4. Pareto front of the bi-objective optimization results.

4. Conclusions

Distillation is an efficient separation technique until a certain top product purity; however, the separation task becomes thermally inefficient when moving beyond this point. Replacing the less favorable region of distillation with a different separation technique can yield significant energy savings. In this work, two different optimization strategies (DFO and mathematical NLP model) are developed to design hybrid distillation schemes involving adsorption and membranes. The DFO strategy utilizes process simulation tools, which are readily available. Although the DFO algorithm cannot guarantee the global optimum, increasing the number of iterations can generate results that are close to the global optimum. So, the DFO strategy is very efficient for preliminary design. The second strategy uses a more rigorous model, and this strategy can be used for obtaining the final design parameters as it can guarantee the global optimum.

Using the simulation-based DFO strategy, the best switching composition for vapor permeation is around 88 mol% methanol, while for adsorption, the optimal switching composition is around 96-98 mol% methanol. It is also concluded that for the adsorption selectivities evaluated, the hybrid distillation adsorption is more economical than the hybrid distillation membrane process. It has also been shown that the retrofitted hybrid columns can be used to increase the distillation processing capacity. The distillation column can achieve a maximum of 20% energy savings and 20% capacity improvement. Future work will focus on comparing the sustainability, safety, and controllability between the distillation and hybrid processes.

Abstract

A framework is proposed to systematically identify promising solid-gas reaction candidates for thermochemical energy storage (TCES) in concentrating solar plants (CSP). It involves four steps: (i) generation of a list of reaction candidates, (ii) screening reactions based on thermodynamic criteria, (iii) solution of a process synthesis model to compute levelized cost of electricity (LCOE) and thermal energy storage (TES) costs, and (iv) selection of candidate reactions. The analyses identify ten reactions that can be economically and energetically superior to the state-of-the-art two-tank molten salt storage system.

Keywords: solar energy, process synthesis and optimization, reaction screening.

1. Introduction

Thermal energy storage is a promising way to manage intermittency of solar energy in concentrated solar power (CSP) plants. Commercially, CSP plants are typically integrated with a two-tank molten-salt sensible heat storage unit. There are two major drawbacks of this system. First, heat is delivered to the power cycle at low temperature (565 °C), resulting in low solar-to-electricity efficiency. Second, due to low energy density of molten-salt, large quantity of material is needed, which can become too costly for large-scale systems. TCES systems, on the other hand, are a more promising alternative because of their high energy density and ability to deliver heat at high temperature.

TCES is based on a reversible reaction, wherein heat is required for the forward reaction and thus, the reaction enthalpy is stored in the products. Today, TCES is at an early stage of development. Fluid-phase and solid-gas reactions are the two classes of TCES systems that have been studied. Recent analyses of fluid-phase reactions show that they suffer from low energy efficiency and high cost due to the need to store reacting gases (Peng et al., 2017). However, solid-gas reactions are more promising because they require less gas storage and the products can be easily separated (expressed as: $A(s) + \Delta H_R \leftrightarrow \nu_B B(s) + \nu_C C(g)$, where ΔH_R is reaction enthalpy).

Figure 1 shows a CSP plant consisting of four components: collector, receiver, TCES system and power cycle. During the day, the collector focuses sunlight onto a receiver, where photons are absorbed and converted into heat. The flow of heat transfer fluid (HTF) is split such that a part of it flows through the reactor (R1) to provide heat to an

endothermic reaction resulting in the decomposition of A and the remaining flows through the power block to provide heat to the working fluid (WF). The products of the endothermic reaction (B and C) are stored and transferred to R2 during the night, where exothermic reaction occurs and provides heat to WF.

Figure 1. Schematic diagram of a CSP plant with solid-gas TCES system.

Previously, most of the studies had focused on improving the performance of a handful of reaction systems and investigating their applicability. However, given the diversity of reactions applicable for TCES, there is a need for a systematic screening approach to find novel reaction candidates. While some work has been done in reaction screening (André et al., 2016; Pardo et al., 2014) based on equilibrium temperature and energy density, it still remains unclear which reactions are competitive in terms of LCOE and TES costs. To this end, we develop a framework to identify reactions based on energetic and economic performance.

2. Screening Methodology

In this section, the screening framework to identify promising TCES systems is outlined. The framework involves generating reaction candidates, eliminating reactions based on thermodynamic criteria, computing LCOE and TES costs for the remaining reactions and selecting the top performing reaction candidates.

2.1. Generating reaction candidates

The following four classes of reactions are considered: (i) oxide/oxide ($A=M_aO_c$, $B=M_bO_d$), (ii) oxide/metal ($A=M_aO_c$, $B=M$), (iii) hydroxide/oxide ($A=M_a(OH)_c$, $B=M_bO_d$), and (iv) carbonate/oxide ($A=M_a(CO_3)_c$, $B=M_bO_d$). Reaction candidates are created such that both A and B are inorganic materials. Additionally, only one gaseous component is allowed to avoid the need for gas separation. Aspen Plus is used to identify applicable materials, and their properties including density, melting point, specific heat capacity, enthalpy, and Gibbs energy (G) are stored.

An algorithm is designed to automatically identify all possible reactions for the collected materials. A total of 364 reactions comprising of 166 oxide/oxide, 162 oxide/metal, 19 hydroxide/oxide, and 17 carbonate/oxide, are identified.

2.2. Eliminating reactions based on thermodynamic criteria

For each of the reactions, equilibrium temperature (T_{eq}) is estimated:

$$T_{eq} = -\frac{\Delta G_R}{R \ln \ln p_C^{v_C}}$$

where ΔG_R , R and p_c are the Gibbs energy of reaction, universal gas constant, and partial pressure of gas C , respectively. The value of p_c is taken to be 0.21 bar for oxide/oxide and oxide/metal reactions, and it is fixed to 1 bar for hydroxide/oxide and carbonate/oxide reactions. For a reaction to be considered suitable for TCES system, its T_{eq} needs to meet two criteria: (i) it should lie within the range 25-2000 °C and (ii) it should be lower than the melting points of A and B so that no phase change occurs. Based on this criteria, 305 reactions are eliminated. The chosen reactions include 34 oxide/oxide, 6 oxide/metal, 7 hydroxide/oxide, and 12 carbonate/oxide. Key properties of the selected reactions are shown in Figure 2. The material prices are taken from the United States Geological Survey mineral commodities database. T_{eq} impacts the overall plant efficiency and ΔH_R affects the storage costs and efficiency. For high efficiency, T_{eq} needs to be in the range 500-1200 °C and ΔH_R needs to be high. It can be observed that there are several reactions with appealing properties, however, it is not clear how these properties impact the energetic and economic performance of the integrated plant. To this end, we developed a process model for an integrated CSP-TCES plant, which is outlined in the next section.

Figure 2. Key properties of reactions obtained after satisfying thermodynamic criteria. Each bubble represents a candidate reaction and its size represents reaction enthalpy.

2.3. Stochastic programming-based process synthesis model

An optimization model is developed (shown in Figure 3) for the design of CSP plants with solid-gas TCES systems (Peng et al., 2020, 2019). The inputs required for the model include material properties (e.g., material price, density, specific heat capacity), reaction characteristics (e.g., reaction enthalpy, equilibrium temperature), plant specifications (e.g., plant location and nameplate capacity), weather data and cost data. In this study, we consider a 100 MW CSP plant with power tower configuration located in Daggett, California (34.87°N, 116.78°W) and its weather data is obtained from the National Solar Radiation Data Base. The assumptions for economic analysis are given in Peng et al. (Peng et al., 2020).

The optimization model considers seasonal and daily variability. We use scenarios to represent seasonal variability and modes to represent daily variability. The optimization model is formulated as a two-stage stochastic programming (SP) model with multiple modes embedded within each scenario. The first stage variables are design variables that include solar field area, receiver area, and TCES equipment sizes. The second stage are operational variables for each scenario and mode including storage hours, flow rates, and operating temperatures. To consider the seasonal

variability in solar irradiance in our analyses, we generate six representative scenarios (i.e., days) from the annual data using centroid clustering algorithm and approximate daily solar irradiance using two modes. While it is possible to consider a more accurate dynamic model with finer temporal granularity, this approach would be unnecessary and infeasible, from a computational standpoint because we aim to screen hundreds of reactions. Furthermore, it was demonstrated in Peng et al. (Peng et al., 2019) that the multimode SP approach is computationally efficient and provides reasonably accurate solutions.

The objective of the model is to minimize the overall LCOE, which is defined as the sum of annualized costs of collector, receiver, thermal storage, and power block divided by the annual electricity generated. The constraints arise from the physical model of plant components, unit mass and energy balances, equipment sizing, and cost calculations. The collector efficiency is fixed to 0.6. The receiver efficiency is a function of temperature such that increasing temperature results in lower efficiency due to radiation and convection losses. Both the reactors are modeled as fluidized bed reactors. We assume that the conversion is 100%, no side products are formed, and the conversion rates and yields remain the same with cycles. For oxide/oxide and oxide/metal reactions, air is used as the source of O_2 and therefore, no gas storage vessels are required. Storage tanks for storing CO_2 and H_2O are required for carbonate/oxide and hydroxide/oxide reactions, respectively. Furthermore, a compressor is also needed for carbonate/oxide reactions because of low boiling point of CO_2 . Supercritical CO_2 Brayton cycle is used for power generation and a model is developed to evaluate its performance at different turbine inlet temperatures (Peng et al., 2020). The optimization model is a nonlinear programming model, formulated in GAMS, and solved using a novel solution technique (Section 2.4).

Figure 3: Overview of optimization-based CSP-TCES process model.

2.4. Solution method

The method is based on three ideas. First, tight lower and upper bounds of the first-stage and second-stage variables are computed through constraint propagation based on the initial bounds on a set of key variables including the temperature of R1 (T_{R1}), R2 (T_{R2}), and HTF (T_{HTF}). Second, the space of these variables is divided into small subregions and the model is solved in each of the regions to global optimality using ANTIGONE (Misener and Floudas, 2014). Third, to accelerate the convergence, we use two strategies. First, when solving the model in a new subregion, we add a cut based on the best objective function value obtained in the explored subregions so far, thereby enabling pruning of nonpromising subregions. Second, if any of the decision variables lie at the bounds of the current subregion, the subregion that shares the decision variable is selected as the next region to be explored, leading to the identification of good solutions quickly. Computational comparisons with other methods suggest that our solution method finds the global minimum faster for several problem instances.

3. Results

The solar-to-electricity efficiency (η^{s-e}), which depends on the efficiencies of the four plant components, is used as the primary energetic metric. Receiver efficiency decreases with increase in receiver temperature (T_r) and power cycle efficiency increases with increasing turbine inlet temperature (T_p). Due to heat transfer limitations, the following relationship holds between the operating temperatures:

$$T_r = T_{HTF} > T_{R1} > T_{eq} > T_{R2}$$

T_p lies between T_{R1} and T_{R2} , and moves closer to T_{R2} as the fraction of sensible energy storage decreases. Since T_r is always higher than T_p , it is impossible to have low T_r and high T_p . For high η^{s-e} , T_r should be in the range of 500-1200 °C and the difference between T_r and T_p ($T_r - T_p$) should be small to reduce exergy losses. However, if $T_r - T_p$ is small, less sensible heat is stored, which leads to high storage costs. The optimization algorithm balances these trade-offs such that design and operational decisions are obtained resulting in minimum LCOE.

The top ten reactions identified based on LCOE and TES costs are shown in Figure 4. LCOE for the selected reactions range from 11.2-12.9 ¢/kWh and TES costs range from 8.2-23.1 \$/kWh_{th}. Importantly, all the selected reactions have the potential to lead to lower LCOE and TES costs than the two-tank molten salt storage system. Note that seven of the ten promising reactions in terms of LCOE belong to oxide/oxide class, whereas two belong to hydroxide/oxide class, and one belongs to carbonate/oxide class. In terms of TES cost, seven reactions belong to oxide/oxide class, two belong to hydroxide/oxide class, and one belongs to oxide/metal class. Only two reactions are found to be promising in terms of both LCOE and TES costs, which implies that low TES costs do not imply low LCOE and underscores the importance of simultaneously considering all the components of a CSP plant.

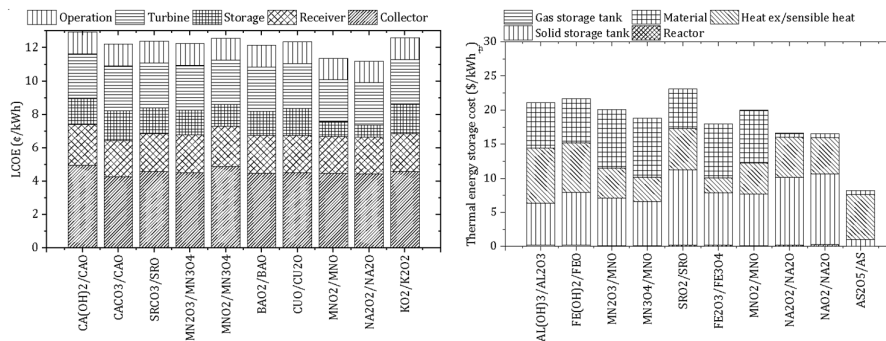

Figure 4. Top ten reactions selected based on (a) LCOE and (b) TES costs.

4. Conclusions

We developed a framework to systematically screen reactions for thermochemical energy storage. First, we identify a total of 374 reactions belonging to oxide/oxide, oxide/metal, hydroxide/oxide, and carbonate/oxide classes. Two thermodynamic criteria are then applied to eliminate 305 reactions. A stochastic programming-based optimization model is solved using a novel solution strategy for the remaining reactions to compute LCOE

and TES costs. Our analyses identify ten reactions that can be energetically and economically superior to the two-tank molten salt storage system.

Table 1. Key reaction properties and the overall efficiency for the selected reactions.

Reactions	T_{eq} (°C)	Material price (\$/ton)	ΔH_R (kJ/kg)	η^{s-e}
Ca(OH) ₂ /CaO	521.0	150.0	1341.9	0.19
CaCO ₃ /CaO	895.9	100	1664.9	0.22
SrCO ₃ /SrO	1159.0	954.4	1349.3	0.21
Mn ₂ O ₃ /Mn ₃ O ₄	901.0	2535.2	203.6	0.21
MnO ₂ /Mn ₃ O ₄	536.3	2535.2	646.2	0.20
BaO ₂ /BaO	742.2	1738.8	475.5	0.22
CuO/Cu ₂ O	1031.8	5650.0	816.4	0.21
MnO ₂ /MnO	905.6	2535.2	1509.5	0.22
Na ₂ O ₂ /Na ₂ O	868.1	157.0	1117.2	0.22
KO ₂ /K ₂ O ₂	885.7	776.0	314.3	0.21

Key properties and η^{s-e} of the top reactions selected based on LCOE are shown in Table 1. As expected, for a reaction system to be competitive, η^{s-e} needs to be high. For the selected reactions, η^{s-e} range from 0.19-0.22 and the corresponding T_{eq} range from 521-1159 °C. Mn₂O₃/Mn₃O₄ and MnO₂/MnO reaction systems have similar T_{eq} , but the latter has higher reaction enthalpy, which leads to low $T_r - T_p$, resulting in higher efficiency. Higher reaction enthalpy of MnO₂/MnO system compared to Mn₂O₃/Mn₃O₄ leads to lower storage costs for MnO₂/MnO system. The material price of CuO/Cu₂O is 37 times more than Ca(OH)₂/CaO, but LCOE is lower for the former due to its marginal higher η^{s-e} . This illustrates how small improvements in efficiency can impact the process economics.

Abstract

Failure in appropriately managing complex municipal solid waste systems in general and waste plastics in particular negatively affects public health and environment.

A decision-making tool incorporating concepts of logistics and supply chain, considering different types of waste was developed. A multi-objective, multi-period mixed-integer linear programming (MILP) formulation, focusing on the plastic recycling network, incorporating features of multimodal transportation was implemented. The model aims at minimizing net present cost (NPC) and environmental impacts, illustrated by a case study of a Swiss waste treatment cluster. A reference situation was used for benchmarking and 7 new scenarios considered - corresponding to different plastics collection configurations.

From the solutions space, designs arise that lead to a 2-fold decrease of NPC at the expense of increasing by 20 % current emissions, as well as solutions that provide small net gains in environmental aspects - close to 3 %, albeit a 4-fold increase in NPC due to large investments in recycling facilities and increased transportation costs.

This work sheds light on the impact of supply chain and logistics aspects on the separate collection and treatment of waste plastics, in the context of a real municipal waste treatment policy, where a thermodynamic model to deal with the conversion processes is integrated into the general supply chain decision. As a result, important insights to guide decision-makers were obtained.

Keywords: Waste plastics, MSW, Recycling, Thermovalorization, Supply chain

1. Introduction

As reported in (Bhada-Tata et al., 2018) due to rapid urbanization and population growth, an increase in *per capita* generation of waste - and plastic waste in particular - is foreseen. If not properly managed, waste might have a significant impact on population health, environment, and economy. Designing an integrated waste management system is a strategic Supply Chain (SC) problem as it refers to long-term decisions on a combination of functional elements in the waste chain, from generation, storage, collection, separation and transportation to treatment, distribution, and disposal.

Management of plastic waste presents additional challenges, such as low transport efficiencies (due to low material density), as well as frequent contamination with other types of plastics as described in (Bing et al., 2013). Moreover, plastics have a high energy content - valuable from a thermovalorization point of view: if segregated, municipal solid waste (MSW) loses an important share of its energetic content. Thus, recycling and energy recovery present themselves as competitors for treating this

particular kind of waste contrasting, according to (Groot et al., 2014), with the general belief of routing waste plastic for recycling facilities whenever possible.

This work is a necessary step to a generalized superstructure of plastic waste treatment and conversion routes. Logistics and supply chain considerations are core concepts that have proved to be relevant from an economic perspective, as recently confirmed by (Colvero et al., 2020), and might condition tactical, operational and investment decisions. Furthermore, heat integration between units explores synergies and trade-offs between recycling and thermovalorization of different waste fractions.

2. Problem statement and mathematical formulation

The problem is generically formulated as a multi-echelon, multi-period, multi-commodity and multi-stakeholders. The goal is to determine the set of optimal configurations along the Pareto front and characterize each solution by the cost and associated emissions; each solution yields the optimal allocation of waste flows, the number of products and by-products, and the transport structure used. System boundaries include waste collection, transportation, and processing of the different waste flows, with respective costs and emissions associated. Unlike many similar studies, it was considered that the introduction of a separate collection of plastics affects not only quantities but also composition and heating value of the combustible waste.

The model is divided into two phases: parameter estimation and mathematical optimization. As it is often not possible to get specific collection costs by municipalities, a model based on the work of (Groot et al., 2014) was used for the first task. The optimization problem was formulated using mixed-integer linear programming.

The economical objective - Net present cost (NPC) - is given by the sum of operating and investment costs (Eq. 1). Binary variables ($\Psi_{i,t}$ and Ψ_i) account for the existence or not of a given unit (waste conversion units, sorting centres and recycling facilities, as well as transport units), while continuous variables ($f_{i,t}$ and f_i) account for the size of each unit. t_t^{op} represents the operating time of each time step $t \in T$.

Transport and supply chain nodes are represented by units i belonging to the set L , containing sub-sets Lu and Ls , for which investment is required and waste is sourced, respectively. Units have a fixed (c_i^{inv1}) and variable (c_i^{inv2}) investment, fixed ($c_{i,t}^{op1}$) and variable ($c_{i,t}^{op2}$) operating costs as well as fixed ($c_{i,t}^{imp1}$) and variable ($c_{i,t}^{imp2}$) environmental impacts. Each unit contains relevant information to define mass and energy requirements. Investment costs were annualised using an interest rate (ar) and project lifetime (n), while operating costs were discounted with a monthly interest rate (mr).

$$\min NPC = \sum_{t \in T} \frac{\sum_{i \in L} (c_{i,t}^{op1} \cdot \Psi_{i,t} + c_{i,t}^{op2} \cdot f_{i,t})}{(1 - mr)^t} \cdot t_t^{op} + \frac{i(1 + ar)^n}{(1 + ar)^n - 1} \cdot \sum_{i \in Lu} (c_i^{inv1} \cdot \Psi_i + c_i^{inv2} \cdot f_i) \quad Eq. 1$$

Multi-objective optimization was used to address conflicting objectives, particularly the trade-off between costs and emissions. Environmental impact - Eq. 2 - was used for (ε -constraints) formulation, using the GWP 100a method, corresponding to the IPCC 2013 global warming potential impact method, as well as the ecological scarcity method (ESM). The widespread use of the former and the tailor-made criteria for Switzerland of the latter motivated the choice. Values were retrieved from Ecoinvent database v.3.6.

$$ENV = \sum_{t \in T} \sum_{i \in L} (c_{i,t}^{imp1} \cdot \Psi_{i,t} + c_{i,t}^{imp2} \cdot f_{i,t}) \cdot t_t^{op} \leq \varepsilon \quad Eq. 2$$

Constraints were added to ensure full waste collection (Eq. 3), with $\dot{M}_{w,i,j,t}$ the mass of waste $w \in W$, received in each SC node and $gen_{w,i,t}$ the waste type generated per origin. Minimum (f_i^{min}) and maximum (f_i^{max}) facilities capacities (Eq. 4), as well as resource consumption (Eq. 5, Eq. 6), with $\dot{m}_{r,i,t}^+$ the reference quantity of resource $\forall r \in R$ needed in each SC node were also considered. Mass balances are closed (Eq. 7), for each SC node. Heat cascade formulation (Eq. 8, Eq. 9) was added, following the formulation developed by (Maréchal and Kalitventzeff, 1998), in which residual heat ($\dot{R}_{t,k}$) is transferred according to the 2nd law of thermodynamics, from higher ($k + 1$) to lower temperature levels (k).

$$\sum_{j \in L \setminus L_s} \dot{M}_{w,i,j,t} = gen_{w,i,t}, \forall w \in W, \forall i \in L_s, \forall t \in T \quad Eq. 3$$

$$f_i^{min} \cdot \Psi_{i,t} \leq f_{i,t} \leq f_i^{max} \cdot \Psi_{i,t}, \quad \forall i \in L, \quad \forall t \in T \quad Eq. 4$$

$$\dot{M}_{r,i,t}^+ = f_{i,t} \cdot \dot{m}_{r,i,t}^+, \quad \forall r \in R, \forall i \in L, \forall t \in T \quad Eq. 5$$

$$\dot{M}_{r,i,t}^- = f_{i,t} \cdot \dot{m}_{r,i,t}^-, \quad \forall r \in R, \forall i \in L, \forall t \in T \quad Eq. 6$$

$$\sum_{i \in L} \dot{M}_{r,i,t}^- = \sum_{i \in L} \dot{M}_{r,i,t}^+, \quad \forall r \in R, \forall t \in T \quad Eq. 7$$

$$\sum_{i \in L} \dot{Q}_{i,t,k} \cdot f_{i,t} + \dot{R}_{t,k+1} - \dot{R}_{t,k} = 0, \quad \forall t \in T, \quad \forall k \in K, \text{ with } T_{k+1} \geq T_k, \quad Eq. 8$$

$$\dot{R}_{t,k} \geq 0, \quad \dot{R}_{t,k_{max}+1} = \dot{R}_{t,1} = 0, \quad \forall t \in T \quad Eq. 9$$

The MILP problem is written in AMPL and solved by CPLEX (v12.7.0.0). Every experiment was run on a Microsoft Windows v10.0.18363 machine equipped with a 2.4 GHz Intel(R) Xeon (R) 8 core processor with 16GB of RAM.

3. Case Study

3.1. Structure

A waste management system in western Switzerland was used as case-study and comprises: (i) **Waste Source Nodes** - Municipalities, Waste Dumping Centers and Industries, with the source of waste assumed to be the centre of each municipality; (ii) **Recycling Chain** - Plastic waste from municipalities can be routed to different sorting centres, where they are separated and washed from contaminants. Plastics are then routed to a recycling centre; recycled polymers are absorbed by the market while by-products are routed to thermovalorization units; (iii) **Thermovalorization Centers** - Waste from municipalities, industries and separation centres (contaminants and by-products) go to thermovalorization units for heat and electricity recovery or cement plants to be used as fuel; (iv) **Transshipment Centers** - Only train stations are considered based on their ability for handling intermodal transport; (v) **Markets** - Recycled polymers, heat and electricity are absorbed by market units, mimicking real demand.

The waste streams considered are MSW (comprises domestic and industrial from municipalities), Polyethylene Terephthalate (PET) bottles, Polyethylene (PE) bottles (high and low density), and mixed plastics (MP) - which comprises other types of

plastics and small fractions of PE and PET. A tax on waste bags (0.058 \$/L) was considered as well as its variation due to separate collection of plastics.

3.2. Collection scenarios

Scenario analysis was used to study distinct collection policies. The optimization algorithm is then free to select the set of best paths for each type of waste at hand, with respect to compatibility constraints.

Figure 1 – Plastic collection scenarios - white bags refer to current implemented taxed bags and include MSW for all scenarios; yellow bags refer to taxed plastic bags.

Selected scenarios, defined in collaboration with the industrial partners (Figure 1), comprise the current state (Ref) used for benchmarking - on which PET and small fractions of PE are separately collected and recycled, with the remaining MSW routed for thermovalorization - as well as different configurations for plastics collection. Scenarios 4 to 7, on which a plastic taxed bag (0.035 \$/L) was considered, were also investigated. An extreme scenario (8) without any sorting was also studied.

4. Results and Discussion

For comparison, results were normalized by the amount of waste. illustrates the solution generation and dispersion for both environmental impacts assessed. Negative values indicate profitable systems and net environmental benefits.

Figure 2 - Pareto points; circles refer to ESM and squares to the GWP 100a method; numbers next to symbols represent different collection scenarios (Figure 1) and letters indicate different configurations within each scenario; Ref identifies the reference collection scenario.

Regardless of the impact method, several system configurations achieve better economic and environmental metrics than the reference situation. For GWP, several configurations for collection strategy 3 (3a to 3d), in which PET and PE are collected together, can achieve moderately better (up to 25 %) economic performance compared with the reference system, though degrading environmental performance (up to 13 %). Solution for scenario 8, on which all wastes are collected in one undifferentiated bag, shows the lowest cost of all configurations due to reduced logistics costs - achieving a reduction of 100 % (equivalent to duplicate profit). However, environmental impact is degraded by 20 %. On the opposite spectrum of the plot, solution 2a and 3e perform slightly (up to 3 %) better environmentally but to the cost of considerable investment on new recycling units, which were chosen to address the increased collection of PE - converting thus the system to a non-profitable one - for the time horizon considered.

Figure 3 - Environmental impact (a) and NPC (b) partition by activity

ESM shows the benefit of using a more comprehensive indicator. Contrarily to GWP, the reference scenario does not belong to the Pareto curve, which implies that more interesting solutions are sure to be found. Similarly to GWP, solutions in which waste is collected all together (scenario 8) yield more profitable configurations to the price of degrading environmental indicators (8a and 8b); however, if natural gas co-burn is allowed, better environmental indicators are achievable (8c, 8d and 8e) associated with the off-set of heat and electricity. Solutions on the end spectrum (5a, 2a and 6b) perform better (up to 25 %) environmentally to the expense of heavy investment.

Cost and environmental partition by type of activity were studied in more detail for Pareto solutions using GWP indicator - Figure 3. Logistics have a considerable economic impact - close to 40 %, contrasting with very reduced (ca. 2 %) environmental impacts. Conversely, thermovalorization emissions account for the largest share of environmental impact albeit at a reduced cost. However, those emissions are compensated by the off-set of heat and electricity production for market demand. Recycling shows an environmental off-set larger than the associated emissions, although costs do not follow the same pattern - the recycling process can be more expensive than the production of the corresponding plastics. Besides, for solutions 2a and 3e, investment in new recycling

facilities surpasses the operational expenditures with thermovalorization and are comparable with the logistics annual costs; furthermore, the environmental benefit it brings comes at an expense of 18 and 28 \$/kgCO₂-eq, respectively.

The allocation of flows for each of the Pareto configurations shows that the total segregation of plastics (scenarios 4,5,6,7) is not part of the optimal set of solutions for the current set of waste flows and market prices. It seems reasonable to assume that the plastic content currently collected with the MSW taxed bag brings added value to the system and does not create a substantial environmental burden.

5. Conclusions

A superstructure-based approach comprising thermovalorization and recycling units embedded on a SC network was developed to study the collection and management of plastic waste. Cost and environmental indicators show that better economic performance is linked with scenarios with no plastic segregation, keeping the energetic potential of plastic within the thermovalorization perimeter and reducing logistics costs; however, it comes with higher environmental burdens. Reduction (3 % on average) of emissions is possible, for configurations that promote a separate collection of plastic waste and invest in new recycling facilities. Nevertheless, the cost associated is substantial.

Given the current set of assumptions, plastic waste currently collected with MSW taxed bag brings added value to the system, as a consequence of efficient energy recovery in thermovalorization units, not posing a major environmental threat. Solutions are heavily dependent on the nominal waste flows as well as environmental and economic assumptions. An extensive uncertainty analysis to first identify hotspots on the input parameters is desirable, followed by uncertainty propagation. On the technology side, if carbon capture, usage and storage (CCUS) technologies are added, different flow allocations might be expected, due to increasing environmental performance of thermovalorization units.

Abstract

The selection of phase change material (PCM) is essential for the development of efficient thermal energy storage (TES) processes. Due to their benign properties, ionic liquids (ILs) have been demonstrated to be a new type of promising PCM. Unfortunately, there is a lack of systematic study on the optimal selection or molecular design of IL-PCMs for TES. In this work, a computer-aided molecular design (CAMD) method is proposed to systematically design IL-PCMs for a practical TES process. The influences of different IL properties, such as latent heat, heat capacity, and thermal conductivity, are simultaneously captured with a detailed TES process model. Optimal ILs holding a best compromise of all the properties are identified by solving an optimization-based CAMD problem where the TES performance of the process is maximized. It is found that our optimally designed IL-PCMs show much higher TES performance than the industrial state-of-the-art PCMs.

Keywords: phase change material, heat storage, ionic liquid, computer-aided molecular design

1. Introduction

Thermal energy is widely available and easy to access, which can be stored in the form of latent heat, sensible heat, or both. Generally, latent heat storage is more attractive than sensible heat storage because of its high energy density (Abhat 1983). Among all the latent heat storage approaches, the solid-liquid phase transition is most attractive for large-scale use due to its small volume change. In such a system, a phase change material (PCM) absorbs heat from a high-temperature heat transfer fluid (HTF) and melts whereas it releases heat to the cold HTF when it solidifies (Mehling and Cabeza, 2008).

PCM selection is essential for developing highly efficient TES systems. Organic PCMs usually have low thermal conductivity and they are normally volatile and flammable; inorganic salts suffer a lot from corrosion and supercooling (Kenisarin and Mahkamov, 2007). These drawbacks promote the development of new high-performing TES materials. Organic salts, which are also known as ionic liquids (ILs), consist of an organic cation and an organic or inorganic anion. This new type of chemicals is thermally stable, nonflammable and nonvolatile (Zhang et al., 2006). Moreover, the wide range of melting temperature spanning from negative up to 100 °C (Plechkova and Seddon, 2008) and the ability to tailor the properties (Zhou et al., 2012) by changing the cation, anion, and/or the substituents make ILs very promising PCMs. Despite that, except a few scattered

experimental studies (Terasawa et al., 2010; Vijayraghavan et al., 2013), there is a lack of systematic work on the optimal selection or molecular design of ILs for TES.

So far, most of the previous work is focused on the heat of fusion when selecting PCMs. However, one should note that in reality, rarely are these materials being used only during the phase change period. In fact, the latent heat storage is always combined with sensible heat storage. In this context, in addition to melting point and latent heat, heat capacity is also essential for selecting PCMs. Moreover, thermal conductivity needs to be considered as well because it can greatly affect the heat transfer rate. The impact of all the different properties can be captured only when a real TES process is studied and modelled.

In this work, a computer-aided molecular design (CAMD) based method (Austin et al., 2016; Song et al., 2018; Zhou et al., 2019; Zhou et al., 2021) is proposed to systematically design IL-PCMs for a practical TES process. Different group contribution-based models are employed to predict the key properties of ILs that affect the TES process performance. Combining these property models with a detailed TES process model, an optimization-based CAMD problem is finally formulated and solved to identify the best IL-PCM possessing a maximal TES performance.

2. Modeling

The TES device is depicted in Figure 1. As shown, the spherical PCM capsules with a diameter of 0.04 m are packed in a cylindrical TES tank ($D = 1.0\text{ m}$ and $l = 1.52\text{ m}$) where the high-temperature HTF water at 343.15 K flows through the tank with a mass flow rate $\dot{m} = 0.0796\text{ kg/s}$. Initially, all the PCM spheres have a temperature of 323.15 K and the space between PCM capsules in the tank is already filled with water at the same temperature. When the thermal charging process is started, hot water flows in from the top of the tank and meanwhile the solid PCMs start to absorb heat. The PCM starts to melt when the temperature reaches its melting point and the TES process is completely finished when all the PCMs reach 343.15 K . However, this process can be terminated earlier because the thermal charging rate decreases over time.

Figure 1. Layout and details of the thermal storage tank

In order to evaluate the TES performance of an IL-PCM for the thermal storage process illustrated in Figure 1, two types of models are generally required. They are IL property models that link IL structures to their physical properties and process models that predict the TES performance based on the IL properties.

2.1. Process Modeling

It is assumed that the HTF water has a one-dimensional axial flow and temperature distribution. Only heat convection is considered in this flow direction. For the PCM spheres, one-dimensional radial heat conduction is considered. The density, thermal conductivity, and heat capacity of the PCM are assumed constant during the whole TES process. Moreover, the heat conduction between different PCM spheres are neglected and the ambient heat losses and radiation heat transfer are also neglected. As indicated in Figure 1, the cylindrical tank is discretized into 38 equal sections ($N_z = 38$) in the fluid flow direction. The height of each section equals 0.04 m, making one tank section containing exactly a single layer of PCM capsules. The entire PCM capsule is discretized into 13 control volumes ($N_r = 14$) along the radial direction and the discretization index of N_r represents the position where water locates. Such a TES system is governed by a set of heat balances in the form of partial differential equations, which are discretized and solved as algebraic equations using the explicit finite difference method (Shi et al., 2021).

2.2. Property Modeling

As indicated by the process model, five thermo-physical properties of PCM, i.e., melting point T_m , latent heat L , density ρ , thermal conductivity λ , and heat capacity C_p , are required to quantify the TES performance of a PCM. Group contribution (GC) methods (Zhou et al., 2018; Song et al., 2020) are widely used in CAMD to predict physical properties of compounds (Austin et al., 2016), due to their easy incorporation within mathematical optimizations and high qualitatively correct estimations. Different GC models are employed to predict the five properties of ILs. They have been elaborated in Shi et al. (2021).

2.3. TES Performance Evaluation

The thermal storage power of the system represents the TES performance of an IL-PCM. However, one should note that the thermal storage power is not a constant during the charging process. In the beginning, heat transfer is fast because the temperature gradient between PCM and water is high. However, the thermal storage power decreases gradually as the PCM temperature gets closer to the water temperature. Therefore, an average TES power, defined as the total stored heat over the thermal charging time, is used to represent the overall TES performance of the material.

3. Results and Discussion

3.1. Effect of IL Properties on the TES Power

As evidenced by the process models, five IL properties including the melting point T_m , latent heat L , density ρ , thermal conductivity λ , and heat capacity C_p are required to quantify the TES power of the IL-PCM. When the T_m of the IL is low, the temperature gradient on the solid-liquid interface (i.e., between the outer-layer melted PCM and the inner-layer melting PCM) is large, which makes the latent heat absorption faster and consequently leads to a higher TES power. Except T_m , all the other properties show positive effects on the TES performance of the material and the reason can be easily understood from the physical knowledge about the TES system. Additionally, the

significance of the property effect can be quantified by a parameter sensitivity study with the process models.

3.2. Computer-Aided IL Design

The CAMD method is used to design the optimal IL-PCM in this work. In total, 59 IL building groups including 54 cation-anion-pair groups and 5 substituent groups are considered for IL design. In CAMD, a molecule is represented by a vector of group numbers. Typically, several equality and inequality constraints on the number of groups must be considered in the CAMD program to ensure that the generated ILs are structurally reasonable. For the complete list of the 59 IL groups and all the necessary structural constraints, one could refer to Shi et al. (2021) where the solution strategy of the CAMD problem is also elaborated.

In order to determine the average thermal storage power of an IL-PCM in the TES system (see Figure 1), a total thermal charging time needs to be pre-specified. In this work, we assume that the hot water at 70 °C is generated by solar heat and thus the thermal charging time depends on the total sunshine duration. Figure 2 shows the average monthly sunshine hours in Germany from June 2019 to May 2020 (Statista website). As indicated, the annually average sunshine time is about 5.5 hours/day. Thus, 5.5 hours is set as our thermal charging time for the IL-PCM design.

Figure 2: Average sunshine time in Germany from June 2019 to May 2020

3.3. Design Results

The group combinations and molecular structures of top nine ILs are listed in Table 1 and plotted in Figure 3, respectively. The five key physical properties and corresponding average TES power (P_{ow}) of the PCMs are also summarized in Table 1. In order to demonstrate the advantage of model-based PCM design, the TES performance of the designed IL-PCMs is compared with that of an industrial benchmark PCM paraffin wax # 60. As indicated, all of the top nine ILs show a substantially higher TES power than the wax. When comparing them, it is found that the influence or contribution of the heat capacity and thermal conductivity, indicated by the product of the property difference and its corresponding sensitivity value, on the thermal storage power is very small. Even though the wax has a higher latent heat that can increase its thermal storage power, wax's higher melting point (note T_m has a large negative effect) and the much lower density make this material worse than the designed ILs.

Table 1. Top 9 IL-PCMs identified from CAMD for 5.5-hour thermal charging time
(Pow in W, T_m in K, C_p in J/(kg·K), ρ in kg/m³, L in kJ/kg, λ in W/(m·K))

Rank	Group combinations	Pow	T_m	C_p	ρ	L	λ
1	2 CH ₂ , 1 OH, 1 [MPy][TfO]	5277	323.8	2171	1426	134.3	0.158
2	2 CH ₂ , 1 OCH ₃ , 1 [MPy][TfO]	5225	324.0	1758	1333	151.6	0.152
3	1 CH ₂ , 1 OCH ₂ , 1 CH ₃ , 1 [MPy][TfO]	4995	324.0	1758	1333	115.8	0.152
4	1 CH ₂ , 1 OCH ₃ , 1 [MIm][TfO]	4958	323.2	1644	1387	94.60	0.160
5	1 CH ₂ , 1 OH, 1 [MPy][TfO]	4760	327.6	2166	1474	137.3	0.162
6	1 CH ₂ , 1 OCH ₂ , 1 OCH ₃ , 1 [MIm][I]	4719	323.4	1812	1450	71.70	0.159
7	1 CH ₂ , 1 OCH ₃ , 1 [MIm][NO ₃]	4684	325.7	1538	1221	129.7	0.196
8	2 OCH ₃ , 1 [Im13][BF ₄]	4648	325.3	1661	1314	100.7	0.183
9	1 CH ₂ , 1 OCH ₃ , 1 [MPy][TfO]	4644	327.7	1793	1374	155.3	0.156
BM	Paraffin Wax # 60	3403	333.1	2150	850	190.0	0.230

[MPy][TfO] is found to be the most favorable IL group, and OH and OCH₃ are the preferred functional groups for maximizing the TES power of the ILs. It is also found that two CH₂ groups are most beneficial for the ILs [MPy(CH₂)_nOH][TfO] and [MPy(CH₂)_nOCH₃][TfO]. Increasing the alkyl-chain length results in a lower melting point, leading to a higher TES power due to the large negative effect of T_m . However, when the number of CH₂ group is larger than 2, the melting point becomes lower than 323.15 K, which results in a significantly lower TES power due to the absence of latent heat storage contribution (note that the initial temperature of the PCM is 323.15 K). Moreover, when comparing the first with the second ILs and comparing the fifth with the ninth ILs, it is found that OH is slightly better than OCH₃ when [MPy][TfO] is selected as the main group. The reason is that even though OCH₃ contributes more to the latent heat, the OH group has a larger contribution to both the heat capacity and density, which determines its superiority over OCH₃ for increasing the TES power of the IL-PCM.

Figure 3: Molecular structures of the top 9 ILs identified from CAMD

4. Conclusions

The CAMD method is employed to design ILs as PCMs for a practical TES process. The influence of different IL properties on the TES performance is simultaneously captured with a detailed TES process model. The optimal IL structure that possesses a best compromise of all the properties is identified by solving an optimization-based CAMD problem where the average TES power of the IL-based thermal storage system is maximized. It is found that our designed ILs perform better than the conventional PCM in terms of the average TES power.

Abstract

Solvents are key to many chemical processes. To find optimal combinations of solvents and processes, solvent and process design have to be integrated. In this work, we present a method for the integrated thermo-economic design of separation processes and solvents that achieves a high level of the desired integration. The method is based on our 1-stage Continuous-Molecular Targeting-Computer-aided Molecular Design method. The PC-SAFT equation of state is used as thermodynamic model to calculate both equilibrium and transport properties. Computer-aided molecular design allows designing the solvent as a degree of freedom of the process optimization. To allow for ease of use, we implemented the method in the process flowsheeting software gPROMS ProcessBuilder, enabling the convenient definition of the flowsheet. We present the method for the integrated design of a physical absorption process to separate CO₂ from power plant flue gases.

Keywords: CAMPD, PC-SAFT, CO₂ absorption, carbon capture.

1. Introduction

Identifying optimal solvents for separations is an essential task in the chemical industry. Economically efficient separations require an optimal combination of process and solvent. For this purpose, solvent design must be integrated into process design (Papadopoulos et al., 2018). However, the integration of solvent design adds many discrete degrees of freedom to the process optimization leading to mixed-integer nonlinear programs (MINLP) (Gani, 2004). To solve the resulting MINLP problems, systematic solution approaches have been developed in recent years (Papadopoulos et al., 2018).

Many solution methods employ equilibrium thermodynamic models. In this case, process performance can be assessed by a thermodynamic objective function, as, e.g., demonstrated for the design of CO₂ absorption processes by some of the authors (Lampe et al., 2015; Stavrou et al., 2014). However, thermodynamically optimal solvents can still be undesirable in terms of economics since investment costs are neglected.

To quantify investment cost, equipment design needs to be integrated into the process and molecular design. Equipment sizing additionally requires the transport properties of the designed molecule. In pioneering work, Pereira et al. (2011) directly integrated a CAMD formulation into process design for physical CO₂ absorption. Here, transport properties

and equipment sizing were based on empirical correlations. While limited to the design of n-alkanes, the work demonstrates the advantages of the integrated thermo-economic design. The group extended their work, e.g., by domain reduction (Gopinath et al., 2016) to remove infeasible process and molecular design regions. However, the lack of consistent models for transport properties with strong predictive power has enforced equipment sizing based on heuristics, which may not accurately capture trade-offs between processes, equipment, and molecule. Furthermore, the application of such design methods is usually challenging and limited to expert software, limiting their wider adoption.

In this work, we present the integrated thermo-economic design of solvents and separation processes based on the 1-stage Continuous-Molecular Targeting-Computer-Aided Molecular Design (1-stage CoMT-CAMD) method (Schilling et al., 2017a; Schilling et al., 2017b). In 1-stage CoMT-CAMD, a consistent thermodynamic model for equilibrium and transport properties is used, the PC-SAFT equation of state. The integration into the process flowsheeting software gPROMS ProcessBuilder enables a straightforward application of the integrated design. So far, 1-stage CoMT-CAMD has only been applied for Organic Rankine Cycles. Here, we extend the method for the integrated thermo-economic design of solvents and separation processes. For this purpose, diffusion coefficients and mass transfer need to be predicted. We demonstrate the method for a physical CO₂ absorption process.

2. The framework of 1-stage CoMT-CAMD

1-stage CoMT-CAMD aims at maximizing the economic benefits offered in the molecular design space (Schilling et al., 2017b). The resulting problem is formulated as MINLP, Problem (1), based on the generic formulation introduced by (Gani, 2004):

$$\begin{array}{ll}
 \min_{x, y^s} & f(x, \theta, \kappa) \\
 \text{s.t.} & \left. \begin{array}{l}
 g_1(x, \theta, \kappa) = 0 \\
 g_2(x, \theta, \kappa) \leq 0 \\
 \kappa = k(x, \theta, y^s) \\
 p_1(x, \theta) = 0 \\
 p_2(x, \theta) \leq 0 \\
 \theta = t(x, y^s) \\
 F_1 \cdot y^s = d \\
 F_2 \cdot y^s \leq d \\
 x_{\text{lb}} \leq x \leq x_{\text{ub}} \in \mathbb{R}^m \\
 y_{\text{lb}}^s \leq y^s \leq y_{\text{ub}}^s \in \mathbb{Z}^l
 \end{array} \right\} \begin{array}{l}
 \text{equipment model} \\
 \text{PC-SAFT (transport)} \\
 \text{process model} \\
 \text{PC-SAFT (equilibrium)} \\
 \text{CAMD} \\
 \text{process degrees of freedom} \\
 \text{molecular structure}
 \end{array} \quad (1)
 \end{array}$$

In Problem (1), a thermo-economic objective function f is optimized (e.g., the net present value), depending on process and equipment variables x (e.g., pressure levels), equilibrium properties θ (e.g., enthalpies), and transport properties κ (e.g., viscosities). The process and equipment models encompass equality constraints g_1, p_1 (e.g., energy balances or mass transfer correlations) and inequality constraints g_2, p_2 (e.g., limitations of pressure levels or flooding conditions), respectively. The equilibrium properties θ and transport properties κ of the molecules are calculated using the PC-SAFT equation of state (Gross and Sadowski, 2001) (for details, see Section 3). A CAMD formulation is used to integrate the molecular design into the process design. Here, the designed molecule is represented by the integer vector y^s , which contains the number of a particular group of the molecular structure. The structural feasibility of the molecular structure is ensured by equality and inequality CAMD constraints (F_1, F_2) (Struebing, 2011).

The resulting degrees of freedom of the full MINLP problem are the process and equipment variables x and the molecular structure of the molecule y^S . To allow for an easy and fast application of the method, we have integrated the 1-stage CoMT-CAMD method into the commercial process modeling software gPROMS ProcessBuilder (Process Systems Enterprise, 1997-2021) in the work of Schilling et al. (2020). Thereby, the process flow-sheet can be quickly developed and adapted using the equipment model libraries of ProcessBuilder. The CAMD model and equipment sizing models are directly integrated as libraries into ProcessBuilder. Thus, the overall integrated design problem can be set up based on drag-and-drop flowsheeting. The MINLP can be directly defined and solved in gPROMS ProcessBuilder, allowing for an integrated design with one user-friendly tool. The MINLP is solved by the standard local MINLP solver OAERAP (Outer Approximation/Equality Relaxation/Augmented Penalty) of gPROMS ProcessBuilder. OAERAP combines an outer-approximation formulation with a relaxation strategy. Initially, the integer variables are relaxed to identify a hypothetical, optimal molecule, the target. Subsequently, an outer-approximation formulation identifies the optimal real molecule jointly with the corresponding optimal process settings and equipment sizes. Integer-cuts are used to obtain a ranking of optimal molecules. Here, the MINLP is solved repeatedly and previous solutions are excluded from the design space using integer-cut constraints.

3. Equilibrium and transport properties based on PC-SAFT

The key to the proposed method is the detailed molecular picture underlying the modern thermodynamic model used to calculate the equilibrium and transport properties of the designed molecules: the perturbed-chain statistical associating fluid theory (PC-SAFT) (Gross and Sadowski, 2001). In PC-SAFT, each molecule is described by a set of typically 3 to 7 pure component parameters. The physical background of these parameters makes the overall model based on PC-SAFT particularly suited for relaxation strategies in optimization algorithms. PC-SAFT is linked to the CAMD formulation by the homosegmented group-contribution (GC) approach of PC-SAFT (Sauer et al., 2014), which calculates the pure component parameters from the molecular structure y^S .

PC-SAFT is used to calculate both equilibrium and transport properties in every state of the process. The model is based on the residual Helmholtz energy. To obtain absolute equilibrium properties, we calculate the heat capacity of the ideal gas as reference property from the molecular structure using a GC approach (Joback and Reid, 1987). The transport properties κ are calculated from PC-SAFT based on Rosenfeld's entropy-scaling. Therein, the transport properties were found to depend on the residual entropy univariately. Using the dependency, GC approaches have been developed by some of the authors for viscosities η (Lötgering-Lin et al., 2018), thermal conductivities λ (Hopp and Gross, 2019), and self-diffusion coefficients D^S (Hopp et al., 2018) based on entropy-scaling and PC-SAFT. From the self-diffusion coefficient D_k^S of component k , we calculate the diffusion coefficient D_{ik}^∞ in infinite dilution of component i in component k using the empirical correlation:

$$D_{ik}^\infty = D_k^S \left(\frac{m_k^{0.34} \sigma_k}{0.5(m_i^{0.34} \sigma_i + m_k^{0.34} \sigma_k)} \right)^{2.97}, \quad (2)$$

where the segment number m and diameter σ are pure component parameters of PC-SAFT. The diffusion coefficients in infinite dilution are transformed into Maxwell-Stefan diffusion coefficients using the predictive Darken equation (Liu et al., 2011). From the Maxwell-Stefan diffusion coefficients, we calculate the required Fick diffusion coefficients using the thermodynamic factor (Taylor and Krishna, 1993) from PC-SAFT.

In this work, we consider functional groups of branched alkanes, cyclic alkanes, and aromatics. We constrain the molecular design space of the cyclic molecules to single ring structures. Further functional groups can be easily considered as soon as the group contributions are fitted to measurement data or the polar contribution of PC-SAFT is integrated into gPROMS ProcessBuilder.

4. Case study: Design of a carbon capture system with physical absorption

We exemplify 1-stage CoMT-CAMD for the integrated design of the solvent and process of a carbon capture system with physical absorption. We investigate precombustion carbon dioxide capture from the syngas stream of a coal-fired integrated gasification combined cycle power plant. The syngas feed contains hydrogen, carbon dioxide, and water. We notably account for water in the system due to its significant impact on the phase equilibria. The process topology includes the primary unit operations absorption, desorption, and carbon dioxide compression (Figure 1). Following Stavrou et al. (2014), the absorber has a fixed number of 7 equilibrium stages with a constant CO₂ capture rate of 90%. The desorption proceeds in two stages: a first flash stage, which feeds a hydrogen-rich gas back to the absorber, followed by a desorption flash. The process parameters are taken from Stavrou et al. (2014). The heat exchangers are modeled as shell-and-tube heat exchangers in counter-flow, assuming single-phase forced convection (Gnielinski, 1975).

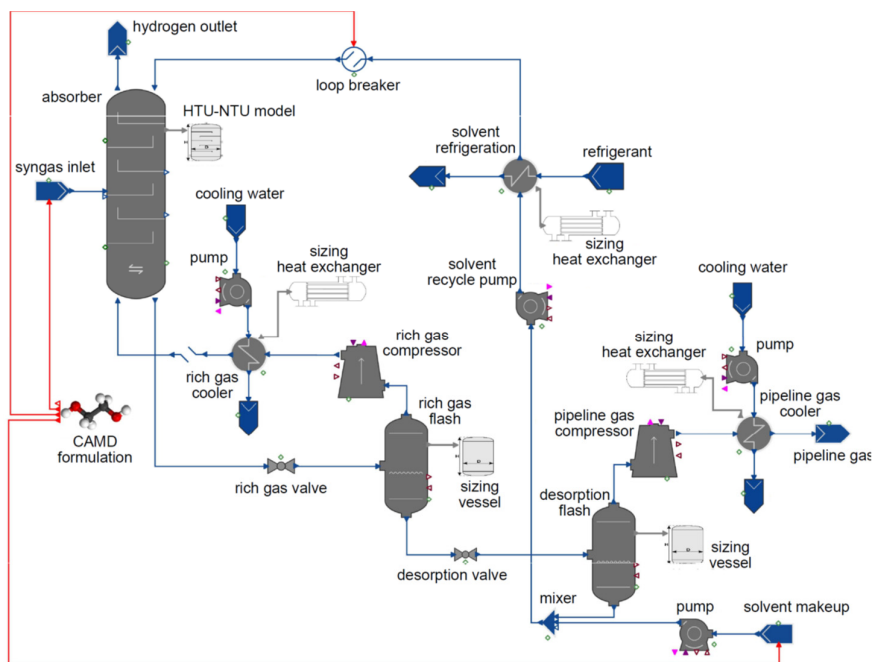

Figure 1: Flowsheet for CO₂ capture by physical absorption. The CAMD model and the sizing models of the equipment are directly linked to the process flowsheet. The flowsheet is created using gPROMS ProcessBuilder 1.2.

The absorption column is sized based on the height and number of transfer units using the so-called HTU-NTU method (Sinnott, 2005). The height of a transfer unit is sized

using the mass transfer correlation of Onda et al. (1968) depending on the mixture's viscosity and diffusion coefficients. We consider binary diffusion coefficients of hydrogen/carbon dioxide (gas phase) and solvent/carbon dioxide (liquid phase). The column diameter is obtained from the flooding conditions (Sinnott, 2005).

The resulting MINLP optimization problem consists of 5 continuous process degrees of freedom (e.g., mass flow rates or pressure levels) and 33 binaries representing the molecular structure of the solvent. The objective function f_{tot} is defined as the annual costs per mass of captured CO₂ calculated from investment cost and operational cost for electricity, cooling, solvent loss, and hydrogen loss. We assume a depreciation period of $n = 5$ a and an interest rate of $i = 0.08$. Initially, the relaxation problem is solved, leading to a hypothetical, optimal solvent, the target, with a target value of 15.99 €/t_{CO₂}. A ranking of the top 5 solvents is calculated using 1-stage CoMT-CAMD, identifying branched C10-C12 alkanes as the best solvents (Table 1). The optimal identified solvent is n-undecane, with costs of 16.0 €/t_{CO₂}, which is very close to the target, indicating no further room for improvement in the considered molecular space. In practice, alkanes are not used for physical CO₂ absorption. Thus, while the results demonstrate the advantages of an integrated design, future work should integrate further promising functional groups for CO₂ absorption, e.g., ethers. The identified solvents show an optimal trade-off between operational and investment costs. Solvents with longer chains reduce the operational cost f_{op} but lead to higher investment costs f_{inv} due to higher viscosities. If only the operational cost f_{op} without investment cost f_{inv} is considered as the objective function, branched C12-C13 alkanes, and thus solvents with longer chains are identified. The trade-off between economics, process, and molecule is captured within our integrated design framework leading to overall optimal solutions. Identifying a ranking of the top 5 solvents requires ca. 22 h using an Intel-Xeon CPU with 3.0 GHz and 64 GB RAM.

Table 1: Target and top 5 identified solvents minimizing the total annual cost per mass of captured CO₂ f_{tot} , and the annual operational (f_{op}) and investment (f_{inv}) costs per mass of captured CO₂.

Rank	Name	f_{tot} in €/t _{CO₂}	f_{op} in €/t _{CO₂}	f_{inv} in €/t _{CO₂}
-	target	15.99	12.70	3.29
1	n-undecane	16.00	12.71	3.29
2	n-dodecane	16.08	12.67	3.41
3	methyldecane	16.13	12.78	3.35
4	dimethylnonane	16.32	12.88	3.44
5	n-decane	16.47	13.29	3.18

5. Conclusion

In this work, we present a method for the integrated thermo-economic design of solvents and separation processes in chemical engineering. For this purpose, modern physically-based thermodynamic models based on PC-SAFT were linked to a CAMD formulation and rigorous models of the separation processes. Our 1-stage CoMT-CAMD method enables the solvent design based on thermo-economic objectives using detailed models to size the equipment. We implemented the method into the commercial process modeling software gPROMS ProcessBuilder to allow for a straightforward definition of the integrated design problem. For a physical absorption process to separate CO₂ from power plant flue gases, our method systematically identifies the thermo-economically optimal solvent and the corresponding optimal process. The integrated design of solvents and separation processes allows reducing the cost for CO₂ capture.

Abstract

The associated natural gas produced on crude oil offshore platforms is often flared. The potential of two small-scale Gas-to-Liquids processes to monetise this gas whilst reducing carbon dioxide emissions is investigated in this work. Compact NETmix microreactors are considered for the reactor stages, and the process energy expenditure is reduced through heat integration of endothermic reforming stages, where syngas (a mixture of hydrogen and carbon monoxide) is produced, with exothermic Fischer-Tropsch stages, which convert syngas into liquid fuels. The base concept of the two Gas-to-Liquids processes considered differs mainly on the reforming stage: Steam Methane Reforming or Dry Methane Reforming. The two Gas-to-Liquids routes proposed are compared in terms of capital expenditure, operational expenditure and their emissions reduction potential compared to flaring.

Keywords: Gas-to-Liquids, Steam Methane Reforming, Dry Methane Reforming, Heat Integration, Aspen

1. Introduction

According to the World Bank's Global Gas Flaring Reduction Partnership (GGFR), gas flaring releases about 400 million tons of CO₂ equivalent emissions each year (GGFR, 2020). Remote offshore crude oil platforms and floating vessels are amongst the main contributors to these emissions. Given their limited access to a gas market, when associated gas cannot be reinjected to increase oil production, or used onsite, it ends up being flared or vented to the atmosphere (IEA, 2020). Flaring reduction initiatives, like Zero Routine Flaring by 2030 from the World Bank, and tighter environmental regulations are driving a growth in the Gas-to-Liquids (GTL) market.

Gas-to-Liquids processes comprise two main steps: 1) conversion of gas, such as natural gas (NG) into a mixture of carbon monoxide (CO) and hydrogen (H₂), called synthesis gas or syngas, followed by 2) conversion of this syngas into a mixture of long liquid hydrocarbon (HC) chains by Fischer-Tropsch (FT) reactions. The most common industrial method for syngas production is Steam Methane Reforming (SMR). However, given the potential to re-use part of the carbon dioxide present in some reserves, Dry Methane Reforming (DMR) is also receiving increased attention (Wang et al., 2018).

In this work, the potential of both routes to monetise NG flared at a crude oil production facility is assessed. For GTL processes to present an attractive alternative for monetisation of associated gas and remote/stranded natural gas reserves, where conventional means of transportation are not practical or economical, it is essential to develop technologies for small scales (100-1000 bpd) with a fraction of the capital costs of conventional large-scale plants (Chen and Grossman, 2019). The study considers small-scale facilities, with 500 bpd production scale, and performs process simulation calculations, heat integration and economic estimations using AspenTech software packages. To reduce the installation size and improve the energy efficiency of the process, compact microreactors based on the NETmix technology are assumed for all reaction steps. These reactors are characterized by very high heat transfer coefficients (Costa et al., 2017), which together with heat integration of the processes mitigate the two major challenges associated with small-scale GTL.

2. Methodology and Process Description

The processes were simulated in Aspen Plus[®] using the Peng-Robinson property model, recommended when hydrocarbons and light gases are present, and the ENRTL-RK model for process sections containing electrolytes. The process flowsheets from Figure 1 comprise a heat exchanger network, capable of integrating process heat and minimizing energy consumption, which was developed in Aspen Energy Analyzer[™] through Pinch analysis. Equipment costs were estimated with Aspen Process Economic Analyzer[™], with the exception of the reactor costs, whose costs were obtained from the NET4CO₂ Collaboratory Laboratory, the entity with expertise in building these type of reactors (Lopes et al., 2008). Capital expenditure (CAPEX), operational expenditure (OPEX) and carbon footprint were assessed for both processes.

Figure 1a shows the Aspen flowsheet of the GTL process via SMR. It includes four major steps: NG steam reforming, CO₂ capture with amine scrubbing, FT reaction and FT syncrude purification. A mixture of natural gas and steam is pre-heated and fed to the SMR NETmix reformer R-01, at 860 °C and 20 bar with kinetic expressions based on the work of Tonkovich et al. (2007), and with a steam-to-carbon molar ratio of 2.3. This gives a global hydrocarbon conversion of 79 % and a final H₂/CO ratio of 4. The CO₂-rich syngas is pressurised to 33 bar (to minimise stage requirements, absorbent flow rate and overall equipment size) and is scrubbed with a 40 wt. % Methyl-diethanolamine (MDEA) solution. 89 % of CO₂ is removed from the syngas with a 98 wt. % purity.

The CO₂-lean syngas is sent to the Pressure Swing Adsorption (PSA) system T-03 with 80 % molar H₂ recovery. A fraction of the H₂ produced is fed back to the process to correct the H₂/CO molar ratio to 2. Although it is not depicted in Figure 1a, the remaining portion of H₂, with 99.5 wt. % purity, is diluted with other streams containing light gases from the purification stage (streams 53 and 59) and it is fed to the furnace for energy recovery purposes. The Fischer-Tropsch reaction occurs in R-02, the NETmix FT reactor,

operating at 250 °C and 30 bar, with kinetic model obtained from Almeida et al. (2013), leading to a CO conversion of 88 %. Finally, the FT syncrude produced is separated from lighter hydrocarbons in flash vessels V-02 and V-04 and from water in decanter V-03.

The GTL via DMR differs mainly in the feedstocks, processing steps (NG dry reforming and Water-Gas Shift instead of steam reforming) and heat integration network. In Figure 1b, a natural gas stream containing 70 % (v:v) CO₂ is pre-heated before entering the NETmix dry reforming reactor R-01, with kinetic expressions based on the work of Richardson and Paripatyadar (1990), operating at 900 °C and 4 bar, and with 98 % conversion. The resulting syngas with a H₂/CO ratio of 0.6 is sent to the Water-Gas Shift (WGS) reactor R-02, operating at 180°C and 3 bar and simulated with kinetic expressions from Amadeo and Laborde (1995). R-02 is responsible for raising the H₂/CO ratio from 0.59 to 2. After WGS, the processing steps are the same of GTL via SMR: syngas is scrubbed with the same solution of MDEA, giving a 96 % recovery and 98 wt. % purity; FT reactor R-03 is simulated at the same operating conditions with 87 % CO conversion; and the final purification step is also performed with two flash vessels and one decanter.

The heat integration of the GTL via SMR process resulted in a network of 11 heat exchangers, while the GTL via DMR has a network of 13 heat exchangers (these values do not include reboiler and condenser from the stripper). Note that to achieve the same production of 500 bpd, DMR uses less NG. This reduction of NG per barrel of product is larger than the increase in the heat of reaction for the DMR case, relative to the SMR. This contributes to significantly less heat to be integrated for the DMR case in comparison to the SMR, 18 MW against 30 MW. In addition, DMR is a more heat-efficient process, integrating 39 % of available process heat, compared to 32 % via SMR. Both processes have a similar energy conversion efficiency of around 65 %.

3. Results & Discussion

Table 1 compares the CAPEX and OPEX associated with both SMR and DMR routes. It is possible to conclude that SMR has the highest capital investment, being the compressors, the 4 packed towers of the PSA system and the heat exchanger network the most expensive equipment. Regarding OPEX, cooling water costs have the highest impact for SMR, while electricity is the main expense for DMR (mainly for C-01 compressor, which departs from 3 bar instead of 20 bar as in SMR). Nevertheless, the CAPEX + OPEX cost estimated for FT syncrude, for both routes, is lower than the average Brent crude oil price in 2019, \$64.36/bbl (MWV, 2020) and is about 1/5 of target cost for synthetic e-fuels (Bosch, 2020).

GTL via SMR leads to a 28 % reduction of carbon emissions when compared to the flaring of the same natural gas, while GTL via DMR increases emissions by 10 %. SMR takes advantage of H₂ combustion in the furnace, avoiding the need of burning extra natural gas to meet heating needs. Both proposed GTL plants are within the limits of 1700 m² topside area and 3130 Mtonne weight estimated for an offshore 5000 bpd modular GTL concept (Kwon et al., 2015). For a 500 bpd capacity, the estimated topside area and weight are one and more than one order of magnitude below the limits, respectively.

A sensitivity analysis on the impact of interest rate, operational lifetime and NG cost on the CAPEX and OPEX for DMR case is presented in Figure 2a-c. The lowest CAPEX is achieved for around 20 years of operation. A 10 % raise on the interest rate increases

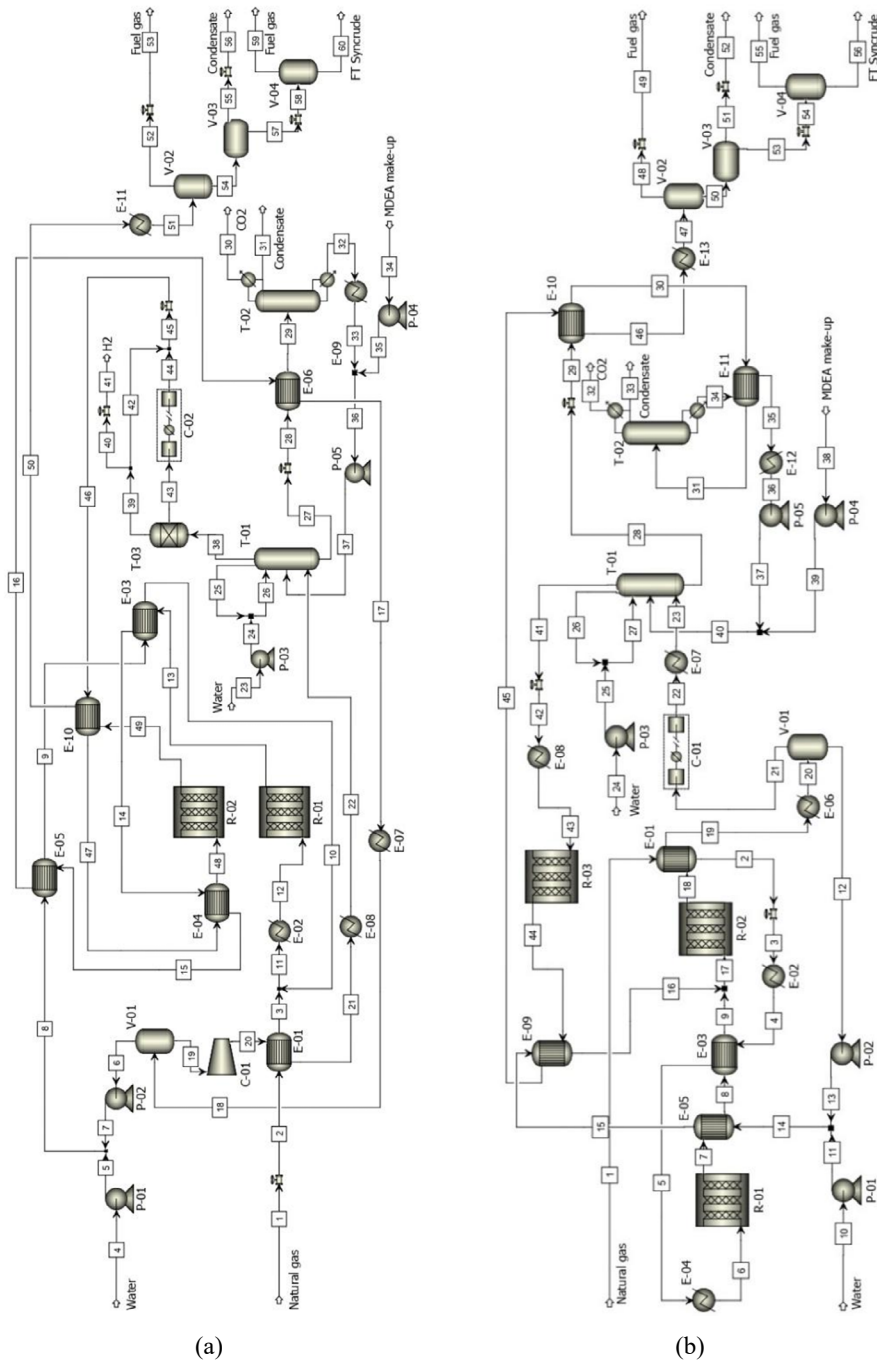

Figure 1. Aspen Plus® flowsheets: (a) GTL via SMR, (b) GTL via DMR.

CAPEX in 550 %, demonstrating the importance of the interest rate on the economically feasibility of a GTL project.

Table 1. Estimated capital and operating costs for small-scale GTL via SMR and DMR, for 20 years operation lifetime, 4.5 % interest rate, and \$0.01/kg of NG.

Reforming	SMR	DMR	Reforming	SMR	DMR
Capital	(10 ⁶ \$)	(10 ⁶ \$)	Operation	(\$/bbl)	(\$/bbl)
Compressors	5.4	3.1	Natural gas	4.4	7.7
Pumps	0.65	0.35	Water	0.062	0.031
Drums	0.51	0.49	Cooling water	8.74	7.9
PSA towers	4.0	-	Electricity	5.54	14
Absorber	0.47	0.45	OPEX	19	30
Stripper	0.97	0.86	Carbon footprint (kgCO ₂ e/bbl)	820	1450
SMR reactor	1.5	-	Total area* (m ²)	178	113
DMR reactor	-	1.0	Weight* (Mtonne)	2.6	0.9
WGS reactor	-	2.5	*preliminary estimates without detailed equipment design or plant layout. Pumps, compressors, boilers, furnaces and piping were not considered.		
FT reactor	1.1	0.87			
Catalysts	0.053	0.050			
Furnace	2.5	1.7			
Heat exchanger network	3.2	2.5			
Cooling tower	0.65	0.65			
Total capital	27	19			
CAPEX (\$/bbl)	20	14			

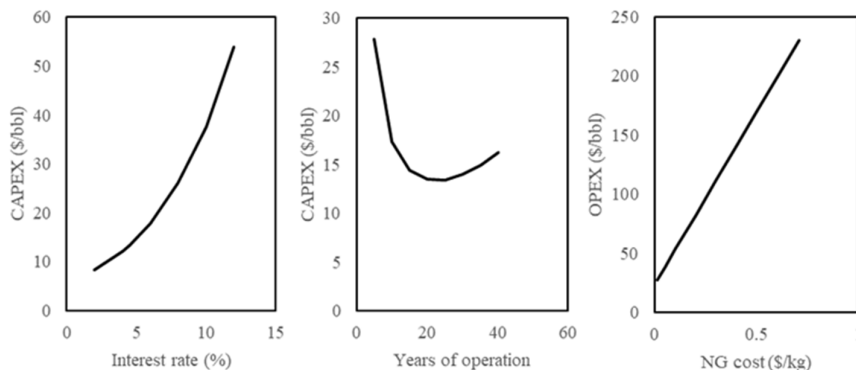

Figure 2. Impact of (a) interest rate on CAPEX, (b) operation lifetime on CAPEX, assuming an interest rate of 4.5 %, and (c) NG cost on OPEX for DMR.

4. Conclusions

Comparing the two small-scale GTL routes, the SMR is the most economically favourable, with \$20/bbl of CAPEX and \$19/bbl of OPEX and enables a 28 % reduction on carbon emissions when compared to flaring, which is advantageous particularly in a scenario of rising CO₂ emission taxes. Nevertheless, the choice between SMR and DMR

must be made carefully, since the decision on the route to follow is highly dependent on NG field size, composition, CO₂ availability, taxes, oil markets, among other factors.

Abstract

A novel method for automated flowsheet synthesis based on reinforcement learning (RL) is presented. Using the interaction with a process simulator as the learning environment, an agent is trained to solve the task of synthesizing process flowsheets without any heuristics or prior knowledge. The developed RL method models the task as a competitive two-player game that the agent plays against itself during training. The concept is proven to work along an example with a quaternary mixture that is processed using a reactor or distillation units.

Keywords: process synthesis, machine learning, reinforcement learning, automated method.

1. Introduction

Automated process synthesis is a central research field of process systems engineering. It can be grouped into three categories (Siirola, 1996): superstructure optimization, evolutionary modification, and systematic generation. In the latter one, a flowsheet is created sequentially by adding more and more process units from a predefined set. The decision process is usually done with heuristics that are based on prior knowledge. Prominent examples are the well-known expert systems. In the present work, a novel machine-learning (ML)-based method in the category systematic generation is introduced. As ML and artificial intelligence (AI) are rapidly expanding fields, a lot of research focuses on applying these kind of techniques in computer-aided process engineering. In the area of process synthesis, ML is for example applied to create surrogate models for reducing computational cost in simulation (Eason and Cremaschi, 2014). AI offers however more potential (Dimiduk et al., 2018), including recognizing system structures and components and making recommendations for the final design. The type of ML techniques, that could address these kind of problems, seems to be reinforcement learning (RL). The objective of RL is to teach an agent, which could be for example a neural net, to master a given task through repeated interactions with its

environment. This concept is already applied in process engineering, however almost exclusively in process control. Among rare exceptions are Zhou et al. (2017), who employed RL to set experimental conditions for the optimization of chemical reactions. Khan and Lapkin (2020) demonstrated that it is possible to identify promising processing routes in hydrogen production by using a RL approach. Given one of the open streams in the process, the agent was trained to choose a process unit, which is then connected to this stream.

The present work shows a RL based method, which provides the whole flowsheet as input for the agent. The decision is hierarchical: at first, the agent chooses one of the open streams to work with and afterwards a suitable process unit. This approach is an extension of the work of Göttl et al. (2021), in which the agent chooses an open stream and the corresponding process unit at once from a flat, non-hierarchical action space. The agent is trained without the usage of prior knowledge or heuristics. Through repeated process simulation during the training phase of RL, the agent develops artificial process engineering intuition. After briefly explaining the methodology, an example proves the concept to work.

2. Methodology

Framework. The present work is an extension of the method of Göttl et al. (2021), where we refer to for a description of the details. The framework for RL is depicted in Figure 1. The environment is a steady-state process simulator that contains all physical knowledge, i.e. models of thermodynamic properties and a given set of standard process units. The agent does not have any prior knowledge and learns only through interaction with the environment. The agent takes actions on the environment by sequentially adding process units to a flowsheet. The agent observes the stream table that is obtained as result of the process simulation performed in the environment. After the agent decides that the flowsheet synthesis is complete, it obtains a reward from the environment, e.g. some monetary cost function of the process simulation results like the net present value.

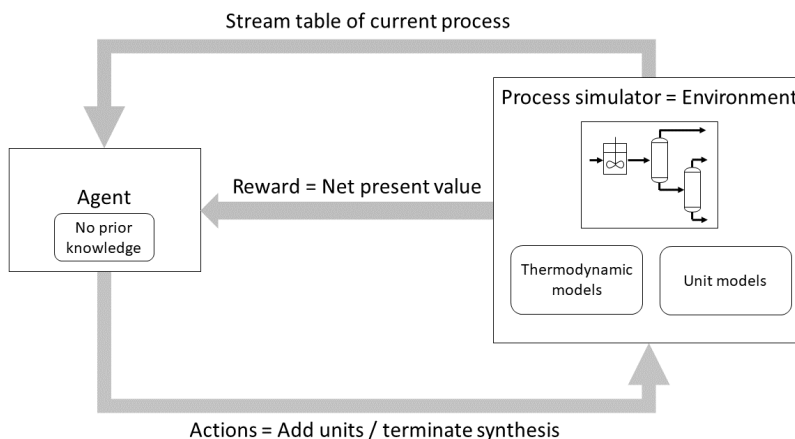

Figure 1: Framework for formulating flowsheet synthesis as reinforcement learning problem.

The presented framework is quite general and is further specialized to yield a proof of concept. A major assumption/limitation in the present work is that the agent takes only concrete actions, e.g. choose an open stream and afterwards place a process unit. The agent does not specify any continuous operation parameters of the apparatus. The reason for this limitation is two-fold: on the one hand, a robust simulation environment can be employed (cf. below). On the other hand, the used RL methods are native in discrete decision spaces and would require computationally expensive extensions for continuous parameters. Despite the limitation to discrete decisions, interesting design problems can be considered as the most important decisions in conceptual design are discrete.

Process Example. As example process in the environment, we chose a chemical model system that is zeotropic and consists of four compounds A (low-boiler), B, C and D (high-boiler). In a reactor with heterogeneous catalyst, the following, kinetically controlled reaction $A + B \rightarrow C + D$ happens. The following process unit are available to the agent:

- Place a distillation column with one of the following sharp split: D1 (A - BCD), D2 (AB - CD), D3 (ABC - D).
- Place a reactor (denoted R) with a fixed residence time. The kinetic is of first order in A and B: $\dot{n}_A^{\text{in}} - \dot{n}_A^{\text{out}} = 5 \text{ kmol/h} \cdot x_A^{\text{out}} x_B^{\text{out}}$
- Place a mixer (denoted M) to combine two streams.

D1, D2, D3 and R are applied to any single open stream, whereas M requires two open streams as input. The net present value is used to evaluate the obtained processes in the case studies. Since the complexity of its calculation is not relevant for the presented methodology and the process models are rather simple, a rather simple scheme is used: the output streams of the process yield a positive value when they are pure C or D. If an output stream consists of a mixture, it is assigned a negative value depending on its composition (the components A and B have a lower value than C and D). Costs for process units are assumed flat and annualized over 10 years. Energy costs are neglected.

SynGameZero method of reinforcement learning. Numerous off-the-shelf RL methods could be tried out on the problem shown in Figure 1. We have identified two major challenges: a) It is not trivial to reward the agent after every action immediately. For example, think of a multi-step separation sequence that only works successfully after a recycle has been closed. After placing the first process unit of the sequence, a constructive reward is hard to determine. b) For the same reasons, the problem is prone to local optima. Powerful exploration schemes are thus indispensable.

In the present work, both challenges are tackled simultaneously using a novel method called *SynGameZero* - Flowsheet Synthesis in a Game Environment with Zero Knowledge (Göttl et al. 2021). The task of creating a profitable flowsheet is modelled as a two-player game. Two competing players create a flowsheet for the same task. The game is turn-based and at each turn, a player can add a process unit in its own flowsheet or terminate the flowsheet synthesis. Both players are able to see their own and the opponents flowsheet. The game ends, when both players have completed their flowsheets. The game winner is the player who yielded a higher net present value. If the net present value is tied, the player who completed the flowsheet first wins the game. The winner obtains the reward $r = 1$, the loser $r = -1$. The agent is trained by playing many games against itself to win the game. Such a game-like setup allows us to use a modified version

of the efficient techniques proposed by Silver et al. (2017) that have been successfully used to master the board game of Go.

Agent setup. A state of the environment consists of the present flowsheet structure and the stream table (from simulation). This information is stored together in a flowsheet matrix. The input for the agent consists of two of those matrices – one for the flowsheet of the player whose turn it is, one for the flowsheet if its opponent. The agent consists of an artificial neural net (ANN) and a tree search. As mentioned before, the agent first chooses an open stream in the flowsheet to work with and afterwards a process unit, which is placed at the chosen stream. Therefore the ANN is also divided into two (connected) parts, the first one being responsible for choosing a stream, the second one being responsible for choosing a process unit. The first part of the ANN takes the flowsheet matrices as input and outputs a vector \mathbf{p}_1 and a scalar v_1 . The vector \mathbf{p}_1 represents a probability distribution (its entries are in the range [0; 1] and sum up to 1) and has one entry for every stream in the flowsheet and an additional entry for an action called T, which terminates the flowsheet synthesis. The vector suggests, which open stream should be taken (for adding a process unit). The scalar v_1 is an estimate of the reward (range [-1; 1]) at the end of the game for the current player. The second part of the ANN is connected to the last hidden layer of the first part and takes as additional input a vector, which indicates which stream was chosen. This part of the ANN outputs a vector \mathbf{p}_2 and a scalar v_2 . The vector \mathbf{p}_2 has one entry for every available process unit and similarly as \mathbf{p}_1 it represents a probability distribution. v_2 is another estimate of the reward. To improve its performance, the agent does not directly select the actions with the highest probabilities in \mathbf{p}_i . Instead, all outputs of the ANN are used to guide a tree search to plan several actions in advance. To avoid extensive computations, the tree search is adaptive in depth and does not use a full enumeration of all actions. Only promising actions are explored, where \mathbf{p}_i and v_i quantify the word promising. The action taken by the agent is ultimately decided based on the statistics of the tree search (basically it is counted how often each possible action was taken during the tree search). The ANN is trained with these statistics to give better suggestions for actions and estimates of the reward in the future. The tree search is described in detail in Göttl et al. (2021).

3. Example case study and results

To prove the concept to work, the same flowsheet problems as approached by Göttl et al. (2021) are considered. At the beginning of each game during training, one of the following feed situations is chosen randomly: in situation 1 two feed streams of the types $[\dot{n}_A; \dot{n}_B; 0; 0]$ and $[0; 0; \dot{n}_C; \dot{n}_D]$ are considered. In situation 2 two feed streams of the types $[\dot{n}_A; 0; \dot{n}_C; 0]$ and $[0; \dot{n}_B; 0; \dot{n}_D]$ are considered. In situation 3 one feed stream of the type $[\dot{n}_A; 0; \dot{n}_C; \dot{n}_D]$ is considered. In situation 4 one feed stream of the type $[0; \dot{n}_B; \dot{n}_C; \dot{n}_D]$ is considered. The non-zero entries are sampled randomly out of the interval [0.2; 1.2] kmol/hr before each game. Both players obtain the same flowsheet problem (identical feed streams) and try to create a process, which yields a higher net present value than the process of the opponent. As explained before, the cost function yields the largest net present value for flowsheets, where C and D leave the process with a high amount and as pure streams.

Figure 2 shows four stages of the agent's development over the progress of the training process specified by the amount of completed training steps. Panel a) in Figure 2 shows an example for a winning flowsheet at the start of the training process. The agent chose to terminate the flowsheet synthesis right at the beginning of the game. This is not

surprising, as the ANN is initialized with random weights and therefore its suggestions do not provide useful solutions to the given problems. After 2000 training steps in panel b), placing a distillation column to separate C and D is the first priority of the agent. This is a useful action since pure C and pure D have a high value. Additionally, the agent already has learnt that placing a reactor at the upper stream is useful, but it is not able to separate C as a pure product yet. Later in panel c) the agent favors to mix the streams first to have a common downstream sequence to save apparatus cost. After 20,000 steps in panel d), the agent has learnt that it is constructive to mix in the CD stream only after the reactor. To do so, it has to prioritize a reactor at the AB stream as first action. Overall, the agent achieved similar results for all of the four feed situations as the agent proposed by Göttl et al. (2021) by employing the described hierarchical action structure.

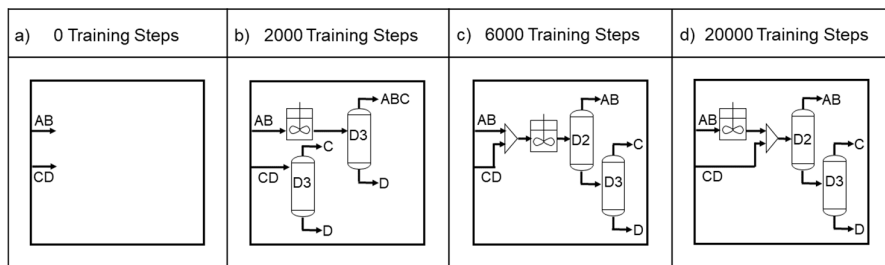

Figure 2: Evolution of the agent over the progress of the training. The shown flowsheets are examples for the winning flowsheet, created by the agent, at different stages during training for situation 1.

4. Conclusions

This contribution gives a further proof-of-concept that reinforcement learning (RL) can be used to train an agent without any prior knowledge to synthesize useful flowsheets for chemical processes in sequential manner. The problem of producing a profitable flowsheet is reformulated into a competitive two-player game that is played by the agent during training. This reformulation improves the efficiency of the training significantly, because it motivates exploration of alternatives. An agent that combines an adjustable artificial neural network (ANN) with an adaptive tree search for forward planning proved efficient and successful. The obtained results in a rather simple process example are promising. The introduction of a hierarchical structure of the actions provides an interesting approach to consider more sophisticated problems in the future (e.g. non-ideal chemical systems, more complex process units). Compared to a flat action space it allows integration of a larger number of process units without the problem of an exploding number of possible actions. Also, additional hierarchy levels could be included, for example to specify continuous parameters (on a discretized range) in the apparatus models.

Abstract

Methane and methanol as synthetic fuels can be produced from synthesis gas or syngas. A proton-conducting solid oxide electrolysis cell (H-SOEC) becomes a promising technology that can produce syngas from the co-electrolysis of steam and CO₂. In this work, the synthetic fuel production from syngas produced by a H-SOEC was modelled and simulated through Aspen Plus simulation software. The composition of syngas and synthetic fuel were calculated by using the minimization of Gibbs free energy. Firstly, the steam to CO₂ (S/C) molar ratio in feed was determined to satisfy the suitable stoichiometric number of each fuel. Further, the H-SOEC operating temperature was optimized. The simulation showed that at operation of H-SOEC as 650 °C and 1 atm, the optimal S/C molar ratio for methane and methanol productions is 4.69 and 3.52, respectively. Then, the effect of operation in fuel production was examined. The results indicated that methane flowrate of 0.2 kmol/h can be provided when reactor operates at 250 °C and 3 atm. For methanol production, 0.13 kmol/h of methanol can be generated at reactor operation as 250 °C and 80 atm. In addition, it was found that the methane production does not release CO and CO₂ to nature. Therefore, it can be concluded that the integrated system of H-SOEC and methane production is more attractive feature.

Keywords: Solid oxide electrolysis cell, Co-electrolysis, Proton-conducting, Synthetic fuel, Synthesis gas.

1. Introduction

A solid oxide electrolysis cell (SOEC) is a reverse mode of solid oxide fuel cell that can produce H₂ from separation of steam through electricity. In case of a proton-conducting SOEC (H-SOEC), it can produce more purifier H₂ than the conventional SOEC since no dilution of steam in the product stream (Lei et al., 2020), as seen in Figure 1a. The co-electrolysis of steam and CO₂ through a H-SOEC (Figure 1b) can provide the gas mixture consisting primarily of H₂ and CO which is referred to synthesis gas or syngas. Compared with the conventional method of syngas production (e.g. steam reforming and gasification), the co-electrolysis of H-SOEC is more attractive feature. If the power used

is generated from renewable resource, the syngas production through H-SOEC becomes clean technology. This method not only eliminates the consumption of fossil fuels which have price crisis but also can reduce the CO₂ emission due to the recycling or reusing CO₂ during production.

Although syngas is perceived as energy carriers that tend to replace the fossil fuels in the future, the energy storage in form of other chemicals or fuels is great interest due to ease of use and handling (Léonard et al., 2016). In this work, the productions of methane and methanol have been focused since both fuels are the most promising fuel and feedstock that can be further used in many applications (Bernardi et al., 2019). Interestingly, if this production uses the syngas produced from H-SOEC as an environmentally friendly method, it may be claimed that the obtained synthetic fuels are clean. Moreover, it can call this operation as Power-to-Chemical.

Since, the production of each synthetic fuel requires different stoichiometric number, the operations of H-SOEC to provide syngas for each synthetic fuel may be different. Motivated by this, this works aims to identify the favourable operating conditions of H-SOEC that satisfying each synthetic fuel. This work is performed through the simulation by using Aspen Plus simulator. Furthermore, the influence of reactor operation for synthetic fuel production is studied.

2. Modelling of Synthetic Fuel Production

In this work, the model of the synthetic fuel production from syngas produced by a H-SOEC is developed and designed through Aspen Plus simulation software, as shown in Figure 2. The equation of state as IDEAL is used in the simulation. The simulation of syngas production is firstly performed to identify the appropriate H-SOEC operation for each fuel. Next, the obtained syngas is treated before sending to the reactor for methane or methanol production. For syngas production, steam (STEAM *stream*) and carbon dioxide (CO₂ *stream*) is fed to the anode (ANODE) and the cathode (CATHODE), respectively. The anode is represented by *RStoic* reactor model where the electrochemical reaction of steam is carried out. Therefore, the steam utilization or steam conversion (X), as expressed in Eq. (1), should be specified to determine the current density (i) used for syngas production.

Figure 1 Schematic of H-SOEC for (a) hydrogen production and (b) syngas production.

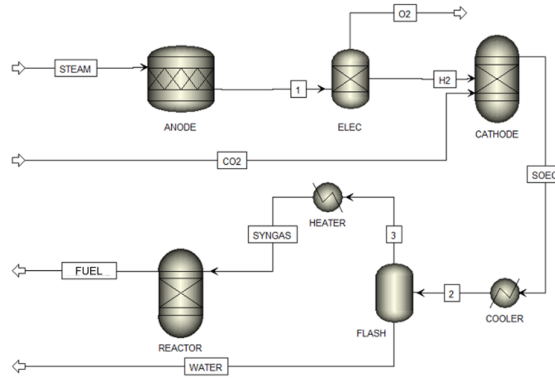

Figure 2 Flowsheet of synthetic fuel production from syngas produced by H-SOEC.

$$X = \frac{iAN_{\text{cell}}}{2F\dot{n}_{\text{H}_2\text{O},\text{in}}} \quad (1)$$

where A is cell area (m^2), N_{cell} is cell number and $\dot{n}_{\text{H}_2\text{O},\text{in}}$ is inlet steam flowrate (kmol/h).

Before the gas product from the cathode is used to produce synthetic fuel, the gas mixture is cooled down in the cooler (COOLER) and sent to the flash drum (FLASH) to remove water. Then, the dry syngas (SYNGAS *stream*) is fed into the reactor (REACTOR) to generate the desired synthetic fuel (FUEL *stream*). The chemical reaction that can be occurred in the reactor depends on type of synthetic fuel. For the methane production, Sabatier and methanation reactions can be carried out in the reactor (Stempien et al, 2015). In case of methanol, the reactions occurred in the reactor may be hydrogenation of CO and CO₂ (Kiss et al., 2016). Since the possible chemical reactions are based on equilibrium, *RGibbs* reactor model is used to calculate the fuel composition.

3. Model Validation

To ensure that the electrochemical reactions can be accurately predicted the performance of H-SOEC, the comparison between the simulation results and experimental data extracted from the literature is performed and the results are summarized in Table 1. The experiment of Ruiz-Trejo and Irvine (2012) used platinum electrodes and BCZY electrolyte that have the thickness as 100 and 200 μm , respectively. 500 cells of H-SOEC is fabricated with specific area of 0.04 m^2 . The anode side is fed with 95% steam and 5% hydrogen. As seen in Table 1, the deviation of results obtained from simulation and experiment is about 10% which is acceptable.

Table 1 The comparison of cell potential obtained from simulation and experimental data (Ruiz-Trejo and Irvine, 2012) at current density of 400 A/m^2

H-SOEC temperature ($^{\circ}\text{C}$)	Cell potential (V)		Deviation (%)
	Experiment	This simulation	
550	1.58	1.39	9.9585
600	1.42	1.30	8.1945
650	1.31	1.22	6.4210

4. Results and Discussion

4.1. H-SOEC operation

In this part, the operation of H-SOEC is determined to provide syngas that is suitable for synthetic fuel production. Firstly, the effect of steam to CO₂ (S/C) molar ratio in feed stream on stoichiometric number (S) as expressed in Eq. (2) is studied.

$$S = \frac{\dot{n}_{\text{H}_2} - \dot{n}_{\text{CO}_2}}{\dot{n}_{\text{CO}} - \dot{n}_{\text{CO}_2}} \quad (2)$$

where \dot{n}_i is the molar flow rate of species i (kmol/h).

For the investigation on the effect of S/C molar ratio, there are two methods performed: (1) steam molar flow rate is increased while CO₂ molar flow rate is constant and (2) CO₂ molar flow rate is decreased with a constant value of steam flow rate. Therefore, the effect of these variations on cell potential is considered as shown in Figure 3a. When the H-SOEC is operated at 650 °C and 1 atm with different S/C molar ratio (0.5, 1, 2, 3, 4 and 5), it can be seen that the variation of steam flow rate has more impact than that of CO₂ flow rate. Since increasing steam flow rate leads to an increase in current density, according to Eq. (1), and this causes significant increases in all voltage losses that include activation, ohmic and concentration losses and thus, the cell potential used for syngas production is higher. Conversely, the variation of CO₂ flow rate does not affect to cell potential. Therefore, to avoid the variation of cell potential or keep current density as constant during the study on the effect of S/C molar ratio, the reduction of CO₂ flow rate is considered.

Figure 3b presents the stoichiometric number as a function of S/C molar ratio. The simulation results indicate that increasing S/C molar ratio or decreasing CO₂ molar flow rate can increase stoichiometric number. However, it can be observed that the stoichiometric number becomes a negative value when S/C molar ratio is below 1. This indicates that the amount of steam fed into H-SOEC is not enough to generate H₂ for reacting with CO₂. From the simulation results, when the suitable stoichiometric number for methane and methanol production as 3 and 2 are specified, the optimal S/C molar ratio can be provided as 4.69 and 3.52 respectively. As expected, since the suitable stoichiometric number of methane production is more than and thus, the required S/C molar ratio is also higher.

Figure 3 The effect of S/C molar ratio on (a) cell potential and (b) stoichiometric number.

Next, the influence of H-SOEC temperature on stoichiometric number and CO production is investigated, as shown in Figure 4. In this study, the H-SOEC temperature is varied as 550, 600 and 650 K while H-SOEC pressure and S/C molar ratio are constant value as 1 atm and 4.62, respectively. Figure 4a shows that the increment of H-SOEC temperature can reduce the cell potential used for syngas production. This is because higher temperature operation leads to decreases in reversible cell potential, activation loss and ohmic loss. In addition, it is found that increasing H-SOEC temperature can shift the reverse water gas-shift reaction toward and thus, more CO can be produced as seen in Figure 4b. As a result, H-SOEC should be operated at high temperature to provide higher CO while the power consumption is lower.

Under the operation of H-SOEC at 650 °C and 1 atm, for methane production that the S/C molar ratio of 4.69 is specified, it can provide the gas product consisting of 58.3% H₂, 9.2% CO, 7.5% CO₂ and 25% H₂O. For methanol production that setting the S/C molar ratio as 3.52, the product stream is composed of 52.8% H₂, 11% CO, 10.2% CO₂ and 26% H₂O.

4.2. Reactor operation for methane and methanol production

In this part, the operating condition of each reactor on each fuel production is considered to achieve the highest amount of required synthetic fuel. Considering reactor temperature for both fuel productions, it is found that increasing operating temperature cause a reduction of fuel production. This is because the reactions occurred in both reactors are exothermic reaction in which is favourable to low temperature. Therefore, higher temperature operation becomes a negative effect on product composition. The simulation results indicate that the reactor for methane production should be operated at 250 °C and 3 atm in which the methane molar flow rate of 0.2 kmol/h can be produced. While, the operation at 250 °C and 80 atm is suitable for methanol production. Under these operating condition, the methanol of 0.13 kmol/h can be generated. Besides the operation condition of reactor, the effluent of each reactor is considered. The results reveal that the methane production does not release CO and CO₂ to nature. Unlike methane production, there are some amount of CO and CO₂ release during methanol production. Then, comparison between methane and methanol production is considered. It is found that although higher S/C molar ratio is required for methane production, lower operating condition of reactor and no carbon emission are main reasons to make this process is more attractive.

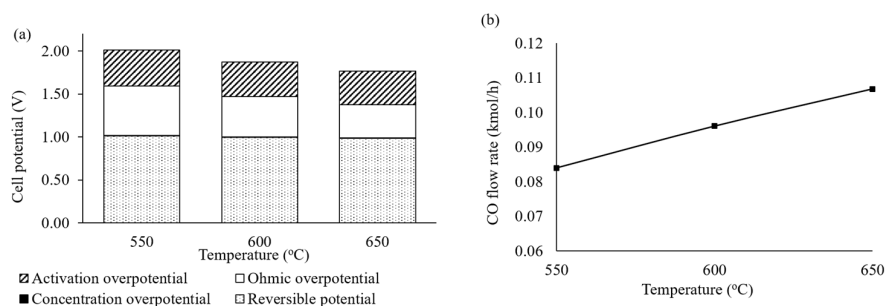

Figure 4 The effect of H-SOEC temperature on (a) cell potential and (b) CO flow rate.

5. Conclusions

This work focused on the methane and methanol production from syngas derived from H-SOEC. The simulation through Aspen Plus simulator was performed to determine the optimal operating condition of H-SOEC and each reactor. Since the methane and methanol production requires different stoichiometric number, the operation of H-SOEC to provide syngas for each fuel is different. One of factors affected to stoichiometric number is S/C molar ratio in feed. The simulation results showed that increasing S/C molar ratio can increase stoichiometric number. For methane production, stoichiometric number of 3 is required which is corresponded to S/C molar ratio of 4.69. In case of methanol production, the H-SOEC must be operated with the S/C molar ratio of 3.52 to satisfy stoichiometric number as 2. Further, the impact of H-SOEC operating temperature on cell potential and gas product is determined. The simulation result revealed that the cell potential used for syngas production is lower when the H-SOEC temperature is higher. In addition, increasing operating temperature leads to an increase in CO amount in gas product. Finally, the operating temperature of reactor used to produce synthetic fuel was examined. For the methane production, the reactor that Sabatier and methanation reactions carried out should be operated at 250 °C and 3 atm. While, the reactor for methanol production must be operated at 250 °C and 80 atm to achieve the highest amount of methanol. Under the operation of each reactor, it was found that the production of methane (0.2 kmol/h) is higher than that of methanol (0.13 kmol/h). Interestingly, it was found that there are no CO and CO₂ emission to environment while some amount of CO and CO₂ can be found in methanol production. Therefore, it can be concluded that the integrated system of H-SOEC and methane production is more attractive feature in terms of production rate and carbon emission.

Abstract

Refinery operations are always sensitive to optimization, and due to the increasingly adverse effects of COVID-19 on energy sectors, its importance had increased significantly. This thesis aims to analyze the reactor temperature that yields a higher RON (octane measurement) value in isomerate product using all available information in the isomerate production network. The main explanatory variables that can affect the RON value can be divided into three categories: feed impurities, isomerization reactor operations, deizohexanizer column operations. Isomerate feed network is quite complex and fed by different crude distillation units and cracker units. Various reactions occur in the isomerization reactors, and depending on the feed content, the reaction mechanism changes. This thesis applies machine learning algorithms to build a model that can capture the relationship between RON and reactor temperature with the other explanatory variables.

We implemented a number of machine learning algorithms to assess their performance on the problem, specifically Linear Regression, Decision Tree, Random Forest, XGBoost, Support Vector Regression, and KNN. Comparing with the linear regression, we achieved 0.82 decreases in the mean absolute error. The mean absolute error of the XGBoost model is 0.08 RON. We find a temperature value with the selected model that yields a higher RON number by trying different temperature values while keeping the same values for the other variables. If we used the suggested temperature by our model, we predict that we could obtain a 0.2 RON increase in the validation zone resulting in an annual profit increase of 528 000 USD Dollar.

Keywords: isomerization unit, octane optimization.

1. Introduction

A refinery produces a wide variety of products. Some of them are high-value light products such as gasoline, jet fuel, and diesel, and others like residual oil can be considered by-products. Gasoline is one of the most common transportation fuels for cars and trucks. The essential quality specification of gasoline is the octane number. It is a measure of the knock resistance and defines gasoline's behavior in the engine during combustion. Refineries adjust the units' operation so that octane in the gasoline meets the specifications. The most common type of octane rating worldwide is Research Octane Number (RON).

One of the most significant contributors to the gasoline pool is the isomerization unit. Isomerization is the principal reaction that takes place in isomerization reactors. It is converting normal paraffin to iso-paraffins to increase the octane number of light straight naphtha (feed). The reaction occurs in a hydrogen atmosphere, over a fixed bed of catalyst, and at operating conditions that promote isomerization and minimize side reactions such as hydrocracking.

In this work, our objective is to find the operating conditions that maximize the octane number in the isomerization unit in Tupras. The primary operating process variable is the reactor inlet temperatures. An upper limit exists for the number of iso-paraffins in the reactor product at any given outlet temperature (equilibrium imposed by thermodynamics). As reactor temperature is raised to increase isomerization, the equilibrium composition will be approached more closely. At very high temperatures, the concentration of iso-paraffins in the product will decrease because of the downward shift in the equilibrium curve, even though high temperatures give a higher reaction rate. Therefore, this work's central question is, "what the reactor inlet temperature should be?" However, of course, the outlet reactor temperature is not the only factor affecting the octane number. There are many other factors such as reactor pressure, deisohexanizer's column operations, undesirable hydrocarbons in the feed inlet, weather conditions, and many more. It is possible to measure some of these variables, such as pressure, continuously. Nevertheless, online analyzers are needed to measure others like feed content. However, online analyzers that measure feed components are absent in many refineries due to high initial and maintenance costs.

This work will select all isomerate product network as our system boundary. Moreover, we will use the most powerful and successful machine learning algorithms to capture linear and nonlinear relationships. For this purpose, we will use Random Forest, Extreme Gradient Boosting, k- Nearest Neighbors, Support Vector Regression, and of course, Linear Regression for the baseline.

2. Method

To maximize the octane number in the isomerization unit, we first have to study which variables affect this number. The most important variable is reactor temperatures. In the normal operation of Isomerization Unit, having once set the pressure, feed rate, and hydrogen flows, the main operating variable is reactor inlet temperatures. There is an upper limit for the amount of iso-paraffins in the reactor product at any given outlet temperature. This is the equilibrium imposed by thermodynamics, and it can be reached only after infinite time. As reactor temperature is raised to increase isomerization, the equilibrium composition will be reached that point faster. However, at excessively high temperatures, the concentration of iso-paraffins in the product will actually decrease because of the downward shift in the equilibrium curve. So, the use of temperatures higher than necessary to reach equilibrium yields nothing other than to increase the amount of hydrocracking. Therefore, the relationship between the temperature and octane number is not linear. As we increase the temperature, considering the other variables fixed, the octane number will rise first, and then it will be decreased. In the modeling part, we take the minus square of temperature to represent this relationship.

Another variable is liquid hourly space velocity (LHSV). It is defined as the volumetric hourly flow of the reactor charge divided by the catalyst volume in the reactors. Increasing LHSV might lead to lower product isomer ratios (low octane number)

The third variable we study is pressure. Higher pressure yields to increase the rate of isomerization reactions.

The fourth variable we pick for this model is C7+ Hydrocarbons. C7 paraffins hydrocrack to C3 and C4, low in octane number. And those which do not hydrocrack will be isomerized to a mixture, again, a lower octane number. Therefore, we do not want a high C7+ content in the isomerization reactors. Unfortunately, unlike the other variables, we cannot measure the C7+ content in the feed, so we have to inferential for this situation.

All of the above variables are related to the reactor or reactor feed. However, there is also Deisohexanizer (DIH) column operation, which can greatly affect the octane number. This column aims to recover product isohexane and pentanes from the stabilized reactor products. The basic aim is to remove all pentanes and 2-2 DMB overhead while minimizing the overhead 3-methylpentane content. Unlike C7+ content in the reactor feed, we have analyzers in here.

Heat input, reflux rate, pressure, all of the column temperatures are good candidates for the inputs for octane prediction.

Two variables set the octane of the main DIH top:

1. The pentane composition of the overhead. The total amount of pentane in this stream is set by the feedstock composition. Namely, the iso-pentane content is set by the C5 isomerization in the reactors. The higher the concentration of pentanes in the feedstock, the lower the product octane.
2. The amount of 2-methylpentane and 3-methylpentane in the overhead. The higher their concentration in the overhead product, the lower the octane.

Especially for the second item, let's imagine that we eliminate all of the methylpentanes. However, this will require more reflux and more recycling to the reactor system. Namely, it is costly. There is an optimization between the product octane vs. utility consumption.

Our target variable is octane number, and it is measured in two different approaches:

- (i) We have an analyzer, and it can sample the data and provide the result roughly in one hour. We have six-year data, which approximately 17500 data (the analyzer's uptime is not 100%). However, generally, the analyzer cannot provide the real result's ground truth.
- (ii) We also have samples taken from the lab, which are approximately around 500 data. It is very low compared to the analyzer, but the reliability is higher than the analyzer.

But before the octane number, the other target variable is feed content in the reactor. In reality, it is quite hard to predict the octane number without predicting the feed content. We do not have any analyzer; however, we know which units directly send to reactor feed, and we know their operating conditions.

Four separate units can feed the isomerization reactors, each with different operating conditions, specifications, and constraints. But all of these four units generate light straight-run naphtha. To infer the feed content, we consider them as possible candidates of those upstream units in the column operations: input flow rates, input temperature, all column temperatures, all column pressures, tray temperature controller, steam feed flows, reflux flow rates, bottom flow rate, distillate flow rate. Also, we generated these features:

reflux overfeed, temperature differences between bottom and top of the columns, distillate over bottom.

I used BarutoSharp to select the most important features. It is a wrapper feature selection method that uses both the Boruta feature selection algorithm with Shapley values [1]. It successfully reduces the column number from 30 to 5-10.

After that, I use other powerful machine learning algorithms, specifically Random Forest, AdaBoost, XGBoost, KNN, SVR, and Linear Regression, to predict the feed content reactor [2].

After obtaining the feed content, I follow a very similar approach to predict the octane number in the isomerate product. The only difference is that since I have not many columns, we do not need to reduce the number of columns, so we skipped the BorutaSharp part. Predicting the octane number is not enough to optimize it. We have to shift the process to optimum conditions. For this aim, the main process variable we need to determine is reactor temperature. Based on the other process variables conditions, we predict the octane number and predict again under the following scenarios: (i) We increased all reactor by λ and kept all the other variables simultaneously. (ii) We increased all reactor temperatures by $\lambda/2$ and kept all the other variables at the same level. (iii) We decreased all reactor temperatures by λ and kept all the other variables at the same level. (iv) We decreased all reactor temperatures by $\lambda/2$ and kept all the other variables at the same level, where λ is the max absolute deviation

3. Results and Discussion

After constructing isomerate product data, we implemented the most powerful machine learning algorithms to predict RON. In the following table, we can see the result of each prediction. We used train data MAE and test data MAE as the evaluate algorithm. Next, we showed the Actual vs. Predicted values only for the test data. Finally, we randomly select validation data to see how that algorithm could predict RON throughout a week.

Table 1. Model Results

Algorithm Name	Hyperparameters	Train MAE	Test MAE	Actual vs. Predicted	Validation Range: 83-88
Decision Tree	Max Depth: 10, best 11 Min Samples Leaf: 2, best 10 Min Samples Leaf: 10, best 10 Max Features: 11 Complexity Parameter: 0.001, best 0.001	0.08	0.11		
Random Forest	Max Depth: 10, best 9 Min Samples Leaf: 2, best 10 Min Samples Leaf: 10, best 10 Max Features: 11 Complexity Parameter: 0.001, best 0.001 Number of Trees: 270, best 270	0.08	0.09		
XGBoost	Max Depth: 10, best 7 Min Samples Leaf: 2, best 2 Min Samples Leaf: 10, best 10 Number of Trees: 10000, best 10000 Learning Rate: 0.1, best 0.1	0.07	0.08		
Linear Regression	All	0.75	0.9		
Support Vector Regression	Grid of Param C: 1000, best 10 Nonlinearity: 0.001, best 0.001 Kernel: RBF, best 0.001	0.05	0.06		
KNN	Nearest Neighbor: 1, best 1 K: 1, best 1	0.06	0.09		

Based on the results, almost all algorithms performed well. The only complex algorithm is linear regression. It has considerable high training and testing MAE. Furthermore, when we check validation data, it has a massive variance in prediction. Other than that, all of the algorithms can be applied in real-life plants. Support Vector Regression provides the minimum error, so let us take a closer look at it.

First, I changed the validation data to a different week, and it looks like it did a great job following the trend again.

Figure 1: XGBoost RON Model, Validation Data.

Now, let us remember our problem definition. We aim to find the reactor temperature at given conditions to maximize the RON value. So we prepared data composed of the main factors that can affect the RON: the feed conditions, reactor conditions, DIH conditions. To answer our question, we need to keep other conditions (DIH and feed) stable and find the reactor's optimum temperature profile. If the selected algorithm was linear regression, this was a trivial job. By substituting each variable's current values, we could find the optimal temperature except the reactor temperatures. However, we cannot back-calculate the exact temperature value using algorithms like SVR. So, we follow a heuristic approach. Again, we keep the other than reactor conditions simultaneously, but we introduced four different datasets derived from the original (the real one). Before that, we defined the maximum allowable temperature change with a single set change. For example, if the temperature set is 160, we defined the minimum and maximum deviation from 160 to prevent the catalyst from deactivation. Let us call this max absolute deviation λ . We substitute the values into the algorithm for each dataset and predict the RON. Furthermore, for some fixed intervals, or if the RON value is decreasing continuously, we can re-iterate the procedure. This procedure is also suitable for refinery operating conditions since we cannot change the temperatures frequently, and we cannot change it more than the maximum allowable limit.

However, when we implement this on SVR and KNN, we see no change from using these datasets. The main reasons for this situation; for SVR, there are no reactor temperature data in support vectors. So no matter what temperature we choose, we will observe the same RON value. This situation is observed for the KNN algorithm too. One explanation for this situation is that there are explanatory variables with correlation and more critical than that between inputs. For example, there will be more C6+ in the DIH column when there is a low temperature. Thereby, the bottom flow rate and bottom temperature of the DIH column will be increased. The bottom flow rate and bottom temperature support vectors, but the reactor temperature are not. One may suggest removing DIH operation variables. However, in that case, we observe a significant decrease in accuracy, as we will see in the later section.

Besides KNN and SVR reactor temperature insensitivity, all tree algorithms significantly respond to reactor temperature change. Since the Xgboost algorithm leads to minimum test MAE, we selected Xgboost as the best algorithm for our work.

For the same validation dataset, when we implement our heuristic approach, we can find the temperature value, which will give a higher value of RON content.

Figure 2: Temperature Sensivity of the Model.

The blue line is the predicted RON, and the red line is the actual RON value. If we changed the temperature by λ amount, we could see a significant increase during some intervals. On average, we could increase the octane content by around 0.2 just by changing the reactor temperature. However, increasing temperature incur some cost too. So when there is no significant octane change by increasing or decreasing reactor temp, it would be best to minimize the energy loss that is given to the reactor.

4. Conclusions

This study aims to find the reactor temperature that yields a higher RON value in isomerate product. For this purpose, we used all information in the isomerate product network to extract information that can affect RON value. Namely, we prepared data related to the impurities in the feed content, reactor operations, and DIH operations. Then we back-calculated a better temperature value for any give condition by keeping other variables the same and changing only the reactor temperature. After calculating the X-factor, we also gathered data related to the DIH and reactor operations. We employed Linear Regression, Decision Tree, Random Forest, XGBoost, Support Vector Regression, and KNN to predict RON and make a robust model. Although the SVR yielded the least mean absolute error, since it was not sensitive to temperature change, we select the second-best model, XGboost, to model between explanatory variables and the output. The model provided with the 0.08 mean absolute error in the test data, and the model can follow the trend quite well. By feature importance, we see that the most impactful features are created by domain knowledge, and without them, the algorithm performs poor results. With the model obtained, we find a temperature value that yields a higher RON number by substituting different temperature values while keeping the same values for the other values. With such change, we could obtain a 0.2 RON increase in the validation zone. If we expand it to it all year, the overall profit is 528 000 USD Dollar.

Abstract

Physicochemical property estimation methods serve as the basis for the design of molecules that enhance the functionality and efficiency of products and processes. The need to provide reliable pure component properties through quantum chemistry computations and/or experimental measurements is a major bottleneck to the goal of faster and cheaper to market the desired products. Hence, the development of approximate but qualitatively accurate models is vital to progress in the field of Computer-Aided Molecular Design (CAMD), among others. With group contribution (GC) as a dominant molecular representation, semi-empirical methods have been the most popular class in generating approximate property models for CAMD owing to their low computational cost and direct incorporation into optimization models. Recent advances in machine learning have stimulated widespread interest and progress towards closing the gap between semi-empirical and quantum chemistry methods. Herein, we use machine learning and data analysis methods to address the shortcomings of the current GC-based models by synthesizing the next-generation property estimation models and tools for the fast and accurate estimation of 20 physicochemical properties central to CAMD.

Keywords: CAMD, Group-contribution, Machine-learning, Property prediction models.

1. Introduction

In engineering research efforts aiming to improve the functionality and performance of products and processes, the accurate estimation of pure component properties is of paramount importance (Marrero & Gani, 2001). The primary strategy for obtaining

values of these properties and forming theories on their dependency on the structure is experimental observations, involving time-consuming experiments to create a knowledge-based model describing the underlying phenomena. Yet, it rapidly becomes prohibitive to acquire experimental values in literature when searching for ideal sets of properties because of the combinatorial explosion issue of the various potential configurations of atoms (Gani, 2004). Computational techniques, such as Density Functional Theory, have been applied to guide experimental efforts, but, given the high computation time that grows nonlinearly and sharply with molecular size, such methods still form a major bottleneck (Heinen et al., 2020). Consequently, more accurate models connecting molecular representations to properties are needed to build on the approximate underlying functions that describe the needed chemical properties.

Machine learning has recently emerged to play a transformative role in several fields by uncovering complex interactions in high-dimensional domains and systematically searching for a suitable function in the hypothetical space (Jordan & Mitchell, 2015). In the domain of molecular systems, machine learning has been considered for: pure component properties prediction (Yalamanchi et al., 2019), the generation of lead molecules while efficiently exploring the chemical space (Jin et al., 2018), and the creation of competitive novel quantitative structure-property relationship methods (Goh et al., 2017). In the domain of molecular design, the notable method is the GC family of methods (Marrero & Gani, 2001) that have been widely used in CAMD due to their invertibility, easy incorporation within mathematical models, and highly accurate estimates at an affordable computational cost (Alshehri et al., 2020). Properties of chemical structures are described in this class of approaches as functions of the number of molecular fragment occurrences called functional groups (Gani, 2019).

This paper combines the most recent previous works (Hukkerikar et al., 2012) on GC based property estimation approaches with the next-generation property models using machine learning and data analytics techniques for applications in CAMD. Such methods are intended to resolve the shortcomings of current GC models and reduce the accuracy gap between experimentation and estimates. Several models are devised for the following 20 pure component properties given in order of dataset size: octanol-water partition coefficient ($\log P$), normal melting point (T_m), normal boiling point (T_b), oral rat toxicity (LD_{50}), aqueous solubility ($\log Ws$), acid dissociation constant (pK_a), standard enthalpy of formation (H_f), Hildebrandt Solubility Parameter ($HSolp$), liquid molar volume (L_{mv}), critical temperature (T_c), critical pressure (P_c), critical volume (V_c), standard Gibbs energy of formation (G_f), normal enthalpy of fusion (H_{fus}), fathead minnow 96-h LC50 ($LC_{50(FM)}$), photochemical oxidation potential (PCO), bioconcentration factor (BCF), Auto Ignition Temperature (AiT), enthalpy of vaporization at 298K (H_v), and permissible exposure limit ($OSHA-TWA$). The criteria for inclusion of a candidate property for modelling is a minimum of 400 data-points. The dataset has more than 22,000 molecules, but the size of the experimental values of properties ranges from 12,193 to 422 data points for $\log P$ and $OSHA-TWA$, respectively. In the following section, a brief description of the methods involved in synthesizing the GC-simple and GC-ML models and tools is provided. The use of the new models in CAMD is highlighted through two case studies involving crystallization solvent design and surfactant design in the third section, followed by conclusions in the final section.

2. Methods

2.1. Group-Contribution Methods: GC-Simple

The MG (Marrero & Gani, 2001) property prediction model for pure components has the form in Eq. (1) for the vector of the number of occurrences for each group n and the vector of the regressed group contributions, c .

$$f(y) = \sum_{i=1}^{NF} c_i^F n_i^F + \sum_{j=1}^{NS} c_j^S n_j^S + \sum_{k=1}^{NT} c_k^T n_k^T \quad (1)$$

The regression method applied is similar to previous works (Hukkerikar et al., 2012), where the regressed group contributions of different orders are optimized sequentially or simultaneously. These model parameters (ie., regressed group contributions) of the model are obtained at the optimum value of the squared error function with a tuneable parameter w_k Eq. (2), reducing the difference between the true and predicted property values.

$$S(\underline{c}^F, \underline{c}^S, \underline{c}^T) = \min w_k \sum_{j=1}^N (y_j - \hat{y}_j)^2 \quad (2)$$

2.2. Group Contribution Methods: GC-ML

For a vector \underline{n} of group counts and vector \underline{y} of property values for vector \underline{m} data-points (molecules), Machine Learning methods seek to learn distributions over possible functions that fit the given data best according to a specified objective function. The ML-model has the form, given by Eq. (3).

$$f(y) = f_i(\underline{c}_{ML}, \underline{n}, \underline{\theta}) \quad (3)$$

where, \underline{c}_{ML} is a matrix of regressed parameters of size (NK, NP) with NP being the total number of parameters and NK being the size or order of the learning function; \underline{n} is the vector of group counts and $\underline{\theta}$ is a set of additional parameters introduced for the ML model. In principle, Eq. (2) or a probability function is minimized through a regression method. For the uncertainty estimate, the covariance function as well as the Jacobian matrix are needed (section 2.3 for more details).

2.3. Regression of the model parameters

GC-simple models have been obtained by fitting the models defined by Eq. (1) and minimizing the function defined by Eq. (2) using the Support Vector Regression (SVR), method, while, the machine learning-based models have been obtained using the GP regression method, minimizing a probability function. The data-set for each property is divided into 20 parts with 19 of them used for the learning (regression) step and the remaining set used for test (validation) step. The uncertainty estimate of a predicted property value is calculated from the covariance functions and the measured data of the molecules used in the regression step, as in Eq. (4).

$$Uncertainty_{estimate} = \pm [diag J(P^*) COV(P^*) f(P)]^{1/2} .t(v, (\alpha/2)) \quad (4)$$

Where the Jacobian Matrix $J(P^*)$ represents the local sensitivity, of the property model f to variations of the regressed parameter values ($P^* = \underline{c}_{ML}$); $COV(P^*)$ is the covariance matrix of the regressed parameters; is the degrees of freedom (total number of parameters minus the number of not regressed parameters); $t(v, (\alpha/2))$ is the t -distribution corresponding to v and $(\alpha/2)$ percentile. The additional parameters from

the regression step for the GC-ML-model are ℓ , the length scale parameter; and σ the signal variance that regulate the horizontal and vertical variances of the covariance function.

3. Results and Discussion

3.1. Performance analysis of the developed property models

The performances of the regressed models are evaluated using the fraction of experimental data points of properties that lie within 1%, 5%, and 10% of absolute relative error. Under the GC-ML models, the average of the model performance for predicting property values within 1% relative error is boosted to 85% across all properties as visualized in Fig. 1, compared to 32% under simultaneous regression and GC-simple models (not shown in Fig. 1). More details results, including the regressed parameters can be found in Alshehri et al., (2021).

Figure 1: The training and testing performances for the developed property models for molecules predicted under the 1% relative error threshold.

3.2. Data Analysis

The generation of synthetic data can be broadly categorized into two approaches, process-driven and data-driven (Goncalves et al., 2020). In data-driven approaches, generative models based on probability distribution and function approximation methods are used to generate synthetic data. The primary task of generated datasets is to aid in the model development process by complementing the experimental data in tuning the model parameters. Table 1 gives the number of generated data points for each of the properties in the available measured datasets. For these results, the properties having less than 1000 experimental data are selected. The property datasets with the new data points are used to test the developed GC-simple and GC-ML models with acceptable model performance.

Table 1: New datasets generated using data analysis techniques

Chemical property	H_{fus} [kJ/mol]	P_c [bar]	T_c [K]	V_c [cc/mol]	V_c [cc/mol]	G_r [kJ/mol]
Experimental Data	749	774	776	773	425	756
Generated Data	62	100	135	104	55	60

3.3. Application of developed models in hybrid CAMD

Crystallization solvent case study: This case study is taken from (Chai et al., 2020) and the hybrid CAMD method (Liu et al., 2019) has been used, which is a

decomposition-based method to solve mixed-integer nonlinear programming models. Here, in the inner-loop a CAMD problem is solved with the GC-simple models and in the outer-loop the GC-ML models are used to check additional properties. Also, only the uses of pure component property models are highlighted here. 2-Mercaptobenzothiazole (MBT) is an important vulcanization accelerator used in the rubber industry. However, its purification through a solvent-based method replacing the usual acid-base method needs to be investigated. First, a set of building blocks are selected for the inner-loop: CH₃, CH₂, CH, C, OH, CHCOO, aC-CH₃, aCH, aC-Cl. The molecular structure and property constraints used in the inner-loop are given in Table 2. The candidate solvents and their properties from the inner-loop of CAMD are listed in Table 3. For the set of feasible compounds, in the outer-loop additional properties not included in the inner-loop are checked with the GC-ML models and their values are listed in Table 4.

Table 2: List of molecular structure and property constraints.

Name	Lower	Upper
Total Group Number	3	8
Repeat Group Number	0	7
Functional Group Number	1	6
Molecular Weight M_w [g/mol]	80	200
Normal Melting Point T_m [K]	173	310
Normal Boiling Point T_b [K]	373	600
Flash Point F_p [K]	273	393
Hildebrand Solubility Parameter at 298 K δ [MPa ^{1/2}]	18	21
Fathead Minnow 96-hr LC_{50} FM [mol/L]	0	4.8

Table 3: List of feasible solvent candidates for crude MBT crystallization. The values in parentheses are measured experimental values.

Feasible Molecule	Mw [g/mol]	T_m [K]	T_b [K]	F [K]	HSol P [MPa ^{1/2}]	$LC_{50(FM)}$ [mol/L]
1	116.20	231 (239)	451 (449)	340	21.10	3.41(3.51)

8	CCCC(O) C	1.7 0	2.11	12. 00	0. 94

Surfactant design: The surfactant design problem (Liu et al., 2019) has also been solved with the new property models (see Table 5). In this problem, T_m , T_b , and $LC_{50(FM)}$ are used in the inner-loop and LogP and OSHA-TWA are used in the outer-loop.

Table 5: List of inner- and outer-loop properties for a candidate surfactant.

SMILES	LC ₅₀ ^(FM) [mol/L]	T _m [K]	T _b [K]	Lo gP	OSHA-TWA
OCCOCCOCCOC(CCCCCC) OCCOCCOCCO	3.16	3 4 9	7 2 3	2.7 5	7.99

The details of the best candidate molecule are given in Table 5 together with the inner and outer-loop properties. More details on this problem can be obtained from the corresponding author.

4. Conclusions

In this work, we introduced the next-generation pure component property models and data analytics tools for the estimation of pure component properties to improve the performance and the application range of CAMD problems. Primarily, the Gaussian Process method is adopted for building nonlinear property models that handle complex molecular structure-property relationships while quantifying uncertainties in the predicted values. Compared to currently-used methods, the new generation of methods yields significantly improved performance. The uses of the simple GC-models and

ML-based models have been highlighted for previously solved CAMD problems in a hybrid scheme. More work is needed to find the optimal computational framework for accommodating a set of models with different complexities and data from different sources in a more practical solution route to CAMD problems with likely applications in drug and other complex molecular design problems. Note that although the uses of the pure property models have been highlighted in the CAMD problems, a lot of other properties (functional and mixture properties) are also needed for their complete solution.

Abstract

Reverse osmosis (RO) membranes play a key role in wastewater treatment units as they are used to remove salts and other pollutants effectively. RO membrane performance is affected by many different factors such as feed characteristics and operational parameters during operation. The aim of this study is to analyse the influence of feed characteristics of municipal wastewater (conductivity, oxidation reduction potential (ORP), total suspended solids (TSS), turbidity and chemical oxygen demand (COD)) and operational parameters (feed pressure, flow rate and temperature) on RO membrane performance in a municipal wastewater recovery plant using machine learning (ML) techniques. XGBoost, random forest, artificial neural networks (ANNs) and multiple linear regression (MLR) were employed to predict three RO membrane performance indicators (pressure difference across membranes, salt passage and permeate flow rate). The methods that can predict salt passage, permeate flow rate and pressure difference among membranes with the highest accuracy were found as ANNs, random forest and MLR, respectively. Considering the developed models, temperature was found to be the variable affecting all three RO performance parameters. Salt passage was found to be highly affected by feed water conductivity and feed flow rate was determined to be the most influential parameter for the permeate flow rate and pressure difference.

Keywords: machine learning, artificial neural networks, random forest, wastewater treatment, reverse osmosis membranes.

1. Introduction

In wastewater treatment plants, monitoring RO membrane performance is very important. Besides, the factors influencing RO membrane performance are worth investigation to understand the process dynamics for effective operation. Data-driven models are becoming increasingly popular as they can model complex process dynamics without the need for physical models (Del Rio-Chanona et al., 2019). Machine learning techniques are used to develop models which can learn from data. ANNs are common machine learning algorithms used for prediction (Odabaşı et al., 2014; Robert, 2003). They have been employed successfully in various studies in the field of membrane performance (Cabrera et al., 2017; Farahbakhsh et al., 2019; Jawad et al., 2020; Roehl et al., 2018). Random forest and eXtreme Gradient Boosting (XGBoost) methods are other most common tree-based ensemble machine learning algorithms used for supervised machine

learning problems. The random forest method is a popular algorithm because it can handle outliers and noise effectively (Larose, 2005). The XGBoost method (Chen and Guestrin, 2016) is a relatively new algorithm that introduces regularization parameters to prevent overfitting and it was developed for increasing the performance and speed.

In this work, the influence of the feed characteristics of municipal wastewater and operational parameters on RO membrane performance were studied using different machine learning methods (random forest, XGBoost, ANNs and MLR) in a municipal wastewater recovery plant. The best performed models were employed to determine the influence of the input parameters on RO membrane performance indicators (salt passage, pressure difference and permeate flow rate). In this study, we aimed to extract knowledge from a large-scale treatment system and compare the performances of different ML models on different performance indicators. We believe that investigating the influence of the input parameters for RO membrane operation should be given more attention to understand the system dynamics better.

2. Methodology

The two years of historical data of one RO train from the municipal wastewater recovery plant of TUPRAS Izmit Refinery was used. Both operational and laboratory data were used and the data was collected on a daily basis. The database was divided into two sections as training data and test data. Model building, parameter optimisation and validation of the models were performed using training data whereas the accuracy of the model was tested on test data which was not included in model building process. Most widely used ML models such as XGBoost, random forest, ANNs and MLR were used to build models and predict three RO membrane performance indicators (pressure difference between feed and retentate, salt passage and permeate flow rate). The performances of different models were compared using root mean square error (RMSE) as a performance metric. 10 fold cross validation (cv) method, which is the most commonly used validation method, was employed for parameter optimisation of the models. Then, the models which resulted in minimum RMSE on test data prediction were determined as best performed models for predicting RO membrane performance indicators. The influence of input variables were investigated using the best performed models and the details of the input significance analyses are explained in the Results section.

RStudio 1.2.133526 was used for computational analyses. `xgboost` (Chen et al., 2020), `randomForest` (Liaw and Wiener, 2002) and `neuralnet` (Fritsch et al., 2019) packages of RStudio were employed for XGBoost, random forest and ANN methods, respectively. For XGBoost model, the maximum number of rounds (trees to build) was optimised. Learning rate, maximum depth of the trees and early stopping rounds were fixed to 0.3, 6 and 10, respectively. For the random forest model, the number of trees to grow was optimised. For ANN analysis, Z-score normalization was performed before building the model. Then, number of hidden layers and neurons were optimised. Logistic activation function was selected as an activation function and threshold for the partial derivatives of the error function as stopping criteria was set to 0.1.

3. Results

In order to predict RO membrane performance indicators (salt passage, permeate flow rate and pressure difference), different ML methods were implemented and compared. The best performed models that resulted in minimum RMSE on test data prediction are

used to detect the most influential parameters on three RO membrane performance indicators. Feed pressure, flow rate, conductivity, TSS, ORP, COD, turbidity and temperature were used as input parameters. The RMSE values of different models for each RO membrane performance indicator were presented in Table 1.

Table 1. RMSE values of validation and test data prediction using different methods

Methods	Salt passage		Permeate flow rate		ΔP	
	10-fold-cv	Test	10-fold-cv	Test	10-fold-cv	Test
	RMSE	RMSE	RMSE	RMSE	RMSE	RMSE
XGBoost	0.91	0.77	3.90	6.64	0.33	0.64
Random forest	0.71	0.65	7.32	10.51	0.35	0.63
ANNs	0.76	0.91	4.36	5.12	0.34	0.58
MLR	0.76	0.85	3.77	4.35	0.39	0.66

For salt passage prediction, a random forest model performed superior to other methods (Table 1). The RMSE of test data prediction was found to be 0.65. The actual and predicted salt passage values of test data are presented in Figure 1a. In random forest method, mean decrease in Gini (IncNode Purity) is used as a measure to analyse the variable importance (Kuhn et al., 2008). This measure represents the performance of each split considering the input parameters using Gini index. If the value of mean decrease in Gini of an input variable is high, this variable has a higher variable importance. Hence, considering the random forest model, it was found that the feed conductivity and temperature had more effect on salt passage than other parameters (Figure 1b).

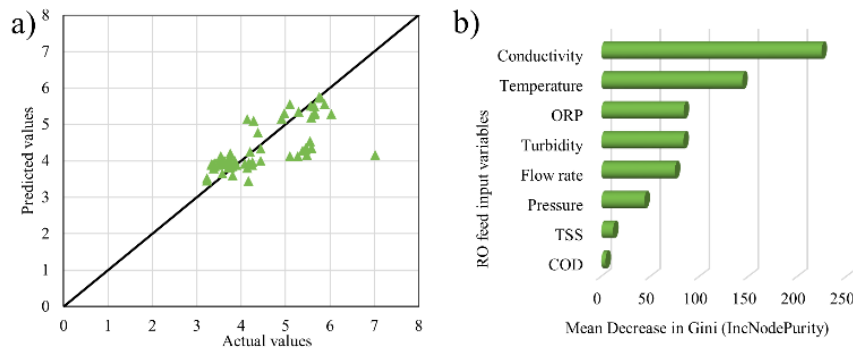

Figure 1. Analysis of salt passage a) actual versus predicted values of test data (number of trees = 100), b) variable importance analysis

Bartels et al. also showed that when the feed water salinity increases, salt passage also increases (Bartels et al., 2005). Hence, the conductivity of the feed water has a significant effect on salt passage and ion removal efficiency. Secondly, a change in the feed water temperature of RO membrane trains causes the RO membrane pore diameters to change. If the feed water temperature increases, pore diameters expand and more ions can pass through the RO membranes. Hence, salt passage increases (Al-Bastaki and Al-Qahtani, 1994; Jin et al., 2009).

For the permeate flow rate prediction, the accuracy of the MLR model was found to be the highest and the RMSE value of test data prediction was found to be 4.35. The actual and predicted permeate flow rate values are shown in Figure 2a. In order to determine the relative importance of the input variables according to MLR model, the significant input variables of which p-values were found to be smaller than 0.05, were considered. In Figure 2b, the absolute values of the coefficients of significant input variables are given. Feed flow rate was found to be the major factor affecting permeate flow rate. Considering the strong linear correlation between feed and permeate flow rate (0.96), the success of the MLR model and the importance of the feed flow rate were expected. Temperature appeared to be the second influential factor for permeate flow rate. Regarding the expansion of the RO membrane pore diameters due to high temperature operation, the feed flow can pass through the pores more easily and the permeate flow rate increase. (Boulahfa et al., 2019).

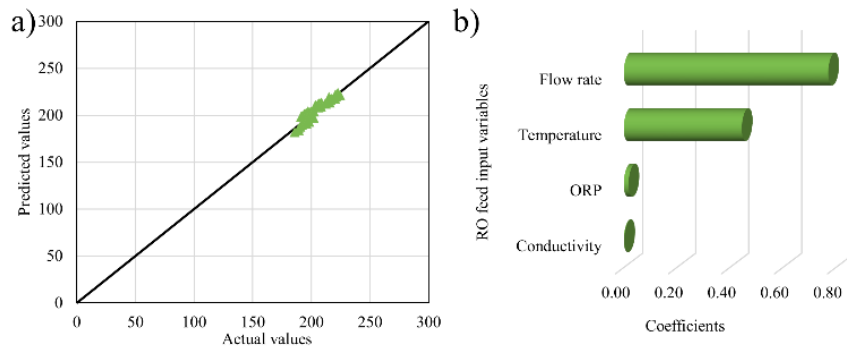

Figure 2. Analysis of permeate flow rate, a) actual versus predicted values of test data, b) variable importance analysis

Lastly, ANN model performed better than other methods for predicting the pressure difference across RO membranes with a minimum RMSE of 0.58 on test data prediction (Table 1). The actual and predicted pressure difference values are given in Figure 3a. In order to determine the variable importance according to ANN model, Olden's method (Olden et al., 2004) was employed. Olden's method is based on connection weight approach that uses raw input-hidden and hidden-output connection weights in the neural network. According to the Olden's method, feed flow rate was found to affect the pressure difference significantly and this situation is expected considering the system hydraulics. Secondly, temperature was found to affect pressure difference. An increase in temperature causes a pore expansion of the RO membranes, hence, the pressure difference between the stages of the train is expected to be lower.

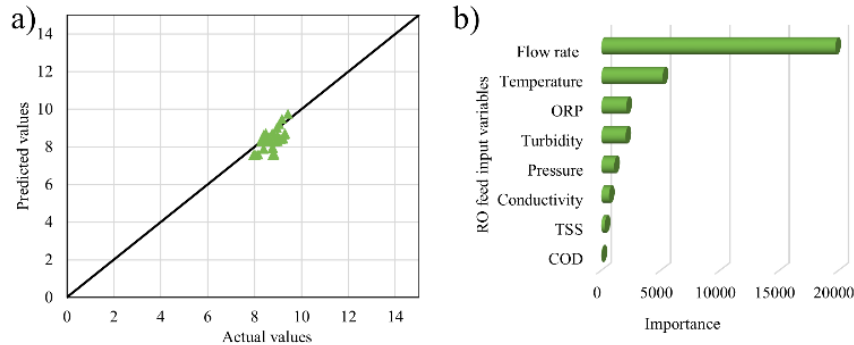

Figure 3. Analysis of pressure difference a) actual versus predicted values of test data (neural network with two hidden layer (2-12 neurons)), b) variable importance analysis.

4. Conclusions

In this study, the factors affecting RO membrane performance were investigated using different ML tools (random forest, XGBoost, ANNs and MLR). Salt passage, permeate flow rate and pressure difference were used as RO membrane performance monitoring indicators whereas the feed characteristics of municipal wastewater (such as conductivity, ORP, TSS, turbidity and COD) and RO membrane feed operational parameters (such as feed pressure, flow rate and temperature) were considered as input parameters. Among four different methods, ANNs and random forest methods performed better for predicting the pressure difference and salt passage, respectively. For permeate flow rate prediction, the MLR method was found to be more successful than other methods due to strong linear correlation between feed and permeate flow rate. According to the variable importance analyses considering the best performed models, temperature was found to be significant for all RO membrane performance indicators whereas conductivity and feed flow rate were found to be major factors affecting salt passage and permeate flow rate, respectively.

Abstract

Novel low-temperature technologies have been recently studied for CO₂ removal from low-quality natural gas or biogas. The aim of this work is to compare the performances of a low-temperature distillation process with those of other two processes, respectively based on physical absorption and a combination of both, depending on the CO₂ content varied between 10 and 70 mol%. Each process has been simulated, with attention to energy-saving issues, using Aspen HYSYS[®] V9.0 and Aspen Plus[®] V9.0. This study points out that novel technologies based on low-temperature distillation are the best option for CO₂ separation from low-quality natural gas or biogas and that, by combining a bulk CO₂ removal by low-temperature distillation with a finishing step by physical absorption, it is possible to reduce the energy consumptions of the separation achieved by physical absorption only. These outcomes suggest the importance of further investigating novel low-temperature and hybrid CO₂ removal technologies.

Keywords: natural gas purification, physical solvents, low-temperature distillation, hybrid technologies

1. Introduction

The challenge operators in the gas industry have to face in some countries is the economically viable separation of CO₂ from fields where its content is even higher than 70 mol% (Pellegrini et al., 2019). It is well known that, when the acid gases make up an appreciable fraction of the total gas stream, the cost of removing them by heat regenerable solvents may be out of proportion to the value of the treated gas. To overcome this, physical solvents can be used, which are regenerated by pressure reduction. It has been also proved (Langé et al., 2015) that conventional CO₂ separation methods based on chemical absorption are not energetically convenient respect to novel low-temperature (low-T) technologies when the CO₂ content in the feed gas exceeds 8-9 mol%. The recent interest in this type of processes is proved by the intense research on measurement and calculation of CO₂ frost points in natural gas and other mixtures (Pellegrini et al., 2020). To our knowledge, no comparison can be found in the literature between low-T and physical absorption technologies. To fill this gap, this work compares the performances of a process based on low-T distillation and one based on physical absorption using Dimethyl Ether of Polyethylene Glycol (DEPG) for CO₂ removal from natural gas/biogas. In addition to that, a hybrid configuration, consisting of low-T distillation for a bulk CO₂ removal and physical absorption as a finishing step, has been considered taking into account the recent interest in hybrid technologies (mainly for pre-/post-combustion CO₂ capture) due to their lower energy consumption.

2. Methods

The three process schemes taken into account in this work have been simulated with Aspen HYSYS[®] V9.0 (AspenTech, 2016a) and Aspen Plus[®] V9.0 (AspenTech, 2016b). These simulators are powerful aids in the design of processes, provided that the correct property package is selected, as specified in the following, depending on the specific system under investigation. They also offer the possibility of automatically specifying a desired value for some flowsheet variables using tools properly available for this purpose (e.g., the Design-Spec tool in Aspen Plus[®]). In all the simulations, the following specifications for the feed and product streams have been considered.

i) Natural gas (NG) feed stream: it has been assumed as a binary CH₄-CO₂ mixture (CO₂ molar fraction in the range 10-70 mol%), available at 35 °C and 50 bar with a total molar flowrate of 5000 kmol/h.

ii) Treated NG stream: its temperature and pressure have been set, respectively, at 25 °C and 50 bar and a CO₂ content of 2 mol% has been specified to produce a pipeline-quality NG.

iii) CO₂ product stream: it has been subject to further treatment, when needed, to bring it to its bubble point at 50 bar. This pressure value is suitable for its use for Enhanced Oil Recovery (EOR) purposes. For the process schemes involving the use of a solvent, the composition of the CO₂ product recovered from the solvent regeneration unit has been checked to ensure it meets the limit contents acceptable for injection into a depleted oil well and, in particular, that the CH₄ content is below 2 mol%.

The three different CO₂ removal technologies have been compared on the basis of their energy consumptions evaluated by means of the “Net Equivalent Methane” (NEM) method, considering that the following energy requirements are involved: i) heating above ambient temperature, ii) cooling below ambient temperature, iii) gas compression and liquid pumping. The calculation procedure and the parameters needed to convert them into the equivalent amount of methane can be found in the literature (De Guido et al., 2018). In addition to that, also the equivalent CO₂ emissions (Pellegrini et al., 2015) have been determined for each process scheme.

3. Process schemes

3.1. Low-temperature distillation

The process, which performs CO₂ removal by means of extractive distillation (Holmes and Ryan, 1982), has been simulated in Aspen HYSYS[®] V9.0 (AspenTech, 2016a) using the Soave-Redlich-Kwong (SRK) Equation of State. The reader can refer to a previous work (Pellegrini et al., 2018) for the process flowsheet to which some changes have been made in this work since the treated gas is a pipeline-quality gas rather than LNG. The entrainer, i.e. n-butane (nC₄), enters the extractive distillation column on the third tray from the top to avoid its entrainment. Its flow rate has been set at 10 moles/100 moles of feed and its temperature has been adjusted in each simulation to create the minimum discontinuity in column profiles. The feed gas has been subject to cooling and expansion prior entering the tower (25 theoretical trays) to reach its dew point at the operating pressure of 40 bar. The top product stream is, then, compressed to 50 bar and used for feed gas pre-cooling. The bottom product stream, which contains CO₂ and the entrainer, is expanded to 30 bar to remain under the nC₄ critical pressure, and it is fed on the 31st stage (from the top) of the regenerative distillation unit (40 theoretical trays), where CO₂ is separated from nC₄. CO₂ is recovered from the top and is, then, pumped and heated up to reach the final desired conditions. The bottom stream

from this column contains nC_4 (99.99 mol% purity), which is recycled to the extractive distillation tower, after mixing with an appropriate make-up stream, being pumped to 40 bar and cooled down to the desired temperature. This process belongs to the class of low-temperature CO_2 separation processes because of the temperature ($-85.3\text{ }^\circ\text{C}$) reached at the top of the extractive distillation column.

3.2. Physical absorption using DEPG

The physical absorption process using DEPG has been simulated in Aspen Plus[®] V9.0 (AspenTech, 2016b), selecting the “Acid gas: physical solvents” property package, which uses the PC-SAFT Equation of State. The process comprises an absorption section and a solvent regeneration section (Figure 1).

In the absorber, operated at 50 bar and consisting of 10 theoretical trays, the feed gas is contacted counter-currently with the lean solvent that is fed at the top at $20\text{ }^\circ\text{C}$. The treated gas obtained at the top of the absorber is heated up to $25\text{ }^\circ\text{C}$, when needed. The rich-solvent withdrawn at the bottom is sent to the regeneration section, which is performed in three flash drums, with the first two ones operated adiabatically and the last one operated non-adiabatically at atmospheric pressure. This requires some heat to be supplied to reach a final purity for the regenerated solvent set equal to 98.5 mol%. For inlet CO_2 contents up to 20 mol%, the first flash drum has been operated at 18 bar, whereas the pressure of the second one has been adjusted to avoid exceeding a 2 mol% content of CH_4 in the CO_2 product stream. This adjustment has turned out to be no more required at higher inlet CO_2 contents, for which the two flash drums have been operated at 27.6 and 13.8 bar, respectively (Kohl and Nielsen, 1997). The CO_2 stream separated in the regeneration section is compressed and cooled down to reach the final desired conditions. The lean solvent is recycled to the absorber after mixing with a make-up stream, pumping to 50 bar and cooling to $20\text{ }^\circ\text{C}$.

Since the heat required for solvent regeneration in the last flash drum is significant (it accounts for 56-76 % of the overall energy consumption in terms of NEM) as the CO_2 content in the inlet gas decreases from 70 to 10 mol%, heat recovery has been considered for energy-saving purposes. Indeed, the required heat can be provided by the liquid product from the third flash drum, which has to be cooled down before entering the absorber, and by the CO_2 product stream, which is available at temperatures above $500\text{ }^\circ\text{C}$ after compression. However, when the CO_2 content in the feed stream is ≤ 20 mol% additional heating is required, which is supplied by the hot compressed vapours from the intermediate flash drum (not shown in Figure 1).

3.3. Hybrid process: low-temperature distillation and physical absorption using DEPG

The hybrid process (Figure 2) is based on the Dual Refrigerant CO_2 Fractionation + Selexol flow scheme (Ross and Cuellar, 2010) and consists of a bulk removal step that reduces the CO_2 content down to 20 mol% by low-T distillation, and a finishing step performed by physical absorption into DEPG.

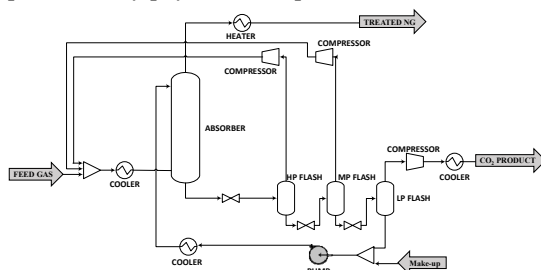

Figure 1. Flowsheet of the physical absorption process using DEPG.

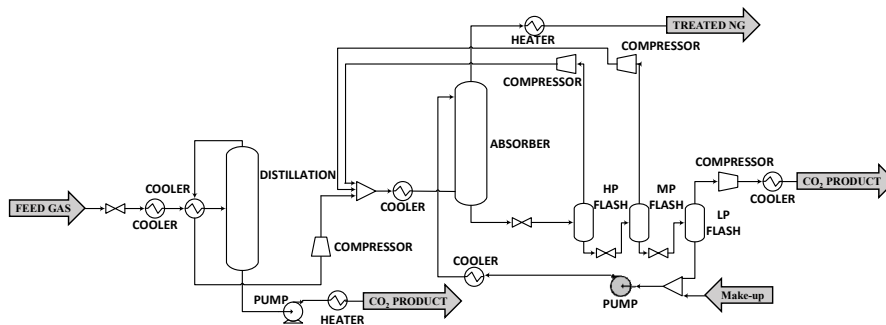

Figure 2. Flowsheet of the hybrid (low-temperature distillation + physical absorption) process.

Simulations for it have been carried out in Aspen Plus[®] V9.0 (AspenTech, 2016b), dividing the flowsheet into two sections, in which the SRK Equation of State and the PC-SAFT Equation of State have been used, respectively. The feed gas is first expanded to 40 bar, the operating pressure of the distillation column, chosen to maintain a certain margin to the critical point, avoiding higher traffic in the column. After expansion, it is cooled down (at least partially) to its dew point using the partially treated NG vapour stream exiting the top of the distillation column, which is available at about -54 °C. From the bottom of this column, pure CO₂ (99.99 mol%) is obtained, which is pumped and heated up to reach the final desired conditions. The top product of the distillation column is compressed to 50 bar and fed to the absorber, after mixing with the recycled streams from the first two flash drums in which the rich-solvent is regenerated. Prior entering the absorber, it is cooled down, assuming cooling water is used as cooling medium. The treated NG is obtained from the top of the absorber close to ambient temperature and it is heated up, when needed, to 25 °C. The rich-solvent is regenerated in three flash drums as in the process based on physical absorption only. The lean solvent is pumped to 50 bar and cooled down to 20 °C before being fed at the top of the absorber. The same energy recoveries as in the physical absorption process described above have been considered in the finishing step for improving the process energy consumptions to avoid supplying heat to the last flash by an external utility.

4. Results and discussion

Figure 3a shows the results of the energy analysis for the three process schemes described above. For CO₂ contents in the feed gas < 60 mol% the process scheme with the lowest energy requirements results to be the one based on low-T distillation. Energy requirements for the physical absorption process are slightly higher up to 25 mol% CO₂, but the difference increases significantly at higher CO₂ molar fractions. Above 60 mol% CO₂ in the feed gas, the hybrid process where the finishing step is accomplished by means of physical absorption into DEPG becomes more convenient. The same observations can be made when considering the equivalent CO₂ emissions, shown in Figure 3b. In Figure 3a, the results for another hybrid process investigated in a previous work (De Guido and Pellegrini, 2019) are also shown. In that case, the finishing step was carried out by chemical absorption into a 40 wt% MethylDiEthanolAmine aqueous solution. This hybrid process turns out to be more convenient than the physical absorption process at CO₂ inlet contents > 50 mol%, but it is more energy-demanding of the other two process configurations in the whole investigated range for CO₂ molar fractions.

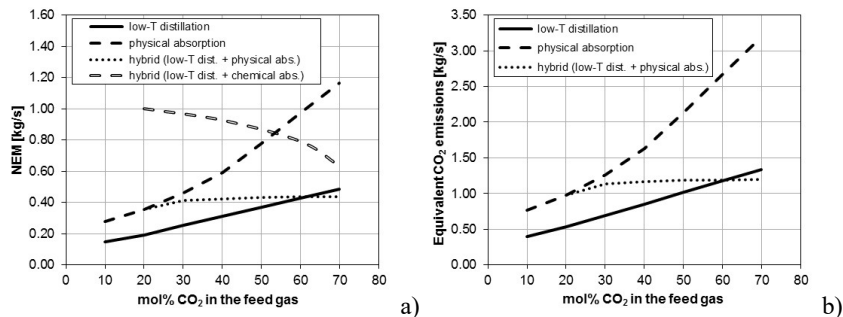

Figure 3. a) NEM consumption [kg/s], and b) equivalent CO₂ emissions [kg/s] for the three process schemes investigated in this work.

It is also important to point out that in the low-T distillation process CH₄ losses with respect to the amount of CH₄ fed to the process (Figure 4a) are practically negligible thanks to the fact that a specification on the CO₂ product purity can be directly imposed. It is also interesting to compare the different processes focusing the attention on the CO₂ product. Figure 4b shows the composition of this stream for the different investigated processes when the CO₂ content in the feed gas is 50 mol%. The bar related to the hybrid configuration refers to the composition of the CO₂ product obtained by mixing the stream withdrawn from the bottom of the distillation column and the stream recovered from the third flash in the finishing step. It is possible to state that the low-T distillation process is the only one that allows getting an almost pure CO₂ product (99.99 mol% purity). When CO₂ removal is performed by physical absorption or the hybrid configuration, the CO₂ product is contaminated with some methane, due to its co-absorption into the solvent, but not with DEPG thanks to its very low volatility.

The results presented in this work can be also interpreted in terms of operating costs. As for investment costs, some preliminary observations can be made. Considering, for example, the number of pieces of equipment, it is possible to observe it is the lowest in the process based on low-T distillation. On the contrary, the hybrid one involves the highest number of pieces of equipment, though they are of lower size with respect to those involved in each standalone CO₂ removal technology the hybrid process combines. A detailed economic analysis is required for a correct assessment of the capital expenses of the process configurations compared in this work.

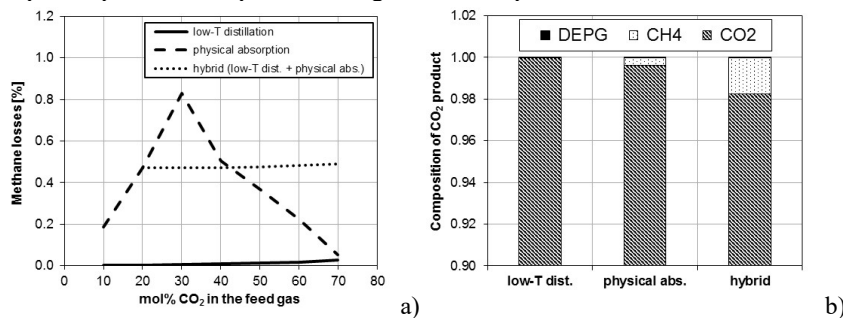

Figure 4. a) Methane losses [%] for the three process schemes investigated in this work; b) composition (molar fractions) of the CO₂-rich product obtained from the three considered process schemes when the CO₂ content in the feed gas is 50 mol%.

5. Conclusions

This work contributes to the current research on novel technologies for CO₂ removal from low-quality natural gas/biogas, which allow overcoming the high energy requirements of conventional technologies. For this purpose, three process schemes respectively based on low-T distillation, physical absorption into DEPG and a combination of the two (hybrid process) have been simulated in Aspen HYSYS® and Aspen Plus®.

The results of the energy analysis suggest that:

- i) low-temperature distillation involves lower energy consumptions and equivalent CO₂ emissions for CO₂ separation from low-quality natural gas or biogas;
- ii) the combination of low-temperature distillation for a bulk removal and physical absorption for a finishing step allows reducing the energy consumption of the process based on physical absorption only;
- iii) if methane losses and the purity of the CO₂ product stream are taken into account, low-temperature distillation has to be preferred to the other CO₂ separation processes.

Future studies will extend the comparison to other physical solvents and hybrid configurations. The latter ones are interesting options for reducing process energy consumptions, but require further research to design competitive processes taking into account factors like the properties of the feed gas and the desired purity of the products.

Abstract

In this study, polydispersed spherical particulate systems are examined using the Eulerian-Eulerian (EE) and Lagrangian-Eulerian (LE) modelling approaches in the context of wellbore cleaning operations in the drilling industry. The particle sizes considered here are between 0.5 mm and 1mm, whereas a Power Law rheological model is used for the fluid phase description. The EE approach implemented herein applies the Kinetic Theory of Granular Flow (KTGF) in ANSYS Fluent® and accounts for the particle size differences by representing them as different phases within the flow domain. In addition, the LE approach (employing the Dense Discrete Phase Model – DDPM) represents this difference with the aid of a size distribution model (the Rosin Rammler model). The findings of our computational experiments show that neglecting the size disparity may lead to severe under/overestimation of key variables such as the pressure drop, and particle deposition tendencies; thus, leading to decreased model performance.

Keywords: Polydispersity, cuttings transport, Discrete Phase Model, Rosin-Rammler

1. Introduction

Excessive drillpipe torque, slow drilling rates, and stuck drillpipe are some of the operational challenges faced by drilling engineers during wellbore cleaning (Epelle and Gerogiorgis, 2018a; Zhu et al., 2019). These problems culminate to significantly increased capital and operating expenditure over the drilling and production time horizons. Thus, numerical tools and recent advances in computing developed by the process systems engineering community have been readily applied to understand cuttings transport phenomena with complex non-Newtonian fluids under unfavourable downhole conditions. Particularly, numerous studies that apply Computational Fluid Dynamics (CFD) for the description of annular multiphase (fluid-solid) transport of dense and dilute particulate mixtures have emerged over the past decade (Yilmaz, 2012; Hajipour, 2020; Tang et al., 2020). However, a prevalent assumption in these studies is the existence of a monodispersed system of particles (both in terms of size and shape), which is never the case in real field operations. CFD studies accounting for polydispersed cuttings distribution are scarce, thus motivating the present study. We address this limitation here by applying the Kinetic Theory of Granular Flow (KTGF) and the Dense Discrete Phase Model (DDPM). A comparative assessment of these modelling methods is also presented.

2. Methodology

This study implements the EE model as the first case study for the multiphase flow description in the annulus (Fig. 1a). This model considers the particles of different diameters (Table 1) as continuous separate phases that interact with the non-Newtonian fluid phase via the interphase momentum exchange coefficient. This continuum assumption of the solid phase implies the kinematic and discrete nature of the solid phase are not explicitly accounted for; however, the application of KTGF enables the estimation of the kinematic properties via closure models. Thus, for each particulate phase, we hereby implement closure models for the granular viscosity, granular bulk viscosity, solid pressure, radial distribution and elastic modulus, respectively, using ANSYS Fluent[®].

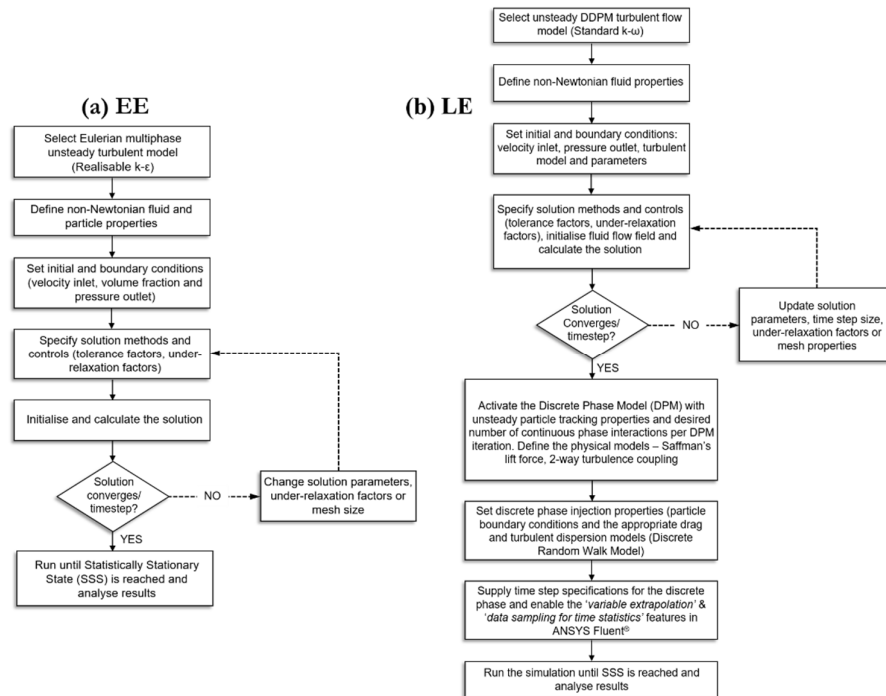

Figure 1: Implemented methodology for the EE and LE model.

Conversely, the LE model which utilises statistically computed particle trajectories coupled with an Eulerian description of the fluid phase is employed. Specifically, the DDPM is applied, given its ability to handle high particle concentrations in the annulus compared to the DPM model, which is limited to dilute particulate suspensions (<12%). For the particulate phase description, the Rosin-Rammler size distribution model is implemented (parameters shown in Table 1). The stepwise procedure for the implementation of this model is shown in Fig. 1b. Although more computationally demanding, this approach better describes the particulate phase motion via the integration of the force balance on the particles in the Lagrangian reference frame. Epelle and Gerogiorgis (2018b) discusses further contrasting differences between these approaches.

A preliminary assessment of the turbulent models in ANSYS Fluent, showed better stability of the *Realisable k-ε* model for the EE simulations and *Standard k-ω* for the LE simulations, respectively. The computational domain was constructed to model wellbore trajectories obtainable in deviated drilling operations, consisting of horizontal, inclined and vertical sections. Discretising the domain with hexahedral elements resulted in a robust mesh with 665,600 elements, and optimal orthogonality, aspect ratio and skewness factors; this yielded grid-independent results. The Quadratic Upstream Interpolation for Convective Kinematics scheme (QUICK) was applied for the discretisation, whereas pressure-velocity coupling was performed using the Semi-Implicit Method for Pressure Linked Equations (SIMPLE algorithm). Supercomputing resources with 16 processing cores (2.4 GHz Intel®-Xeon® CPU) and 32GB of RAM (University of Edinburgh) have been employed to solve the models to full convergence (time step = 0.0005; tolerance factor = 0.001). Table 1 provides further details on the boundary conditions of this study.

Table 1: Simulation input parameters.

	EE model	LE model
Computational geometry		
Casing diameter, d_c (m)	0.113	0.113
Drillpipe diameter, d_{dp} (m)	0.180	0.180
Total length, L (m)	2.340	2.340
Fluid properties		
Composition	0.5% CMC solution	0.5% CMC solution
Fluid density, ρ_l (kg.m ⁻³)	1,000	1,000
Yield stress, τ_0 (Pa)	0	0
Consistency index, K (Pa.s ^{<i>n</i>})	0.5239	0.5239
Flow behaviour index, n	0.60	0.60
Particle properties		
Cuttings density, ρ_p (kg.m ⁻³)	2,800	2,800
Sphericity, ψ	1.00	1.00
Cuttings diameter, d_p (mm) & Rosin-Rammler parameters for the LE model	0.50 (d_{p1}), 0.75 (d_{p2}), 1 (d_{p3})	Min. $d_p = 0.5$; max. $d_p = 1$; mean $d_p = 0.75$; spread parameter = 3.368; number of diameters = 3
Drilling variables		
Cuttings inlet velocity, v_p (m.s ⁻¹)	0.25	0.25
Cuttings inlet volume fraction (-)	0.15 (d_{p1}), 0.2 (d_{p2}), 0.15(d_{p3})	0.5
Drill mud (fluid) circulation velocity, v_l (m.s ⁻¹)	1.5	1.5
Wellbore eccentricity, e	0.6	0.6
Drillpipe rotation (rpm)	100	100

Particles of perfect sphericity ($\psi=1$) are utilised in this study; however, a rather complex but more realistic flow scenario is one in which both size and sphericity distribution models are applied (this is beyond the scope of this study). Computations involving this added complexity will benefit from the availability of experimental data describing such conditions; nonetheless, these are very scarce. The herein described modelling procedure, has been experimentally validated (for monodispersed cuttings) as reported in Epelle and Gerogiorgis (2018a). We present the findings from this study in the subsequent section.

3. Results and Discussion

The cuttings volume fractions for the respective particulate phases of the EE model and the LE model are shown in Fig. 1. Generally, the 0.75 mm particles occupy a significant portion of the annulus, with higher averaged volume fractions observed. This is attributable to its relatively higher inlet volume fraction compared to the other particle sizes (Table 1). However, it can also be observed that the concentration of the smallest particles (0.5 mm) at the annular base is highest, although with significantly unoccupied regions in the upper/wider annular section. Contrary to the observation in a monodispersed scenario (in which smaller particles are more readily transported by the fluid (as shown in Epelle and Gerogiorgis, 2018a), a polydispersed scenario reveals that smaller particles can cause some transport difficulties. It is worth highlighting that the maximum concentration (denoted as the dark red region) has a value of 0.25, and does not reflect a packed bed (volume fraction > 0.63 in ANSYS Fluent[®]). The LE model on the other hand shows a rather unified bulk movement of the particles (although with some faint red regions). This observation can be attributed to the implementation of size distribution model in the flow domain, in contrast to the alternative EE scenario in which the particulate phases are recognised as separate although interacting (Pang et al., 2018).

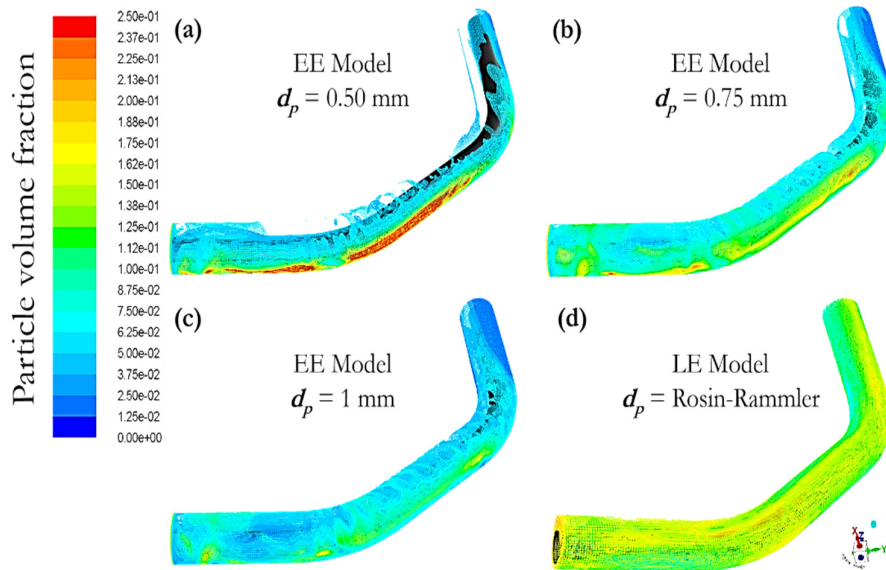

Figure 2: Particle volume fractions as calculated using the EE vs. the LE model.

On analysing the velocity contour plots for the different particle sizes of the EE model, no significant differences in the velocity magnitude were observed; thus, a single particle velocity plot of the EE model is compared with the LE model, as shown in Fig. 3. However, both plots similarly portray the wider annular sections as the regions of high velocity; this observation is attributable to the eccentricity of the domain. Furthermore, the velocities in the horizontal-to-inclined region of the annulus of the EE model shows significantly higher values compared to the LE model. The inherent treatment of the solid phase as a continuous phase and the consequent overestimation of the solid phase velocity is the likely reason for this observation, compared to the LE method, in which the discrete

behaviour of the particles is preserved. It is also worth mentioning that the EE model showed significantly better numerical stability with the specified rotary boundary condition at the drillpipe walls compared to the LE model. Hence, the rotational effect was only gradually applied (and repeatedly increased) to the LE model to ensure stability. This difference in the addition of this extra velocity component (via rotation) has also quite plausibly resulted in the higher velocities which are observed in EE model results.

Figure 3: Mean particle velocity contours as calculated using the EE vs. the LE model.

Fig. 4a presents a summary of the volume-averaged properties (over the entire computational domain) for the EE and LE model, respectively. For reasons previously explained, a 27% overestimation of the velocity by the EE model (taking the LE model as the true value) is observed. The radial velocity components for both models are similar; thus indicating that the axial and tangential velocities are the main contributors to the difference observed in the velocity magnitude. Conversely, the EE model under-predicts the volume fraction by 25% as observed in Fig. 4a. This presented volume-averaged value for the EE model was also averaged over the 3 particle diameters. The observed dissimilarity in volume fraction may be associated with the difference in the particle handling methods of both models (separate particulate phases vs. size distribution model).

Figure 4: Comparison of velocity components (similar) and pressure drop (considerably different) for EE vs. LE models. (Nomenclature for velocities - VM: velocity magnitude; RV: radial velocity; AV: axial velocity; VF: volume fraction; TV: tangential velocity).

Fig. 4b highlights a clear difference in the calculated pressure drop across the entire computation length for the EE and LE models. A discrepancy of up to 1300 Pa is observed between models. Despite the higher travel velocities observed with the EE model, the pressure drop is lower. Given the more accurate representation of the particle-particle interaction by the LE model (via individually computed particle trajectories), the resulting pressure drop from such momentum exchange is likely to be greater than that for a scenario in which constitutive (closure) relations are used, as is the case for the EE model.

4. Conclusions

This study has evaluated the influence of particle polydispersity on the cuttings transport efficiency in a deviated annulus and comparatively analysed the differences between the EE model (via KTGF) and the LE model (via DDPM). Presented velocity and particle concentration profiles indicate that flow complexity will further increase due to multiple momentum transfer mechanisms (particle-fluid and particle-particle interactions) resulting from polydispersity. The findings of our computational experiments show that neglecting the size disparity in the system may lead to an overestimation of the depositional tendencies of the particles; thus, leading to inaccurate predictions. Thus, incorporating particle polydispersity is a necessary step towards improving the predictive performance of CFD models in wellbore cleaning operations. From a computational cost perspective, the LE model required roughly 2 times the time and effort needed for the EE model. The numerical stability of the LE model proved sensitive to the rotational effect of the drillpipe. Further work may consider the effect of polydispersity in both the particle size and sphericity; such endeavours will certainly require experimental measurements for model validation purposes. Nevertheless, we must note that the CFD approach we have developed and present is based on quantitatively and qualitatively validated sub-models (under monodispersed conditions) that have achieved grid-independent solutions: no significant difference in accuracy is expected for polydispersed transport conditions.

Abstract

Organic synthesis is a critical step in producing any Active Pharmaceutical Ingredient (API): it encompasses a series of organic (mostly catalytic) reactions and separations, whose purpose is to arrive at a solution of a target molecule, which must then undergo crystallisation for purification, followed by secondary (downstream) processing towards the final (commercially available) formulation. Consequently, studying and optimising industrial-scale API production requires reliable process unit (especially reactors and separators) and system descriptions, to track key chemical (esp. impurity) concentrations. The present paper describes a Digital Twin (DT) which is currently under development for a particular API target: its goal is to evaluate multicomponent adsorption of Volatile Organic Compound (VOC) emissions from licensed salbutamol synthesis, via industrial FTIR data for mixtures of dichloromethane, chloroform, toluene, methanol and ethanol. A combination of first-principles (e.g. PDE-based adsorption) and data-driven (e.g. PCA) methodologies is essential in order to ensure techno-economically optimal performance.

Keywords: Digital Twin (DT), Hybrid Modelling, Pharmaceutical Manufacturing.

1. Introduction

Pharmaceutical manufacturing plants consist of a wide range of complex unit operations, from upstream processing aimed at synthesis of Active Pharmaceutical Ingredients (APIs) to intermediate purifications and downstream processing for final product formulation. For high plant performance at minimal total cost and solvent waste *under licensed design*, operators continuously assess key units, frequently with only input-output data available. First-principles modelling is desirable, yet parameterisation is often arduous and elusive, especially in case of inherently dynamic operation under sensor accessibility constraints.

Since API production processes are complex (Nagy et al., 2020), with several organic feeds, key intermediates and solvents, many specific interactions are not well understood. Relying on first-principles models (FPM) with hundreds of Partial (PDE) or Ordinary Differential (ODE) and/or Algebraic Equations (AE) is impractical, since such equation systems are costly to formulate and cumbersome to parameterise under time pressure. Statistical (e.g. Latent Variable) methods such as Principal Component Analysis (PCA) are widely used to explore industrial data (if abundant) and discover causality patterns. Employing data-driven models (DDM) to bridge the model fidelity gaps is imperative, especially with industrial production Big Data routinely stored. Operational challenges may however impede DDM use without a FPM basis, especially for licensed processes. For example, an existing (legacy) DDM approach may credibly capture API plant yield and key output quality attributes, but also miss secondary performance characteristics (e.g. VOC emissions) entirely, just because it was neither meant nor built to address them.

Numerous recent publications present elaborate process model implementations aimed at plantwide pharmaceutical process design: frequently high fidelity has been ensured by employing detailed kinetic (e.g. Arrhenius), thermodynamic (e.g. UNIFAC, PC-SAFT) and/or material property submodels based on or developed via previously published data. Techno-economic optimisation studies based on such high-fidelity submodels credibly pinpoint process improvements and quantify savings vs. current API production protocols (Jolliffe & Gerogiorgis, 2016; Diab & Gerogiorgis, 2019), but in all cases require access to (and abundance of) public-domain datasets, invariably unavailable for new ventures.

Hybrid process modelling has emerged as an industrially promising alternative which receives ever-increasing literature attention (Oliveira, 2004; von Stosch et al., 2014; Glassey & von Stosch, 2018, Yang et al., 2020); a recent comprehensive review (Chen et al., 2020) and some implementations, mostly in secondary (downstream) pharmaceutical processing (Ismail et al., 2019; Bascone et al., 2020) have showcased its definite potential. Nevertheless, exploring and securing the validity domain of hybrid modelling approaches is not trivial, especially regarding feasibility (Kahrs & Marquardt, 2007; Bae et al., 2020). The latter study distinguishes two types and three broad categories of hybrid models: in the first (serial) type and category, the black (DDM) only informs the white (FPM) box. In the second (embedded) type, the two are either separate (but fully interacting) entities (with the FPM however being the only handling final outputs), or are entirely fused without executional distinction, featuring full integration at higher development expense. Dynamic optimisation relies on valid domain constraints extracted from the use of DDM.

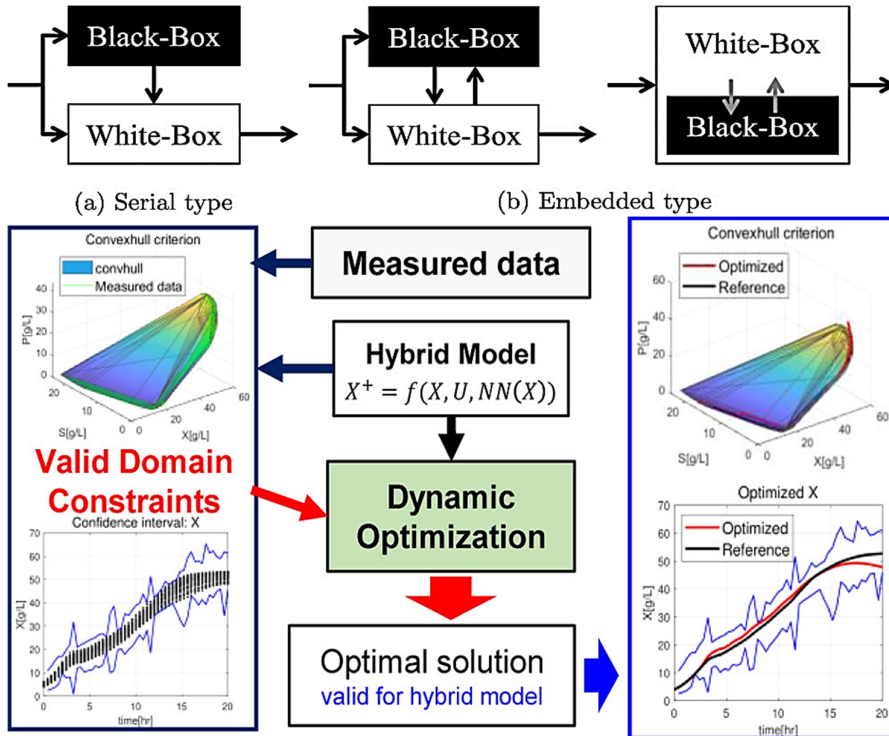

Figure 1: Hybrid model structures and dynamic optimisation strategy (Bae et al., 2020).

2. Salbutamol Manufacturing Process Description

Salbutamol is a proven bronchodilation medication: reliably expanding lung airways to comfort patients with respiratory conditions, it is commonly prescribed against Chronic Obstructive Pulmonary Disease (COPD), bronchitis, emphysema and other ailments. Manufacturing this API requires 4 feedstock compounds (*diacetate*, *glycyl*, *benzyl*, *base*), all produced in the *licensed plant* within a salbutamol batch production schedule (Fig. 2). Prior to this project, the first two (*diacetate* and *glycyl*) subsystems were conclusively identified as the two major VOC sources, thus forming the exclusive focus of our study. Therein, VOC emissions originate from distillation units needed for solvent separation. Mass balance analysis for the majority of VOC emissions has previously indicated that: (1) for *diacetate production*, VOCs come from dichloromethane (DCM) atmospheric and vacuum distillation (occurring in vessel 3/V3), and toluene distillation (in vessel 4/V4). (2) for *glycyl production*, VOCs originate from chloroform and toluene distillation (V3).

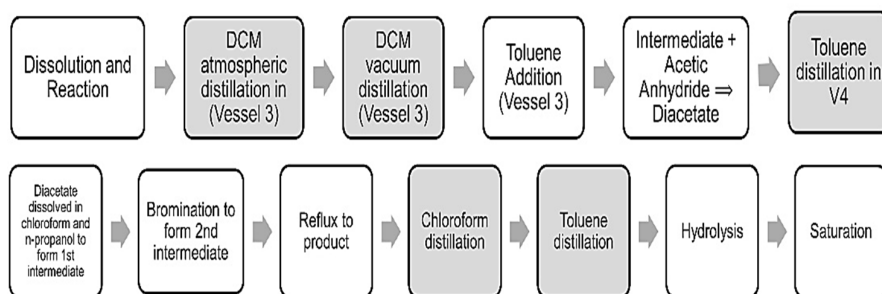

Figure 2: Diacetate (top) and glycyl (bottom) production schedules (grey denotes separation steps).

Fig. 3 shows the licensed VOC abatement system: all solvent emissions from salbutamol production are simultaneously fed to the same treatment (fixed activated carbon bed) unit. Technical (VOC abatement efficiency) but also economic (Operating Expenditure/OpEx) performance strongly depend on this subsystem, whose operation is not fully quantified.

Figure 3: The VOC abatement system (a star denotes the FTIR sensor sampling point of the stack).

3. A Digital Twin (DT) for VOC Capture and its Potential in Pharma 4.0

A *Digital Twin (DT)* is a software entity interfaced with hardware, enabling simulations to probe how design/control changes affect performance, but also e.g. maintenance needs. When interfaced with process (measured) data, DTs can continuously improve and grow (e.g. re-parameterisation via DDM and/or AI), thus ensuring sustainable model relevance. Advances via DT use emerge rapidly in Pharma 4.0 (Casola et al., 2019; Lopes, 2020; Rasheed et al., 2020), at considerably faster pace than other fields (Aversano et al., 2020).

Chemical synthesis of APIs relies on organic solvents (alcohols, ketones, halogenated hydrocarbons) for conducting reactions and separations at adequate yield and safety. Many VOCs evaporate at temperatures much lower than 100 °C: due to high toxicity and catastrophic environmental impact, they must be reliably captured from gas emissions of several units: feed patterns, volumes and conditions govern unit performance (Fig. 4), Consequently, adsorbent material procurement and/or regeneration costs are a challenge. There are *two major technical problems* with the efficiency of modern VOC capture units:

- *First*, the VOC adsorption carbon beds can be quickly and irregularly saturated, due to the widely variant gas feed composition. Consequently, the bed (activated carbon) material must undergo frequent regeneration, a costly task invariably outsourced.
- *Second*, the impure feed stream composition (from the numerous organic synthesis miniplants hosted within a single multi-purpose API manufacturing site) always varies widely in terms of organic solvents, volumes and loads contained in emissions, affecting VOC capture performance, efficiency and above all the total annual cost.

Figure 4: Operating principle and internals of a commercial VOC adsorption column (Forbes, UK).

The present paper addresses the analysis (towards optimisation) of multicomponent VOC adsorption from pharma emission mixtures on industrial activated carbon beds (Fig. 3-4). This project aims to combine first-principles (physics-based) and data-driven process modelling, to create and use a **Digital Twin** (advanced performance evaluation system), to understand, interface datastreams and improve the VOC capture unit at an API plant. The validated Digital Twin can be used to **analyse and predict** carbon bed performance against feed composition variation, and thus comparatively evaluate improvements (e.g. feed gas routing) via **techno-economic (cost) optimisation** (MILP/MINLP) methods.

The key goals of this ongoing project are to: **(1)** Use formal **Data Analytics**, i.e. Principal Component Analysis (**PCA**) to extract process features and elucidate key trends; this has already born fruit, producing key original results towards DDM of VOC capture (Fig. 5), **(2)** Develop **FPM for Multicomponent Adsorption** and study various key VOC mixture combinations, thereby quantifying the effect of feed variability on bed operation (Fig. 5), **(3)** Build and validate the **DT**, evaluating its **predictive potential** vs. VOC bed history, **(4)** Compare **DT simulation predictions** vs. plant efficiency data for given API batches, **(5)** Perform **DT-based dynamic optimisation** to reduce Operating Expenditure (OpEx) via optimal gas routing and mixing, under API plant throughput and emission constraints. Our DT combines best-in-class components: physics-based (FPM) descriptions rely on detailed equation systems capturing macro- (flow) and micro- (adsorption) transport phenomena, emission thermodynamics/phase equilibria, and VOC capture vessel design. Industrial data on VOC emissions vs. production conditions have been compiled from a dedicated gas monitoring station for the salbutamol API plant (Montrose, Scotland, UK), with special attention to VOC-critical production stages (namely distillation separations). Statistical (DDM) descriptions successfully use Principal Component Analysis (PCA), an established methodology we employ to correlate feed compositions (and changes) to bed output patterns, since breakthrough times (esp. due to selective adsorption) vary greatly.

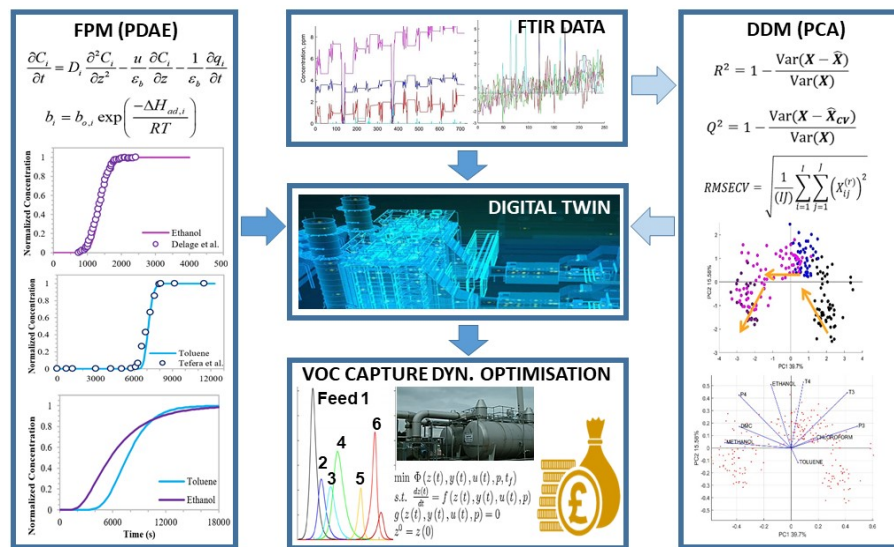

Figure 5. DT architecture: FPM and DDM frameworks and results towards dynamic optimisation.

A DT attains real economic value when *interfaced with process measurements*, hence datastream procurement from both inlet and outlet points of the VOC capture bed is key. The combination and complementarity of FPM and DDM offers unprecedented potential. Design (column flow topology) and operational (feed gas stream mixing and/or routing) modifications can be tested (and benefits computed) *in silico*, prior to hopeful adoption. Once the VOC capture DT is conclusively validated vs. industrial data, it will be used to:

- Quantify VOC capture (carbon bed) performance in detail
- Map VOC capture efficiency vs. feed/condition variations
- Evaluate and identify superior gas emission handling protocols
- Perform a comparative techno-economic analysis of all promising modifications
- Propose respective VOC capture trial runs for the API manufacturing plant.

4. Conclusions

Elaborate plantwide process models describing complex upstream (API) manufacturing need accurately capture thermodynamics (phase equilibria), separations and economics for many operating scenarios and conditions (pressure, temperature, feeding, mixing), but parameterising them is a laborious affair, given the multiphase and multicomponent mixtures and the resulting complications ubiquitous in API syntheses (Nagy et al., 2020). Licensed pharmaceutical manufacturing inevitably relies on significant solvent volumes for many (especially reaction/separation) uses, with environmental repercussion risks. The Digital Twin (DT) addressing VOC emissions abatement uses formal Data Analytics, has identified causality patterns via industrial production data, and develops predictive potential for dynamic cost optimisation of a VOC capture unit (feed patterns, conditions).

Abstract

One of the main drawbacks of the so-called two-step approach in Real-time Optimization (RTO) is the long waits for stationary operation. To overcome this issue, a hybrid RTO (HRTO) approach has been proposed in the literature in which a dynamic estimation is carried out, followed by economic optimization. Despite generally presenting a good performance, the original proposition is highly dependent on the availability of a dynamic process model, which could hinder or even make the design of a plant-wide HRTO infeasible. In this work, an HRTO strategy able to perform in the absence of a rigorous dynamic model is developed. A Hammerstein model structure is proposed to replace the dynamic model, and three HRTO architectures are introduced. These architectures are compared to the original HRTO and to a two-step static RTO without the steady-state detection stage. The approaches with less internal model variation present better performance over the approaches that are more sensitive to changes due to the arising of undesirable oscillatory behavior. This issue must be further investigated and overcome.

Keywords: Real-time Optimization, Parameter Estimation, Kalman Filter, Surrogate models, Williams-Otto Reactor.

1. Introduction

Real-time optimization (RTO) is a term commonly used in reference to a class of optimization strategies that uses real-time measurements in an optimization feedback loop in order to overcome uncertainties and achieve process optimality under a certain set of constraints (Darby et al., 2011). One of the most accepted classifications of RTO methods divide them on how the measurement is used to adapt the optimization problem. In the implicit methods, the adaption is carried out directly on the input variables such as in Self-Optimizing Control (Skogestad, 2003), Necessary Condition of Optimality (NCO) tracking (Srinivasan et al., 2003), and Extremum-Seeking Control (Morosanov, 1957). Within the class of explicit methods, an additional subdivision considers whether the adaption is carried out in the process model or in the optimization problem itself. In the first subclass, it is assumed that the main source of uncertainty is parametric such as in the two-step approach (Jang et al., 1987), in which a static

parameter estimation problem is solved before an economic optimization. In the second one, it is assumed that the source of uncertainty is due to structural mismatch between the process model and plant. Hence, modifiers are added to the optimization problem in order to match the Karush-Kuhn-Tucker (KKT) conditions of the model-based problem to the real plant problem, such as in ISOPE (Gao and Engell, 2005), Constraint Adaption (Marchetti et al., 2008) and Modifier Adaption (Chachuat et al., 2008).

The so-called two-step approach is the most widespread RTO method in industry (Câmara et al., 2016). However, the long waits for steady condition, especially in frequently disturbed or slow dynamic processes, is one of the main drawbacks of the strategy (Darby et al., 2011). In this context, two different research groups proposed to replace the static parameter estimation with a dynamic parameter estimation, such as the Extended Kalman Filter, giving origin to the Hybrid Real-Time Optimization (HRTO) approach (Matias and Le Roux, 2018; Krishnamoorthy et al., 2018). Despite generally presenting satisfactory performance results, the HRTO depends on the availability of a rigorous dynamic process model, structurally similar to the static process model, which is costly, time-consuming, and could even make the design of a plant-wide HRTO infeasible. Herein, the term “rigorous dynamic process model” is used in reference to a dynamic phenomenological model based on first principles of mass, energy, and momentum balances. In order to overcome this drawback, in this work, three HRTO architectures that are able to perform in the absence of a rigorous dynamic model are developed and compared.

2. Hammerstein model structure

It is assumed that an adequate static model of the plant is available:

$$\begin{aligned} 0 &= F(x^s, u, \theta) \\ y^s &= G(x^s, u, \theta) \end{aligned} \quad (1)$$

in which, $x^s \in R^{n_x}$ are the state variables in stationary state, $y^s \in R^{n_y}$ are the measured variables in stationary state, $u \in R^{n_u}$ are the input variables and $\theta \in R^{n_\theta}$ are the vector of parameters and unmeasured disturbances on which uncertainty occurs. In addition, the functions $F: R^{n_x} \times R^{n_u} \times R^{n_\theta} \rightarrow R^{n_x}$ and $G: R^{n_x} \times R^{n_u} \times R^{n_\theta} \rightarrow R^{n_y}$ are the static mapping of the states and the outputs related to the inputs and parameters, respectively. For the sake of simplifying notation, this model will be represented as $y^s = y^s(u, \theta)$.

A general Hammerstein structure consists of a static mapping of the inputs and parameters into the output variables and a linear dynamic model to make the transition from the current state to the mapped steady state. Considering a discrete linear dynamic model of the type of autoregressive with exogenous input (ARX) to approximate the plant dynamics, the Hammerstein model is given by:

$$y_k^h = A_k y_{k-1}^h + B_k y_{k-1}^s(u_{k-1}, \theta_{k-1}) \quad (2)$$

in which, $y_k^h \in R^{n_y}$ is the vector of output variables provided by the Hammerstein model at instant k . In addition, the squared matrices A_k and B_k gather the dynamic parameters to be identified from process data during operation, but can also be kept constant. Here, two models are proposed which exploit this structure, they are:

- i. model 1: $B_k = (I - A_k)$;
- ii. model 2: A_k and B_k are independent.

It is noteworthy that model 1 presents the property to match the stationary conditions of the static model, and it has half of the number of dynamic parameters to be identified compared to model 2.

3. HRTO architectures

The proposed HRTO architectures based on the Hammerstein model presented in Section 2 are described below:

- **HRTO-HEKF-fixed**: the adjustable parameters are estimated by an Extended Kalman Filter (EKF) layer that considers the Hammerstein model as its internal dynamic model, named Hammerstein EKF (HEKF), wherein the dynamic matrices of the model are kept constant. The estimated parameters are then kept fixed in a subsequent static optimization layer;
- **HRTO-HEKF-adaptive**: the adjustable parameters and the dynamic matrices of the Hammerstein model are simultaneously estimated by the HEKF layer;
- **HRTO-HEKF-RELS**: the adjustable parameters are estimated by the HEKF layer, but the dynamic matrices of the Hammerstein model are estimated by a Recursive Extended Least Squares (RELS) estimator with a forgetting factor.

These approaches are compared with the following architectures:

- **HRTO-EKF**: the original HRTO, in which the true dynamic model of the process is known and the adjustable parameters are estimated by an EKF layer;
- **RTO-LSE**: the original two-step RTO, in which the adjustable parameters are estimated by a nonlinear Least Squares Estimator (LSE) subjected to the static model. In this approach, no steady-state detection is performed, so the LSE runs regardless of the dynamic nature of the data.

3.1. Hammerstein EKF algorithm

The algorithm for the parameter estimation in the EKF framework is very well described in the Appendix of Krishnamoorthy et al. (2018). Using their nomenclature, the application for Hammerstein models gives the following augmented *a priori* state estimation:

$$\begin{bmatrix} y_{k|k}^h & \theta_{k|k} \end{bmatrix} = \begin{bmatrix} A_k y_{k-1}^h + B_k y_{k-1}^s(u_{k-1}, \theta_{k-1}) & \theta_{k|k-1} \end{bmatrix} + \begin{bmatrix} w_{y,k} & w_{\theta,k} \end{bmatrix} \quad (2)$$

in which, $w_{y,k}$ and $w_{\theta,k}$ are artificial zero-mean noise, so that $w_{y,k} \sim N(0, Q_y)$ and $w_{\theta,k} \sim N(0, Q_\theta)$. Therefore, the process noise covariance matrix is augmented as

$\tilde{Q} = \text{diag}([Q_y, Q_\theta])$. In the HRTO-HEKF-adaptive the elements of the dynamic matrices are estimated simultaneously to the adjustable parameters, so the columns of these matrices are stacked up and concatenated with vector θ .

3.2. RELS algorithm

The algorithm of the RELS with forgetting factor α is very well presented in Rodríguez-Blanco et al. (2017). Using their nomenclature, the application for the Hammerstein models are $\hat{\phi}_k = y_k^h - y_k^s$, $\varphi_{k-1}^T = y_{k-1}^h - y_{k-1}^s$ and $\hat{\beta}_k = (A_k)^T$ for model 1 and $\phi_k = (y_k^h)^T$, $\varphi_{k-1}^T = \left[(y_{k-1}^h)^T, (y_{k-1}^s)^T \right]$ and $\hat{\beta}_k = \left[(A_k)^T, (B_k)^T \right]^T$ for model 2 and the initial covariance matrix of the prediction error is given by $\Sigma_0 = I/\alpha$.

4. Case Study: The Williams-Otto Reactor

The Williams-Otto Reactor with three reactions was exploited as a case study. It is a classical benchmark for real-time optimization studies, where several phenomena can be observed, such as inverse response and change of the gain sign. Its equations, parameter values, and notations can be found in Forbes and Marlin (1996).

In this study, we consider X_C as an unmeasured variable, so the set of measured variables are $y = [X_A, X_B, X_E, X_P, X_G]^T$, the degrees of freedom of the optimizer are $u = [F_B, T_R]^T$ and the set of adjustable parameters were in fact two unmeasured disturbances $\theta = [F_A, W]^T$. The kinetic parameters were considered fixed and perfectly known. To initialize the Hammerstein models, an offline identification problem was run around a nominal point, $u_n = [2, 70]^T$ in $[kg/s, ^\circ C]$ and $\theta_n = [1.8275, 2105]^T$ in $[kg/s, kg]$, distant from the nominal optimum point, $u^* = [4.2, 85.9]^T$ in $[kg/s, ^\circ C]$. Finally, a scenario of parameter variation was designed to test the approaches. For the approach HRTO-HEKF-RELS, two values of the forgetting factor α were tested, 0.5 and 0.99. A sampling time of 60s was considered in a simulation window of $N = 450$ sampling times in which a decreasing ramp was subjected to the reactor holdup, W , and a pulse disturbance was subjected to the feed flow rate of A , F_A , as shown in Figure 1.

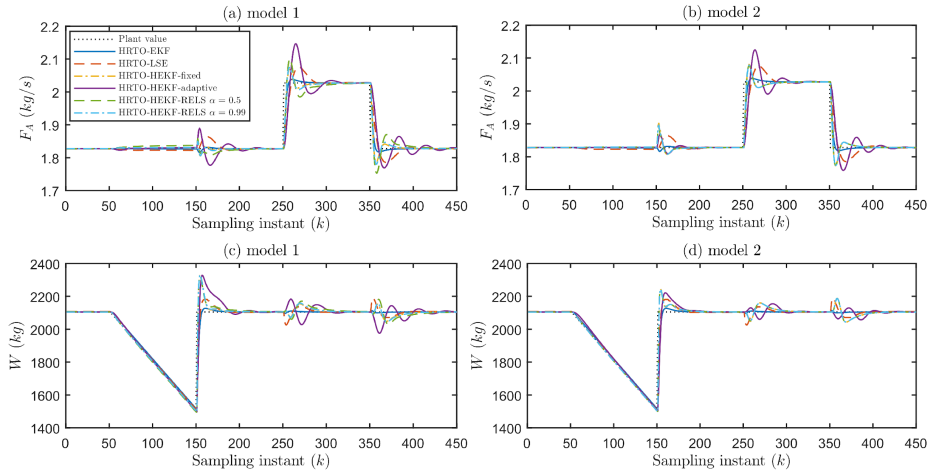

Figure 1: Performance of the different HRTO architecture over a scenario of parametric variation: (a) estimation of F_A with HEKF and RELS using model 1; (b) estimation of F_A with HEKF and RELS using model 2; (c) estimation of W with HEKF and RELS using model 1; (d) estimation of W with HEKF and RELS using model 2.

In order to compare all approaches in this scenario, a normalized Mean Squared Error (nMSE) for each variable is shown in Table 1.

Table 1: nMSE comparison between HRTO architectures

Variables	HRTO-EKF	RTO-LSE	model 1				model 2

The nMSE for each variable i , using the true plant value as reference, is given by:

$$nMSE_i = \sum_{k=1}^N \frac{\hat{y}_{i,k} - y_{i,k}^p}{y_{i,k}^p} \quad (2)$$

in which, the hat emphasis $\hat{(\cdot)}$ and the superscript $(\cdot)^p$ represent the estimated value and the true plant value, respectively.

It is straightforward from Figure 1 that all approaches were able to estimate the true value of the parameters after a stabilization period, which confirms the potential of the Hammerstein approaches to substitute the rigorous dynamic model in the architecture of the HRTO, opening up a vast range of possibilities of applications. Surprisingly, the RTO-LSE presented a good performance in parameter estimation during transient regions, suggesting that HRTO could be applied directly to classic RTO structures, just by removing the steady-state detection stage and increasing the running frequency of the optimization loop. However, this approach is the most costly one among the other structures analyzed, as shown in Table 2, it is almost 11.5 times more costly than EKF and 23 times more costly than the proposed HEKF. This preliminary conclusion about the RTO-LSE should be verified by testing with many other case studies.

Table 2: Average time consumption for each stage in loop (ms)

Stage	HRTO-EK F	RTO-LSE	model 1				model 2			
			HRTO-HEKF		HRTO-HEKF-RELS		HRTO-HEKF		HRTO-HEKF-RELS	
			fixed	adaptive	$\alpha = 0.5$	$\alpha = 0.95$	fixed	adaptive	$\alpha = 0.5$	$\alpha = 0.95$
Plant Optimization	2.04	2.08	2.08	2.08	2.25	2.05	2.07	2.08	2.40	2.15
Estimation	1.94	22.94	0.74	0.98	0.95	0.86	0.69	1.03	0.98	0.82
Model Optimization	11.92	12.81	11.95	12.03	12.95	12.03	11.99	12.09	13.69	12.23
Total simulation loop	16.95	39.31	15.89	16.35	17.35	16.07	15.84	16.49	18.35	16.31

In general, approaches using model 1 presented a greater adaption capability over approaches using model 2, due to the lesser number of parameters to estimate. However, this capability does not necessarily reflect better parameter estimation; in fact approaches using model 2 presented a greater overall accuracy on parameter estimation. In addition, the approach HRTO-HEKF-RELS with $\alpha = 0.99$ was very similar to the HRTO-HEKF-fixed for both models, which is a reflection of the low adaptability capacity of the RELS strategy with high value of the forgetting factor. For the approaches HRTO-HEKF-RELS with $\alpha = 0.5$ and HRTO-HEKF-adaptive, the higher adaptability capacity was able to reduce the nMSE for the output variables, but presented a worst parameter estimation accuracy than the HRTO-HEKF-fixed, even though the models used in this approach were identified far from the operating point and in a fixed parameter scenario.

It is noteworthy that the approach HRTO-HEKF-adaptive presented an undesirable oscillatory behavior, which appears due to the arising of oscillatory modes in the Hammerstein models during operation. This effect should be avoided and further investigated.

5. Conclusion

In this work, different HRTO architectures were proposed based on the use of a Hammerstein model structure that combines the available static process model with a linear ARX identified from past data to provide approximate dynamics. Therefore, the requirement of availability of a rigorous dynamic process is removed from the original proposition of the HRTO, enabling it to be used in a large range of applications. The proposed methodologies showed satisfactory performances in parameter estimation and adequate computational costs. However, they presented no resources to prevent the arising of unstable and undesirable oscillatory modes on the Hammerstein model during the adaptive process, this should be further investigated.

Abstract

Methanol is a clean fuel and is considered an important chemical feedstock. It is usually produced by catalytic conversion and can be produced from carbon dioxide and thus could significantly contribute to the reduction of direct CO₂ emissions to the atmosphere. Despite a number of technologies have been developed for its synthesis, post-production treatment is fundamental for obtaining a high purity methanol stream. Purification is generally carried out by distillation, with significant energy consumption.

The raw product exiting from the methanol production section is mainly composed of methanol and water, with traces of other components and is fed to the purification section. This section is composed of two separation units. The first unit aims at removing the low boiling impurities which exit from the top and the second one, the most energy demanding, treats the heavier stabilized methanol-rich stream to increase its concentration in methanol for obtaining a product with high purity.

This work focuses on the optimization of the process, with the study of possible modifications for obtaining energy saving and the selection of the best one on the basis of a techno-economic analysis.

Simulations have been carried out by using the commercial software ASPEN Plus[®]. The thermodynamic method based on the Non-Random-Two-Liquid (NRTL) model, suitable for this system and for the low pressure conditions, has been employed and a rate-based approach has been considered for simulating the columns.

The alternative configurations favour a reduction of the influence of the methanol purification section on the total costs of the production plant.

Keywords: methanol, distillation, energy saving, configurations, economic analysis.

1. Introduction

Methanol can be produced from fossil or renewable sources and is employed for energy production in the marine, automotive and electricity sectors (Ptasinski et al., 2002), in addition to be a fundamental commodity in the chemical industry, used for plastics, paints and cosmetics (Methanol Institute, 2020). The chemist George Andrew Olah was a great supporter of the "methanol economy" for the capability of this compound to provide an efficient mean to store energy and of being used as a convenient fuel as well as a raw material for synthetic hydrocarbons and their products, thinking of it as a possible substitute to natural oil and gas (Olah, 2004, 2005, 2013; Olah et al., 2018).

Methanol is mainly produced from syngas or by other routes starting from methane (Lange, 1997, 2001). Generally, most of the production comes from natural gas, though about 10% originates from distillation of heavy cuts of oil or from coal in locations where

natural gas is not available or cannot be easily supplied. Its production is usually obtained by catalytic conversion also starting from the CO₂ removed from other streams, therefore it could significantly contribute to the reduction of direct greenhouse gas emissions to the atmosphere (Van-Dal and Bouallou, 2013). The methanol price is characterized by fluctuations depending on the market conditions and on the market locations, so that values ranged from 500 \$/ton to 190 \$/ton in the last three years (MMSA, 2020). For this reason, a low-cost production is fundamental. In particular, post-production treatment is needed for obtaining a high purity methanol stream and is generally carried out by distillation, with relevant energy consumptions (Zhang et al., 2010).

In the literature, many works focused on the production path of methanol. Some researchers proposed different kinetic models for the synthesis of this substance, considering different catalysts, while other authors studied the overall scheme of production (Zhang et al., 2016) starting from different raw materials (Rivarolo et al., 2016), including sugarcane bagasse (Renó et al., 2011), CO₂ removed from other industrial processes (Abdelaziz et al., 2017; Atsonios et al., 2016; Kourkoumpas et al., 2016; Pérez-Fortes et al., 2016; Szima and Cormos, 2018) and also renewable hydrogen (Galindo Cifre and Badr, 2007) or using different types of energy as the solar one (Kim et al., 2011). Only few papers focused on a reduction of the economics of the process through the analysis and the comparison of different schemes (Shahandeh et al., 2014; Shahandeh et al., 2015). Doulas and Hoadley (Douglas and Hoadley, 2006) performed a thermal and economic comparison of schemes with two and three columns, with enhanced heat integration. Sun et al. (Sun et al., 2012) considered a 5-column heat integrated distillation scheme and compared the obtained savings with the 4-column scheme though with a higher capital cost and complexity of operating many distillation columns. Kiss et al. (Kiss et al., 2016) proposed the addition of a stripping unit with wet hydrogen to remove CO and CO₂ from the water-methanol mixture. Many works (Abdelaziz et al., 2017; Atsonios et al., 2016; Pérez-Fortes et al., 2016; Szima and Cormos, 2018; Van-Dal and Bouallou, 2013), then, considered a scheme based on the presence of a flash and a distillation column, though without focusing on the optimization of the purification section. This type of scheme has been considered in the present work.

The aim of this paper is the study of different configurations for the section of purification of the raw methanol stream in order to determine the one which reduces the investment costs and the operating costs, mainly due to the energy consumptions on the basis of a techno-economic analysis.

2. Methodology

The mixture considered in this paper contains mainly methanol and water (the ratio methanol / water is equal to 1.96), with traces of ethanol and other light gases residual from the previous steps of reaction. The purification section must produce a methanol-rich stream of AA grade, according to the International Methanol Producers and Consumers Association (IMPCA), for which a minimum weight fraction of methanol in the product stream of 0.9985 is required, with a content of water lower than 0.1 % wt. As additional specification, in this work a recovery of the methanol entering the purification section of at least 90% has been considered.

The simulations for the design and the evaluation of the performances of the different schemes have been carried out in ASPEN Plus[®], selecting for the thermodynamic description of the system a γ/ϕ method based on the Non-Random Two Liquids (NRTL) theory (Renon and Prausnitz, 1968), which has been found accurate for the representation of the phase equilibria of the components of the feed stream (Allocca, 2020). The tool

Sensitivity provided within the process simulator has been employed for analyzing the influence of the main parameters of the column.

All the obtained results have been used as input for the economic analysis, which includes the evaluation of both investment and operating costs, performed on the basis of the *Preliminary Design Estimate* method and the average operating costs reported in Turton et al. (Turton et al., 2012) and the optimal configuration has then been identified.

3. The considered schemes

In this section the three considered configurations are described. The first one (*Scheme A*), taken as reference, is the simplest one while the other ones, *Scheme B* and *Scheme C*, are characterized by the addition of a heat exchanger and also of a splitter in order to obtain economic advantages.

Indeed, since the reboiler duty represents the main operating cost of this plant and energy management is recognized as a key point in the design of chemical processes (Luyben, 2020), *Scheme B* and *Scheme C* have been analysed and optimized in order to minimize both investment costs and operating costs.

3.1. Scheme A

One single distillation column cannot perform the separation for obtaining a product stream with all the above-mentioned specifications, mainly because of the presence of the residual gases from reaction in the feed stream. Therefore, a flash or another distillation column are usually employed to remove this incondensable species upstream of the column used for the separation of methanol and water.

The raw methanol stream (stream 1) is fed to the flash unit, where most of the lightest components are removed and exit from the top (stream 2). The liquid stream (stream 3), rich in methanol and water, is fed to the distillation column, provided with a partial condenser and a partial reboiler (Figure 1).

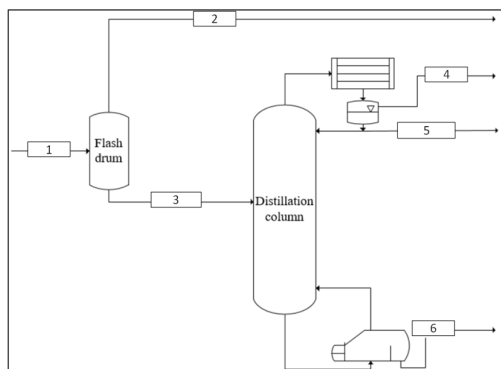

Figure 1. Base scheme (*Scheme A*) for the purification section of the methanol production plant.

The methanol-rich stream (stream 2), with the required specifications, is obtained at the top of the column as liquid distillate, while a water-rich stream with a small amount of ethanol exits from the bottom of the unit. The vapor distillate is composed of the incondensable gases which have not been removed in the previous flash. The pressure of the feed, equal to 2 bar, is reduced to 1.25 bar to separate most of the gases from the liquid in the flash, before entering the distillation column, operated at atmospheric pressure.

The characteristics of the column (height, feed stage, bottom to feed ratio) have been optimized with the aim of fulfilling the required specifications while maintaining low investment and operating costs.

3.2. Scheme B

A common method for energy saving consists in pre-heating the stream fed to the distillation column with the bottom product stream exiting the reboiler in a process-process heat exchanger. The water-rich stream is fed to the hot side of the unit for heat transfer, where it is cooled, transferring its heat content to the cold fluid, the liquid exiting from the flash unit to be warmed.

The variation in the feed temperature influences the profiles inside the distillation column, so that for the same column height of *Scheme A*, the optimal bottom to feed ratio and feed stage have been determined.

3.3. Scheme C

A splitter for dividing the flash liquid product stream before the heat exchanger can be added to achieve a reduction in the reboiler duty (Deshmukh et al., 2005) because of the higher temperature obtained for the preheated stream. In particular, the liquid exiting from the flash (stream 3 in Figure 1) is split into two streams, with the same composition and with the flowrate depending on the splitting fraction. One part of the stream is directly fed to the distillation column without variations in its temperature, while the other part is fed to a process-process heat exchanger similar to the one of *Scheme B* for pre-heating and is then fed to the distillation column at a different height. When the splitting fraction, defined as the fraction of stream directly fed to the distillation tower, is equal to 0, the process layout of *Scheme B* applies, with all the stream being pre-heated before being separated in the distillation column, while when the splitting fraction is equal to 1 the base scheme (*Scheme A*) is considered, with no pre-heating.

The splitting fraction and the feed stages of the two streams entering the column have been optimized for *Scheme C*. To determine the values of these variables an iterative procedure has been applied, since the result of each one depends on the value of the other ones.

4. Results

Table 1 reports the results of the economic evaluation of the plant, as for the investment costs and for the operating costs. When compared to *Scheme A*, *Scheme C* results in the largest savings, with an 11.23% reduction in capital costs and a 13.32% reduction in operating expenses.

Table 1. % variation in investment and operating costs obtained with *Scheme B* and with *Scheme C* if compared to *Scheme A*.

	% variation in investment costs	% variation in operating costs
<i>Scheme B</i>	+1.93%	-1.24%
<i>Scheme C</i>	-11.23%	-13.32%

For *Scheme B*, the exchange of heat between the hot stream, available at a pressure slightly above the atmospheric one and at about 100°C, and the cold stream at 40°C makes the overall stream fed to the column at a temperature higher than the one in *Scheme A*. However, because the flowrate of the water-rich stream exiting the reboiler is much lower

than the one of the cold stream, this latter reaches only the temperature of 55°C if a $\Delta T_{\text{approach}}$ of 5°C is considered.

As for *Scheme C*, the optimal result is for a splitting fraction equal to 0.9, which allows for obtaining the lowest reboiler duty. The resulting profile in the process-process heat exchanger is reported in Figure 2. Due to the lower flowrate of stream to be heated, the temperature increases much more than the one of the hot stream in *Scheme B*. The hot stream enters the column with a vapour fraction of about 20%, reducing the energy requirements for the reboiler.

Figure 2. Temperature profiles for the hot and cold streams in the process-process heat exchanger for *Scheme C*.

5. Conclusions

This work focused on the study of a methanol purification plant, being methanol a relevant clean fuel and a chemical feedstock. The analysis of different configurations for the section of purification of the raw methanol stream has been carried out in order to obtain a methanol product with the specifications required by IMPCA while minimizing the costs. Three different schemes have been considered, a base case with a flash unit and a distillation column and two more complex cases, characterized by the pre-heating of all the stream fed to distillation (*Scheme B*) or by the splitting of this stream to have only a partial pre-heating before entering the column (*Scheme C*). On the basis of the techno-economic analysis carried out, *Scheme C* resulted the most performing one, allowing for both a reduction of the energy consumption and of the investment costs.

Abstract

Dimethoxymethane (OME₁) is a potential blend component for diesel fuel that enables dramatic reductions in pollutant formation. With current technology, however, the production of OME₁ from renewable electricity would be less efficient than other power-to-fuel processes. We therefore present an alternative process based on a different synthesis route: direct oxidation of methanol. We use deterministic global optimization to maximize the exergy efficiency of the process. The problem can be solved globally despite the complexity of the flowsheet and the detailed phase equilibrium and enthalpy models used for most units. In contrast, only simple models are used for distillation. The effects of this simplification and that of heat integration are quantified. The optimized process has a higher exergy efficiency than the benchmark and eliminates all external heat demand.

Keywords: Design, global optimization, power-to-fuel, oxymethylene ether, methylal

1. Introduction

Alternative fuels are urgently needed for reducing the greenhouse gas and pollutant emissions of the transport sector. A promising candidate is dimethoxymethane (OME₁), which can be used as a compression ignition fuel itself with suitable additives or blended in diesel fuel. In either case, the formation of soot and nitrogen oxides can be drastically reduced compared to diesel fuel (Omari et al., 2017). OME₁ is also an intermediate in pathways for producing longer-chain oxymethylene ethers (Burger et al., 2010), which can directly replace diesel fuel with only minor engine modifications.

The current production of OME₁ is based on methanol and aqueous formaldehyde solution (Weidert et al., 2017). By combining such an OME₁ production process with formaldehyde production from methanol and methanol production from renewable hydrogen (H₂) and carbon dioxide (CO₂), OME₁ can be produced in a power-to-fuel process chain, which we call the *benchmark process chain* in the following. However, this benchmark process chain for converting H₂ and CO₂ to OME₁ has an exergy efficiency of only 73 %, in contrast to around 90 % for methane, methanol, or dimethyl ether (Bongartz et al., 2019). This lower efficiency can be attributed to the accumulation of losses in the three process steps. Among these, formaldehyde production has the lowest efficiency.

A number of alternative synthesis pathways for OME₁ that avoid a separate formaldehyde production process have been explored (Sun et al., 2019). Among these, the direct oxida-

tion of methanol to OME₁ (Tatibouët, 1997) is promising for short-term implementation because heterogeneous catalysts with high conversion and selectivity have been developed. In this direct oxidation, formaldehyde is converted in-situ to OME₁ immediately after its formation over a bifunctional catalyst. Despite the considerable work on catalyst development, no optimized process has been presented and analyzed yet.

In this contribution, we thus design a power-to-fuel process for producing OME₁ from H₂ and CO₂ via direct oxidation of methanol. To achieve maximum efficiency, we aim at leveraging recent developments in global flowsheet optimization using our open-source optimizer MAiNGO (Bongartz et al., 2018). In the following, we first introduce the proposed process concept. Next, we describe the flowsheet optimization problem and its solution with MAiNGO. To ensure tractability of the global flowsheet optimization, only simple models are used for distillation columns, and no heat integration is considered during optimization. Finally, we quantify the impact of the simple distillation models and conduct pinch analysis to enable comparison with the benchmark process chain.

2. Process Concept

The proposed process concept consists of two sub-processes: conversion of H₂ and CO₂ to methanol, and conversion of methanol to OME₁ (see Fig. 1). For the first sub-process, multiple concepts have already been proposed. Herein, we slightly adapt the concept for methanol production of Van-Dal and Bouallou (2013): We omit the low-pressure flash drums for separating remaining traces of CO₂ from the produced methanol, because we do not expect CO₂ to impact the downstream reaction of methanol to OME₁.

In the second sub-process, the main reaction is

Reaction (1) occurs in the gas phase in fixed-bed reactors at ambient pressure and moderate temperatures (Sun et al., 2019). For the present analysis, we select the catalyst by Liu et al. (2008), which enables peak values of >90% for methanol conversion and selectivity to OME₁ at temperatures of 393 K to 423 K. Conversion increases with temperature whereas selectivity decreases. The main side products are methyl formate (MF) and formaldehyde (FA). Although the experiments were conducted with an O₂-N₂ mixture with 17 mol% of O₂, we assume that the performance is the same with air as oxidant.

After the reactor, gas-liquid separation is achieved through low-temperature cooling. The gas stream consists of N₂ and unreacted O₂. The liquid stream contains water, methanol, OME₁ as well as some MF and FA. Mixtures of water, methanol, OME₁, and FA exhibit several azeotropes (Kuhnert et al., 2006). The addition of MF, in contrast, does not introduce additional azeotropes according to model predictions (Deutz et al., 2018). Since MF is also the most volatile component, it is withdrawn as top product of column D2. The remaining mixture is similar to the one in OME₁ production from methanol and aqueous FA. In that context, Weidert et al. (2017) proposed a pressure-swing distillation to overcome the methanol-OME₁ azeotrope. The first column of their setup has a reactive section to convert leftover FA to OME₁, and a side product draw to remove methanol. Herein, we remove the side draw and instead obtain a methanol-water mixture as bottom product of D3 that is recycled to D1, since D1 already separates methanol from water.

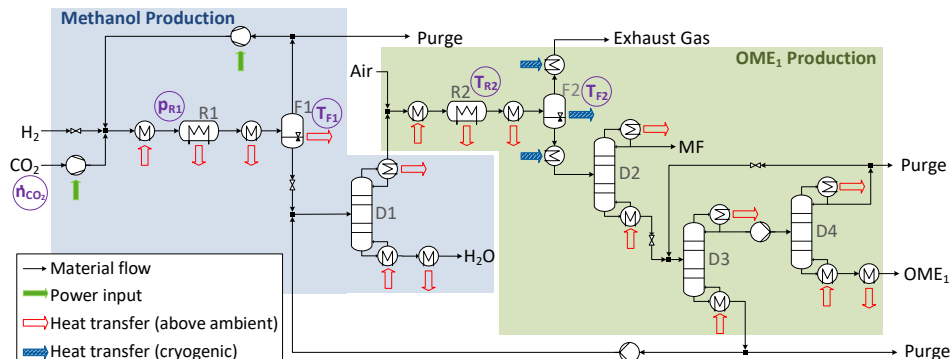

Figure 1: Process flow diagram for the production of OME₁ from H₂ and CO₂ via direct oxidation of methanol. Figure adopted from Bongartz (2020). Combustion of purge streams and the MF stream for energy recovery is not shown for simplicity.

3. Flowsheet Optimization

Given the flowsheet in Fig. 1, we aim at maximizing its exergy efficiency, which is a thermodynamically consistent measure for the quality of energy conversion processes. Such flowsheet optimization problems are nonconvex and should thus be solved with global optimization methods. However, these are computationally expensive. To ensure tractability, we use a three-stage procedure: First, we optimize the entire flowsheet globally using simple models for the most challenging units in the flowsheet, i.e., the distillation columns. Second, we use the results as initial values to optimize the columns locally using rigorous models. Third, we conduct pinch-based heat integration for the fixed optimized process.

3.1. Global Optimization with Simple Distillation Models

The global optimization of the flowsheet is described in detail by Bongartz (2020) and only key points are summarized here. The design variables are shown in circles in Fig. 1. Their allowable ranges are given in Table 1. The objective is the exergy efficiency

$$\eta_{\text{ex}} = \frac{\dot{n}_{\text{OME}_1} e_{\text{OME}_1} + \sum_{k \in \mathcal{Q}_{\text{out}}} \dot{E}_{Q,k}}{\dot{n}_{\text{H}_2} e_{\text{H}_2} + \dot{n}_{\text{CO}_2} e_{\text{CO}_2} + \sum_m \dot{W}_m + \sum_{k \in \mathcal{Q}_{\text{in}}} \dot{E}_{Q,k}}, \quad (2)$$

with \dot{n}_i and e_i denoting the molar flow rate and molar exergy of species i , respectively, $\dot{E}_{Q,k}$ the exergy of heat flow k , and \dot{W}_m the power consumption of compressor m . No internal heat integration is considered for simplicity. Instead, all heat flows that correspond to exergy leaving and entering units are assigned to the sets \mathcal{Q}_{out} and \mathcal{Q}_{in} , respectively.

The process is modeled with species molar flow rates and overall enthalpy flow rates. The balances are limited to species that occur in appreciable quantities in the corresponding parts of the flowsheet. Enthalpies are computed with the DIPPR-107 equation for heat capacity, the DIPPR-106 equation for enthalpy of vaporization, and the AspenPlus correlation for enthalpy of solution of Henry components. For the compressors, we use a fixed isentropic efficiency and an entropy model also based on the DIPPR-107 equation. In reactor R1, we enforce equilibrium of methanol formation and reverse water gas shift. In reactor R2, we correlate the yields of Liu et al. (2008) as a function of temperature

Table 1: Design variables for flowsheet optimization (adopted from Bongartz (2020)).

Symbol	Description	Unit	Range	Solution Point
\dot{n}_{CO_2}	CO ₂ inlet flow rate	kmol/s	[0, 1]	0.251
p_{R1}	Inlet pressure reactor R1	bar	[60, 70]	70.0
T_{F1}	Temperature flash drum F1	°C	[30, 110]	100
T_{R2}	Temperature reactor R2	°C	[120, 140]	124
T_{F2}	Temperature flash drum F2	°C	[-100, 25]	-94.6

using second degree polynomials. FA formation is neglected (i.e., counted as unreacted methanol), which is conservative because FA would be further converted to OME₁ in the reactive section of D1. Phase equilibrium is modeled with the extended Antoine equation and Henry’s constant correlation and solvent mixing rules from AspenPlus. In the second sub-process, we additionally use NRTL for the nonideal liquid mixture. For the columns D1–D4, we use the Underwood shortcut for the minimum reflux ratio. The actual reflux ratio is chosen 30 % higher for finite column height. The azeotropes at the top of columns D3 and D4 are introduced as pseudo-components as proposed by Vogelpohl (2002).

The problem is written in a reduced-space formulation (Bongartz and Mitsos, 2017), which is a hybrid between equation-oriented and sequential-modular formulations: The optimizer does not see all model variables, but rather only the degrees of freedom and few variables for decoupling the equation systems, e.g., those in tear streams. The other variables are computed sequentially from the model equations. Flash calculations are handled as described by Bongartz and Mitsos (2019). In total, the problem has 58 optimization variables, 53 equalities, and 19 inequalities. An equation-oriented formulation would have several hundred variables and equalities. The problem is implemented via the C++ API of MAiNGO v0.2.0.4 (Bongartz et al., 2018)¹ and solved to a relative optimality tolerance of 10^{-2} on 12 cores of an Intel Platinum 8160 with 2.1 GHz in 12 h of wall clock time using MPI parallelization. The optimal values of the design variables are given in Table 1. The exergy efficiency computed via Eq. (2) is 83 %. Local instead of global optimization results in anything from the global to substantially suboptimal solutions (e.g., 11% efficiency) or no feasible points, depending on the initial guess. For details, see Bongartz (2020). Note that this optimal efficiency cannot be compared to the benchmark process chain because of the simplified treatment of distillation and heat integration.

3.2. Local Optimization of Distillation Columns with Rigorous Models

To obtain reliable values for the energy demand for distillation, we optimize the columns locally with equilibrium tray-to-tray models, using the results from the previous sections as initial points. To achieve reasonable column designs, we minimize the total cost comprising heating, cooling, and capital cost estimated with the method of Guthrie (1969). Minimizing exergy destruction would result in excessively large columns. Design variables are the reboiler and condenser duties, the number of stages, and the feed stage. Purity constraints are imposed for OME₁ and wastewater (≥ 99.5 mol %) and the MF sent to combustion (≥ 80 mol %). The problems are formulated and solved as described by Kraemer et al. (2009): The integer variables for the number of trays and the feed tray are

¹The model is available in the C++ and text input formats of MAiNGO and in GAMS format under the name *DirectOxidationOME* in the GloPSE library at <https://git.rwth-aachen.de/avt.svt/public/glopse>.

Table 2: Reboiler duties of the distillation columns per unit of OME₁ produced (MJ/kg).

	D1	D2	D3	D4
Simple model	5.13	1.75	1.87	6.67
Rigorous model	2.61	1.37	1.04	0.57

Table 3: Utility demands per unit of OME₁ after heat integration of the optimized power-to-OME₁ process using rigorous (vs. simple) distillation models.

	Energy / MJ/kg	Exergy / MJ/kg
Heat at ≥ 136 °C	0 (1.98)	0 (0.54)
Cooling at -25 °C	-1.18	0.24
Cooling at -95 °C	-2.05	1.38
Heat at 128 °C	-5.47 (-4.90)	-1.41 (-1.26)

relaxed, and integrality is enforced through Fischer-Burmeister constraints in a series of successive nonlinear programs. The problems are solved with SNOPT (Gill et al., 2005) through GAMS, using external functions for the thermodynamics. The reboiler duties computed with the rigorous column models differ significantly from those with the simple models (see Table 2), in particular for D4, which has an azeotrope as top product. The overall heat demand of the process is 50 % less than predicted with the simple models. Still, the exergy efficiency according to Eq. (2) only rises to 84 % compared to 83 % with the simple models, since the exergy of the reboiler duties is small compared to that of the H₂. The rigorous column models are thus not crucial for determining the overall exergy efficiency. This may however be different for economic or environmental objectives.

3.3. Heat Integration

In the flowsheet optimization, all heat flows were considered directly in Eq. (2). This corresponds to utilities with matching temperatures being available for all heat flows, which is unrealistic. Therefore, we apply the same procedure as for the benchmark process chain: We conduct pinch analysis for full heat integration and assume a small number of utilities for the remaining heating and cooling demand. The process needs cryogenic cooling at -25 °C and -95 °C and no external heating, while it can export some heat at 128 °C (see Table 3). The resulting exergy efficiency of the process is 77 %, which is significantly lower than the 84 % predicted with the simplified treatment of heat flows. Nevertheless, the efficiency is higher than that of the benchmark process chain (73 %). Furthermore, the fact that no heat input is required is a clear advantage over the benchmark process chain. If we relied on the simple distillation models, we would erroneously conclude that the process did have a net heat demand at 136 °C (cf. Table 3).

4. Conclusion

A process for producing OME₁ from H₂ and CO₂ via direct oxidation of methanol was presented. The exergy efficiency of the process was maximized with the deterministic global optimization solver MAiNGO using detailed models for most of the flowsheet, but treating distillation and heat integration in a simplified way. According to an analysis with rigorous distillation models and a realistic setting for heat integration, the exergy

efficiency is 77 % as compared to 73 % for the literature benchmark. Still, equivalent comparison in a simulator as well as cost optimization would be desirable. The results show that global optimization of relatively complex flowsheets with moderately many degrees of freedom is possible with MAiNGO. However, more work is needed to allow for detailed distillation models. The results also underline the importance of realistic scenarios for heat integration and utilities, which should be considered in the optimization.

Abstract

Machine Learning allows for the modelling and analysis of complex systems for which little mechanistic knowledge is available and is therefore envisioned as a powerful tool for the development of new designs with applications in engineering problems. In this work, we propose a framework based on dimension reduction, clustering, and self-organizing maps for the modelling and analysis of devices from materials and operation data, from which useful information can be drawn to inform future designs and developments. We demonstrate the applicability of this approach by analysing a high-temperature polymer electrolyte membrane fuel cell (HT-PEMFC). It was found that out of the 12 input variables studied, temperature, oxygen stoichiometric ratio, and ionomer binder ion exchange capacity are the most influential for achieving high power HT-PEMFC. This framework could be extended as new data becomes available about the different device components.

Keywords: Machine learning, materials science, energy conversion, device design.

1. Introduction

In recent years, there has been an increasing interest in the benefits of Machine Learning (ML) for materials discovery, i.e. the prediction of materials properties from molecular or structural information (Ong, 2019). However, the integration of materials and device level modelling could accelerate the deployment of newly discovered materials in real-life applications. One such application suitable for this approach is that of the development of low cost polymer electrolyte membrane fuel cells for automobile applications. High-temperature polymer electrolyte membrane fuel cells (HT-PEMFCs) pose a promising option for lowering the cost of hydrogen-powered vehicles. These fuel cells operate in the temperature range of 120 to 250 °C and offer simpler heat and water management in comparison to the conventional low-temperature fuel cells (LT-PEMFCs) (Xiao et al., 2005). Because of the high temperature, the cell stack radiator is minimized and the humidification of the feed gas is no longer needed. This is particularly important for stacks used in medium and heavy duty vehicles. Additionally, HT-PEMFCs tolerate CO in the hydrogen fuel stream, which enables the use of cheaper hydrogen (Venugopalan et al., 2020). These aspects significantly lower the cost of

hydrogen-powered setups for vehicles, which can in turn can lead to a more widespread adoption of cleaner transportation technologies. Despite its benefits, however, current designs of HT-PEMFCs show lower power density, high platinum metal loadings, and limited temperature range and water tolerance (Lee et al., 2019; Quartarone et al., 2017). Therefore, new developments are needed for HT-PEMFCs to be suitable for transportation applications. In this work, we implemented an ensemble of machine learning techniques, integrated with a semi-empirical model to bridge materials and device level modelling, and to explore the design search space for a high-temperature polymer electrolyte membrane fuel cell.

2. Related Methods

Figure 1 shows a schematic of the data analysis process employed. We used Uniform Manifold Approximation and Projection (UMAP) for dimension reduction and Hierarchical Density Based Spatial Clustering of Applications with Noise (HDBSCAN) for clustering to classify a variety of design configurations according to their peak power density as a measure of performance. We then fed the clustered data set into a self-organizing map (SOM) implementation so that the SOM algorithm would be induced to find three clusters. After this, component maps were generated to gauge the influence of each variable over the design performance. The overall result is a tool for the exploration of a high dimensional design space with the capability to related the lower dimensional representations to physically meaningful variables. Following is a brief description of the methods used.

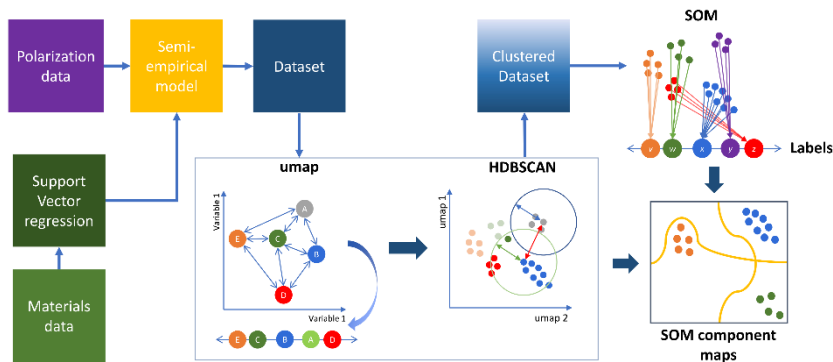

Figure 1. Schematic representation of the proposed framework for the sensitivity analysis.

2.1. Synthetic data

The data for the machine learning-based analysis was obtained from a 0-D polarization model substantiated using experimental data. A detailed description of the experimental procedures can be found elsewhere (Venugopalan et al., 2020). The 0-D, semi-empirical model was based upon existing HT-PEMFC models that are physics-informed with distributed parameters (Kregar, 2020; Oh et al., 2014; Yin et al., 2020) and features some semi-empirical expressions (Cheddie, 2007; Scott & Mamlouk, 2009; Sousa et al., 2010) to describe overpotential losses. This approach was selected because it accurately predicts data with few adjustable parameters, and it has relevant descriptors that factor how H_3PO_4 content in the membrane and CO in the feed gas stream impact HT-PEMFC polarization. The key assumptions for the model were: continuum level, steady state

operation, ideal gas behaviour, no gas crossover, no water transport considerations, and uniform distribution of catalyst and ionomer binder and gas transport properties across the electrodes and gas diffusion layers. The model uses two Support Vector Regression (SVR) with a radial basis kernel function (Drucker et al., 1997) to predict materials conductivity from their composition at a given temperature. In particular, the SVR implementation proposed by Chang and Lin (Chang & Lin, 2011) was used. The model serves as a bridge between the materials data and the device performance prediction, allowing the simulation of new configurations that will be later added to the training dataset for the ML procedures. To deal with the variability of the polarization model, we introduced gaussian noise following the expected distribution of this variability. This noise will later be removed using a denoising capable clustering technique.

The synthetic dataset was obtained using a stochastic generator. To produce different configurations 12 input variables were allowed to take different values around a base case in a uniform distribution within a given interval (e.g., \pm base value \times 40%). For example, a given configuration would include a lower catalyst loading, and higher temperature and pressure while another configuration would have the same catalyst loading but with a smaller membrane thickness.

2.2. Dimension reduction and Clustering

A density-based clustering (DBC) approach was adopted. DBC finds clusters of any shape, as opposed to centroid based clustering which assumes a shape (i.e. a sphere of equal variance) for the clusters. Also, in DBC, data points in sparse regions are not required to be assigned to a cluster but rather identified as noise. Additionally, introducing hierarchical clustering (HC) finds nested relationships amongst data instead of flat partitions in the data. This characteristic enables a more complex clustering with higher resolution. In this research we used the implementation proposed by McInnes and Healy (McInnes & Healy, 2017). Prior to the clustering we used UMAP for dimension reduction. UMAP is a neighbour graphs-based dimension reduction technique, meaning that a graph is first built for the high dimensional data and then it is embedded in a low dimensional space using a force directed layout using cross entropy to measure the distance between the high dimensional graph and the low dimensional graph. The resulting low dimensional embedding is denser, providing a better starting point for HDBSCAN (McInnes & Healy, 2018).

2.3. Self-Organizing Maps

SOMs are a type of artificial neural networks that use competitive and collaborative learning to generate a low dimensional representation of a dataset based on a measure of similarity amongst the data. SOMs are based on the notion of vector quantization, in which the input data is partitioned in number contiguous regions, each one represented by a model vector (Kohonen, 2013). Every input data is then associated with the model vector that best matches with it (competitive learning) and then its spatial neighbours are modified for better matching as well (collaborative learning). The result is a graphical representation of the high-dimensional dataset in a low-dimensional (typically two-dimensional) plot in which regions of similar entities are close together and far apart from dissimilar ones. The contribution of the different features of the data to the distribution on the map can be traced by examining the model vectors. Here, we employed the implementation designed by Moosavi et al (Moosavi et al., 2014).

3. Results and Discussion

Figure 2a and 2b present the SVR models for the prediction of conductivity, κ^{H^+} , as a function of ion exchange capacity (IEC) and temperature T for both the membrane and the ionomer binder. Figure 2c shows the accuracy for the prediction of the polarization data. In general, the three models show a good fit with the experimental, thus providing a reliable source for synthetic data.

Figure 2. Model prediction against experimental data for (left) SVR for membrane conductivity, (centre) SVR for ionomer binder conductivity, (right) semi-empirical model for polarization. Measured data from (Venugopalan et al., 2020).

The implementation of UMAP for dimension reduction and HDBSCAN for clustering using the generated dataset resulted in 5 clusters. These clusters were further grouped into 3 and identified as low, medium, and high-performance, according to the peak power density.

Figure 3 shows a representation of the clusters projected onto the SOM. The training of the SOM was successful in the sense that it distinctly segregates the three regions of low (Figure 3a), medium (Figure 3b), and high (Figure 3c) performance (as measured by peak power density). With this mapping, the component maps can now be obtained to identify which of the variables under study has more influence on the high-performance cluster.

Figure 3. UMAP-HDBSCAN clusters projected onto the self-organizing map. The third one from the left shows the cluster for higher performance as measured by peak power density. Colours represent model weights difference (blue being small differences and green being large differences). Dots represent the clusters.

The component maps for the 3 variables that are most influential over the high-performance cluster are shown in Figure 4. Out of the 12 variables explored,

oxygen stoichiometric ratio, SO_2 (Figure 4a); ion exchange capacity of the ionomer binder, IEC_{io} (Figure 4b); and operating temperature, T (Figure 4c); were found to be the most influential over the high-performance cluster. These observations were cross validated using a Space Greedy Search (SGS) analysis (Figure 5) as described by Zhu *et al.* (Zhu *et al.*, 2018). For the SGS analysis the original clusters from the UMAP-HDBSCAN stage were used. Although the influence of these variables over the other clusters is not so regular, a clear tendency to be highly relevant for the high-performance cluster is observed. Therefore, optimized values for T , IEC_{io} , SO_2 are needed to achieve high performance. Furthermore, the component contributions show the relative importance of temperature and oxygen availability with respect to the other operating conditions. On one side, this suggests that mass transfer phenomena such as oxygen permeability (associated with oxygen availability) plays a major role on the fuel cell performance. On the other hand, operating temperature could provide a greater boost in performance than, for example, pressure, which should be considered for new designs.

Figure 4. Component maps for the 3 most relevant variables to the high-performance cluster: (left) oxygen stoichiometric ratio, SO_2 ; (centre) ion exchange capacity of the ionomer binder, IEC_{io} ; and (right) operating temperature, T . Colours represent degree of influence (blue being small contributions and green being large contributions). Dots represent the clusters.

Figure 5. Contribution plot from the Space Greedy Search analysis between clusters (a) 5-2, (b) 5-3. Red boxes indicate the highest contributions.

4. Conclusions

Our results show that density-based clustering, combined with neighbor graphs dimension reduction, and SOM analysis, helps identify physically meaningful patterns in the operation data. These patterns can in turn be related to the materials properties

predicted by support vector regression via the semi-empirical model, providing information for both the design of the materials and the appropriate device conditions needed for a cost-effective operation. The modular nature of this approach provides an easy way to incorporate it into the manufacturing process of such materials and devices.

Abstract

We develop SPICE (Synthesis and Process Intensification of Chemical Enterprises), which is a software tool for chemical process design and discovery. Primarily based on the building block representation of various physicochemical phenomena, SPICE offers a comprehensive set of toolkits to perform (i) benchmarking to determine the theoretical bounds on process design opportunities and maximum intensification targets, (ii) conceptual process design, (iii) process synthesis and optimization, (iv) process simulation and analysis of both intensified and non-intensified unit operations, (v) identification of intensification hotspots for existing processes and (vi) property-performance mapping towards elucidating new materials for intensification purposes. The benefits and the applicability of SPICE as a process design platform are demonstrated through multiple case studies.

Keywords: Process Synthesis, Intensification, Building Blocks, Software Prototype

1. Introduction

Increased competition, environmental regulation, rise of unconventional feedstocks, and volatile market conditions have contributed to renewed interest in process design and intensification methods for the chemical process industry. Several new design and synthesis platforms/prototypes (e.g., ProCAFD, MIPSYN, Pyosyn, and Synopsis, among others) have emerged. Computer-aided process intensification is now considered as an integral part of conceptual design. However, discovering novel processes without relying on pre-postulated conceptual design alternatives remains a challenge. One can potentially address this by adopting “bottom-up” representations that use generic but finite number of design elements encapsulating all the fundamental physicochemical phenomena and functions that constitute a chemical process. Recently, Hasan and co-workers (Demirel et al., 2017) proposed such a representation based on design building blocks that allow us to generate numerous designs of unit operations, process configurations and flowsheets without explicit consideration or knowledge of all plausible alternatives beforehand. This departure from unit operations-based representation to design elements provide a systematic new way for computer-aided optimal process design and intensification.

In this work, we describe the development of a design software tool based on the building block representation. We call this as SPICE (Synthesis and Process Intensification of Chemical Enterprises). The overall SPICE framework is depicted in Figure 1. SPICE offers a comprehensive toolkit with the following functionalities:

- (i) fast benchmarking and targeting for determining the theoretical bounds on process design opportunities and maximum intensification targets,
- (ii) conceptual process design,
- (iii) process synthesis and optimization,
- (iv) simulation, and analysis of intensified and non-intensified unit operations,
- (v) identification of intensification hotspots for existing processes, and
- (vi) property-performance mapping to elucidate materials for intensification purposes.

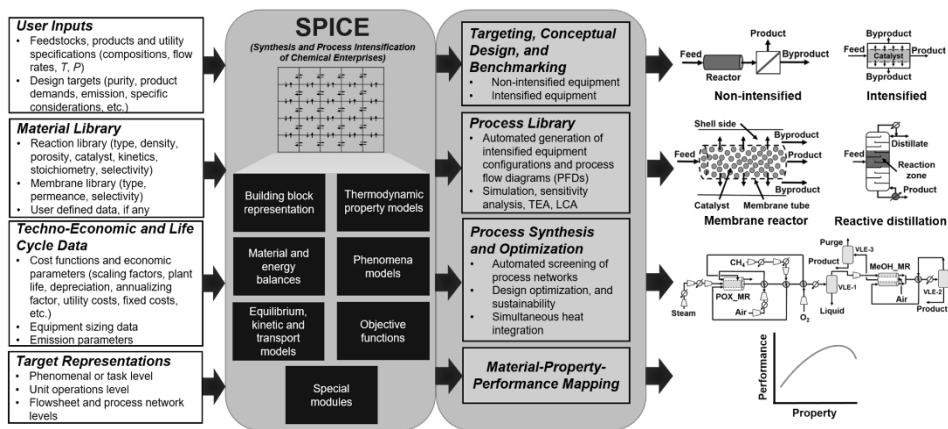

Figure 1: SPICE framework.

For specified/user-selected inputs of feedstocks, product specifications, material properties, and techno-econo-environmental parameters, SPICE generates a rank-ordered list of design configurations with optimal sizing and a comprehensive analysis of various target metrics. Combining the thermodynamic minimum energy calculation with the Feinberg Decomposition theory (Feinberg and Ellison, 2001), SPICE can determine the theoretical attainable limits for any reaction-separation system. Users can further perform detailed process simulation, sensitivity analysis, and techno-economic analysis (TEA). Furthermore, SPICE provides options for multiobjective optimization at the conceptual design stage to automatically generate Pareto solutions considering the techno-economic and environmental trade-offs. Finally, under the material property-performance mapping section, users can perform parametric studies to find the effect of material properties on the process performance in terms of product purity, quality, conversion, energy, and cost.

2. SPICE Framework

2.1. User Interface

Users specify the feedstock availability and compositions, minimum product purity, productivity and demands, and the operating ranges for temperatures, pressures and

flow rates. They can also select the set of potential phenomena to be considered. For a system involving reactions, the material library provides information to the users on reaction stoichiometry, equilibrium and kinetics. For separations, users can indicate their choices for VLE, membranes, solvents and absorbents. Additionally, users can define new materials with their own data. SPICE also accepts user-defined cost functions and economic parameters such as scaling factor, plant life, depreciation rate, annualized factor, utility costs, raw material costs, fixed costs, etc. Finally, users can select the level of design details (short-cut or rigorous) by selecting the appropriate models.

SPICE also allows specialized submodules focusing on specific set of phenomena and intensification options (Figure 2). For new designs, users can choose SPICE_GEN. Alternatively, for a known process, SPICE_RF finds retrofitting hotspots and SPICE_OPT optimizes the process. Users can also restrict to only SPICE_HI (heat integration), SPICE_MARS (membrane-assisted reactive separation), SPICE_RD (reactive distillation), SPICE_MS (membrane separation), SPICE_MD (membrane distillation), SPICE_ED (extractive distillation), SPICE_DWC (dividing wall column), SPICE_MRD (membrane-assisted reactive distillation), and SPICE_MED (membrane-assisted extractive distillation).

Figure 2: SPICE sub-modules for specific phenomena.

2.2. Building Block-Based Representation

The building block-based superstructure (Demirel et al., 2017; Li et al., 2018; Demirel et al., 2019) is used to represent the overall design problem, which is formulated as a single mixed-integer nonlinear program (MINLP). Each block has two design elements, namely the block interior and the block boundaries. A block interior is characterized by a temperature, a pressure, a phase, and a composition of chemical species. The interactions between two adjacent blocks are controlled by a common boundary. A boundary can be either unrestricted, semi-restricted or completely restricted (Figure 3a). Streams go through an unrestricted boundary without restrictions. A semi-restricted boundary indicates that there exists a mass-transfer interceptor which represents separation phenomena (e.g., membrane, VLE interface). A completely restricted boundary implies zero-flow across. External feed streams are introduced and products can be withdrawn from each block. Additionally, jump flows allow interaction between non-adjacent blocks.

A combination of the block interior and the boundaries are used to represent different phenomena (Figure 3b). For instance, a reactor block interior is filled with catalyst. Two blocks separated by a common semi-restricted boundary represents separation phenomena (phase contact, permeation, pervaporation, etc.). When several blocks are arranged in a two-dimensional grid, we call it a superstructure (Figure 3c). This arrangement embeds different equipment (an example is shown in Figure 3d). By

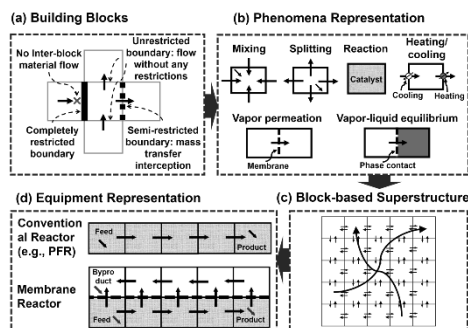

Figure 3: Building block representation.

arranging many such building blocks in different orders, numerous flowsheets can be generated and screened.

2.3. Material and Energy Balances

The MINLP model includes fundamental material and energy balance constraints for each block. For block $B_{i,j}$, where i and j denote the coordinate of the block in the 2-D grid, the material balance (Eq. 1) includes species flowrates through each of the four boundaries. $F_{i,j,k}$ and $R_{i,j,k}$ denote horizontal and vertical flows, respectively; $G_{i,j,k}$ captures the consumption/generation due to chemical reaction, $M_{i,j,k,f}$ and $N_{i,j,k,p}$ represent feedstock f and product p flows, respectively; and $J_{i,j,i',j',k}$ allows jump flows from block $B_{i,j}$ to block $B_{i',j'}$ for species k . The energy balance (Eq. 2) ensures that the enthalpies and the heat and work exchanges via internal transformation and external utility are preserved.

$$F_{i,j-1,k} + R_{i-1,j,k} - F_{i,j,k} - R_{i,j,k} + G_{i,j,k} + \sum_{f \in FS} M_{i,j,k,f} - \sum_{p \in PS} N_{i,j,k,p} + \sum_{(i',j') \in Link} J_{i',j',i,j,k} - \sum_{(i,j) \in Link} J_{i,j,i',j',k} = 0, \quad \forall i, j, k \quad (1)$$

$$EF_{i,j-1} + ER_{i-1,j} - EF_{i,j} - ER_{i,j} + EG_{i,j} + EM_{i,j} - EN_{i,j} + EJ_{i,j}^f - EJ_{i,j}^p + W_{i,j}^{comp} - W_{i,j}^{exp} + Q_{i,j}^h - Q_{i,j}^c = 0, \quad \forall i, j \quad (2)$$

$$f_{i,j,k,ph}^{ph} - M(1 - z_{i,j,ph}) \leq \Phi_{i,j,k} \leq f_{i,j,k,ph}^{ph} + M(1 - z_{i,j,ph}), \quad \forall i, j, k, ph \quad (3)$$

$$f_{i,j,k,ph}^{ph} = f^{rxn} (T_{i,j}, P_{i,j}, y_{i,j,k'}, V_{i,j,ph}, z_{i,j,ph}), \quad \forall i, j, k, ph \in Rxn \quad (4)$$

$$f_{i,j,k,ph}^{ph} = f^{equil} (K_{i,j,k,ph}^{eq}, T_{i,j}, P_{i,j}, y_{i,j+1,k'}, z_{i,j,ph}), \quad \forall i, j, k, ph \in Equil \quad (5a)$$

$$f_{i,j,k,ph}^{ph} = f^{equil} (K_{i,j,k,ph}^{eq}, T_{i,j}, P_{i,j}, y_{i+1,j,k'}, z_{i,j,ph}), \quad \forall i, j, k, ph \in Equil \quad (5b)$$

$$f_{i,j,k,ph}^{ph} = f^{rate} (\lambda_{k,ph}, DF_{i,j,k,ph}, d_{i,j,ph}, z_{i,j,ph}), \quad \forall i, j, k, ph \in Rate \quad (6)$$

2.4. Thermodynamic Property Model

Thermodynamic property models are an important and integral part of any process design and synthesis platform to accurately estimate the properties of each associated species. However, these models are highly nonlinear, nonconvex and involve large number of equations, which increase the complexity. To overcome this, SPICE exploits data-driven surrogate thermodynamic models for several properties like specific enthalpy, specific heat capacity, density, and saturation pressure. These fitted models often offer high accuracy ($R^2 > 0.99$) over a specified range while reducing the computational demand.

2.5. Phenomena Models

Eq. 3 is the phenomena assignment constraint, where, ph denotes the phenomena set. Here, $\Phi_{i,j,k} := G_{i,j,k}$ for $ph \in Rxn$, $\Phi_{i,j,k} := y_{i,j,k}$ for $ph \in Equil$, and $\Phi_{i,j,k} := \{F_{i,j,k}, R_{i,j,k}\}$

for $ph \in Rate$. Based on the value of $z_{i,j,ph}$, the corresponding phenomena model $f^{ph}(T_{i,j}, P_{i,j}, y_{i,j,k}, V_{i,j,ph}, \lambda_{k,ph}, DF_{i,j,k,ph}, d_{i,j,ph})$ is activated. Basic models representing various chemical phenomena, including reaction and separation, are included within the framework (Eqs. 4-6). Separation phenomena are classified in two groups, namely the equilibrium-based phenomena (Eqs. 5a-b) and the rate-based phenomena (Eq. 6). Here, $T_{i,j}$, $P_{i,j}$, $y_{i,j,k}$, $V_{i,j,ph}$ and $DF_{i,j,k,ph}$ are block interior variables representing temperature, pressure, composition, catalyst amount, and driving force across the boundary, respectively, while $\lambda_{k,ph}$ and $d_{i,j,ph}$ are block boundary variables denoting mass transfer coefficient and mass transfer area, respectively. Equilibrium-based phenomena includes vapor-liquid, liquid-liquid, and vapor-vapor phase contact, and are observed in distillation, flash, solvent extraction, absorption operations. Rate-based phenomena includes gas permeation, liquid permeation and pervaporation that are

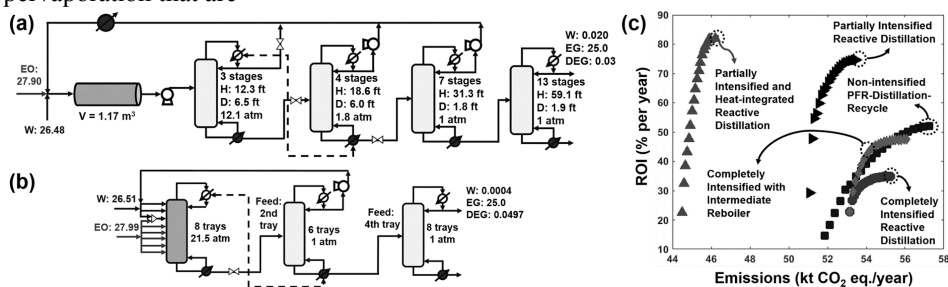

Figure 4: SPICE generated flowsheets (a-b) and multiobjective optimization results (c).

common to membrane-based separation. The assignment of phenomena to the block interiors and the boundaries is dictated by the binary variable $z_{i,j,ph}$.

2.6. Design Objectives

SPICE allows to use several built-in objective functions, such as, maximize {total annual profit (TAP), return on investment (ROI), yield, and conversion}, or minimize {total annual cost (TAC), energy, emission, size, and maximum allowable reactor temperature}, among others. Additionally, users can modify these functions based on their needs.

3. Case Studies

3.1. Ethylene Glycol Production

Here, we demonstrate the SPICE framework in designing an intensified process for ethylene glycol (EG) production from ethylene oxide (EO) and water (W) with minimum TAC while producing 25 kmol/h EG with 99.8 % (mol) purity. As this process involves reaction and vapor liquid equilibrium separation (distillation), we select SPICE_RD module. First, a unit operation based process synthesis and integration is performed, which yields a process with TAC of 12.42 MMS\$/y. The resultant flowsheet (Figure 4a) contains an adiabatic reactor and four distillation columns to achieve the target purity. Additionally, heat integration is considered between the condenser of the first distillation column and the re-boiler of the second distillation column. When phenomena-based synthesis approach is considered, a novel intensified flowsheet (Figure 4b) is obtained with 12.33 MMS\$/y TAC, utilizing only

three major equipment (Demirel et al., 2019). We have also considered sustainable process intensification using multiobjective optimization for EG production considering both economic and environmental objectives. The resultant pareto solutions from SPICE_RD for several intensified, partially intensified and non-intensified designs are shown in Figure 4c (Demirel et al., 2020).

3.2. Shale Gas Conversion to Methanol

Methanol processes are equilibrium-limited and energy intensive, and have lower methanol yield. We have applied the SPICE framework to search for better process configurations with maximum TAP. First, we optimize a base-case flowsheet (Ehlinger et al., 2014) using the SPICE_OPT module. The resultant flowsheet has a TAP of 12.7 MM\$/y and a ROI of 22 %. We then switch to SPICE_RF and use the optimized base-case as a warm-start when searching for flowsheets with higher TAPs. This generates a new intensified and heat-integrated flowsheet as presented in Figure 5. This flowsheet has a TAP of 38 MM\$/y (200 % improvement) and a ROI of 52 % (136 % improvement). The improvements are due to several changes. First, it considers only two reactors and excludes the WGS reactor and the CO₂ separator. Second, the reactors are now replaced by membrane reactors. The membrane reactor for partial oxidation (POX_MR) separates

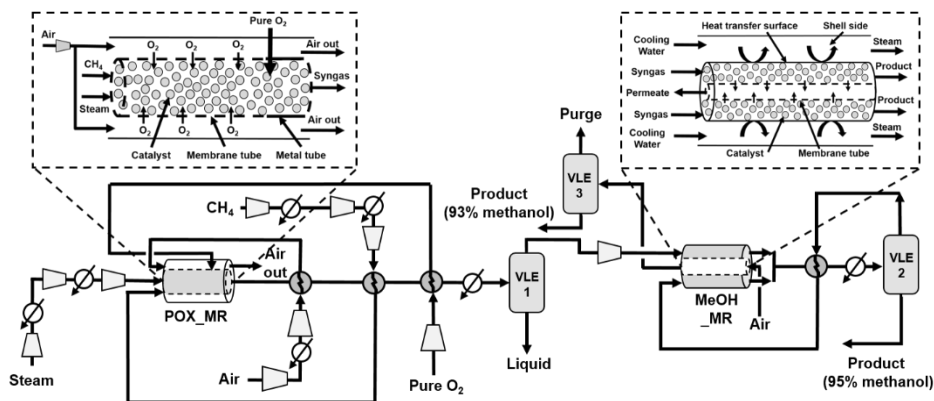

Figure 5: Intensified and heat-integrated process flowsheet for methanol synthesis.

the required O₂ from air and performs the reaction simultaneously, which reduces the consumption cost of expensive pure O₂ by 33 %. The intensified MeOH_MR, on the other hand, increases the methanol yield by 17 % through in-situ removal of the products from the reaction mixtures. Finally, heat integration between the inlet and outlet of POX_MR reduces the utility cost by 58 %.

4. Conclusions

SPICE is a comprehensive process design software prototype. It is a toolkit with the capabilities to benchmark, design, synthesize and intensify chemical process systems. Tests suggest that new processes can be systematically designed with significant reduction in energy and cost for important design problems. The new pathways may not always use fully-intensified systems, specially in the presence of multiple conflicting objectives, which again highlights the need for a comprehensive design package such as SPICE.

Abstract

Carbon Dioxide Integration mainly targets the recovery of CO₂ streams, and assesses the allocation of those recovered streams into CO₂-using sinks, with an overall aim of attaining a minimum cost of a CO₂ network that could meet a prescribed emission target. Meeting emission targets often introduces numerous challenges, especially when energy intensive processes are involved. Hence, CO₂ Integration aims to identify appropriate CO₂ capture, allocation, and utilization options. There exists numerous processes (or CO₂-using sinks) that convert CO₂ streams into value added products, while generating revenue in some cases. However, many CO₂ sink options may be costly, especially if a high purity CO₂ stream is required in the process. Thus, the incorporation of treatment units is imperative, to separate CO₂ gas from the remaining gaseous emission material, which is in fact the most expensive design step in CO₂ integration systems. This study focuses on assessing the effect of varying the temperature of the solvent to be used in the treatment stage of CO₂ on the overall performance of the entire integration network attained. A MINLP formulation has been established based on key design parameters whilst taking into consideration important technical performance constraints that effectively describe the system to be assessed. A more detailed cost model for the treatment units was developed, to establish the effect of varying the emission reduction targets onto the overall performance of CO₂ integration systems.

Keywords: Carbon Integration, GHG emissions, Treatment, Carbon dioxide, Cost models

1. Introduction

Carbon capture utilization and sequestration (CCUS) has emerged as one of the most promising solutions to reduce large amounts of CO₂ especially as the global community adopts climate targets. CCUS involves many steps starting from capture of CO₂ from emission sources, transportation of CO₂ and finally either biological or geological sequestration or in utilization in CO₂ converting technologies. Each step creates a challenge especially due to the large energy requirement. However, the major influence on CCUS cost depends on energy intensive CO₂ treatment especially when dealing with CO₂ dilute streams (IPCC, 2005). There has been a plethora of work in the area of carbon capture using adsorption, absorption, and membrane processes (Ochedi et al. 2020) each varying in efficiency and cost. The most widely applied CO₂ separation technology in industry and that work well with dilute streams is CO₂ adsorption process (Hussin and

Aroua, 2020). Thus, this work aims to understand the effect of varying temperature and pressure in CO₂ adsorption units on the cost of overall CCUS network. Many of the cost items are lumped into single estimation parameters. This study aims to more accurately capture the design of such systems based on a detailed cost model for the absorption-stripping stage within the network.

2. Methodology

To be able to study the various effects of solvent properties within the treatment stage on the overall design of CCUS networks, it is imperative to find appropriate models that can correlate those effects. In doing so, such models can then be integrated onto the original CO₂ Integration model (Al-Mohannadi and Linke, 2016, Al-Mohannadi et al., 2015), with appropriate adjustments and modifications. In this paper, the primary focus was on the following three different solvent properties: density, viscosity, and Henry's constant. It should be noted that all those properties are a function of temperature. Since most common solvents that are used in the absorption stage for CO₂ removal from flue gas effluents are amines, the appropriate correlations that describe amine property behaviour as a function of temperature were identified as follows, and have been used in this study:

The liquid (solvent) density ρ_L as a function of temperature can be found using Eq. (1) below:

$$\rho_L = a_1 + a_2T + a_3T^2 \quad (1)$$

Where a_1 , a_2 and a_3 are equation parameters obtained from DiGuilio et al. (1992), and T is the temperature of the solvent.

The liquid (solvent) viscosity μ_L as a function of temperature can be found using Eq. (2) below:

$$\ln \mu = b_1 + \frac{b_2}{T - b_3} \quad (2)$$

Where b_1 , b_2 and b_3 are equation parameters obtained from DiGuilio et al. (1992). To find Henry's constant, Eq. (3) below can be used from Li (2017)

$$\ln H = c_1 + c_2T + c_3T^2 \quad (3)$$

Where c_1 , c_2 and c_3 are equation parameters. Values for those 3 equation parameters are based on the correlations provided by H.B. Liu et al. (1999).

3. Mathematical Formulation

The mathematical formulation of the main optimization problem for CO₂ integration falls under the general form of a Non-Linear problem, in which a central objective function ($f(x)$) is subjected to network equality and inequality constraints $h(x)$ and $g(x)$.

$$\min f(x) \quad (4)$$

$$h_i(x) = 0, i \in I = \{1, \dots, a\} \quad (5)$$

$$g_j(x) \leq 0, j \in J = \{1, \dots, b\} \quad (6)$$

Eq. (4) represents the objective function, $f(x)$, which aims to minimize the overall cost of the overall CCUS network in the form of piping, compression, pumping, treatment and sink processing. The overall cost covers both capital and operating costs for which the network is designed to operate. Cost and revenue calculations were based on the model by Al-Mohannadi and Linke, 2016, except for the treatment unit cost, which was developed based on solvent property data, and the respective column sizing calculations (both diameter and height). Moreover, the material of construction was also included in the treatment cost evaluation. Hence, the treatment unit cost in this work is a function of the dimensions of the treatment units (diameter and height), which in turn are functions of the gas feed flow, gas stream properties, the solvent feed flow and the respective solvent feed properties (Brunazzi et al 2002). The cost of the system generated by the model is determined by summing the operating and annualized capital costs (assuming 20 years plant lifetime). The central variable in the optimization problem (x) is the carbon-dioxide flowrate (which can either be treated or untreated). Even though temperature can also be a decision variable, studying the effect of varying temperature on the system would not be possible, since only 1 optimal solution (at the optimal temperature) would be reported. Hence, temperature was kept as a parameter, for the purpose of this study.

This objective function combined to two different sets of constraints: equality constraints $h(x)$ (Eq. (5)), and inequality constraints $g(x)$ (Eq. (6)). Equality constraints primarily cover the mass and component balances of captured and uncaptured (treated and untreated) CO₂ flows throughout the CCUS network. Inequality constraints $g(x)$, on the other hand, involve production and performance requirements, which involve imposing a minimum net CO₂ emission requirement onto the overall CCUS network, in addition to quality constraint limits on each CO₂ within the network to ensure acceptable CO₂ quality and effective sink performance. The exact mathematical expressions associated with all equality and inequality constraints are outlined in Al-Mohannadi and Linke, 2016. In order to be able to solve the optimization problem, What'sBest9.0.5.0 LINDO Global Solver for Microsoft Excel 2010 (Lindo, 2010), was used to implement the model, on a laptop with Intel® Core™ i7-2620M, 2.7 GHz, 8.00 GB RAM, 64-bit Operating System.

4. Results and Discussion

The effect of varying the solvent temperature within the treatment unit was investigated in this work for Methyl Diethanolamine, also known as MDEA. This solvent is well-known for having quite effective CO₂ removal efficiencies. A case study that involves four different CO₂ emission sources (involving an Ammonia plant, a Power-plant, a Refinery and a Steel plant) and six different CO₂ utilization sinks (involving Enhanced Oil Recovery, a Greenhouse option, a Storage option, a Methanol plant, a Urea plant, and an Algae space), i.e, 4 source options that could potentially be matched with 6 different sinks, to meet a prescribed CO₂ target. The setup resembles the case that has been previously presented by Al-Mohannadi and Linke (2016), apart from the treatment handling. A treatment model that enables the assessment of solvent property variations, whilst providing sizing calculations for all treatment units has been used. The operating lifetime assumed was 20 years. In order to explore the effect of varying the temperature on the solvent, and hence onto the overall CCUS network design, six different optimization problems have been attempted, where each is assigned a different overall net capture target as follows: 5%, 10%, 20%, 25%, 35% and 45%, which are in line with

the capture targets reported by Al-Mohannadi and Linke (2016). The temperature could vary between 20 and 27 °C for each of the six different cases involving different net capture targets. Higher temperature ranges could be investigated in a similar manner, subject to data availability. A total of 42 runs have been made, and the results obtained are summarized in Figures 1-3. First off, Figure 1 presents the treatment cost variation as a function of solvent temperature, for the different net capture targets that have been considered.

Figure 1. Treatment cost variation as a function of solvent temperature for different net capture targets

A consistent increase in the overall treatment cost for all cases was observed, when comparing the various capture target cases, due to associated changes in solvent properties that require larger treatment units (in terms of diameter and height). Nevertheless, it should be noted that the highest treatment cost jump was observed between the 10% and 20% capture cases. Moreover, the 5% case was the least sensitive to temperature variations since this case involved the least amount of treatment to meet the capture target. When the total network cost comes into perspective, the trend observed slightly differs since the total network cost involves the costing of other entities that are independent of treatment solvent properties. Figure 2 shows the total network cost variation as a function of solvent temperature for the different net capture targets. It is evident that both the 5% and 10% capture cases become the least sensitive to those temperature variations, while the 45% capture case being the most expensive case explored. The big cost gap that was observed between the 45% capture case and the rest of the cases was attributed to the sink processing costs, which were found to be the least in the 45% capture case. Some of the cases have reported a negative total cost for the run, indicating a revenue-generating case in which the total cost of the network was less than the revenue generated.

Figure 2. Total Network cost variation as a function of solvent temperature for different net capture targets

Figure 3. Relative cost variation of all remaining entities within CCUS network (compression, pumping, piping, sink processing) as a function of solvent temperature, for different net capture targets

Furthermore, the 45% capture case required the most treatment, when compared to the rest of the cases. Finally, the relative cost variation of all remaining entities within CCUS network (compression, pumping, piping, sink processing), as a function of solvent temperature for different net capture targets are illustrated in Figure 3. It is evident that when the relative cost of all those entities combined (with respect to the total cost) is observed, and a decrease in the overall cost of those entities combined has been observed across the temperature range which has been studied. The least sensitive case was the 45% capture case, as it required the most treatment, to meet the capture target.

5. Conclusions

The solvent temperature effect was investigated for different net capture CO₂ reduction targets. It was observed that the total network cost increases with solvent temperature. It was also found that at low CO₂ targets, the temperature did not affect the overall cost, while the 45% capture case was the most expensive. The increased cost was not solely due to the temperature of the solvent but also due to the deployment of non-revenue sinks such as geological storage.

Abstract

The extremely high temperatures in the Western Sahara region has to lead to difficulties in the supply of water and food. Sabkha-Tah in Morocco is one of the regions in the Western Sahara, which possesses conditions that prevent the farming of certain crops. Nevertheless, the region has the advantage of being in a zone 60 m below sea level. This geographical advantage has the potential to reduce energy consumption in the reverse osmosis unit (RO). An energy, water, and food nexus study that takes advantage of the region's geographical characteristics are performed. A multi-generation system that produces cooling, power, and freshwater for a greenhouse situated in the Sabkha-Tah is proposed and thermodynamically analyzed. The freshwater is supplied through a RO unit that uses the hydrostatic pressure of falling water from the Atlantic Ocean. Cooling is supplied through an absorption cooling cycle that uses the waste heat of the Rankine cycle condenser, while a solar-powered Rankine cycle is used to feed the system with the required power. The system uses a parabolic trough collector (PTC), which utilises the high solar irradiance in Sabkha-Tah to generate the energy needed by the Rankine cycle. The PTC uses Cu/Therminol VP1 nanofluid as the working fluid to enhance the efficiency of the system. The study results show a reduction in the RO's power consumption from 5.561 to 2.51 kWh/m³ by using an energy recovery turbine (ERT) and the hydrostatic pressure of the falling water. The system shows that 46.18 kW of pump work can be saved when using the hydrostatic water pressure. The overall energy and exergy efficiencies for the multi-generation system are calculated to be 60.81% and 29.76%, respectively, using TherminolVP1 in PTC, while the energy efficiency increased by 0.014% using nanofluid (Cu/TherminolVP1) with a volume fraction of 0.02.

Keywords: Reverse osmosis; nanofluids; gravitational energy; nexus; multi-generation.

1. Introduction

A multigeneration system that supplies a greenhouse in Sabkha-Tah with cooling and freshwater is proposed in the study. Figure 1 shows the diagram for the studied system with all subsystems included. The sun supplies the energy used to power the system which produces cooling, freshwater, and electricity. The system consists of several subsystems such as a greenhouse, RO unit, absorption cooling cycle, PTC, energy storage, water storage, and Rankine cycle. The annual values of solar irradiance and temperatures of the region were used in this study (Climate, 2019; Solargis, 2019). Sabkha-Tah region has a large area of 250 km² which allows for building a greenhouse with a proposed dimension of 20 m by 20 m and is to be used to grow tomatoes. The system is powered by a parabolic

trough collector (PTC) that uses Therminol VP1 and Cu/ Therminol VP1 nanofluids as the working fluids. The electricity produced by the Rankine cycle is used to meet the electrical needs of the greenhouse and also feeds the community. The desalination technology used is the reverse osmosis unit as it needs high pressure which can be met using the natural advantage of the region. The hydrostatic pressure obtained from the 60 m column of water between the Atlantic Ocean level and the depleted zone level is used along with the energy recovery turbine to reduce the energy required in the RO pump. An ammonia-water absorption cooling cycle is used to provide cooling for the greenhouse and surrounding buildings. At night-time, the greenhouse will require no cooling as the maximum temperature at night in this region is 20 °C. Moreover, an overhead water storage unit uses its potential energy to supply water to the greenhouse at night instead of the pumps.

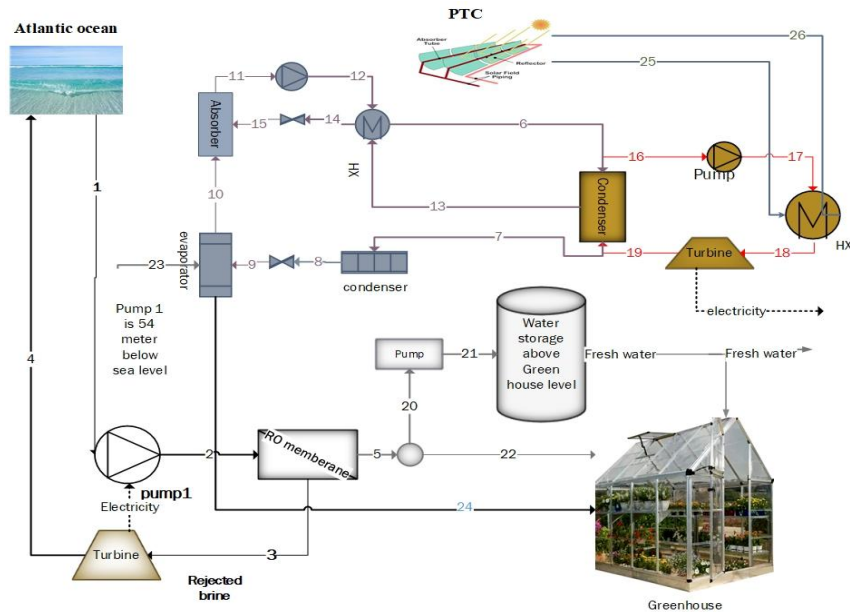

Figure 1: Schematic diagram of the proposed system for the depleted zone in Sabkha-Tah, Western Sahara, Morocco.

2. Methodology/Analysis

The proposed system is analysed using the first and second laws of thermodynamics, properties such as enthalpy, entropy, and specific exergy are determined for each component. The mass, energy and exergy balance equations were used to calculate the thermodynamics properties for each state point (Sorgulu & Dincer, 2019). The area required for one tomato plant and the water consumption per plant is calculated based on published studies (Snyder, 1914). The solar collector is modelled based on the mathematical approach presented in studies related to parabolic trough collectors (PTC) (Okonkwo, Abid, & Ratlamwala, 2019; Okonkwo, Abid, Essien, et al., 2019). Cu/TherminolVP1 is the heat transfer fluid used in the PTC and its properties were calculated using published studies (Azizi et al., 2015; Bruggeman, 1935). The mass, energy, and exergy balance equation for the components of the absorption cooling cycle are shown (Molani & Ziapour, 2019). The design specifications of the RO unit used in this work are similar to the design presented in (Kianfard et al., 2018) and the RO

mathematical model was validated against an actual RO plant that uses spiral wound type membrane. The mathematical model used for the current work is based on (Nafey & Sharaf, 2010). Finally, the overall energy and exergy efficiencies of the integrated system are defined as follows (Sorgulu & Dincer, 2019):

$$\eta_{en,ov} = \frac{\dot{W}_{net} + (\dot{m}_{fw} \times h_{fw})_{RO} + Q_{ACS,ev}}{\dot{Q}_{solar} + (\dot{m}_{sw} \times h_{sw})_{RO}} \eta_{en,ov} = \frac{\dot{W}_{net} + (\dot{m}_{fw} \times h_{fw})_{RO} + Q_{ACS,ev}}{\dot{Q}_{solar} + (\dot{m}_{sw} \times h_{sw})_{RO}} \quad (1)$$

$$\eta_{ex,ov} = \frac{\dot{W}_{net} + (\dot{m}_{fw} \times ex_{fw})_{RO} + \dot{E}x^{Q_{ACS,ev}}}{\dot{E}x^{Q_{solar}} + (\dot{m}_{sw} \times ex_{sw})_{RO}} \quad (2)$$

$$\eta_{ex,ov} = \frac{\dot{W}_{net} + (\dot{m}_{fw} \times ex_{fw})_{RO} + \dot{E}x^{Q_{ACS,ev}}}{\dot{E}x^{Q_{solar}} + (\dot{m}_{sw} \times ex_{sw})_{RO}}$$

where, \dot{m}_{rb} , \dot{m}_{fw} and \dot{m}_{sw} , \dot{m}_{rb} , \dot{m}_{fw} and \dot{m}_{sw} represents the mass flowrates of the rejected brine, freshwater, and seawater, respectively, while \dot{W}_{net} , \dot{Q}_{solar} and $Q_{ACS,ev}$ are the net power, input solar radiation and cooling from absorption cooling cycle, respectively. $\dot{E}x$ represent the exergy term.

3. Results and Discussion

Each state point in the system was thermodynamically analysed. Temperature (T), pressure (P), enthalpy (h), entropy (s), and exergy (ex), the concentration of ammonia (C_{AM}) and the mass flow rate (m) at each state point are presented in Table 1. The working fluid used is different in each cycle. The Cu/Therminol VP1 nanofluid is the working fluid used in the analysis of the PTC. Table 1 presents the physical properties at each state point.

Table 1: Thermodynamics proprieties for all state points in case of the nanofluid.

NO	T (K)	P (kPa)	h (kJ/kg)	ex (kJ/kg. K)	X (g/kg)	C_{Am} (%)	m (kg/s)

26	356.5	141.26	-	-	-	-	-

Figure 2 shows how the region's depth affects the specific power consumption in the RO unit. The RO unit utilized in this study has a recovery ratio of 0.3, and it is integrated with an energy recovery turbine (ERT), which achieves lower specific energy consumption than the conventional RO unit. The power required for both units decreases as the region's depth below sea level increases. A depth of 534 m below sea level is required to generate enough pressure for the proposed RO unit to operate with no energy input from the pumps. The energy efficiency for the overall system and that of the PTC with varying solar irradiance change is presented in Figure 3. A little improvement in the PTC's energy efficiency is noticed as the solar irradiance increases. The working fluid's volumetric flow rate is optimized at solar radiation of 600 W/m^2 , beyond this, the energy efficiency is constant and begins to drop as radiation gets higher. Using Cu/Thermnoil VP1 nanofluid increases the PTC energy efficiency by 0.08% as compared to the base fluid, as can be seen in Figure 3. The overall energy efficiency is simply a ratio of the useful output from the system to the energy input. The absorption cooling cycle coefficient of performance sharply decreases as the solar radiation increases. This increase in solar radiation causes the heat available in the Rankine cycle condenser to also increase, all the excess heat is consumed in the absorption cycle's condenser. As a result, cooling remains the same and finally leads to lower overall energy efficiency. The enhancement in the overall energy efficiency was as low as 0.014% because the nanofluid usage can reduce only the input power to the PTC circulating pump. The electricity consumption in that pump is deficient compared to the overall input power to the system, hence resulting in a small enhancement.

Figure 2: Effect of seawater salinity on the RO's specific power consumption (SPC).

Figure 3: overall and PTC energy efficiencies versus solar radiation.

Table 2 presents the results of some key calculated outputs at an irradiance of 600 W/m 2 . It also shows a comparison between the outputs when using the nanofluid and only the base fluid in the PTC.

Table 2: The main calculated values at solar irradiance of 600 W/m 2

Parameter	Therminol VP1	Cu/Therminol VP1 nanofluid
Electricity consumption in RO	226 kW	226 kW
The volume flowrate of freshwater	90 m 3 /h	90 m 3 /h
Absorption cycle cooling output	4936 kW	4936 kW
Absorption cycle heat input	3042 kW	3044
Heat input to Rankine cycle	3940 kW	3943
Electricity production of the Rankine cycle	897.9 kW	898.9 kW
Area of greenhouse	9389 m 2	9389 m 2
Number of tomato plants	25239 plants	25239 plants
Electricity production of the whole system	636.3 kW	637.5 kW

4. Conclusions

In this study, a multi-generation system is proposed for use in Sabkha-Tah to produce energy, cooling, and freshwater for a tomato greenhouse. The system uses the geographical feature of the region, which is situated 60 m below sea level. In the proposed system, water from the Atlantic Ocean is pumped into the RO membrane to produce fresh water. The electricity and cooling needs are supplied using the absorption cooling cycle and Rankine cycle, respectively. The study presents a novel reduction in the power consumption of the reverse osmosis unit. The RO system's required power is reduced when using an energy recovery turbine and by taking advantage of the region's depleted

level, which is 60 m below the sea level. The RO-specific power consumption decreases from 3.065 to 2.511 kWh/m³. The system's overall energy and exergy efficiencies are calculated to be 60.8% and 29.76%, respectively, when base fluid (TherminolVP1) is used in the PTC. However, when using Cu/TherminolVP1 nanofluid in the PTC, the overall energy and exergy efficiency is improved by 0.08% and 0.014%, respectively.

Abstract

The structure of a catalytic reactor integrating two reactions is yield-optimized in terms of distribution of active sites of two catalysts in a hybrid pellet, using a two-scale (pellet and reactor) approach. POD-Galërkin model reduction is adopted to reduce the burden of the optimization algorithm. Results show that optimal structuring can have a key role in catalyst process intensification, in terms of yield, chosen as the performance indicator and thus also as the objective function for the optimization problem.

Keywords: hybrid catalyst pellet, process integration, optimal reactor structuring.

1. Introduction

A catalytic fixed-bed reactor integrating two or more reactions poses a problem of performance optimization in terms of best selection of its structural parameters. Beyond temperature and residence time, the distribution of the catalytic active sites in the solid as well as the size of the pellets play a key role. In an earlier work, the yield-optimal distribution of catalytic active sites was determined for a single spherical hybrid pellet where two consecutive isothermal chemical reactions with one reversible step under arbitrary kinetics occur (Bizon and Continillo, 2019). A Proper Orthogonal Decomposition (POD) model reduction approach was employed to limit the computational effort related to the resolution of the optimization problem. Later on, the non-isothermal case of a hybrid pellet was tackled (Bizon and Continillo, 2020), and a Discrete Empirical Interpolation Method (DEIM) approach was combined with POD-Galërkin to best deal with the strong non-linearities due to the presence of the Arrhenius terms. In this work, the study is extended to the whole reactor, and the optimal distribution of catalytic active sites within a single pellet is determined with reference to the process enhancement on the apparatus level. This is a multiscale problem, in that the state variables are distributed along the reactor length and within the pellets, thus, to limit the computational expenses, the discretized model of the pellet is reduced using POD.

2. Mathematical model and solution methodology

Two reversible chemical reactions of the first order in a catalytic fixed-bed reactor made of spherical hybrid pellets take place under non-isothermal and steady-state conditions:

The mass and energy balance equations for a pellet, written in dimensionless form, are:

$$\frac{d^2 \beta_A}{d\xi^2} + \frac{2}{\xi} \frac{d\beta_A}{d\xi} - \Phi_1^2 f_1 \frac{\tilde{r}_1}{\tilde{r}_{1,ref}} = 0 \quad (2a)$$

$$\frac{d^2 \beta_B}{d\xi^2} + \frac{2}{\xi} \frac{d\beta_B}{d\xi} + \Phi_1^2 f_1 \frac{\tilde{r}_1}{\tilde{r}_{1,ref}} - \Phi_2^2 f_2 \frac{\tilde{r}_2}{\tilde{r}_{2,ref}} = 0 \quad (2b)$$

$$\frac{d^2 \beta_C}{d\xi^2} + \frac{2}{\xi} \frac{d\beta_C}{d\xi} + \Phi_2^2 f_2 \frac{\tilde{r}_2}{\tilde{r}_{2,ref}} = 0 \quad (2c)$$

$$\frac{d^2 \theta_p}{d\xi^2} + \frac{2}{\xi} \frac{d\theta_p}{d\xi} + \delta_1 \Phi_1^2 f_1 \frac{\tilde{r}_1}{\tilde{r}_{1,ref}} + \delta_2 \Phi_2^2 f_2 \frac{\tilde{r}_2}{\tilde{r}_{2,ref}} = 0 \quad (2d)$$

where $\beta_i = C_{p,i}/C_{ref}$ denotes reactant concentration within the pellet, $\theta_p = T_p/T_{ref}$ is the temperature of the pellet and $\xi = r/R_p$ is the radial coordinate with R_p being the pellet radius. Symbols Φ_j and δ_j are, respectively, Thiele modulus and dimensionless enthalpy, and f_1 and f_2 in Eq. (2) are the local volume fractions of the pellet occupied by active sites catalysing, respectively the first and the second step of the process described by Eq. (1). The boundary conditions associated with the above balances are:

$$\left. \frac{d\beta_i}{d\xi} \right|_{\xi=0} = 0, \quad i = A, B, C; \quad \left. \frac{d\theta_p}{d\xi} \right|_{\xi=0} = 0 \quad (3a)$$

$$\left. \frac{d\beta_i}{d\xi} \right|_{\xi=1} = \text{Bi}_m (\alpha x_i - \beta_i(1)); \quad \left. \frac{d\theta_p}{d\xi} \right|_{\xi=1} = \text{Bi}_q (\theta_g - \theta_p(1)) \quad (3b)$$

Under the assumptions that the gas, flowing in a plug flow through the catalytic bed, obeys the ideal gas law and that the pressure drop can be neglected (this last assumption clearly limits the applicability of this particular model to the cases in which the assumption is verified to a significant extent), the component mass balances, the continuity equation and the energy balance for the gas are:

$$\frac{d}{d\zeta} (\alpha x_i v) + \Gamma_m [\alpha x_i - \beta_i(1)] = 0, \quad i = A, B, C \quad (4a)$$

$$\frac{d}{d\zeta} (\alpha v) + \Gamma_m \sum_i [\alpha x_i - \beta_i(1)] = 0 \quad (4b)$$

$$v \frac{d\theta_g}{d\zeta} + \Gamma_{q1} [\theta_g - \theta_p(1)] + \Gamma_{q2} (\theta_g - \theta_q) = 0 \quad (4c)$$

with x_i being component molar fraction, $v = u/u_{ref}$ – dimensionless interstitial gas velocity and $\zeta = z/L_r$ – dimensionless reactor length. The conditions at the reactor inlet are:

$$x_i|_{\zeta=0} = x_{m,i}; \quad \alpha|_{\zeta=0} = \alpha_m; \quad \vartheta_g|_{\zeta=0} = \vartheta_m; \quad v|_{\zeta=0} = v_m \quad (5)$$

More details on the model formulation and definitions of the dimensionless parameters are reported in a previous work (Bizon and Continillo, 2021). The optimization problem is to find f_1 maximizing the yield of C with respect to A, defined as:

$$\max_{f_1} Y_{CA,r} = \frac{\dot{n}_{C,out}}{\dot{n}_{A,in}} \quad \text{subject to } 0 \leq f_1 \leq 1 \text{ and } f_2 = 1 - f_1. \quad (6)$$

Figure 1. Distribution of f_1 and f_2 within the pellet for $\zeta_{cat} = 0.7937$.

Considering that the core-shell arrangement of the active sites within bifunctional pellets is a promising approach to process integration and intensification (Sánchez-Contador et al., 2019; Bizon et al., 2020), the optimization procedure seeks the optimal radius of the pellet core ζ_{cat} . Functions f_1 and f_2 are defined by sigmoid functions as:

$$f_1(\xi) = \frac{1}{1 + \exp[-A \cdot (\xi - \xi_{cat})]} \quad \text{and} \quad f_2(\xi) = 1 - f_1(\xi) \quad (7)$$

Figure 1 shows the distribution of f_1 and f_2 determined according to Eq. (7) with $A = 100$ and $\zeta_{cat} = 0.7937$, that gives equal pellet volume occupied by each of the two catalysts. Considering that the catalyst arrangement with the active sites enhancing the first step of the process located in the pellet core proved to overperform the reverse arrangement, only the arrangement with catalyst one located in the pellet core and catalyst two in the shell is considered in this study. The solution of the optimization problem given by Eq. (6) requires the resolution of the two-scale reactor model. The most straightforward approach consists in the transformation of the infinite-dimensional problem (Eq. (2)-(5)) into a finite-dimensional form using the finite difference method. Given the core-shell nature of the pellet, as many as $N = 101$ discrete nodes are necessary to obtain satisfactory solution accuracy for the pellet sub-model. On the other hand, to account for possible hot spots, $M = 501$ discrete nodes along the reactor are needed to discretize the gas phase balance equations. Thus, to reduce the computational effort related to resolution of the optimization problem, a model-reduction technique is adopted. Following the approach described in Reference (Bizon and Continillo, 2021), in this study Proper Orthogonal

Decomposition (POD) combined with Gal rkin projection (Holmes et al., 1996) is employed to reduce the dimensionality of the smaller scale model, i.e. the pellet sub-model. The POD-Gal rkin procedure consists in the orthogonal projection of the full-order finite-dimensional system onto a low number of POD modes generated from the full-order model (FOM) snapshots. Consider the following parameter-dependent system of N algebraic equations resulting from the discretization of the boundary value problem (Eq. (2)-(3)):

$$\mathbf{A}\mathbf{y}(\mu) + \mathbf{F}(\mathbf{y}(\mu)) = 0 \quad (8)$$

For the case here considered, the model μ represents the location of pellet within the bed and the value of ζ_{cat} for which the FOM was resolved. The POD basis, $\Psi = [\psi_1, \psi_2, \dots, \psi_N] \in \mathbb{R}^{N \times N}$, is then determined by solving the eigenvalue problem:

$$\mathbf{C}\Psi = \Lambda\Psi \quad \text{where} \quad \mathbf{C} = \frac{1}{M_s} \mathbf{Y}\mathbf{Y}^T \quad (9)$$

where \mathbf{Y} is the matrix of snapshots obtained from FOM simulation and M_s is the number of snapshots used for the determination of the POD basis. Since in this study POD-Gal rkin is used to reduce the pellet model coupled with the gas model, both embedded in the optimization algorithm, it is necessary to construct a POD basis that is able to approximate accurately the system behavior as it develops with the variation of the decision variable. Over the years, different sampling strategies were proposed to construct the so-called global POD basis (Kuan et al., 2019), however, until now there is no reliable sampling policy. In this study, the procedure based on k -means clustering (Bizon and Continillo, 2021) is employed to extract the most informative snapshots from a large number of solution profiles within the pellet. Considering that the optimal value of ζ_{cat} is expected to be close to 0.7937 (radius at which core and shell have equal volume in a sphere), the FOM was simulated for three values of ζ_{cat} , i.e. 0.75, 0.8, 0.85, 0.9 and 0.95, and then the k -means algorithm was run on the ensemble of intrapellet solution profiles collected along the reactor for all values of ζ_{cat} . For each state variable, a separate POD basis was determined using the $M_s = 100$ most informative snapshots.

3. Results and discussion

The values of the main parameters used in the simulations are summarized in Table 1.

Table 1. Main model parameters used in the numerical simulations.

Parameter	Value	Parameter	Value
D_{eff}	$10^{-6} \text{ m}^2 \cdot \text{s}^{-1}$	R_p	$2.5 \cdot 10^{-3} \text{ m}$
$k_1(T_{in}) = k_2(T_{in})$	2.95 s^{-1}	T_{in}	400 K
$k_{.1}(T_{in}) = k_{.2}(T_{in})$	0.15 s^{-1}	u_{in}	$0.7 \text{ m} \cdot \text{s}^{-1}$
L_r	8 m	λ_{eff}	$10^{-4} \text{ kW} \cdot \text{m}^{-1} \cdot \text{K}^{-1}$

Representative centroid of clusters employed to construct the POD basis for the concentration of intermediate product B within the pellet are shown in Fig. 2a, whereas Fig. 2b. shows the leading POD modes determined for β_B . The intrapellet solution profiles vary with the location of the pellet in the reactor, due to ongoing chemical process and

variation of the composition of the flowing gas, and also with the variation of the catalyst arrangement represented by the variable ζ_{cat} . As shown in Fig. 2a, the k -means procedure permits to select the most informative profiles while skipping those that are practically the same, and thus do not contribute, in terms of information content, to the POD basis.

Figure 2. Representative solution profiles of $\beta_B(\xi)$ within the pellet selected using k -means clustering (a) and leading POD modes for the concentration of component B (b).

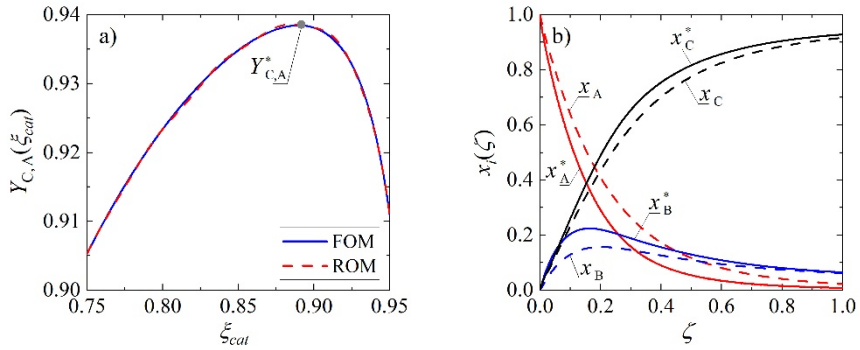

Figure 3. Values of the objective function $Y_{C,A}$ determined using FOM and ROM (a), and molar fractions of the reactants in the gas phase along the reactor determined using ROM for optimal value of ζ_{cat}^* (solid lines) and for reference value $\zeta_{cat} = 0.7937$ (dashed lines).

After analysing the convergence of the ROM constructed using different truncation order, the value of $K = 19$, for each intrapellet state variable, was selected to run the optimization algorithm. Figure 3a shows the comparison of the objective function determined using FOM and ROM, together with the location of the optimum, determined by the MATLAB *fmincon* function with the submerged *fsolve* function for the resolution of the full- and reduced-order reactor model. It can be observed that the ROM approximates very accurately both the objective function and the location of the optimum. The optimal value of ζ_{cat} results to be higher than the one corresponding to the 1:1 volume ratio, $\zeta_{cat} = 0.7937$, of the pellet occupied by the first and the second type of the catalytic active centres. Increasing the value of ζ_{cat} from the reference value equal to 0.7937 to optimal value, i.e. $\zeta_{cat}^* = 0.8901$, permits in fact (Fig. 3b) to enhance the conversion of A near the reactor inlet. Values of the optimum location and corresponding values of the objective function are in Table 2 together with the computational time expenses. Despite the relatively high number of the POD modes used to build the ROM, mainly as a

consequence of the core-shell structure of the pellet, the ROM still allows considerable time saving, both when performing a single simulation and computing the optimization of the pellet structure.

Table 2. Comparison of optimal values and computational time of FOM and ROM ($K = 19$).

Model	ξ_{cat}^*	Y_{CA}^*	Single sim. time, s	Optimization time, s
FOM	0.8901	0.9384	88.064	1573
ROM	0.8846	0.9386	18.904	385

4. Conclusions

Adopting the optimal structuring found in this study will positively impact the production and is foreseen as a practical gain in many processes of industrial interest. Although more detailed than most literature models, this approach has still some limitations in that it does not address reactor non-idealities: the hybrid plug-flow fixed-bed reactor model is in fact adopted, and the pressure drop is assumed to be negligible. The model reduction procedure complicates the preparation of the numerical code, but the computational gain is expected to be well worth the effort as the dimension of the problem is increased. Even in this low dimensional case, POD-Galërkin helps even though, with this particular problem, accuracy requires a relatively large number of modes to be included in the ROM.

Abstract

Knowledge of appropriate kinetic models for the design of the reactive distillation column is critical and directly affects the performance parameters. In many industrially important reactions, a pseudo-homogeneous concentration-based kinetic model is more suitable for process design. The present work offers a design procedure of hybrid reactive distillation columns (HRD) to obtain the desired selectivity of intermediate product in reaction schemes for which a pseudo-homogeneous concentration-based kinetic model is best suited. This work is in continuation with our previous work on selectivity engineering with HRD columns [Hasan et al., 2013a, b; Hasan et al., 2014a, b; Hasan et al., 2015; Singh et al. 2018; Singh et al. 2019] in which we developed generalized algorithms for the design of HRD columns to obtain the desired selectivity of intermediate products in different types of multi reaction schemes. However, all the previous investigations are restricted to mole fraction-based kinetics. As a result, here, we examined the potential of HRD for pseudo-homogeneous concentration-based kinetic models and developed an algorithm to obtain HRD column designs of the desired selectivity.

Keywords: Hybrid Reactive Distillation, Pseudo-homogeneous, Concentration-based kinetics, Selectivity, Design

1. Introduction

For designing HRD columns or any large reactor, one should know well-determined kinetics, which includes the effects of all parameters on elementary and side reactions that can predict the actual mechanism of reactions. Although the kinetics of industrially relevant reactions having rigorous thermodynamic approach with activity coefficients are more accurate for the study purpose, however pseudo-homogeneous concentration-based kinetics equally holds good results and best suited for process design [Ronnback et al., 1997]. In this work, we developed a conceptual design algorithm to design HRD columns to obtain desired selectivity for the multi reaction systems with pseudo-homogeneous concentration-based kinetics. To illustrate the above point, a model series type reaction scheme has been studied as an example and a combined graphical-simulation algorithm is developed using the concepts of attainable region approach.

2. Design Methodology

It is well known that in a CSTR, the reaction occurs at the outlet conditions. Therefore, the reaction and mixing vectors are collinear given by material balance [Glasser et al. (1987)]. In any other CSTR type arbitrary reactor, the reaction will not occur at the outlet conditions, and hence the collinearity condition is no more valid. The composition in this arbitrary reactor can be controlled by similarly introducing separation attributes as in the case of reactive distillation.

Fig. 1. The analogy between Arbitrary reactor (R) and HRD Column

Consider HRD column with only one reactive stage as shown in Fig. 1. The reaction does not occur at product stream composition (P), which is the end composition found by substantially mixing the top (distillate), bottom streams. The composition at which reactions occur in it is governed by separation attributes (vapor to feed ratio, distillate to feed ratio, number of stages, etc.). Therefore, potential reaction stage compositions that provide the desired selectivity in composition space can be obtained as discussed in the next section.

2.1 Locus of Reactive Concentrations (LRCs)

Consider a series reaction scheme (Eq. 1) with kinetic rate constants $[k_1 \ k_2] = [1 \ 1]$. The reaction occurs in liquid phase only with feed as pure reactant A.

$$[r_A \ r_B \ r_C] = [-k_1 C_A^*, k_1 C_A^* - k_2 C_B^*, k_2 C_B^*]$$

Fig. 2a. Selected reactive concentration, C^* on locus of reactive concentrations (LRCs).

Fig. 2b. Transformed, X^* on locus of reactive stage compositions (LRSC).

Assuming constant density and volume system. The bounds in concentration space can be taken as equivalent to the reactant's initial concentration in case of single reactant schemes. Based on desired selectivity choose a point, P as shown in Fig. 2a. Now by taking the component mass balances on arbitrary reactor one can easily write Eqn. (2). The LHS of this equation is nothing but the slope of line AP. Using Eqn. (2) plot the locus of reactive concentrations, as shown in Fig. 2a.

$$\frac{C_{BP} - C_{BF}}{C_{AP} - C_{AF}} = \frac{k_1 C_A^* - k_2 C_B^*}{-k_1 C_A^*} \quad (2)$$

where,

C_{AF}, C_{BF} = Concentration of component A and B in inlet stream

C_{AP}, C_{BP} = Concentration of component A and B in outlet stream

It should be noted here that by choosing the point, P in the concentration space the conversion and selectivity gets fixed as given by Eqn. (3). For constant density and volume system ($v_0=v$).

$$\text{Selectivity} = (C_{BP}v - C_{BF}v_0)/(C_{AF}v_0 - C_{AP}v) \quad (3)$$

$$\text{Conversion} = (C_{AF}v_0 - C_{AP}v)/(C_{AF}v_0)$$

Now, one can transform the reactive concentrations into reactive mole fractions by using Eqn. (4) and thereby plot the locus of reactive stage compositions (LRSCs) in the mole fraction composition space as shown in Fig. 2b.

$$X_i^* = \sum_{i=1}^{N_c} C_i^* V_r / n, \quad X^* = [X_A^* X_B^* X_C^*] \quad (4)$$

In the RD column, if the reaction occurs at a composition belonging to any of the LRSC, our desired selectivity is ensured.

2.2 Algorithm Steps

The design methodology is based on the fact that if we separate reaction and distillation features of HRD configuration as shown in Fig. 3a, then the resulting configuration (Fig. 3b) consist of arbitrary reactor and separator system that gives the performance same as HRD configuration (Fig. 3a). This will enable us to find the desired operating parameters required to obtain the design of the desired selectivity.

Fig. 3. (a) Hybrid (RD) column. (b) Arbitrary Reactor Separator System (Non-RD).

- i. Select any point P (Fig. 2a) in the concentration space according to the intermediate product's desired selectivity, B.

- ii. Join points, A (30, 0) and P (9, 5.25) to find the slope of line AP. Using Eqn. (2) plot the locus of reactive concentrations (LRCs). One can calculate the selectivity and conversion using Eqn. (3). For the present example, selectivity = 0.25 and conversion = 0.70.
- iii. Select any C^* on the locus of reactive concentrations as shown in Fig. 2a. For the ongoing example we have selected $C^* = [C_A^* \ C_B^* \ C_C^*] = [12, 9.6, 2.3]$. The third concentration is calculated by the summation equation (applicable for constant density and volume system only).
- iv. Specify the volumetric feed flow rate ($v_0 = 0.5$ m³/sec) to the arbitrary reactor and calculate the volume of reactor, V_R using any of the Eqn. (5) or (6).

$$C_{AF} - C_{AP} = (V_R / v_0) * r_A(C^*) \quad (5)$$

$$C_{BF} - C_{BP} = (V_R / v_0) * r_B(C^*) \quad (6)$$

- v. Calculate the total number of moles, n using Eqn. (6).

$$n = \sum_{i=1}^{N_c} n_i; \text{ where, } n_i = C_i^* V_r \quad (7)$$

- vi. Transform the selected reactive stage concentration, $C^* = [C_A^* \ C_B^* \ C_C^*] = [12, 9.6, 2.3]$ into reactive stage mole fraction, $X^* = [X_A^* \ X_B^* \ X_C^*] = [0.4267, 0.32, 0.2533]$ using Eqn. (4).
- vii. Calculate damkohler number, Da by employing the material balance of either component A or B on arbitrary reactor using Eqn. (8) or (9). Also find the concentration of component C in the product stream using Eqn. (10).

$$C_{A,0} - C_{A,P} + Da \left(\frac{-k_1 C_A^*}{k_{ref}} \right) = 0 \quad (8)$$

$$C_{B,0} - C_{B,P} + Da \left(\frac{k_1 C_A^* - k_2 C_B^*}{k_{ref}} \right) = 0 \quad (9)$$

$$C_{C,0} - C_{C,P} + Da \left(\frac{k_2 C_B^*}{k_{ref}} \right) = 0 \quad (10)$$

Where, H' = volumetric catalyst hold-up & Damkohler number,

$$Da = (H' \times k_{ref}) / v_0, \quad k_{ref} = 1$$

- viii. Calculate the flow rate of product stream P, of arbitrary reactor from Eqn. (11) that is sent to non-RD column as shown in Fig. 3b.

$$F_P = v_0 (C_{AP} + C_{BP} + C_{CP}) \quad (11)$$

- ix. Specify the hypothetical feed to Non-RD column using Eqn. (12).

$$X_{feed_NonRD} = [X_{afeed} \ X_{bfeed} \ X_{cfeed}] \quad (12)$$

where, $X_{ifeed} = (C_{iP} * v_0) / F_P$, for $i = A, B, C$

- x. Next, define the total number of stages ($N=12$) and location of feed ($N_{fl}=6$).
- xi. Find out operating parameters so that the feed stage composition of the Non-RD column coincides with chosen reactive stage composition, X^* . To achieve this draw family of curves as shown in Fig. 5, for different $V:F$ (boil-up to feed ratio) and for a range of $D:F$ (Distillate to feed ratio). Adjust the operating parameters to meet the required condition. After finding suitable parameters with the help of family of curves, plot Non-RD column profile in composition profile.

Fig. 5. Family of feed stage compositions at different values of $V:F$ (range of $D:F$)

Fig. 6. Identical non-RD and RD column profiles

- xii. Simulate the RD column using the same operating parameters and plot the column profile of RD column. The close match of column profiles shown in Fig. 6, indicates feasible design obtained with the help of a simple HRD column. Table 1 shows the feasible design specifications meeting our requirements of desired selectivity for the reaction scheme given by Eq. (1).

Table1: Design specifications of hybrid RD Column for reaction scheme having pseudo-homogeneous concentration-based kinetic model

Column configuration	Non-RD Column	RD Column
Number of components, NC	3	3
Rate Constant [$k1, k2$]	[1,1]	[1,1]
Volatility order [$A B C$]	[$B > A > C$]	[$B > A > C$]
Reaction Volume	-	0.8203
Number of stages, N	12	12
Feed location, N_{fl}	6 th Stage	6 th Stage
Feed flow rate, F	15	15
Feed composition, X_f	(0.3, 0.1750, 0.5250)	(1, 0, 0)
Feed stage composition, X^*	(0.4267, 0.3200, 0.2533)	(0.4267, 0.3200, 0.2533)
Number of reactive stages, N_r	-	1
Location of Reactive stage, N_{rl}	-	6 th Stage
Damkohler Number	-	1.6406
Distillate to feed ratio, $D:F$	0.1377	0.1377

Vapor to feed ratio, $V:F$	2.381	2.381
End Compositions after mixing the the distillate, side draw and bottom streams	(0.3, 0.1750, 0.5250)	(0.3, 0.1750, 0.5250)

3. Conclusions

A conceptual design algorithm of the hybrid RD column is developed to obtain the desired selectivity design in case of a series reaction scheme with a pseudo-homogeneous concentration-based kinetic model. Presented methodology generates multiple feasible designs which is reliant on feed location, number of moles involved in the reaction, volumetric flow rate, number of stages etc., and can be accessed in terms of operating and capital cost to determine a good/optimal design for the given set of design goals. It is applicable to single feed configurations with reactant(s)/intermediate boiling in residue curve map. The developed method provides good initialization for rigorous simulation and optimization for industrially relevant multireaction systems.

Abstract

This contribution presents an integer-linear model of a post-combustion carbon capture plant featuring discrete sizing, part load operation and dynamic behavior. In particular, the model covers a design space from 200 t_{CO₂}/h (size of Petra Nova) down to 7.5 t_{CO₂}/h, a part load operation range from 50% to 100%, and a CO₂ concentration range from 7.5% to 12%. Starting with detailed, partly rate-based, models in Aspen Plus and deriving linear performance planes thereof allows to bring process model information into a linear system modeling domain for a reasonable range of design specifications.

By applying this model to a low-emission energy system design optimization, its practicability and added value could be demonstrated. The simulations show that especially for systems with high non-dispatchable energy generation, the information about the carbon capture plant's dynamic behavior is essential. To fit the scope of this paper, the mathematical formulation of the model is reported in a condensed manner. However, all information required to formulate the model is provided.

Keywords: CCS, MILP, energy system design, low emission

1. Introduction

The importance of carbon capture and storage (CCS) for decarbonizing our society is widely recognized in the scientific community and among policy makers. Although the topic of CCS experienced extensive research in the last decades, its role in integrated, low-emission energy systems has started to be addressed only recently. A reason for this is the high level of complexity of detailed energy system models, which further increases by applying detailed CCS models. Nevertheless, with the shift of conventional electricity generators like gas turbines from baseload operation to backup operation for non-dispatchable renewable energy sources, the ability of integrating CCS into energy system modeling is crucial. We aim at filling this gap by developing a linear post-combustion capture model which is compliant with the multi-energy system (MES) modeling framework developed in earlier works (Gabrielli et al., 2018a, 2018b). The model is based on simulations of a monoethanolamine (MEA) carbon capture process in Aspen Plus and features discrete sizing, part load operation and dynamic behavior. To showcase the model, we apply it to design a low-emission energy system which supplies the electricity demand of the Dutch province of Zeeland. In a multi-objective optimization for total system cost and annual CO₂ emissions, the trade-offs between renewable energy technologies (solar and wind energy) and conventional ones (gas

turbine) with CCS are investigated. Section 2 will describe the model and its verification, Section 3 shows the results of the model's application to the energy system design, and Section 4 will conclude this contribution.

2. Modeling

2.1. Process model

The model in Aspen Plus is a complete description of the MEA-based carbon capture process including absorber, stripper, heat exchangers, pumps, and a compressor for the lean vapor compression. Note, however, that compression of the CO₂ stream for any downstream activities like storage is not included. A water wash section to recover liquid from the CO₂ product stream was omitted to limit the number recycles. The equilibrium based process model was refined with a rate-based absorber model according to Amirkhosrow et al. (2020). To couple the two domains, the Murphree efficiencies obtained from the standalone rate-based absorber model were applied to the equilibrium absorber column. To account for the change of the Murphree efficiencies with changes in operating conditions, the equation reported by Zhang et al. (2016), describing the effect of flue gas flow rate, CO₂ concentration and solvent flow rate, was used. Since the solvent-to-flue gas ratio is fixed in this work, the original equation was adapted accordingly. Key constraints of the process are a capture rate of 90% and a CO₂-purity of at least 95%.

2.2. Linear performance planes

The linear model is supposed to describe the electricity and heat demands as a function of flue gas flow rate and CO₂ concentration. The flue gas flow rate is treated as part load operation for a plant of fixed size. To simplify the model, three discrete sizes are considered, i.e. design point flue gas flow rates of 15 kg/s, 80 kg/s, and 350 kg/s. For each of those design sizes, the flue gas flow rate was varied between 50% and 100% of the design flow rate (part load), and the CO₂ concentration was varied between 7.5% and 12%. Starting with a minimum number of 12 data points, enough simulations were conducted to achieve an R² value of 95% for the linear performance plane described as

$$\chi_e = \alpha_e \cdot F_e + \beta_e \cdot [CO_2] + \gamma_e \quad (1)$$

where χ_e is the demand of energy carrier e , α , β , and γ are the fitting parameters, F is the flue gas flow rate, and $[CO_2]$ is the CO₂ concentration. The parameters are shown in Table XY. The performance planes were implemented according to the following equations

$$Q_{e,t} = \sum_{i \in I} \alpha_{e,i} \cdot F_{i,t} + \left(\beta_{e,i} \cdot [CO_2]_t + \gamma_{e,i} \right) \cdot u_{i,t} \quad \forall t \in T, \quad e \in E \quad (2)$$

$$M_t^{CO_2} = \sum_{i \in I} [CO_2]_t \cdot F_{i,t} \cdot \theta \quad \forall t \in T \quad (3)$$

$$J = \sum_{i \in I} \left(k_i^c + k_i^m \right) \cdot x_i \quad (4)$$

where Q is the energy consumed, M^{CO_2} is the mass of CO_2 captured, and C is the cost; k^c and k^m are the cost coefficients for investment cost and operation and maintenance costs, respectively; u and x are booleans for operation and installation, respectively; i and t indicate the discrete plant size and time instance, respectively. Furthermore, the model is subject to the following constraints: non-negativity for all variables; only one plant size can be installed and operated; upper and lower limit for flue gas flow rate according to plant size and operation state (flow rate is zero when plant is not operating); upper and lower limit for flue gas CO_2 concentration. The dynamic behavior is constrained as described in the following section.

Table 1: Overview of fitting parameters for linear performance planes

Design Flue Gas Flow Rate kg/s	Electricity			Heat		
	α kg/s	β wt-%	γ -	α kg/s	β wt-%	γ -
15	0.004	0.05	-155.20	0.60	40.9	-7.07
80	0.004	0.30	-0.05	0.68	239.2	-44.0
350	0.004	1.39	-0.22	0.58	897.8	-150

2.3. Dynamic behavior

The dynamic response to changes in the flue gas flow rate was assessed using literature values. The dynamics for changes in CO_2 concentration were neglected since this value is not expected to fluctuate significantly. To model dynamic behavior in linear models, three key parameters are required, namely the time until equilibration, the maximum rate of change, and the time constant. The latter is obtained by fitting a first-order dynamic function such that its integral fits the integral of the real dynamic data. For more details about this approach, the reader is referred to Gabrielli et al. (2018b).

Figure 1: Original response curve and first-order approximation for the reboiler heat duty

For ramping behavior, the time until equilibration was found to be 3 h and the maximum rate of change is 20% (Bui et al., 2020; Luyben, 2013). Using the dynamic data reported in (Luyben, 2013) to derive the time constant showed that over the course of the re-equilibration process (3 h) the delayed response is compensated by a subsequent overshoot. This leads to an almost stepwise ramping behavior for the first-order dynamics. Figure 1 shows this on the example of the reboiler duty, but similar outcomes were obtained for all data of interest. Hence, the time constant was neglected and the dynamic behavior described as an instant increase in the response variable to a change of maximum 20% of flue gas flow rate, followed by 3 hours of steady-state operation, i.e. no additional change in flue gas flow rate can occur in this time period.

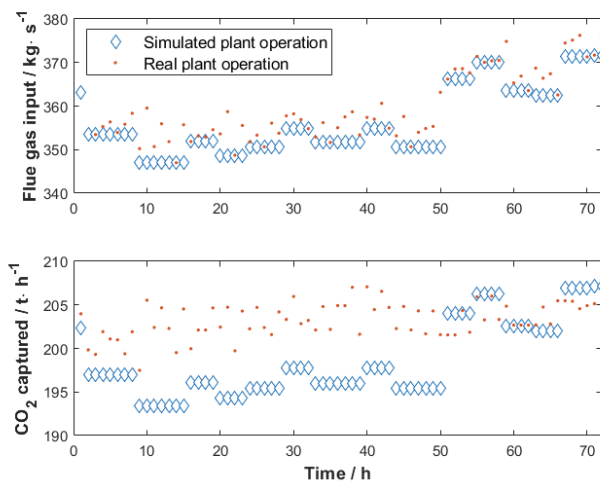

Figure 2: Comparison of real data from the Petra Nova plant with the model performance.

2.4. Model validation

The model was validated using the publicly available operation data of Petra Nova over a 72 h time period (Mitsubishi Heavy Industries, 2017). Assuming a constant CO_2 concentration, the flue gas flow rate was calculated from the published data on captured CO_2 and capture rate. Figure 2 shows the result of feeding the model with the derived flue gas data and maximizing the CO_2 captured. The dynamic limitation of the model is clearly visible, and the total CO_2 captured in the analyzed 72 h period only deviates 2% from the real data. A major contributor to this deviation is that the real capture rate is not exactly at 90% but slightly decreases from 93.6% to 87.6%.

3. Application

3.1. System description

To showcase the model developed in this work, an energy system consisting of photovoltaic panels, wind turbines, batteries, a single-cycle natural gas turbine, and the post-combustion capture unit was designed to satisfy the electricity demand of the Dutch province of Zeeland (3.24 TWh/y). The multi-objective optimization for total system cost and CO_2 emission was carried out based on hourly resolved weather and demand data from the year 2019. The natural gas price is assumed constant at 30

EUR/MWh (average 2008-2019) (Statista, 2020) and a CO₂ tax of 25 EUR/t, inspired by current European Emission Allowance prices, was applied.

3.2. Post combustion capture in low emission energy systems

To investigate the effect of carbon capture on the energy system, a set of Pareto-optimal designs was generated for the same system with and without the option for carbon capture. The resulting Pareto-fronts can be seen in Figure 3. Due to large uncertainties in the cost estimates, the findings for cost should be used for comparative rather than absolute interpretation. Furthermore, the cost of carbon sequestration or utilization is not included. It can be observed that the addition of PCC to the system improves the Pareto front. This results from the fact that the gas turbine with PCC replaces most of the wind turbine and PV installations for a wide range of designs. Only for deep decarbonization (below 0.1 t_{CO2}/MWh) renewable energy sources are used at significant extent. This can be explained by the carbon capture rate, which limits the decarbonization to 90% if all electricity was to be supplied by gas turbines. Hence, the capacity of installed gas turbines below this emission limit decreases until it reaches zero for a carbon-free design. Once passing the threshold of 0.1 t_{CO2}/MWh, the operation mode of the gas turbine switches from baseload to backup for renewables abruptly. Figure 4 shows the operation of the gas turbine (using CO₂ produced as a proxy) and the PCC units for the design allowing for 100 kt_{CO2}/y, zoomed in on a 72 h time period. The flexible operation of the gas turbine is obvious. However, less obvious but more important, the operation is constrained by the dynamics of the PCC unit which shows in the periods of steady state operation which never violate the 3-hour constraint. While the dynamics of the gas turbine and the PCC unit are not strictly coupled, the limit on CO₂ emissions does not allow the gas turbine to operate out of sync with the PCC unit.

Figure 3: Pareto front for the energy system design for the province of Zeeland.

4. Conclusion

In this contribution, we derived linear performance planes to describe the electricity and heat demands as (a) a continuous function of flue gas flow rate and CO₂ concentration and (b) a discrete function of size. These performance planes are valid for a parameter range wide enough to cover most fossil energy conversion technologies found in practice. Together with the information provided on the dynamic behavior, a complete MILP can be formulated. The application of the derived model to a simple case study showed the importance of having such a model available for the design of low-emission energy systems. In particular, the dynamic behavior was found to play a significant role for deep decarbonization. The key novelty of this work is the achieved flexibility in the design of energy systems with CCS. Thus far, CCS has been applied in these kinds of optimizations in a coupled, non-flexible manner, e.g. a coal-fired power plant with 90% of its CO₂ captured. The model presented herein decouples those units and allows the optimization algorithm rather than the user/operator to decide whether CCS should be used at all, to which extent it should be used, and, if properly implemented, with which technologies it should be combined. Furthermore, the link from system level to process simulation level has proven significant added value.

Figure 4: Operation of the gas turbine and PCC units for the design allowing for 0.03 $t_{\text{CO}_2}/\text{MWh}$, zoomed in on a 72-h time period. The dashed-blue line shows the CO₂ produced from the gas turbine and therefore represents the gas turbine operation

Abstract

The granulation process using rotary drums technology, is an essential unit operation to form good quality granules in many industries such as food processing, pharmaceutical, petrochemical and mineral processing.

The main objective of this work is to study and analyze, by CFD approach, the dynamics of solid fertilizer granules and the fluid phase, within an industrial inclined rotary drum granulator. Particularly, we studied the impact of the rotational speed, and angle of inclination of the equipment on the particles size distribution (PSD) within the solid phase. The three-dimensional CFD model that we are adapting is based on an Euler-Euler multiphase flow approach coupled with the kinetic theory of granular flow (KTGF), the appropriate model and numerical schemes were selected based on previous studies (Zheng et al. (2019)). As could be proved by experiments and simulation results, the particles size distribution depends on the rotational speed and show regime transition along the rotary drum. Our study demonstrates the capability of multiphase CFD model to predict the solid and fluid flow behaviors, and analyze the PSD of fertilizer granules inside the inclined rotary drum granulator.

Keywords: Fertilizer, CFD, PSD (Particles Size Distribution), Kinetic Theory of Granular Flow (KTGF), rotary drum, granulator

1. Introduction

Rotating drums are present in many industrial processes; pharmaceutical, fertilizers, and food industries. Their areas of applications include granulation, cooling, coating, milling, reactions, drying, and mixing (Zheng et al. (2019)). As a process, it may penalize these industries in terms of profitability, quality of finished product and respect of commercial and environmental constraints. Indeed, this operation presents a serious challenge for manufacturers because its performance depends heavily on the operating parameters and the geometrical characteristics (Epelle and Gerogiorgis 2018).

CFD is used extensively to solve numerous industrial challenges due to the maturity of computational methods and advanced computing speeds and its ability to predict the

results of real experiments. Different numerical approaches have been proposed to predict the transverse and axial particle motion and particles size distribution in rotary equipment. Physical models for the particles flow analysis have been developed to relate the flow behavior to the key operating parameters as rotational speed, filling level, and inclination angle (Santos et al. (2013)).

2. Mathematical Model development

Computational Fluid Dynamics (CFD) has proven its effectiveness as a predictive tool for complex flows modeling. Regarding multiphase CFD modeling of granular flows in rotary drums, both the Eulerian approach and the Lagrangian approach are used. Several studies (Arruda et al. (2009); Nascimento et al. (2015)) used Discrete Element Method (DEM) as lagrangian simulation approach to study different rotary drum configurations: with and without flights. The numerical results agreed well with experimental observations, but for all this cases the simulations were done either with a reduced dimension of the drum; or the particles diameter with a specific ratio that define the number of particles in the axial direction. The mean advantage of DEM simulations is their ability to consider the particles shape characteristics and allowing to the track the particles through the computational domain. However, it is limited to reduced scale equipment due to the computational time.

Alternatively, the Eulerian-Eulerian (E-E) approach is commonly adopted for CFD simulations involving several (N) phases, and these phases are assumed to form interpenetrating continua. The dynamic behavior of a multiphase system with air and fertilizer granules can be described through Multiphase Navier-Stokes (NS) equations composed by continuity and momentum equations to be solved for each phase in the Eulerian framework. Also, the E-E approach is less computationally expensive, and is the most widely applied approach in the study of hydrodynamics of multiphase flows including granular phases. Due to the continuum assumption of the particle phase, the E-E approach requires additional closure models. The kinetic theory of granular flow (KTGF) is a tool developed from the kinetic theory of gases to describe the kinematics of a granular media. It is used to describe the particle motion in fluid-solid flows due to the inherently random particle movement caused by the fluid mechanics. It (KTGF) proves its effectiveness in rotary drum systems hydrodynamic studies, when coupled to NS equations in CFD model.

2.1. Model description

To model a multiphase flow, it is essential to take into account the conservation laws and the interactions between the present phases. In this work, the Eulerian multiphase model coupled with a KTGF model is used to model the air and fertilizer granules flow inside the inclined rotary drum granulator. The model solves momentum and continuity equations for each phase. The continuity equations for gas-solid mass conservation are given by the following equations:

$$\frac{\partial(\alpha_g \rho_g)}{\partial t} + \nabla \cdot (\alpha_g \vec{v}_g \rho_g) = 0 \quad (1)$$

$$\frac{\partial(\alpha_s \rho_s)}{\partial t} + \nabla \cdot (\alpha_s \vec{v}_s \rho_s) = 0 \quad (2)$$

Where, \vec{v} and α and ρ are respectively velocity, volume fraction and density of air (gas) and fertilizer particles (solid) phases. The air volume V_g is defined by :

$$V_g = \int_V \alpha_g dV \quad (3)$$

Details on the air and solid momentum, particles phase stress description, collision and drag forces, and the particles characteristics from the KTGF are given in Santos et al. (2013).

The conservation of the gas and solid momentum is given by the following equations:

$$\frac{\partial}{\partial t} (\alpha_g \rho_g \vec{v}_g) + \nabla \cdot (\alpha_g \rho_g \vec{v}_g \vec{v}_g) = -\alpha_g \nabla p + \nabla \cdot \bar{\tau}_g + \alpha_g \rho_g \vec{g} + \alpha_g \rho_g (\vec{F}_{q,g} + \vec{F}_{lift,g} + \vec{F}_{vm,g}) \pm (K_{gs}(\vec{v}_g - \vec{v}_s)) \quad (4)$$

$$\frac{\partial}{\partial t} (\alpha_s \rho_s \vec{v}_s) + \nabla \cdot (\alpha_s \rho_s \vec{v}_s \vec{v}_s) = -\alpha_s \nabla p - \nabla p_s + \nabla \cdot \bar{\tau}_s + \alpha_s \rho_s \vec{g} + \alpha_s \rho_s (\vec{F}_q + \vec{F}_{lift,s} + \vec{F}_{vm,s}) + (K_{gs}(\vec{v}_g - \vec{v}_s)) \quad (5)$$

\vec{F}_q , \vec{F}_{lift} , \vec{F}_{vm} are the external body force, lift force and virtual mass force, respectively. Only drag and gravity are considered in the present investigation. Details on the air and solid momentum exchange coefficient, the particles phase stress description, the collision and drag forces, also the particles characteristics integrated by the KTGF are given following the model of Santos et al. (2013).

2.2. Numerical simulation conditions

The CFD code used for this study is the commercial ANSYS Fluent 2020 R2, and calculations have been developed to predict the flow behavior of a multiphase bed composed by granules and air within the flow domain defined as a rotating cylinder representing the rotary drum granulator. The rotating drum is inclined by 3.57° , and with real industrial dimensions as defined in Table 1. At the initial state, the granulator (Gr) contains a bed of granules with a height of 1250 mm and air. The granules are supposed spherical and the initial volume fraction is set to 0.65 to define the granular bed as a portion of the total domain, and the remaining spaces are filled with fluid phase (air).

The PSD is defined in the solid region by patching two superposed zones, each zone contains a granules bed with the unified diameter (Table1). We simulated the system with three different rotational speeds: 8 rpm (rotation per minute), 16 rpm and 24 rpm. The physical characteristics of the studied system and the simulated phases are presented in the following table: The Multiple Reference Frame (MRF) approach was used to define the rotational motion of the flow domain. For the boundary conditions at the inlet, a constant flow rate is specified and at the outflow of the rotary drum, pressure outlet boundary condition is assumed. No velocity slip exists at solid walls and the standard wall functions are used for near-wall treatment. A velocity magnitude is set at the inlet and zero-gauge pressure is set at the outlet.

2.3. Computational domain

Figure 1: Mesh of the computational domain

One important step in CFD modeling is the mesh construction that represents the computational grid. A grid convergence test is done, in which the computational domain is discretized using three different grids containing a coarse, medium and fine mesh tetrahedral cells. The solid fraction distribution was determined using the different grid sizes with 8372, 66 330, and 508 440 mesh elements, representing the coarser, medium and refined mesh respectively as showed in Figure 2. Since the difference between numerical predictions obtained using the fine and the medium grids is negligible, the medium grid (Figure1) was selected to maintain a balance between computation load and numerical accuracy.

Figure 2: Cross sections from grid independence test

3. Results and analysis

3.1. Flow behavior and regimes transition for air-granules simulation

In order to study and to analyse the different regimes of the granular bed motion with an homogeneous particles distribution, the rotational speed of the granulator was varied between 8 and 24 rpm. Results in Figure 3 show the transition between the known typical transverse bed motions: rolling, cascading, and cataracting (Mellmann (2001)) during rotation. When the speed increases the arch of the kidney-shaped bed increases.

for model validation, CFD results are compared with published experiments and simulated data (Santos et al. (2013)). The hydrodynamic of the solid phase presents a transition inside the vessel at different levels, depending on the inclination angle degree. This shows the im- portance of the rotational speed in optimizing the granulation process. Each efficiency in monitoring the granulator key parameters will control the hydrodynamic flow that govern the particles size enlargements in the granulation process.

Figure 3: Regime transition for different levels of rotational speeds

3.2. Transverse flow behavior with particles size distribution (PSD)

The fertilizer granules bed was set by defining two zones with a unified diameter for each one. The diameters of particles are respectively: $1.00 \cdot 10^{-3}$ mm, and $1.00 \cdot 10^{-2}$ mm.

Figure 4 : Initial states of two zones with solid fraction

When the PSD is considered, the inclination angle effect is clearly distinct as the key parameter controlling the regimes transitions within the rotary drum. Figure 5 exposes the results for the three simulations with different rotational speeds. At the inlet part the dominant regime is the "slipping" one.

Figure 5: Particles distribution along the rotary drum (particles with d_2)

By increasing the rotational speed, the transition from the "slipping" to the "rolling regime" at the middle of the fluid domain, also the gravitational forces impact more the

particles flow behavior due to the slope at that level, and in the zone until the outlet of the drum a "crushing regime" characterizes the flow.

The computational time of the dynamic particles motion also increases exponentially with the increase of the approximately in double times the computational cost exists between the less and high values degree of rotational speeds.

4. Conclusion

Solid–gas two phase particle dynamics in a rotary drum granulator was modeled and simulated using the Eulerian Granular Multiphase Model using the Euler–Euler approach along with the Kinetic theory of granular flow. Regimes transitions is studied within the flow behavior in an industrial-size granulator and have been investigated using a three-dimensional CFD model. The simulation results for an inclination angle of 3.57 degree and rotational speed between 8 and 24 rpm, allow a prediction of the multiphase flow behavior with identification of the inclination angle and rotational speed as key parameters that control the mixing and the size enlargement of particles. The simulation results were compared to experimental studies already done using glass bills (Rong et al. (2020)). The numerical results agreed well with experiment studies measurements.

Abstract

Flowsheet design and optimization constitute one of the key challenges in the chemical engineering and process optimization communities. Software tools for digital design and flowsheet simulation are readily available for traditional chemical processing problems such as distillation and hydrocarbon processing, however tools for pharmaceutical manufacturing are much less widely developed. This paper introduces, PharmaPy, a Python-based modelling platform for pharmaceutical facility design and optimization. The versatility of the platform is demonstrated in simulating continuous, batch, and hybrid process flowsheets.

1. Introduction

Pharmaceutical products have been traditionally manufactured in batch facilities, permitting the flexible use and operation of equipment for the production of a variety of low volume – high value products. However, the transition to continuous operation is desirable given the advantages with regard to controllability, safety, consistency of product quality, reduced manual labor, and reduced equipment sizes, often leading to significant decreases in capital and operating expenditures.

Although end-to-end continuous operation is a desirable goal, the physics and chemistry of the phenomena involved can prevent the processing tasks required by the process from being operated in a truly continuous mode, making the best operating mode a combination of batch/continuous/semibatch processing steps. This hybrid operation poses challenges for process modeling and design as a consequence of the dynamic and often discontinuous nature of the resulting flowsheet model. Moreover, the combinatorics of the potentially large number of possible flowsheet configurations resulting from the possible choices of unit operation types and operating modes can present significant computational challenges.

To address these challenges, it is desirable to develop a tool that allows simulation of a representative set of dynamic drug substance (DS) and/or drug product (DP) unit operations and that offers a consistent framework for material/energy interchange between these operations. Such a modeling tool would enable rigorous comparison between unique flowsheet configurations in terms of technical viability and economic

performance, and would allow process design to be aligned with the Quality-by-Design and Quality-by-Control paradigms (Food and Drug Administration (FDA) 2004).

Commercial flowsheet simulation tools, such as Aspen Plus (2013) and gPROMS (Process Systems Enterprise 2020), are widely available and certainly are sufficient for conventional chemical process simulation and design. However, the focus of these software packages is not on pharmaceutical manufacturing. PSE does offer gPROMS FormulatedProducts as a platform for digital twin analysis of active pharmaceutical ingredient (API) synthesis and drug product processing, but the scripting capabilities, such as those seen within the IDAES framework (Lee et al. 2021), are lacking. We want to address the gap in available software by providing an open-source tool that enables flexibility in user control while still offering adequate modeling fidelity and numerical accuracy. Note that the goal is not to replace tools like gPROMS FormulatedProducts, rather it is to offer a complementary platform to fill the gap in end-to-end hybrid process design and operation that these established tools do not address.

2. Description of PharmaPy

The software tool PharmaPy is implemented in Python to incorporate powerful, pre-existing computational packages and utilize flexible scripting capabilities. It has two major themes as a platform for the design and optimization of pharmaceutical facilities (Casas-Orozco et al. 2020). The first theme addresses process modeling and simulation. PharmaPy utilizes state-of-the-art numerical tools, such as Sundials (Hindmarsh et al. 2005), which are required for the efficient solution and inter-communication of dynamic DS/DP pharmaceutical unit operation models. The package employs the sequential modular equation-solving strategy (Hillestad and Hertzberg 1986) and an object-oriented software architecture and organization of the model library.

The second theme addresses superstructure and flowsheet optimization. Here, PharmaPy utilizes a semi-heuristic algorithmic structure. First, we coordinate the generation of flowsheet alternatives using full-space combinatorial analysis. Subsequently, the full space of flowsheet designs is reduced using design feasibility constraints along with an experimentally conscious rule-based system. Finally, the reduced set of flowsheet alternatives may be compared in a simultaneous optimization scheme in Pyomo.GDP (Chen et al. 2018). In addition to these two computational themes, PharmaPy provides an open-source collection of common pharmaceutical unit operation models, which will be accessible to users through the PharmaSystems Hub (<https://pharmahub.org/groups/pharmasystems>).

The process of utilizing PharmaPy for flowsheet simulation and/or optimization begins with the creation by the user of a data file containing the physical and thermodynamic properties of participating species. Next, the pharmaceutical unit operations and their connections are selected and/or defined using text-based, object-oriented programming in Python. The flowsheet may then be executed in a manner appropriate to the function being performed, i.e. parameter estimation, process simulation or flowsheet optimization. The text-based, open-source representation of PharmaPy allows the process of running flowsheets, especially when analysing various operating conditions and/or equipment specifications, to be systematized with a high degree of user control.

Ultimately, users may then employ the second theme, mentioned above, to compare and contrast alternative flowsheet representations in an automated, direct optimization framework. This second theme is still in development stages, thus flowsheet alternatives in this study are generated and compared manually. In the next section, analysis focuses

on the first theme of PharmaPy and is illustrated with simulations of three concrete flowsheet alternatives, comparing and contrasting API production under continuous, batch, and hybrid operating modes.

3. Case studies

3.1. Description of the flowsheets

Three flowsheets describing the synthesis and separation of lomustine were used as proof-of-concept case studies to demonstrate the capabilities of PharmaPy. Lomustine is an API for the treatment of brain cancer, for which a continuous synthesis framework has been recently reported (Jaman et al. 2019). Lomustine (L) is produced in a sequence of two reactions: in the first reaction, an intermediate (I) is synthesized from 2-chloroethyl isocyanate (ISO) and cyclohexylamine (CHA); in the second reaction, species I reacts with tert-butyl nitrite (TBN) to produce lomustine and tert-butyl alcohol (TBA). A third, undesired reaction between ISO and TBA yields a condensation subproduct (SUB1).

The first flowsheet alternative for lomustine synthesis is the continuous process (except the last recovery step, done by batch filtration) shown in Figure 1. The flowsheet model consists of two plug flow reactors (PFRs) in series, followed by a solvent switch operation (VAP01) in which THF is replaced by Heptane (C7), facilitating improved lomustine crystallization. Afterwards, a slurry containing lomustine crystals is formed in a mixed suspension, mixed product removal (MSMPR) cooling crystallizer (CR01), modelled by a one-dimensional population balance including nucleation, size-independent growth, and dissolution. The output stream from CR01 is collected in a dynamic receiver HOLD01 (which operates in semibatch mode), and then, the collected material is sent to a batch filter (F01), where lomustine crystals are recovered. Reactors R01 and R02 are initially filled with THF, whereas VAP01 and CR01 have their holdups initially filled with C7. All units are initialized at standard temperature and pressure, except for VAP01, which is required to operate at vapor-liquid equilibrium under vacuum.

The reactions are assumed to be first order with respect to participant species. Lomustine solubility (S) in C7 as a function of temperature (T) was fitted to a polynomial form of the type $S = A + BT + CT^2$, using experimental data, and further modified to the form $S' = (1 + \alpha x_{THF}) \cdot S$ (x_{THF} : liquid mole fraction of THF, α : empirical factor) to account for the significant increase of lomustine solubility caused by the presence of THF in the solution (Mackey et al. 2020). The inhibition effect of species other than lomustine on its crystallization growth kinetics was represented by a simplified multi-impurity model (Borsos, Majumder, Nagy 2016):

$$p_{imp} = 1 - \alpha \sum_i \left(\frac{K_i C_i}{1 + \sum_j K_j C_j} \right)$$

where α is an effectiveness factor, C_i are mass concentrations (kg m^{-3}) and K_i are adsorption constants ($\text{m}^3 \text{kg}^{-1}$). The second flowsheet is an end-to-end batch version of Figure 1, with R01 and R02 modeled as batch, stirred tank reactors. The solvent switch operation in VAP01 is carried out by mixing the contents from R02 with C7 after the

reaction is completed, and then boiling off the solution until a desired THF composition is attained. Batch crystallization is performed with a linear cooling temperature profile.

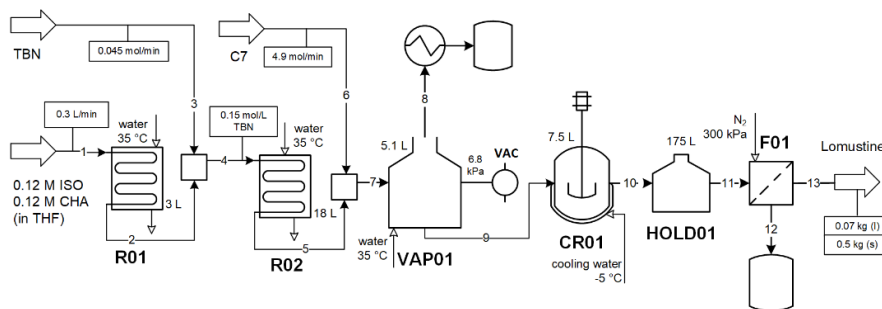

Figure 1. Schematic of the continuous flowsheet

The third flowsheet is a hybrid operation, where lomustine is synthesized continuously in R01 and R02 (Figure 1), and the resulting effluent (collected in HOLD01) is transferred to VAP01, where semibatch solvent switch is executed by vaporizing the solution while continuously feeding C7. Finally, batch crystallization and batch filtration are carried out under the same conditions as the end-to-end batch process.

Regardless of the operation mode, two key factors are to be considered for process design purposes: i) degradation temperature of lomustine (308 K, Mackey et al. 2020), and lomustine solubility in the liquid phase. These factors must be continuously monitored during the solvent switch operation in VAP01, where significant temperature and solvent composition changes are expected. The dynamic models used to describe the operation of the evaluated operating modes consist of systems of ODE/DAEs, and are drawn from the literature (Rawlings, Miller, and Witkowski 1993; Sahlodin, Watson, and Barton 2016). The balance equations which are PDEs (i.e. the PFRs and crystallizers) are discretized either by upwind or high-resolution schemes (LeVeque 2002). The continuous and hybrid operation explicitly considers the start-up of each piece of equipment from the initial conditions described above. Lomustine production for each flowsheet is 0.5 kg of dry lomustine in the exiting filtration cake. Residence times, and cycle times, in R01 and R02 were kept equivalent between the two flowsheets respectively.

3.2. Results

As shown in Table 1, more operation time must be allocated to produce 0.5 kg lomustine in the continuous flowsheet compared to the batch and hybrid flowsheets. It should be noted, however, that the initial transient state that must be completed before attaining steady-state operation contributes to this deficiency. This effect can be observed in Figure 2, where there is an initial period with no lomustine in CR01 and HOLD01.

This start-up period results in no lomustine crystal production during the first 1.6 hours of operation.

Figure 2. Concentration profiles for continuous crystallization-receiver set.

Table 1. Processing times

Unit	Time (min)				
	Batch	Residence		Operation	
		Continuou s	Hybri d	Continuou s	Hybri d
R01	10	10	10		
R02	60	60	60		
VAP01	102	5	--	438	
CR01	60	18.8	--		60
F01	9	--	---	90	2
Total	241	--	---	528	370

As seen in Figure 2, by the time crystals are first formed in CR01 (ca. 1.6 h), 37.3 L of liquid without any lomustine (a mixture of mostly C7 and THF) is already accumulated in HOLD01. This means that for the time period covered by the shaded region in Figure 2, crystals in the stream entering to HOLD01 get diluted to some extent, since this slurry gets mixed with a volume of sub-saturated liquid. This ultimately contributes to low lomustine productivity observed for the continuous process.

Another important factor to consider is the attainable degree of separation in VAP01 for the continuous case. Figure 3 shows a steady-state VAP01 composition of 22 and 76 mol% THF and C7, respectively, operating between 6.3 kPa and 6.9 kPa and a heat transfer media temperature of 308 K. This final remaining composition of THF in the outlet stream of VAP01 increases the solubility of lomustine in C7 by a factor of 2.4, inhibiting lomustine crystallization in the continuous case.

Moreover, the equilibrium temperature in VAP01 for the continuous case must be relatively low, here at 291 K, to ensure solubility constraints are met by the THF/C7 solvent mixture. In contrast, vaporization in the batch case realizes much greater separation of THF in VAP01. These conditions result in a final solution with 12.7 kg/m³ of lomustine in VAP01 (lower than the continuous case, Figure 3) but with much lower THF content (1.4 mol%) and higher temperature (301 K). The differences in vaporization lead to differing final crystallization temperatures, 268 K in continuous and 283 K in batch, to achieve similar recovery of lomustine. These results suggest that diverting material from CR01 during the startup period could increase crystal yield. Moreover, an improved solvent switch operation such as a staged distillation column may be necessary to circumvent the high solubility caused by the remaining THF, especially in the continuous operation, after the vaporization step proposed in this work.

Figure 3. Solvent molar fractions (top) and mass concentration of solutes (bottom) in VAP01 for the continuous flowsheet. Dotted line: Lomustine solubility.

Under the hybrid mode, the semibatch solvent switch allows operation at lower temperatures compared to the batch case (slow addition of C7) which results in slower evaporation of THF and subsequently a final liquid with higher THF composition. Given that THF increases lomustine solubility, batch crystallization in the hybrid case operates at higher initial concentration, which leads to increased yield and less reaction time needed to manufacture 0.5 kg of lomustine crystals.

4. Conclusions

This work demonstrates the features of PharmaPy to analyze a diverse set of pharmaceutical flowsheets, through the use of dynamic, first-principle models. In the case study presented, start-up effects and thermodynamic limitations mark the key differences and challenges in translating an end-to-end batch process to a fully continuous operating.

Abstract

This work presents a computer-aided framework for the screening of deep eutectic solvent (DES) systems by using the α -tocopherol extraction from methylated oil deodorizer distillates (MODD) as an example of practical relevance. Taking advantage of the differences in the hydrogen bond donating abilities of α -tocopherol and methyl linoleate (model compounds in MODD), the DES screening task is to select suitable components that can achieve the associative extraction of α -tocopherol by *in situ* DES formation at high selectivity against methyl linoleate. The COSMO-RS model is employed in the DES screening for two purposes: (1) The solid-liquid equilibria between α -tocopherol and each candidate component are calculated to check the potential for DES formation and identify the existence of a proper liquid window. (2) The infinite dilution capacity and selectivity of different components for the α -tocopherol/methyl linoleate extraction are predicted to estimate their potential for the separation task. The components preselected by COSMO-RS evaluation are further examined regarding other physical as well as environmental, health, and safety (EHS) properties.

Keywords: Eutectic solvent, component screening, COSMO-RS, α -tocopherol extraction

1. Introduction

Eutectic solvent systems, in most cases also coined as deep eutectic solvents (DES), not only have physicochemical properties similar to ionic liquids (ILs), such as negligible vapour pressure and a wide liquid phase existence range, but also feature green and sustainable characteristics such as non-toxicity, biodegradability and low cost (Smith et al., 2014). For these reasons, DES are widely expected as promising alternative to conventional organic solvents in many chemical processes, especially for the extraction of natural products from bio-resources, for instance, the extraction of α -tocopherol from methylated oil deodorizer distillates (MODD) (Qin et al., 2017). However, despite the great interests in DES, most current studies still rely on empirical knowledge to experimentally test different combinations of components (Abbott et al., 2017; Qin et al., 2019) while computer-aided methods guiding DES selection are still scarce. So far, only few works (Bezold et al., 2017; Salleh et al., 2017) have attempted to theoretically design or screen DESs, which are limited to a small set of already reported DESs or hypothetical component combinations assuming eutectic system formation. Moreover, while mainly

concentrating on the application performance of DES, their environmental, health, and safety (EHS) properties are usually taken for granted, even without an estimation of such properties of the pure components. Very recently, our group developed a quantitative correlation model for the prediction of freezing point depression to facilitate the search of novel DES and subsequently proposed a systematic DES screening method integrating the estimation of EHS properties of components (Song *et al.*, 2020a). Nevertheless, due to the limited availability of experimental data, this method only applies to DES with choline chloride (ChCl) as the hydrogen bond acceptor (HBA) and cannot directly estimate the eutectic temperature without knowing the eutectic composition. In the present contribution, we propose a general framework for screening DES systems that could virtually cover any component of interest. The extraction of natural α -tocopherol from MODD, an abundant by-product in vegetable oil refining, is taken as an industrially relevant case study.

2. Method

As α -tocopherol is a weak hydrogen bond donor (HBD) while methylinoleate (model of the undesirable MODD components) is a weak hydrogen bond acceptor (HBA), the DES screening task in the case study is formulated as to select suitable HBA components that can *in situ* form DES with α -tocopherol at high selectivity against methylinoleate. In this context, a computer-aided DES screening framework is proposed as shown in Figure 1. It consists of five steps: (1) collection of candidate components, (2) generation of COSMO files, (3) estimation of DES formation, (4) evaluation of extraction potential, and (5) assessment of physical and EHS properties. In the following, each of these steps is briefly described.

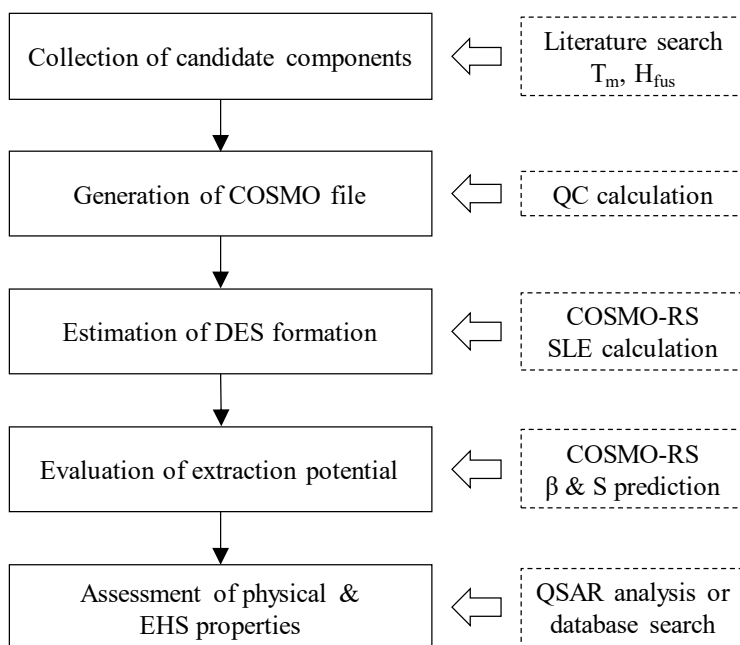

Figure 1. Framework for the computer-aided screening of DES.

2.1. Collection of candidate components

To maximize the probability of finally identifying a suitable component, the first step is to collect a significant number of candidates. However, estimating the DES formation between two components essentially requires not only the evaluation of the non-ideality of mixtures, but also the pure component fusion properties (i.e., melting temperature and fusion enthalpy or entropy). Therefore, we only collect the candidate components with known fusion properties, which include already reported components of DES systems as well as other potential ionic liquids or salts.

2.2. Generation of COSMO file

As the next two steps are based on the COSMO-RS model (Eckert and Klamt, 2002), the COSMO files of all the collected candidate components are required. In this work, all the COSMO files of the collected conventional candidates, and α -tocopherol and methylinoleate in the target mixture are already covered in the current COSMObase, and can be directly taken for use. For salt components, their COSMO files need to be calculated as ion pairs (cation-anion) since Abranches et al. (2019) have demonstrated that this manner is more reliable than the one as electroneutral mixture (cation, anion) for SLE prediction of DES systems by COSMO-RS. The details for the COSMO file calculation of salt components can refer to our earlier work (Song et al., 2020b).

2.3. Estimation of DES formation

The COSMO-RS solid-liquid equilibria (SLE) prediction is performed to check whether component combinations can form DES or not. With the required COSMO files and fusion properties of each component, the SLE of binary systems can be calculated from Eq. (1) by neglecting the secondary term related to heat capacity upon melting:

$$\ln x_i^L \gamma_i^L = -\frac{\Delta H_{fus,i}}{RT} \left(1 - \frac{T}{T_{m,i}} \right) \quad (1)$$

where ΔH_{fus} and T_m represent the fusion enthalpy and melting temperature; x and γ stand for the mole fraction and activity coefficient in the liquid phase, respectively. The liquidus curves (solubility curves) of the two component in the systems are calculated separately, and their intersection point, if it exists, is identified as the eutectic point (T_e). By comparing the predicted T_e with the T_m of two individual components, the potential formation of DES systems can be estimated.

2.4. Evaluation of extraction potential

After checking the possibility of forming DES systems, different candidate components should also be evaluated with regard to their extraction potential. In this step, the infinite dilution capacity (C) and selectivity (S) on the mass basis of different candidates for the extraction task are calculated as defined in Eqs. (2) and (3).

$$C = \frac{1}{\gamma_i^\infty} \times \frac{MW_i}{MW_{com}} \quad (2)$$

$$S = \frac{\gamma_j^\infty}{\gamma_i^\infty} \times \frac{MW_i}{MW_j} \quad (3)$$

Here, γ_i^∞ and γ_j^∞ are the infinite dilution activity coefficients of the target solute (i) and the dilute (j) in each candidate component to be evaluated; MW_i , MW_j , and MW_{com} denote the molecular weights of i , j , and candidate component, respectively. Similar criteria have

been demonstrated to be effective for screening ionic liquids as solvent with high mass-based extraction performance (Song et al., 2017) and thus are also used here for DES component selection.

2.5. Assessment of physical and EHS properties

As there is currently no general method for predicting the physical and EHS properties of DES systems, such properties of the individual components are analysed instead as empirical reference. In this step, the candidates retained after the above steps are first searched through chemistry databases (e.g., PubChem) to check whether there are experimental data on the related properties; if no experimental data are available, quantitative structure-activity relationships (QSAR) models from literature are then sought for preliminary analysis, as introduced by Song et al. (2020a). The candidates with desirable physical properties and potential EHS compatibility are finally retained as promising DES components for further studies.

3. Application

In the case study for the extraction of α -tocopherol from methylolinoleate, overall 133 candidates with known fusion properties are collected from literature. This candidate database includes 21 salts and 62 conventional components that have been involved in already reported DES systems as well as 50 salt compounds (in some cases can be referred as ionic liquids) newly introduced here.

The COSMO files of all the collected salt components are calculated by Gaussian 09 (Frisch et al., 2009) following the same procedure as introduced earlier (Song et al., 2020b). As it has been demonstrated that the conformers of salt component have a notable effect on the SLE prediction by COSMO-RS, different anion locations around cation are taken into account as initial configuration for the geometric optimization in the procedure. For each salt component, two to six stable conformers are correspondingly obtained and are selected simultaneously in the SLE calculation.

To screen components that can form a DES if mixed with α -tocopherol, the binary SLE of {candidate component + α -tocopherol} are calculated by COSMO-RS and compared with those of {candidate component + methylolinoleate}. As both α -tocopherol and methylolinoleate are of low polarity (as implied by their structures of long alkyl chain, Figure 2) and high fusion enthalpy (56.28 and 48.16 kJ/mol, respectively, as estimated by the Joback method (Joback and Reid, 1987)), COSMO-RS can be considered as a reliable approach for predicting the T_c of such systems (Song et al., 2020b).

Figure 2. Molecular structures of (a) α -tocopherol and (b) methylolinoleate.

After the SLE calculation, the DES formation of different binary systems is judged by:

$$\min(T_{m,A}, T_{m,B}) - T_{c,cal} > 5 \text{ K} \quad (4)$$

where $T_{m,A}$ and $T_{m,B}$ represent the melting temperatures of two individual components, and $T_{e,cal}$ is the eutectic temperature calculated by COSMO-RS. By applying Eq. (4), only the combinations with a predicted T_e that is at least 5 K lower than the melting temperatures of both two components are selected for potential DES formation. It is worth mentioning that the judgement of “true” DES may be more physically complex than simply based on the difference between the T_e of mixture and melting temperature of pure components, as discussed by Martins et al (2019). However, as we mainly focus on the application potential here, Eq. (4) can be used for the purpose of fast screening. Based on this constraint, 36 of the 133 candidates are retained. Besides, 9 candidates with melting points below 293.15 K that are directly applicable as extraction solvents are also kept for comparison of the separation potential in the next step.

The C and S of the 45 candidates retained above for the α -tocopherol and methylinoleate extraction at 293.15 K are calculated based on Eqs. (2) and (3). As compared in Figure 3, the 9 additional candidates (with T_m below 293.15 K) have much lower C and S than the 36 candidates selected based on the judgement of DES formation. This comparison well demonstrates the advantage of the strategy of associative extraction of α -tocopherol from methylinoleate over the direct extraction approach. The best candidate with the highest C and S is $[P_{4,4,4,4}][MeSO_3]$ and the second one is $[N_{4,4,4,4}][Cl]$. Following that, $[N_{2,2,2,2}][Cl]$, $[N_{6,6,6,6}][Br]$, R-camphor, and $[N_{5,5,5,5}][Br]$ are better than the remaining ones. These six candidates can be regarded as the top six candidates from the point of view of their extractive power. When further investigating these candidates in PubChem, R-camphor is found to be flammable and hazardous to health while the other 5 salt candidates have currently not been reported to violate critical EHS criteria. It is interesting to note that $[N_{4,4,4,4}][Cl]$ has already been experimentally demonstrated to be able to form DES with α -tocopherol. It exhibits an excellent extraction performance for this separation task (Qin et al., 2017). This finding confirms the suitability of the proposed DES component design method, and indicates that the other selected candidates, especially $[P_{4,4,4,4}][MeSO_3]$, are very interesting to be assessed in future experimental studies.

Figure 3. Comparison of the extraction potential of the 45 retained candidate components.

4. Conclusions

In this work, a computer-aided framework for the screening of DES systems based on the SLE prediction by COSMO-RS is presented and applied to the case study of searching suitable HBA components for the associative extraction of α -tocopherol from methylolinoleate. This framework could be readily extended or adjusted to other similar processes to rationally guide the DES or DES component selection prior to costly experiment studies.

E-mails: malbreiki@hbku.edu.qa

Abstract

A photo-electrochemical reactor has been gaining interest and has been seeking improvements in design, production efficiency, and cost reduction. As these improvements can make a photo-electrochemical reactor compatible with renewable fuel production devices, photo-electrochemical reactors' design aspects are critical to reaching optimal performance through distinct and optimal reactor architectures. Thus, this study demonstrates designing factors related to single and double reactors following prior design decisions and performance indicators as these decisions play a significant role in achieving optimal design. Therefore, the results demonstrate that simplicity, functional convenience, and operational costs are the major decisions that need to be taken before the designing phase. Overall operation yield, current efficiency, energy efficiency, overall selectivity, and specific energy consumptions are performance indicators used to compare designed reactors. These decisions and indicators can provide insights into practical reactors' designs.

Keywords: PEC, single reactor, double reactor, design, design indicator

1. Introduction

The most abundant energy sources is solar energy, but it is scattered and intermittent, this requiring storage through a fuel conversion (e.g., ammonia, hydrogen, etc.). Photosynthesis is a route that is a viable low temperature for solar fuel generation. Artificial photosynthesis applies the same concept as photosynthesis using semiconductors that capture lights and attached to electrodes covered by catalysts. Then, catalysts generate hydrogen or other products and generate oxygen through electrochemical reactions. Extensive research has been devoted to developing solar-driven electrolysis materials; however, the design aspects of the electrochemical system have gained little attention. The design aspects of these systems are critical because the combination of the materials that offer optimum performance in such a system is significantly dependent on the system's architecture and operating conditions.

Significant efforts have been devoted to the development of photo-electrochemical (PEC) reactor performance for solar-driven fuels. One of the first works conducted by Fujishima and Honda in 1972 proposed the use of flat plates of single-junction light-absorbers attached in an electrolyte as PEC (Fujishima and Honda,

1972). After their work, multi-junction PEC reactors have been suggested. Multi-junction PECs increase photocatalysis efficiency due to improvements in the sunlight absorption (Khaselev and Turner, 1998). Additionally, two electrode reactors: a photoactive semiconducting and a metallic counter (e.g., SrTiO₃ and KTaO₃), have been suggested for solar fuel production (Domen et al., 1980). PEC systems can be used for various fuels such as hydrogen, ammonia, and methanol. Recent studies have investigated designs based on nano-structured and micro-structured components where the embedded nanoparticles in the electrolyte serve as electrocatalytic reaction sites and as a light absorber. Consequently, such a structure allows a larger specific surface for the reactions to occur and enhances the sunlight (James et al., 2009).

One of the significant components in double or compact PEC reactors is separators. Separators facilitate product extraction, increase safety, increase performance, and limit products and electrolytes to crossover, thus limit unwanted reactions to happen. Separators can be polymer membranes, thin capillaries, and porous media. Prior research proposed using multi-functional membranes that provide multiple processes, including product separation, ionic conduction, reactivity, and structure support (Yang, 2010). Such membranes can be obtained using nano-composite materials.

The design aspects of photo-electrochemical reactors are critical to reaching optimal performance through distinct and optimal reactor architectures. Some of the significant design criteria for photo-electrochemical reactors focuses on; (i) maximization of solar photons' absorption by photo-electrodes for higher production yield, (ii) minimization of product gases reaction/recombination by proper separation, and (iii) minimization of possible losses occurring between electrodes. The second and the third design criteria are typical for solar-driven reactors and conventional (electricity-driven) reactors. In contrast, the first design criteria are only for solar-driven reactors as it targets maximization of solar photons absorption. Previous studies emphasize that PEC without solar concentrating optics can only operate at a peak current density of 10-30 mA cm⁻². On the other hand, if an external electricity source is applied, the PEC is used at the current density of 1 A cm⁻². Such differences impacted the optimal PEC design (Haussener et al., 2012).

There exists a considerable body of literature on PEC reactor materials. However, the design aspects and criteria of PEC reactors are still faded. Reactor performance indicators for designers to compare and evaluate the manufactured PEC are not collected in solid form, and general rules to follow before designing the PEC are also missing in the literature. Thus, additional studies to understand the fundamental tenets of design criteria are required. In this regard, the objectives of this study are as follows:

- Presenting advantages and disadvantages of implementing electrochemical reactions in single and double reactors.
- Revealing design criteria for selection of reactor type.
- Demonstrating general rules before designing PEC reactors.
- Providing reactor performance indicators to evaluate and compare PEC reactors.

2. Advantages and Disadvantages of PEC Reactor Types

Differences between two types: single and double reactors are presented in the proceeding sections, following a brief description of each reactor.

2.1. Single PEC Reactor

Open beaker cell is a single and the most basic PEC reactor. The cell is filled with electrolyte in which the reactor body is submerged. Anode and cathode electrodes are positioned in the same electrolyte. There is no membrane in such a reactor. So, for ammonia production via a single PEC reactor, hydrogen passes through the anode and is converted into protons, which then transports through the electrolyte to the cathode over which nitrogen passes. Moreover, one of the issues facing open baker cells is that cathode and anode reaction in the same reactor body makes product quantification less convenient. Another problem of a single PEC reactor is the electrolyte leaking and air diffusion into the reactor.

Several studies suggested using proper sealing to prevent air diffusion into the reactor and electrolyte leaking (Bosserez et al., 2015). The air distribution into the reactor can cause several issues, such as overestimating oxygen production in the cell as the oxygen can act as an electron acceptor at the anode. Similarly, underestimation of hydrogen production in the cell can occur as the oxygen can recombine with hydrogen. Regarding PEC single reactor body materials, the body of these reactors can be made of glass such as Quartz and Pyrex since these material types are visible and UV-light illumination. However, these materials are expensive, so they are not preferable. Hence, polymer materials (e.g., Teflon and Poly Ether Ketone) are used in building such reactors (Bosserez et al., 2015). A single PEC reactor's significant drawback is recombination reactions due to a mixture of products (hydrogen and oxygen gases). There is also a safety concern if the hydrogen concentration reaches the explosion limit (Schröder et al., 2004). Thus, proper PEC design can collect produced hydrogen separately.

2.2. Double PEC Reactor

One of a double PEC reactor's main features is separating cathode and anode electrodes via a membrane. Various conditions can be maintained in each compartment in the double reactor. Higher Coulombic efficiency can be obtained because of the diffusion of oxygen into an anode compared to a single reactor. Most of the double PEC reactor designs are based on a proton exchange membrane (PEM) with the occurrence of water formation reaction in the opposite electrochemical direction. The membrane is placed in the middle of the two compartments where anodic and cathodic reactions occur, and it is placed with appropriate sealing to prevent leaking. In such a reactor, the critical parameters for improving reactor performance are the suitable choice of electrolyte, electrolyte volume, and ionic path length (Hernández-Pagán et al., 2012). One of the main disadvantages of double PEC is the membrane occurrence as the membrane increases the set-up cost and increases complexity. As reported in the literature, the membrane's price is 24% of the total fuel cell (Perry et al., 2020).

3. Design Criteria – Single or Double Reactor

One of the first decisions researchers/designers can take in PEC reactor design is using a single or double reactor. The single reactor operates where the cathode and anode are in a single electrolyte compartment, whereas the double reactor operates with separated cathodic and anodic electrolyte compartments by a membrane. The absence of a membrane is one of the main advantages of a single reactor. The reactor's design becomes more straightforward. The cost becomes lower as the materials associated with

the membrane, such as gaskets and fittings, are not needed in a single chamber, and membrane degradation is not considered. As recorded in the literature, the membrane's cost in a PEM fuel cell accounts for about 24% of its total cost (Perry et al., 2020). Furthermore, a single type photo-electrochemical reactor without a membrane has more negligible ohmic resistance than a double type as the membrane impedance is absent.

On the other hand, a double photo-electrochemical reactor avoids producing unwanted side reactions due to the separation of catholyte and anolyte electrodes. One of the complex decisions in the double reactor is selecting membrane-type, whether cationic or anionic. The membrane-type needs to maintain the material balance of both reactions in cathode and anode to maintain neutrality and avoid pH changes. Cationic membranes repel neutral molecules and anions, and they are stable in the alkaline environments as they produce a chemical imbalance when OH^- is consumed. Whereas anionic membranes repel neutral molecules and cations and are unstable in alkaline environments, they keep the chemical balance by replacing OH^- from the electrolyte. Besides, bipolar membranes have been introduced to overcome the challenges limitation of cationic or anionic membranes. Bipolar membranes have two layers structure of cationic and anionic, which prevent unwanted products from crossover. However, these membranes still need care as some undesired ions can cross over (Blommaert et al., 2020). The disadvantages of bipolar membranes are delamination and dehydration (Shen et al., 2017).

4. Initial Decisions During Reactor Design

Despite the diversity of PEC reactors, some general rules are required in reactor design. Noting that these rules sometimes provide conflicting requirements of the reactor design. Hence, a critical thinking approach needs to be applied to achieve a suitable design.

- *Simplicity*: The reactor design needs to meet the process requirements while keeping the design structure as simple as possible. This can be achieved by lowering the capital and operational costs and rendering the used technology.
- *Reliability and functional convenience*: The reactor must handle routine process operations such as product extraction and maintenance. For example, the reactor should facilitate inspection of electrodes and membranes followed by replacing parts or cleaning. The reactor also needs to operate in a high degree of safety, reliability, and security.
- *Integration*: The reactor should integrate into the overall process or environment directly and conveniently. Hence, the shape, space, and reactor ancillaries must be considered. It may be advantageous to have all operations such as gas separation and solvent extraction within the reactor body in some cases.
- *Reaction engineering parameters*: This category covers optimization of selectivity, mass transport rate, current distribution, and production rate. To achieve the optimal speed and selectivity of production, current distribution, and control of the potential are required. For example, high production rates involve a uniformly high mass transport over the electrode.
- *Operational costs*: These costs can be minimized by several factors, including (a) low and reliable reactor components, (b) small reactor voltage, which results in a

suitable choice of the material and shape of the electrodes, and (c) absence of high power mechanical devices for pumping purposes or electrode movement.

5. Reactor Performance Indicators

Since there is a variety of reactor designs, the need for reactor performance indicators is essential. Table 1 shows the reactor performance indicators and the expressions of the indicators and their observations. These indicators help designers to evaluate the performance of the manufactured reactor.

Table 1: Reactor performance indicators

Reactor Performance Indicator	Definition	Expression	Observations
Fractional conversion (x)	The fraction of reactant, that is consumed by the electrochemical reaction	$x = \frac{m_i - m_t}{m_i}$	m_i , initial molar amount of reactant m_t , molar amount at time t
Overall operational yield (θ_p)	The maximum molar amount of desired product obtained from 1 mole of reactant	$\theta_p = \frac{m_p}{n_p m_i}$	m_p , moles of reactant converted to product n_p , number of moles reactant consumed
Current Efficiency (\emptyset)	The yield based on electrical charge passed during electrolysis	$\emptyset = \frac{WnF/M}{q}$	W , weight of active material n , number of electrons transferred per mole reaction F , Faraday's constant M , molecular weight of the material q , total charge
Overall Selectivity (S_p)	The ratio of desired product to total products	$S_p = \frac{m_p/n_p}{\sum m_{p,i}/n_{p,i}}$	m_p , moles desired product of P n_p , number of moles of wanted product of P $m_{p,i}$, moles of all product $n_{p,i}$, number of moles of all product
Specific Energy Consumption (SEC)	The amount of substance on a mass	$SEC = \frac{-nFE_{cell}}{\emptyset M}$	E_{cell} , cell potential
Energy Efficiency (E)	It can be indicated with respect to energy yield	$E = \frac{\Delta G \emptyset}{nFE_{cell}} = -\frac{(E_e^C - E_e^A)\emptyset}{E_{cell}}$	E_e^C , equilibrium potential for cathode E_e^A , equilibrium potential for anode

6. Conclusions

This study summarizes the main design criteria for PEC reactors. As there are various PEC reactor designs, this study lists some reactor performance indicators to compare and evaluate PEC reactors, including energy efficiency, fractional conversion, current

efficiency, etc. Besides, we listed few general rules to consider when designing PEC, such as simplicity, reliability and functional convenience, integration, reaction engineering parameters, and operational costs. Design criteria for selecting the type of reactor (single or double) have been presented, and the results have shown that a double reactor has more advantages compared to a single reactor as different conditions can be maintained in each compartment of the double reactor, higher Coulombic efficiency can be obtained because of diffusion of oxygen into the anode. However, the existence of a membrane causes more complexity in the reactor.

Abstract

The advanced exergoeconomic analysis performed on different industrial processes is used to determine the avoidable exergy destruction and inversion cost rates in order to increase the rentability and sustainability of a factory. This study focuses on the performance of an advanced exergoeconomic analysis of a double effect evaporation process (DEEP) of coffee extract in a factory located in Ecuador. The avoidable and unavoidable exergy destruction cost rate and the avoidable investment cost rate were determined for each component by exergoeconomic balances using the results from the process simulation with the best operational conditions and with the worst operational conditions. The avoidable exergy destruction cost rate represents 18.3% of the overall exergy destruction cost rate. It was estimated that around 70.3 \$/h of the overall operational costs could be saved if the exergetic efficiency of the first double effect evaporator (D-101) and the steam condenser (E-103) increased from 46.3% to 60.7% and 52.3% to 61.6%, respectively. Additionally, an increment of the initial concentration of soluble solids in the extract can reduce the avoidable operational costs by 15%.

Keywords: Advanced exergoeconomic analysis, Process simulation, Double effect evaporation, Avoidable cost rate

1. Introduction

Instant coffee is a widely consumed product worldwide, its market is projected to grow in the next seven years (Coherent Market Insights, 2019). One of the steps in industrial-scale instant coffee production is the evaporation of water from the extract in order to increase the concentration of soluble solids in preparation for the drying process. This evaporation process is energy-intensive, and consumes large amounts of fossil fuels since water has a high latent heat. Additionally, previous studies show that this process has low energetic and exergetic efficiencies (Mojarab Soufiyan et al., 2016), which lead to a high level of energy waste, and consequently raise production costs. In order to address these inefficiencies, it is not only necessary to identify and quantify the losses, but also to determine the fraction of avoidable losses. The advanced exergoeconomic analysis developed with computational tools allows for the determination of the exergy destruction rate and the avoidable and unavoidable costs of each component of the system. This analysis therefore becomes an important decision-making tool in production industries to reduce operational costs and increase the sustainability of the processes.

Some conventional exergy analyses have been done in food industries that have evaporation as part of their process, such as the production of tomato paste (Mojarab Soufiyan et al., 2016), powdered milk (Bühler et al., 2018), and yogurt (Mojarab Soufiyan and Aghbashlo, 2017). However there are no advanced exergoeconomic analyses performed in food industries; these studies would allow for the determination of the real potential for improvement of each component of the process (Liu et al., 2020).

In this context, this work presents an advanced exergoeconomic analysis of the double effect evaporation process of coffee extract, by using real operational data from a factory located in Ecuador. The aims of this study are to identify the main sources of exergy destruction that significantly affect the operational cost, and to quantify the avoidable cost that could be reduced. Additionally, a parametric study is performed to analyze the effect the initial concentration of soluble solids has on the operational cost indicators.

2. Methodology

2.1. Process Description

Figure 1 describes the double effect evaporation process of coffee extract in a factory located in Ecuador. Coffee extract (stream 1) is an aqueous solution with an initial concentration of soluble solids of 18 w/w%, from *Robusta* and *Arabica* beans. This extract is pumped to a heat exchanger (E-102) for pre-heating it up to 50°C by using steam. The steam is generated in the boiler (B-201) by using fuel oil N°6. Meanwhile, an already concentrated extract (stream 7) leaves the second effect (D-102); part of it is mixed with the heated extract and recirculated to D-102. The other part is sent to the first effect (D-101). The evaporated water (stream 11) in D-102 enters the condenser (E-101), where the temperature is reduced from 50°C to 32°C. The condensate water (stream 15) is mixed with condensate from de D-102 (stream 16) and then it is discarded. The concentrated coffee (stream 8) that leaves the D-101 reaches a concentration of 50 w/w% and then it is cooled from 66°C to 11°C in a heat exchanger of multiple flow (E-103), where cooling-tower water (C1) and chilled water (W3) are used.

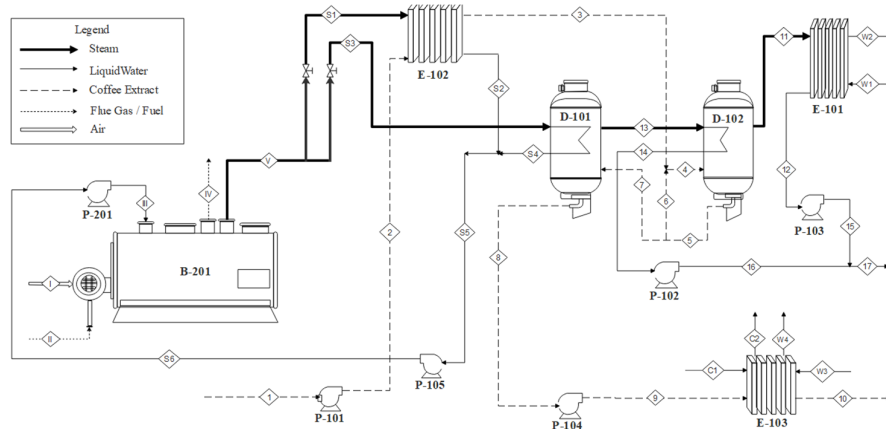

Figure 1. Process flow diagram of the double effect evaporation of coffee extract and the steam generation unit.

The process simulation was developed taking into account the following assumptions:

- The system was at steady state and the elevation in the coffee extract boiling point, due to concentration of solution, was assumed to be negligible.
- The heat loss rate and the pressure lost in all the components were negligible.
- A complete combustion was assumed in the combustion chamber.
- The steam and gases were considered as ideal gases when the pressure was below 1000 kPa. For higher pressures, the SRK-Equation was used as the equation of state.
- The coffee extract and liquid water were considered as ideal solutions.

2.2. Advanced Exergoeconomic Analysis

The advanced exergoeconomic analysis of the double effect evaporation process of coffee extract was performed with the aim to determine the avoidable (AV) and unavoidable (UN) exergy destruction cost rates and investment cost rates at a component level. This analysis was done with the real operational data (ROD) from the plant. The dead state in the system was considered at 298 K and 1 atm. For each component the best operational conditions (BOC) and the worst operational conditions (WOC) were established based on a previous study (Morosuk and Tsatsaronis, 2019) as shown in Table 1. The BOC were used for the process simulation in Pro/II[®]. The values of each state and the results from the k th component were used to perform the exergetic analysis (to calculate $\dot{E}_{D,k}^{UN}$), the economic analysis (to calculate $c_{F,k}$) and the exergoeconomic analysis at a component level (to calculate $\dot{C}_{D,k}^{UN}$). The thermodynamic model formulation was performed in Engineering Equation Solver (ESS), software.

Table 1. Values of Parameters for Different Operation Conditions.

Component	Parameter	ROD	BOC	WOC
D-101	ΔT_{min} [°C]	35.0	9.5	50.2
D-102	ΔT_{min} [°C]	15.1	5.0	20.0
P-101	η_{is} [-]	0.80	0.95	0.70
P-102	η_{is} [-]	0.80	0.95	0.70
P-103	η_{is} [-]	0.80	0.95	0.70
P-104	η_{is} [-]	0.80	0.95	0.70
P-105	η_{is} [-]	0.80	0.95	0.70
E-101	ΔT_{min} [°C]	4.0	2.0	23.0
E-102	ΔT_{min} [°C]	77.0	10.0	85.0
E-103	ΔT_{min-cw} [°C]	10.0	2.0	20.0
E-103	ΔT_{min-rw} [°C]	6.0	2.0	20.0
B-201	λ [-]	1.24	1.00	1.93
P-201	η_{is} [-]	0.80	0.95	0.70

The equations used for the exergetic analysis, the economic analysis (TRR methodology) (Bejan et al., 1996) and the advanced exergoeconomic analysis (Petraokopoulou et al., 2012) are presented in Table 2. The auxiliary equations and specific costs for were obtained from a previous study (Tinoco-Caicedo et al., 2020).

Table 2. Equations used for Exergy, Economic and Advanced Exergoeconomic Analyses.

Exergetic/Economic Analyses		Advanced Exergy/Exergoeconomic Analyses	
Parameters	Equations	Parameters	Equations
Exergy Balance	$E = E^{PH} + E^{CH}$	Exergoeconomic Balance	$\dot{C}_{p,k} = \dot{C}_{F,k} + \dot{Z}_k - \dot{C}_{D,k}$
Exergy destruction rate	$\dot{E}_{D,k} = \dot{E}_{F,k} - \dot{E}_{P,k}$	Exergy destruction cost rate ($\dot{C}_{D,k}$)	$\dot{C}_{D,k} = c_{F,k} \dot{E}_{D,k}$
Levelized Total Revenue	$TRR_L = CRF \sum_{j=1}^n \frac{TRR_j}{(1 + i_{eff})^j}$	Relative cost difference (τ_k)	$\tau_k = \frac{c_{p,k} - c_{F,k}}{c_{F,k}}$

Exergetic/Economic Analyses		Advanced Exergy/Exergoeconomic Analyses	
Parameters	Equations	Parameters	Equations
Requirement levelized carrying charges	$CC_L = TRR_L - FC_L - OMC_L$	Exergoeconomic Factor (f_k)	$f_k = \frac{\dot{Z}_k}{\dot{Z}_k + \dot{C}_{D,k}}$
Annual carrying charges (\dot{Z}_k^{CI})	$\dot{Z}_k^{CI} = \frac{CC_L}{\tau} * \frac{PEC_k}{\sum_k PEC_k}$	Unavoidable Exergy destruction rate ($\dot{E}_{D,k}^{UN}$)	$\dot{E}_{D,k}^{UN} = \dot{E}_{X_{P,k}} \left(\frac{\dot{E}_{X_{D,k}}}{\dot{E}_{X_{P,k}}} \right)^{UN}$
Annual operating and maintenance costs (\dot{Z}_k^{OM})	$\dot{Z}_k^{OM} = \frac{OMC_L}{\tau} * \frac{PEC_k}{\sum_k PEC_k}$	Unavoidable Exergy destruction cost rate ($\dot{C}_{D,k}^{UN}$)	$\dot{C}_{D,k}^{UN} = c_{F,k} \dot{E}_{D,k}^{UN}$ $\dot{C}_{D,k}^{AV} = \dot{C}_{D,k} - \dot{C}_{D,k}^{UN}$
Annual total costs (\dot{Z}_k)	$\dot{Z}_k = \dot{Z}_k^{CI} + \dot{Z}_k^{OM}$	Unavoidable investment cost rate (\dot{Z}_k^{UN})	$\dot{Z}_k^{UN} = \dot{E}_{X_{P,k}} \left(\frac{\dot{Z}_k}{\dot{E}_{X_{P,k}}} \right)^{UN}$ $\dot{Z}_k^{AV} = \dot{Z}_k - \dot{Z}_k^{UN}$

Furthermore, the unavoidable investment cost for the kth component was determined following the same methodology (simulation, exergetic analysis, economic analysis and exergoeconomic analysis), using the worst operational conditions (WOC) which implies the lowest possible component purchase costs (Gungor et al., 2015).

3. Results and Discussion

The results from the advanced exergoeconomic analysis are shown in Table 3. The components that have the highest avoidable exergy destruction rate ($\dot{E}_{D,k}^{AV}$) are (in descending order): B-201, D-101 and D-102. However, the components that have the highest avoidable exergy destruction cost rate are (in descending order): D-102, E-103 and D-101. These results are interesting because although B-201 is responsible for 71.7% of the overall avoidable exergy destruction rate, it only represents the 4.6% of the overall avoidable operating costs ($\dot{C}_{D,k}^{AV} + \dot{Z}_k^{AV}$). On the other hand, despite having a low $\dot{E}_{D,k}^{AV}$, the E-103 is responsible for 15.9% of the overall avoidable exergy destruction cost rate. This is due to this component having the highest specific cost of the system (2×10^{-3} \$/kJ) because it uses tower water and chilled water for cooling the concentrated extract.

Table 3. Results of the Advanced Exergoeconomic Analysis

Comp.	f_k (%)	r_k	$\dot{E}_{D,k}^{AV}$ (kW)	$\dot{E}_{D,k}^{UN}$ (kW)	$\dot{C}_{D,k}^{AV}$ ($\frac{\$}{h}$)	$\dot{C}_{D,k}^{UN}$ ($\frac{\$}{h}$)	\dot{Z}_k^{AV} ($\frac{\$}{h}$)	\dot{Z}_k^{UN} ($\frac{\$}{h}$)
E-101	2.0	4.5	0.4	51.0	2.4	300.1	0.7	5.4
D-102	55.0	1.5	27.9	12.7	57.2	26.2	7.8	93.5
D-101	86	6.4	27.7	60.6	4.3	9.3	4.1	78.1
E-103	8	8×10^{-4}	1.6	2.0	13.1	16.5	8×10^{-3}	2.7
B-201	8	2.5	168.5	596.9	4.2	15.0	0.2	1.3
E-102	23	7.4	6.8	13.3	1.1	2.2	4×10^{-2}	0.9
P-101	89	2.8	0.6	0.3	3×10^{-2}	0.1	1×10^{-2}	0.7
P-102	90	2.7	0.6	0.2	0.1	2×10^{-2}	4×10^{-2}	0.7
P-104	91	2.9	0.2	0.2	2×10^{-2}	2×10^{-2}	2×10^{-2}	0.4
P-103	91	2.6	0.6	0.2	0.1	2×10^{-2}	3×10^{-2}	0.7
P-105	93	3.0	0.1	0.1	1×10^{-2}	1×10^{-2}	3×10^{-3}	0.3
P-201	93	3.8	1×10^{-2}	0.1	1×10^{-3}	1×10^{-2}	1×10^{-3}	0.2

Additionally, component D-102 was found to have the greatest improvement potential, given that 68.6% of its exergy destruction costs are avoidable. In contrast, the pumps don't have improvement potential, as they account for less than 1% of the overall avoidable operating costs.

The required modifications should be focused to reduce the exergy destruction cost rate (even if this results in a higher investment cost), because the components that have the highest operating cost, also have the lowest exergoeconomic factor (less than 10%). These modifications could be done through changes to the operating conditions or through structural changes in the three components with the highest avoidable cost (D-102, E-103 and D-101) in order to increase their exergetic efficiency.

Figure 2 shows that an increase in the initial concentration of soluble solids in the extract from 18 w/w% to 26 w/w% causes a reduction of the avoidable exergy destruction cost rates of the D-101 and D-102, from 5.5 \$/h to 3.3 \$/h and 71.5 \$/h to 46.8 \$/h, respectively. Additionally, the avoidable investment cost in D-101 and D-102 are reduced from 4.5 \$/h to 3.7 \$/h and 8.6 \$/h to 7.1 \$/h, respectively.

Figure 2. Effect of the initial concentration of soluble solids in coffee extract on the $\dot{C}_{D,k}^{AV}$ and \dot{Z}_k^{AV} of the components (a) D-101 and (b) D-102.

Figure 3 shows that an increment of the initial concentration of soluble solids increases the r_k value in both evaporators (D-101 y D-102), causing a reduction of the final product cost from 22931 \$/T to 21875 \$/T. Furthermore, f_k presents an increment in evaporators D-101 and D-102 of 3.9% and 5.6%, respectively. This means that an increment in the initial concentration of coffee extract could also improve the balances between the investment rate and exergy destruction cost rate.

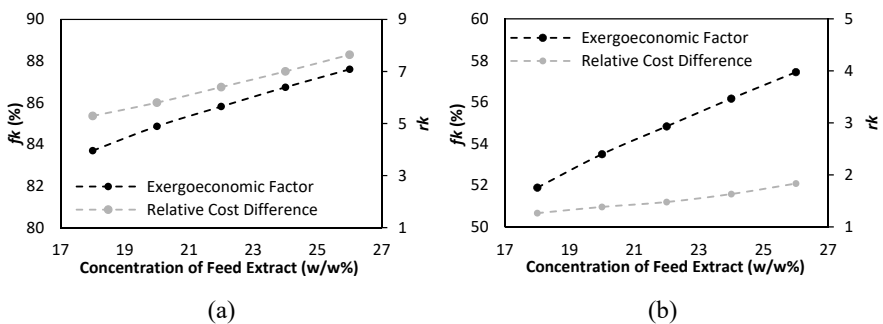

Figure 3. Effect of the initial concentration of soluble solids in the coffee extract on the r_k and f_k of the components (a) D-101 and (b) D-102.

4. Conclusions

The purpose of this study was to perform an advanced exergoeconomic analysis of the double effect evaporation process of coffee extract. The results of this research show that although B-201 is the component with the highest avoidable exergy destruction rate, it does not have a high avoidable cost rate. The components that have the highest potential for improvement are D-101, D-102 and E-103 because they have the highest avoidable exergy cost rate. Additionally, the initial concentration of soluble solids proved to be a significant parameter for the process, given that an 8 w/w% increase of the initial concentration of soluble solids reduced the avoidable exergy destruction cost by 15%.

These results suggest that a reduction of the avoidable exergy destruction rate in these components can be achieved and it is possible to have annual savings of $\$8.37 \times 10^5$ in the overall operating costs.

Further research is needed to optimize the solid-liquid extraction of coffee, in order to achieve a higher initial concentration of soluble solids in the coffee extract. Also extended parametric and structural change studies are recommended in the double effect evaporation process in order to maximize the exergetic efficiency and minimize the operational costs.

Abstract

The energy requirement for the separation of a given mixture via a multistage membrane cascade depends on the choice of the cascade and its operating conditions. Identifying the optimal cascade along with its optimal operating conditions is challenging, since it requires the solution of a nonconvex mathematical program. To address the challenge, we propose novel Mixed Integer Nonlinear Programs (MINLPs) that are formulated such that they can be solved using off-the-shelf global optimization solvers. We illustrate the practicality of our models with two case studies: (1) separation of p-xylene from o-xylene (2) recovery of natural gas liquid (NGL) from shale gas. Further, for NGL recovery, we determine the target selectivity and permeability that will enable membrane technology to outcompete the conventional demethanizer. These target values provide guidance for experimental groups that are developing new membrane materials for NGL recovery.

Keywords: membranes, optimization, energy efficiency, shale gas

1. Introduction

For some separations, membrane technology has been demonstrated to be advantageous because of its operational simplicity, modular scale-up flexibility, and relatively low capital cost. Nowadays, membranes are used in important applications such as water desalination, natural gas sweetening, and nitrogen production. Owing to the commercial success in the above applications and some other applications, there has been an increased interest in expanding the use of membranes to other separations. Nevertheless, a majority of state-of-the-art membranes still have at most moderate permeability and selectivity values. This can be a limitation for separations that require both high purity and recovery of the component of interest; as a single membrane stage is typically insufficient to meet the specifications. One alternative to overcome the limitation is to use a multistage membrane cascade. It is well-known that a plethora of cascades exists even for the simplest case of a binary mixture (Agrawal, 1997). However, the energy requirement and the cost between alternative cascades can differ substantially. Moreover, even for a given cascade, the energy requirement and the cost can vary with the operating conditions. Identifying the optimal cascade along with its optimal operating conditions is challenging, since the equations governing the permeation process are nonconvex. Here, we develop two optimization models: (1) a Mixed Integer Nonlinear Program (MINLP) that is applicable for both liquid and gaseous binary mixtures (2) an MINLP that is applicable for a multicomponent gaseous mixture. For brevity, we highlight only the key elements

of our models, and refer the reader to Chavez Velasco et al. (2020); Chen et al. (2020) for further details.

While many optimization models have been proposed in the literature (e.g. Qi and Henson, 2000; Adi et al., 2016), our models differ in the following aspects. First, several formulations oversimplify the permeation process which leads to a significant reduction in model's fidelity. We, on the other hand, retain the essential physical aspects of the permeation process that are often ignored in the oversimplified models. Second, most of the studies rely on optimization solvers that do not always yield the global optimum. Here, we guarantee global optimality of the solutions by formulating the problem such that it can be solved using global optimization techniques, such as those implemented in BARON (Tawarmalani and Sahinidis, 2005; Kılınç and Sahinidis, 2018). The rest of the paper is outlined as follows. In section two, we describe the key elements of the proposed optimization models. In section three, we illustrate the practicality of our approach with two case studies. Finally, in section four, we present concluding remarks.

2. Two novel membrane cascade optimization formulations

2.1. Single-stage permeator model

The validity of the optimal solution depends on the fidelity of the single-stage permeator model. In this work, we use a permeator model that is reasonably accurate, and at the same time, is viable for global optimization. We use flux equations derived from the solution-diffusion theory (Wijmans and Baker, 1995) together with the crossflow model (Weller and Steiner, 1950) to model the permeation across a membrane. The governing equations constitute a system of differential algebraic equations (DAE) shown below:

$$\frac{dx_i}{df} = \frac{y_i - x_i}{f}, \quad y_i = \frac{S_i(x_i - \gamma_i y_i)}{\sum_{i=1}^n S_i(x_i - \gamma_i y_i)}, \quad x_i(f^{in}) = x_i^{in}, \quad i = 1, \dots, n. \quad (1)$$

Here, n denotes the number of components in the mixture, x_i and y_i denote the local mole fraction of component i on the retentate and permeate sides, respectively, f denotes local retentate flow, S_i denotes the selectivity of component i with respect to the component n , x_i^{in} denotes the mole fraction of component i in the inlet stream, and $\gamma_i = \{1/r$ for gases, $\exp(-V_i \Delta P / RT_0)$ for liquids} where r , ΔP , R , V_i and T_0 correspond to the transmembrane pressure ratio, transmembrane pressure difference, the universal gas constant, molar volume of component i , and the operating temperature, respectively. We solve the DAE system in Eq. (1) analytically for binary mixtures (see Chavez Velasco et al. (2020)). For a multicomponent mixture, we approximate the DAE system with a piecewise constant parametrization technique (see Chen et al. (2020)). Extensive numerical studies show that the approximated solution agrees well with the exact solution of the DAE system.

2.2. Proposed formulations

In this subsection, we briefly describe our optimization models. Figure 1 shows the superstructure we considered for binary liquid separations. The superstructure for binary gaseous mixtures has the same stream connections, but the pumps are now replaced with compressors. In either of these networks, the permeate stream from each stage can be recycled to any of the two immediate previous stages, or can be withdrawn from the cascade to be part of the final permeate product. Moreover, the feed can be located at any of the membrane stages. In the case of multi-component gaseous separations, currently,

we have considered a simpler cascade superstructure where the permeate stream can only be recycled to the previous stage.

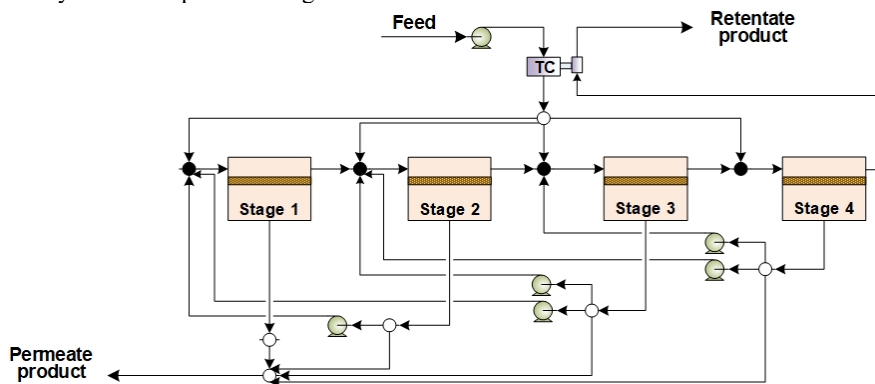

Figure 1: Cascade superstructure for binary liquid separations (Chavez Velasco et al., 2020). TC stands for turbocharger

The optimization problem for both binary and multi-component separations is summarized as: for a given feed, find the membrane cascade with at most N stages along with its operating condition that separate the given mixture into two product streams with a specified composition while minimizing the energy consumption. The optimization problem is formulated as MINLP. Here, binary variables are introduced to regulate the flows along the paths that connect various splitters and mixers. Whereas continuous variables model stream compositions and flows. Furthermore, in the case of binary separations, the pressure ratio (or trans-membrane pressure difference) was modeled as a continuous variable. Nevertheless, in the case of multicomponent gaseous separations, the pressure ratio is modeled as a discrete variable as it helps to expedite the convergence. The objective function computes the total power needed to operate the pumps (or compressors). The main constraints in the optimization model are: 1) overall and component mass balance constraints around mixers, splitters and each membrane, 2) single-stage permeator model for each of the membranes in the cascade, 3) constraints to restrict flows along specific paths.

2.3. The challenge of guaranteeing global optimality

To obtain global optimality certificate in a reasonable amount of time with BARON (Kılınç and Sahinidis, 2018), we derive additional cuts for the problem using physical insights and by exploiting mathematical properties of the governing equations. Some of these cuts, although implicit in the model, are not implied in the relaxation. Therefore, providing these cuts explicitly helps in expediting the convergence characteristics of BARON. We refer the reader to Chavez Velasco et al. (2020) for the details and numerical experiments demonstrating their potential.

3. Exploring the potential of membrane cascades

The energy requirement of a membrane cascade depends on the permselectivity of the chosen membrane. When evaluating the energy potential of a membrane-based process for a given separation, one of the following scenarios can be found: 1) a specific membrane with a specific permselectivity is available, 2) no specific membrane is available, and thus, the permselectivity is unknown. In the first scenario, the solution of

our proposed optimization model would allow to identify the optimum-energy membrane cascade along with its optimal operating condition. Then, the energy consumed by this cascade can be compared against the energy required by alternative separation options. If it happens that the optimum cascade consumes higher energy than that of alternative separation processes, or as in scenario 2, no specific membrane is available for the given separation task, it becomes relevant to determine what would be the target membrane permselectivity that is needed for the membrane-based process to make it more energy efficient. The following examples illustrate this targeting procedure. All membrane cascade optimization cases discussed in this section were solved to 5% of global optimality gap using BARON 18.5.8 (Kiliç and Sahinidis, 2018).

3.1. Separation of *p*-xylene/*o*-xylene

We consider the separation of a liquid mixture with 65 mol% *p*-xylene and rest *o*-xylene at 1 bar and 30 °C. Our goal is to recover *p*-xylene with 99 % recovery at 99.5 % purity. First, we consider a membrane with a *p*-xylene permselectivity of 50. For these conditions, the optimal four-stage membrane cascade identified by our approach consumes 52 kW per mole of feed for pumping the feed and the recycle streams¹. Membrane permselectivity values of 60, 77, and 106 would reduce the membrane cascade power by 10 %, 20 %, and 30 % respectively. The procedure illustrated here helps in guiding material researchers to determine the membrane target properties needed for a given application.

3.2. Natural gas liquid (NGL) recovery from shale gas

Here, the objective is to separate shale gas into a CH₄-rich stream and an NGL stream containing C₂H₆, C₃H₈, C₄H₁₀, and C₅H₁₂. Traditionally, this separation is performed using a cryogenic demethanizer (Yoon et al., 2017). However, the traditional technology is not suitable for modularization, and membranes are perceived as a potential alternative for modular plants. Nevertheless, even the state-of-the-art membrane materials have a low selectivity towards CH₄ (around 5 for C₂H₆/CH₄), so a single membrane stage is not sufficient to meet the desired product specifications. Most of the membranes designed for this separation have a reverse permselectivity, meaning that the heavy components, NGL, permeate faster than the light component, CH₄ (Merkel et al., 2000). For a comparative analysis between a cryogenic demethanizer and a membrane cascade, we consider 200 million standard cubic feet per day (MMSCFD) of shale gas from the Bakken Basin, which contains 60 % CH₄, 20 % C₂H₆, and 20 % C₃₊ (C₃H₈, C₄H₁₀ and C₅H₁₂ lumped as a single component). The feed and the retentate are assumed to be at 30 bar. Since the feed is already at high pressure, we send it directly to the cascade without any further compression. Furthermore, given that the separated retentate stream needs to be transported via pipeline, we also do not consider the expansion of this stream for the purpose of recovering energy from it. This eliminates the turboexpander shown in Figure 1. For the demethanizer, we simulated in Aspen Plus the process flowsheet proposed by Yoon et al. (2017). Our simulation shows that the demethanizer consumes 12,000 kW to produce CH₄ with 96 % recovery and 94 % purity. In our analysis of the alternative separation through a membrane cascade, we approximated the feed as three-component feed, which has 60 % CH₄, 20 % C₂H₆, and 20 % C₃H₆. Here all the C₃₊ components are lumped as a pseudo component with the same selectivity as C₃H₆. The selectivity of CH₄/C₂H₆ is 5 for a polymeric membrane (Starannikova et al., 2006) and we assumed a

¹ The efficiencies of the pumps and the turbocharger were assumed to be 75% and 80% respectively

selectivity of 100 for $\text{CH}_4/\text{C}_3\text{H}_8$. After solving our MINLP, we found that the optimum two-stage and three-stage membrane cascades would require a total energy of 84,181 kW and 28,456 kW respectively to produce CH_4 with the same recovery and purity as that obtained from the demethanizer². By performing sensitivities on $\text{C}_2\text{H}_6/\text{CH}_4$ permselectivity, we determined that a target selectivity of 25 and 20 would be needed for the two-stage and three-stage membrane cascade respectively in order to consume the same energy as the demethanizer.

It is important to mention that the viability of using either a cryogenic demethanizer or a membrane cascade not only depends on energy consumption, but also on economics. Therefore, we also calculate and compare the net present value (NPV) for the two processes. The NPV, which accounts for both capital and operating costs, was calculated assuming a plant-life of 15 years and 10 % discount rate. We note that although the membrane permeance does not affect the power consumption of a membrane cascade and the cost of the compressors, it strongly affects the required membrane area, and consequently the membrane cost. To identify the target combination of permeance and permselectivity that would be needed for the analyzed separation through a two-stage cascade, we generated the permeance-selectivity curve shown in Figure 2. This plot provides useful guidance to quickly determine if a two-stage membrane cascade would be economically attractive. To elaborate, if the membrane permselectivity and permeance falls above the corresponding curve in Figure 2a), an optimum two-stage membrane cascade would be more economical than the conventional cryogenic demethanizer. Different from the Robeson upper bound curve which reflects the challenge of improving both permeance and selectivity, the permeance-selectivity curve introduced here provides a lower bound on permeance and selectivity for an economically attractive process. Figure 2b) shows the net present value distribution for the circled point in the permeance-selectivity curve.

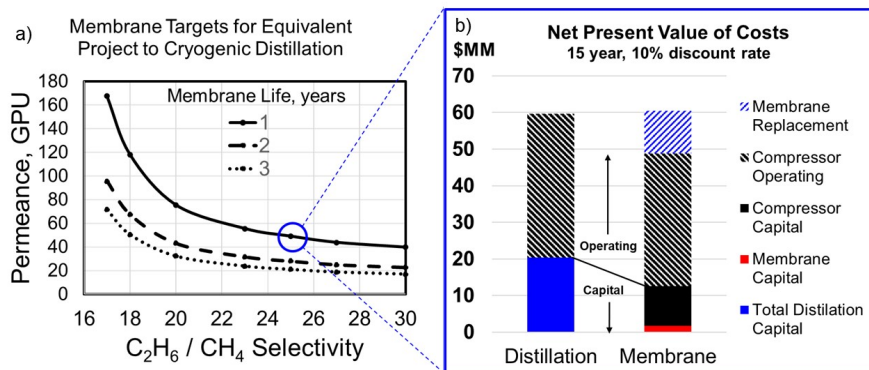

Figure 2: a) Net present value breakdown of the cryogenic demethanizer and the membrane cascade as function of selectivity and permeance. All points on each curve yield the same net present value, and require the same energy consumption as that for the cryogenic demethanizer. b) Cost distributions for the circled point in a)

² For each compressor in the membrane cascades we assumed an isothermal efficiency of 75%

4. Conclusions

In this article, we have briefly described two different membrane cascade optimization models that for a given mixture, either liquid or gaseous binary mixture, or multicomponent gaseous mixture, finds the optimum membrane cascade along with its corresponding operating conditions that minimize the energy input. To illustrate the utilization of our proposed MINLP models, we analyzed two separation examples. For these examples, we described a targeting procedure that for a given separation, helps to determine target membrane properties such as permselectivity that would be needed to outperform the energy efficiency of alternative separation options. Furthermore, for the analyzed separation of NGL from shale gas, we introduced an easy-to-use graphical tool that guides on which combination of permselectivity and permeance would be needed for a two-stage membrane cascade in order to be economically attractive as compared to a conventional demethanizer process.

Techno-economic evaluation of Carbfix technology for carbon storage in the US

María Paz Etcheverry, Haoshui Yu*, Emre Gençer*

MIT Energy Initiative, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139, United States
haoshuiy@mit.edu, egencer@mit.edu

Abstract

Carbfix is a technology to permanently store captured CO₂ and other sour gases from emission sources as rocks in the subsurface. CO₂ charged water is injected into the basalts to promote the carbonization of CO₂. The dissolution of CO₂ into the aqueous phase facilitates the mineralization of CO₂. It has been demonstrated that over 95% of CO₂ captured and injected was turned into a rock in the subsurface in less than two years. In the original project, this technology aims to store CO₂ from geothermal power plants in Iceland. However, it can be applied to the CO₂ capture from a combined-cycle natural gas power plant as well. This study would like to apply this technology to store the CO₂ from a combined-cycle natural gas power plant to achieve the near-zero emission target. Therefore, the CO₂ storage process has to be modeled and optimized based on this technology. In this process, the water consumption is determined by the depth of the injection well, the temperature, and the water's salinity. The capital costs (injection wells, monitoring wells, injection surface facilities) and operating costs (maintenance, electricity, water cost) interact with each other. In this study, a detailed techno-economic evaluation of Carbfix technology is performed in the context of a 500 MW combined cycle power plant in the US. The sensitivity analysis is carried out with respect to water price, electricity price, equipment cost, etc. The key factors are identified based on the tornado diagram. This methodology can be integrated with the power plant and CO₂ capture model to optimize the whole system simultaneously in future work.

Keywords: Carbfix technology, techno-economic evaluation, operating cost, capital cost, sensitivity analysis

1. Introduction

Increasing CO₂ concentration can largely be attributed to the usage of fossil fuels. Carbon capture and storage (CCS) play a fundamental role in achieving the goals of the Paris Agreement to limit global warming to 1.5-2°C (Snæbjörnsdóttir et al., 2020). It is reported that 37% of the total man-made greenhouse gas emissions are from the power sector (Selosse and Ricci, 2017). Therefore, the decarbonization of the power sector is the primary target on the way to a zero-emission world. However, large-scale deployment of CCS has yet to be achieved (Snæbjörnsdóttir et al., 2020). To accommodate the huge storage demand of CO₂ in the future, CO₂ storage technology has become of interest to both academia and industries. Carbfix technology, in which CO₂ is injected into reactive basaltic rocks, is one of the promising technologies for CO₂ storage because of the abundance of basaltic rocks on Earth's surface (Gislason and Oelkers, 2014). It has been demonstrated that over 95% of CO₂ captured and injected was turned into carbonate

minerals in the subsurface in less than two years in Carbfix technology. Carbonate minerals provide a long-lasting, thermodynamically stable, and environmentally benign CO₂ storage solution (Gislason et al., 2010). However, a huge amount of water is consumed to dissolve the CO₂ during the injection. Therefore, the cost of water and electricity to drive the pumps in the system has to be evaluated precisely before the implementation of the technology along with a natural gas power plant. Ragnheidardottir et al. (2011) assessed the costs of Carbfix technology for the Hellisheidi geothermal power plant. However, the geothermal power plant has its characteristics, and the cost analysis heavily depends on the application. This study aims to evaluate the techno-economic performance of the Carbfix technology to extend it from a geothermal power plant to natural gas combined cycle power plant located in the vicinity of North American Basalt Formations such as the Columbia Plateau basaltic aquifer in Washington state.

2. Problem statement and methodology

This study is novel in that it determines the cost per ton of CO₂ stored in USD and understands the cost drivers for implementing Carbfix technology in the US market. The cost model for the Carbfix system follows the framework allocation described below, and it is directly linked to the performance model which calculates the storage unit performance requirements based on the upstream technical assumptions. Performance and cost analysis including the profitability and sensitivity assessment are implemented in a MS Excel spreadsheet. There are three types of costs calculated by this model:

2.1 Site Costs

The site costs are those costs specific to the site itself. They are categorized into two categories:

Site screening: Involves the evaluation of regions within a larger area to identify selected areas that are potentially suitable for basalt mineralization and CO₂ storage. The site screening cost is based on the study of Smith et al. (2001), adjusted for inflation.

Permitting and licensing: Mainly associated with Environmental Impact Assessment, which is a crucial process to the successful permitting of the project. The licensing and permitting costs are estimates provided by the Carbfix team, converted to US dollars.

2.2 Capital Costs

The capital costs are fixed, one-time expenses incurred on the design, purchase of equipment, installation, and construction of the storage unit. The purchase of the land is excluded from capital costs. They are categorized into five categories:

Design: The cost associated with the conceptual, preliminary, and detailed engineering design of the whole system. It is calculated as 12% of the remaining capital costs.

Injection well: The cost associated with the engineering, procurement, and construction of a single injection well. It is calculated using a unit rate-based cost estimating as a function of depth. Quantities and rates in the breakdown were validated with the Carbfix team. Assumed diameter: 12", depending on the injected flow.

Monitoring well: The cost associated with the engineering, procurement, and construction of single monitoring well. The monitoring well cost is a lump sum estimating provided by the Carbfix team. Assumed diameter: 9".

Equipment: Includes pump compressors, valves, piping, and instrumentation, aside from the wells. The cost of equipment is scaled using the pilot project equipment cost (Ragnheidardottir et al., 2011) adjusted by inflation and the following formula:

$$\text{Capex Scaling Factor} = (\text{Flow}_{\text{scaled}}/\text{Flow}_{\text{pilot}})^{0.6}$$

Installation: The labor and machinery costs involved in the installation of equipment. It is scaled using the pilot project installation cost (Ragnheidardottir et al., 2011) adjusted by inflation and the formula above.

2.3 Operation & Maintenance (O&M)

The O&M costs are the costs incurred for maintaining and operating the whole system. They are categorized into four categories:

Fixed O&M: The cost of operating and maintaining the system regardless of the CO₂ tones stored. It is assumed as 2.5% of Capex.

Electricity: The cost associated with energy requirement for the injection, split up between pumping (7.5%) and auxiliary systems (92.5%). It does not include compression (CO₂ pressure provided by source). It is assumed that pumping energy requirements scale linearly with flow rates from the pilot case, and auxiliary system power consumption uses the power scaling factor (Ragnheidardottir et al., 2011). Electricity price from Washington state, USA (International Energy Agency, 2020).

$$\text{Flow Scaling Factor} = \text{Flow}_{\text{scaled}} / \text{Flow}_{\text{pilot}}$$

$$\text{Power Scaling Factor} = (\text{Flow}_{\text{scaled}} / \text{Flow}_{\text{pilot}})^{0.25}$$

Water: The cost associated with water consumption, based on the performance model requirements and the average industrial water price in the USA (Bunch et al., 2017).

Monitoring: it involves the cost of operating the monitoring well provided by Ragnheidardottir et al. (2011) adjusted by inflation, converted to US dollars.

3. Case study

The case study inputs are based on a combined-cycle natural gas power plant plus a thermal amine CO₂ capture unit (Table 1). However, both the power plant and the CO₂ capture unit are out of scope. The injection site is considered to be nearby the power plant, so the CO₂ injection pressure is equal to the CO₂ dispatch pressure from CO₂ capture unit. The target injection formation is assumed at 400-800 m depth consisting of basaltic lavas (Alfredsson et al., 2008). The reservoir capacity is such that it can store the power plant's annual emissions over a 30-year life (24Mt of CO₂).

Table 1. Upstream system characteristics

Nameplate Cap. (MW)	500
Capacity Factor	0.56
Generation (MWh/year)	2,452,800
Emissions (t/year)	833,158
Capture Eff.	95%
CO ₂ Pressure (bar)	30

Table 2. Storage unit performance details

CO ₂ Flowrate (kg/s)	25.1
H ₂ O Flowrate (l/s)	552.2
Injection Wells	6
Monitor Wells	1
Energy Req (kWh/year)	56,690,312
Lifetime (years)	30

By using the assumptions above and the referenced upstream system technical characteristics (Table 1), a performance model for CO₂ storage is executed (Table 2). The ratio of water to CO₂ required to dissolve the CO₂ stream at equilibrium is 22, defined as a function of temperature, pressure (or depth), and salinity of the water (Gislason et al., 2010). When at the injection well, both the CO₂ and water streams are injected separately until a depth in which the water reaches the same pressure as the CO₂ (around 350m for a 500m well, water level 100m), allowing the full dissolution while descending in the injection well. The number of injection wells is based on an assumed well injectivity of 92 l/s, and associated energy requirements are scaled utilizing a flow scaling factor of 35 and a power scaling factor of 4 from respective formulas (Ragnheidardottir et al., 2011). The ratio of monitoring wells to the injection well is 9 (National Petroleum Council,

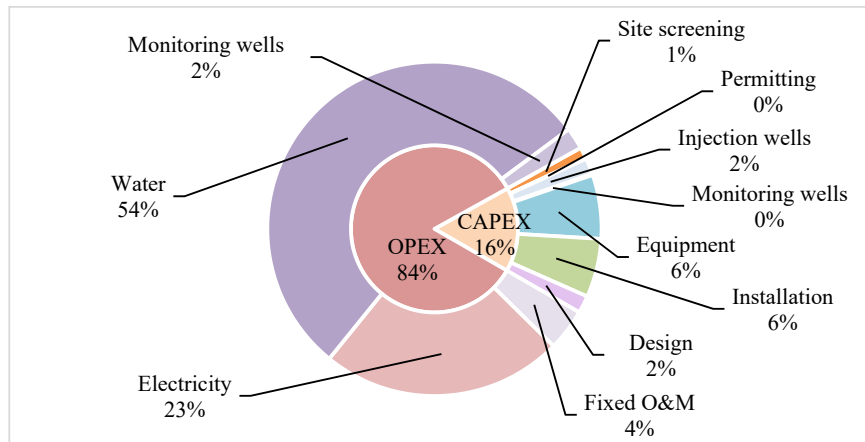

2019). Table 3 summarizes cost analysis based on the performance model. Figure 1 shows the component level contribution in annualized costs (site costs considered under capex). Once cost estimation is done, a profitability assessment optimizes the CO₂ storage price to reach an acceptable internal rate of return (IRR) for the project. Each of the cost estimation components described in Section 2 were assessed using a cash flow model with the assumptions in Table 4. Taxes and escalation are not considered at this point.

Figure 1. Component level CO₂ storage price contribution for case study

The case study results in a required price of 21.9 USD/tCO₂. Subsequently, sensitivity analysis was applied to profitability, setting low and high inputs for all the components based on market prices across the US. The tornado in Figure 2 shows the analysis' results. In addition, the CO₂ storage price was evaluated by benchmarking within the US. According to the storage cost assessment performed by FE/NETL (Grant and Morgan, 2017), there are four saline formation regions with a storage cost of 15USD/tCO₂ and one region, North Central, with a cost of 22USD/tCO₂. In 2019, the NPC updated each region's storage costs using the FE/NETL model assumptions but modifying the

requirements for site screening and monitoring activities (National Petroleum Council, 2019). As a result, sites requiring strict monitoring would likely be excluded during initial site selection. These adjustments to the assumptions had the effect of reducing the cost of storage by approximately 50% compared with the FE/NETL results (Grant and Morgan, 2017). The US Carbfix price standing among typical US saline storage prices is shown in Figure 3. As noted, it is significantly higher than NPC prices. This is mainly because the NPC report considered a volume-weighted average cost only for regions with significant volumes of CO₂ storage, such as 11-135 Gt of CO₂.

Figure 2. Tornado diagram for case study price

Figure 3. Saline formation CO₂ storage cost by region compared to US Carbfix cost

4. Conclusions

This paper reviews the cost analysis for a proposed case study in the US, based on the Carbfix pilot project and methodology. The cost analysis is used for the purposes of profitability and a sensitivity assessment.

The resulting cost is heavily weighted in operational costs, specifically water and electricity, which should be carefully examined for cost reduction strategies. More research should be carried out to study the water requirement to acquire the correct reactions and minimize water, and thus power usage. If minimum water quantity is achieved, using seawater or recycling water from the reservoir, once the CO₂ carbonated,

are the main alternatives to reduce costs. In terms of electricity, although the case study price for electricity is among the lowest in the US, there is some room for improvement by considering on-site generated renewable energy. It was also found that well borehole depth affects the cost significantly when varying depth from 400m to 800m. Although the single injection well cost increase with depth, water demand decrease, which creates important cost reductions. However, injectivity rates from a different formation than the one assumed in the case study can determine a different number of injection wells, altering the results.

The profitability assessment results in a price of 21.9 USD/tCO₂, which is higher than the current prices for saline formations in the US. However, Carbfix technology seems to be a good alternative when conventional storage formations are not available. By improving water demand and costs, the US Carbfix CO₂ storage price may become competitive. The tornado diagram shows that the total price of 11.3USD/tCO₂ can be achieved with a minimum cost of water.

In light of the findings, it is recommended to perform a study for different basalt formation locations around the US, getting specific data regarding the reservoirs and available utilities. In future work, this methodology will be integrated to SESAME framework, which is a system-scale energy analysis tool to assess the system-level greenhouse gas (GHG) emissions of today's changing energy system.

Abstract

In this work, molecular simulation is utilized to perform the adsorption based separation of the ammonia-hydrogen-nitrogen mixture on Metal-Organic Frameworks (MOFs) operating conditions relevant to enabling low-pressure Haber-Bosch. MOFs are nanoporous structures that possess several desirable features; among them is the tunability in which one can target specific molecules through replacement or functionalization of organic linkers, metal nodes, and finally, cage decoration. This study aims to provide an efficient ammonia separation to reduce operating pressure in the ammonia reactor and highlight MOFs' potential as material for novel applications in gas-gas separation. The pressure/temperature swing adsorption operational scheme is investigated, and the working delivered capacity and purity of ammonia are determined accordingly. Molecular simulation provides a way to examine nanomaterial potential in such applications inspecting a range of process conditions where the material is characterized based on loading, selectivity, and regeneration ability. Following an initial computational screening, Co₂Cl₂BBTA MOF is selected, and force field modifications have been done to fit experimental data. Besides analyzing the performance of Co₂Cl₂BBTA, encapsulation of ionic liquid (IL) [bmim][Tf₂N] effect was analyzed from structural and adsorption properties. Interestingly, an optimum IL loading is determined based on the performance objective. Purity factor reached 93.3% at IL loading of 0.372 weight fraction. When considering capacity and purity factor, IL composition in MOF corresponding to 0.165 weight fraction revealed the best performance. Implementation of adsorption enhanced Haber-Bosch is expected to reduce immensely the amount of electrical power utilized to recycle the unreacted syngas to the ammonia synthesis reactor and produce ammonia at high pressures desirable for urea synthesis.

Keywords: Molecular simulation, metal-organic framework, ammonia, separation processes, efficiency

1. Introduction

The Haber-Bosch process is the primary method in producing ammonia from nitrogen and hydrogen. Ammonia produced, utilized mainly as fertilizers, currently responsible for approximately 1.8% of carbon dioxide global emissions (The Royal Society, 2020). Efforts have been made to decarbonize the process, hoping to reduce the emission-intensive nature by implementing renewable energy sources. A critical parameter that drives current research investigations is to reduce the pressure and thus energy demand of ammonia production. One way to reduce pressure is by implementing

absorption/adsorption processes to target ammonia as it is produced. Palys et al. modeled an absorbent enhanced ammonia synthesis and optimize the operating conditions to minimize the cost (Palys et al., 2018). The work was motivated by introducing enhanced absorbent ammonia using a bed of supported alkali metal salt (Malmali et al., 2018; Wagner et al., 2017).

Metal-organic frameworks (MOFs) have been linked to ammonia in the literature due to MOFs' potential towards air purification of toxic chemicals (Wang et al., 2018). In 2018, a MOF was reported as the highest loading and capacity of ammonia (Rieth and Dincă, 2018). The top material showed 8.56 mmol/g capacity under personal protection equipment relevant conditions. The capacity value is higher than the previous state of the art HKUST-1 MOF by 27% (Rieth and Dincă, 2018). At equilibrium, on the other end, the adsorption at 1 bar reached 19.79 mmol ammonia per gram of the MOF (Cu₂Cl₂BBTA). Also, ammonia adsorption was studied in four MOFs (MIL-47, IRMOF-1, IRMOF-10, and IRMOF-16) (Yu et al., 2012). Ammonia adsorption on these MOFs indicated relatively weak ammonia-MOF interactions.

One way to functionalize a MOF for a particular application is evolved because of these materials' permanent porosity. The incorporation of organic materials inside MOFs' cages has been investigated in the literature, mostly for CO₂ capture. The most common molecules are ionic liquids (IL), which has several desirable and unique characteristics to bind to polar molecules. Han et al. constructed IL incorporated in MOF composite for increased ammonia adsorption capacity (Han et al., 2020). The materials thus possess several adsorption sites important for capturing ammonia in humid and dry conditions. The obtained structure of [BoHmim][Zn₂Cl₅]@MIL-101(Cr) was shown to have a record of 24.12 mmol/g at 1 bar and 298 K. Not only this excellent capacity is observed under dry conditions but also at conditions nearing the water-saturated ammonia solution as water provides additional sites for ammonia adsorption.

This work investigates MOFs' potential towards integration in the ammonia synthesis loop in low-pressure adsorption enhanced Haber-Bosch conditions using molecular simulation. The exploration is initiated by screening a small MOFs dataset followed by adsorption performance evaluation. Moreover, the influence of IL encapsulation in MOFs on ammonia capacity and selectivity is examined.

2. Methodology

2.1. Screening of MOFs and Force Field Modification

In this work, the structure set from (Rosen et al., 2019) was used for screening purposes and evaluating structure-property relationships. The dataset is based on experimental MOFs with various organic linkers and metal nodes. Structures in this dataset are open metal site MOFs which present a higher loading capacity of polar molecules. Grand Canonical Monte Carlo (GCMC) simulations have been throughout the study to compute the adsorption properties of structures using RASPA software (Dubbeldam et al., 2016). Structural parameters such as pore limiting diameter (PLD), largest cavity diameter (LCD), and pore volume have been evaluated using zeo++ code (Willems et al., 2012). Ammonia and nitrogen have been modeled using the TraPPE force field (Martin and Siepmann, 1998; Zhang and Siepmann, 2010), whereas hydrogen is modeled using Darkrim-Levesque three-site model. MOFs have been assumed as rigid structures and parameters for non-bonded interactions obtained from Universal Force Field (UFF) parameters (Rappe et al., 1992). Although the choice of force field impacts gas separation performance evaluation, Dokur and Keskin showed that MOFs' ranking using metrics is

not sensitive (Dokur and Keskin, 2018; McDaniel et al., 2015). The structures are first screened for ammonia capture properties using a combination of ideal selectivity of NH_3/N_2 using the ratio of Henry's constants at 298K (K_t^0) and the adsorption of ammonia at 1 bar and 298K (N_{ads,NH_3}). Factor f in Eq. (1) combines the importance of ammonia capacity while desiring selectivity.

$$f = \frac{K_{NH_3}^0}{K_{N_2}^0} \times N_{ads,NH_3} \quad (1)$$

As a result of the presence of open metal sites (OMS), computational of the adsorption figures are not precise due to the rise of unique interactions between adsorbates and the unsaturated metal centers (Daglar and Keskin, 2020). Here, we modify the MOF structure's UFF structure, altering its cohesive energy to match ammonia's adsorption isotherm before performance evaluation. This technique has been previously used to fit experimental adsorption properties data (Pérez-Pellitero et al., 2010).

2.2. Encapsulation of Ionic Liquid and Performance Evaluation of MOFs and IL@MOFs

In this work, IL pairs' insertion was accomplished in the canonical ensemble at various IL loading values as implemented previously in the literature (Mohamed et al., 2020, 2019). The LJ and point charges of atoms in [bmim][Tf₂N] IL were obtained from the literature (Androulaki et al., 2012). Computations towards adsorption properties were carried similar to the procedure aforementioned. The investigation of MOF and IL@MOF towards the enhanced Haber-Bosch process was to estimate adsorption of the studied structures at adsorption and desorption conditions. Adsorption conditions at 20 bar and 170 °C, whereas desorption conditions are at 13 bar and 500 °C. Ammonia mole fraction at the reactor's outlet is 4.5% (Palys et al., 2018). As a result, the adsorber's inlet has a mole composition of 23.9%, 71.6%, and 4.5% of N₂, H₂, and NH₃, respectively. The composition of the desorption conditions was determined per the equilibrium adsorption at the adsorption stage. Equilibrium absolute adsorption is determined in multicomponent GCMC simulations. Three critical indicators are investigated, the regenerability factor R% (Bae and Snurr, 2011), used here for ammonia adsorption as in Eq. (2), and a new parameter P that can be observed as the purity of the stream after the desorption step (Eq. (3)). Parameter P is similar to the working capacity indicator in previous literature studies. In order to combine purity with capacity, metric S is introduced in Eq. (4).

$$R\% = \frac{\Delta N_{NH_3}}{N_{ads,NH_3}} \times 100\% \quad (2)$$

$$P = \frac{\Delta N_{NH_3}}{\Delta N_{NH_3} + \Delta N_{N_2} + \Delta N_{H_2}} \quad (3)$$

$$S = P \times \Delta N_{NH_3} \quad (4)$$

3. Results and Discussion

The first part of the results is related to the initial screening of the selected set of structures. Equation 1 is used to highlight the best performing materials for ammonia capacity and best selective ones. The initial screening demonstrated that Co₂Cl₂BBTA

(BBTA: 1H,5H-benzo(1,2-d:4,5-d')bistriazole), Ni-BTP (1,3,5-tri(1H-pyrazol-4-yl)benzene) and $\text{Cu}_3(\text{DMTRZ})_2(\text{ox})_2$ are the highest f factor among the MOFs in the dataset while possessing required PLD for the particular application. The factor reached 12.3, 26.3, and 18.1 for the MOFs, respectively. It has to be noted that if one observes the ideal NH_3/N_2 selectivity, MOFs built from 1,3,5-benzenetricarboxylate (BTC) organic linker exhibit the highest selectivity behind $\text{Cu}_3(\text{DMTRZ})_2(\text{ox})_2$. However, the combination of capacity and selectivity is the goal behind this screening. Structural analysis showed that $\text{Co}_2\text{Cl}_2\text{BBTA}$ and Ni-BTP have LCD of 10.3 and 14.9 Å, respectively, which can be exploited via IL's insertion to increase materials' adsorption selective properties.

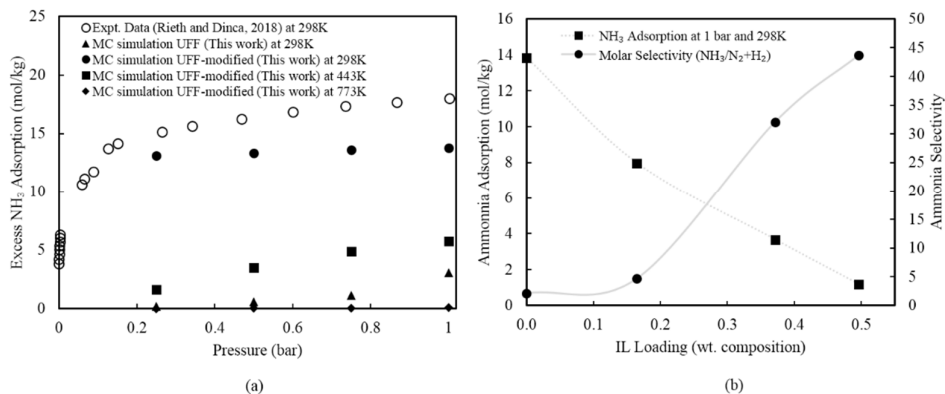

Figure 1. (a) Adsorption isotherms of NH_3 in $\text{Co}_2\text{Cl}_2\text{BBTA}$ at different temperatures and pressures (b) effect of IL loading composition on adsorption and selectivity of ammonia

To obtain precise performance evaluation, adsorption isotherms, especially ammonia, have to fit experimentally available data. As mentioned in the methodology section and because the generic force field does not resemble interaction between MOFs with OMS and adsorbates, further modification of the MOF's LJ parameters must be conducted. Among the top three candidate materials, $\text{Co}_2\text{Cl}_2\text{BBTA}$ has to be selected for this study as it has been studied experimentally and presented the highest ammonia capacity at the time of its publication. Several trials to modify the UFF towards a better agreement with experimental ammonia adsorption data, most notably between 0.5 and 1 bar. The depth of the potential well of the LJ potential ϵ was adjusted to 2.25 times the previous UFF, and relatively good agreement can be seen in Figure 1(a) to the experimental measurements. The modified parameters do not provide an accurate representation of the isotherm at the near zero-pressure limit; thus, further modification and incorporation of quantum chemistry computation are necessary. The adjusted value reflects the increase in dispersion-repulsion interactions cohesive energy of NH_3 . Figure 1(a) also reveals the influence of temperature on the adsorption isotherm using the modified force field. The effect of temperature is useful to better select adsorption and desorption conditions based on the sorbent.

Incorporation of IL inside MOFs' cavity can result in enhanced adsorption or selectivity depending on the studied mixture's components. The insertion of [bmim][Tf₂N] in $\text{Co}_2\text{Cl}_2\text{BBTA}$ was accomplished computationally at three different IL loading

(composition). The IL loading effect on structural properties such as free volume and surface area have been studied first. Then, adsorption of ammonia at 1 bar and 298K using the modified force field for the MOF. It can be observed that the presence of IL reduced the available volume significantly in the MOF. IL loading at 0.372 has reduced the free volume up to 64% relative to the pristine MOF. Besides, from Figure 1(b), adsorption of ammonia per kg of the total structure (MOF+IL) decreases as more ILs pairs are incorporated. The reduction in adsorption per mass can be explained as ILs covers essential favorable adsorption sites for ammonia. Meanwhile, selective adsorption is favored higher IL loading structures as a result of cavity volume reduction.

Co₂Cl₂BBTA and ILs incorporated structures are also investigated based on the conditions relevant to the low-pressure Haber-Bosch process. Relevant parameters have been calculated as described in the methodology section for the structures. The low vapor pressure of ammonia presents a challenge for high capacity and selectivity since the mole fraction of ammonia at the inlet is as low as 4.5%. The metrics results show that IL inclusion increases the purity parameter *P* which a factor of selectivity at adsorption and desorption conditions (Table 1). The inclusion of ILs reduces the free volume, which increases the selectivity significantly towards ammonia at adsorption conditions. The parameter *P* reaches a maximum at 0.372 weight fraction, while higher IL reduced the figure. However, when combining *P* with the working capacity of ammonia, lower IL loading composition at 0.165 shows the best at 1.533. The reason is the working capacity is slightly lower than pristine MOF while having better selectivity. The regenerability factor reached 72.68% for the pristine MOF. Reduction in regenerability factor is observed as ILs pairs increase in number as expected.

Table 1. Performance parameters for Co₂Cl₂BBTA MOF and IL encapsulated structures

IL weight composition	Ammonia adsorption (mol/kg) at adsorption condition	<i>P</i>	<i>S</i>	<i>R</i> %
Pristine MOF	3.311451	0.626	1.507	72.68
0.165	3.145765	0.761	1.533	64.03
0.372	1.496324	0.933	0.584	41.86
0.496	0.381627	0.915	0.084	24.13

4. Conclusions

Adsorption enhanced Haber-Bosch has the potential to reduce the pressure in the ammonia synthesis loop. High ammonia affinity at relatively lower partial pressure is necessary to achieve significant adsorption figures. In this work, MOFs have investigated the implementation of a low-pressure ammonia synthesis loop using molecular simulations. The study is initiated by screening synthesized MOFs small dataset, in which candidate materials were highlighted. Co₂Cl₂BBTA MOF was selected as one of the three top-performing materials, while experimental adsorption data is available. Modification of generic force to describe LJ parameters of MOFs was carried out to fit experimental data. Following that, performance evaluation of Co₂Cl₂BBTA and IL encapsulated MOF Co₂Cl₂BBTA was determined using several metrics and indicators, including purity and regenerability of adsorption sites. It has been shown that IL loading plays a role in increasing selectivity towards ammonia while reducing the capacity. An optimum composition is set given the objective function. From an overall point of view, these adsorbents increase the cost of the system's separation and may jeopardize the purity of the product. However, they provide a means to reduce the intensity of the ammonia

chemical plant. Therefore, a possible synergy between adsorption based and vapor-liquid separations could be a viable alternative.

Abstract

Enantiomers are molecules found in two variants being non-superimposable mirror images of each other. Chemical synthesis typically produces a 50:50 % mixture of both enantiomers. The separation of such a mixture is crucial for many applications, because enantiomer and counter-enantiomer often have completely different effects on biological organisms or the human body. However, the separation is a challenging task, as the physical properties of both enantiomers are identical.

The presented work consists of two parts, which are based on model optimization. The first part of this paper describes the process of fitting the model to experimental data described in (Gänsch et al., 2020). The focus of the second part is on optimization considering two conflicting objectives: total harvested product mass and purity of the product. A sensitivity analysis presented in (Gänsch et al., 2020) is used as a basis for the selection of optimization variables. Some parameters have a significant impact, and their optimization allows to control not only the key characteristics as productivity and purity, but also the mean crystal size. The genetic algorithm CMAES (Hansen, 2006) and parallel computing techniques are applied for optimization.

Keywords: enantiomers, separation, mathematical modelling, population balance equation, genetic optimization

1. Introduction. Enantiomers and process setup

Enantiomers are optically active stereoisomers being non-superimposable mirror images of each other. They can exist as levorotatory (-) and dextrorotatory (+) molecules and are denominated usually as L and D. While possessing identical physical properties, enantiomer and counter enantiomer may have different effects on biological organisms and the human body. Based on the physical identity of the enantiomers, separation becomes a challenging task that requires right technique and operation conditions. In the concept of the preferential crystallization (PC), a desired enantiomer is separated from a racemic solution by providing its single seeds. Cooling crystallization technology is applied to promote crystal growth in the solution. Detailed explanation of the PC concept is provided in (Coquerel, 2006). The setup of the fluidized bed crystallizer considered in this work and a proof of principle were given in (Temmel et al, 2020).

Super-saturated solution enters the bottom of a tubular crystallizer (see Fig. 1) and causes growth of seeding crystals inside the crystallizer. Small crystals move with the liquid flow to the crystallizer top and are recycled in a feed tank. Larger crystals sink to the bottom, are crushed in a mill and sent back to the crystallizer as new feed. The product is withdrawn at an outlet on the side of the crystallizer. This is done in a periodic pulsewise manner. To describe the periodic product removal, the triggering of an upper photo sensor (position h_s , Fig. 1) has to be modeled. It is assumed that the product withdrawal is initiated by the volume fraction of the liquid phase at the sensor position h_s falling below a pre-specified volume fraction $\epsilon_{desired}$. In a next step the withdrawal of a segment of the suspension is described. In the model, this is assumed to happen instantaneously, i.e. the suspension located within the height segment Δh_p located above the product outlet, H_{prod} , is taken out as the harvested product. The removed volume in the height segment Δh_p is equal the volume between the two sensors, Δh_s . During product collection the suspension above $H_{prod} + \Delta h_p$ moves downwards over the length Δh_p . In a last modeling step, the upper part of the crystallizer, which is now “empty”, has to be replenished. This is done by filling up the empty top segment of the crystallizer with pure liquid possessing the racemic inlet composition.

Figure 1. Scheme of a single fluidized bed crystallizer for continuous preferential enantioselective crystallization.

Process model and variables

Crystallization processes are complex and difficult to model and control, e.g. they are multicomponent systems, multiphase systems, there are property, space and time dependent variables. However, when information of the solubility and kinetics are available, modeling and further control of the separation process is possible. For understanding and designing the process, it is not enough to rely only on experimental studies. The model used should be sufficiently detailed, and at the same time allow computations to be performed with reasonable effort.

A model, which provides a reasonable compromise between these conflicting objectives, has been published in (Mangold et al., 2017). It could be shown that that model describes the interaction between crystal growth, particle transport, and fluid dynamics in the isothermal case with reasonable accuracy. A refined process model from (Gänsch et al., 2020) distinguishes between the L and the D enantiomer. This allows to evaluate the purity of the withdrawn product, which is important when productivity of chiral substance increases. Further, it is well known that crystallization kinetics crucially depend on the temperature, for this reason an energy balance equation is added. Detailed description of the model assumptions and equations is provided in (Gänsch et al., 2020).

A few of the main model assumptions are listed below (for further details, see Gänsch et al., 2020). The crystal population is described by a number density function that depends on a single space coordinate h in direction of the liquid flow, a single property coordinate L representing a characteristic crystal size, and on time t . Plug flow conditions are assumed for the liquid. The particle velocity, which differs from the liquid velocity, is described by the classical model by Richardson and Zaki (Richardson and Zaki, 1954). Prediction of the crystal shape is based on available experiment data and it is described by the sphericity parameter ψ (Binev et al., 2015). The only asymmetry between the two enantiomers comes from the initial conditions. Crystal growth is modeled by experimentally validated kinetics (Temmel et al., 2020). Nucleation kinetics of a similar structure as the growth kinetics are assumed in order to assess the purity of the product. Instead of assuming a constant product flow rate as in (Mangold et al., 2017), the periodic, pulse-wise withdrawal of product crystals is modeled. As a simple model of the disperser, we use a standard population balance model with breakage.

The developed model allows for studying the process and making predictions in terms of productivity, yield and mean product crystal size.

Laboratory experiments described in (Gänsch et al., 2020) are used as nominal case for the presented study. It could be shown that the model agrees reasonably well with experimental data. However, a systematic adaptation of parameter values not accessible to direct measurements has not been done, yet. This is one objective of this contribution with the aim to provide a valid and efficient process model. The second objective is to maximize productivity and purity by finding optimal operation conditions in numerical optimizations. Both tasks are non-trivial due to the high system order of the process model, the inherent nonlinearities of the process, and the periodic operation regime.

Model parameters

Based on the sensitivity analysis presented in (Gänsch et al., 2020), it was determined that not all parameters equally affect the key characteristics of the crystallization process. For a better understanding of the process, all the model parameters are divided into two groups. The first group of parameters has confirmed values obtained from separate measurements made in the laboratory. The values of the second group are based on the preliminary study.

Due to the availability of laboratory experiments, only those parameters are fitted in the following chapter that do not have experimentally confirmed values. Four model parameters belong to the second group and are chosen as optimization variables:

x_1 - critical breakage size L_c , [μm]. The critical particle size L_c , above which breakage may occur, is chosen as the gap between rotating blade and stationary parts of the disperser.

x_2 - desired fraction of the fluid $\varepsilon_{desired}$ at the sensor position, which in the model determines the triggering of a new product removal pulse.

x_3 - number of daughter crystals p in a break-up event inside the mill

x_4 - sphericity ψ . It is defined as the ratio of the surface area of a sphere, which has the same volume as the particle, to the surface area of the particle.

Asparagine monohydrate is used as an example, corresponding data on solubility and kinetic parameters were obtained experimentally and presented in (Temmel et al.,2020).

2. Optimization of the process model

Parameter fitting

The main idea of this chapter is to minimize the difference between the values of the objective functions OF obtained by experimental and simulation methods using a genetic algorithm CMAES (Hansen, 2006).

The focus of this optimization round is to achieve productivity close to the nominal case described in (Gänsch et al., 2020). Desired productivity as well as results of performed simulations presented in Table 1.

$$OF_1 = (f_{sim}^1 - f_{exp}^1)^2, \quad (1)$$

where f^1 - productivity $Pr, [g \cdot l^{-1} \cdot h^{-1}]$

Table 1. Results of the productivity fitting

f_{exp}^1	33.1						
Iteration GA	1	2	3	4	5	6	7
f_{sim}^1	41.07	38.4	37.4	37.1	36	35.82	31.33
OF_1	63.52	28.09	18.49	16	8.41	7.4	3.13

The use of the CMAES algorithm allows us to get closer to the experimental productivity. However, achieving the desired productivity leads to a decrease in other process characteristics. In order to find compromise between conflicting criteria, the extended objective function OF_2 defines a weighted square error of four criteria f^k :

f^1 - productivity $Pr, [g \cdot l^{-1} \cdot h^{-1}]$;

f^2 - time between 2 withdrawals after reaching cyclic steady state $\Delta t, [h]$;

f^3 - mean crystal size of the product $\bar{L}, [\mu m]$;

f^4 - standard deviation of the product size distribution $\sigma, [\mu m]$;

$$OF_2 = w_1 \cdot (f_{sim}^1 - f_{exp}^1)^2 + w_2 \cdot (f_{sim}^2 - f_{exp}^2)^2 + w_3 \cdot (f_{sim}^3 - f_{exp}^3)^2 + w_4 \cdot (f_{sim}^4 - f_{exp}^4)^2 \quad (2)$$

Since the criteria f^k have due to their nature a different scale, they are weighted with weighting coefficients w_k , which assure similar impact of each criterion on the objective

function OF_2 . For this the values $w_1 = 0.08, w_2 = 26, w_3 = 0.07, w_4 = 0.0028$ were chosen.

The results of the parameter identification are summarized in Table 2. The parameter fitting process shows an improvement of the criteria.

Table 2. Results of the model fitting

Criteria	Experiment	Simulation	1	2	3	4	5
f^1	33.1		35	48.54	49	47.88	47.6
f^2	0.65	1.7	1.22	1.16	1.08	1.06	
f^3	271.4	291	269.88	273.14	271.34	271.02	
f^4	58.2	16.50	13.63	12.76	12.53	12.31	
OF		60.71	33.19	32.87	28.12	27.18	

Optimization of the operating parameters

After finding the reference solution and achieving the quantitative agreement between the simulation and experiment results, we return to sensitivity analysis to determine parameters for further optimization. It was confirmed (Gänsch et.al, 2020) that operating parameters such as inlet liquid concentration c_{in}^i , and inlet volume flow rate V_{in} play a significant role in the crystallization process. The focus of this section is on the periodical steady state solution of the crystallization process and its dependence on the operating parameters.

The bi-criterial optimization problem is converted to a single objective problem by introducing a Pareto coefficient w varying from 0 to 1. The resulting optimization function is presented in the form:

$$OF_3 = (1 - w) \cdot \text{purity} + w \cdot \text{product} \quad (3)$$

The aim of the simulation is to find optimal operating parameter values to increase the productivity and the purity of the product enantiomer.. When using the coefficient $w=0$, the purity of desired enantiomer is maximized, when using the coefficient $w=1$, emphasis is on the amount of harvested mass. As an initial estimate for new points on the Pareto front, the maximum value of the objective function calculated of the previous step is used.

Figure 1. Pareto Front, obtained by using the CMAES algorithm. Number of individuals inside population $\lambda=88$ for the first iteration, $\lambda=33$ for subsequent iterations. Initial conditions for the inlet volume flow rate and the inlet liquid concentration were used from

the reference case (Gänsch et.al, 2020). Operation condition corresponding to the depicted points are given in the Appendix.

As a result of operating parameters optimization, suitable values for the inlet liquid concentration and the inlet volume flow rate were determined depending on the goal set.

Conclusions

Improved parameter fitting made it possible to provide a model that simulates key process characteristics as productivity, time window between harvestings, mean crystal size, and standard deviation of the withdrawal product. Subsequent optimization of essential operating parameters has demonstrated the potential of the process with respect to achieve high purity and productivity. The evolutionary algorithm CMAES showed high efficiency and is promising for other studies. In view of the big data and the complexity of calculations, parallelization techniques should be applied.

Abstract

Waste tyres are part of solid waste materials that are toxic to the environment but have the potential to be converted to something of value. South Africa contributes approximately 11 million tyres to the global 1.5 billion tyres produced per annum. With waste tyres identified as a potential energy source due to its high carbon content and heat value, it is not surprising that the government of South Africa has invested in the creation of waste tyre management plan intending to recover products and energy from this waste material. In this paper, a waste tyre to methanol and electricity process is assessed from a thermodynamic and environmental perspective. Two key factors are analysed, carbon efficiency and chemical potential efficiency. The purpose of this study is to contribute to this research by finding the limit of performance for the conversion of waste tyres to methanol and power from a fundamental thermodynamic perspective. For the system developed a carbon efficiency of 54.6% and the chemical potential efficiency of 63% were achieved. Equally the system produces 2.42 GJ/ ton of waste tyre and has the potential to generate a revenue of \$ 620/ton of waste tyre. The study shows converting tyres to methanol is achievable, however, 45% of the carbon resource will end up as carbon dioxide.

Keywords: gasification, waste-to-methanol, electricity, carbon emissions, efficiency

1. Introduction

Solid waste materials such as biomass, waste tyres, and municipal solid waste, have been shown to contain adequate energy content to have the potential to substitute fossil fuels in the production of power and useful chemicals. Many existing technologies currently used for solid fossil fuels can be utilised easily to accommodate these waste materials, thus making the transition to alternate fuels achievable. Much of research in energy has largely focused on the optimization of technologies such as gasification, pyrolysis, combustion and liquefaction to estimate the optimum operating conditions to efficiently convert solid waste materials to useful products and power.

Developing countries such as South Africa have seen an increase in energy needs as the economy grows to include the participation of previously disadvantaged persons. However, South Africa's energy needs have been in dire straits in the last decade with the state producer Eskom losing most of its available capacity plunging the country into severe rolling blackouts, requiring upwards of 6000MW of power demand to be removed from the electrical grid to prevent a catastrophic failure of the nation's power network. Equally, the country saw the cost of liquid fuels also increasing due to the weakening currency and fluctuations in global crude oil prices, and demand. In 2020 the government announced plans to diversify South Africa's energy sources which will embrace new entrants and capacity into the energy space. This will allow generation for own use and securing power from independent power producers (IPP), creating easy access to cheap and clean energy (South Africa, 2020).

In terms of waste generation, the country has identified 38 waste streams that need to be diverted from landfills, and one such waste materials is waste tyres. South Africa contributes approximately 11 million tyres to the global 1.5 billion tyres produced per annum. Waste tyre recycling is identified in the National Waste Management Strategy (NWMS) as an area which can contribute towards South Africa's economic growth and the creation of green jobs (Godfrey and Oelofse, 2017). Waste tyres have a high carbon content and heat value, much of the research on waste tyres have been dedicated to recover products and energy from this waste material.

Methanol is a promising clean-burning fuel with a high octane number, and is an antecedent to the production of more complex chemical structures, such as dimethyl ether, methylamine, acetic acid, methyl tertiary butyl ether, etc (Dalena et al., 2018). The conversion of waste tyres to methanol and electricity would contribute to the country's energy mix. Studies by (Borgogna et al., 2019; Rivarolo et al., 2016) show that there is an environmental benefit to converting waste into methanol than burning it for energy as the CO₂ emissions reduced by an average of 14%. Whereas (Iaquaniello et al., 2017, 2018) studies show that converting refuse-derived fuel to methanol leads to about 40% and 30-35% reduction in greenhouse gas emissions for methanol production from fossil fuels and bio-resources, respectively. Waste to methanol process CO₂ emissions are half the emissions produced by waste to energy route.

The purpose of this study is to contribute to this research by finding the limit of performance for the conversion of waste tyres to methanol and power from a fundamental thermodynamic perspective.

2. Methodology

In this work, the thermodynamic efficiency of the process converting waste tyre to methanol and power is measured using two basic metrics, mainly; carbon efficiency and chemical potential efficiency. The properties are described as follows:

$$\text{Carbon Efficiency } (C_{eff}) = \frac{\text{moles of C in the desired product}}{\text{moles of C in the feed}} \quad (1)$$

$$\text{Chemical Potential Efficiency } (\eta_{cp,eff}) = \frac{\text{Gibbs free energy of combustion of products}}{\text{Gibbs free energy of combustion of feed}} \quad (2)$$

Equation 1 measures how much of the carbon in the feed stream ends up in the desired products. Less than 100% carbon conversion leads to carbon dioxide emissions. Equation 2 measures how much of the chemical potential stored in the feed material is translated to the desired products during chemical transformation (Sempuga & Yao, 2017). The thermodynamic properties of waste tyres utilised in this work can be found in (Mavukwana et al., 2020).

3. Result and discussion

3.1. Methanol production from tyres

The process starts with the gasification of tyres with steam to produce syngas. Steam is selected as the gasification agents since it yields a higher composition of H₂/CO compared to oxygen. The syngas from gasification is cleaned of acid gases and its H₂/CO ratio is adjusted in the water gas shift reactor to meet the required ratio for methanol in the synthesis reactor. The recommended ratio of H₂/CO is 2. The adjusted syngas is fed to the methanol synthesis reactor to produce methanol and water.

The overall material balance for the process producing methanol is:

$$\Delta H = 73.99 \text{ kJ}, \quad \Delta G = 105.36 \text{ kJ}$$

The performance of this process in equation G1 is as follows:

$$\text{Carbon efficiency} = 81.4\%$$

$$\eta_{cp} = 86.3\%$$

It is assumed that all the available sulfur leaves as hydrogen sulphide, since chemicals in the tyre rubber, such as zinc oxides, prevent sulfur-oxidising.

Equation (G1) represent the ideal process or the maximum achievable conversion of waste tyres to methanol. This process represents a case where all the operating units are energy integrated, with all the units that are exothermic sending their energies to the endothermic gasification step. That is, the water-gas shift, and the methanol synthesis will send all their energy to the gasification step, to try and achieve an adiabatic process. However, the overall mass balance of the process shows that the system still requires energy input. If this energy is not added the process would thus be infeasible. One strategy for supplying this energy is to combust a portion of the tyre feed.

Figure 1 shows the system that is fuelled by burning an additional number of tyres. The process is fully integrated and the overall material balance for the system is:

$$\Delta H = -29.9 \text{ kJ}, \quad \Delta G = 0 \text{ kJ}$$

The performance of this process in figure 1 equation G2 is as follows:

$$\text{Carbon efficiency} = 66\%$$

$$\eta_{cp} = 70.1\%$$

Therefore, supplying the required energy by burning an additional number of tyres increases the carbon emissions and thereby reduces the carbon efficiency to 66% and the chemical potential efficiency decreases to 70%. However, the process in figure 1 is not possible with conventional technology. Since the gasification step operates at higher

temperatures than the other units, the transfer of energy between the various process units would have to be done against a temperature gradient and practically that might require expensive equipment (Fox & Stacey, 2019).

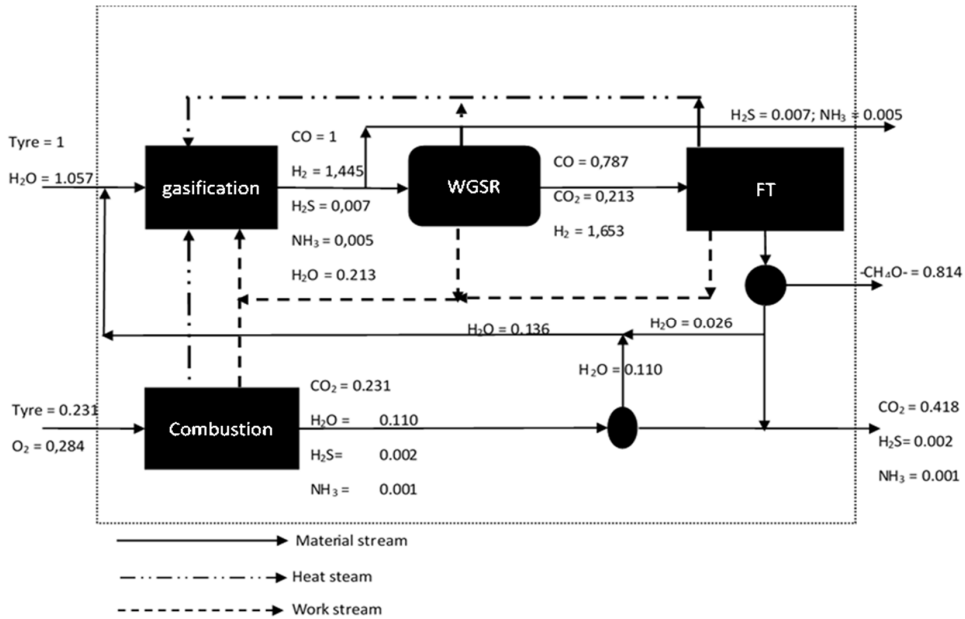

Figure 1: Fully integrated methanol process

Due to practical difficulties in implementing Figure 1, let us consider the approach of partial integrating the process, by supplying the energy needed for the gasification step only.

Figure 2 and equation G3 shows the overall material balance to produce methanol when additional tyres are burned to supply the energy needed for the gasification step only.

The performance of this process in Figure 2 and equation G3 is as follows:

$$\text{Carbon efficiency} = 57.6\%$$

$$\eta_{cp} = 70\%$$

The decision to not fully integrate the G3 process means more tyres need to be burned, since the energy from the water gas shift and methanol synthesis is no longer available. This leads to higher carbon dioxide emissions and thus the carbon efficiency of the process reduces to 57%. The system also produces excess work, if not recovered the system will lose it to the environment. The excess energy is recovered by applying heat engines at the different units. This leads to the production of 82.55 kW of shaft work which can be converted to electricity as shown in Figure 2.

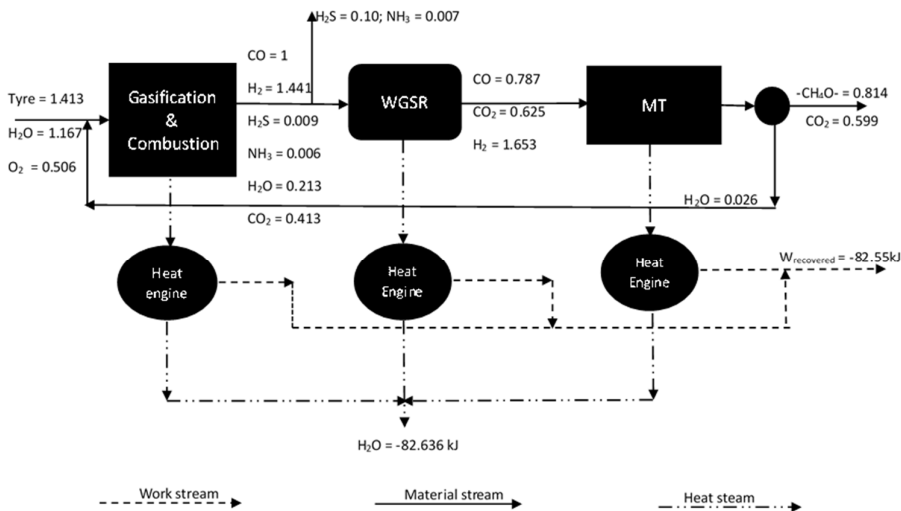

Figure 2: Partially integrated methanol process

3.2. Effect of temperature

The process is described on Figure 2 and equation 3 is assumed to be operating at the Carnot temperatures. The Carnot temperature can be viewed as the “ideal” temperature to operate a process, since neither heat nor work is being wasted. However, Carnot temperatures often prove to be impractical. Reaction kinetics are a common limitation to the use of Carnot temperature which necessitates a deviation from the ideal. For instance, gasification operates at temperatures above 1000°C to ensure high conversion of the carbon sources whereas the water gas shift and methanol synthesis reactor must operate at temperatures befitting the catalyst used. 1300°C is recommended for gasification of waste tyres (Mavukwana et al., 2020), 450°C for water gas shift and 220°C for the methanol synthesis. Operating at a temperature other than the Carnot temperature results in the loss of some of the potential work. To compensate for the lost work, more feed is burned. However, this increases the CO₂ emissions even more. The operating temperature for the water gas shift reactor is greater than the Carnot temperature, which means the unit will require further work input since operating at higher temperatures than Carnot temperature recovers more work than the system can provide. Using the notion of heat engines, the work produced by the process reduces from 82kW to 48 kW, which is equivalent to 2.42 GJ/ ton of waste tyre. An additional amount of 0.492 mol/s of tyres is required to make the process feasible. However, the carbon efficiency decreases to 54.6% and the chemical potential efficiency decreases to 63%. This, therefore, means that converting tyres to methanol is achievable, however, 45% of the carbon resource will end up as carbon dioxide. Furthermore, by operating the gasification unit at elevated pressures and then expanding the gaseous products, extra work will be recovered.

3.3. Revenue potential

The revenue potential of the process is obtained by a difference of the product selling price and of the cost of feed material. The analysis excludes the capital costs associated with each pathway. When electricity is sold at \$ 0.098/kWh and methanol sold at \$

480/ton (Global petrol prices, 2019), a waste tyre to methanol process has the potential to generate a revenue of \$ 620/ton of the tyre.

4. Conclusion

This work presented a method for process analysis at the “systems” level. This method allows a “big-picture” perspective. Such an elevated perspective further allows for the possibilities and limits to be investigated before significant time and resources are expended in more details-orientated methods. The analysis presented here focused on the performance limits of converting waste tyres to methanol and power. A notable result of this method shows that high process efficiency can only be achieved through a high degree of process integration and with the practice of co-production. Highly specialized processes that focus on producing only a few products, will always make a sacrifice in overall process efficiency. This study showed that 45% of the carbon feed is lost to carbon dioxide when tyres are converted to methanol and power. However, the process has a revenue of approximately \$ 620/ton of waste processed. Therefore, from an economic perspective, converting waste tyres to methanol is preferable to landfilling, as it reduces the volume of a hazardous waste stream by converting it to a useful transportation fuel and power. However, another pollutant, CO₂ is produced.

Analysing the robustness of multi-stage bioseparations to measurement errors

Robert Milton, Emma Chandler and Solomon F. Brown

University of Sheffield, UK
r.a.milton@sheffield.ac.uk

Abstract

Protein extraction is essential to the design and manufacture of bioproducts. A benign method of increasing academic and commercial interest is aqueous two-phase extraction (ATPE) (Iqbal et al., 2016), wherein a phase forming additive (in this case polyethylene glycol with phosphate buffer) separates an aqueous mixture into a target-rich top phase and a contaminant-rich bottom phase. This paper concerns a multistage separation, performed by repeating the ATPE iteratively to achieve a target protein yield or purity (Rosa et al., 2009). A McCabe-Thiele diagram is used to compute the number of stages required to achieve the target.

Unfortunately, the protein phase equilibrium curves used to construct the McCabe-Thiele diagram are subject to substantial variation depending on the precise composition and temperature of the mixture being separated. In order to assess the reliability of a multi-stage ATPE, we examine the robustness of the McCabe-Thiele diagram to variations in the phase equilibrium curves. It is seen that error propagation is weak, in that the same number of stages are required to achieve target under a variety of error scenarios. When this is not the case, a novel method of predicting the number of extra stages required is presented.

Keywords: protein extraction, multi-stage extraction, ATPE, model uncertainty, error analysis

1. Introduction

The extraction and purification of biomolecules is central to the manufacture of a vast range of bio-pharmaceuticals and speciality biochemicals (Doran, 2012). Aqueous Two-Phase Extraction (ATPE) is an efficient, benign and environmentally-friendly, low-cost and easily scalable bioseparation technique (Azevedo et al., 2009), suitable for batch or continuous processing. A solute is fractionated between two aqueous phases, e.g two polymer solutions or a polymer and a salt, accumulating preferentially in one of the phases. ATPE has been implemented with a diverse range of solutes (Iqbal et al., 2016), including proteins, enzymes (Kula et al., 1982), nucleic acids, antibodies (Rosa et al., 2013), viruses, metals and metal ions.

A multistage fractionation, repeating the same ATPE, is often needed to meet the exacting requirements for purity and yield demanded in bio-processing applications (Chandler et al., 2021; Rosa et al., 2009). A Solute is extracted from lean phase x to rich phase y ,

Figure 1: A schematic experimental design for a 3-stage ATPE.

iterating through stages according to

$$a_{y,n+1} - a_{x,n} = -A \leq 0 \quad (1)$$

where a denotes amount of solute (in mol or kg), of which A is lost during each stage. Starting from $a_0 := a_{x,0} > a_{y,0} := 0$, N stages are required to reach a desired goal

$$Xa_0 \geq a_{x,N} = a_{y,N+1} + A \quad (2)$$

Where the goal is removal of $X \times 100\%$ solute (contaminant), x is the extract phase. Where the goal is recovery of $(1 - X) \times 100\%$ of solute (product), x is the waste phase. The process is illustrated in Figure 1.

The iteration through stages is classically expressed in the McCabe-Thiele diagram Figure 2(a), stepping between the operating line $a_y = a_x - A$ and the phase equilibrium curve $a_y = a_y(a_x)$ lying above it. Experimentally, however, the total amount $a := a_x + a_y > 0$ is measured more reliably and accurately than either phase, as protein is known to precipitate into the interface between phases (Chandler et al., 2021; Andrews and Asenjo, 1996). Therefore we work with phase equilibrium curves written as

$$f(a) := a_y = a - a_x \quad (3)$$

and an operating line (which is usually not straight) depicting

$$f_{n+1} = a_{x,n} - A = a_n - f_n - A \quad (4)$$

as shown in Figure 2(b). The midpoint between the equilibrium curve and the operating line is the straight line $2f = a - A$. The goal Equation (2) becomes $f_{N+1} \leq Xa_0 - A$.

This paper studies the robustness of the iteration to measurement errors in the construction of the McCabe-Thiele diagram, essential to planning multistage ATPEs effectively. Such analyses have only been conducted for liquid-vapour fractionations (Medina et al., 1974),

Figure 2: A 3-Stage McCabe-Thiele iteration depicted (a) classically and (b) in total amount terms.

exploiting the particular algebraic form of equilibrium curve in these systems. Section 2 of this article analyses the propagation of errors through McCabe-Thiele iteration. The robustness of the number of stages N required to achieve X with respect to errors in the phase equilibrium curve $f(a)$ is described in detail. This analysis is applied to the extraction of haemoglobin using 13% w/w PEG 1500 (polyethylene glycol, a polymer) and 11.2% w/w potassium phosphate (at pH 8.0) in Section 3. This is a particularly awkward extraction to perform experimentally, and so an ideal test and application of theory. Discussion is provided in Section 4.

2. Error Analysis

We are primarily concerned with errors in the equilibrium curve f , whose value differs from truth \hat{f} by $\delta f_n := f_n - \hat{f}_n$.

This error propagates through the amount a_n , shifting it from its true value \hat{a}_n by $\delta a_n := a_n - \hat{a}_n$

The total error of equilibrium evaluation linearises to

$$e_n := f_n - \hat{f}(\hat{a}_n) = \delta f_n + f'_n \delta a_n \quad (5)$$

where $e_1 = 0$. Introducing $g := (1/f' - 1) > 0$, substitution in iteration Equation (4) yields

$$e_{n+1} = g_n e_n - (g_n + 1) \delta f_n \quad (6)$$

An easy induction on Equation (6) provides the goal error

$$e_X := \frac{e_{N+1}}{a_0} = - \sum_{n=1}^N \frac{(g_n + 1) \delta f_n}{a_0} \prod_{k=n+1}^N g_k \quad (7)$$

This formula is easily adjusted to incorporate (less significant) errors in the initial con-

centration (δa_0) and the stagewise loss (δA_n)

$$e_X = \frac{\delta a_0 - \delta A_0}{(g_0 + 1)\hat{a}_0} \prod_{k=0}^N g_k - \frac{\hat{a}_{x,N}}{\hat{a}_0} \frac{\delta a_0}{\hat{a}_0} - \sum_{n=1}^N \frac{(g_n + 1)\delta f_n + \delta A_n}{\hat{a}_0} \prod_{k=n+1}^N g_k \quad (8)$$

Restating these results for classical McCabe-Thiele iteration is simply a matter of replacing f with y and

$$g := \left(\frac{1}{f'} - 1 \right) = \left(\frac{\partial a_y}{\partial a_x} \right)^{-1} \quad (9)$$

When error invalidates apparent succes at stage N , the goal is not truly achieved until

$$\hat{f}_{N+J+1} \leq Xa_0 - A < \hat{f}_{N+1} \quad (10)$$

Linearising an arbitrary approximant f about A

$$f_n := f_A + f'_A(a_n - A) \quad \forall n > N \quad (11)$$

such that

$$\sum_{j=1}^J g_A^{-j} \delta f_{N+j} \leq \sum_{j=1}^J g_A^{-j} \delta f_A \quad (12)$$

eventually recasts Equation (10) as

$$Xa_0 - A - \frac{(g_A + 1)}{(g_A - 1)} \hat{f}_A \geq \left(\hat{f}_{N+1} - \frac{(g_A + 1)}{(g_A - 1)} \hat{f}_A \right) g_A^J \quad (13)$$

The goal is therefore achievable if and only if

$$(g_A - 1)\hat{f}_{N+1} < (g_A + 1)\hat{f}_A \quad (14)$$

It would appear one has some freedom to choose f , provided Equations (12) and (14) are satisfied. The other quantities in this formula should be opaque: $\hat{f}_A := \hat{f}(A)$ can be measured carefully in advance, and \hat{f}_{N+1} is the result given by any failed extraction.

3. Results

This Section analyses errors in the extraction of haemoglobin using 13% w/w PEG 1500 and 11.2% w/w potassium phosphate (at pH 8.0), experiments described in Chandler et al. (2021). This system is one of the more difficult ATPes, because a significant amount of haemoglobin precipitates into a solid interface between the top and bottom phases, where it joins contaminant solids. Such interface effects are a common problem in protein ATPes (Andrews and Asenjo, 1996), but usually less dramatic. The interface is variable and hard to measure, but may be inferred from the top and bottom phases. A compromise must be struck between recovering target precipitate and rejecting clogging contaminant solids. The compromise in Chandler et al. (2021) took the extract phase y as 87% of the top phase, plus the interface whenever the total haemoglobin a exceeded 0.458mg in

Figure 3: Phase equilibrium curves fitting various quadratics to experimental data f .

a 1.555ml system. Otherwise the interface was added to the waste phase x , along with the bottom phase and the remainder of the top phase. Figure 3 shows the results of OLS fitting of quadratic phase equilibrium curves

$$a^{-I} f(a) = B_2 a^{2-I} + B_1 a^{1-I} \quad (15)$$

The Good equilibrium curve fits the extract phase with $I = 0$. The Bad equilibrium curve fits the extract phase with $I = 1$, overemphasizing the goodness of fit at small a . The Combo equilibrium curve takes $I = 0$ to fit the top, bottom and interface curves separately, then allocates the interface phase post hoc by combining these three quadratics.

In analysing errors in the equilibrium curve, we must accommodate another difficulty with this system, which is the proximity of the equilibrium curves to the midpoint line (and therefore the operating line(s)) in Figure 3. For the purpose of analysis we use the Good equilibrium curve as f , and take in turn each other curve as truth \hat{f} . Included in

f	B_2	B_1	e_2	e_4	J	Predicted X
Good	-0.012	0.582				
Combo (I in W)	-0.122	0.465	0.029	0.012	0	
Combo (I in E)	-0.105	0.672				
Bad	0.225	0.384	-0.020	-0.132	3	0.04
Good-	0.155	0.450	-0.007	-0.079	1	0.14
Good-	0.071	0.516	-0.004	-0.038	0	
Good+	-0.095	0.647	0.005	0.033	0	
Good++	-0.179	0.713	0.010	0.057	-1	

Table 1: Results of McCabe-Thiele iteration, using the experimental values $A = 0.069\text{mg}$, $a_0 = 0.5\text{mg}$ and $X = 0.1$, corresponding to 90% recovery of haemoglobin. The first row is used as f , yielding $N + 1 = 4$, the remaining rows used successively as \hat{f} to assess errors. The final column gives the X achieved in Equation (13).

the latter are versions of the Good equilibrium curve in which the coefficient B_1 is shifted up (+) or down (-) by its regression standard error once or twice, setting B_2 to obey the expectation $\bar{f} = B_2\bar{a}^2 + B_1\bar{a}$. This is designed to invite failure – the slowest equilibrium curves to reach the goal will be those true ones whose gain in each step is squeezed by proximity to the midpoint (and therefore operating) line.

The results are collected in Table 1. The number of stages required is quite robust, despite the fact that errors accumulate quite dramatically between e_2 and e_4 , an effect clearly exacerbated as the equilibrium curve is lowered towards the midpoint line. Shifting B_1 up or down by two standard deviations only subtracts or adds 1 stage, lesser shifts having no effect.

Equation (13) is seen to be an excellent predictor of extra stages, although it narrowly fails to achieve the goal when the Good– curve represents truth. The failure is small (an extra stage will fix it), and Good– skirts very close to the operating line, so one expects errors to creep in.

4. Conclusions

In this short paper we have presented and tested an analysis of error propagation in the McCabe-Thiele method applied to multi-stage ATPE. It is hoped the analysis provided in Section 2 will be applied to many other ATPE processes. Equations (7) and (8) might provide useful error bounds, though these remain somewhat elusive. More valuable are Equations (13) and (14) giving the requirements for extra steps. These strongly encourage experiments to refine the phase equilibrium curve around the goal $f(Xa_0)$ and the stagewise loss $f(A)$ (which will often be close to $f(0) = 0$). The comparison with experimental results shows excellent agreement, given that we have chosen one of the most difficult ATPEs imaginable to perform this research on.

Abstract

Methyl ethyl ketone (MEK) is a widely used chemical in the industry. Most of the MEK uses are directly related to industrial application; however, recent studies suggest the use of MEK as a possible fuel for spark-ignition engines. The industrial process to produce MEK is performed through the hydration of butylene and the dehydration of that alcohol. Butylene is produced from oil cuts. However, petroleum is a recognized finite resource and is pointed out as a major cause of environmental issues. An alternative to improve a process is process intensification (PI). In this work, an intensified alternative to produce MEK from 2,3- Butanediol is proposed. 2,3-Butanediol might be produced by a fermentation process based on renewable biomass. The intensified alternatives consist of a reactive distillation column, an extractive distillation column, and three conventional distillation columns. The novel alternatives produce and purify MEK, 1,2-BD, 2MPL, and water, from 2,3-BD using calcium phosphate as catalyst were modelled in Aspen Plus. To evaluate the intensified alternative, it was considered the energy requirements per kilogram of MEK, conversion, selectivity as well as an environmental impact index, the greenhouse gas emissions. The RD column resulted in a conversion of 99.86 % and a selectivity for MEK of 44 %. After evaluation, the direct scheme resulted as the most promising one, with energy requirements of 2790 kcal/kg_{MEK} (11.6 MJ kg_{MEK}). Regarding the environmental impact, the direct scheme reported 7.07 tCO₂/h of greenhouse gas emissions.

Keywords: Methyl-Ethyl Ketone Production, Process Intensification, Biofuels Production, Hybrid Processes, Downstream Process.

1. Introduction

Political and governmental organizations have promoted agreements to mitigate the environmental effects generated using fuels derived from petroleum. An important sector to achieve the agreed objective is transportation, which in fact contributes with 23% of total CO₂ emissions. Even though electricity has been highlighted as a promising alternative for CO₂ reduction, biofuels are designated as responsible for reducing CO₂ emissions. Recently, methyl ethyl ketone (MEK) has been screened as a possible biofuel. MEK, also named 2-butanone, is a common industrial compound. Its use is mainly oriented as a solvent. Currently, MEK production is generated primarily as an oil-derived cut. However, Hoppe et al. (2016) carried out interesting studies that prove the feasibility of using MEK in internal combustion engines. Hoppe et al. (2016) concluded that the use of MEK generates greater heat of combustion, lower emissions

of greenhouse gases and better cold ignition. In a green process framework, MEK can be produced directly by fermentation, however, the process yields are quite low, $0.004 \text{ g}_{\text{MEK}}/\text{g}_{\text{glucose}}$ (Yoneda, Tantillo and Atsumi, 2014). On the other hand, an interesting process with the highest yield potential is using 2,3-Butanediol (2,3-BD) as an intermediary. 2,3-BD can also be produced by fermentation of lignocellulosic material, but unlike MEK fermentation, the yield in the production of 2,3-BD is high and the theoretical limit is quite close, $0.5 \text{ g}_{2,3\text{-BD}}/\text{g}_{\text{glucose}}$ (Syu, 2001). Once 2,3-BD is produced, it can be dehydrated and converted directly to MEK. As mentioned, the final part of the process is dehydration of 2,3-BD. This process has been addressed on multiple occasions. The use of zeolites, clays, calcium phosphate, etc has been reported; and most of the cases with selectivity between 90-95%. However, despite the large number of papers published in this regard, none of these papers addresses production kinetics in detail. In an interesting work reported by Song (2016), a set of detailed equations and reaction kinetics were reported for the dehydration of 2,3-BD to 1,3 Butadiene and Methyl Ethyl Ketone over a catalyst of Calcium Phosphate. In subsequent work, Song et al. (2017) presented an alternative to produce and purify MEK from 2,3-BD. In their proposal, they presented a production scheme based on a reactor followed by a series of separation columns and decanter, making a total of 10 separation units and a reactor (See Figure 1). Most of all separation units are distillation columns.

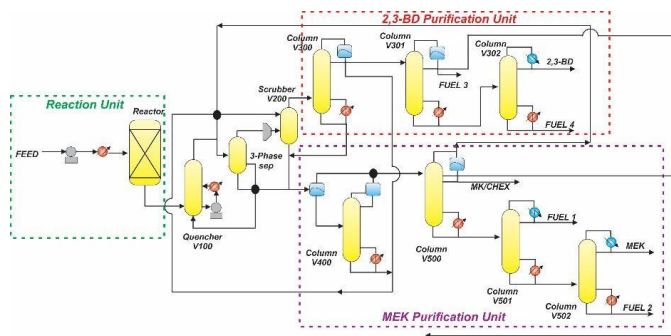

Figure 1. Conventional process to produce MEK from 2,3-BD

An alternative to improve a process is the intensification of the process (PI). PI is distinguished by five characteristics: reduced size of equipment, the increased performance of the process, reduced equipment inventory, diminishment in using utilities and raw materials, and increased efficiency of process equipment (Ponce-Ortega, 2012). Considering the background mentioned, the aim of this work is to propose intensified alternatives based on intensified schemes such as reactive distillation and extractive distillation to produce and purify MEK in order to improve energy requirements and the number of equipment, having as reference the current technology to produce MEK. For comparison purposes between the intensified alternatives, it will be used the energetic requirements per kilogram of MEK, the CO₂ global emissions and an environmental index (the eco-indicator 99). So, the target is to generate new and feasible technology to improve the current MEK production.

2. Intensified Alternative and Kinetics

Song et al. (2017) presented a proposal for MEK production. In the reaction stage, all reaction can be summarized as follow:

Table 1. Chemical reactions and kinetic parameters for MEK production

Reaction	Activation energy	Kinetic constant
1) $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^1} C_4H_8O(3B2OL) + H_2O$ $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^1} C_4H_8O(3B2OL) + H_2O$	2.33 E+05	7.45E-04
2) $C_4H_8O(3B2OL) \xrightarrow{r^2} C_4H_6(1,3 - BD) + H_2O$ $C_4H_8O(3B2OL) \xrightarrow{r^2} C_4H_6(1,3 - BD) + H_2O$	2.82E+05	4.41E-04
3) $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^3} C_4H_8O(MEK) + H_2O$ $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^3} C_4H_8O(MEK) + H_2O$	1.93E+05	6.64E-04
4) $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^4} C_4H_8O(2MPL) + H_2O$ $C_4H_{10}O_2(2,3 - BD) \xrightarrow{r^4} C_4H_8O(2MPL) + H_2O$	1.66E+05	1.27E-04

Being 2,3-BD, 3B₂OL, 1,3-BD, MEK and 2MPL, 2,3-Butanediol, 3-Buten-2-ol, 1,3-Butadiene, Methyl Ethyl Ketone, and 2-Methylpropanal respectively. In the reference case of Figure 1, Song et al. (2017) considered a reasonable number of decanters which result in many waste streams and consequently only 1,3-BD and MEK are partially recovered. The reason for such design is the thermodynamic complexity of the stream to be purified. In the mixture of five components, there are 4 azeotropes: 3 heterogeneous between 1,3-BD and H₂O, MEK-H₂O, and 2MPL-H₂O respectively, and 1 azeotrope homogeneous between 3B₂OL-and H₂O. As shown in Figure 2, the alternative presented in this work is designed considering a reactive distillation column and an extractive distillation column, using glycerol as extractant. The intensified alternative accomplish a recovery constraint of at least 98% wt for all components, and a purity constraint of 99.5% wt for MEK, 99% wt for 3-Buten-2-ol, 99% wt for 2MPL, 99% for 1,3-butadiene and 99.99% for glycerol, the purity of MEK is set in such number since 99.5% wt is the lowest purity for being considered as fuel (Penner et al., 2017). As highlighted by Huang et al. (2005) there is no general and structured methodology for the optimal design of reactive distillation columns. Therefore, in this work, the heuristics proposed by Subawalla and Fair (1999) were considered. This heuristic is summarized in an algorithm that can be used to estimate parameters such as column pressure, location of the reactive zone, theoretical stages of the column, reflux ratio, column diameter, etc. These variables were varied with the objective of increasing the yield and production of MEK. The size of the holdup was not established arbitrarily, to find an appropriate value the guide proposed by Barbosa and Doherty (1988) was followed. The methodology initially consisted of specifying the compositions of the products and the value of the reflux ratio (obtained with the strategy of Subawalla and Fair; in this way, the volume of the plates could be found so that the chemical reaction was carried out. The implementation of the algorithm proposed by Subawalla and Fair

(1999) is simple but does not guarantee the optimal design. Esta no es la única metodología, disponible, algunas ideas basadas en la integración de building block. These building blocks can be associated with different process phenomena (Demirel et al., 2017) Based on the results of the short methods, they were rigorously simulated in compliance with the MESH equations using the Radfrac module of Aspen Plus. In order to warranty the minimal energy consumption, several sensitivity analysis were performed to identify the correct design parameters.

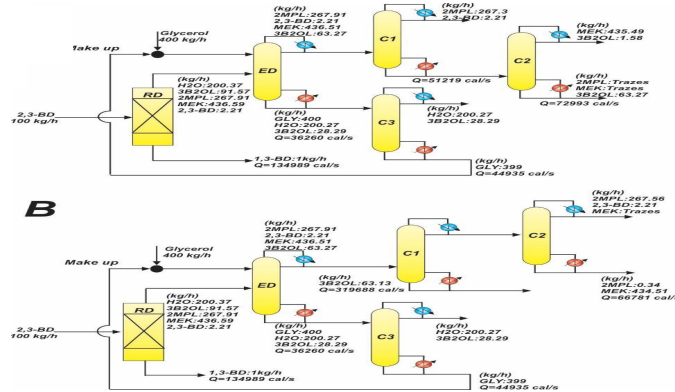

Figure 2. Intensified process to produce MEK from 2,3-BD

3. Performance Evaluation Indices

A major drawback in the operation of distillation columns is the energy requirements. The first performance index is the energy requirements. The main idea is to realize the amount of energy invested in the process which is further represented in units like MJ/Kg_{MEK}. The second performance index is the eco-indicator 99 (EI99). The eco-indicator 99 is calculated as follow (Goedkoop, M., & Spriensma, 2000):

$$EI99 = \sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k} \quad (5)$$

Where β_b represents the chemical b released per unit of reference flow due to direct emissions, $\alpha_{b,k}$ is the damage caused in category k per unit of chemical b released to the environment, ω_d is a weighting factor for damage in category d , and δ_d is the normalization factor for damage of category d . Finally, the third performance index is greenhouse gas emissions, which are indeed related to the energy requirements. The CO₂ emission is calculated as follows (Gadalla et al., 2005):

$$[CO_2]emiss = \left(\frac{Q_{fuel}}{NHV} \right) \left(\frac{C\%}{100} \right) \alpha \quad (6)$$

Where $\alpha = 3.67$ is the ratio of molar masses of CO₂ and C, while NHV (kJ/kg) represents the net heating value of fuel with a carbon content of C%. For CO₂ emission calculation, we assume that the energy involved in both processes, reaction-separation and intensified process comes from burning CH₄ gas. The target is to generate as little as it is possible CO₂ emissions.

3. Results

Once the intensified was designed and through a sensitivity analysis a minimal energy requirement obtained, the conversion and selectivity for the MEK production were

calculated, obtaining a conversion of 99.86% and a selectivity of 44%. The energy consumption of the intensified scheme was 1218797 kcal/h (5073 MJ/h). Thus, considering the total production of MEK, energy consumption would be 2786 kcal/kg_{MEK} (11.6 MJ/kg_{MEK}). Equally weighting all compounds, MEK, 1,3-BD, and 2MPL; The energy consumption for the entire product would be 1218 kcal/kg_{PROD} (5.07 MJ/kg_{PROD}). Moreover, in the hypothetical scenario where all MEK produced as fuel was burned, with 31.45 MJ/kg as energy density, the energy profit would be 8601 MJ. The design parameters for the intensified alternative are shown below.

Table 2. Design parameter for the intensified alternative

	RD	ED	C1	C2	C3
Number of stages	80	50	80	46	30
Reactive Stages	10-80	---	---	---	---
Solvent (kg h ⁻¹)	---	400	---	---	---
Reflux ratio	2.95	0.5	5.488	4.712	0.039
Feed stage	76	5, 46	23	25	14
Operative pressure (kPa)	101.353	101.353	101.353	101.353	101.353
Distillate flowrate (kg h ⁻¹)	999	770	270	437.6	230
Reboiler duty (kcal h ⁻¹)	485962	130535	184390	256145	161765
CO2 Emissions (ton h ⁻¹)			7.07		
Eco-Ind (points y ⁻¹)			1.825E+06		

The energy involved in the upstream process in the scheme reported by Song et al. (Figure 1) (Song, Yoon, and Lee, 2017) is 11140000 kcal/h (46640.96 MJ/h) to produce 4385 kg/h of MEK. Thus, the energy consumption per kilogram of MEK is 2540.5 kcal/kg_{MEK} (10.64 MJ/kg_{MEK}). So far, the scheme presented by Song et al. (2017) seems interesting, however, when it is considered the production of the other purified by-product (3340 kg of 2,3-BD) the picture changes completely. If the production of MEK and 2,3-BD is considered together, the energy requirements change to 1142.1 kcal/kg_{PROD} (6.04 MJ/kg_{PROD}). In other words, when jointly considering the production of MEK and all the by-products generated in the process, the intensified scheme proposed in this article overwhelmingly exceeds that presented by Song et al. (2017) by an average amount of 76kcal/kg_{PROD} (0.97 MJ/kg_{PROD}). It should be noted that, due to the lack of data published by Song et al. (2017) in this analysis, the energy consumption of the reactor is not being considered. However, it can be inferred that the energy consumption of the scheme presented by Song et al. (2017) would increase since as discussed Song et al. (2017), the reactor operates at a temperature of 360 °C. On the contrary, in the energy analysis, the energy consumption of the reactive distillation column was considered. In this way, we can assume a favorable scenario for the intensified scheme in terms of energy consumption. Probably one of the reasons why the intensified process energetically exceeds the conventional scheme presented by Song et al. (2017), is the number of decanters present in the whole process. Note, for example, that in the scheme presented in Figure 1, several streams called “fuel” are presented, which can be inferred as a MEK stream but with a lower purity to consider MEK as fuel for ignition purposes. The above is assumed due to the presence of a stream named specifically MEK. Additionally, note that there is at least one waste stream in which MEK is involved (MEK/CHEX stream) which shows that the recovery

of MEK may not be high. Unfortunately, in the work of Song et al. (2017), a complete mass balance is not presented to verify these assumptions.

4. Conclusions

In this chapter, the intensified technology proposal to produce MEK was analyzed, having 1,2-BD, 2MPL, and water as by-products. 2,3-BD was used as a raw material in a reactive distillation column, having previously studied calcium phosphate as a catalyst. Once the reactive distillation column was implemented, it was possible to obtain conversion of 99.86% and a MEK selectivity of 44%. At the outlet of the reactive distillation column, an effluent with the compounds was obtained and purified using an extractive distillation column and three conventional distillation columns. After evaluation, the intensified alternative resulted with energy requirements of 2790 kcal/kg_{MEK} (11.6 MJ/kg_{MEK}). Regarding environmental impact the greenhouse gas emissions, that scheme A reported 7.07 tonCO₂/h. Even though, there is not a direct and fair comparison; previous work has proposed a conceptual design using a reactor and a set of 10 separation units accomplishing to purify MEK and 1,3-BD. In this work, the intensified scheme can purify all products obtained in the reactive distillation, with less equipment and higher selectivity for MEK. So, we consider most promissory this intensified alternative in comparison with the conventional alternative previously presented.

Abstract

In recent years, process intensification and design under uncertainty have been topics of major concern in the Process Systems Engineering (PSE) domain. Flexible unit design resulted of particular interest when applied to bio-processes since biomass shows an intrinsically unstable nature with respect to the year's seasons and their location. Spirits distillation can be seen as a millenary bioprocess. It is based on well-established techniques that were, at first, mainly empirical and relied on the expertise of the distillers. During the last decades, available technologies allowed a deeper knowledge of the process impact on the final product properties by means of a detailed modelling of the aroma compounds and process units performances. Therefore, the flexibility analysis focused on an Armagnac continuous distillation process whose detailed modelling and simulation were carried out in collaboration with the French National Interprofessional Office of the Armagnac (BNIA) by means of ProSimPlus[®] simulator. The Armagnac continuous distillation, performed this way since the 14th century, is a highly energy integrated system since the feed stream is used as a coolant for the column condenser and wood or gas combustion as the reboiler duty. The heat integration has been included in the analysis and showed to substantially constrain the process flexibility. In particular, the preheater was detected as the most critical unit from and possible design alternatives have been proposed. In conclusion, the presented flexibility analysis allows a more detailed understanding of the Armagnac distillation process and a better analysis of the perturbations impact on the product properties. Moreover, it sets the basis for future studies on advantages and drawbacks of process intensifying alternatives from a flexibility perspective.

Keywords: flexibility, energy integration, distillation, Armagnac, ProSimPlus[®].

1. Introduction

In recent years, bioprocesses have seen a renewed interest in the Process Systems Engineering due to the sustainability goals imposed by the EU. However, in the food and beverage industry, agricultural feedstocks exploitation is at the basis of a relevant number of centuries old processes and related well-established procedures. In this list of bioproducts, spirits can be certainly classified among the eldest ones. Their production processes have been widely studied from the fermentation up to the ageing phase and the resulting methodologies give rise to thousands of different product varieties according to the specific way they are performed. As the majority of processes based on agricultural feedstocks, they are affected by uncertain raw material properties along the year's seasons

and according to their geographic location. The impact of these uncertainties on the thermodynamic feasibility constraints in water-alcoholic mixtures have been indeed discussed in detail by Di Pretoro et al. (2020a).

This research work focuses on an Armagnac distillation case study. Armagnac is one of the main spirits produced in France, in particular in the south-western region. In order to meet the French AOC label requirements, it should be produced by continuous distillation in a specific tray column, during a specific time of the year and with fixed product properties in terms of alcoholic composition (JORF, 2015). All these product standards are thus coherent with previous remarks about bio-processes characteristics. Moreover, the “alambic armagnacais” is a highly process-intensified unit since the feed stream is preheated by the top product and, at the same time, it serves as a condenser coolant as later discussed in more detail. On the other hand, wood, sometimes replaced by gas fuel, is used as heat duty in the reboiler. The constraining impacts of process intensification from a flexibility point of view was introduced in recent studies by Di Pretoro et al. (2021) and the same procedure based on the flexibility indicators is used in this work.

For all these reasons, the presented case study is totally worth a flexibility assessment both to highlight the impact of uncertainties on bioprocesses with very strict product standards and to discuss the effects process intensification from a flexibility perspective.

2. Flexibility assessment

In the PSE domain, the flexibility assessment tool is based on well-established procedures aimed at quantifying the ability of a system to accommodate a set of uncertain parameters. This analysis is carried out by means of the several flexibility indices proposed in literature during the last decades.

These indicators can be mainly classified in two categories, namely deterministic and stochastic, and the former will be explored in this research work. In particular, the class of deterministic indices estimates the maximum magnitude of the disturbance load, of one or more uncertain parameters at the same time, that can be withstood by the system without becoming infeasible regardless of its probability.

The best established and most commonly used deterministic flexibility index is the one proposed by Swaney and Grossmann (1985), hereafter called F_{SG} .

Figure 1 – Swaney & Grossmann deterministic flexibility index

It is defined as the solution of the following flexibility index optimization problem:

$$F_{SG} = \max \delta \quad (1)$$

$$s. t. \max_{\theta \in T(\delta)} \min_z \max_{j \in J} f_j(d, z, \theta) \leq 0 \quad (2)$$

where θ refers to the uncertain variables, d to the design parameters, z to the control variables. Finally, δ is the scaling factor of the hyperrectangle:

$$T(\delta) = \{\theta: \theta^N - \delta\Delta\theta^- < \theta < \theta^N + \delta\Delta\theta^+\} \quad (3)$$

represented in Figure 1.

These indices were then used to perform the flexibility analysis of the Armagnac distillation case study that is presented in detail in the following section.

3. The Armagnac distillation case study

As previously discussed, this research work will focus on the Armagnac spirit. It is produced in the south-western region of France and, by law, the distillation should take place between the end of the grapes harvest and the 31st march of the following year.

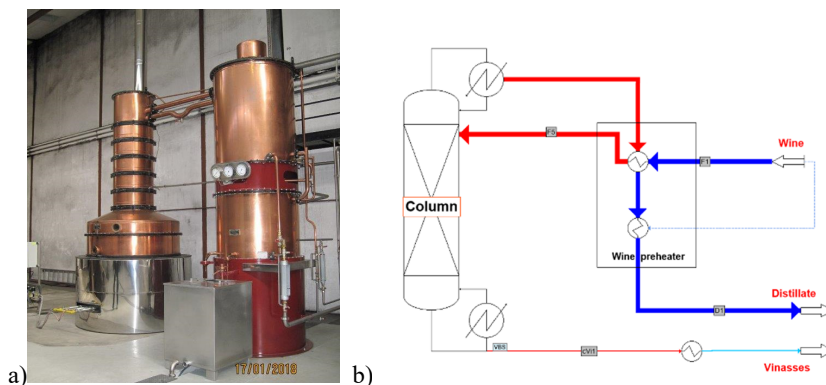

Figure 2 – a) Armagnac distillation layout and b) ProSimPlus[®] process simulation diagram

The “alambic armagnacais”, shown in Figure 2a, is an atmospheric tray distillation column. The wash, that in this case is wine, is produced by fermentation of white grapes and its alcohol (ethanol) by volume concentration (hereafter ABV) at 20°C should range between 7.5% v/v and 12.0% v/v. Before ageing, the distillate ABV is fixed between 52.0% and 72.4 % v/v according to the last regulation (JORF, 2015). The commercial product is obtained by reducing the aged distillates to a minimal ABV of 40% v/v.

A 15 trays (condenser and reboiler included) column was simulated (cf Figure 2b) considering an ideal behaviour for the vapor phase and using the NRTL activity coefficient model to describe the liquid phase non-ideality (Puentes et al., 2018a). Since the purpose of this study is to define the feasibility boundaries of the operation, mainly water and ethanol were accounted for in the distillation unit since volatile aroma do not affect mass and energy balances due to their low concentrations (Sacher et al., 2013). The employed binary interaction parameters are those obtained by Puentes et al. (2018b).

Process parameters	Name	Value	Unit
	Wine inlet temperature	13.1	° C
Process specifications	Alcohol loss (bottom)	1	%
	Distillate temperature	18	°C
	Distillate ABV	≥ 52	%
Deviation	Wine ABV	0.5	%
	Wine flowrate	0.05	m ³ /h

Table 1 – Process parameters and specifications

For this flexibility assessment an innovative approach was used. The wine ABV was selected as the first uncertain variable since it is the parameter that mainly vary according to the available wine. Then, the feed flowrate was included as a second uncertain variable. When operating the particular “alambic armagnacais” column, the feed flowrate is the second manipulated variable together with the reboiler heat duty. Therefore, this flexibility analysis is carried out from a unit design perspective, with an external perturbation and a manipulated variable as uncertain parameters. The column layout is fixed as well as the alcohol losses in the vinasses and the distillate temperature after the wine preheater. The distillate ABV cannot be fixed but the AOC constraints should be respected. The reboiler heat duty and the preheater surface area sizing are calculated for the variable operating conditions, i.e. ABV and wine flowrate. Finally, process parameters and specifications are resumed in Table 1.

4. Results

The “alambic armagnacais” flexibility assessment was then performed according to the well-established procedure proposed by Di Pretoro et al. (2019) for distillation units. In particular, the feed ABV uncertain interval ranged from 7,5 - 12 % according to the actual legislation, while its flowrate uncertain domain varied from 0.6 to 1 m³/h that is the capacity range of the studied alambic unit. The required heat transfer surface area as well as the distillate ABV value trends will be discussed over the entire uncertain domain and coupled with the flexibility index. It is finally worth remarking that the following are intentionally very conservative results since they are obtained for a distillate temperature at the outlet of the preheater equal to 18° C that is the desired value and not the upper boundary (that is about 25 °C).

4.1. Sensitivity analysis

Figure 3a shows the trend of the distillate ABV variable. For the given specifications, it achieves higher value if the feed ethanol content is lower. This phenomenon is due to the fact that, since the alcohol losses are fixed at 1 %, in case of higher ethanol fraction in the feed a more severe vaporization is required and, thus, a higher amount of water is withdrawn with the distillate that results in a more diluted mixture. For the same reason, the ABV value increases along with the feed flowrate due to the less effective preheating and the lower amount of water in the top vapor in absence of a rectifying section.

On the contrary, the required heat transfer surface area (Figure 3b) increases for higher ABV in the feed due to the more severe separation conditions related to the product streams adjustments in order to keep low the ethanol losses in the bottom.

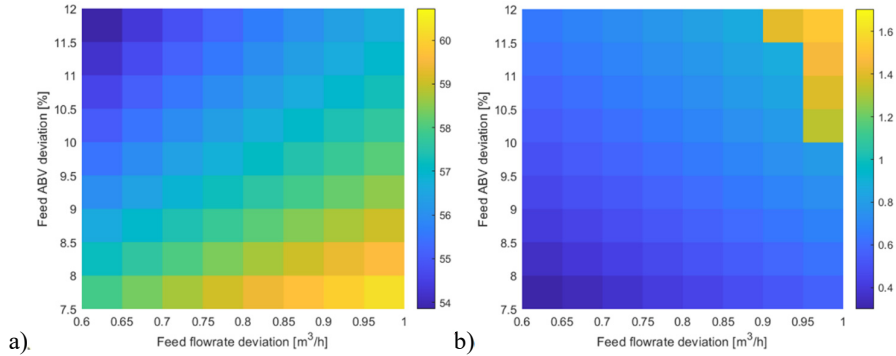

Figure 3 – a) Distillate ABV % and b) preheater heat transfer surface area (log₁₀-scale)

Moreover, considerable inlet flowrates have also an impact on the preheater size due to the higher thermal capacity of the process stream. These two phenomena, i.e. poor ethanol losses allowed combined with a more heat to be exchanged, result in an exponential growth of the preheater heat transfer surface area.

4.2. Flexibility results

Figure 4 – a) Distillate ABV and b) preheater heat transfer surface area vs flexibility

The outcome obtained by coupling the flexibility index with the previous results is shown in Figure 4. The plots should be read as follows: F_{SG} equal to δ corresponds to δ times the $\Delta\theta$ deviation both for the value of the feed ABV (0.5 %) and for its flowrate (0.05 m³/h) and both positive and negative. Thanks to the domain convexity it was possible to simplify the nonlinear optimization solution algorithm by using the vertex analysis.

On the one hand, the maximum ABV that can be obtained increases with the deviation magnitude. All the values over the uncertain interval fall in the required ABV range despite the very constraining specifications selected. On the other hand, the required heat transfer surface slightly increases for a flexibility index between 0 and 6, while an exponential growth can be detected for higher deviation magnitude. Besides the impact of the higher capacity, this trend is the expected consequence of process intensification as already highlighted by Di Pretoro et al. (2021).

Therefore, from the flexibility assessment results, a few important aspects can be deduced. First of all, the ABV plot shows that the operation feasibility is not compromised in the operation range. Then, the flexible design for the preheater not only

allows quantify the unit oversizing but also highlights the process limitations from a flexibility perspective. Since, in the alambic distillation common practice, the feed flowrate is used as manipulated variable to manage the top ABV specification, the flexibility analysis outcome suggests not to approach flowrates higher than 0.9 m³/h. Indeed, poor heat integration would be performed under those operating conditions.

5. Conclusions

The alambic simulation and flexibility analysis were successfully performed over the selected uncertain domain. The obtained results allowed to identify the criticalities of the operation and the most constraining design parameters of the distillation unit that represent the bottleneck from a flexibility point of view.

In particular, the desired distillate temperature can be achieved with a reasonable preheater sizing for moderate deviation magnitude while it becomes more and more difficult to attain if higher deviations are expected. Even for this unit then, the consequences of the process intensification result to be evident and critical for the operation. Therefore, in these cases, suitable design solutions can be applied. One of them could be the addition of a coil fed by water on the utility side in order to enhance the distillate cooling down to the desired temperature. Although already adopted in the common practice, further studies and a detailed flexibility assessment could allow to analyse this additional process integration solution and outline in detail its limitations.

Abstract

To enhance the availability of superstructure optimization as a tool in process design for industries as well as science this work presents a fully *Open sUperstrucTure moDeling and OptimizatiOn fRamework* (OUTDOOR). This framework is written in Python using object-oriented programming in combination with algebraic modeling utilizing the PYOMO modeling language. In addition, an Excel-based data preparation tool, called Excel-Wrapper is presented. It provides an intuitive way to prepare process data and generate superstructures, which are ready-made for solving using open-source as well as commercial optimization solvers.

Keywords: Superstructure Optimization, Python, Open Source

1. Introduction

Superstructure optimization is a powerful tool to perform preliminary process design. Superstructure models map all possible flowsheets to produce a product from a specified set of raw materials. Such models are defined as mixed integer (non)-linear mathematical programming (MI(N)LP) models and can be solved for different objective functions, e.g. minimal production costs using open-source and commercial optimization solvers. Superstructure models have been applied to different areas, from biomass-based economy up to power-to-x processes (Galanopoulos et al., 2019; Kenkel et al., 2020). However, they can be formulated in different ways leading to unnecessary complexity and ambiguity. The common practice is that research groups develop their own models and tools, often using commercial software, e.g. GAMS. Only a few software solutions for generic superstructure optimization have been presented, none of them being fully open source (Mencarelli et al., 2020). In addition, the application of superstructure models in industry is limited by its complicated algebraic formulation and data provision. Generally, straight forward graphical solutions are preferred over complex mathematical models and extensive programming codes.

This work proposes an approach to solve both problems, presenting an *Open sUperstrucTure moDeling and OptimizatiOn fRamework* (OUTDOOR). This framework is setup in Python using a combination of modular object-oriented programming and

algebraic model formulation in PYOMO. Its focus is to construct deterministic MILP models to solve superstructure design problems.

2. Programming and modeling fundamentals

The presented framework is a tool for intuitive construction of superstructure models. It utilizes different concepts such as superstructure optimization modeling, object-oriented programming as well as the open-source optimization modeling language (PYOMO). The combined effort leading to OUTDOOR is briefly discussed in the following sections.

2.1. Superstructure optimization and algebraic modeling

Superstructure optimization is a methodology which is used for process design. It is based on mathematical models derived from mass- and energy balances in combination with cost calculation of capital expenditures and operational costs to optimize process flow sheets for different objective functions (Quaglia et al., 2015)]. These models are formulated as depicted in Eq. (1). Here \mathbf{c} and \mathbf{b} are vectors of known constant parameters, while \mathbf{x} is a vector or variables (continuous as well as integer), and A is matrix of known parameters.

$$\begin{aligned} & \text{maximize } \mathbf{c}^T \mathbf{x} \\ & \text{s. t. } A\mathbf{x} = \mathbf{b} \\ & \mathbf{x} \geq 0 \end{aligned} \tag{1}$$

Recurring equations are often formulated using indexed variables and parameters. For example, the electricity demand E_u^{EL} of a unit operation u is dependent of the total inlet flow F_u^{IN} and a specific factor p_u (kWh/t_{input}). If this holds for each unit operation u in a set of U , the equations can be written as shown in Eq. (2).

$$E_u^{EL} = p_u \cdot F_u^{IN} \quad \text{with } u \in U \tag{2}$$

The fixed parameters of p_u are then supplied to the model as an indexed list of a set U inside of a data file.

2.2. Object-oriented programming

Object-oriented programming, in contrast to procedural programming, uses classes and objects as containers to allocate attributes and methods. These objects can be used to store data related to unit operations (such as the presented specific electricity demand p_u) directly in the process unit object. This way process-data can be built up around the process classes and objects, presenting a more intuitive way to handle and store data compared to indexed lists.

2.3. PYOMO Modeling language

PYOMO is a Python-based, open-source optimization language with a diverse set of capabilities to solve algebraic optimization models, while providing access to optimization solvers such as CPLEX or IPOPT. (Hart et al., 2017) The user benefits from PYOMO implemented direct access to solver configurations and solver output regarding calculation procedure, infeasibilities or other occurrences.

3. OUTDOOR

OUTDOOR combines the concepts that were discussed in the earlier sections. It provides an intuitive workflow for superstructure model creation and solving. Figure 1 depicts the main concepts and workflow of the application of OUTDOOR, and will be discussed in the following sections.

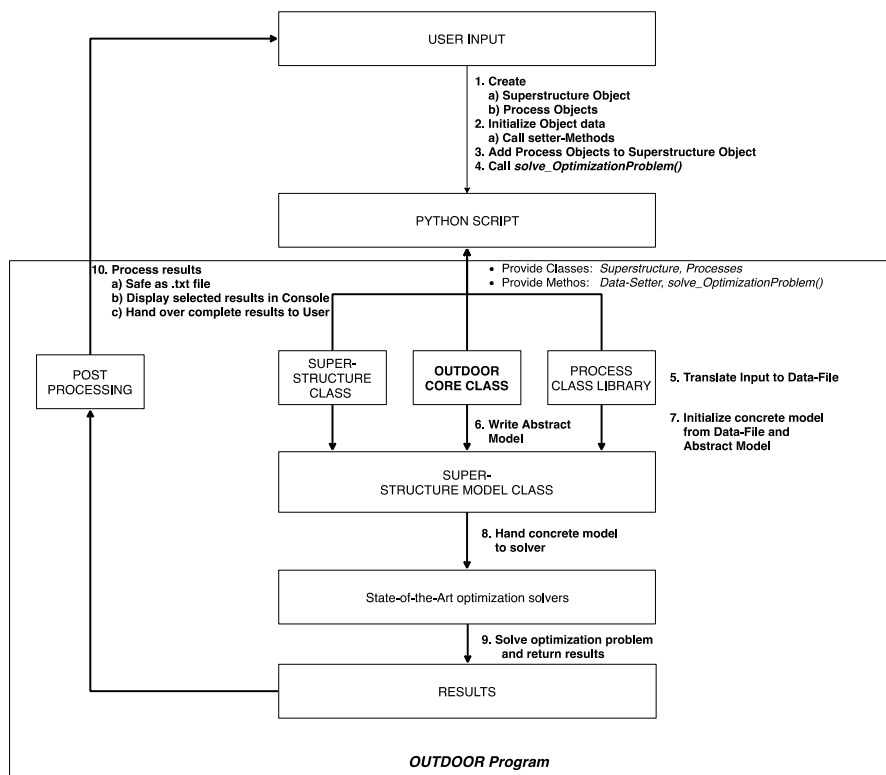

Figure 1: Visualization of the OUTDOOR workflow.

3.1. User input

As a first step user input is required. This input of data can be divided into two categories. The first category is the superordinate system data. An object of the provided *Superstructure-Class* is created and initialized using Python scripting. This object demands important attributes such as the costs for electricity, the occurring chemical compounds or reactions or the desired product and objective. The second category is the input of considered unit operations. Different objects of the *Process-Classes* such as stoichiometric reactors or stream splitters are created and initialized with their respective data such as the required electricity demand or stoichiometric coefficients. The initialization of data of the different objects (step 2) is performed by calling predefined setter-methods, which are provided by the Classes.

Next, (step 3) the process objects are added to the superstructure creating a complete superstructure system with all unit operations and external parameters such as electricity

prices. An input of initial guesses is not required at this state, however it could be necessary in the future to investigate more complex problems. When all inputs are provided, the user calls the `solve_OptimizationProblem()` method from the OUTDOOR module (step 4) to start the OUTDOOR program and solve the optimization problem.

3.2. OUTDOOR program

OUTDOOR processes the inputs provided by the user in a series of steps. First (step 5) the data in the process and superstructure objects is translated to a Python dictionary. Generally, two different types can be generated. The first one comprises easy convertible parameters and the second one comprises complex convertible parameters.

The specific electricity demand p_u (kWh/ t_{input}) is an illustration of a parameter of the first type. It stores only a numeric value which has to be converted into the right format while being assigned to the right unit operation.

Other relationships however, demand more complex translation methods. One example is the allocation of the referred reference flow of the electricity demand calculation. This flow can be the total inlet flow as depicted in Eq. (2). It could also be the outlet flow, or even just specific components of one of these flows. Hence, a method which translates correlations like “outlet flow” or “inlet flow” into algebraic understandable parameters is required. The procedure of these methods will be explained exemplary for this electricity demand reference flow in the following. The program needs two different information. The delivery of these information is still conducted during the input-phase of the user. One of the already mentioned setter-methods of the process class asks if “FIN” or “FOUT” has to be considered. Another setter-method demands the input of a Python list of components or the string “all components”.

During the calculation, the program calls a translation method which transforms the input of the user into process specific $\kappa_{EL,u,i}^1$ and $\kappa_{EL,u}^2$ parameters. The first one is a binary parameter being 1 if the component i is to be considered for electricity in unit operation u . The second parameter determines if the reference flow is the inlet (Value = 1) or the outlet flow (Value = 0). These parameters are integrated into the algebraic model using $\kappa_{EL,u,i}^1$ as equation parameter and $\kappa_{EL,u}^2$ as a conditional factor in construction of the constraint (cf. Figure 2).

```
def ElectricityBalance_1_rule(self,u):
    if self.kappa_2_ut[u,'Electricity'] == 1:
        return self.REF_FLOW_EL[u] == sum(self.FLOW_IN[u,i] \
            * self.kappa_1_ut[u,'Electricity',i] for i in self.I)
    elif self.kappa_2_ut[u,'Electricity'] == 0:
        return self.REF_FLOW_EL[u] == sum(self.FLOW_OUT[u,i] \
            * self.kappa_1_ut[u,'Electricity',i] for i in self.I)
    else:
        return self.REF_FLOW_EL[u] == 0
```

Figure 2: Python code example for calculation of references flow in electricity consumption

Subsequent to the translation of input into the right format, the program creates the generic equations of the model (step 6). This model is written as an object of the PYOMO *AbstractModel Class*, which means it contains empty parameters which can be filled at a later stage using a data file.

Step 7 of the program uses the created Python dictionary (data file) and the abstract model to create a concrete model, depicting the algebraic formulation of the defined superstructure. This model is then handed over to the selected optimization solver using the capabilities of the PYOMO modeling language (Step 8) and optimized for the defined objective function (Step 9)

3.3. User output

After the solver found a solution to the optimization problem, the complete raw results are returned to the user. It is possible to check the solutions for the variables and constraints utilizing the Python console. However, to simplify the results access, the OUTDOOR program also processes them (step 10). This step includes the presentation of selected results in the Python console as well as the saving of the main results as a .txt file into a chosen folder. The main results include the net production costs and CO₂ emissions, the cost breakdown and the energy consumption details including heat integration details.

3.4. Extensions and development

OUTDOOR depends on the user input data in form of a Python script using the definition of objects as well as calling setter-methods and the *solve_OptimizationProblem()* - method. This is however, not really user friendly for non-programmers. Therefore, two extensions are under development. The first module is an *Excel-Wrapper*. This tool enables user to insert data via a predefined Microsoft Excel template, Afterwards the user has to start the *Excel-Wrapper* tool, which itself creates the objects, calls the solve-function and saves the results. The second module presents a graphical user interface in which processes can be created by drag and drop, and data can be provided by popup tables. Other features of interest which are under development include more detailed and customized error handling and output, as well as capabilities for multi-criteria decision making and robust decision making taking stochastic programming into account.

4. An example: Power-to-methanol process

The goal of this case study is to investigate renewable methanol production with three different CO₂ sources as well as five hydrogen supply technologies and two offgas utilization methods. Two objective functions were considered in the superstructure optimization: i) Minimal net production costs and ii) Minimal net production CO₂ emissions. Detailed outcomes of the study are presented in Kenkel et al. (2020).

To construct and solve the superstructure model, OUTDOOR is applied in combination with the Excel-Wrapper. All relevant data was entered into the predefined Excel sheet provided by OUTDOOR. Data on considered unit operations was implemented in single Excel sheets. Figure 3 depicts an excerpt of this user input in form of the specific energy demand, reference flow and component for one unit operation. Afterwards, OUTDOOR automatically translated the input into a readable data file, formulated the general model including mass- and energy balances as well as cost and emission functions. The generated model is automatically handed to the Gurobi solver and optimization results in terms of chosen technologies, net present costs and emissions, as well as costs and energy break-down are presented in the Python console as well as in a .txt. file. The cpu time of the data collection using the excel-wrapper is 0.016 seconds. The construction of the superstructure objects takes 2.3 seconds, resulting in a MILP with 29411 variables (5746 binary) and 43581 constraints. The cpu time for solving this problem and returning the results using Gurobi is 11.1 seconds.

Energy Related Factors

Reference Flow	FOUT	FOUT	
Considered Component	H2	H2	
Considered Component			
Considered Component			
Considered Component			

Figure 3: Excerpt of Excel-based parameter input for OUTDOOR

5. Conclusions

The main programming concepts and workflow of the *Open sUperstrucTure moDeLing and OptimizatiOn fRamework* (OUTDOOR) were presented in this work. This framework enables the initialization of data as unit operation related attributes using object-oriented programming, while still writing the actual model as algebraic model utilizing the PYOMO optimization language. To connect both of these concepts, different methods in terms of so-called translation functions were developed. To further strengthen the applicability of the tool an Excel-Wrapper was developed which uses data stored in predefined Excel-Templates as well as the Class-specific methods to create the superstructure, solve it and display and save the results. First results were derived using a beta-version of the framework. These results were presented in Kenkel et al. (2020).

Abstract

The open-ended complexity of abiotic conditions in bioreactors means that it is generally infeasible to model its dynamic behaviour comprehensively. Learning optimization-oriented probabilistic models encoding a parsimonious representation is far more efficient for bioprocess development and optimization. In this work, active inference is integrated with reinforcement learning to demonstrate that useful probabilistic models for bioreactor optimization can be learned by balancing optimization-oriented and information-seeking objectives. The baker's yeast bioprocess is used as a case study. For online Bayesian update of model parameter distributions, simulation results demonstrate that highly informative data can be sampled by minimizing the variational free energy of the expected future. The resulting probabilistic model is thus biased towards bioreactor optimization.

Keywords: active inference, optimization, probabilistic models, reinforcement learning.

1. Introduction

Even though is not yet accepted nor recognized, abstract (e. g., macroscopic or cybernetic) models used for bioreactor optimization are too shallow to account for the complexity of switching in metabolic pathways when responding to changes in the abiotic conditions (Richelle et al., 2014). A challenge in modeling for optimization is how such models can be learned from designed experiments given (i) the rich complexity of profiling operating conditions, and (ii) the circular dependence of model learning and information content of sampled data, which may lead to suboptimal performance. As most bioreactor models are not a veridical representation over a wide region of operating conditions, it is infeasible to achieve parametric precision comprehensively, let alone design optimally informative experiments for this objective (Martínez et al., 2013; Luna and Martínez, 2017). Probabilistic models are more efficient to deal with the process-model structure mismatch and hidden states present (Daunizeau et al., 2014). In this work, we illustrate how ideas from active inference (Tschantz et al., 2020) can be integrated with reinforcement learning (Sutton and Barto, 2018) to unify optimization-oriented and information-seeking

objectives in modeling for optimization using the variational free energy of the expected future (Parr and Friston, 2019) over the shrinking horizon of a dynamic experiment.

2. Probabilistic modeling and active inference

A probabilistic (causal) model of a bioreactor is defined by a joint probability distribution over the following set of stochastic variables:

- x ; y : the $n \times n_t$ hidden states time-series; the $p \times n_t$ observations (sampled data),
- u : the $n_u \times n_t$ manipulated (controlled) inputs time-series,
- θ ; φ : the $n_\theta \times 1$ evolution parameters; the $n_\varphi \times 1$ observation parameters,
- α : the state noise precision (structural errors),
- σ : the measurement noise precision (analytical and sensor calibration errors).

From sample to sample in a dynamic experiment, these variables follow the equations:

$$\begin{aligned} x_t &= f(x_{t-1}, \theta, u_{t-1}) + \eta_t; \quad \eta_t = N(0, \alpha^{-1}\mathbf{I}), & \text{(hidden) state evolution} \\ y_t &= g(x_t, \varphi) + \varepsilon_t; \quad \varepsilon_t = N(0, \sigma^{-1}\mathbf{I}), & \text{observation (samples)} \end{aligned} \quad (1)$$

where f (resp. g) is the first-principles model (observation model), and η_t (observation ε_t) is the state (resp. measurement) modeling errors (noise). A probabilistic model m of a bioreactor is completed by specifying the (initial) Gaussian prior distributions for its parameters θ, φ . Also, Gamma distribution priors are defined for the precision hyperparameters α, σ . Given these priors, the left part of Eq. (1) induces a (so-called semi-Markovian process) prior density on the trajectory of hidden states x . Similarly, the right part of Eq. (1) yields a likelihood function which measures how plausible an observation y is when the bioreactor content is sampled at time t . Uncertainties from noisy observations and model imperfections are thus taken explicitly into account.

In the variational Bayesian framework, model identification (or inversion) entails the estimation of the marginal likelihood or evidence of a bioreactor model, that is a probabilistic description of the main (causal) metabolic mechanisms by which sampled data are generated. Probabilistic Bayesian treatment of an experiment data makes full usage of prior assumptions regarding the statistical distributions for initial conditions, evolution/observation parameters and state/measurement noise (Daunizeau et al., 2014). Inverting a probabilistic model m requires approximating the conditional density $p(\xi|y, m)$ of the unknown hidden states and parameters $\xi = \{x, x_0, \theta, \varphi, \alpha, \sigma\}$ given a data set of sampled measurements y and computing the model evidence $p(y|m)$. Nonlinearities in the probabilistic model prevent exact analytical solutions to the model inversion problem which can approximately be solved using Bayesian variational approaches such as active inference. Active inference is a normative theory that unifies observation, external stimulus and model learning under a single imperative—the minimization of the variational free energy (Parr and Friston, 2019). More specifically, probabilistic model learning is posed as the maximization of a free-energy lower bound $F(q)$ for the model evidence with respect to an approximate density $q(\xi)$:

$$F(q) = \langle \ln p(\xi|m) + p(\xi|y, m) - p(\xi) \rangle_q = \ln p(y|m) - \mathcal{D}_{KL}(p(\xi); p(\xi|y, m)) \quad (2)$$

where \mathcal{D}_{KL} is the Kullback-Leibler divergence between two distributions and the expectation $\langle \circ \rangle_q$ is taken under the approximate posterior distribution q . As can be deduced from Eq. (2), maximizing the functional $F(q)$ with respect to q drives the Kullback-Leibler divergence between $p(\xi)$ and the exact posterior $p(\xi|y, m)$ to zero. The reader is referred to the work of Daunizeau et al. (2014) for methodological details and the therein described VBA Toolbox for variational Bayesian analysis.

Active inference proposes that the modeler’s goal or intent are encoded in the probabilistic model as a prior preference for favourable observations (e. g., higher biomass productivity or protein expression). Thus, active inference demands that parameter distributions in the probabilistic model are based on data sampled from favourable operating conditions. This can be achieved by means of online experimental redesign aiming at minimizing the free energy of the expected future (Parr and Friston, 2019), which corresponds to the trajectory of hidden states that is expected to occur from applying the optimal sequence of decisions (sampling times and manipulated inputs) that maximise the model evidence in the desired region of operating conditions.

Let $z_{t:T}$ denote a sequence of variables through time, $z_{t:T} = \{z_t, \dots, z_T\}$, and let define a policy as a sequence of actions $\pi = \{u_t, \dots, u_{T-1}\}$. In “modeling for optimization,” the specific aim is to minimize the free energy of the expected future \tilde{F}_π , which is defined as:

$$\tilde{F}_\pi = \mathcal{D}_{KL}(q(y_{t:T}, x_{t:T}, \Phi|\pi) \| p^*(y_{t:T}, x_{t:T}, \Phi)); \Phi = (\theta, \varphi, \alpha, \sigma) \quad (3)$$

where $q(y_{t:T}, x_{t:T}, \Phi|\pi)$ models the probability distribution for future trajectories in a dynamic experiment under a given policy π , whereas $p^*(y_{t:T}, x_{t:T}, \Phi)$ defines the joint probability distribution for the optimal trajectory of the hidden states, model parameters and preferred observations. Thus, when \tilde{F}_π is driven to zero, the policy π becomes the (probabilistic) optimal policy. Notice that by minimizing \tilde{F}_π , the surprise $-\ln p(y_{t:T}|m)$ is also minimized, which implies that the Bayesian model evidence is also maximized.

3. Adaptive optimization-oriented experimental design

In this section, we describe an efficient implementation of the proposed objective function for online experimental redesign in the context of reinforcement learning (Sutton and Barto, 2018). To select actions for purposely biasing the model, we iteratively optimise a policy π at each time step t using different samples from the distributions of model parameters. A pseudocode for the proposed algorithm for adaptive experimental design is shown in Fig. 1. The internal loop has a forward pass where the density $q(y_{t:T}, x_{t:T}, \Phi|\pi)$ is increasingly converted into a posterior density upon simulated data using a stagewise greedy redesign procedure based on Thompson sampling (Russo et al., 2018) of the posterior distribution $q(\Phi)$ for model parameters. At each stage, an action is chosen by solving an optimization problem for the expected look-ahead reward based on the predicted impact on the biased model evidence $r_t(\hat{y}_{t+1}) = \ln p(r(\hat{y}_{t+1})|\Phi, u_t)$ of simulated data \hat{y}_{t+1} for alternative redesign decisions in a bounded compact set Ω :

$$u_t^* = \operatorname{argmax}_{u \in \Omega} r_t(\hat{y}_{t+1}) \quad (4)$$

where r is a reward (or desirability) function for observations and their underlying hidden states. The predicted observation \hat{y}_{t+1} and the action u_t^* are then used to generate the posterior distribution for model parameters $\hat{q}(\Phi_k)$ to be used at $t+1$. Thompson sampling is again applied and using Eq. (4) the action u_{t+1}^* is calculated and the corresponding simulated observation \hat{y}_{t+2} is computed. This forward pass is finished when u_{T-1}^k is

computed and the k th policy $\pi_k = \{u_t^k, \dots, u_{T-1}^k\}$ is completely defined. For each iteration of the outer loop, a different policy π_k is computed. The generated sequences are then ranked based on their corresponding cumulative rewards \mathcal{R}_k over the planning horizon $[t, \dots, T]$. From the top ranked policy π_t^* , only the first action u_t^* is used for redesigning the dynamic experiment in the bioreactor and, at the next sampling time $t+1$ the observation y_{t+1} is obtained. Using experimental data (u_t^*, y_{t+1}) , the joint posterior distribution $q(\Phi)$ for the parameters of the probabilistic model is updated using variational Bayesian inference (based on the Laplace approximation) and the master (external) loop begins re-estimating the optimal policy π_{t+1}^* from $t+1$ until the end of the experiment at time T .

4. Case study: Baker's yeast

The macroscopic model proposed by Richelle et al. (2014) for fed-batch baker's yeast production process in which the nitrogen and glucose consumptions are coordinated is used to test the adaptive experimental procedure in Fig. 1. The model includes a reaction

in which the nitrogen and α -ketoglutarate are consumed to produce biomass. Also, the inhibition effect on glucose consumption by the accumulation of α -ketoglutarate is accounted for. The model has 15 parameters that define the reaction rates in biomass and ethanol production and consumption of glucose, nitrogen, and α -ketoglutarate. The concentration of α -ketoglutarate is a hidden state which is inferred using the model. The inputs which are redesigned in each experiment are the feeding rate profiles for glucose and nitrogen. The duration of each modelling experiment is fixed to 20 hours, bioreactor initial conditions are known, and its content is sampled every hour to measure the concentration of biomass, ethanol, glucose, and nitrogen. Sample processing time is assumed equal to 30 min, leaving a maximum of 30 min to compute the redesign decision to be applied at the next time step. The parameter K in the algorithm (Fig. 1) is set to 10.

The aim is to purposefully bias model identification towards operating conditions that maximize the total amount of biomass that can be obtained at the end of the culture. Thus, the reward function r_k is defined to achieve a steady increase in the biomass concentration for consecutive samples. Results obtained are summarized in Fig. 2 and Fig. 3. Notice that due to initial uncertainty (prior distributions), for the first experiment exploration is significantly high. Also note that final biomass concentrations for modeling run #1 and #2 in Table 1 are quite high despite they are not “one-shot” optimized feeding profiles using the probabilistic model with the updated parameter distributions. After two modeling experiments, as shown in Table 2, the parameter distributions have been updated to make the probabilistic model biased towards the most profitable region of operating conditions (Richelle, et al., 2014) where biomass production is higher.

5. Concluding remarks

A novel probabilistic method for modeling the dynamic behaviour of bioreactors in the most profitable region of operating conditions is proposed. Based on simulation data, a dynamic experiment is redesigned online through active inference. Reinforcement learning is used to maximize the Bayesian model evidence, that is, minimize surprise.

Abstract

In this work, the numerical simulation of bubbles of kerosene in a column with water is performed by using the Smoothed Particles Hydrodynamics (SPH) method. The SPH method allows a good representation and monitoring of the interface between two or more miscible or immiscible fluids, advantage that can be used to study the hydrodynamic of bubbles in an immiscible environment). In this study, the contribution of the surface tension and wetting model in a biphasic flow of bubbles of kerosene along a column filled with water is analysed. The simulations are performed using a modify version of the free access code DualSPHyics. The validation is performed by coding the case of an ascending bubble and comparing the numerical results with the data reported in the literature. Several 2D simulations of kerosene injection in a column with water for three different flow rates, contact angles and injector diameters are performed, bearing a total of 27 cases of study. The center of mass and rise velocity in the validation case have good agreement with the data reported the literature. In the cases of injection, it has been determined that the length of injection is the principal parameter affecting the size of the bubbles. In conclusion, the SPH method can properly and naturally represent the creation of the bubbles due to its purely Lagrangian description. The surface tension model allows a stable surface drop during the rise of the bubble; moreover, with this model it is possible to study the rise of drops for different regimes.

Keywords: Multiphase flow, SPH, CFD, Rising Bubble, Injection of Bubble.

1. Introduction

The problems that exist in the injection of bubbles for processes of absorption, distillation and design of reactors make their study complex, due mainly to the wide variety of configurations related to the spatial distribution of both phases in the column. Many authors in the literature had studied the rise of drops and bubbles. Hysing et al. (2008) propose reference configurations for quantitative validation and comparison of incompressible interfacial flow codes, which model two-dimensional bubbles that rise in columns of liquid. The reference quantities: circularity, centre of mass and mean elevation velocity are defined and measured to control convergence towards a reference solution. Zhang et al. (2015) analyse several cases of individual bubbles rising through viscous

fluids, and the SPH results are validated by both experimental data and other numerical results in the literature. Furthermore, bubble coalescence phenomena are simulated in both vertical and horizontal directions and the results agree well with the experimental data. The bottom pressure in the equation of state was found to be essential to keep the multiphase interface smooth and stable when the Bond number is relatively small. In the study by Vahabi & Kamkari (2019) the increase and deformation of a single bubble in a viscoelastic fluid that obeys the Giesekus model is numerically simulated by a modified version of weakly compressible smoothed particle hydrodynamics (WC-SPH). In this work, the numerical simulation of the injection of a kerosene bubble in a water column is presented using the standard method of Smoothed Particles Hydrodynamics (SPH) which has increased its application for studies of computational dynamics of fluids. The numerical model used to simulate interfacial tension is based on a pairwise force of interaction between particles reported by Tartakovsky and Panchenko (2016). The simulations were performance using a modify version of the free code DualSPHysics v3.2 (Crespo et al., 2015). In the section 2 is presented the complete SPH numerical model used in the simulations. In the section 3 is presented a validation test of the rising bubble to prove the accuracy and convergence of the numerical results. In the section 4 are reported several simulations where different values of the inlet velocity, the injection diameter and the contact angle are evaluated as the injection conditions. Finally in the section 5 is reported the conclusions.

2. The SPH Numerical Model

For viscous incompressible flows, the governing equations are given by the Navier–Stokes equation expressed in SPH form as

$$\frac{d\mathbf{v}_a}{dt} = - \sum_b m_b \left(\frac{p_a + p_b}{\rho_a \rho_b} + \Gamma \right) \nabla_a W_{ab} + \mathbf{g} \quad (1)$$

where ρ is the density, p the pressure, \mathbf{v} the velocity field, W is the kernel function, \mathbf{g} is the gravity acceleration and Γ is the viscosity dissipative term. In a standard SPH formulation, where the pressure is given as a function of the density, local variations of the pressure gradient may induce local density fluctuations in the flow. Therefore, the flow is modelled by an artificial fluid that is approximately incompressible. The mass of a fluid element remains constant and only its associated density fluctuates. Such density fluctuations are calculated by solving the continuity equation expressed in the SPH in Eq. (2). The dynamical pressure p_d , which for simplicity we shall denote by p , is calculated using the relation expressed in Eq. (3) (Becker and Teschner, 2007).

$$\frac{d\rho_a}{dt} = \sum_{b=1}^N m_b (\mathbf{v}_a - \mathbf{v}_b) \cdot \nabla_a W_{ab}, \quad (2)$$

$$p = p_0 \left[\left(\frac{\rho}{\rho_0} \right)^\gamma - 1 \right] \quad (3)$$

where $\gamma=7$, $p_0 = c_0^2 \rho_0 / \gamma$, ρ_0 is a reference density, and c_0 is the sound speed at the reference density. This equation enforces very low density fluctuations since the speed of sound can be artificially slowed with accurate results in fluid propagation. The viscous term in equation (1) is modelled using the artificial viscosity model proposed by Monaghan (1992) due to the simplicity and numerical stability. Finally, the surface tension is modelled according to Tartakovsky and Panchenko (2016) where a Pairwise-Force is inserted in the Eq. (1)

$$\frac{d\mathbf{v}_a}{dt} = - \sum_b m_b \left(\frac{p_a + p_b}{\rho_a \rho_b} + \Gamma \right) \nabla_a W_{ab} + \mathbf{g} + \frac{\mathbf{F}_a}{m_a} \quad (4)$$

where \mathbf{F}_a is calculated from the interaction particles using the Eq. (6) .

In Eqs. (4) the pressure gradient is written in SPH form using the symmetric representation proposed by Colagrossi and Landrini (2003), which ensures numerical stability at the interface between two media with large density differences, while the surface tension term F_a is calculated according to the sum of the F_{ab} formulations given by Tartakovsky and Panchenko (2016) in Eq. (6).

$$\Gamma = \begin{cases} \frac{-\alpha \bar{c}_{ab} \mu_{ab}}{\rho_{ab}} & \mathbf{v}_{ab} \cdot \mathbf{r}_{ab} < 0 \\ 0 & \mathbf{v}_{ab} \cdot \mathbf{r}_{ab} \geq 0 \end{cases}, \quad (5)$$

where $\mu_{ab} = h \mathbf{v}_{ab} \cdot \mathbf{r}_{ab} / (\mathbf{r}_{ab}^2 + \eta^2)$, $\bar{c}_{ab} = 0.5(c_a + c_b)$, where c_a y c_b are the speed of sound for particle a and b respectively, $\eta^2 = 0.01h^2$ and α is a free parameter that can be adjusted according to the simulation case.

$$F_{ab} = \begin{cases} S_{ab} \cos\left(\frac{1.5\pi}{3h} |r_b - r_a|\right) \frac{r_b - r_a}{|r_b - r_a|}, & |r_b - r_a| \leq h \\ 0, & |r_b - r_a| > h \end{cases}, \quad (6)$$

where the S_{ab} parameter can be calculated from the surface tension fluid, the smoothing length the kernel function and the contact angle between the wetting fluid and the bound as is reported by Tartakovsky and Panchenko (2016).

No-slip boundary conditions are implemented at the walls of the vessel using the method of dynamic boundary particles developed by Crespo et al. (2007). In this method, a linear distribution of uniformly-spaced particles is placed at the walls of the enclosure, with separations of $\approx h/1.42$. This external particles are used to cope with the problem of kernel deficiency outside the computational domain. The wall particles are updated using the same loop as the inner fluid particles and so they are forced to satisfy Eqs. (9) and (10). However, they are not allowed to move according to Eqs. (14) and (15) so that their initial positions and velocities ($\mathbf{v}_w = \mathbf{0}$) remain unchanged in time. In this way, the presence of the wall is modelled by means of a repulsive force, which is derived from the source term of the momentum Eq. (1) and includes the effects of compressional, viscous, and gravitational forces.

3. Simulation of ascending bubble.

For the validation case the numerical approach and convergence of the numerical SPH model was verify. One bubble of air in a column filled with water was set according to the parameters reported by Hysing et al. (2009). The initial condition of the simulation is shown in the Figure 1 where the radio of the bubble is 2.5 centimetres, the simulation was performance in 2D considering the bubble as a circular shape. The ratio between the density and viscosity of the disperse phase (ρ_1) and the continuous phase (ρ_2) is $\rho_1/\rho_2=0.1$. The value of gravity acceleration is 1 m/s^2 , the surface tension is 24.5 and the Re and Eo dimensionless numbers are 35 and 10 respectively. The evolution of the center of mass of the bubble was compared with the numerical data reported by Hysing et al. (2009). Moreover, four simulations with different number of particles (1250, 5000, 20000 and 40000) were performance to evaluate the convergence of the numerical results. In the Figure 2 is shown the numerical convergence and error ($\varepsilon=RMSE$) of the SPH data with the numerical results reported by (Hysing et al., 2009).

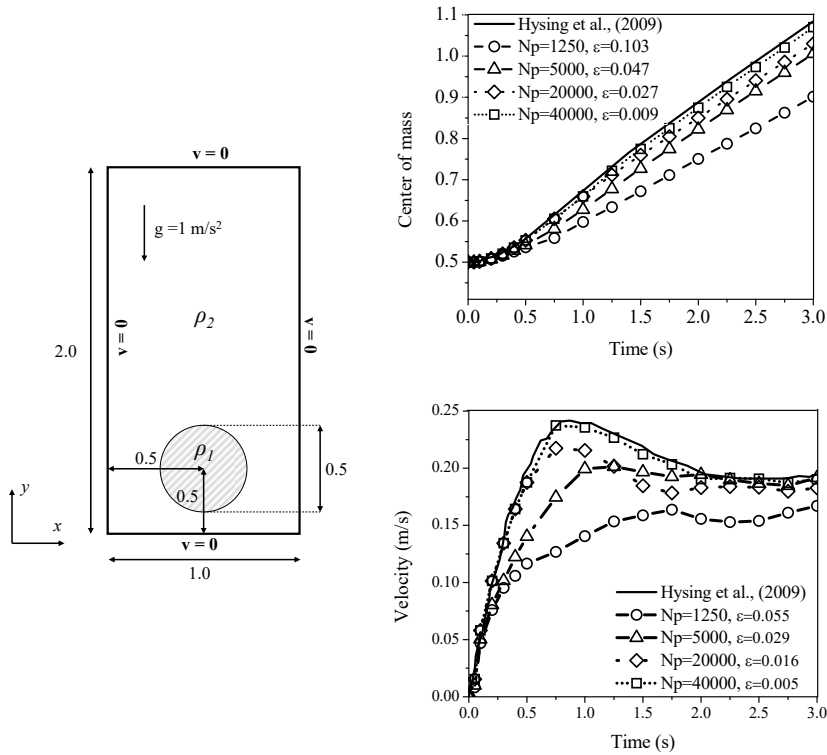

Figure 1. Left frame: Initial condition and dimensions of the simulation of an air bubble in water used in the validation case. Right frame top: Center of mass. Right frame bottom: Rise velocity.

4. Influence of Injection Conditions.

A 2D simulation of a kerosene flow with different injector diameters was carried out. Bubbles do not, in truth, have the capacity to exist in two dimensions. However, it is possible to create an environment in which they behave as though they existed only in two dimensions for example in a "sandwiching" the foam between two sheets of glass. So long as the separation of the sheets of glass is much smaller than the cell size of the bubbles, the foam can be treated in two dimensions. In two dimensions, the foams still follow the Young-Laplace equation for thin films, but the cell walls are only circular arcs instead of a three dimensional curve. It was chosen to use three different flows ($q = 1, 2, 3 \text{ cm}^3/\text{min}$), three injection length ($L=1, 1.5, 2 \text{ mm}$) and three contact angles ($\theta = 90^\circ, 50^\circ, 130^\circ$) to carry out the analysis of injection conditions in the creation of bubbles. In this way, they were made 27 study cases. The fluid and SPH parameters used for the simulations are shown in Table 1 and the geometry is shown in Figure 2. In the left frame of the Figure 3 is shown the evolution of the bubble formed by injection of Kerosene in the column filled with water. The variation of the area of the bubbles formed due to different injections conditions is reported in the right frame of the Figure 4. The numerical results show that the length of injections is the principal parameter that modify the size

of bubbles, moreover, when the contact angle increase the size of bubble decrease but to a lesser extent.

Table 1. Initial parameters for the SPH simulations in the injection study case.

Parameter	Amount	Parameter	Amount
Water density	1000 kg/m ³	Total simulation time	4 s
Kerosene density	890 kg/m ³	Gravity	9.8 m/s ²
Water viscosity (α)	0.05	Total particles (Np)	145961
Kerosene viscosity (α)	0.05	Surface tension	47 - 49 mN/m

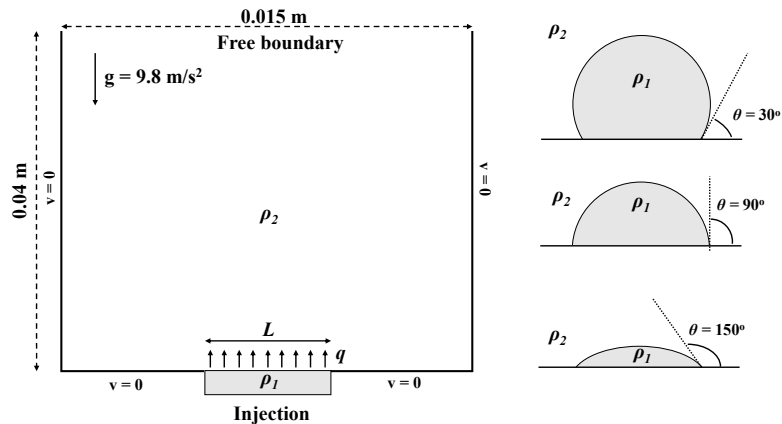

Figure 2. Left frame: Initial condition and dimensions for the simulations of analysis of injection conditions. Right frame: Contact angles for the fluid injected.

Figure 3. Left frame: Example of the evolution of one bubble. Right frame: Area of the bubbles obtained from numerical results.

5. Conclusions.

In conclusion, the SPH method can properly and naturally represent the creation of bubbles due to its purely lagrangian description. The model reported in the methodology and solved with the SPH method generates representative results with good precision as is prove with the numerical results obtained in the validation test. The surface tension model allows a stable surface drop during the rise of the bubble; moreover, with this model it is possible to study the rise of drops for different regimes. According to the parameters used in simulations, the length of injections is the principal parameter that modify the size of bubbles. The size of bubbles don't be affected by the flows used in the simulations. The 2D simulation is enough to know the area and speed of the bubbles, however, it is not able to predict well the shape of the bubbles. So, a 3D simulation is preferable for cases where is necessary to know about the shapes, movement and other important events.

Abstract

In classical thermodynamic, the estimation method of pure compounds properties was based on Newtonian physics, which required experimental data. It is proven to be inadequate for the growing demand of the novel chemical synthesis. There were several studies on the prediction of the pure compound properties based on QSPR methods. However, the conventional group-contribution based methods predictive capability was limited by the available measured data. Therefore, this study aims to approach the property prediction with a novel statistical-based method. The proposed method is derived using supervised machine learning algorithms. The experimental data used to train and validate the models were collected from the published literature. These data set are composed of the alkanes, alkenes, and alkynes derivatives containing 1-12 carbon atoms. The results show the improved accuracy of the model prediction compare to the conventional method in terms of root mean square error (RMSE) and mean absolute percentage error (MAPE).

Keywords: Properties prediction, Machine learning, Organic compounds

1. Introduction

Normal boiling point is defined as the temperature at which the vapor pressure of a liquid is equal to the atmospheric pressure. This thermo-physical property is important to design and calculation unit equipment of chemical engineering such as storage tank, vessel, flash drum, distillation column and so on. Typically, normal boiling point can be obtained as a result of the experiment. The boiling point is usually measured by small-scale simple distillation and microscale method (Shriner et al., 2004); however experimental measurements are often difficult, time-consuming, expensive, and sometimes hazardous. When the property is not accessible, the prediction methods are alternatives to determine the normal boiling point.

In general, normal boiling point of a compound is related to its molecular structure. Different models were used to correlate the boiling points of organic compounds with the different methods i.e. Constantinou and Gani (1994) develop a group contribution for estimating properties of pure compounds; Cordes et al. (2002) proposed a group contribution method for estimation of normal boiling point of organic compounds;

Al-Malah (2013) proposed a correlation between molecular weight and carbon atomic fraction to the normal boiling point of hydrocarbons; and Ghasemitarbar and Movagharnajad (2016), develop a new group contribution model to estimate the normal boiling point of organic compounds. These estimation methods can use to estimate normal boiling point for organic compounds, but it limited in nonetheless. In recent years, the large amount of information leading to the development of predictive techniques as machine learning which can find correlation from the dataset. Díaz et al. (2018) successfully used to predict the viscosity of ionic liquids with artificial neural network (ANN) models.

In this work, the proposed method is developed a novel method by applying machine learning techniques. The normal boiling point of organic compounds is expressed as a function of the simplified molecular-input line-entry system (SMILES).

2. Methodology

2.1. Data set

The accuracy and precision of prediction models depend on the number of experimental data and the comprehensiveness of the applied data set. In this work, the data set for the normal boiling point consists of 560 compounds. The experimental data are taken from ProCAPE software and the CRC Handbook (2010). The database of hydrocarbon compounds includes the following categories:

- (1) Normal paraffin: n-alkane.
- (2) Non-normal paraffin: example: iso-alkane, methyl-alkane, and ethyl-alkane.
- (3) Naphthene: cyclo-alkane.
- (4) Olefin: example: alkene, methyl-alkene, and ethyl-alkene.
- (5) Diolefin: example: alkadiene, methyl-alkadiene, and ethyl-alkadiene.
- (6) Cyclic olefin: cyclo-alkene, methyl-cylo-alkene, and ethyl-cyclo-alkene.
- (7) Alkyne: example: acetylene, propyne, and butyne.

The smile structure used to train and validate the models was collected from the published literature. To preparing data, the attribute set consists: the number of carbon atom 'C', the number of double bonds '=', the number of triple bonds '#', the number of branches '(', and the number of rings 'numeral' was created. The data set that consists of these 5 attributes were divided into a training set (460 compounds) and a test set (100 compounds).

2.2. Supervised machine learning algorithms

Supervised learning is a machine learning task for the predictions of unknown values by learning a model from labeled training data consisting of a set of training example input-output pairs (Russell and Norvig, 2010). The training set use to train the model by selected learning algorithms. To measure the accuracy of the learned model, the performance of the resulting model was measured on a test set of examples that are distinct from the training set. If the results are not satisfactory then changing learning algorithms is available. The options of supervised machine learning are classification and regression when the output is a finite set of values and a number, respectively. In this work, the regression methods are used to predict normal boiling point of compounds. A flowchart of the supervised machine learning model is displayed in Figure 1.

2.3. *Model development*

To select the appropriate regression methods, need to find correlations between each attribute and the experimental value. The attributes mentioned in the previous section, the number of carbon atoms has the best tendency to predict the normal boiling point properties as shown in Figure 2. Then we choose the number of carbon atoms as the basis of the prediction, the effect of this attribute is presented in equation (1). However, the values obtained from the first prediction were very different from experimental data. Thus, using the other attributes are used to improve the approximate value to the actual value. To find an effect of double bonds, triple bonds, branches, and rings. The regression methods were used to estimate as weight. The combination of first and second prediction is expressed in equation (2).

$$\beta_i^0 = \alpha x_i^\beta \quad (1)$$

$$y_i = \beta_i^0 + \sum \beta_i x_i \quad (2)$$

where β_i^0 is a first predicted value based on the number of carbon atoms, β_i is a second predicted value based on double bonds, triple bonds, branches, and rings, x_i is an explanatory variable, y_i is a dependent variable, α and β are constants from prediction.

2.4. Data analysis

The performance analysis of predicted normal boiling point of this method used root mean square error (RMSE) and mean absolute percentage error (MAPE).

3. Results and discussion

The novel supervised machine learning method was evaluated by using a data set composed of 560 compounds belonging to the most chemical families of compounds. The number of carbon atoms ranges from 1 to 12. The predicted value of normal boiling point using the novel method in comparison with the experimental data are presented in Figure 3. The values of the predicted normal boiling point as well as the status in the

Figure SEQ Figure * ARABIC 1 Supervised learning flowchart

Figure SEQ Figure * ARABIC 2 Plot of the experimental normal boiling point versus the number of carbon atom

method (the training set or the test set) are presented as supplementary information. The Statistical parameter of the method is presented in Table 1. For this method, the RMSE and MAPE are 8.340 and 0.016, respectively.

As a result, it seems possible to use the novel machine learning method to predict the chemical properties with this attributed label. Nonetheless, the problem with using this method is the inability to clearly specify the difference between similar compounds, examples are shown in Table 2. These six compounds have the different SMILES structures and boiling points; however, their set attributes are the same with 7 number of carbon atoms, 1 number of double bonds, and 1 number of rings. Therefore, the predicted boiling points of these 6 compounds turned out to be identical.

3.1. *Comparison to other prediction methods*

To demonstrate the accuracy of the novel method with other works developed for the similar purpose. The prediction result will be compared with those of MG (Marrero and Gani, 2001), CG (Constantinou and Gani, 1994), and JR (Joback and Reid, 1987). The comparison results are presented in Table 3.

Comparing to MG method, this novel method exhibits far lower error in terms of both RMSE and MAPE for every chemical category. Similarly, this method exhibits an improved accuracy of the prediction over JR method. Although the CG method made a better prediction to the alkanes and alkenes groups; the novel method still exhibits lower error overall.

Figure SEQ Figure * ARABIC 3 Plot of the predicted normal boiling point versus the experimental normal boiling point

Table SEQ Table * ARABIC 1 Statistical parameter of the obtained method.

Table SEQ Table * ARABIC 2 Prediction of the normal boiling point with the similar attributed label

Table SEQ Table * ARABIC 3 Comparison of proposed for functional compounds ; Where is the experimental value of normal boiling point (K), is the predicted value of normal boiling point (K), and is the number of data point.

4. Conclusions

The novel supervised machine learning method has been applied for the prediction of chemical properties. The aim of this development is to simplify the input; as well as improve the prediction accuracy. Normal boiling point has been selected for the demonstration of the method. In the first regression step, the number of carbon atoms shows the best tendency with the predicted property; therefore, it is used as the primary attribute. Then the other attributes are used to improve the approximation value accuracy with weighted regression.

The results of the estimated normal boiling points of 560 chemical compounds in 7 categories show acceptable error for both the training and the test sets. Around 1.6% error of prediction in term of mean absolute error has been achieved. Comparing to the conventional methods, this novel method exhibits far lower error than the

Marrero-Morejon and Gani method, a bit improvement over Joback and Reid method, and a comparable result to Constantino and Gani method. However, it is worth noted that the mentioned conventional methods are developed for the prediction of a bigger data set of chemical compounds. Therefore, the error may increase over the expansion of the data set involved, which need to be addressed in further study.

In conclusion, the novel supervised machine learning method has been proven to be useful for the prediction of normal boiling points of chemical compounds with simplify input. It should be further applied for the prediction of various other properties; as well as further applied for larger group of compounds. Moreover, the supervised machine learning method can also be used for the improvement of the conventional group-contribution methods by re-parameterization the groups attributes.

Abstract

In this contribution, we propose an algorithm for replacing non-linear process simulation integrated in multi-level optimization of an energy system superstructure with surrogate models. With our approach, we demonstrate that surrogate models are a valid tool to replace simulation problems in multi-stage optimization frameworks and enable the improvement of their computational performance. Furthermore, we want to show that the quality of the results is not penalized and flexibility is provided to the optimization.

It is desired to keep the amount of labeled data samples needed to create the surrogate model to a minimum, since their creation is computationally expensive.

In our algorithm, sampling methods are used to create an initial set of data points in the input domain in the decision variables of the simulation model to be replaced.

ANNs are trained on the initial training set. Using Dropout as a Bayesian approximation for quantifying the uncertainty of a prediction, the predictions can be qualified. New data points are continuously labelled and added to the training set based on the achieved prediction quality, until a minimum quality of the model is met. When applied in the optimization superstructure, the ANN can only be used when the prediction quality for the given data point is satisfying. Integrating these surrogate models in an optimization framework of an energy system will allow to only access the computationally expensive simulation when the quality of the prediction of the surrogate model is not sufficient. Simultaneously, a continuous improvement of the surrogate model will be achieved by using the created simulation results to parallelly refine the surrogate model by adding the created data points to the training set and therefore improve the model's validity range.

It is found that the methodology of continuously adding the data points based on the prediction uncertainty improves the quality of the surrogate model. Initial results indicate that when applied in the optimization framework, the suggested methodology holds potential to improve computational time and flexibility.

1. Motivation and Background

One of the main challenges we are facing as society is moving away from fossil energy carriers, searching for alternatives to sustainably and safely provide energy. Industries converting woody biomass hold a great potential of supporting the energy transition by valorizing their resources in such a way they can on the one hand help to provide storage options of volatile energy carriers, and on the other hand reduce their emissions and thus increase their carbon efficiency. Selecting and integrating the biorefinery processes in a complex industrial energy system requires systematic approaches like computer simulation, mathematical modelling and superstructure optimization. These techniques lead to highly complex, large scale mixed integer nonlinear optimization models that face some computational challenges (Cozad et al., 2014). High computational cost, noisy

function evaluation of simulation-based optimization models as well as solving issues due to complexity and non-convexity of rigorous first-order process influence the efficient solution generation (Fahmi and Cremaschi, 2012). In an attempt to reduce a model's complexity and to address the issues described above, the interest in developing surrogate models has increased over recent years. Surrogate models are especially interesting for application to multi-objective optimization problems that include superstructure consideration. These types of models are computationally expensive - due to the presence of many possible alternative configurations and operating conditions that need to be taken into account (Teske, 2014) - and hence, calculating the model at each iteration point is not practical. With surrogate models, new calculations or estimations can be performed in less computational time than with the original model. Furthermore, they are able to generalize the model result without running into convergence issues.

Especially artificial neural networks (ANNs) have been widely applied in chemical process modeling (Nascimento et al., 2000; Teske, 2014; Fahmi and Cremaschi, 2012; Tock and Maréchal, 2014). It was reported that neural networks have the ability to fill gaps in the search grid caused by the absence of analytical solutions (Nascimento et al., 2000) and that integrating surrogate models of certain processes in the optimization reduces the computational time considerably without penalizing the power plant operation quality (Tock and Maréchal, 2014).

Apart from ANNs, other approaches such as polynomial- and Kriging-based techniques were proved to be valid for surrogate modeling in process design (Caballero and Grossmann, 2008; Henao and Maravelias, 2011; Pedrozo et al., 2020).

Alternatively to using static data sets for training a surrogate model, one can let the machine decide which data to add best at the current state. Active learning is especially valuable when labelling data is computationally expensive, or where the purpose is to update the model by data that arrives continuously (Settles, 2012). Active learning is closely linked to hyperparameter optimization, as there the goal of the both is to choose data and model parameters in the most efficient way (Jablonka et al., 2020; Lookman et al., 2019). The objective of the research presented is to develop an approach for designing surrogate models of chemical process units with an active learning strategy. The design shall help to replace complex simulation of chemical processes in optimization frameworks with more flexible design and avoid non-convergence issues in the master optimization. Correlations between the inputs and outputs of the complex non-linear relations should be detected and replaced in the global optimization framework. Since labelling data is computationally expensive; it is anticipated to leave the number of data points at a minimum, and the surrogate model shall be able to continuously improve itself.

2. Methodology

2.1. Energy system design and optimization strategy

Figure 1: simplified OSMOSE methodology (Kermani, 2018)

Systematic modelling and optimization approaches are required to design complex energy systems. The mass and energy integration and optimization model of an industrial sector used in this study is built in the OSMOSE platform, which is continuously developed in the Industrial Process and Energy Systems Engineering Group (PESE) at EPFL (Figure 1). OSMOSE follows a two-stage decomposition approach, where the slave problem consists of a mass and energy integration framework developed as a mixed-integer linear programming (MILP) problem. Depending on the case study, it contains non-linear process unit simulations modelled in commercially available software. An evolutionary, multi-objective optimization algorithm is used in the master problem to solve a mixed-integer nonlinear programming (MINLP) problem considering economic and environmental objectives (Gassner and Maréchal, 2009).

2.2. Adaptive Surrogate model design

The relationship between the design variables and the system responses of complex thermochemical processes currently approximated by flowsheeting software in the overall energy system superstructure (see grey box in Figure 1) shall be investigated. For this purpose, a reliable presentation of the respective process with as few label generations as possible is anticipated. Integrating the developed surrogate model in the energy system superstructure shall allow for an estimation of the quality the surrogate model achieves for each provided prediction, and respectively enable the model to improve itself continuously.

2.2.1. Surrogate model design

For addressing the requirement of as few labelling points as possible when creating the model, we propose the algorithm shown in Figure 2.

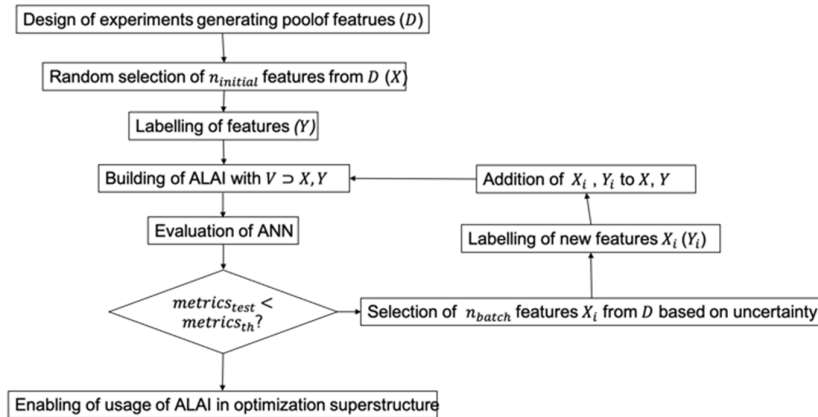

Figure 2: Proposed algorithm for designing ALAI

Design of experiments

The design space D is created by drawing samples for the design variables of the process that shall be replaced in an initial design of experiment (DoE).

Initial feature and label generation

For a randomly selected feature subset X of samples from D of the size $n_{initial}$, the respective labels Y are created by calling the simulation software with samples present in X . *Artificial neural network design and evaluation*

ANNs are used to replace the flowsheeting process models in the presented approach. Features X and labels Y are transformed to distributions centered around zero and unity variance by applying standard scaling. The model is built and trained on a share of the provided data V , the remaining share is used for testing. Depending on the performance of the ANN, the Active Learning Artificial Intelligence (ALAI) instance is accepted to be used in the OSMOSE superstructure instead of the flowsheeting software. Hereby, the performance is determined by the metrics achieved for evaluating the test set. In case the metrics is not satisfying, the ALAI instance is further improved by adding more datapoints to V .

Adaptive model improvement

For adding new datapoints to V , the uncertainty of the prediction ALAI makes on the remaining unlabelled features in D is measured. We label the sample points with the highest obtained uncertainty and add them to V . For approximating the uncertainty of a prediction, we use Dropout layers in the ANN as it is demonstrated by Gal and Ghahramani (2016). According to Gal and Ghahramani (2016), when applying Dropout, layer nodes are randomly deactivated following a Bernoulli distribution during training. A neural network with Dropout applied before every weight layer is mathematically equivalent to a Bayesian approximation of the Gaussian process (Gal and Ghahramani, 2016). To apply this concept, a second ANN including Dropout layers is built with the same hyperparameters as the first one and added to the ALAI instance. For each sample in D , we obtain a range of corresponding predictions from the ANN with Dropout. With this range of predictions per sample, the standard deviation can be computed and applied as a measure of uncertainty (Gal and Ghahramani, 2016). The unlabeled samples with the highest uncertainty are labelled and the resulting new features x_i and labels y_i are added to the training and testing data. This procedure is repeated i times until the resulting test metrics of the ALAI instance satisfies the quality demands.

2.2.2. Surrogate model application and continuous improvement

After the designed ALAI instance has achieved high enough quality for being integrated in the energy system superstructure defined, it can replace the call of the flowsheeting software. When OSMOSE calls for the flowsheeting unit that has been replaced by ALAI, the labels \hat{y}_i for the features x_i given by the master optimization are predicted with the

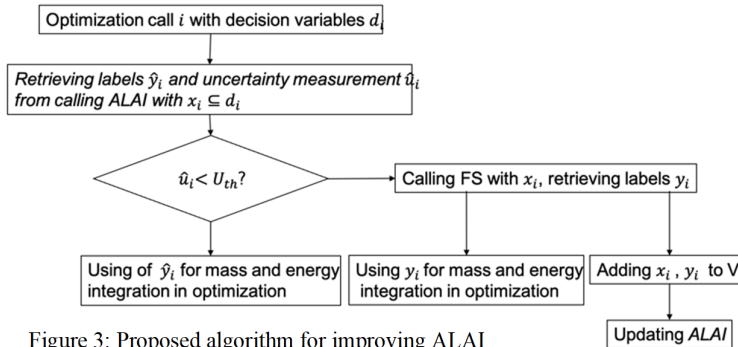

Figure 3: Proposed algorithm for improving ALAI

the ANN without dropout. Apart from the predicted labels, ALAI returns the predicted uncertainty \hat{u}_i by using the ANN with dropout layers. The results of the ANN are used in the master optimization if the uncertainty of the prediction is lower than a specified threshold U_{th} . However, if ALAI returns a high uncertainty for the given prediction, the call is discarded and instead, OSMOSE is calling the original flowsheeting software to label the samples and continue the optimization call. Parallel to completing the optimization call with the generated labels y_i , x_i and y_i are added to dataset V and ALAI is updating itself with the new set of training data.

3. Case study

The overall energy system used for validation of the suggested approach consists of a Fischer Tropsch (FT) production unit modelled with the flowsheeting software Belsim Vali, a steam network superstructure and various utilities and service that interact with each other. For validating the suggested approach, the flowsheet for the FT fuel production is approximated with an ALAI instance. The decision variables the master optimization can chose include 7 variables (operating conditions) that affect the FT production, and 63 outputs (operating conditions, mass and energy flows) are predicted by the flowsheet that are needed by OSMOSE. For starting the ALAI design, a design of experiments with 10000 sampling points of the 7 features is performed, out of which $n_{initial} = 1000$ random samples are labelled and added to V with which the initial ANNs are trained. The regression metrics for evaluating the models performance chose is the mean squared error (MSE) The maximum accepted MSE for testing with the initial ANN design MSE_{th} is set to 15%. The size of data batches added to V in each iteration i is set to $n_{batch} = 300$. For predicting the uncertainty of generated labels \hat{y}_i , the ANN with Dropout is evaluated 200 times. For being accepted in for being used in the optimization, ALAI needs to predict an uncertainty smaller $\sigma_{th} = 10\%$ for respective decision variables.

4. Preliminary results and discussion

When initially applying the proposed methodology for training the model adaptively, the test MSE reaches below 15% after 25 iterations, or 8200 labelled datapoints. We decided to stop the adaptive training here and work on further model improvements, so that the performance of ALAI can be improved before adding more labelled data. Using the current version of ALAI with OSMOSE results in 72% OSMOSE calls using ALAI, while the rest is calling the flowsheeting software. The call of an ALAI instance from OSMOSE takes approximately 30% less computational time than calling a the original flowsheeting software.

Figure 4: Mean squared error development

However, when validating the results OSMOSE computes with ALAI to the ones that are achieved with the flowsheeting software, considerable deviations in objective functions

of 23% are observed, which means the ALAI performance has to improve considerably before being applied. Future work will include the optimization of the ALAI's hyperparameters, in order to achieve the required metrics with fewer labelled datapoints. Furthermore, combining multiple ANNs for prediction and using combinations of other algorithms such as Random Forests and Kriging interpolation shall be investigated for performance improvement. The effects of different threshold for metrics and uncertainty will be investigated, and the results of the optimization will be further validated by comparing them to the results achieved with applying flowsheeting instead of ALAI.

Abstract

Optimum selection of input variables, number of hidden neurons and connections between the network elements delivers the best configuration of an artificial neural network (ANN), resulting in reduced over-fitting and improved performance. In this study, a superstructure-oriented ANN design and training algorithm is suggested and implemented on an industrial Ethylene Oxide (EO) plant for the prediction of product related variables (i.e. EO production rate). Proposed formulation is a mixed integer nonlinear programming problem (MINLP), which takes the existence of inputs, neurons and connections of the network into account by binary variables in addition to continuous weights of existing connections. Investigations show that almost 90% of the connections are removed compared to the fully connected ANN (FC-ANN) with 50% decrease in the number of inputs of the ANN, approximately. The modified ANN delivers a better prediction performance over FC-ANN, which suffers from over-fitting.

Keywords: machine learning; artificial neural networks; superstructure optimization; process modelling; mixed integer nonlinear programming

1. Introduction

Ethylene oxide (EO), a captive product used for the production of ethylene glycols (MEG, DEG, and TEG), is produced through selective oxidation of ethylene and oxygen in the presence of an Ag supported α -Al₂O₃ catalyst in the EO/EG plant located in the Socar Turkey/Petkim Petrochemical plant in Turkey. The EO process takes place in two parallel fixed-bed multi-tubular reactors at a temperature and pressure range of 240–260 °C and 17–18 bar, respectively. Both ethylene epoxidation and EO combustion occur in the reactors and only the former is desirable. Side reactions reduce the EO yield and an increase in CO₂ emission from the plant. From both safety and optimum control perspectives, the monitoring of the concentrations of the streams, which are measured through two separate online gas chromatography (GC) instruments, is of great importance. The former is designed for hydrocarbons and permanent gases whereas the latter focuses on the chlorine-based compounds. The operating strategy of the reactors is

to maximize the EO yield under various operational constraints. The simplified process flow diagram of the process is shown in Fig. 1.

Figure 1: Simplified process flow diagram of EO process.

High number of criteria is considered during EO production at the desired levels under the continuous and sluggish catalyst deactivation. These criteria lay the foundation of the features of information matrix exploited throughout this study as detailed in Table.1. All the feed compositions are measured before the reactor (i.e., after EO and CO₂ absorption section). Fresh VCM feed is introduced into the reactor inlet stream right before the reactor. Real-time optimization and automation of such a complex process is a challenging task, requiring significant effort in first principles and mechanistic modeling. Alternatively, Artificial Neural Networks (ANNs) are promising empirical models to estimate the product related variables from easily measurable variables (i.e. temperatures and pressures).

Table.1 Descriptions of the features and inputs.

TAG Description	Unit	TAG Description	Unit
Lean absorbent flow rate	t/h	Fresh C ₂ H ₄ feed	t/h
CO ₂ absorber overhead pressure	kg/cm ² g	Fresh CH ₄ feed	kg/h
Feed composition (C ₂ H ₄)	% (v/v)	CH ₃ Cl (methyl chloride) in the recycle	ppm
Feed composition (O ₂)	% (v/v)	VCM (Vinyl chloride monomer) in the recycle	ppm
Feed composition (N ₂)	% (v/v)	C ₂ H ₅ Cl (ethyl chloride) in the recycle	ppm
Feed composition (Ar)	% (v/v)	Reactor A coolant pressure	kg/cm ² g
Feed composition (CH ₄)	% (v/v)	Reactor A inlet pressure	kg/cm ² g
Feed composition (C ₂ H ₆)	% (v/v)	Flow rate to reactor A	t/h
Feed composition (CO ₂)	% (v/v)	Fresh VCM feed to reactor A	kg/h
Feed composition (EO)	% (v/v)	Product composition (EO)	% (v/v)
Fresh O ₂ feed	t/h		

2. Methodology: Optimal Superstructure-based Design of ANNs

The standard application of ANNs includes using fully connected networks, where all inputs, neurons and outputs are entirely connected. Fully connected ANN architectures (FC-ANNs) have high number of parameters. Typically, as the dimensions get larger, higher number of connections and parameters are introduced. It is usually expected that the increase in the number of parameters provides higher capability of fitting to the training data. Nevertheless, it is worthwhile here to mention that this increase may easily result in overfitting, and therefore poor prediction capability of the ANN model. Introducing more data is usually not a satisfactory effort as new data do not carry

additional statistical information unless they are collected from a different location in the plant. A feedforward ANN model is generally expressed as:

$$y = f_1(A \cdot f_2(B \cdot u + C) + D) \quad (1)$$

where f_1 and f_2 are output and hidden layer activation functions respectively. A typical activation function is the hyperbolic tangent function, which is used in this study as well. A and B are weight matrices; C and D are bias vectors; u is the input vector and y is the output vector. Related ANN parameters are all continuous, and theoretically unbounded, and their dimensions depend on the number of inputs, outputs, and number of neurons which is determined manually before training. Identification issues of these ANN parameters may result in poor testing performance. A typical solution to this problem is to include a regularization term to penalize the large values of ANN parameters, which unfortunately cannot regularize the hyper parameters ([1]). Pruning is another method to reduce the number of connections in ANNs ([2-3]). Dua proposed using a general mixed-integer optimization formulation to eliminate overfitting by detecting the optimal configuration of ANNs ([4]). Both number of neurons and existence of the interconnections are included in the objective function. Yet, this formulation does not consider selection of optimum input variables. Moreover, resulting formulations are either mixed-integer linear programs with fixed parameter weights or small scale MINLPs with fixed structures, number of nodes and/or interconnections, exhibiting poor flexibility. On the other hand, this significant study shows that much better test, and thus prediction performance can be achieved with fewer neurons and connections.

In this study, a novel MINLP (mixed-integer nonlinear programming) formulation is developed for the design and training of an optimal architecture feedforward ANN (OA-ANN), by modifying traditional ANN equations. The MINLP formulation introduces additional binary variables to the traditional ANN equations to represent the existence of network elements. The resulting superstructure formulation also takes the selection of the input variables into account in addition to the number of hidden neurons and connections, which in turn maximizes the overall flexibility and strength of the formulation. Accordingly, the proposed MINLP problem, whose objective is to minimize the number of connections of the ANN, is given by:

$$\begin{aligned} & \min_{A_{binary}, B_{binary}, C, D, N_{binary}, U_{binary}} \sum_{i,j} A_{binary,ij} + B_{binary,ij} \\ \text{s. t. } & F = \sum_{i=1}^N \|f_1((A \circ A_{binary}) \cdot \text{diag}(N_{binary}) \cdot f_2((B \circ B_{binary}) \cdot \text{diag}(U_{binary}) \cdot u_i + C) + D) - y_i\| \\ & F \leq \varepsilon \\ & A_{binary,ij} \leq N_{binary,j} \\ & B_{binary,ij} \leq U_{binary,j} \\ & A_{i,j}, B_{i,j}, C, D \in [-4,4] \\ & A_{binary}, B_{binary}, N_{binary}, U_{binary} \in \{0,1\} \end{aligned} \quad (2)$$

where \circ is the Hadamard product operator; u_i and y_i are the i^{th} input and output sample respectively. N is the number of samples used for the training. $A_{binary,ij}$ and $B_{binary,ij}$ are matrices with binary values representing the existence of connections. N_{binary} and U_{binary} are the binary vectors defining the existence of a neuron and an input, respectively. The existence of a particular connection between a neuron and an input is defined by the binary variable $B_{binary,ij}$. A_{ij} is the continuous weight parameter of the connection between the j^{th} neuron and the i^{th} output. Similarly, B_{ij} represents the connection between an input and the corresponding neuron. ε is the upper bound for the overall training error. This

way, a trade-off is included into the training, which in turn is expected to increase the test performance after implementing the proposed formulation. Please note that suggested formulation has the flexibility to result in a fully connected network once ε is set to a small value. In other words, a fully connected ANN is the upper bound of the suggested formulation. Problem (2) is a non-convex, and generally a large-scale MINLP, which is quite challenging to solve to the global optimum. In this work, an adaptive and evolutionary algorithm is used to solve the resulting non-convex MINLP problem. This method has a similar idea with [5] and it decomposes the original MINLP into an integer program (IP) and a nonlinear program (NLP). IP's only include binary decision variables that can be adjusted during optimization, whereas NLP's only involve continuous decision variables. The IP stands on the outer loop and is solved via the genetic algorithm based IP solver of Matlab while the inner loop NLP is solved by using IPOPT ([6]). Two problems are solved sequentially until the tolerance value of the original problem objective value or the maximum wall clock time is reached.

Please note that IPOPT is a local solver and might add randomness to the outer problem as the IP solution is based on a black-box genetic algorithm. Thus, we do not propose any integer cuts to be provided during the iterations. In addition to that, sensitivity analysis of the proposed method might be of interest to fully assess the regularization of the optimal ANNs using heuristic solutions, which is left as a future study. A global NLP solver can also be used for the inner problem to deal with the aforementioned challenges. On the other hand, investigations show that suggested method usually provides a sufficient heuristic solution in less than 3 min.

3. Results and Discussion

The proposed MINLP based approach is tested on the industrial EO plant. Corresponding data cover hourly measurements of 105 randomly selected days. We tested different training ratios, e.g. 20%, 50%, and 70%, to demonstrate the impact of the approach. OA-ANN architecture from the training with 20% of the data is shown in Fig. 2 as a typical demonstration. In the design of OA-ANN with 20% of the data for training, 9 inputs, out of 20, are selected from which connections exist to hidden layer as shown in Fig. 2. The thickness of the connections represents the absolute magnitude of the corresponding weight. Note that only significant connections are maintained, eliminating the ineffective connections and thereby tightening the non-linear training optimization problem.

Figure 2: OA-ANN for 20% training data

In addition, the OA-ANN architecture, with only 4 hidden layer neurons, does not have a fully connected architecture as the selected inputs do not have connection to all hidden neurons. As a result, a more efficient information flow is obtained through the network.

On the other hand, there are many different architectures which may deliver a similar performance since the MINLP problem is highly non-convex and inherently contains input multiplicity both due to input variable correlations and parameter dependencies. Accordingly, the heuristic solution method and even the optimization algorithm tuning parameters might result in different architectures. The selected inputs include the lean absorbent flow rate, absorber overhead pressure, feed composition of N₂ and Ar, feed CO₂ composition, fresh O₂ feed, fresh CH₄ feed, Vinyl chlorine monomer and ethyl chloride feed. Note that some input variables show significant correlation and there are many subset combinations to deliver a similar performance. Thus, the selected inputs, likewise the structure in Fig. 2, is not a unique solution; different initial guesses and MINLP solution approaches would result in a different optimal subset. Fig. 2 also reveals the impact of the input variables on the network, which is represented by the thickness of the connection and scaled by the corresponding weight. For instance, N₂ composition in the feed contributes to the network calculations in smaller scale compared to the chlorine compounds, which have a significant impact on the process control. A similar observation is also valid for O₂ feed, as well.

Detailed training and test performance comparison of FC-ANN and OA-ANN at various training ratios are presented in Table 2 which includes some common statistical measures.

Table 2: OA-ANN and FC-ANN detailed performance comparison

Train ratio	20%				50%				70%			
	OA-ANN		FC-ANN		OA-ANN		FC-ANN		OA-ANN		FC-ANN	
	Train	Test	Train	Test	Train	Test	Train	Test	Train	Test	Train	Test
RMSE	0.003	0.004	0.0001	0.0140	0.003	0.0035	0.0004	0.031	0.0045	0.005	0.0004	0.047
CV	0.046	0.061	0.008	0.147	0.051	0.061	0.018	0.25	0.065	0.093	0.017	0.296
MAE	-	0.424	-	2.481	-	0.49	-	4.53	-	0.37	-	1.03

Table 2 includes root mean square error (RMSE), coefficient of variation (CV) and maximum absolute error (MAE) as a comparison metric. Due to the eliminated overfitting, the training and the test performances of OA-ANN show a good agreement at all training ratios. Although FC-ANN demonstrates significantly lower training error with high number of connections, it suffers from larger test error compared to OA-ANN. Similar insight can also be obtained from CVs. In all cases, test performance of OA-ANN is superior to FC-ANN despite higher training error. The architecture comparisons are given in Table 3. The network dimensions of OA-ANN are significantly less than FC-ANN in all training ratios, providing additional computational advantages when ANN update is necessary. Overfitting causes poor test performance as shown in Fig. 3. This issue stems from high number of connections in FC-ANN, whose weights could not be identified based on the statistical content of the current training data. Both FC-ANN and OA-ANN test results are demonstrated in addition to normalized measurements in Fig. 3. Note that the OA-ANN has a better capability to predict a different operating condition, as shown between sample numbers 400-500.

Table 3: OA-ANN and FC-ANN architecture comparison

	OA- ANN			FC-ANN
	20%	50%	70%	-
Neurons	4	3	5	10
Connections	22	19	26	210
Inputs	9	9	8	20

Figure 3: Test data performance of OA-ANN and FC-ANN.

4. Conclusion

The design and synthesis of ANNs is a challenging and important task. Ineffectively large networks provide significant test errors due to over-fitting. Test performance of the proposed approach is significantly better compared to the FC-ANN, despite using approximately 10% of the connections and half of the inputs only. Reduced input space is advantageous for the real-time operation when model update or sensor failures are under consideration. Furthermore, the OA-ANN is superior in various training ratios, more robust to extrapolation and prediction of different operating conditions. The heuristic MINLP solution algorithm provides a satisfactory network architecture and still has theoretical potential for development. Our current focus includes the implementation to actual plant.

Novel Tool for Selecting Surrogate Modeling Techniques for Surface Approximation

Bianca Williams and Selen Cremaschi*

Department of Chemical Engineering, Auburn University, Auburn, AL, United States

selen-cremaschi@auburn.edu

Abstract

Surrogate models are used to map input data to output data when the actual relationship between the two is unknown or computationally expensive to evaluate for several applications, including surface approximation and surrogate-based optimization. Many techniques have been developed for surrogate modeling; however, a systematic method for selecting suitable techniques for an application remains an open challenge. This work compares the performance of eight surrogate modeling techniques for approximating a surface over a set of simulated data. Using the comparison results, we constructed a Random Forest based tool to recommend the appropriate surrogate modeling technique for a given dataset using attributes calculated only from the available input and output values. The tool identifies the appropriate surrogate modeling techniques for surface approximation with an accuracy of 87% and a precision of 86%. Using the tool for surrogate model form selection enables computational time savings by avoiding expensive trial-and-error selection methods.

Keywords: surrogate model, process design/optimization, surface approximation

1. Introduction

Surrogate models are simplified approximations of more complex, higher-order models. They are used to map input data to outputs when the actual relationship between the two is unknown or computationally expensive to evaluate. Surrogate models are of particular interest where expensive simulations are used or when the fundamental relationship between the design variables and output variables is not well understood, such as in the design of cell manufacturing processes (Williams et al., 2020). Surrogate models can also be constructed for surrogate-based optimization when a closed analytical form of the relationship between input data and output data is not available or is not conducive for use in conventional gradient-based optimization methods. Several techniques have been developed for surrogate modeling, requiring a systematic approach for selecting which technique may be appropriate for an application.

Current standard practices for selecting which surrogate model form is appropriate rely on process-specific expertise. Numerous studies have been conducted to compare surrogate modeling techniques (Davis et al., 2017). However, most of these only evaluate a few models on a limited number of functions or applications. Recently, progress has been made in generalizing the process for selecting a surrogate model to approximate a surface by using meta-learning approaches to build selection frameworks (Cui et al., 2016; Garud et al., 2018). These frameworks provide “best” recommendations for surrogate modeling techniques based on the attributes calculated

from the data being modeled and avoiding expensive trial-and-error methods. Few of the developed meta-learning tools take model complexity into account, which can lead to overfitting, or consider that multiple models might perform similarly to the one identified as best.

This work aims to comprehensively investigate the performance of several different surrogate modeling techniques for approximating smooth, continuous functional relationships and to link that performance to the characteristics of the data being modeled. The performance metric used for evaluating how well the surrogate modeling techniques approximate surfaces is the adjusted R^2 , which considers both model accuracy and complexity. Simulated data was generated using a suite of optimization test functions. Data attributes were calculated based only on input and output values for each dataset to represent its overall behavior. Attributes that have the most influential relationships for predicting the adjusted R^2 were selected using feature reduction. These attributes were used as inputs to construct a Random Forest based tool to make predictions on the surrogate models' performance and provide recommendations for which surrogate modeling technique(s) may be most accurate for the dataset.

2. Computational Experiments

2.1 Test Functions

The test functions used to simulate data for constructing the surrogate models and the recommendation tool are from the Virtual Library of Simulation Experiments optimization test suite (Surjanovic & Bingham, 2013). The functions are divided by their shapes, which include the categories: multi-local minima (29 functions), bowl-shaped (31 functions), plate-shaped (9 functions), valley-shaped (12 functions), and other-shaped (18 functions) that do not fit into the other four categories. Functions with two (29 functions), four (20 functions), six (17 functions), eight (17 functions), and ten (16 functions) inputs were used.

2.2 Surrogate Model Performance Comparison

Input-output pairs were generated from each test function using three different space-filling sampling methods: Halton Sequence Sampling, Sobol Sequence Sampling, and Latin Hypercube Sampling (LHS). Data was generated at seven different sample sizes (50, 100, 400, 800, 1200, and 1600 samples), producing 693 total datasets. Eight surrogate modeling techniques were used for comparison: multivariate adaptive regression splines (MARS);(Friedman, 1991), random forests (RF);(Breiman, 2001) single hidden layer feed-forward artificial neural networks (ANN);(Haykin, 2009), extreme learning machines (ELM);(Haykin, 2009), Gaussian process regression (GP);(Rasmussen & Williams, 2005), support vector machines (SVM);(Drucker et al., 2002), Automated Learning of Algebraic Models using Optimization (ALAMO);(Cozad et al., 2014) and radial basis function networks (RBFN);(Gomm & Yu, 2000). Surrogate models were trained using the input-output pairs with each of the surrogate modeling techniques for the test functions. This process yielded 16,632 trained models. When necessary, the hyperparameters of each surrogate modeling technique (such as the number of hidden neurons for the neural network-based models and the number of trees in RF models) were optimized before training the models using ten-fold cross-validation. After the surrogate models were trained, the adjusted- R^2 values were calculated for each modeling technique-dataset pair.

2.3 Recommendation Tool Construction

Cui et al. (2016) and Garud et al. (2018) extract information from the datasets for use in their recommendation frameworks in the form of attributes. The attributes include common statistical measures, such as mean and standard deviation, gradient-based attributes, and attributes related to the extrema of the output values. We have defined additional attributes, including the first four statistical moments of the determinants of the estimated Hessian matrices of the datasets, and as the number of data points in the dataset, to use as potential inputs for predicting the model performance with the recommendation tool, resulting in a total of 40 attributes. The attributes aim to capture the overall behavior of the underlying model that generated the dataset. They were calculated for the datasets generated from the 99 test functions and used to construct the surrogate model recommendation tool.

A RF model was trained for each surrogate modeling technique to predict its adjusted- R^2 value using the identified attributes as inputs. Random forests are decision tree-based machine learning models, where the final output of the model is the average of the value predicted by every decision tree in the forest. Feature reduction was performed to determine which attributes had the most influence on the predicted output value for each modeling technique. Feature reduction techniques included linear and rank correlations (Zou et al., 2003) between the adjusted- R^2 value and the attributes, and the built-in feature selection method in RF models. In RFs, features are selected based on how well they improve the data separation at each decision node in each decision tree in the RF (Brieman, 2001). For each dataset, based on the adjusted- R^2 values, each of the surrogate modeling techniques was classified as either being recommended or not recommended for both the predicted and actual metric values. These classifications were compared and used to evaluate the quality of the selection recommendations.

3. Performance Metrics

The adjusted- R^2 value is used to assess the surrogate models' performance for surface approximation. The formula for calculating adjusted- R^2 (\hat{R}^2) is shown in Eq. (1).

$$\hat{R}^2 = 1 - (1 - R^2) \left[\frac{n - 1}{n - (k + 1)} \right] \quad (1)$$

In Eq. (1), R^2 is the R-squared regression coefficient, n is the number of data points in the training set, and k is the number of model parameters (or hyperparameters). The adjusted- R^2 takes into account both the surrogate model accuracy and complexity (Miles, 2005). Taking complexity into account is essential in ensuring that the model is not overfit as overfit models do not generalize well to new data. \hat{R}^2 values typically fall between zero and one, with an \hat{R}^2 of one indicating a perfect fit. However, with the adjustment for model size, adjusted- R^2 values can become negative.

The metrics used to evaluate the performance of the recommendation tool (i.e., the classification of surrogate modeling techniques given a dataset) are accuracy, precision (Sokolova & Lapalme, 2009), and the hit ratio (Cui et al., 2016). The accuracy is the percentage of recommendations that are correct. Precision is the probability that a model classified as recommended should actually be recommended. The hit ratio is the percentage of the time the model with the highest calculated adjusted- R^2 is included in the set of recommended models. All three performance metrics range from 0 to 100%. Monte Carlo cross-validation was used to evaluate the performance of the

recommendation tool with 100 Monte Carlo trials. Each trial had a test set size of 75, which was about 11% of the total simulated data.

4. Results and Discussion

4.1 Surrogate Model Performance

The surrogate modeling technique that yielded the model with the highest adjusted- R^2 value was selected as the “best” one. For each shape category, the number of times a technique was selected as best was tabulated. These tabulated values were divided by the total number of datasets in the category to calculate the fraction of datasets for which each surrogate modeling technique was selected as the best performing (Fig. 1). There was no significant difference in the adjusted- R^2 values among the three sampling methods. Therefore, only results for Sobol sequence sampling are shown here. For valley, bowl, and other-shaped functions, GP models provide the highest adjusted- R^2 . However, ALAMO and MARS models produce the highest adjusted- R^2 most frequently for bowl and multi-local minima-shaped functions, respectively. These results indicate that the underlying function shape has an effect on which surrogate modeling technique may be most appropriate for approximating a dataset. While in general, GP models may provide the most accurate approximation, specific shape characteristics may lead to another technique’s being more appropriate. It should be noted that although these results only reflect a single technique being selected with the highest adjusted- R^2 , in many cases, there were multiple techniques with values that were not significantly different than that of the highest adjusted R^2 value.

Figure 1- Percentage of datasets grouped by function shape for which each surrogate modeling technique had the highest adjusted- R^2

4.2 Attribute Selection for Adjusted- R^2 Prediction

From the comparison results, we can conclude that there is a relationship between the underlying shape of the surface being modeled and the performance of each of the surrogate modeling techniques. The minimum Mahalanobis distance (De Maesschalck et al., 2000) between any two points in the simulated dataset was moderately correlated to the calculated adjusted- R^2 of RF models, with a linear correlation coefficient of -0.58 and a rank correlation coefficient of -0.71. The position of the data points in the dataset and how close they are to each other may be correlated to the approximation of RF

models due to the need for the models to partition the design space of the surface when determining the decision nodes in each tree in the RF model. Data points that are closer together lead to smaller partitions and more accurate predictions.

For the feature selection by RF models, each technique had a different set of selected attributes for prediction. For ALAMO, ANN, RBFN, and SVM models, 18 different attributes were selected as important. Random forest models selected 19, 11, 20, and 17 attributes as important for ELM, GP, MARS and RF models, respectively. The attribute most commonly selected as being important for predicting the adjusted- R^2 was the minimum Mahalanobis distance between training points. Other commonly selected features include those related to the distributions of output values, specifically the relative size of the output distribution tails and the output distribution skewness, and the ratios of the average estimated gradient to the minimum and maximum estimated gradients for all of the data points in the dataset. These results suggest that the distribution and location of the sample points and the relative steepness and smoothness of the surface have a high level of influence on how well each of the surrogate models is able to approximate that surface.

For all of the neural network-based models (ANN, ELM, and RBFN) and RF models, the attribute selected with the highest importance was the percentage of the simulated data points that were located in the upper tail of the output distribution. The closely related attributes of the ratio of the upper and lower tail sizes and the skewness of the output value distribution were selected as most important for GP and MARS models, respectively. These attributes may have an effect on the accuracies of all these techniques as having data unevenly concentrated (or sparse) at the extreme values may skew models to predict more accurately in areas of data concentration and less so for other areas of the design space. For example, in the case of RF models, uneven tails could cause decision nodes in the model trees to split more frequently at the extremes of the output values while more finely split partitions are really needed elsewhere, such as where the gradients are steeper. For the neural network-based models, the on-off nature of the hidden layer nodes may make them more suitable for making accurate predictions for surfaces where large areas of the design space have similar output values, creating flat or nearly flat areas. The coefficient of variation (COV) was selected as the most important feature for the prediction of the performance of SVM models. The COV is inversely related to the signal-to-noise ratio of a surface (Wang et al., 2013). This attribute may be important for SVM model performance as the support vectors fitted in the model construction can easily become sensitive to noise as they are only dependent on a small set of the data used to train the model (Sabzekar et al., 2011). For ALAMO models, all of the selected attributes had roughly equal amounts of importance.

4.3 Recommendation Tool Performance

The selected attributes were used as inputs to train a RF model for the eight techniques to predict the adjusted- R^2 for a given dataset. Based on the predicted adjusted- R^2 value, the recommendation tool then classifies each of the surrogate models as being recommended or not for that dataset. This recommendation scheme allows for multiple similarly performing surrogate modeling techniques to be suggested for use in surface approximation. The selection tool identified which techniques should be recommended for the simulated datasets with an accuracy of 87%. The precision, or the probability that a recommended technique should actually be recommended, was 86%. The hit ratio, the percentage of time techniques that had the highest adjusted- R^2 for a dataset were included in its set of recommended models, was 80%.

5. Conclusions

Selecting an appropriate surrogate modeling technique depends on the characteristics of the dataset being modeled. We identified attributes of datasets that are appropriate for use in predicting the adjusted-R² value. Using these attributes, we have constructed a tool that can recommend surrogate modeling techniques for approximating a dataset with 87% accuracy and 86% precision. Future work on the tool will include expanding it to surrogate-based optimization recommendations and investigation of additional attributes and machine learning techniques to improve recommendation quality.

Abstract

ProREFD is a computer-aided software for refrigerant design, analysis and verification, which consists of six tools that are suitable for different aspects of refrigerant design and verification. The six tools are the following: three databases plus a search engine; pure component properties estimation; mixture properties estimation; refrigerant selection and/or design; refrigeration cycle simulation; and modelling. The database tool consists of a database of measured pure component properties of especially selected refrigeration related compounds; a database of measured vapor-liquid equilibrium data of binary mixtures; and a database of measured binary azeotrope data. The property estimation tools employ a collection of especially developed and tested property models suitable for refrigeration processes. The refrigerant selection and/or design tool helps the user to select and/or design a refrigerant (single compound or mixture), given a set of target properties. The refrigeration cycle simulation performs simulation for the selected refrigerant and specified cycle operation conditions. The modelling tool is used to revise and/or add new property or process models. The paper presents the different implemented tools in ProREFD and highlights its use through several illustrative examples.

Keywords: Refrigerant, Refrigerant design, Properties, Refrigerant cycle simulation

1. Introduction

Refrigeration systems, whether for industrial or home applications, are very common since they perform the important operation of maintenance of temperature at a desired value. The selection and testing of any refrigerant involve many steps, such as identifying a suitable chemical (single compound or mixture) through evaluation of its properties, testing its efficiency in the actual refrigeration operation, matching of the desired operational specifications and many more. Moreover, due to increased health, safety and environmental concerns, the refrigerants selected for application must satisfy environmental, safety and sustainability constraints. Therefore, there has been a continued interest in finding new refrigerants that are significantly better than the currently available ones (Wei, 2007; Sahinidis et al., 2003). In this case, a computer-aided tool as a virtual reality that can systematically guide the engineer through the steps of

refrigerant selection and/or design as well as verification would be very useful, especially, if it can quickly and reliably identify promising candidates and thereby reduce time and cost for refrigerant development by focusing on experiments only at the last step to verify the performance of a small set of promising candidates. With these objectives in mind, the ProREFD software has been developed as a computer-aided hybrid data-model based tool suitable for refrigerant design, analysis and verification by extracting already developed tools from ProCAPD (Kalakul et al., 2018) and OptCAMD (Liu et al., 2019) but including especially developed property models for refrigerant molecules and their associated measured data as well as refrigeration process model. The goal of ProREFD is to mimic the steps typically employed in reality mode for refrigerant selection and verification. It should also be able to provide typical analysis tools such as databases, property estimation (pure component and mixture properties) tools that help with the virtual selection and verification steps as well as virtual analysis of available refrigerant candidates. The objective is not to replace experiments but to guide and focus them. This paper gives an overview of the ProREFD software, highlighting the work-flow and data-flow of its main functions as well as a short description of its six main tools. The use of the different tools of ProREFD is highlighted through illustrative examples.

2. Overview of ProREFD and its embedded tools

ProREFD is a systematic computer-aided tool, which combines the main steps of any refrigeration system study by providing the necessary functions (tools) and their associated models and sub-tools. The six tools of ProREFD, highlighted in Figure 1 (overview) and Figure 2 (data-flow and work-flow) are briefly described below.

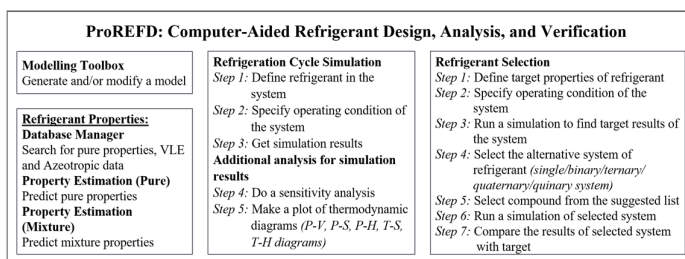

Figure 1: Overview of ProREFD

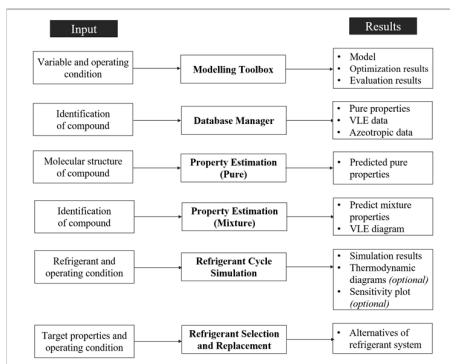

Figure 2: Information flow of each feature in ProREFD

2.1 Tools of ProREFD

Tool-1: Modelling Toolbox (MoT) is a mathematical modelling solver, which consists of in-house algebraic solvers, integrators, ordinary differential equation solvers and optimizers. MoT (Fedorova et al., 2015) is an equation-based simulation software that allows users to perform simulation processes without having to write any source code and has an option to convert models into COM-objects for use with external software.

Tool-2: As shown in Fig 1, the Database Manager is a tool for searching and retrieving of the refrigerant properties (pure compounds and/or mixtures). The search engine allows forward search (given a compound identification, show all available properties) and an advanced reverse search (given a set of target properties, show all compounds that match the property targets). This feature is very useful in the selection of a refrigerant based on measured properties. The database tool also includes a collection of measured binary mixture data in terms of PTxy-data from phase equilibrium experiments as well as a collection of binary azeotropic data. Table 1 lists the available data related statistics for the three databases.

Table 1: Statistics of available data in the Database Manager

Pure properties statistic		VLE data statistics				Azeotropic data statistics		
Compound	Known refrigerants	Binary pairs	Data sets	Data points	Compounds	Binary pairs	Data points	Compounds
1766	306	1340	9304	113887	214	795	2130	238

Tool-3: Property Estimation (Pure), is a property estimation toolbox for pure compounds (see Fig 1). This toolbox allows users to predict the properties of 60 different pure component properties. As refrigerant compounds are usually small molecules, the well-known group contribution property estimation methods that are suitable for larger molecules have been found to be not suitable. Therefore, a new set of property models for a basic set of properties (normal boiling point and critical properties) have been developed (Kuprasertwong et al, 2021). Using these properties, other pure component properties, such as, heats of vaporization, heat capacities, densities, etc., are computed through validated models. As environmental properties of refrigerants are important, properties such as ozone depletion potential, global warming potential, auto-ignition temperature, etc., are also estimated. This toolbox is integrated with the modelling toolbox so that model parameters can be fine-tuned with available measured data.

Tool-4: Property Estimation (Mixture) is the toolbox (see Fig. 1) that provides the predicted properties of refrigerant (organic) mixtures that are needed for refrigeration system design and analysis. For a specified binary or multicomponent mixture, this toolbox predicts, as highlighted in Fig 2, phase equilibrium properties (Vapor Liquid Equilibrium), saturated conditions (bubble/dew points) as well as properties for a given phase such as density, viscosity, liquid or vapor enthalpies and heats of vaporizations. Also, for this toolbox, a collection of validated in-house mixture property models is available (correlations, cubic equations of state, PC-SAFT, etc.).

Tool-5: Refrigeration Cycle Simulation is a toolbox that allows users to perform simulations of a refrigeration cycle comprising of evaporator, compressor, condenser and expansion valve units connected in a single-loop (see Fig 1 for more details). The refrigerant can be a single molecule or a mixture of up to 5 compounds. Before simulation, the tool checks if the given operating conditions and the properties of the refrigerant satisfy a set of consistency rules. This toolbox also computes, employing in-house

equations of state, thermodynamic diagrams (such as pressure-enthalpy diagrams) and embeds the cycle operation into these diagrams. Another useful feature of this toolbox is a sensitivity analysis option, where the sensitivity of compound properties or operational variables to the calculated Coefficient of Performance (COP) are checked. More details of the process models are given in (Kuprasertwong et al., 2021).

Tool-6: Refrigerant Selection is the toolbox that helps to design, select and optimize refrigerants (single molecules or mixtures) for a specific application based on user defined requirements (target properties), as highlighted in Fig 1). Users can select and compare the feasible alternatives based on their target properties, additional properties (not used as targets) as well as refrigeration cycle performance. More details on the refrigerant selection method is given in (Kuprasertwong et al, 2021). Note that exact matches of all Set-1 target properties are possible, while for Set-2 target properties they are satisfied within the defined bounds.

3. Application Examples

In this section, two main toolboxes of ProREFD, which are Refrigerant Cycle Simulation and Refrigerant Selection including comparison of calculations with external software are highlighted through illustrative examples.

3.1. Application example 1: Verify the refrigeration cycle operation of R-134a

In this case, 1,2,2-Tetrafluoroethane (R-134a) is used in a refrigeration cycle operating with room temperature and ambient temperature of 298.15 and 303.15 K, respectively. The evaporator pressure and condenser pressure are set to be 3.5 and 15 bar with 0.9 isentropic efficiency of the compressor. The R-134a mass flow rate is 180 kg/h. The expansion valve is assumed to be an isenthalpic system. Using the properties of R-134a (retrieved from the database), the consistency rules are checked and are found to be satisfied. Next, the cycle simulation is performed and the COP is determined. Next, the thermodynamic diagram is calculated and the operation of the cycle conditions is embedded into it. Finally, by perturbing the operating conditions (such as condenser pressure or evaporator pressure), the improvement of COP is checked. Figure 3 shows several screen shots from ProREFD. On the left-hand side, the refrigeration cycle simulation is shown together with the specified and calculated values. On the right-hand side (top), the thermodynamic diagram is shown and on the right-hand side (below), the sensitivity analysis plots are shown. From the thermodynamic diagram, it can be seen that decreasing the condenser pressure or increasing the evaporation pressure can increase the COP. The sensitivity analysis shows that T_b (normal boiling point) is the most sensitive property of the refrigerant and the critical pressure, although used to check the consistency rules, is not sensitive to COP.

3.2. Application example 2: replace R-134a

In this example the replacement of R-134a with other refrigerants (single, binary mixture, and ternary mixture) are highlighted. For verification, the refrigeration cycle is considered to operate at the same conditions as given in section 3.1. Results for selected refrigerant alternatives are highlighted in Figure 4 (screenshots from ProREFD). Figure 4 shows that the Refrigerant Selection toolbox allows users to replace a specified refrigerant with other

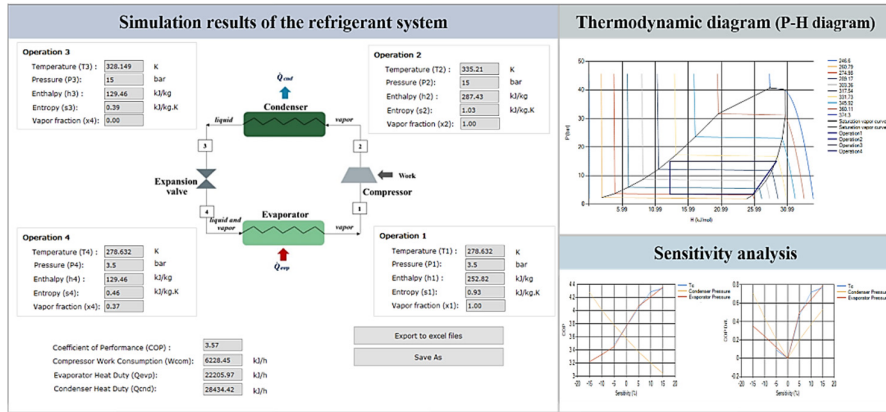

Figure 3: Results from Refrigeration Cycle Simulation function

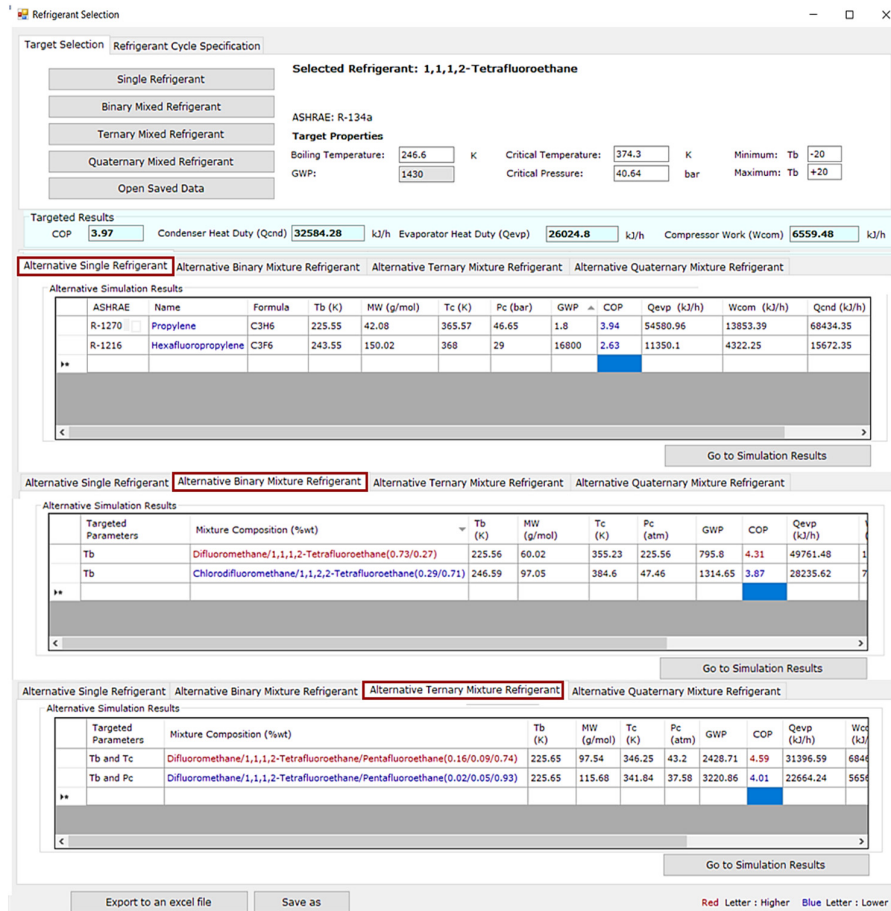

Figure 4: Results from refrigerant selection function

single or mixture refrigerants. Here, the reverse database search and/or molecular-mixture design methods (Kalakul et al., 2018) are employed to determine the alternatives. Furthermore, users can compare each designed alternative and optimize it to achieve the most efficient refrigeration cycle. See also Sahinidis et al., (2003) for a similar example.

3.3. Application example 3: ProREFD refrigeration cycle model validation

The simulated refrigeration cycle results with R-134a as the refrigerant, which are given in section 3.1, are compared and cross-validated with simulations of the same refrigeration cycle at the same conditions and for the same refrigerant with two external process simulators (PRO/II and AspenPlus). The simulated results given in Table 2 confirm that at least the three software tools give approximately similar results.

Table 2: Comparison of results from ProREFD with commercial simulators

Parameters	Unit	Calculation Source		
		ProREFD	External Simulator-1	External Simulator-2
COP		3.57	3.59	3.60
Evaporator Heat Duty (Q_{evap})	kJ/h	22,206	22,061	22,132
Compressor Work (W_{comp})	kJ/h	6,228	6,148	6,154
Condenser Heat Duty (Q_{cond})	kJ/h	28,434	28,210	28,286

4. Conclusion

The capabilities of ProREFD have been highlighted through illustrative examples. The Refrigerant Selection toolbox has the potential to find appropriate candidates that may not exist in any database of refrigerants, especially mixed refrigerants. For Refrigeration Cycle Simulation, the features of embedding the simulation results on the thermodynamic diagrams help to identify how to change the operating conditions to improve the process performance. The sensitivity analysis helps to identify the parameters of the refrigerant that can influence the process operation the most. Hence, ProREFD is a promising software tool that can play a leading role in refrigeration process development by helping to find promising candidates and more sustainable solutions rapidly, reliably and efficiently. ProREFD is unique as no other tool that have all the functions integrated in one software could be found. Due to unavailable property data, currently, the number of compounds with boiling points below 250 K is not many. Consequently, the number of new refrigerants that can be generated is also limited. To overcome this issue, current and future work is increasing the number of small molecules with 1, 2 and 3 carbon atoms so that truly novel alternative refrigerants can be found.

Abstract

The use of autosamplers connected to high throughput analytical devices allows for a high sampling frequency and analytics with reduced manual labor, leading to better process characterization (Maurer et al., 2015; Hofer et al., 2020). Increased sampling often leads to a significantly increased information content in the generated data. However, in combination with miniaturized or lab-scale reactors, the effect of volume change by the frequent sampling becomes challenging.

Sampling leads to fast, almost instantaneous volume changes in the reactor. This process represents a discontinuous behavior in the continuous-time kinetic model. A commonly applied so-called “time stepping” method ignores the discrete behavior and relies on the solver’s local error estimator to solve continuous-time differential equations. Therefore, in regions where discontinuities of the solution or its derivative occur, the method may fail to deliver an accurate solution. An alternative is the so-called “event driven” method, which explicitly accounts for discontinuities in the model. During the solution (integration) of the model, the method accurately locates time points, where discontinuities occur (event detection), e.g., volume changes and continues the solution process (Dieci and Lopez, 2012). It is well-known that proper handling of discontinuities can significantly increase the models' accuracy and reduce simulation runtime (Alsoudani, 2016). Still, bioprocess developers often ignore or tolerate discontinuities when implementing models in simulation software. Hence, this contribution highlights the importance of a proper handling of discontinuities in a relevant common case study for bioprocess development. Results are presented for the determination of kinetic parameters of Sonnleitner and Käppeli’s (1986) *Saccharomyces cerevisiae* growth model on a lab-scale fed-batch process with fast volume changes caused by frequent sampling. It turns out that the “time stepping” method misses several volume changes. In contrast, the “event driven” method does not. Accordingly, the “event driven” method yields accurate model predictions which are not affected by the reactor volume’s prediction error and thus improves the model calibration, lowers parameters uncertainty, and supports a robust convergence to the best fitting model parameters.

Keywords: parameter estimation, kinetic modelling, event driven modelling

1. Introduction

The acceleration of bioprocess development for decreasing time to market (TTM) of biopharmaceuticals has not only been known since the COVID-19 pandemic. For this purpose, mechanistic models represented by systems of ordinary differential equations (ODE’s) are indispensable tools for bioprocess design, monitoring, and control (Narayanan et al., 2020). However, the challenge of underfitting these models is present when an insufficient number of observations is used for model calibration. This problem

usually leads to correlated model parameters, which could hinder clear interpretations of the results. Autosamplers and automated analytical devices allows for tackling this challenge by increasing the sampling frequency without additional manual labor (Maurer et al. 2015; Hofer et al. 2020). Frequent sampling inevitably leads to significant volume changes in the reactor, which besides being a bottleneck in miniaturized systems, needs to be properly considered during modelling steps.

Volume changes of an ideal stirred tank reactor are usually modeled by considering mass balance equations. The changes in the volume over time is calculated as the difference between input and output flow rates (Doran, 2012). It is widely accepted to consider sampling volume F_{Sampling} as a part of the flows that are leaving the reactor (Rocha, 2003; Callewaert and De Vuyst, 2000; Kager et al., 2020). Hence, volume changes are written usually as (where V : volume, F : liquid mass flow rates):

$$\frac{dV}{dt} = F_{\text{in}} - F_{\text{out}} = F_{\text{Feed}} + F_{\text{Base}} + F_{\text{Acid}} - F_{\text{Sampling}} \quad (1)$$

In usual fed-batch fermentation, the measured flow rates (except F_{Sampling}) usually show comparatively smooth curves. These curves are represented by discrete signals and can be transformed to smooth functions with relatively little effort, e.g., by applying a smoothing filter and by subsequent interpolation using piece-wise spline interpolation. Avoiding discontinuities on the right-hand-side of eq. 1 can significantly improve the efficiency and accuracy of its solution (Alsoudani, 2016). F_{Sampling} represents strongly discontinuous curves defined by (negative) pulse signals. A transformation of these sharp peaks by smoothing is not a viable solution. The result is highly nonlinear terms, which would require an (inefficient) dense time grid for accurate integration of eq. 1.

In the “time stepping” method (TSM), which is implemented by using standard ODE solvers, the sampling volume is calculated by the integration of eq. 1 considering a (negative) pulse signal. The method relies on the solver error estimator to determine the step size (Dieci and Lopez, 2012). Hence, in regions where discontinuities of the solution or its derivative occur, i.e., sampling timepoints, there is a probability to miss certain events such as sampling volume, causing inaccurate volume calculation. This is exemplarily shown in Figure 1. This results in a wrong volume mass balance and therefore affects subsequent calculations. The extent of the errors resulting from improper handling of samples volumes depends on the ratio of the sampled volume to the reactor volume. The errors are expected to have a bigger influence on smaller platforms, e.g., miniaturized bioreactor systems (< 0.3 L), where often no reactor volume measurement is available.

Figure 1: Modeling of volume changes due to sampling. Sampling volumes are considered by a “sampling” flow rate represented by a flow pulse signal. The time stepping method (TSM) does not accurately track the sudden changes in the flow pulse signal. The ODE solver steps miss the second pulse (overstepping problem), which has an immediate effect on the volume.

In contrast, the “event driven” method (EDM) accurately locates time instances (so-called events) where instantaneous sampling happens. At these time points, the integration is stopped, the volume is updated, and the integration is restarted with the updated volume as initial condition. By this, the EDM efficiently prevents missing any sample, leading to a correct and robust volume balance during model simulations.

It is noted that established simulation software like *gProms* and *Modelica/Dymola* use built-in routines to automatically detect discontinuities, locate events, and restart integration (Process Systems Enterprise Limited, 2013; Dynamic Modeling Laboratory, 2004). However, in low-level modeling languages such as the frequently used *MATLAB* (*ODE Suite*, 2020) or *Python* (*SciPy* package, 2020), the proper handling of discontinuities needs tailored solutions and special programming efforts as the ODE solvers provide only the basic functionalities by the so-called “event functions”.

2. Materials and Methods

2.1. Cultivation process and Sampling

A *S. cerevisiae* fermentation process is considered as an experimental case study. Samples were withdrawn from the fermentation medium at irregular time intervals either by-hand (10 samples of roughly 20 ml per sample) or automatically using (Numerica from Securecell) autosampler (20 samples of roughly 7 ml per sample) and distributed along the time of the experiment. The reactor's initial volume was 1.5 liter. The experiment consists of a batch and a fed-batch phase with different feed regimes.

2.2. *S. cerevisiae* fermentation model

The model from (Sonnleitner and Käppeli, 1986) considers the growth on glucose and ethanol substrates. It describes fermentative and oxidative growth based on all forms of biomass specific intake ($q_s^{oxidative}$, $q_s^{reductive}$, $q_{ethanol}$) using ($Y_{biomass/glucose}^{oxidative}$, $Y_{biomass/glucose}^{reductive}$, $Y_{biomass/ethanol}$) yields parameters. Total growth is written as:

$$\mu_{total} = Y_{biomass/glucose}^{oxidative} \cdot q_s^{oxidative} + Y_{biomass/glucose}^{reductive} \cdot q_s^{reductive} + Y_{biomass/ethanol} \cdot q_{ethanol} \quad (2)$$

Mass balances equations are (x: biomass, s: glucose, e: ethanol, F: flow rate)

$$\begin{aligned} \frac{dC_s}{dt} &= -(q_s^{reductive} + q_s^{oxidative}) \cdot C_x - \frac{F_{in}}{V} \cdot C_s + \frac{F_{Feed}}{V} \cdot C_{s,in} \\ \frac{dC_e}{dt} &= (q_s^{reductive} - q_e) \cdot C_x - \frac{F_{in}}{V} \cdot C_e \\ \frac{dC_x}{dt} &= \mu_{total} \cdot C_x - \frac{F_{in}}{V} \cdot C_x \end{aligned} \quad (3)$$

2.3. Time-stepping method (TSM) versus event-driven method (EDM)

Eq. 1 is used to model volume changes in both methods. In EDM, $F_{Sampling}$ is omitted from eq. 1, and an external algebraic equation is used instead to account for volume changes. Figure 2 illustrates the working principles of the TSM and EDM. In the EDM, to accurately locate each sampling timepoint t_s , the simulation time interval is separated into k sub-intervals, where for each sampling point 1, 2, 3 ... K, the volume is corrected outside the ODE system using the additional algebraic equation; $V = V - \Delta V$. Following

the integration is restarted with the updated volume. In TSM, the sampling volume rate is integrated into eq. 1 without special treatment. The same initial conditions applied to both methods.

2.4. Convergence analysis of parameter estimation

To highlight the negative effects of improper handling of sampling volume, the model predictions are fitted to the experimental data. The performance of the fitting is assessed by applying either TSM or EDM. The following parameters

$\theta = [q_s^{max}, q_{O_2}^{max}, Y_{biomass/glucose}^{oxidative}, Y_{biomass/glucose}^{reductive}, Y_{biomass/ethanol}]$ are selected for estimation based on the local parameter sensitivities and

an identifiability analysis based on importance ranking (López et al., 2013). The robustness of both methods is assessed through a Monte Carlo approach. 500 uniform distributed initial parameter guesses are generated over a +/- 25% interval around the literature's nominal values (Sonnleitner and Käppeli, 1986). For each parameter realization, an estimation problem was solved using *MATLAB R2017b* "ODE15s" solver and the nonlinear fitting algorithm "lsqnonlin". Normalized residual sum of squares (NRSS) between model predictions and measurements was used as an objective function.

3. Results and Discussion

Figure 3 (right) shows a visual comparison of one simulation run to highlight the differences in the calculated volume using both methods. It can be noticed that TSM oversteps certain sampling times and consequently doesn't update volume correctly. The wrong volume affects the other model states (concentrations) described in eq. 3 and displayed in Figure 3 (right) for two identical model simulations. The error becomes more pronounced towards the end of the simulation as its effect accumulates over time.

In TSM, to account for sampling volume changes correctly, solver steps must exactly locate sampling times. However, TSM locates solver steps based on the integrator's local error estimator, which is a tool to control approximation error at each step. If the solver oversteps a sampling time interval, the local error estimator does not indicate an approximation error. Consequently, sampling instances are located by chance. Therefore, by evaluating the model at slightly different initial conditions or with slightly different parameter values, the solver may overstep very different sets of sampling timepoints. The accuracy of model simulations might be strongly affected. This is also critical for model parametrization, as the deviations in model volume and predictions are different at each optimization run, which adds artificial noise to the optimization problem. This is shown in Figure 3 (left).

In contrast, EDM accurately locates all sampling events and uses an external algebraic equation to correct the volume and to restart the integration at each sampling timepoint. By doing this, it suppresses the noise and provides accurate and reproducible model simulations. This behavior is illustrated in Figure 3 (left), which shows the optimization

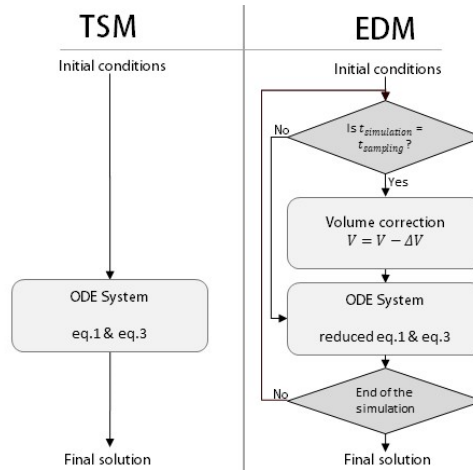

Figure 2: TSM and EDM for handling instantaneous volume changes because of sampling.

surface for two selected parameters. The noisy nature of the surface in TSM reduces the effectiveness of the gradient-based optimizer to seek an optimum. Tables 1 & 2 highlight this observation by comparing the means of prediction errors of the calibrated models obtained by both methods. The two-tailed p-value of the t-test is less than 0.0001, indicating a strong statistical significance. The results clearly indicate a higher probability to obtain better predictions using EDM and to converge to the best fitting parameter estimates. Reducing the solver tolerance in TSM might reduce these effects but not completely avoid them, as the error estimator still does not directly address the underlying reason of the problem, aside from increasing the computational cost.

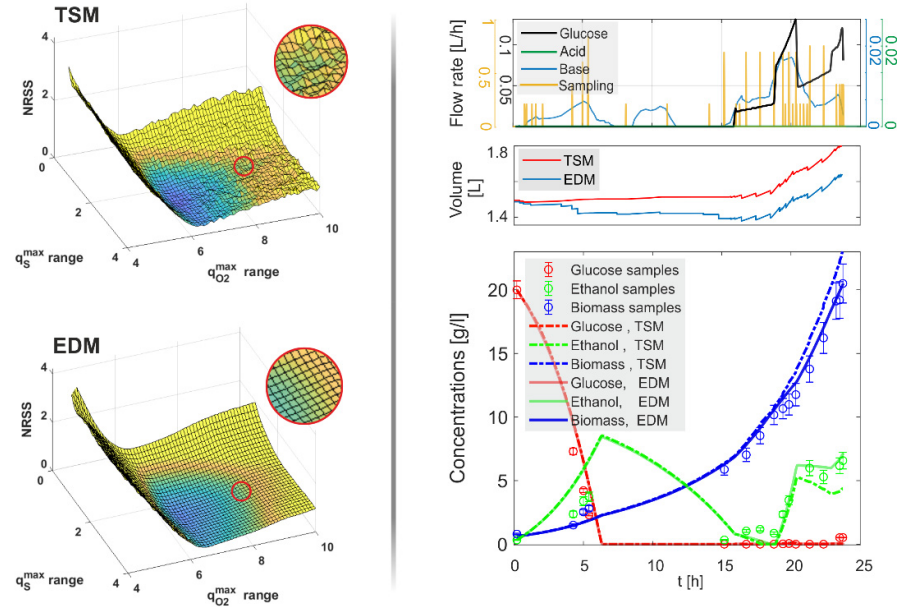

Figure 3: Left) States, flow rates and volumes calculated by the same model and parameters using EDM and TSM. Using TSM certain sampling times are overstepped. EDM delivers accurate results by accurately locating sampling times. Right) Optimization (NRSS) surfaces are smoother in case of EDM compared to standard TSM, allowing for a better convergence and efficiency of gradient-based optimization algorithms.

Table 1 & 2: Results of Monte Carlo procedure ($n=500$). EDM shows a statistically significant lower mean of the model prediction errors.

		<i>TSM</i>	<i>EDM</i>			
<i>Mean of prediction error</i>		3.1	2.3			
<i>Standard deviation (σ)</i>		1.65	1.35			
		θ_1	θ_2	θ_3	θ_4	θ_5
<i>Mean of Estimated. θ</i>	TSM	3.28	6.81	0.46	0.05	0.70

<i>95% confidence interval</i>	TSM	0.97	2.50	0.16	0.018	0.24
	EDM	0.92	2.25	0.14	0.016	0.24

4. Conclusion

Using EDM to consider sampling volume in *S. cerevisiae* fermentation models delivers more reproducible and accurate model predictions. Moreover, for model calibration, the quantitative analysis reveals a significantly improved convergence of the parameter estimation algorithm. Accordingly, EDM results are obtained with a lower prediction error and parameters uncertainty. The reason is a smoother optimization surface that leads to more robust convergence to the best fitting model parameters.

EDM is ready-for-use in high-level symbolic modelling languages such as *gProms* and *Modelical/Dymola*. In low-level languages, e.g., *MATLAB* or *Python*, EDM can be implemented with a reasonable effort using available initial value solvers with event detection. Hence, this method is simple to implement for fermentation processes with high sampling rates and platforms where explicit weight measurements are crucial but not available or hard to obtain, e.g., mini multi-bioreactor systems. This will allow for more consistent results, resulting in reduced iterations in bioprocess development and, therefore, a decreased time to market (TTM) of biopharmaceuticals.

Process System Engineering Tool Integration in the Context of Industry 4.0

Manuel Rodríguez Hernández*, Ismael Díaz Moreno

Universidades Politécnica de Madrid, José Gutierrez Abascal 2, Madrid 28006

manuel.rodriguez@upm.es

Abstract

The objective of this work is to have a model (or series of models) of a process plant that is available during the whole lifecycle of the system (process + product). To achieve this goal, we use a Model Based Engineering approach. In this work we will show how very different tools can be integrated and applied for a single process, we will illustrate (as a proof of concept) the integrations of the following tools (and languages): Aspen, Excel, MATLAB, and surrogate models. This will be demonstrated using Phoenix Integration software that provides mechanisms to automate the execution of different simulation and modelling tools in a single simulation workflow. In this integration, besides the tool integration, we will show how a superstructure optimization using an Aspen model (rigorous model) can be implemented and the simulation and optimization of a process composed of some rigorous units along with some surrogate units. The process used is the production of ethylbenzene from benzene and ethylene.

Keywords: Tool integration, model based engineering, process integration

1. Introduction

Industry is in constant evolution. Nowadays we are in what is called the fourth industrial revolution, Industry 4.0 (Schwab, 2016 and Kagermann et al., 2013). Its target is to make more efficient and flexible plants, reduce times and costs of projects and products lifecycle. This target has a strong basis in the use of digital twins. In the case of process plants there are a lot of specific software packages that are used by different agents (operators, maintenance workers, engineer, etc) in all the phases of the plant from planning to decommissioning this generates numerous documents and data that are prone to have inconsistencies (Fillinger et al., 2019) which can have an important impact on the plant in several aspects like safety or economic performance (Herzig, 2014). Several existing initiatives address the data transfer between tools, like Cape Open Laboratories Network (CO-LaN, 2018) for process simulators or the Namur initiative for data exchange between P&IDs and process control systems (NAMUR, 2018). Most of these approaches lack of a holistic view and focus on specific phases in the lifecycle. A Model Based Systems Engineering approach is needed to cover all the development phases, and to guarantee the traceability and consistency along the complete plant time span (Friedenthal, 2014). Several software frameworks exist for MBSE like Syndeia provided by Intercax (Bajaj et al., 2016) or ModelCenter provided by Phoenix Integration. In this work we use the latter to show tool integration in different applications following a Model Based Engineering approach, the ongoing work is to extend this approach to cover from the requirements of the process/product to its conception, design and operation.

2. Phoenix Integration ModelCenter

ModelCenter is a software developed by Phoenix Integration. It is an environment for Model Based Engineering (ModelCenter 2020). It is a vendor-neutral software which allows the integration of different tools in a single automated workflow. Several analyses can be conducted on the created workflow as design of experiments, optimization or trade studies.

The software also can create Response Surface Models (surrogate models) that can be used instead of or combined with original models in order to reduce computational burden or search for a global optimization solution. Finally, an important feature of the software (not presented in this work) is the enabling of Model Based Systems Engineering in order to have a complete framework to develop a process/product including the whole lifecycle and guaranteeing the achievement of the established requirements.

ModelCenter includes some plug-ins for some tools (like MATLAB, Maple PTC, Ansys, etc.), although almost any external program can be wrapped and included in a library of available models. The simulation/analysis workflow is created by dragging and dropping wrapped applications from the library and combining them using if-then branches, loops or other flowchart-like constructs. Any program that can use a text file as an input and output file is easily wrapped, basically ModelCenter operates writing user values into the input file and reading the results from the output file. The wrapped models can be distributed in different machines with different operating systems. In this paper we will show the integration of MATLAB, Aspen and Excel and the use of surrogates in simulation and optimization.

3. Tool integration

3.1. Process description

Benzene and ethylene are fed to an isothermal Continuous Stirred Tank Reactor (CSTR) where ethylbenzene (EB) is produced along with some diethylbenzene (DEB) as side product. The effluent of this CSTR is fed to another reactor (in this case it is adiabatic) where transalkylation of the DEB with benzene to EB is produced. The outlet stream is fed to a separation section with two distillation columns, the first one separates non reacted benzene as distillate that is recycled to the first reactor and the second one obtains the EB product at the top and non-reacted DEB at the bottom that is recycled to the second reactor. Figure 1 shows the developed Aspen simulation file of the process.

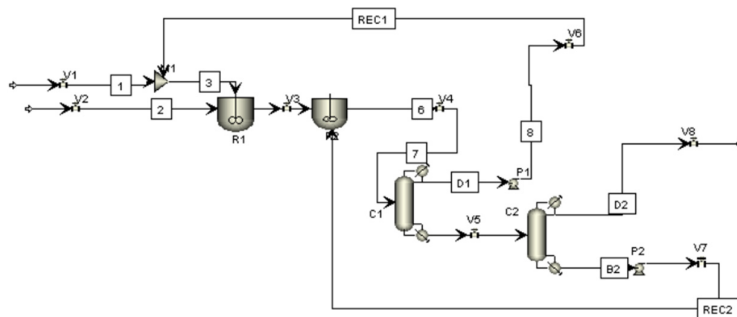

Figure 1. Ethylbenzene production process

3.2. Tool integration, an extra value to software communication

This section shows how different tools can be integrated in a single workflow and automate a simulation of the process. The ethylbenzene process is simulated according to the data provided by (Luyben, 2011). There is a tradeoff in the reactors volume and the amount of B recycled in order to minimize costs. A case study has been created to include an Excel file where the initial data and results are stored, an aspen file with the simulation and a MATLAB file that computes the Total Annualized Costs. Fig 2 (left) shows the wrapped models, the aspen model is *etilb-master* and has been created writing to the text input file (.inp file) and reading to the report text file (.rep file). Fig 2. (right) shows how the costs can be also calculated in Excel and in separate files for different equipment costs and then combined to get the overall amount. This allows to work by different users without interference in different parts of the process. This integration provides the mechanisms to establish initial requirements, perform the simulation and assess the achievement of the requirements, guaranteeing consistency between different views or parts of the model and traceability of the whole process.

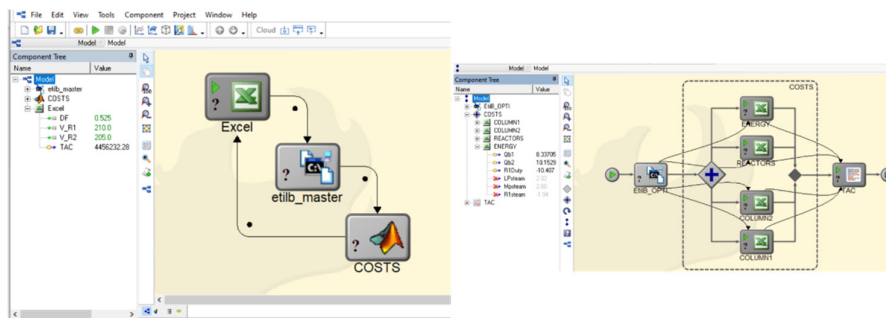

Figure 2. Tool integration: MATLAB, Aspen and Excel integration

4. Model Integration and applications

4.1. MATLAB inside Aspen

Sometimes, the available models in Aspen cannot represent a complex unit or a model of a unit has already been developed for some other purpose. In this case it would be desirable to integrate the external model into the Aspen process flow diagram. Model reuse and interoperability has been an important research field and some important initiatives have been developed (CO-Lan, 2018).

Using this framework, the integration is straightforward, in Aspen the Reactor is removed from the model and an input stream is added to the flowsheet. The original input is fed to the MATLAB model that calculates the output from the reactor and sends it to Aspen which calculates the flowsheet and obtains a new stream that should be equal to the MATLAB input. ModelCenter includes a module called Converger that changes the input to MATLAB until convergence is achieved. Basically, it is the convergence of a tear stream as it happens in a recycle or design spec in Aspen. A model developed with any other software or programming language could be integrated in the same way or even more than unit could have been replaced (for example one reactor developed with MATLAB and the other one with Python).

4.2. Superstructure optimization inside Aspen

In the design of a process several alternatives have to be considered. In order to get the optimal process, a superstructure optimization is usually created. This is usually created with a simplified model as the equations (and, overall, the physical properties) are not available. Still, in case of implementing the equations it takes an important amount of time while the Aspen model is many times available and its development is usually easier. The optimization problem is the same outlined previously, the tradeoff between reactors volume and recycled benzene but in this case the costs of the different routes are included in the optimization. In this case, we show how a superstructure can be created using the rigorous Aspen model. Fig 3. shows the superstructure created with two possible reactors (one CSTR and one PFR) and two possible separations (a flash and a distillation column). Splitters have been added to the simulation to allow for the different process paths. New feeds to the column and the flash have been added with a negligible amount, this is to avoid initial convergence problems with the simulation for the non-selected route. The flowchart (bottom left of the figure) optimizes the process sending different Boolean values to the splitters.

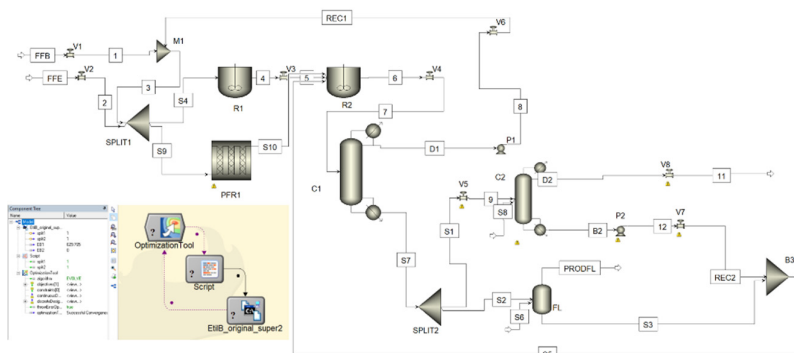

Figure 3. Superstructure optimization using Aspen rigorous model

The result obtained is the original flowsheet, CSTR and distillation column. This case can be combined with the previous one commented in section 4.1 and some of the units could be external models developed with other software than Aspen.

4.3. Using Surrogates

The use of surrogate models is gaining importance lately, if well designed, they can have similar performance than the original models (in the range of values of its design) allowing for faster execution and global optimization. ModelCenter has a module to create Response Surface Models. In this case we have created a surrogate model of the ethylbenzene process and a surrogate model of the process and the costs. ModelCenter provides two methods to create the surrogates, Polynomial and Kriging, and different Design of Experiment techniques (Full factorial, Orthogonal Array, Central Composite, Box-Behnken, Latin-Hypercube, etc). Several methods can be run for a DoE.

In this case Orthogonal Array supplemented with Latin-Hypercube was used to get the surrogate model with the Kriging approximation. Fig 4. shows the validation of the two surrogate models against the original one (left). The original process is in the middle and

the two surrogated alternatives are up and down, the results are compared in order to validate the surrogates. The implementation of the optimization using the surrogated model of the process is shown in Fig 4 right.

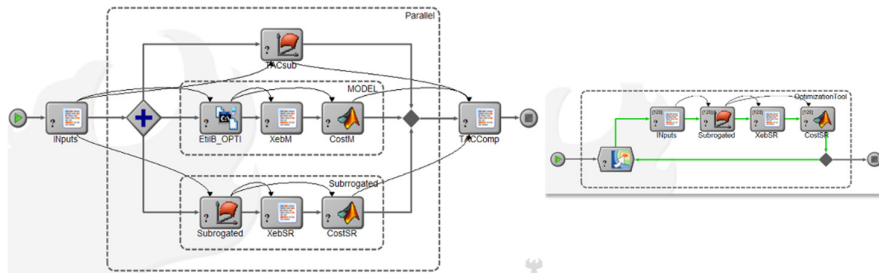

Figure 4. Surrogate modelling implementation, simulation (left) and optimization (right)

Next table shows the optimization results obtained using Aspen and using both surrogate models.

Table 1. Surrogate modelling performance comparison

	Simulation	Process Surrogate	Complete Surrogate
Reactor volume (m3)	248.4	248.4	248.4
Recycled Benzene (kmol/h)	1513	1522	1510
TAC (\$/y)	3.94M	3.98M	3.92M
Execution time	40min	3min	1min

4.4. Future applications

The next applications that the authors are working on are:

Multiscale modelling. Our research focus is not only on the lifecycle of the process but also in considering all the scales needed in a model from molecular modelling to macro scale modelling. Molecular modelling is approached with the integration of COSMOThermX, used for properties prediction of complex substances, with process simulation tools (such as Aspen Plus). The macro scale model and its impacts are being done integrating LCA tools, in this case SimaPro. The final target is to have an automated multiscale process for decision making, obtaining the optimal components and operating conditions to get the most sustainable process (considering the three dimensions economic, environmental and societal).

Operational integration. The multiscale modelling is mostly used in the design phase, in the operational phase the integration of standard engineering applications is important to guarantee a good plant performance. P&ID integration into the operating model, alarm recognition or safety assessment are some of the functionalities to be integrated with the central model.

Model Based Systems Engineering. The last application the authors are working on is the integration of PSE tools with standard MBSE languages (SysML) and tools (like IBM Rhapsody) in order to guarantee the traceability and consistency from the requirements phase to the commissioning phase. The idea is to have a core single model that will be used from the concept phase (requirements) to the final phase (decommission).

5. Conclusions

Nowadays we are in a digital transformation where models are gaining each day more importance. To have a framework that allows for vertical (whole lifecycle) as well as transversal (different tools and applications in each phase) integration using models that represent the actual process (and product) in a multiscale dimension is the overall goal of this work which is completely aligned with the current digital transformation. In this work we have presented a model-based engineering approach integrating different applications for different uses. This work has presented the potential uses and benefits of having a single model built with different standard software tools and the future steps towards having a model for a holistic view of the process/product to be developed and used.

Abstract

Surrogate models are an efficient method to expedite the process design by superstructure optimization. For their application in biorefineries' process design, several surrogate models are benchmarked in a case study regarding their validation metrics and their performance in a reference superstructure optimization problem. Despite good validation metrics for most surrogate models, their prediction quality in the superstructure optimization does not reflect this. For the use of surrogate models in superstructure optimization, the need for a profound assessment of options, and the possible use of dynamic sampling strategies become evident.

Keywords: Biorefinery, Process Design, Superstructure Optimization, Surrogate Modelling, Machine Learning.

1. Introduction

A key approach in promoting the transition towards a bio-based economy is the conceptual design and implementation of integrated second-generation biorefineries. A conceptual design approach for these biorefineries is Superstructure Optimization (SSO), which yields an optimal candidate process topology, but which is inherently limited by the initial search space and the fidelity of the models (Mencarelli et al., 2019). This contrasts highly with the complexity of fermentation processes and disregards advances in synthetic biology to optimize cell factories (Straathof et al., 2019). However, high-fidelity models, as, e.g., mechanistic models, which resemble the underlying physical, chemical, and biological phenomena with suitable mathematic descriptions, can describe this complexity well.

To facilitate the computational tractability of the SSO with high-fidelity models, surrogate models, which are commonly machine learning or other statistical models, can be used instead in the superstructure formulation (Mencarelli et al., 2020). Regarding the use of surrogate models in SSO, we hence propose and benchmark five different alternatives to determine the most suitable surrogate alternative for a process design task. The first four alternatives comprise 1) a Gaussian Process Regressor, 2) a Support Vector Machine Regressor, 3) a Regression Tree Ensemble, and 4) an Artificial Neural Network

as a surrogate model, which are respectively fitted to flowsheet-wide simulation data over the design space. The fifth alternative serves as a comparison to the prior four and is a regression model based on linear regression in multiple dimensions. Each model is validated, and relevant metrics are assessed and compared. With the respective surrogate models for each flowsheet option in the superstructure, the underlying optimization problem of the SSO, which is classically a mixed-integer nonlinear program, can be reformulated either as a series of nonlinear programs for the first four models or as a mixed-integer linear program for the last surrogate. The optimization problem's solution with each surrogate and validation with the original flowsheet model serves as the benchmarking purpose in this study.

2. Methods

2.1. Gaussian Process Regression

Gaussian Process Regression (GPR) is a prominent type of machine learning model with a plethora of applications. The regression is based on a stochastic process. In this stochastic process, a kernel function correlates any point in the input space to the points used to fit the GPR (Al et al., 2019). GPRs are extremely versatile regarding their application and can interpolate very well with small amounts of data available; however, they work best for low-dimensional problems, steady design spaces, and moderately sized datasets (McBride and Sundmacher, 2019).

2.2. Artificial Neural Network

Artificial Neural Networks (ANN) are another prevalent type of machine learning model with applications reaching from standard machine learning and deep learning tasks up to artificial general intelligence. One of the simplest representations of an ANN is a multilayer perceptron (MLP) with one input layer, at least one hidden layer, and one output layer, where each hidden layer contains a certain number of nodes that use a specific transfer function to calculate the node's outputs to all its inputs (Al et al., 2019). The hyperparameters of the network architecture, e.g., number of layers, neurons, types of the transfer function, and training algorithms, can be screened in the fitting process using a grid search approach to improve the model quality. ANNs are especially suitable for highly nonlinear and high-dimensional systems; however, their functionality is hindered by low amounts of data unless shallow ANNs are used (McBride and Sundmacher, 2019).

2.3. Support Vector Regression

Another heavily used representative of machine learning models for surrogate modelling are support vector machines. The general idea of support vector machines is to fit hyperplanes in the n -dimensional input space to maximize the distance of the points in the input space to the hyperplane by utilizing kernel functions. The fitted hyperplanes then serve as the basis for the regression (Williams and Cremaschi, 2019).

2.4. Regression Tree Ensemble

The last introduced machine learning concept is a so-called regression tree ensemble (RTE), belonging to the class of ensemble methods, where several decision trees are fitted to the data, and the weighted combination of these trees serves as the basis for regression. The concept of a single decision tree is visually very well depicted by dividing input data based on several input criteria onto different branches of the tree. Tree ensembles are

quite powerful as they can effectively fit sparse datasets with exceptional predictive capacities (Thebelt et al., 2020).

2.5. Delaunay Triangulation Regression

In addition to all the introduced machine learning models, the idea behind Delaunay triangulation regression (DTR) as a surrogate model is the extension of the concept of a piecewise-linear function in multiple dimensions (Franke, 1979). Triangulation as a mathematical topology is a homomorphism to the n -dimensional design space $X \in R^n$, consisting of a set of n -simplices. An n -simplex consists of $n + 1$ vertices, which are set to be the sampling points $p_x \in X$ in the design space. Any point x within the simplex can be described as a linear combination of the vertices.

2.6. Surrogate Model Validation

As sampling strategy for each surrogate model, Latin Hypercube sampling is chosen. Alternatively, Sobol sequences can be used with similar results (Williams and Cremaschi, 2019). Each surrogate model type is then fitted to the set of sampled points, while the fit is optimized respectively with a corresponding routine. All machine learning models are cross-validated, employing a k -fold cross-validation. The cross-validation methodology is altered to preserve the convex hull for the DTR surrogate model, as the DTR model intrinsically has no extrapolative capabilities. The calculated validation metrics are the coefficient of determination R^2 and the root mean squared error $RMSE$ for the testing and training datasets with $k = 5$.

2.7. Superstructure Optimization

The superstructure for superstructure-based process design can be transferred into an optimization problem to solve it mathematically. While there are different ways of postulating a superstructure, e.g., as state-task-network or state-equipment network, the underlying optimization problem is commonly a mixed-integer problem (MIP):

$$MIP: z = f(x, y) \quad s.t. \quad g(x, y) \leq 0 \quad h(x, y) = 0 \quad x \in X, \quad y \in [0,1] \quad (1)$$

With z being the objective to be minimized, $f(x, y)$ being the functional relation of respectively one of the surrogate models, $g(x, y)$ representing inequality constraints, $h(x, y)$ representing equality constraints and y defining binary decision variables. If either of the functional relationships is nonlinear, the MIP is denoted as a mixed-integer nonlinear program (MINLP). Due to the strenuous computational tractability for state-of-the-art solvers to solve MINLPs, two different reformulation strategies are chosen: The first is the reformulation to a series of nonlinear programs (NLP), eliminating all integer variables by iterating over each flowsheet alternative. The second option is the reformulation to a mixed-integer linear program (MILP), where all nonlinear functional relations in the model are linearized.

3. Results & Discussion

3.1. Case Study

As a case study, previously presented by Vollmer et al. (2020), a base-case biorefinery setup is chosen, with wheat straw as substrate and xylitol as the product. For this work, one reference flowsheet with fixed topology out of the entire superstructure is chosen. The reference flowsheet involves a pretreatment unit, an evaporator as an upconcentration unit, a fermentation unit for converting the hemicellulosic sugars to xylitol, an evaporation unit, and two crystallization units in the downstream processing (Vollmer et

al., 2020). For all unit operations, mechanistic models based on mass and energy balances and kinetic equations for the respective process are employed. All models are implemented in MATLAB. All models are analyzed regarding their robustness by a comprehensive Monte Carlo-based uncertainty and a variance-based sensitivity analysis. The selected variables for the input space t are the acid concentration for the pretreatment C_{ac} , the fermentation time t_{FX} , the inoculum concentration for the fermentation process C_{inoc} , the vapor fraction of the upconcentration unit v_{UCH} and the evaporation unit v_{EX} . The other variables are set to fix values within their operational ranges. The calculated output variables are the produced mass of xylitol M_{Xyo} , the concentration of two inhibitors (5-HMF and acetic acid) after the final crystallization step C_{Hmf} and C_{AAC} , as well as a ratio φ , indicating the mass of produced CO_2 by steam generation for providing process heat in the upconcentration and evaporation unit per mass of produced xylitol.

3.2. Surrogate Model Creation and Validation Results

The input space with the five variables is sampled with $N = 125, 250, 500,$ and 1000 samples. For the GPR, the SVM, and the RTE, the Statistics & Machine Learning toolbox functionalities of MATLAB are used. An internal routine respectively optimizes the hyperparameters for all three in MATLAB. For the ANN, the functionalities of the Deep Learning toolbox of MATLAB are used. The ANN's fitting is performed by grid search functionalities implemented within the easyGSA toolbox (Al et al., 2019). The DTR model's triangulation is obtained by the Delaunay triangulation functionality of the scipy library for Python. The parity plots in Figure 1 show that the GPR surrogates fit best for all the sampling sizes. The SVM surrogates show a significant amount of outlier for increasing sampling sizes, and the RTE surrogates to a lesser amount. However, the ANN surrogates also show good fitting qualities with a larger variance than the GPR surrogates.

Figure 1: Parity plots of the fit for the GPR, SVM, RTE, and ANN surrogates with all data points.

The validation results for $N = 1000$ samples are shown in Table 1. The metrics for all machine learning surrogates show a good fit. The DTR surrogate predicts unseen data poorly, worsening the quality metrics. Similar metrics result for all other sample sizes.

Table 1: Metrics for the k-fold cross-validation of all surrogates with $N=1000$ samples.

N=1000	GPR	SVM	RTE	ANN	DTR
R^2_{train}	1	0.95	0.99	0.995	1
R^2_{test}	0.981	0.937	0.921	0.985	0.68
$RMSE_{train}$	0.017	2.858	1.057	0.961	0
$RMSE_{test}$	1.818	3.382	3.721	1.602	7.788

3.3. Superstructure Optimization Results

The input variables for the optimization problem are considered in the following range: the acid concentration $C_{ac} = [0.5, 2]$ g/100g biomass, the fermentation time $t_{FX} = [12, 48]$ h, the inoculum concentration $C_{inoc} = [0.5, 3]$ g/L, the vapor fraction of the upconcentration unit $v_{UCH} = [0.4, 0.6]$ and the vapor fraction of the evaporation unit $v_{EX} = [0.99, 0.998]$. Furthermore, the concentration of 5-HMF and acetic acid respectively in the last unit operation cannot exceed $C_{Hmf}, C_{Aac} \leq 0.5$ g/L. Equally, not more than 10 kg of CO₂ can be produced per kg of xylitol produced, so $\varphi \geq 0.1$. The objective is chosen to be the produced amount of xylitol $z = M_{Xyo}$. For all NLPs, a surrogate is fitted to the input samples and, respectively, one output variable and solved with the MATLAB solver finincon (SQP algorithm) and a multi-start method to seek global optimality. For the MILP, one DTR surrogate is fitted to the input samples, capturing all four outputs, implemented in Pyomo and solved with the GUROBI solver. The following table shows the optimization results and the corresponding validation simulation with the original model.

Table 2: Results for the objective function and the constraints from the NLP/MILP (left) and the validation simulation (right).

125	GPR		ANN		SVM		RTE		DTR	
M_{Xyo}	55.9	52.6	54.8	54.2	64.8	0.00	55.2	0.00	47.1	48.2

For the GPR, the predictions are constantly on a high accuracy level independent of the sample size. However, the GPR tends to overpredict the objective function value and to underpredict the concentration constraints. The ANN shows good predictions of the objective functions and no bound infringements except for the case with $N=250$. Both the SVM and the RTE mostly fail to predict the objective value accurately due to poor fitting. Lastly, the DTR model predicts the objective function value accurately for all cases without bound violations despite the impaired validation metrics.

4. Conclusion

It becomes evident that despite the brilliant predictive qualities of most machine learning surrogates, this is not reflected in the SSO. The DTR model performs best in the benchmark, indicating a promising potential as surrogate modelling technique for optimization applications. Possibly, the predictive quality of all models could be improved with dynamic sampling strategies, reducing the inconsistencies in prediction over differently sized datasets. Overall, the crucial role of cross-validation and case-dependent analyses of different surrogate models becomes evident, as sampling size and strategy clearly play a role in the resulting model quality and the optimization results, thus application strategies can hardly be generalized.

Abstract

A comprehensive evaluation of toxic chemicals and understanding their potential harm to human physiology is vital in mitigating their adverse effects following exposure from environmental emergencies. In this work, we develop data-driven classification models to facilitate rapid decision making in such catastrophic events and predict the estrogenic activity of environmental toxicants as estrogen receptor- α (ER α) agonists or antagonists. By combining high-content analysis, big-data analytics, and machine learning algorithms, we demonstrate that highly accurate classifiers can be constructed for evaluating the estrogenic potential of many chemicals. We follow a rigorous, high throughput microscopy-based high-content analysis pipeline to measure the single cell-level response of benchmark compounds with known *in vivo* effects on the ER α pathway. The resulting high-dimensional dataset is then pre-processed by fitting a non-central gamma probability distribution function to each feature, compound, and concentration. The characteristic parameters of the distribution, which represent the mean and the shape of the distribution, are used as features for the classification analysis *via* Random Forest (RF) and Support Vector Machine (SVM) algorithms. The results show that the SVM classifier can predict the estrogenic potential of benchmark chemicals with higher accuracy than the RF algorithm, which misclassifies two antagonist compounds.

Keywords: Predictive modeling, estrogen receptor activity, classification analysis, big-data analytics, image analysis.

1. Introduction

Advancements in machine learning algorithms combined with computational power and storage capacities of modern computers have enabled data-driven modeling as a promising approach for prediction and decision-making in biological and environmental systems (Yin et al., 2015). Specifically, data-driven algorithms enable pathways to understand similarities between complex chemicals (Onel et al., 2019, Onel et al., 2018) and facilitate rapid detection and evaluation strategies for predicting the endocrinological activity of unknown chemicals created during environmental emergencies (Mukherjee et al., 2020). In such catastrophic situations (i.e., hurricanes, earthquakes, etc.), many unknown chemicals are mobilized, increasing the risk of exposure and long-term adverse biological effects on living organisms (Cooper and Wardropper, 2020). Understanding the effects of these novel chemicals on a key transcription factor that regulates the most fundamental biological processes in the human body, such as the Estrogen Receptor- α (ER α), is crucial for diagnosing potential health hazards.

The toxic compounds created during and after environmental emergencies are capable of binding to the ER α and initiating a biological response as agonists or interfere with the receptor function as antagonists (Warfvinge et al., 2020). The agonistic and antagonistic behaviors of chemicals can be measured using cell-based high content/high throughput microscopy imaging, which records numerous intensity and morphology features of treated cells (Szafran et al., 2017). Recently, we have shown that this multidimensional imaging data with population-averaged samples can be used to classify agonist and antagonist benchmark chemicals with high accuracy using linear and nonlinear models (Mukherjee et al., 2020). In this work, we use cell-level data (instead of the population-averaged data) to assess the predictive capabilities of nonlinear classifiers, namely the Random Forest (RF) and the Support Vector Machine (SVM) algorithms. To sustain cell-level information in the dataset, we fit non-central gamma probability distribution functions to the data and use their corresponding distribution shape parameters (i.e., alpha, beta, delta) as the descriptors in our predictive models. We further follow a rigorous training and testing procedure to build and assess the predictive capabilities of our data-driven models.

2. Experimental Data Gathering: High Content Image Analysis

We used high-throughput microscopy and image-analysis pipelines to measure the estrogenic activity of chemicals using an engineered biosensor, a multi-parametric cell-based *in vitro* assay as described in Ashcroft et al. (2011). Biosensor cells were treated for 2 hours with different concentrations of 45 reference endocrine-disrupting chemicals (EDCs) identified by the EPA to be either ER α inactive, agonist, or antagonist. The 45 reference chemicals with known estrogenic activity were supplemented with 8 additional known ER α antagonists to partially balance the number of known agonists and antagonists tested. The cell-level response was imaged and recorded, and 70 size, shape, and intensity features per cell were extracted using custom-built software (Szafran et al., 2014). These features describe several key mechanistic steps of the ER pathway including, ER α expression levels, its subcellular/subnuclear distribution, and DNA binding (Szafran et al., 2017). A single screen of the aforementioned analysis generates 60 GB of image data, from which approximately 50 million object-based data points are extracted. This high-dimensional dataset is reduced prior to the classification model building step using a technique described in the following section.

3. Data Pre-Processing: Dimensionality Reduction

Each complete screen of the EDCs and reference chemicals consists of five 384-well plates with each unique chemical-concentration combination having a minimum of 4 in-screen replicate sample wells. A total of 5 complete screens were completed. For classification model development, a subset consisting of the highest tested concentration of each active (either agonist or antagonist) chemical was generated. This subset contains 32 agonists and 15 antagonist chemicals and 39 cell-level features (the discarded 31 features were of the medium) were utilized. To sustain the cell-level information while making the dataset amenable for classification model building, a non-central gamma distribution with 3 parameters (i.e., alpha, beta, and delta) was fitted for each sample. This reduced the size of the dataset to 0.15 % (by a factor of approximately 3/2000) of its original size. Figure 1 shows example histograms and the fitted non-central gamma distribution for representative compounds 100 μ M Genistein, 100 μ M Fenarimol, and 10 μ M 4-Nonylphenol, and features array total pixel intensity (PI), array mean PI, and array circularity, respectively. In these plots, alpha, beta, and delta, the parameters of the fitted gamma distributions, are shown in the legends. These characteristic shape parameters were calculated for every feature, compound, and concentration.

Figure 1. Non-central gamma distribution fit on the cell-level data for reference compounds. The values of the characteristic shape parameters alpha, beta, and delta are listed on the legends.

Once the parametrization of the dataset is complete, the outliers in each feature-parameter were removed. Following, the dataset was column-wise scaled using the minimum-maximum scaling procedure. Then, for each feature, the data for alpha was plotted against beta, and beta was plotted against delta for all the compounds and concentrations to visualize the distribution of agonist and antagonist compounds in the parametrized space. Figure 2 shows a representative set of plots of alpha versus beta and beta versus delta for the “Nucleoplasm Pixel Intensity (PI) Variance” feature, which quantifies the statistical variance of GFP-ER α pixel intensity in the nucleoplasm of the cell. The visualization results show that agonist and antagonist data points mostly separate into two distinct groups. Yet, several data points belonging to the opposite classes are very close to each other, indicating that a model using linear classification algorithms may not result in high accuracy prediction.

Similar trends were observed for almost all the features. Therefore, the elimination of less indicative features by this qualitative assessment could not be made. To follow this observation with quantitative analysis, we performed Principal Component Analysis (PCA). The PCA results showed that 19 components out of 117 accounted for 90 % of the variance in the original data and 40 components out of 117 accounted for 99 % of the

variance in the data, indicating that the variability across many features in the dataset was similar and not distinct. This result is different from our previous study for the population-averaged data where 5 top informative features led to satisfactory linear and nonlinear classification results (Mukherjee et al., 2020). Note however that the dataset and pre-processing strategies used in the previous study were different from those in this study. Nevertheless, the qualitative difference is noteworthy.

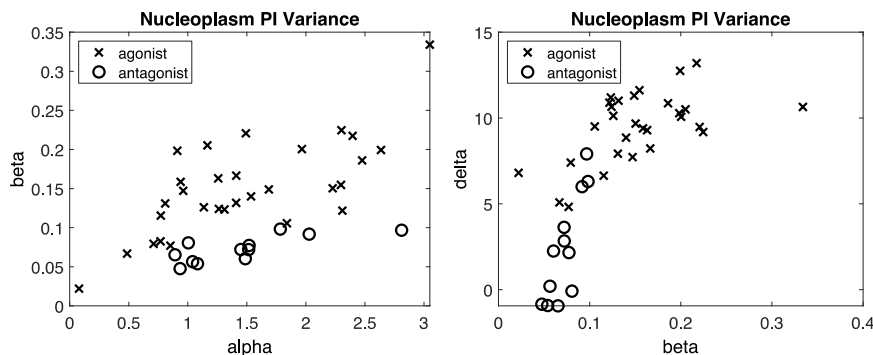

Figure 2. Alpha vs. beta and beta vs. delta plots to visualize the grouping of compounds per feature per concentration based on their estrogenic potentials.

4. Data-Driven Model Building: Nonlinear Classification Algorithms

Once the pre-processing step was completed, the following supervised learning models were built to predict the estrogenic potential of chemicals as agonists or antagonists: (1) The RF classifier, (2) 1-class nonlinear SVMs for predicting agonist or antagonist classes, and (3) 2-class nonlinear SVM. RF fits several decision trees on various sub-samples of the data and uses averaging to improve the accuracy of the classifier prediction and control over-fitting. 2-class SVM finds the optimal separating hyperplane to maximize the width of the gap between the two categories. In 1-class SVM, the width is maximized with respect to the category used for training and the rest are regarded as anomalies.

Figure 3. Algorithm for classification model building.

We follow the steps outlined in Figure 3 for building our classification models using the experimental image analysis data. 70% of the dataset per replicate was used for training and the remaining 30% was used for testing. After dimensionality reduction, in RF, a recursive addition algorithm was followed for simultaneous feature selection and model building. In this method, an RF model using all the features was built and the features were ranked according to their importance in model prediction. Following, the accuracies of model predictions using recursive addition of features in the model were recorded. The

model (and thus features) with the maximum accuracy was selected. In both 1-class and 2-class SVMs, the radial basis function kernel was used, and the model parameters were tuned to maximize the accuracy of prediction of the testing dataset using grid search.

5. Results and Discussions

Table 1. Testing performance of the RF, 1-class SVM, and 2-class SVM classification models.

	Accuracy	Precision	Sensitivity	Specificity	F-Score
RF	0.875	1	0.6	1	0.75
1-class SVM (agonist)	0.763	1	0.763	-	0.865
1-class SVM (antagonist)	0.72	1	0.72	-	0.837
2-class SVM	0.925	0.952	0.8	0.982	0.869

Table 1 lists the model prediction summary statistics for all the model types. For the RF model, the recursive feature addition step resulted in 61 features to be selected out of 117 to yield the maximum predictive accuracy. The final RF model predicts the test data with an accuracy of 87.5%. It correctly classifies 55/55 agonist samples, whereas 10 out of 25 antagonist samples are misclassified as agonists where the prediction sensitivity is 0.6 and the precision is 1. The two antagonist compounds, namely ICI 182 780 and AZD 9496, are misclassified in all 5 replicate datasets. Interestingly, these two chemicals are unique in the tested set of ER α antagonists in that they are known to destabilize ER α expression via the same pathway activated by ER α agonists. As these two chemicals mechanistically resemble agonists, the classification model cannot distinguish them as antagonist chemicals.

Furthermore, the 1-class SVM predicts the agonist class with an accuracy of 76% and the antagonist class with an accuracy of 72%, which are lower than the RF model. The 2-class SVM model, predicts the outcome of the test data correctly with an accuracy of 92.5%, the highest among all analyzed classification models whereas the specificity of the 2-class SVM is reported to be less than the RF model. However, it is observed that the 2-class SVM is more sensitive towards classifying antagonist compounds correctly where ICI 182 780 is correctly classified as antagonist for all replicates by the 2-class SVM. On the other hand, the RF is more precise when classifying agonist compounds correctly where 7,4'-Dihydroxyisoflavone, a weak agonist is misclassified as an antagonist by the 2-class SVM. Therefore, if the dataset has a considerable number of antagonist compounds, then the 2-class SVM will provide higher predictive accuracy, else, the RF will outperform.

6. Conclusions

High-throughput microscopy and single-cell image analysis followed by machine learning were used to predict the ER α activity of environmentally relevant chemicals. Dimensionality reduction was performed on the experimental big-data by fitting a non-central gamma probability distribution function. The scaled characteristic shape parameters of the distribution were used as the features for the classification analysis. Among three different nonlinear classifiers tested, namely the Random Forest (RF) algorithm, the 1-class Support Vector Machine (SVM), and the 2-class SVM, the 2-class SVM predicted the outcome of the test data with the highest accuracy of 92.5%, compared to 87.5% for the RF, and 73.3% and 72% for the 1-class SVMs, respectively. Overall, it

is observed that cell-level information increases the complexity of data handling, analysis, and model building steps. We believe that this study will encourage researchers to investigate further the trade-offs between obtaining additional information from cell-level measurements and increasing the complexity of big-data handling and classification model development. This research was funded by the U.S. National Institutes of Health (NIH) grant P42 ES027704.

Abstract

Li-ion batteries are a popular choice of rechargeable battery for use in many applications like portable electronics, automobiles as well as stationary applications for providing uninterruptable power supply. State of Charge (SoC) and State of Health (SoH) are important metrics of a Li-ion battery that can help in both battery prognostics and diagnostics for ensuring high reliability and prolonged lifetime. The ML algorithms available in the literature for SoC and SoH prediction involves use of various derived features rather than directly measurable features making it difficult for industrial applications. In this work, we use battery data obtained from different batteries to develop supervised models that can be used for the on-line estimation of SoC and SoH. This work involves two parts: a) developing a classifier based on SoH b) dynamic prediction of battery SoC given the past operational data of current, voltage, and temperature of the battery which are easily measurable. Random forest algorithm is used for battery site classification based on the SoH data available from the manufacturer. The battery SoC estimation is performed using a random forest algorithm and Neural network-based NARX model.

Keywords: Li-ion battery prognostics, SoH, SoC, Random forest, NARX.

1. Introduction

Lithium-ion batteries are widely used rechargeable batteries in electric cars, smartphones, laptops, and telecommunication base stations due to their high reliability, high energy density, high efficiency and long cycle life. Since their invention in the late 20th century, Li-ion batteries have established themselves as the frontrunner of rechargeable batteries in providing power solutions across several fields such as military, aerospace, medical, telecommunication, residential, and industrial applications. To ensure a prolonged lifetime as well as optimum performance, it is necessary to continuously evaluate the health condition of the battery. Battery health prognostics refers to the task of assessing the current health of the battery and forecast degradation and detect the occurrence of any abnormalities. For developing reliable techniques for battery health prognostics, accurate estimation of State of Charge (SoC) and State of Health (SoH) plays a major role. SoC is the ratio of available charge in a battery to the maximum attainable charge in that battery at its current health. Although there exist numerous techniques for SoC estimation, there is no technique that meets all the requirements for accurate estimation of SoC online. SoH is an overall battery health indicator that quantifies the deviation of battery behavior from its ideal behavior. Unlike SoC that is well-defined mathematically (though difficult to accurately estimate), there is no unique mathematical representation for SoH as health is a broader concept than what can be represented using a single numerical value.

SoH is an important diagnostic and prognostic measure for battery operation. At any instant of operation, the knowledge of the battery's SoH will help the user to make informed decisions. It is undesirable to operate a battery below a threshold value of SoH as it may result in short-circuiting, thermal runaway and explosion. If a user can a-priori know the SoH, it is possible to predict when the battery may fail.

The objective of this work is to build models using actual battery data collected from four different batteries that could be used for two purposes: develop a classifier based on SoH and perform dynamic prediction of battery SoC given the past operational data (current, voltage, and temperature) of the battery. An online data-based SoC estimator can help the user to decide the range, when to recharge etc and can be implemented in online battery management systems. A historic data-based SoH classification algorithm can help in identifying the current SoH of a battery and can help the user to make decisions on the operating conditions of the battery. Additionally, the dynamic variation of SoC depends on the battery's SoH. Hence, the information derived from the SoH classifier can help in better prediction of SoC in a battery.

1.1. Battery State of Health

Battery state of health is largely identified as a measure of the battery aging process due to capacity degradation or power fade. Estimating battery SoH can help in predicting when the battery should be removed from operation. Since battery health is a difficult measure to quantify, battery SoH is defined in literature as the ratio of the maximum available capacity to the battery nominal capacity. The capacity of the battery could degrade over its operational period due to voltage effects (over-voltage, under-voltage or over-discharge), thermal effects (thermal runaway, reduced power due to low-temperature operation), and mechanical effects (expansion/contraction of electrodes, mechanical stress) (Suresh et al., 2016). When the battery SoH drops below a critical value, the battery is considered to be of poor health and is removed from operation. A newly produced battery would have 100% SoH. The determination of battery SoH is a challenging task as it cannot be directly measured. Several methods are reported in literature for SoH estimation, which includes using battery capacity degradation models developed using first principles models and battery state estimators and data-based lifetime estimation models developed using algorithms like fuzzy logic or neural networks (NN) trained using data collected from accelerated aging experiments (Berecibar et al., 2016; Severson et al., 2019). However, these techniques use various derived features as input and hence, are difficult to implement for industrial applications.

1.2. Battery State of Charge

One of the tasks of the Battery Management System (BMS) is the accurate estimation of the energy stored within the battery for its efficient utilization by avoiding situations of over-charge and over-discharge in a battery. The battery SoC is a physical quantity of the battery that is related to the average Li^+ ion concentration in the negative electrode, which in turn is related to the passage of current during charging or discharging. The battery SoC is a derived quantity and cannot be measured directly. There are various model-based SoC estimation methods where the model could be first principles-based, surrogate first principles-based, data-based or hybrid models (Suresh et al., 2016). Neural network is a powerful and scalable machine learning (ML) tool that can handle multiple inputs and outputs and has good generalization and self-learning abilities. This makes NN suitable for modeling battery characteristics for SoC estimation. Multilayer perceptron architecture trained using the backpropagation algorithm has been used by researchers to model a battery using labeled charge-discharge cycling data available in various

repositories that are obtained through carefully designed experiments. Some of the works cited in the literature (Chemali et al., 2018) use NNs to predict the SoC using battery states such as measured current, voltage, temperature, remaining capacity assuming that the samples are independent of each other. However, the SoC in a battery not only depends on the present values of the independent features like current and voltage, but it also depends on the path taken to reach the present state. In other words, SoC at any time t also depends on the past values of SoC, current, voltage, etc. To account for these causalities, a NN-based NARX (non-linear auto-regressive model with exogenous inputs) model is used in this paper as it has capabilities for time-series modeling, unlike a regular neural net.

2. Battery Data

The data is collected from 48V-3.9kWh battery modules with NCA (Nickel Cobalt Aluminum) electrochemistry used for telecommunication application. The battery module consists of 14 cells, PCBs, and a built-in Battery Management System (BMS). A new battery has 100% SoH, which implies that it has full capacity when it is completely charged. When the battery reaches its end of life, the value of SoH variable is 0%, and this indicates that the battery capacity is 70% of what it had at the beginning of its life. The module starts discharging whenever the network voltage drops below the battery terminal voltage with a lower cut-off voltage of 42Vdc. The module recharges with a constant current/constant voltage (CC/CV) profile when the terminal voltage of the battery drops below the network voltage with an upper cut-off voltage of 56 Vdc. The time-series data for the module charge/discharge current, maximum module temperature, module voltage, SoC and SoH sampled at every 10 minutes is collected from battery modules in four different health condition defined as Site I (100% SoH) , Site II (74% SoH), Site III (49% SoH) and Site IV (24% SoH) over two different time periods named as Dataset 1 (total 24735 data samples) and Dataset 2 (27503 data samples).

3. SoH Classification

The objective is to identify the health status of the battery by building a model using the current, voltage, temperature, and SoC data from the four sites as input features for capturing the underlying behavior and predict the SoH for a new test dataset. An ensemble supervised learning technique of random forest classifier is implemented for classifying the data samples collected from the battery to determine the health of the battery. The random forest classifier is a versatile classification tool that makes an aggregated prediction using a group of decision trees trained using the bootstrap method with extra randomness while growing trees by searching for the best features among a randomly selected feature subset. The input features are first scaled using Min-Max normalization to bring all values into the range $[0, 1]$. 70% of the total data in Dataset 1 (17314 samples) is used for training, and the remaining 30% (7421 samples) is used for testing the predictive ability of the classifier for the same dataset.

Accuracy is the fraction of samples that are correctly identified with respect to the total number of samples tested. Among 7421 test samples, the algorithm correctly identified 6447 samples and hence, the accuracy is 86.87%. The performance of the developed classifier on the test set of Dataset 1 is evaluated using various metrics and is provided in Table 1 along with the confusion matrix. It could be observed that the recall for Site II data is 0.52, which implies that around half the Site II data points were misclassified.

To determine the ability of the developed model in predicting the SoH for a different instant of operation, we tested the developed model on Dataset 2. The input features of Dataset 2 scaled using Min-Max normalization (based on the training data set used for developing the classifier) is used for determining the SoH. The classification using the random forest model yielded an accuracy of 53.19%. Out of the total mislabelled samples, 51% of samples are from Site II. The confusion matrix and various performance metrics for Dataset 2 are presented in Table 2. The precision, recall, and F1 score of Site II are very low compared to other classes indicating that for all the data points that truly belongs to Site II, the percentage of them being labeled as Site II is only 8%, i.e., the number of false negatives is higher for Site II data. It is possible that the true data for Site II is flawed. Site I has very large false positives (Type I error) while site IV has the highest Type II error (False negatives). Site III data has an overall low F1 score.

4. SoC Prediction

A random forest model using time-lagged variables from Site I data of Dataset 1 was implemented to predict the dynamic variation of SoC. The input and output orders were assumed to be 2. When tested on Dataset 2, the model always predicted SoC to be greater than 40%, even though the true SoC was varying between 20% to 100% (ref Figure 1). Whenever the true SoC was below 40, the model predicted it to be close to 40%. The training data obtained from the battery site 1 had battery SOC values in a limited range and did not span the entire 0-100%. Thus, the model was not able to generalize well and

the prediction was of poor quality as shown in the parity plots (Figure 1). NN-based NARX model was used later to improve the quality of SoC prediction.

NARX is a time series modeling method used for modeling non-stationary and non-linear multivariate time series. The NARX model is described by the following equation:

$$y(t) = F(u(t - d_u), \dots, u(t - 1), u(t), y(t - d_y), \dots, y(t - 1)) \quad (1)$$

$u(t)$ and $y(t)$ represent input and output of the model at time t , F is a non-linear function, and d_u and d_y are the input and output order, respectively. The process time delay is assumed to be 0. NARX neural network model is a dynamic recurrent neural network consisting of a feedback connection between its layers. The network prediction is a weighted sum of non-linearly transformed regressor variables. A two-layer feedforward NARX network is used in this work with a hidden layer having a sigmoid transfer function and the output layer having a linear transfer function. The previous values of the input variables and the predicted output variables are stored using tapped delay lines. The output, $y(t)$, being a function of its past values, is sent back to the input layer of the network (through delays). Series-parallel architecture is used to train the network for more accurate predictions using the observed values of battery SoC instead of feeding back the estimated SoC values. This open loop configuration thus becomes similar to feed-forward architecture, where backpropagation could be used for training the network. The model is built using battery current, voltage, temperature, and battery SoH as input features. The SoH information used for SoC prediction is the measured values obtained from battery sites. In case there is no SoH information available, the SoH classifier mentioned in the paper could be used to estimate the SoH, and the accuracy of the SoC prediction will depend upon the accuracy of the classifier. The values of d_u and d_y are assumed to be 2.

Table 1: Confusion matrix and performance metrics of the 4-class SoH classifier on Dataset 1

Dataset 1		Predicted				Dataset 1	Precision	Recall	F1 score
		Site I	Site II	Site III	Site IV				
Actual	Site I	1830	87	114	0	Site I	0.9	0.9	0.9
	Site II	158	738	514	3	Site II	0.84	0.52	0.64
	Site III	40	48	1903	2	Site III	0.75	0.95	0.84
	Site IV	0	6	2	1976	Site IV	1	1	1
						Avg\total	0.88	0.87	0.86

Table 2: Confusion matrix and performance metrics of the 4-class SoH classifier on Dataset 2

Dataset 2		Predicted				Dataset 2	Precision	Recall	F1 score
		Site I	Site II	Site III	Site IV				
Actual	Site I	6813	229	111	5	Site I	0.47	0.95	0.62
	Site II	6270	543	343	3	Site II	0.22	0.08	0.11
	Site III	1073	1528	3445	58	Site III	0.53	0.56	0.55
	Site IV	489	131	2628	3835	Site IV	0.98	0.54	0.74
						Avg\total	0.55	0.53	0.49

70% of the data available for Site I (4642 samples) is used for building the predictive model, and 15% (995 samples) is used for the validation step that ensures network generalization. The remaining 15% of the data from Site I data (995 samples) is used for testing the model. The SoC estimation model is tested on the data from Site II, Site III and Site IV. A single hidden layer is used and the number of neurons in that hidden layer is set to 3. The network is trained using the Levenberg-Marquardt algorithm. The neural net model at epoch 38 was chosen as the best model as it had the least validation error. The training, validation and testing results on Site 1 data of Dataset 1 show very good performance with small RMSE values and R^2 values close to 1 (refer Table 3). SoC prediction using the developed model on Sites II, III and IV of Dataset 1 also show good performance with R^2 values above 0.95 as shown in Table 3. The linear model that best

fits true SoC and predicted SoC for the test set almost coincides with the 45-degree line indicating the goodness of the model as shown in the parity plots presented in Figure 2. Using the NN model built with Site I data of Dataset 1, SoC values are predicted for all the four sites' data in Dataset 2. The results are presented in Figure 3 and Table 4. It could be observed that the model predicts the SoC values for all four classes reasonably well with R^2 values greater than 0.94 in all cases.

Table 3: Performance metrics of NARX neural network on Dataset 1

Site I: Dataset	Mean of residual	Variance of residual	RMSE	R^2	Dataset 1	Mean of residual	Variance of residual	RMSE	R^2
Traihing	3.6×10^{-5}	7.3×10^{-5}	0.008	0.97	Site II	-0.054	0.793	0.892	0.957

Site IV	-0.007	0.533	0.730	0.983

5. Conclusion

This paper has two major contributions to battery health monitoring. Firstly, a data-driven model is built using a random forest algorithm on BMS data and is able to determine the health condition of the battery and identify whether it is in good, bad, worse, or worst health. This is critical as battery SoH degradation affects the accurate estimation of battery SoC. Secondly, a NN-based NARX model is developed for SoC estimation taking into consideration the non-linearity, dynamic nature and SoH of the system. The accuracy of predictions shows that the machine learning approaches trained using actual battery data could provide prognostic solutions to battery health management without the need for a complex physics-based model. The future work aims to develop a predictive model for estimating the remaining useful life of battery based on a hybrid model built using battery data and first-principles model for capacity degradation.

The Adaptive Radial Basis Method (ARBM): An application to the hydrodynamics of liquid-liquid dispersions

Abstract

In industrial unit operations involving liquid-liquid dispersions, switching to model based prediction is essential for equipment design, scale-up and control purposes. In this regard, an Adaptive Radial Basis Method (ARBM) is presented to model the hydrodynamics behaviour of liquid-liquid dispersions, based on the Population Balance Equation (PBE). In this meshfree method, the number density function is expanded by a series of Gaussians (GA) basis at a finite number of particles along the droplet diameter. The supporting particles are allowed to move to change their locations, based on the distribution properties, to accurately track the dynamic evolution of the number density function. Moreover, the Leave-One-Out Cross Validation (LOOCV) algorithm is adapted to optimize the GA shape parameter in a statistical sense. Accordingly, the ARBM neither inverts badly scaled matrices nor requires large number of collocation particles to reconstruct the distribution shape. The ARBM predictions are validated for stirred tank reactors at different levels. The results revealed that, the method is conservative and able to handle sharp and wide distributions, resulting from breakage and coalescence dominant processes respectively. Based on this, the ARBM is convenient and suitable to model liquid-liquid dispersions.

Keywords: ARBM, PBE, breakage and coalescence, Liquid-liquid dispersions

1. Introduction

Liquid-liquid dispersions are very common in different unit operations ranging from batch stirred tank reactors to solvent extraction columns. In such unit operations, the droplet size distribution is the key parameter, which determines the overall efficiency and the range of the operating conditions. Therefore, an accurate prediction of the size distribution is of prime importance. Due to the growing computational power, the computer-based design approach and process digitalization have gained more attention recently. Consequently, there is a growing demand toward rigorous models, which are able to take all of the possible hydrodynamics interactions into account, to describe the prevailing physical behaviour. Unlike the lumped models, which ignore the discreet nature of the dispersion, the population balance model is based on more fundamental basis to account for the local droplet-droplet interactions, which include the breakage and coalescence phenomena. The PBE has a complex integro-differential form and hence analytical solutions are limited to simplified special cases. As a result of this, intensive research efforts have been carried out to develop efficient numerical methods, in terms of

accuracy and computational cost, to solve the PBE. These methods can be categorized into three main groups namely: stochastic Monte Carlo, moments-based and sectional methods. For more information about these methods, the reader can refer to Kumar and Ramkrishna (1996). In a recent work, a novel Radial Basis Method (RBM) (Alzyod and Charton, 2020) to solve the PBE was presented. The RBM avoids the typical numerical diffusion problems, encountered when applying the sectional methods, and conserves the number density function, which is lost when using the moments based methods. In spite of the RBM accuracy, more collocation particles may be required when dealing with sharp or wide moving distributions, for which additional computational efforts may be required. This inherent problem is also reported in the radial basis functions literature, where a set of adaptive particles can be used to avoid it (Driscoll and Heyudono, 2007). Therefore, the main concern of this work is to derive an adaptive version of the RBM to overcome this fundamental problem.

2. Solution of the PBE using the Adaptive Radial Basis Method (ARBM)

In a homogenous space, the dynamic evolution of the number density function, $n(d, t)$, accounting for breakage and coalescence is given by (Kumar and Ramkrishna, 2000):

$$\begin{aligned} \frac{\partial n(d, t)}{\partial t} = S\{n(d, t)\} = & -\Gamma(d)n(d, t) + \int_d^\infty \Gamma(d)\beta(d/d')n(d', t)\delta d \\ & - n(d, t) \int_0^\infty \omega(d, d')n(d', t)\delta d + \frac{d^2}{2} \int_0^d \eta^{-2/3}\omega(\eta, d')n(\eta, t)n(d', t)\delta d \end{aligned} \quad (1)$$

Where d is the droplet diameter, $\eta(d, d') = \sqrt[3]{d^3 - d'^3}$, $\Gamma(d)$ is the breakage kernel, $\beta(d/d')$ is the daughter distribution function, and $\omega(d, d')$ is the coalescence kernel respectively. The main idea behind the ARBM is to replace the unknown nonnegative number density function appearing in Eq.(1) by a series of converging GA radial basis kernels:

$$\hat{n}(d(t), t) = \left(\sum_{j=1}^{N_c} \lambda_j(t) e^{-\left(\varepsilon_p r_j(d(t))\right)^2} \right)^2 \quad (2)$$

Where $\hat{n}(d(t), t)$ is the reconstructed number density function, $\lambda_j(t)$ is the weighting coefficient, and ε_p is the shape parameter. The norm $r_j(d(t)) = \|d(t) - d_j(t)\|$ represents the Euclidean distance between d and the centre particles d_j . Here, the centres are allowed to change their locations, to track the moving density function as follows:

$$d_j(t) = d_1(t) + \left(\frac{d_{N_c}(t) - d_1(t)}{N_c - 1} \right) (j - 1) \quad j = 1, \dots, N_c \quad (3)$$

Where $d_j(t) \in [d_1(t), d_{N_c}(t)]$. The values of $d_1(t)$ and $d_{N_c}(t)$ are calculated using the first three low-order moments as follows:

$$d_{1, N_c}(t) = \frac{\mu_1}{\mu_0} + \left(1 \mp 6\sqrt{\mu_1\mu_2/\mu_1^2 - 1}, \varepsilon_m \right) \quad (4)$$

Where $\mu_k(t)$ is the k^{th} moment, ε_m is the machine epsilon and the operator $\langle \cdot \rangle$ is used to maintain the maximum positive value. Note that, the adapted centers are distributed around the arithmetic mean (μ_1/μ_0) . Therefore, in case of very sharp distributions (approaching zero variance) the ARBM is still able to reconstruct the distribution located at the mean particle location. To reconstruct the number density function, the required unknown weighting coefficients $(\lambda_j(t))$ appearing in Eq.(2) can be calculated by enforcing the condition: $\sqrt{\hat{n}(d_j(t),t)} = \sqrt{n(d_j(t),t)} = s_j(t)$ for all $j = 1, \dots, N_c$ at the adaptive moving particles, which results in following linear system of equations:

$$\begin{bmatrix} s_1(t) \\ s_2(t) \\ \vdots \\ s_{N_c}(t) \end{bmatrix} = \begin{bmatrix} 1 & e^{-(\varepsilon_p \|d_1(t)-d_2(t)\|)^2} & \dots & e^{-(\varepsilon_p \|d_1(t)-d_{N_c}(t)\|)^2} \\ e^{-(\varepsilon_p \|d_2(t)-d_1(t)\|)^2} & 1 & \dots & e^{-(\varepsilon_p \|d_2(t)-d_{N_c}(t)\|)^2} \\ \vdots & \vdots & \ddots & \vdots \\ e^{-(\varepsilon_p \|d_{N_c}(t)-d_1(t)\|)^2} & e^{-(\varepsilon_p \|d_{N_c}(t)-d_2(t)\|)^2} & \dots & 1 \end{bmatrix} \begin{bmatrix} \lambda_1(t) \\ \lambda_2(t) \\ \vdots \\ \lambda_{N_c}(t) \end{bmatrix} \quad (5)$$

This system of equations can be expressed in a compact matrix form as: $S = \phi\lambda$, where ϕ is the radial basis matrix. Note that, ϕ is a real symmetric and positive definite square matrix and hence the resulting linear system of equations has always a unique solution. Indeed, solving this system of equations requires inverting the radial basis matrix, which may lead to inaccurate results if it is nearly singular. To avoid this problem, a proper shape parameter value can be used to minimize the condition number of ϕ . To achieve this, the LOOCV algorithm of Rippa (1999) is adapted and utilized to find the optimal shape parameter value. In this algorithm, the optimal shape parameter is obtained by minimizing the following objective function:

$$e(\varepsilon_p) = \sum_{j=1}^{N_c} |\hat{n}(d_j, t) - n(d_j, t)|^2 = \sum_{j=1}^{N_c} |\lambda_j / \phi_{j,j}^{-1}|^2 \quad (6)$$

Here, $e(\varepsilon_p)$ is the error between the reconstructed and targeted distributions respectively, $\phi_{j,j}^{-1}$ is j^{th} diagonal element of the inverse of radial basis matrix ϕ^{-1} . Note that, using Eq.(6) allows us to minimize the objective function without any prior information about the targeted distribution. Based on this, the resulting linear system of equations given by Eq.(5) can be solved using Cholesky decomposition based on the obtained optimal shape parameter value. Finally, by applying the collocation method at the adapted moving particles locations, Eq.(1) is transformed into the following system of ordinary differential equations:

$$\frac{\partial \hat{n}(d_j(t), t)}{\partial t} = S \{ \hat{n}(d_j(t), t) \} \quad j = 1, \dots, N_c \quad (7)$$

3. Model validation and discussion

This section is devoted to test the ARBM performance. In this regard, the explicit forward first-order Euler's method is implemented to solve the ARBM with a constant time step of $\Delta t = 0.01$ s. Moreover, the integral source terms are approximated using Gauss-Legendre quadrature. To obtain the optimal shape parameter value, a constrained LOOCV-optimization problem is solved using the MATLAB *fmincon* solver. All of the numerical experiments were carried out using a Laptop with 4 GB RAM and 2.4 GHz speed performing a single task.

3.1. Case one: Analytical validation

The first case study is devoted to validate the ARBM predictions analytically for combined breakage and coalescence processes in a uniform stirred tank reactor. In this regard, the analytical solution of McCoy and Madras (2003) is used as a reference solution. The initial locations of the adapted particles are calculated from the initial condition ($3d^2 \exp(-d^3)$). Moreover, a constant coalescence kernel ($\omega = k_c$) is considered, while a power function is assumed for the breakage kernel ($\Gamma(d) = k_b d^3$). The simulation is performed using 25 adaptive particles and the final simulation time is set to 15 s. Figure (1) shows a comparison between the numerical the analytical solutions for two breakage and coalescence dominate cases at three selected time steps: 0, 5 and 15 s respectively.

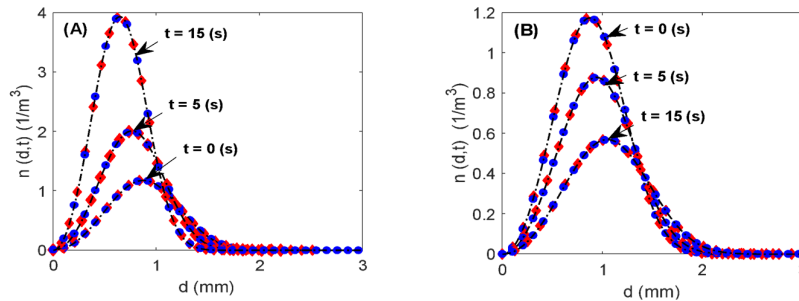

Figure (1): Comparison between the ARBM predictions at the moving particles (diamonds), and at selected stationary particles (circles) and the analytical solution (McCoy and Madras, 2003) (dashed line): (A) Breakage dominant process ($k_b = 0.1$, $k_c = 0.001$). (B) Coalescence dominant process ($k_b = 0.001$, $k_c = 0.1$).

It can be observed that, the adapted particles are able to track the moving distribution for both cases. Therefore, the ARBM reconstructs accurately the shape of distribution at the selected stationary points as compared with the analytical solution. To check the ARBM consistency, the first four low-order moments of the number density are computed and compared with the corresponding analytical moments as depicted in Figure (2). It is clear that, the total number of droplets (μ_0) increases with time for the breakage dominant case, while it decreases for the coalescence dominant case. Moreover, the total volume (μ_3) remains constant as expected for both cases since the total volume of droplets is conserved. Therefore, it can be concluded that the ARBM is a conservative method. An excellent agreement between the numerical and the analytical moments is evidenced.

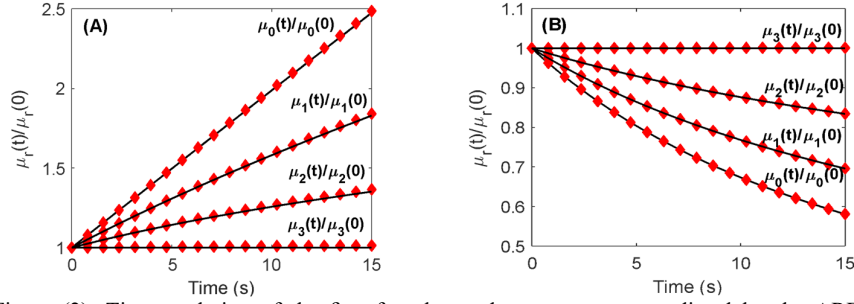

Figure (2): Time evolution of the first four low-order moments as predicted by the ARBM (diamonds), and comparison with the analytical solution (line): (A) Breakage dominant process ($k_b = 0.1$, $k_c = 0.001$). (B) Coalescence dominant process ($k_b = 0.001$, $k_c = 0.1$).

3.2. Case two: Numerical and experimental investigations

In the second case study, the ARBM is numerically validated using the RBM (Alzyod and Charton, 2020) and the Fixed Pivot Technique (FPT) (Kumar and Ramkrishna, 1996). In this regard, the reported experimental data by Qi et al., (2015), in a stirred tank, is used as a reference solution. The chemical test system is heptane in chloroaluminate. Here, the rotational speed is fixed at 500 rpm, while the holdup (α_d) is varied between 0.1 and 0.5 respectively. A normal distribution is used as an initial condition $(a \cdot \exp(-0.5((d - \bar{d})/\sigma)))$.

Concerning the hydrodynamics kernels, the breakage and coalescence kernels are given by (Coualoglou and Tavlarides, 1977):

$$\Gamma(d) = c_1 \frac{\varepsilon^{1/3}}{d^{2/3}(1 + \alpha_d)} \exp\left(-\frac{c_2 \sigma_d (1 + \alpha_d)^2}{\rho_c \varepsilon^{2/3} d^{5/3}}\right) \quad (8)$$

$$\omega(d, d') = c_3 \frac{\varepsilon^{1/3}}{1 + \alpha_d} (d + d')^2 (d^{2/3} + d'^{2/3})^{1/3} \exp\left(-\frac{c_4 \eta_c \rho_c \varepsilon}{\sigma_d^2 (1 + \alpha_d)^3} \left(\frac{dd'}{d + d'}\right)\right)^4 \quad (9)$$

Here c_1 , c_2 , c_3 and c_4 are fitting parameters. These parameters, as well as the initial distribution parameters, are estimated by solving an inverse PBE problem based on the ARBM and kept the same for the RBM and the FPT. The optimization is carried out, using MATLAB *fmincon* solver, to minimize the objective function: $F = \sum_i |n_i^{\text{exp}} - n_i^{\text{sim}}|^2$.

Based on this, the optimized parameters are shown in Table (1).

Table (1): Hydrodynamics optimized parameters

Holdup	a	\bar{d} (mm)	σ (mm)	C_1	C_2	C_3	C_4
0.1	0.1679	0.0892	0.0162	0.5	500.1971	0.3369	482.6460
0.5	0.2267	0.1052	0.0176	0.5	500.1971	0.6461	482.6461

Figure (3) depicts a comparison between the simulated steady state number density function, for two dispersed phase volume fractions, using the three numerical methods and the reported experimental data. A very good agreement is obtained for both cases using the same optimized parameters for all of the numerical methods.

Figure (3): Comparison between the simulated number density and the experimental data at two different dispersed phase holdup values.

4. Summary and Conclusions

The ARBM is introduced to solve the PBE for breakage and coalescence. The method is validated analytically and numerically at different conditions. The ARBM is found to be conservative and able to track the moving number density thanks to the adaptive particles. To assess the ARBM performance, an experimental case study is presented to simulate the hydrodynamics of a stirred vessel. The required kernels parameters are estimated by solving an inverse PBE problem, where a positive validation is obtained.

Abstract

This paper deals with modeling and multi-criteria optimization of an industrial phosphoric acid process. More specifically, the digestion tank where the phosphate ore is attacked by a concentrated solution of sulfuric acid is considered. A process model is first developed based on mass and heat balances along with Pitzer's thermodynamic equation. It is then identified by means of a set of data made up of experimental measurements carried out and measurements taken from the literature. The resulting model is then used within a multi-criteria optimization problem to determine the optimal operating conditions that minimize the phosphate losses and increase the productivity of the phosphoric acid while meeting the constraints on the temperature and on the excess of sulfuric acid. The optimization problem is solved by means of the epsilon-constraint method and the results are consistent with the current operating conditions of the digestion tank. They also show that the implementation of optimal results on an industrial scale would significantly improve the performance of the tank and under maximum safety conditions.

Keywords: Modeling, Multi-criteria optimization, Wet-process, Measurements, Phosphoric acid, Phosphate ore.

1. Introduction

Phosphoric acid is mainly produced by digesting a phosphate-containing mineral (generally apatite) using a concentrated sulfuric acid solution. The digestion is carried out in the wet process which is by far the most common route to produce phosphoric acid. The main reaction that takes place in the digestion tank is highly exothermic and given by Becker (1989) as:

During the digestion, sulfuric acid H_2SO_4 dissociates into H^+ and SO_4^{2-} ions. The H^+ ions react with the phosphate compounds containing phosphorus to produce phosphoric acid H_3PO_4 , and simultaneously the SO_4^{2-} ions are captured by the calcium ions Ca^{2+} to produce solid calcium sulfate $CaSO_4 \cdot xH_2O$. The two reaction products are then separated in a filtration unit downstream of the digestion tank. Phosphoric acid is recovered and mainly used in the production of phosphate fertilizers, while the calcium sulfate is removed from the process as an unwanted by-product.

Figure 1: Schematic representation of an industrial phosphate digestion tank

On an industrial scale, the reaction is carried out in a cylindrical tank made up of nine continuous reactors in series, of the same volume and uniformly distributed. The tank is divided into three sections of three reactors each. Sulfuric acid feed flow rate is divided into three streams each feeding a section of the tank. The phosphate ore is fed into the first reactor of the first section and the product leaves the tank at the last reactor of the third section (Fig.1).

Depending on the operating temperature, the calcium sulfate can be gypsum $CaSO_4 \cdot 2H_2O$ or bassanite $CaSO_4 \cdot 0.5H_2O$. It is therefore very important to control the temperature in order to avoid the production of the bassanite since it increases the viscosity of the reaction mixture in the tank and consequently decreases the filtration performances. Moreover, sulfuric acid feed flow rate and its distribution ratios ($w_1; w_2; w_3$) over the three sections are relevant for optimal operation of the production unit. Indeed, a sulfuric acid deficit during the digestion step causes a decrease in the concentration of SO_4^{2-} ions and consequently the Ca^{2+} free ions tend to capture the phosphate-based ions of the same polarity. HPO_4^{2-} ions are more specifically captured to produce the solid brushite $CaHPO_4 \cdot 2H_2O$ thus decreasing the chemical yield of the process since all the solid phase is removed as an unwanted product. These losses are referred to as syncrystallized losses. Conversely, an excess of sulfuric acid causes on the one hand a local increase in temperature due to the heat of dilution, and on the other hand leads to an excessive production of calcium sulfate which forms a solid layer around the phosphate particles. This is referred to as the coating phenomenon which prevents the particles from further attack by sulfuric acid thus decreasing also the chemical yield. These resulting losses are termed unattacked losses.

In this paper, the objective is to determine the operating conditions of the digestion tank that minimize the phosphate ore losses (syncrystallized and unattacked) while meeting the constraints on the excess of sulfuric acid above the stoichiometric amount and on the reaction temperature. Beforehand, Pitzer's thermodynamic model, needed in optimization, is calibrated using experimental measurements.

2. Optimization problem formulation

The optimal operation of the process described above aims to determine the trade-offs between the following objectives: (i) limit the syncrystallized losses by minimizing the production of the brushite, (ii) improve the process productivity by maximizing the production of gypsum, (iii) minimize the unattacked losses by keeping the excess of sulfuric acid above the stoichiometric amount between two limit values set to ensure optimal operation of the process, (iv) control the reaction temperature in order to limit the production of the bassanite and consequently improve the filtration process downstream.

These objectives are taken into account in the formulation of a constrained multi-criteria optimization problem. The first two objectives are defined as optimization criteria while the last two objectives are taken as constraints. The objective functions, the decision variables, the equations of the process model and the constraints of the optimization problem are detailed in the next section.

2.1. Objective functions

In this optimization problem, the two (conflicting) optimization criteria used are defined by the saturation index of the brushite to be minimized all over the three sections of the digestion tank to limit its production, and the saturation index of the gypsum to be maximized to improve the productivity. The two indices are expressed as:

$$f_1 = \sum_j \log \left(a_{Ca^{2+}} a_{HPO_4^{2-}} k_{s_1}^{-1} \right)^j, \quad f_2 = \sum_j \log \left(a_{Ca^{2+}} a_{SO_4^{2-}} k_{s_2}^{-1} \right)^j \quad (1)$$

where a_j are the activities of the components in the reaction mixture, k_{s_1} and k_{s_2} are the solubility of brushite and gypsum respectively and, j refers to the number of the section.

2.2. Decision variables

The decision variables consist of sulfuric acid excess S_c over the stoichiometric amount required by the reactions, its distribution ratios over the three sections, i.e. ($w_1; w_2; w_3$), and the cooling heat Q_{cool} to be removed from the process to control the temperature.

2.3. Equality and inequality constraints

The constraints involved in the optimization problem include (i) the operating constraints of the process, (ii) and the model equations. Two operating constraints are more specifically involved in the problem. The first one sets the values of the upper and lower limits of the excess of sulfuric acid above the stoichiometric amount required by the reactions in order to minimize the unattached losses. These limits are set at 1 % and 3 % (Becker, 1989). The second one concerns the reaction temperature that should remain below 355 K to avoid the production of the bassanite:

$$1 \% \leq S_c \leq 3 \% \quad \text{and} \quad T \leq 355 K \quad (2)$$

The process model equations consist of material balance Eq. (3), charge balance Eq. (4), equations of equilibrium constants Eqs. (5-6), and heat balance Eq. (7).

$$(M)^{tot} = \sum_{i=1}^{NC} \delta_{M,i} m_i, \quad M \in \{S, P, F, Si, Ca\} \quad (3)$$

$$\sum_{i=1}^{NC} z_i \cdot m_i = 0 \quad (4)$$

$$K_j = \prod_{i=1}^{NC} (m_i \cdot \gamma_i)^{\alpha_{ij}}, \quad j = 1, \dots, NR \quad (5)$$

$$\log(K_j) = \log(K_{j0}) + \frac{\Delta H_j}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \quad (6)$$

$$Q_H + Q_{AG} + Q_{R+D} = Q_{cool} + Q_{out} \quad (7)$$

where NC and NR are the number of components and reactions respectively, $(M)^{tot}$ is the given total inlet concentration of element M (i.e. sulfur (S), phosphorus (P), Fluorine (F), silica (Si), calcium (Ca)), m_i is the unknown molality of the component i involved in the reactions listed in Table 1, $\delta_{M,i}$ is equal to the number of element M in component i . For example, the mass balance on (F) develops as: $(F)^{tot} = 6 m_{H_2SiF_6} + m_{F^-} + 6 m_{SiF_6^{2-}} + m_{HF} + 2 m_{HF_2^-}$. z_i are the electrical charges, γ_i is the activity coefficient of component i . $\alpha_{i,j}$ is the stoichiometric coefficient of component i involved in reaction j . K_{j0} and ΔH_j refer to the equilibrium constant and the enthalpy of the reaction j at $T_0 = 298 K$ respectively, their values are reported in Table 1. Q_H , Q_{AG} , Q_{R+D} , Q_{out} and Q_{cool} are the enthalpy of the inlet products, the agitation heat, the sulfuric acid dilution heat, the enthalpy of the slurry leaving the reactor and the heat to be removed from the process to control the operating temperature respectively.

In addition to the above equations, Pitzer's thermodynamic model (Pitzer, 2018) is used to compute the activity coefficients as:

$$\ln(\gamma_i) = \frac{z_i^2}{2} f + 2 \sum_j m_j \lambda_{i,j} + z_i^2 \sum_{j,k} m_j m_k \lambda'_{i,j} + 3 \sum_{j,k} m_j m_k \psi_{i,j,k} \quad (8)$$

where i, j, k refer to different components and f is the Debye-Huckel function. $\lambda_{i,j}$, $\lambda'_{i,j}$ and $\psi_{i,j,k}$ are the unknown Pitzer model parameters, they should be determined from the equilibrium measurements carried out in this work and presented in the next section. Furthermore, a suitable estimability analysis method is used to determine the most estimable parameters from the available experiments.

3. Experimental data

Different series of experimental measurements of sulfuric and phosphoric acid solutions have been carried out to measure the molalities of the ionic and molecular species involved in the reaction mixture. For all experiments, 98 w% sulfuric acid and 65 w% phosphoric acid are used to prepare several samples. The temperature and concentration of samples are varied respectively from 298 K to 353 K and from infinite dilution to 4 moles/kgw for sulfuric acid and 12 moles/kgw for phosphoric acid. Moreover, calcium sulfate solubility data are collected from the literature (Shen et al., 2020) they consist of gypsum and anhydrite solubilities for a large range of temperatures and concentrations.

4. Results and discussion

The estimability of the unknown parameters of Pitzer's model is carried out using our recently developed method (Bouchkira et al., 2021) and the most estimable parameters are identified by minimizing the mean-square error between the predictions of the model and the available experiments. As example of results, Figs. 2A-C show the sulfuric and phosphoric acid speciation and the calcium sulfate solubility at 298 K. The high values of the Pearson product-moment coefficient r show the good accuracy of the developed model. The multi-criteria optimization problem is then solved within *GAMS* environment using Baron solver based on a branch-and-reduce algorithm to achieve global optimality. The ε -constraint method (Deb, 2014) was used to transform the multi-criteria optimization problem into a single-objective optimization problem which is solved many times to determine the Pareto front. The *CPU* time needed to perform the simulations is about two hours using a Dell Precision T7810 Bi-Xeon 12 x Core 64GB workstation.

Figure 2: (A, B): Sulfuric and Phosphoric acids speciation, (C): Gypsum and Anhydrite solubility

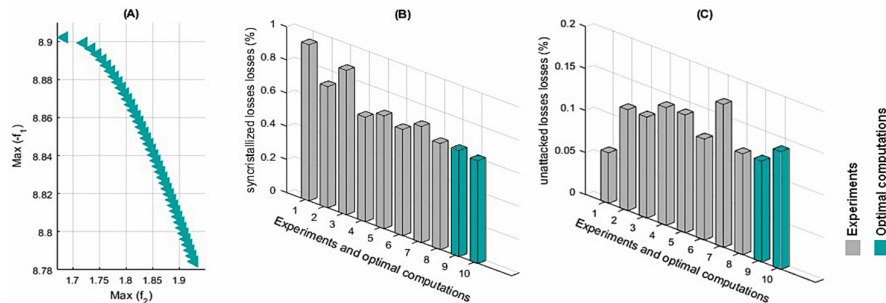

Figure 3: (A): Pareto Front, (B): Syncrystallized losses, (C): Unattacked losses

The Pareto front of the problem (Fig. 3A) shows that: (i) the brushite saturation index is negative for all the optimal solutions meaning that the syncrystallized losses are minimized, (ii) and the gypsum saturation index is positive meaning that the productivity of the industrial units is maximized. To better visualize the optimal solutions, four points of the Pareto front (Fig.3A) are shown in Table 2 with their corresponding decision variables, constraints, cooling heat and phosphate losses. It can be seen that for each point, as the conversion rate of digestion increases from the first to the last section, the demand for sulfuric acid varies in the opposite direction and decreases from the first to the third section for all the computed solutions (i.e., $w_1 \geq w_2 \geq w_3$). Furthermore, sulfuric acid excess lies between 2 % and 3 % which is consistent with the optimal conditions of gypsum crystallization (Becker, 1989). Finally, the heat quantities to be removed via the flash cooler (Fig.1) enable to meet the reaction temperature constraint in order to limit the bassanite production, and to improve the quality of the downstream filtration unit.

Figs. 3B-C show a comparison between industrial losses taken from (El Bouzidi, 2016; Bouchkira and El Fariq, 2017) and the results of two computed optimal solutions chosen from the Pareto front using the Multi-Attribute Utility Theory (Dyer, 2005). The computed solutions are very close to the industrial measurements which are obtained by performing several run-to-run on the plant by changing the values of the decision variables from one run to the next to improve the productivity and minimize the phosphate losses. Moreover, the values of the decision variables used to carry out industrial experiments are sub-optimal and must be adjusted depending on the composition of the phosphate ore which further increases the number of runs. It is easy to understand under these conditions that obtaining these measurements is very costly since it involves significant labor cost, consumes time and huge quantities of reagents, decreases the productivity of the plant and poses some safety issues. Modeling and multi-criteria optimization have proven to be effective since they provide optimal solutions that minimize the number, duration, cost of runs, and security risks.

Table 1: Equilibria involved in the digestion reaction (Aqueous phase)

Equilibria	K_{j0}	ΔH_j (J/mol)	References
1 $\text{H}_2\text{SO}_4 \rightarrow \text{HSO}_4^- + \text{H}^+$	-	-	-
2 $\text{HSO}_4^- \rightleftharpoons \text{SO}_4^{2-} + \text{H}^+$	0.0103	$-1.274 \cdot 10^4$	(Gustafsson, 2011; Pitzer, 2018)
3 $\text{H}_3\text{PO}_4 \rightleftharpoons \text{H}_2\text{PO}_4^- + \text{H}^+$	0.0071	$-4.271 \cdot 10^3$	(Gustafsson, 2011; Ball and Nordstrom, 1991)
4 $\text{H}_2\text{PO}_4^- \rightleftharpoons \text{HPO}_4^{2-} + \text{H}^+$	$4.2 \cdot 10^{-12}$	$-9.266 \cdot 10^3$	(Gustafsson, 2011; Ball and Nordstrom, 1991)
5 $\text{H}_3\text{PO}_4 + \text{H}_2\text{PO}_4^- \rightleftharpoons \text{H}_5\text{P}_2\text{O}_8^-$	0.2550	$-1.329 \cdot 10^4$	(Gustafsson, 2011)
6 $\text{HF} \rightleftharpoons \text{F}^- + \text{H}^+$	$7.2 \cdot 10^{-4}$	$-1.329 \cdot 10^4$	(Gustafsson, 2011)
7 $\text{HF} + \text{F}^- \rightleftharpoons \text{HF}_2^-$	$0.3 \cdot 10^2$	$-4.799 \cdot 10^4$	(Gustafsson, 2011)
8 $\text{H}_2\text{SiF}_6 \rightleftharpoons \text{SiF}_6^{2-} + 2\text{H}^+$	$0.3 \cdot 10^2$	$-4.799 \cdot 10^4$	(Gustafsson, 2011)
9 $\text{CaSO}_4 \rightleftharpoons \text{Ca}^{2+} + \text{SO}_4^{2-}$	0.6394	$-7.200 \cdot 10^3$	(Pitzer, 2018; Shen et al., 2020)

Table 2: Four solutions from the Pareto front (Syn: syncrystallized; Una: Unattacked)

	w_1	w_2	w_3	T^{opt} (K)	S_c (%)	Q_{cool} (Kj/h)	Syn. losses (%)	Una. losses (%)
1	0.73	0.27	0	349.45	2.12	$-1.333 \cdot 10^5$	0.62	0.12
2	0.70	0.30	0	350.25	2.18	$-1.351 \cdot 10^5$	0.64	0.14
3	0.67	0.33	0	350.75	2.23	$-1.355 \cdot 10^5$	0.63	0.16
4	0.63	0.37	0	351.35	2.54	$-1.358 \cdot 10^5$	0.64	0.15

5. Conclusions

Optimal operating conditions of the digestion tank of an industrial phosphoric acid production process are determined by means of a multi-criteria optimization method. The objectives used (i.e. saturation indices) have proved to be effective in minimizing the phosphate losses and increasing the acid productivity. Furthermore, the two inequality constraints on the temperature and on the excess of sulfuric acid above the stoichiometric amount required by the reactions were relevant to ensure an optimal operation of the digestion tank. The optimization results are consistent with the measurements carried out on an industrial installation, thus showing that optimization is a powerful tool for reducing the cost and duration of industrial experiments under maximum safety conditions. However, it is noteworthy that some side reactions can occur due to the impurities present in the phosphate ore which are not considered in this work. Their consideration in future works would undoubtedly improve the performance of the digestion tank.

Abstract

An increasing challenge faced in the process industries is the significant reduction of experience levels in chemical plants due to retirements of the baby boomers and more mobile younger generations. Additionally, many plants have ageing equipment which are deteriorating which changes risk levels with time and impacts repair timing decisions that need to be well informed, balancing budgets versus risk. HAZOP teams have less experience to identify and risk rank hazardous scenarios. This work presents a tool that uses criteria to identify appropriate scenarios and their rating, as well as recommend potential appropriate controls and mitigations. The tool allows dynamic HAZOPs that can be updated with the changing condition of safety critical equipment and suggest temporary mitigation measures, whilst also informing leaders of the risk of delaying repair.

Keywords: hazan, automated risk rating, automated hazop

1. Introduction

In development and in manufacture personnel are required to make many decisions. With changing demographics, for example baby boomers retiring and more mobile younger generations, there is a rapid and significant reduction in expertise and experience in all safety critical roles from leadership, engineers, maintenance, and operations technicians. As a result, tools for development through to manufacturing such as expert informed automated hazard analysis and risk assessment are needed. These will inform design and guide engineers in critical areas and guide critical experiments and data needed.

HAZAN (Hazard Analysis) at early-stage development and HAZOP (Hazard and Operability Studies) for detailed design of chemical plants are used very extensively and are dependent on the knowledge and experience that the team carrying out the study have. “Shortcomings could be due to lack of expertise or experience within the HAZOP team”. (Paul Baybutt, 2015). Importantly, the assessments of the severity and frequency can be inaccurate. “When you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind.” (Thomson, 1883). Inaccurate risk ranking can lead to under controlling risks and have the potential to lead to catastrophic consequences. Alternatively, we can overspend resources for low level risks assigned to high a ranking.

Using published guidance from verified sources the HAZOP Study Tool was developed that improves upon the current flaws in the traditional method of identifying and risk ranking scenarios.

2. Methodology

The HAZOP Study Tool provides guidance for participants of a study in the areas of hazard identification and risk ranking. The tool consists of three main elements. The first helps the identification of the hazardous properties that the process chemicals being used may have. Comparing these hazardous properties to the operating conditions and guidance from several different sources, e.g the Global Harmonized System of Classification and Labelling of Chemicals (GHS), a set of classification criteria that was developed. These determine the nature and relative severity of the hazard of a chemical substance, allows a severity ranking to be assigned to each property, based upon these criteria as such as shown in Table 1.

Severity Ranking				
Insignificant [1]	Low [2]	Medium [3]	High [4]	Serious [5]
FP > OT by 150°C or more	FP > OT by a range of 149°C - 100°C	FP > OT by a range of 99° - 50°C	FP = OT or FP > by 49°C - 1°C	OT > FP
Not classified as a flammable gas	Not classified as a flammable gas.	Category 2	Category 1B	Category 1A
0.5 atm abs > VP > 0.1 atm abs	1 atm abs > VP > 0.5 atm abs	2 atm abs > VP ≥ 1 atm abs	3 atm abs > VP ≥ 2 atm abs	VP ≥ 3 atm abs
AI Temp > OT by 120°C or more.	AI Temp > OT by 90°C	AI Temp > OT by 60°C	Ai Temp = OT ± 15°C	AI Temp < OT

Table 1 - The severity ranking criteria for specific hazardous chemicals (Element 1 of HAZOP Study Tool).

The second element of the tool aids the identification of the failure rate of different types of equipment. This element addresses a common uncertainty or misjudgment that occurs within HAZOP studies. Lack of understanding regarding the failure types and rate of the equipment makes it very difficult to accurately risk rank this hazard. Element two of the study tool aids the ranking of likelihood of equipment failure based upon quantitative criteria as shown in the sample in Table 2. The tool allows a HAZOP team to identify these failure rates for the process equipment in question and guides the user to a likelihood ranking for this hazard.

Sampled Equipment: Ambient Temperature and Pressure Vessel Large Vessel	Likelihood Ranking				
	Extremely Unlikely [1]	Very Unlikely [2]	Low [3]	Likely [4]	Very Likely [5]
	(Per vessel per year)				

Severity/Type of Release	$\leq 1E^{-06}$	$>1E^{-06}$, $\leq 1E^{-05}$	$>1E^{-05}$, $\leq 1E^{-04}$	$>1E^{-04}$, $\leq 1E^{-03}$	$>1E^{-03}$
Catastrophic	$5.00E^{-06}$				
Major				$1.00E^{-04}$	
Minor				$2.50E^{-03}$	
Roof					$2.00E^{-03}$

Table 2 - The likelihood ranking criteria for equipment failure (Element 2 of HAZOP Study Tool)

The third element of the tool provides information regarding the underlying causes and contributors to both equipment failures and equipment-based accidents to aid scenario identification and ranking. Often there is more than one contributor to an incident. The statistics regarding the number of contributors that occur that result in an equipment-based accident are stated and the main contributor and sub-contributors for each type of equipment failure are outlined.

This element of the tool is laid out in several tables, each table shows a variation of ways in which the contributors to an equipment-based accident can be broken down into more specific events that could cause an incident. Each table contains figures and statistics to show the proportion in which each cause has the possibility to have contributed to an incident.

The first table in the third element of the tool which expresses the breakdown of equipment-based accidents into the percentages that shows the proportion in which type of equipment are involved. For example, this draws attention to items' such as piping as data shows that piping is the type of equipment that most frequently causes equipment-based accidents.

The function of the third table is also to aid the identification of the less frequent accident contributors that still carry a high impact. These contributors are like 'black swan' events. To tool aims to predict what otherwise would be unforeseeable or beforehand seem to be beyond what is expected.

3. Applying the Tool

3.1. Case Study based on Williams Geismar Olefins Plant Incident

The plant in question is the Williams Geismar Olefins Plant in Louisiana, USA. This plant produces ethylene and propylene for the petrochemical industry.

The raw materials of the olefin production are cracked before being cooled and separated. This case study will focus on one small section of this process, the depropaniser. This section of the process uses high-pressure distillation to separate propane and propylene. Assumptions that have been made for the purpose of the case study are as follows, the fractionator operates at 55°C and 19 bar.

3.2. Identifying the Hazards

Using the HAZOP Study Tool embedded within excel, a formal process was carried out to identify the potential hazardous scenarios present within the node in question. The

hazardous scenarios identified are as follows, loss of containment (LOC) of propane and/or propylene from heat exchanger/reboiler, from propylene fractionator and/or from pipework.

3.3. Comparing Traditional Risk Ranking to HAZOP Study Tool Assisted Risk Ranking

To make a valid comparison, the same scenario is compared between the traditional risk ranking method of relying upon the knowledge, opinions, and experience of engineers within the HAZOP team against the risk ranking procedure utilizing the HAZOP Study Tool. Ten BEng level chemical engineering graduates were asked to rank one of the hazardous scenarios that was identified, 'LOC of propane and propylene from propylene fractionator that's operating at 55°C and 19 bar', in terms of severity and likelihood. The results are shown in the figures 1 and 2 below.

3.3.1. Chemical Engineering Graduates Rankings

The results as shown in table 3 that 4 engineering graduates ranked the scenario a ranking of 'High (4)' and 6 a ranking of 'Serious (5)'. Although there is an agreement that the severity is significant, almost 50% of engineers rank the severity differently.

Graduate	Severity Ranking				
	Insignificant [1]	Low [2]	Medium [3]	High [4]	Serious [5]
1					
2					
3					
4					
5					
6					
7					
8					
9					
10					

Table 3 - Chemical engineering graduates severity ranking for hazardous scenario.

The likelihood rankings of the hazardous scenario are significantly widespread as shown in table 4. Three engineers rank the likelihood of the loss of containment of a propylene fractionator, 'Very Unlikely (2) which lies between $1E^{-06}$ and $1E^{-05}$. Whereas on the other side of the spectrum, two engineers believe that the likelihood is 'Likely (4)' which lies between $1E^{-04}$ and $1E^{-03}$.

Graduate No.	Likelihood Ranking				
	Extremely Unlikely [1]	Very Unlikely [2]	Low [3]	Likely [4]	Very Likely [5]
1					
2					
3					
4					
5					
6					
7					

8					
9					
10					

Table 4 - Chemical engineering graduates likelihood ranking for hazardous scenario.

3.3.2. HAZOP Study Tool Assisted Rankings

The use of the HAZOP study tool and each of the elements within the tool allowed a conclusion to be made that both propane and propylene presented a ‘Serious (5)’ level of severity in relation to being a fire and explosion hazard and propane presented a ‘Medium (4)’ level of severity in relation to toxicity to aquatic life and environment.

With focus on the vessel in question, or the propylene fractionator, the HAZOP study tool allows the evaluation of the likelihood of a variety of different types of release, such as, ‘Catastrophic release’, ‘25 – 50mm diameter hole’, ‘13mm diameter hole’ and ‘6mm diameter hole’. In this specific case, each of the types of release as listed were concluded to be ‘Very Unlikely (2)’, except for the ‘6mm diameter hole’ that has a failure rate of $4E^{-05}$ per vessel per year and is ranked as a ‘Low (3)’ level of likelihood.

3.4. Discussion

When comparing the traditional, experience and knowledge-based approach to risk ranking and the HAZOP Study Tool assisted method there is a lot of differences that can be observed:

- When the rankings are collated on a risk matrix the traditional method arrived at five different risk rankings, each of which is coming from a verified source, a qualified engineer within the field of chemical engineering. The study tool assisted rankings are based upon semi-quantitative information gathered from verified industry sources which introduces an element of consistency across all processes, regardless of the team carrying out the HAZOP.
- Each person has varying levels of industry experience and knowledge which have an effect on the rankings that are assigned. The HAZOP study tool allows the user to take use the information on the process and compare it to the criteria that has been created based upon varying sources to allow them to arrive at an accurate ranking. The tool provides guidance for personnel of all levels of experience and enables unexperienced personnel to operate competently within a HAZOP team and avoid misleading a study because of their lack of experience.
- It has been shown that assigning likelihood and severity is dependent on experience. Whereas the tool assisted method focuses on breaking down the hazardous scenario in question and providing semi quantitative information that directs the scenario ranking. The tool assisted method breaks a process down and inspects the failure rate of every piece of equipment providing more of a comprehensive overview of how likely the realization of a hazardous scenario really is.

4. Conclusions

The HAZOP study tool is valuable guidance and expert advisor for teams who increasingly lack the depth of experience and expertise due to demographic changes and

younger generation's increased mobility. Methods of passing down knowledge and rapid access in a way that can be used by inexperienced engineers must be developed.

The quality of the judgement of a team or an individual during a risk assessment is highly dependent on the expertise and experience of the team. The outputs from a risk assessment should be considered to be 'high risk' due to the potential of catastrophic consequences if it is done incorrectly. The addition of semi-quantitative guidance adds expertise that can be used by teams to improve scenario identification, risk ranking and identifying mitigations. The HAZAN and HAZOP study tool is an expert advisory tool and a step in the direction of automated risk assessment for a wide variety of chemical processes.

Multi-objective optimization of co-processing of algae hydrothermal liquefaction oil and vacuum gas oil: a survey of algal oil co-processing ratio and gasoline selling price

Shuai Zhang, Qingyu Lei, Le Wu*, Yuqi Wang, Lan Zheng

School of Chemical Engineering, Northwest University, Xi'an 710069, China

lewu@nwu.edu.cn

Abstract

The co-processing of algae hydrothermal liquefaction oil (AHTLO) and vacuum gas oil (VGO) in an existing refinery has been proposed to decrease the production cost of algal bio-fuels by utilizing existing infrastructures of the refinery. Techno-economic analysis of the co-processing of AHTLO and VGO shown that the larger AHTLO co-processing ratio, the higher minimum selling price. In this work, an investigation between the AHTLO co-processing ratio and minimum selling price is conducted by multi-objective optimization (MOO). The proposed MOO model is solved to obtain the Pareto fronts by ϵ -constraint method. The trade-off solution for the co-processing technology is obtained using function evaluation method. The effects of the weight factor on the trade-off solution are also carried out.

Keywords: Algae, HTL, VGO, Co-processing, Multi-objective optimization.

1. Introduction

The development of bio-energy is one of the ways to deal with the problems of resource shortage and environmental pollution. To further reduce the production cost of bio-fuels, the co-processing of bio-oil and vacuum gas oil has been proposed by using the existing refinery infrastructures. The third-generation bio-energy, algae was also used as the raw material to obtain the algae hydrothermal liquefaction oil (AHTLO) which was then co-processed with vacuum gas oil (VGO) in an existing fluid catalytic cracking unit. The co-processing of AHTLO and VGO shown high technical feasibilities (Santillan-Jimenez et al. 2019). A techno-economic analysis shown that the co-processing technique can reduce the production cost of the algal fuels. Furthermore, the minimum selling price (MSP) of gasoline was increased with the increase of AHTLO co-processing ratio. (Wu et al. 2020).

In this work, a multi-objective optimization model is established for the co-processing of AHTLO and VGO in an existing refinery to discuss the relationship between the AHTLO co-processing ratio and minimum selling price (MSP) of gasoline. As there are two kinds of algae production methods, algal turf scrubbers (ATS) and open raceway ponds (ORP), two co-processing scenarios (ATS scenario and ORP scenario) are proposed to illustrate the differences between the two scenarios. The Pareto fronts and the trade-off solution are calculated by ϵ -constraint method and evaluation function method, respectively. The effects of weight factor on the trade-off solution are also discussed.

2. Materials and methods

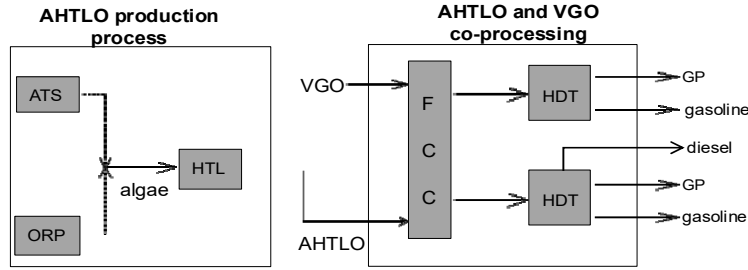

Figure 1: The co-processing diagram

Figure 1 has been shown the basic flowsheet of the co-processing process. This figure can be divided into two parts, the one part is production process of AHTLO, the other part is co-processing of AHTLO and VGO. Algae produced by ATS or ORP can be directly hydrothermally liquefied to obtain AHTLO. Then, the AHTLO and VGO are co-fed into the FCC to produce the co-processing products, gasoline and diesel with bio-carbon. Then, the FCC gasoline and diesel are hydrotreated to obtain the gasoline and diesel fuels.

2.1. Objective functions

In this work, the relation between the co-processing ratio of AHTLO in FCC feed oil and the MSP of gasoline is discussed by using a multi-objective model. It is easy to conduct that more bio-carbon would exist in co-processing product if a larger AHTLO co-processing ratio was adopted. Therefore, the objective functions of the multi-objective model are set as the minimization of the gasoline MSP and the maximization of the AHTLO co-processing ratio. MSP can be calculated by net present value (NPV) and internal interest of rate (IRR) according to the mass balance, energy balance, operating cost, investment cost, profit margin and tax rate. More details can be found in Wu et al. (2020).

$$\max R_{\text{AHTLO}} \quad (1)$$

$$\min \text{MSP} \quad (2)$$

2.2. Constraints

The constraints are main the mass balances of the co-processing process.

$$m_j^{\text{out}} = \sum_i \sum_l m_i^{\text{in}} y_j \quad (3)$$

where m denotes the flow rate, in t/h; superscript *in*, *out* indicate charge and discharge; subscripts i, j are the i^{th} charging port and j^{th} discharging port respectively.

2.3. Trade-off between MSP and co-processing ratio

In this work, the evaluation function is used to obtain the trade-off solutions.

$$u_o^s = (O_o^{\max} - O_o^s) / (O_o^{\max} - O_o^{\min}) \quad (4)$$

$$u^s = \sum_o w_o u_o^s \quad (5)$$

where O indicates the objective function; u is the evolution function; w denotes weight factor; Subscript O indicates O^{th} objective function; Superscript *min*, *max* and *s* are the minimum solution, maximum solution and s^{th} solution of u .

3. Case study

3.1. Basic data

The co-processing of AHTLO and VGO in the FCC unit, the annual operation time is 8400 h and the average annual processing capacity is 1.2 million tonnes. The yield of AHTLO and gas are 44% and 19% in the HTL process. In the FCC unit, the yields of gaseous products, coke, gasoline and diesel are 18%, 6.6%, 99.5% and 91.2%, respectively.

Table 1 presents the basic operating cost of the two algal production method, ATS and ORP, which includes power, nutrients, fresh water, fuel or flocculants, labor and maintenance or insurance.

Table 1: Basic inputs for the ATS and ORP processes (Hoffman et al, 2017)

Operating cost /(\$·t ⁻¹ a)	ATS	ORP
Power	56.12	65.26
Nutrients	/	104.25
Fresh water	/	0.988
Fuel or Flocculants	19.14	56.36
Labor	13.30	14.69
Maintenance/Insurance	29.26	25.53

Note: a) the cost unit is dollar per ash free dry tonne

3.2. Optimal results of ATS scenario

3.2.1. Pareto front in ATS scenario

Figure 2 presents the relations between the MSP of gasoline and the ratio of AHTLO. It can be observed that the MSP increases with the increase of co-processing ratio of AHTLO. When the AHTLO co-processing ratio is 1%, the MSP is 2.04 \$·gal⁻¹. When the AHTLO co-processing ratio is 20%, the MSP is 3.80 \$·gal⁻¹. Considering the relative low MSP of gasoline, the co-processing of VGO and AHTLO to produce gasoline and diesel may be a potential way to partially replace petroleum derived gasoline.

From the breakdown of gasoline price, in ATS scenario. It can be obtained that when the co-processing ratio is 1% and 20%, the proportion of VGO cost in the MSP is the largest proportion, which is 80% and 45%, respectively. Then, as the tax is controlled at 39%, it ranks second with 45% and 42%, respectively. It can be seen from the figure that the cost and tax share of VGO are reduced due to the addition of AHTLO. Since, the scenario does not consume nutrients and fresh water, the proportion of nutrients is 0.

According to Figure 3, the mass balances flow chart of ATS scenario under the condition of AHTLO ratio of 1% and 20%. Since the consumption of energy, nutrition and water can be ignored, in ATS scenario, the input amount is 0 t/h. Algae are produced in ATS,

and AHTLO is obtained by HTL. When the co-processing ratio is 1%, the AHTLO is 1.43 t/h, and the VGO is 141.43 t/h co-processing into FCC. And the obtained gasoline, diesel and GP are 70.91 t/h, 30.38 t/h and 0.73 t/h respectively. When the co-processing ratio of AHTLO is 20%, the AHTLO is 28.58 t/h, and the VGO is 114.28 t/h co-processing into FCC. Products of gasoline, diesel and GP are 70.91 t/h, 30.38 t/h and 0.73 t/h respectively.

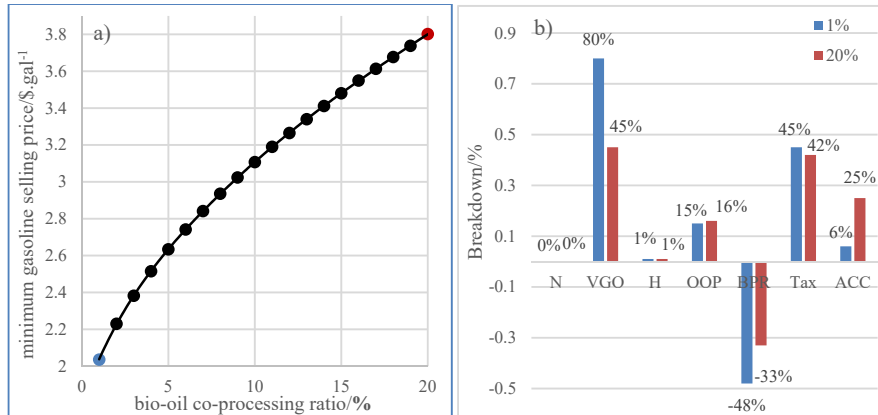

Figure 2: a) The Pareto fronts and the breakdowns of MSPs, b) 1% and 20% AHTLO co-processed (N=Nutrient, H=Hydrogen, U=Utilities, OOC=other operating cost, BPR=by product revenue, ACC=annual capital cost)

Figure 3: Mass balances of ATS scenario (GP=Gas products, fuel gas and LPG)

3.2.2. Effect of the weight factor on the trade-off solution

Effect of the weight factor on the trade-off solution of ATS scenario is shown in Table 2. According to Table 2, when the weight factor is 0.6, the optimal AHTLO ratio is 3% and the corresponding MSP is 2.38 \$·gal⁻¹. The optimal AHTLO ratio would be 8% and MSP would be 2.94 \$·gal⁻¹ if 0.5 is chosen as the weight value. When the weight ratio is less than 0.4, the AHTLO ratio is 20%, and the MSP is 3.80 \$·gal⁻¹; if the weight ratio is more than 0.7, the AHTLO ratio is 1%, and the corresponding MSP is 2.04 \$·gal⁻¹.

Table 2: Effect of weight factor on the trade-off solution of ATS scenario

Weight factor	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1
Bio-oil ratio/%	20	20	20	20	20	8	3	1	1	1	1
MSP/\$·gal ⁻¹	3.8	3.8	3.8	3.8	3.8	2.9	2.3	2.0	2.0	2.0	2.0
	0	0	0	0	0	4	8	4	4	4	4

3.3. Optimal results of ORP scenario

3.3.1. Pareto front in ORP scenario

As indicated in Figure 4a), the relationship between MSP and co-processing ratio, and in Figure 4b), the Pareto frontier diagram. The results are similar to those under ATS scenario. MSP of co-processing production oil increases with the increase of co-processing ratio of AHTLO. When AHTLO ratio is 1%, MSP is 1.62 \$·gal⁻¹; AHTLO ratio is 20%, MSP is 3.70 \$·gal⁻¹. Whether the ratio of AHTLO is 1% or 20%, the effect is likely to replace part of gasoline and diesel refined that from petroleum. Whether the proportion of AHTLO is 1% or 20%, the co-processing effect can reduce the production cost of gasoline and bio-diesel, and it may also replace part of gasoline and diesel oil refined from petroleum.

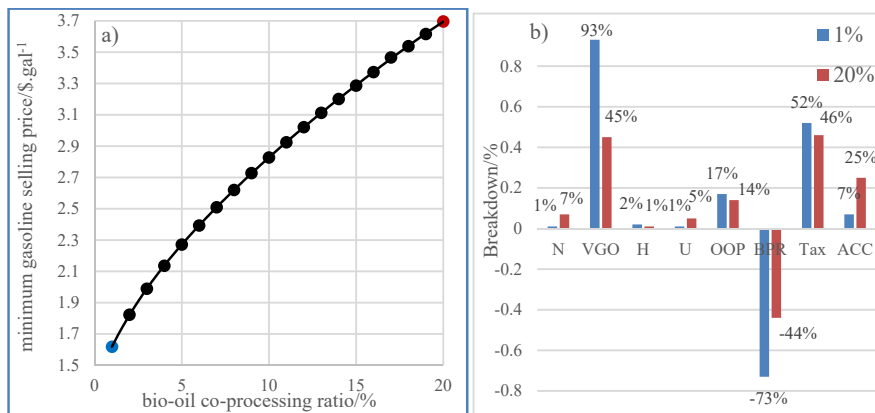

Figure 4: a) The Pareto fronts and the breakdowns of MSPs, b) 1% and 20% AHTLO co-processed (N=Nutrient, H=Hydrogen, U=Utilities, OOP=other operating cost, BPR=by product revenue, ACC=annual capital cost).

The detailed chart which breakdown of gasoline price under the ORP scenario with AHTLO ratio of 1% and 20%. It is similar to ATS scenario. In the MSP, the cost of VOG accounts for 93% and 45% respectively; the second is tax, 52% and 46%, which is also due to the tax control of 39%. Different from ATS, nutrients accounted for 1% and 7%, which was 0% in the ATS.

Figure 5: Mass balances of ORP scenario (GP=Gas products, fuel gas and LPG)

As demonstrated in Figure 5, the mass balance flow chart of ORP scenario under the condition of AHTLO ratio of 1% and 20% is shown. It is similar to ATS scenario, but there are differences in energy, nutrition and water consumption, which are 65.39 t/h and 493.51 t/h respectively; the others are the same as ATS scenario.

3.3.2. Effect of the weight factor on the trade-off solution

Table 3 shows the influence of weight factor on the trade-off solution, which is the same as ATS scenario. When the weight factor is 0.6, the optimal AHTLO ratio is 3% and the corresponding MSP is 1.99 \$·gal⁻¹. The optimal AHTLO ratio would be 8% and MSP would be 2.62 \$·gal⁻¹ if 0.5 is chosen as the weight value. When the weight ratio is less than 0.4, the AHTLO ratio is 20%, and the MSP is 3.70 \$·gal⁻¹; if the weight ratio is more than 0.7, the AHTLO ratio is 1%, and the corresponding MSP is 1.62 \$·gal⁻¹.

Table 3: Effect of weight factor on the trade-off solution of ORP scenario

Weight factor	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1
Bio-oil ratio/%	20	20	20	20	20	8	3	1	1	1	1
MSP/\$·gal ⁻¹	3.7	3.7	3.7	3.7	3.7	2.6	1.9	1.6	1.6	1.6	1.6
	0	0	0	0	0	2	9	2	2	2	2

4. Conclusion

In this work, a multi-objective optimization of the co-processing of AHTLO and VGO in the existing catalytic cracking pyrolysis is carried out to investigate the relation between the MSP and co-processing ratio. As there are two algae growth technologies, ATS and ORP, two scenarios were proposed to give a comparison between the two technologies when the algae were adopted as the raw materials for the HTL process. This study proved that co-processing of AHTLO and VGO can reduce bio-fuels cost. Indicating that AHTLO and VGO may be a potential way to partially replace petroleum derived gasoline in both cases.

Modeling of a software for sizing a wastewater treatment plant

Anass Qoutbane^a, Btissam Khnajer^b, Essediya Cherkaoui^c, Mohamed Khamar^d and Abderrahman Nounah

Civil Engineering and Environment Laboratory (LGCE); Materials, Water and Environment Team; Higher School of Technology of Salé; Mohammed V University in Rabat, Morocco

Abstract

The new wastewater treatment plants in Morocco are increasingly equipped with intensive biological treatment processes (bacterial beds and activated sludge) to the detriment of lagooning. Activated sludge treatment is a very interesting choice given its satisfactory efficiency.

The objective of this work is to list the formulas already published concerning the activated sludge and lagooning technique after having studied its operation, to draw up the sizing algorithms for the most reliable methods and then to program them in order to develop an easy-to-use software for sizing activated sludge type wastewater treatment plants with a low load saving. This software will contribute to reduce the duration of the study as well as of the implementation of the WWTP project and will constitute a tool for decision making.

This program will help designers to design and verify the purification performance. This tool also allows considerable time savings compared to conventional calculation methods while offering easy data entry.

Keywords : wastewater, treatment, program.

1. Introduction

The dimensioning of a wastewater treatment plant follows several steps, first of all by collecting basic data and essential parameters describing the quality and quantity of effluents, in order to be able to estimate the dimensions of each structure constituting the treatment plant. This estimation is often very expensive and generally requires a lot of time, concentration and energy to the WWTP designers, especially when it comes to working on several variants. The objective of this project is to develop a software called EMASN which allows to determine the dimensions of a wastewater treatment plant by lagooning plus de facto a cost estimate from some basic data. In order to achieve this, we use Excel and the programming language 'Visual basic'.

2. Material and method

2.1. Calculation formulas

2.1.1. Lagooning

Wastewater treatment by lagooning is done by various processes based on physical, chemical and biological phenomena.

The decontamination of wastewater requires a succession of steps involving physical, physico-chemical and biological treatments. Apart from the largest waste present in the wastewater, the treatment must allow, at the very least, to eliminate most of the carbonaceous pollution.

Anaerobic basin :

Basin surface = gross BOD5/ (volume load (Cv)Data in meters

Basin volume = Area * Depth

Residence time =Volume / flow rate

Outgoing pollutant load = Input pollutant load - (Efficiency*Input pollutant load)

Optional basins :

Pond surface = BOD5 load at the outlet of the anaerobic ponds / surface load Cs

Basin V = Basin surface * Depth (1.5 m)

Residence time =Volume / flow rate

Outgoing pollutant load = Input pollutant load - (Efficiency*Input pollutant load)

Curing tanks :

Volume of the tank = flow rate * Residence time (5 d)

S(M) = Basin volume / Depth (1 m)

2.2. Language and tool used

Visual Basic (VB) is a third-generation event-driven programming language and integrated development environment created by Microsoft for its COM1 programming model. Visual Basic is directly derived from BASIC and allows rapid application development, creation of graphical user interfaces, access to databases using CAD, ADO and RDO technologies, and the creation of ActiveX controls or objects. Scripting languages such as Visual Basic for Applications and VBScript are syntactically similar to Visual Basic, but are used and behave significantly differently.

3. Results and discussion

3.1. Client

The client (Fig. 1), allows you to orientate yourself towards your directions concerning the software (dimensioning lagoon, activated sludge, bacterial bed, cost estimate).

Figure 1 : Interface du logiciel

3.2. Calcul des débits

The first sizing step is to calculate the incoming wastewater flow (Fig. 2).

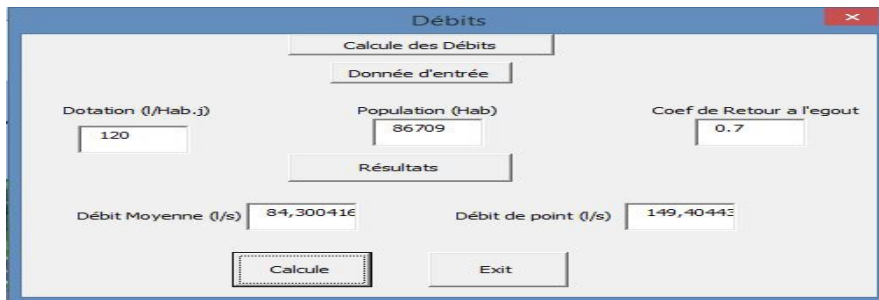

Figure 2: Calculation of Wastewater Inlet Flow Rate

3.3. Calcul des charges polluantes

Through the application of the calculation forum, the user can calculate the pollutant load at the inlet of the WWTP according to the population (Fig. 3).

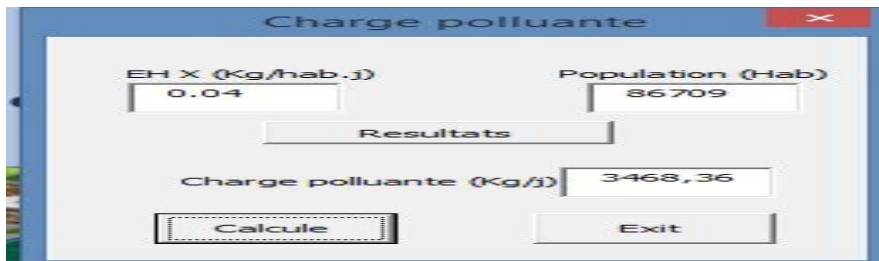

Figure 3: Calculation of the pollutant load at the inlet of the WWTP

3.4. Lagooning

The third step consists in calculating the dimensioning of the treatment basins. (Fig.4).

Figure 4: Basin and Grid Computation Interface

3.4.1. Screening

Before starting the calculation of the treatment basins, it is essential to dimension the elimination grid for large elements.

The screenshot shows the 'Dégrillage' software interface with the following data:

Donnée d'entrée			
Debit de point (l/s)	Espace entre les Barreaux	Epaisseur Des Barreaux (cm)	Vitesse (m/s)
86	0.015	0.002	1.2
Coefficient de colmatage	Tirant d'eau (m)	Facteur de Forme**	Angle d'inclinaison
0.4	0.25	1.8	40

facteur de forme*	
rectangulaire	2,42
circulaire	1,67 à 1,83

Résultats de dimensionnement			
coefficient de vide	0,88235294111	surface de la grille (m ²)	0,20305555551
Longueur (m)	0,38909509711	largeur (m)	0,52186613771
perte de charge	1,01865515711	Nombre des Barreaux	30,6980081031
Refus de la grille (l/h.j)	900		

Buttons: Calculé, Exit

Figure 5: Calculation of grid dimensions

3.4.2 Lagoon dimensions

After the user finishes the calculation of the first step, which is the pre-treatment, he can start the step of calculating the basin volumes. (Fig.6) Based on the calculation formulas and results obtained in the first step, the software calculates

the dimensions of the three treatment basins respecting the residence conditions for each basin, Aerobic, Optional and Maturation.

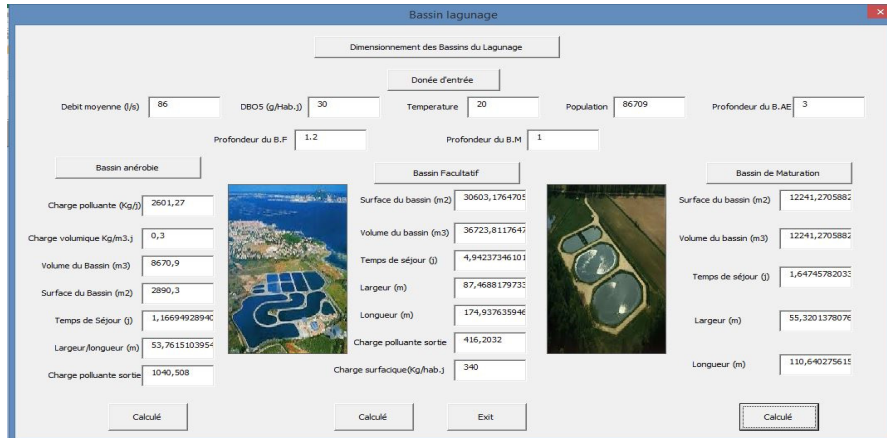

Figure 6: Calculation of basin volumes

3.4.2. Cost Estimate

After determining the technical elements of the project and sizing the volumes of the treatment basins, the user has the power to estimate the project cost. The cost estimate is made in proportion to the number of equivalent inhabitants according to the manual proposed by ONEE-BE. The user must add the field cost according to the study site in order to properly estimate the project and compare the treatment cost with other processes and choose the most appropriate process.

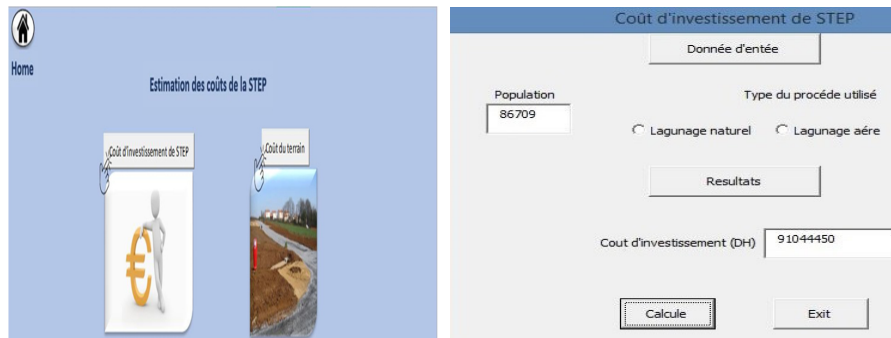

Figure 7: Project Cost Calculation

Conclusion

Today the treatment of liquid effluents, especially wastewater from cities, has become a high priority for the state so that it can preserve its natural resources and protect aquatic ecosystems from pollution caused by the physico-chemical and biological interactions of pollutants with biotopes.

This program makes it easier for designers to design and thus verify the purification performance of natural lagoon-type treatment plants. In addition, this modelled calculation tool offers a significant time saving compared to conventional calculation methods, while providing easy data entry. And it compares the cost of treatment compared to other wastewater treatment processes.

Abstract

Uncertainty in parameters is increasingly considered in the optimization of design and operation of chemical process systems. A possible approach solving such optimization problems under uncertainty is the application of the chance constraint method. However, this approach requires high computational effort for calculating the probability of constraint satisfaction. To quickly solve chance-constrained optimization problems, an approach using data-driven models has been developed and proposed for single chance-constraints. In this contribution, the developed framework for data-driven chance constrained optimization is extended to joint chance constraints and analysed on a basic mathematical nonlinear model for easier evaluation of the method and on a simplified Williams-Otto process model with complex and nonlinear behaviour.

Keywords: Optimization under uncertainty, Joint chance-constrained optimization, Data-driven modelling

1. Introduction

Deterministic optimization approaches are well developed in the process industry and are used for offline and online process optimization (Li et al., 2006). However, many uncertainties within and outside of a process, such as feed stream, demanded product amount and kinetic parameters are often not considered, which can lead to serious deficiencies in the system or to economic loss (Giunta, 2004). To tackle this, approaches for process optimization under uncertainty can be applied on the design and operation of process systems in chemical industry. A possible approach solving such optimization problems under uncertainty is the application of chance-constrained (CC) optimization. However, this approach requires high computational effort for calculating the probability of constraint satisfaction for multidimensional distributions in order to achieve the desired probability level (Ostrovsky et al., 2013). To enable CC optimization in real-time applications even for complex processes, which is not possible using conventional approaches, a data-driven CC optimization framework has been proposed (Weigert et al., 2019). The framework has been successfully tested for single chance-constraints, which are satisfied individually with a prescribed confidence level. To increase the flexibility and robustness of the optimization problem, joint chance-constrained programming can be used which is able to guarantee a user-defined probability level of meeting all restrictions simultaneously. This is generally solved through two approaches of the joint chance constrained problem: sampling based and analytical approximation (Yuan et al.,

2017). In this contribution, we extended the existing framework to joint chance constraints as a new method and analysed its behaviour.

2. Optimization under uncertainty

In general, the basic idea of optimization under uncertainty is to integrate the available stochastic information into the optimization problem formulation. To systematically solve the optimization problems under uncertainty, three different methods can be distinguished: (1) Scenario-based optimization approach, (2) Stochastic approach and (3) Parametric approach (Wets et al., 1994). A possible approach solving such optimization problems using the second method is the application of single chance-constrained optimization which can be formulated as follows:

$$\min_u E(\Phi(x, u, \xi)) \quad (1a)$$

$$\text{s.t. } g(x, u, \xi) = 0 \quad (1b)$$

$$\Pr_i\{h_i(x, u, \xi) \geq 0\} \geq \alpha_i \quad \forall i \in \{0, 1, \dots, n_{h_i}\} \quad (1c)$$

$$u^L \leq u \leq u^U \quad (1d)$$

$$u \in \mathbb{R}^{n_u}, \quad x \in \mathbb{R}^{n_x}, \quad \xi \sim \mathcal{N}(\mu, Cov)$$

with expectation operator E , original objective function Φ , decision variables u , state variables x , uncertain parameters ξ , equality constraints g , and inequality constraints h . In most implementations ξ is assumed to be described by a multivariate normal distribution with the mean value μ and covariance matrix Cov . \Pr represents the probability of complying with the inner constraint being feasible to be greater than a user-predefined confidence level α ($0 \leq \alpha \leq 1$). The uncertain input ξ makes the corresponding output variable $h_i(x, u, \xi)$ also uncertain, so further processing of the inequalities must be carried out in order to quantify possible violations and it can be formulated as Eq. (1c). Another way of formulating the equation is joint chance constraint and can be written as (Arellano-Garcia, 2009):

$$\Pr_j\{h_j(x, u, \xi) \geq 0, \quad \forall j \in \{0, 1, \dots, n_{h_j}\}\} \geq \alpha_j \quad (2)$$

In this case, the joint chance constraint requires the satisfaction of all inner constraints to be satisfied simultaneously with a predefined confidence level. In addition, this approach increases the flexibility of the optimization problem in the inequality variable space resulting in decreased values of the objective function while still retaining the overall probability level.

3. Data-driven input-output and uncertainty modelling

A data-driven CC optimization framework (Weigert et al., 2019) has been developed to reduce the computational cost of the existing chance constrained optimization framework and tested successfully for single chance-constraints. The data-driven framework consists of two submodels: a process model (PM) and an uncertainty model (UM). The PM represents the correlation between the decision variables and the expected values of the objective function and the inequality constraints, while the uncertainty model (UM) determines the probability distribution parameters needed to compute the probability of the inequality constraint as a function of all the decision variables.

3.1. Data preparation and data-driven model generation

To generate the data-driven model (here: artificial neural network, ANN), training and testing data have to be prepared based on the formulation of the chance-constrained optimization problem. Data sampling is performed in a space of predefined decision

variables (uniform distribution) and the uncertain parameter (normal distribution) using the framework, which solves the rigorous model in AMPL. Prior to model training, the following details have to be specified: the output uncertainty at each available input point, the expected values of the objective function and the inequality constraints. In particular, a model for describing the probability distribution is selected and its characteristic parameters are specified as the output variables of the UM. Normal and beta distributions are used in this work. Their defining parameters are the variances for the normal and two positive shape parameters (α and β) for the beta distribution, which can be determined by model training. With prepared data sets and the essential parameters, the process and uncertainty model are trained using the machine learning toolbox Scikit-learn (Pedregosa et. al., 2011).

3.2. Data-Driven Model for process optimization under uncertainty

By applying the PM and the UM to the chance-constrained optimization problem of Eq. (1), only decision variables are required to solve this problem, since the influence of x and ξ on the optimization problem is already included in the submodels. The optimization problem can be now simplified to:

$$\min_u E(\Phi(u)) \tag{3a}$$

$$\Pr_k\{h_k(u) \geq 0\} \geq \alpha_k \quad \forall k \in \{0, 1, \dots, n_{h_k}\} \tag{3b}$$

$$u^L \leq u \leq u^U \quad u \in \mathbb{R}^{n_u} \tag{3c}$$

The framework can solve the optimization problem by obtaining expected objective function values from the PM and the probability information of satisfying the chance constraint from the UM. To calculate the probability in chance constrained optimization using the framework, just the cumulative distribution function (CDF) and the expected values of the inequality constraints from the PM are used. These can be derived directly from the outputs of the PM and the UM which depend on the decision variables.

3.3. Computing the probability of a joint chance constraint

One uncertainty model is created for each individual chance constraint defined by the user. In each model, all probability distribution parameters are determined only as a function of all decision variables to calculate the probability constraint. Therefore, the UMs do not depend on each other and can be used in calculating the probability of joint chance constraint method using the following formula:

$$\Pr_{Joint} = \prod_{j=0}^{n_{h_j}} \Pr_j\{h_j(u) \geq 0\} \quad \forall j \in \{0, 1, \dots, n_{h_j}\} \tag{4}$$

In order to carry out and test the approach for joint chance constraints, the proposed method is implemented in the developed framework.

4. Case study

The testing of the extended framework for joint CC is carried out with two different examples: a simple mathematical equation system, and the simplified Williams-Otto process. In both case studies, training and testing datasets (500,000 sample points) are generated according to the procedure described earlier, and data-driven models for the case study are created based on these datasets. The data generation times for the first and second case are 12400 s and 13240 s respectively, whereas their model training times (both the PM and the UM) are 1231 s and 1501 s.

4.1. Case Study I: Simple mathematical model

In order to evaluate the performance of the proposed approach for joint chance constraints, an arbitrary nonlinear equation system with three active constraints is chosen and can be described as follows:

$$\min_{u_1, u_2} (u_1 - 2.1)^2 + \left(\frac{u_2 - 3.9}{40}\right)^2 \quad (5a)$$

$$\Pr_{\text{Joint}} \left\{ \begin{array}{l} 10 \cdot (\xi_3 + u_1 + \xi_2) - u_2 - 75 \geq 0 \\ \exp(-\xi_2 - u_1 + 5.5) - u_2 \leq 0 \\ -10 \cdot (\xi_1 + u_1)^2 - u_2 + 100 \geq 0 \end{array} \right\} \geq \alpha_{\text{Joint}} \quad (5b)$$

with mean values $\xi_1 = 1$, $\xi_2 = 2$, $\xi_3 = 5$ and decision variables u_1 in the interval [1.2, 2.2], u_2 in the interval [2.0, 16.0]. The joint chance-constrained optimization problem is solved for varying α_{Joint} and uncertainty variances σ . To verify the probability of the optimization result (\Pr_{Solver}), Monte Carlo (MC) Simulation is applied based on the uncertainty parameters in the system. To estimate the probability using this method (\Pr_{MC}), numerous simulations with randomly chosen samples from the uncertain parameter distributions are carried out using the original model with fixed decision variables from the optimization result. Then the number of points in the simulation result is counted which simultaneously satisfy all inequality constraints.

Figure 1: Optimization results: (a) Influence of σ on the objective function value and max. achievable probability, (b) Influence of the probability level α_{Joint} on the objective function value.

Fig. 1 (a) shows the fact that the maximum achievable joint constraint probability decreases with the increasing variance of the uncertainty parameter. This means that all three inner constraints in Eq. (5b) are active simultaneously, affecting the feasible area in which all uncertainty-affected inequality constraints are jointly satisfied. As expected, it can be seen that the objective function value increases with increasing σ value. The objective function values also rise with increasing probability level α_{Joint} (see Fig. 1 (b)), since the optimal solution moves away from the global minimum in order to increase the probability of the distribution being fulfilled. This is also the expected behaviour. According to the optimization results, the probability of the optimization result (\Pr_{Solver}) and the probability obtained by MC simulations (\Pr_{MC}) show a high match rate, and the difference between the two probabilities ($\frac{|\Pr_{\text{MC}} - \Pr_{\text{Solver}}|}{\Pr_{\text{Solver}}}$) is less than 1%. Furthermore, compared to the sampling-based method (Monte Carlo with 10,000 sample points, taking approx. 348 s per iteration), the new approach only takes less than a second to calculate the probability of meeting the joint chance constraint for each optimization iteration. Thus, solving this joint CC optimization problem takes only a few seconds in total.

4.2. Case Study II: Williams-Otto Process

The Williams-Otto process (Williams and Otto, 1960) consists of a continuously stirred tank reactor (CSTR), a decanter, a distillation column and a recycling part of the column into the reactor. Two raw components A and B are fed separately into the CSTR, in which three exothermic reactions take place producing product P, intermediate components C, E and byproduct G. To describe each reaction, an Arrhenius-type kinetic is used. The byproduct G is an expensive waste and hence causes additional costs, which is thus limited to mass fraction 4% at the outlet of the reactor. In addition, it is essential to keep the reactor temperature below 110°C to avoid degradation process. The original model is simplified and therefore the equation system consists of 22 equations. The following optimization problem has been specified for the joint chance constraint:

$$\min_{F_A, F_B} (0.079 - w_P)^2 + (0.045 - w_G)^2 \tag{6a}$$

$$\Pr_{\text{Joint}} \left\{ \begin{array}{l} w_P(F_A, F_B) \geq 0.082 \\ w_G(F_A, F_B) \leq 0.04 \end{array} \right\} \geq \alpha_{\text{Joint}} \tag{6b}$$

The optimization problem has two decision variables, which are the two feed streams for components A and B (F_A and F_B). As uncertain parameters, the three preexponential coefficients of the Arrhenius reaction rates with a standard deviation of 3% of the specified value are used. The objective function is formulated in such a way that the unconstrained global optimum lies outside the feasible area, which enables the constraints (6b) to be activated. The optimization problem for joint chance constraint is formulated based on the description of this section and solved using the data-driven model.

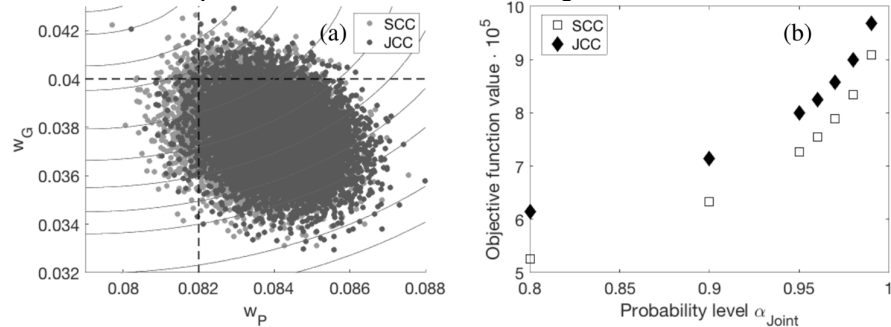

Figure 2: Optimization results: (a) the probability distribution of the concentrations w_P and w_G of the individual sampling point for single and joint chance constraint methods with $\alpha_{\text{Joint}} = 0.95$, (b) Influence of the probability level α_{Joint} on the objective function value.

Figure 2 (a) shows the MC Simulation Results of the concentration w_P and w_G (with 10,000 sample points), taking into account the above mentioned 3 uncertainty parameters at $\alpha_{\text{Joint}} = 0.95$. The single CC method solves the formulated optimization problem by satisfying the two inequality constraints separately ($\Pr_1 \{w_P(F_A, F_B) \geq 0.082\} = 94.8\%$ and $\Pr_2 \{w_G(F_A, F_B) \leq 0.04\} = 94.9\%$, but $\Pr_1 \cap \Pr_2 = 90.4\%$). Since the joint CC approach considers both inequality constraints simultaneously, it is more severe than the single CC with same probability level values. The simulation result distribution keeps a distance from both constraints to jointly satisfy the required probability ($\Pr_{\text{Joint}} = 95.0\%$). In comparison with the single CC, the objective function values from joint CC are shifted to a more conservative solution to simultaneously meet the required concentrations of products and by-products under uncertainty (see Fig. 2 (b)). As already shown in the first case study, the optimization results here also show that the objective function values

increase as expected with increasing α_{Joint} (see Fig. 2 (b)). In this case study, the obtained optimization results also show a good agreement between the probability from the optimization result and probability obtained by Monte Carlo sampling, resulting in a max. deviation of less than 1.5 %. The proposed method also takes less than a second to calculate the probability for each iteration of joint CC optimization compared to the MC sampling technique (approx. 378 s per iteration, with 10,000 sample points). Hence, only a few seconds are required for solving this joint CC optimization problem. Furthermore, the max. operating cooling power limit ($\dot{Q}_{\text{cooling}} \leq 200$ kJ/s), designed not to exceed the max. allowable temperature of the reactor, is integrated into the joint chance constraint (Eq. (6b)) to test the approach for a higher multidimensional distribution. The joint CC optimization problem is formulated and solved successfully at an α_{Joint} of 80 % to 90 %. The maximum possible probability is 90.2 %. The reason for this is that more inequality constraints are jointly considered and therefore the desired probability cannot be reached within a feasible area. The calculation time of the probability for joint CC with these three constraints is not significantly different from the case study II with two constraints.

5. Conclusion and Outlook

In this contribution, an approach for joint CC is proposed to improve the robustness of the single chance constrained optimization solution using a data-driven model. The method is implemented in a developed framework and tested using two case studies. The joint CC method can solve the process optimization problem under uncertainty and provides results while meeting the desired minimum probability level varied from 80% to 99%, which is satisfying all uncertainty-affected inequality constraints jointly. Thus, when constraints are related to safety consideration of a process operation, the joint CC approach using the data-driven model can be applied. In addition, it takes less than a second to calculate the probability of meeting the joint chance constraint. In future work, the extended framework will be tested with measurement data from different chemical processes and will be applied in model-based frameworks for dynamic processes (Weigert et al., 2020). Furthermore, a possible application of the approach for real-time optimization can be investigated.

Abstract

The unsteady state simulation of gas-solid cyclone separator was carried out to investigate the performances of 0.29 m diameter (D_B) cyclones with five different dustbin geometries, including dustbin without dipleg (cylindrical bin) and dustbins with $0.5D_B$, $1.0D_B$, $1.5D_B$, and $2.0D_B$ (divergent conical bin) height divergent conical diplegs. The diameter and total height of five dustbins were $1D_B$ and $2D_B$, respectively. The gas flow and turbulence fields inside the cyclones with the Reynolds number of 280,000 were simulated by Reynolds averaged Navier-Stokes equations (RANS) with Reynolds stress model (RSM). The collection efficiencies were investigated by using discrete phase model (DPM). For model validation, the simulated velocity profiles of the cyclone with cylindrical dustbin have been compared to the previous experimental data available in literature and were in good agreement with the previous results. Further, the simulated results revealed that the Stairmand cyclone with divergent conical and simple cylindrical dustbins respectively represented the highest and lowest collection efficiencies indicated by 50% cut-off diameter, which corresponded to the diameters of 1.692 and 1.744 microns, respectively.

Keywords: CFD, cyclone, dipleg, dustbin, and separation

1. Introduction

Gas cyclones are one of the important gas-solid separators. They are commonly employed in various chemical industries because of their advantages, e.g., simple geometry, no moving parts, low operating cost, etc. They use centrifugal force to remove the solid particles from gas streams. Due to the cyclone advantages, many researchers attempted to enhance their performances by modifying the cyclone parts.

Cyclone inlet, cyclone barrel, cyclone cone, cyclone vortex finder, dipleg, and dustbin were previously studied to improve the cyclone performances by using experiments and computational fluid dynamics (CFD) simulations. The dust outlet geometry was one of the cyclone parts which widely studied by previous works.

Kaya and Karagoz (2009) employed CFD to investigate the gas cyclones prolonged with diplegs. They concluded that the dipleg length considerably affected the collection

efficiency rather than the pressure drop, especially for lower inlet velocities. Elsayed and Lacor (2012) numerically studied the influence of dustbin geometry. They reported that the different pressure drops and collection efficiencies were observed for different dustbin geometries. Moreover, the dust outlet geometry significantly affected the axial velocity profiles. Shapiro and Ben-Shmuel (2012) also used CFD to study the effects of cylindrical and divergent diplegs on pressure drop, cut size, and separation efficiency. Later, the cylindrical dustbins and diplegs (Elsayed et al., 2020) and cylindrical dustbins with various dipleg designs (Parvaz et al., 2020) were numerically investigated.

Although the different dustbin geometries were studied as mentioned earlier, however, the effect of angle for conical dipleg is not investigated. Hence, in this paper, this influence was investigated with the help of CFD. The five different dustbin geometries, including dustbin without dipleg (cylindrical bin) and dustbins with $0.5D_B$, $1.0D_B$, $1.5D_B$, and $2.0D_B$ (divergent conical bin) height divergent conical diplegs, were studied.

2. CFD simulations

2.1. Configurations of gas-solid cyclones

In this paper, the 0.29 m diameter Stairmand cyclone as reported by Hoekstra (2000) was preliminary considered. Further, the Stairmand cyclones with different dust outlet geometry designs were studied. The dimensions of these cyclones can be summarized as depicted in Table 1.

Table 1: Dimensions of the studied gas cyclones

Dimension	Length (mm)				
	$0.0D_B$	$0.5D_B$	$1.0D_B$	$1.5D_B$	$2.0D_B$
Inlet height, a	145	145	145	145	145
Inlet width, b	58	58	58	58	58
Inlet length, L_i	246.5	246.5	246.5	246.5	246.5
Barrel Diameter, D_B	290	290	290	290	290
Cone tip diameter, D_C	108	108	108	108	108
Dustbin diameter, D_D	290	290	290	290	290
Vortex finder diameter, D_V	145	145	145	145	145
Cyclone height, h_T	1,160	1,160	1,160	1,160	1,160
Barrel height, h_B	435	435	435	435	435
Inner vortex finder height, S	145	145	145	145	145
Outer vortex finder height, h_V	435	435	435	435	435
Dipleg height, h_L	-	145	290	435	580
Dustbin height, h_D	580	435	290	145	-

2.2. Grid generation

The hexahedral grids were generated inside gas cyclones with the help of domain decomposition technique (Bumrunghthaichaichan and Wattanusorn, 2019) by using GAMBIT 2.4.6 as demonstrated in Figure 1.

Figure 1: Schematic diagram of cyclone and surface grids for the five tested gas cyclones

2.3. Governing equations

The flow and turbulence fields inside gas cyclones were obtained by solving Reynolds averaged Navier-Stokes equations (RANS) with Reynolds stress model (RSM). Further, the particle motion was simulated by discrete phase model (DPM). The description of these governing equations were clearly described by Elsayed and Lacor (2012).

2.4. Material properties and boundary conditions

The density (ρ) and viscosity (μ) of air were $1.096 \text{ kg}\cdot\text{m}^{-3}$ and $1.81623 \times 10^{-5} \text{ kg}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$, respectively. The solid density were $2,740 \text{ kg}\cdot\text{m}^{-3}$ (Derksen, 2003). At inlet, the velocity-inlet boundary condition type was adopted. The uniform inlet velocity (U_{in}) of $16 \text{ m}\cdot\text{s}^{-1}$ was specified, which corresponded to the Reynolds number based on barrel diameter of 280,000. The turbulence kinetic energy (k) and turbulence kinetic energy dissipation rate (ε) were respectively computed by $k = 1.5(U_{in}l)^2$ and $\varepsilon = C_\mu^{3/4}k^{3/2}/l$. From isotropic turbulence assumption, the normal stresses were $2k/3$. Moreover, the shear stresses were zero. The outflow boundary condition type was assumed at outlet. Further, the no-slip boundary condition and scalable wall functions were employed at the cyclone wall.

2.5. Numerical methods and solution strategy

The ANSYS FLUENT finite volume CFD code was adopted to simulate gas cyclones. The pressure-velocity coupling scheme was SIMPLEC. The spatial discretization schemes of pressure, momentum, turbulence quantities, and Reynold stresses were PRESTO!, QUICK, second order upwind, and first order upwind, respectively (Elsayed and Lacor, 2012). The temporal discretization scheme was second order implicit (Shukla et al., 2011). Further, the time step size of 0.0001 s and maximum iterations per time step of 40 were used. The scaled residuals of 10^{-5} for all quantities were adopted as the convergence criteria.

2.6. Particle motion simulation and collection efficiency prediction

The particle motion was simulated by DPM because of the low particle loading. In order to obtain grade efficiency curves for the five cyclones, the 10,660 uniform particles with the different diameters, including 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, and 10 microns, were released at the cyclone inlet section. The inlet particle and gas velocities were assumed to be identical. Moreover, the collection efficiencies (η) for different particle sizes were evaluated by the number of escaped particles (n_{out}) and the total number of injected particles (n_{total}) and as shown in Eq. (1).

Figure 2: Comparison of (a) tangential velocity profile and (b) axial velocity profile at $z = 0.75D_B$ between the present CFD and the experimental data of Hoekstra (2000)

$$\eta = \left(1 - \frac{n_{\text{out}}}{n_{\text{total}}} \right) \times 100 (\%) \quad (1)$$

2.7. Grid independence study

Regarding to the previous work of Pechmanee (2019), he compared the predicted velocity profiles inside 0.29 m diameter Stairmand cyclone without dustbin of three different grid resolutions, including 90,436, 199,440, and 450,498 cells. The results indicated that the grid independency was obtained by medium grid level. However, in order to eliminate any uncertainties, he employed the fine grid level to study the gas cyclones. So, in the present work, the same grid qualities, e.g., near-wall grid size, growth ratio, etc., were generated inside cyclone barrel and cone. Moreover, the similar grid qualities were also applied inside five different dustbin geometries. The total number of grids for five tested cyclones were 756,788 cells.

3. Validation

The predicted tangential and axial velocity profiles at z of $0.75D_b$ below the cyclone roof were validated by comparing with the experimental data of Hoekstra (2000) as demonstrated in Figure 2. In Figure 2, the predicted profile and maximum value of the tangential velocity are in good agreement with the experiment. Whereas, the comparison shows the underprediction of the axial velocity at the inner vortex region. Due to the complexity of flow inside cyclone, it can be considered that the present CFD model was reasonably employed to study the effect of angle for conical dipleg.

4. Results and discussion

4.1. Cyclone static pressure and pressure drop

Figure 3 represents the contours of static pressure at plane $y = 0$ for five different cyclones. These contours exhibit that the static pressure is found to increase radially from the core vortex at centreline to the cyclone wall. Further, the pressure drop of these cyclones are slightly different. The percentage difference of pressure drop, which can be defined as a ratio of the difference between the maximum and minimum pressure drops to the

Figure 3: Contours of static pressure at plane $y = 0$ for the five tested gas cyclones (unit in Pa)

maximum value, was lower than 1.5%. It can be implied that the dustbin geometries insignificantly affected the cyclone pressure drop.

4.2. Tangential velocity and axial velocity

The tangential velocity and axial velocity contours of five different cyclones are shown in Figure 4. The results reveal that the tangential and axial velocities inside cyclone barrel and cone are slightly different. At the region near cone tip and dustbin, the velocity fields are significantly different, especially for tangential velocity. It can be summarized that the dustbin shapes influenced on the flow patterns.

Figure 4: Contours of (a) tangential velocity and (b) axial velocity at plane $y = 0$ for the five tested gas cyclones (unit in $m \cdot s^{-1}$)

Figure 5: Comparison of (a) grade efficiency curves and (b) tangential velocity profiles at $z = 5D_B$ for five tested cyclones

4.3. Collection efficiency

The grade efficiency curves of five different tested cyclones are plotted in Figure 5(a). Figure 5(a) shows that the cyclone efficiencies are found to increase with increasing the particle sizes and these efficiency curves are similar. However, the 50% cut-off diameters were determined to investigate the collection efficiencies of these cyclones. The cut-off diameters of $0.0D_B$, $0.5D_B$, $1.0D_B$, $1.5D_B$, and $2.0D_B$ cyclones were 1.744, 1.749, 1.711, 1.699, and 1.692 microns, respectively. Meaning that, the cyclone with divergent conical bin ($2.0D_B$ cyclone) provided the best separation performance as comparing with the others because of the highest magnitude of tangential velocity as shown in Figure 5(b).

5. Conclusions

In this paper, the effect of angle for cyclone conical dipleg was investigated by using RANS with RSM turbulence model and DPM. The validation confirmed that the present CFD model was reasonably adopted to study the conical dipleg effect. The simulated results indicated that the dustbin shape affected on gas flow patterns, especially for tangential velocity. Moreover, the 50% cut-off diameter of $2.0D_B$ cyclone was about 3% better than cyclone with cylindrical dustbin ($0.0D_B$ cyclone). Meaning that, the change in angle for cyclone conical dipleg can improve the separation performance.

Abstract

We present a universal inversion method to reconstruct the underlying probability density function (pdf) and its cumulative distribution (cdf) from the embedded information in the quadrature nodes and weights of QMOM. These nodes and weights are evolved according to the kinetics governing the interactions among the particles of the dispersed phase such as nucleation, condensation, evaporation, splitting and aggregation. This pdf is represented by a dynamic histogram supported with moving bin boundaries. The inverted pdf and cdf are general and free of any prior assumption about the type of the distribution. We called this method “InvQMOM” which is supposed to converge to the exact pdf and cdf as the number of quadrature nodes increases. The order of convergence of the inverted pdf is $O(h^2)$ and $O(h^3)$ for cdf, where h is the spacing between the two quadrature nodes that encompass the node from which the point functional value is reconstructed.

Keywords: InvQMOM, probability density, cumulative distribution, Inverse.

Introduction

Population balances is an established transport framework which is used to model the evolution of dispersed phase number density concentration. These systems are of core industrial, biological and medical importance where numerical solutions are called for in general (Bart et al., 2020, Durr and Buck, 2020). The Quadrature Method of Moments (QMOM) is one of the most elegant reduction methods used to solve such complex transport equations (McGraw, 1997). Since its introduction by McGraw (1997) it has found considerable theoretical and applied research during the last two decades (Bart et al., 2020). These applications cover wide areas which include aerosols microphysics, nanoparticle formation, turbulent mixing, dispersed phase flows, crystal morphology, cell growth and differentiation and uncertainty propagation through dynamical systems, to name but a few (Attarakih et al., 2019, 2020, Bart et al., 2020, Durr and Buck, 2020). Since QMOM is an integral averaging method, there is no simple direct and general inversion algorithm to reconstruct the unknown weight function which describes the distribution of the particulate phase from the available average information embedded in its moments. To fill this gap, a universal inversion method is proposed to reconstruct the probability density function and its cumulative distribution from the adaptive quadrature nodes and weights of QMOM. The weights of QMOM are local information propagated along the characteristics of the internal particle space according to the kinetics governing the interactions among the particles of the dispersed phase which include nucleation, condensation, evaporation, splitting and aggregation. This pdf can be represented by a

dynamic histogram supported by moving bin boundaries. The inverted pdf and cdf are general and free of any prior assumption about the type of the sought distribution. We called this method Inverse the QMOM: “InvQMOM” to emphasize the inversion of the pdf from the characteristic points and weights (probability per unit system volume) of the QMOM. The order of convergence of the inverted pdf is $O(h^2)$ and $O(h^3)$ for cdf, where h is the spacing between the two quadrature nodes along the particle property space that encompass the node from which the point functional value is reconstructed.

InvQMOM

The integral form of the Population Balance Equation in one particle property space (particle diameter x) over an average number concentration function $f(x,r,t)$ is given by:

$$\begin{aligned} \frac{\partial m_r}{\partial t} + \nabla \cdot \langle \mathbf{u} \rangle m_r + \int_{x_{\min}}^{x_{\max}} \left[\frac{\partial(Gx^r f)}{\partial x} \right] dx' = \int_{x_{\min}}^{x_{\max}} f \Gamma x^r [\pi_r - 1] dx' \\ + \int_{x_{\min}}^{x_{\max}} \int_{x_{\min}}^{x_{\max}} [\omega f(x) f(x') [x^3 + x'^3]^{r/3} - x^r - x'^r] dx dx', r = 0, 1, \dots \end{aligned} \quad (1)$$

The nonlinear integral source term takes into account particle breakage and aggregation while the integral particle growth term appears as an additional positive source term. The mean velocity vector of the particulate phase is $\langle \mathbf{u} \rangle$, the r^{th} moment of the number concentration function $f(x, \cdot)$ is m_r and π_r is the r^{th} moment of the dimensionless daughter particle size with respect to a given daughter particle distribution where $r = 0, 1, \dots$. Due to the general form of the respective particle growth, breakage and aggregation functions G , Γ and ω , the integral terms in Eq.(1) cannot be written in terms of m_r and hence present a challenging closure problem. These integrals remain without general closure algorithm until the introduction of the QMOM by McGraw (1997) where an adaptive and boundary free Gauss-Christoffel quadrature is introduced by transforming the source term in terms of a finite set of low order moments m_r , $r = 0, 1, \dots, N_q$. This transformation leads to the loss of the local information in the particle number concentration function $f(x, \cdot)$ which becomes latent in the low order moments m_r . Decoding of this information during the evolution of these moments in space and time is a nontrivial problem (Attarakih et al., 2020, 2020, Durr and Buck, 2020). In theoretical physics, this problem is known as the classical moment problem (CMP) and in particular the Stieltjes or Hausdorff moment problem (Gzyl & Tagliani, 2010). The CMP tries to recover a unique and positive number concentration function $f(x, \cdot)$ from its low order moments. The methods of inversion and the method of moments were reviewed recently by Attarakih et al. (2013, 2019, 2020) and Durr and Bruck (2020) respectively. Motivated by the QMOM, one can physically interpret the adaptive quadrature node as characteristic points (discrete curves) in the t - ξ space for homogeneous flow systems where ξ is the particle property space and t is time.

The QMOM

The QMOM can be mathematically presented as an adaptive Gauss-Christoffel quadrature for $0 \leq \xi < \infty$ as follows:

$$(\zeta_j, w_j) = Al(m_r), r = 0, 1, \dots, 2N_q - 1, j = 0, 1, \dots, N_q - 1 \quad (2)$$

where (w) is quadrature weight vector, (ζ) is quadrature node vector and (Al) is a suitable inversion algorithm which is required to solve the following system of nonlinear equations and function of m_r only:

$$m_r = \sum_{j=0}^{N_q-1} w_j \zeta_j^r, \quad r = 0, 1, \dots, 2N_q - 1 \quad (3)$$

Two famous algorithms (A1) are used to solve Eq.(3) which are the PD-Algorithm as adapted by McGraw (1997) and the Chebyshev-QMOM algorithm proposed and evaluated by Upadhyay (2012). Upadhyay (2012) showed that the Chebyshev-QMOM is superior to the PD-Algorithm. The Chebyshev-QMOM algorithm is found to be more robust than the PD-algorithm and can be used for a wider class of problems when high number of nodes is required as in our present work.

InvQMOM with local integral limits

Note that the quadrature weights (w) given by Eq.(2) are probabilities of f(x,.) per unit system volume sampled carefully from precomputed points (nodes) (ζ). By definition, these probabilities are given by:

$$w_j = \int_{\zeta_{j-1/2}}^{\zeta_{j+1/2}} f(x,.) dx, \quad j = 0, 1, \dots, N_q - 1 \quad (4)$$

where $\zeta_{j\pm 1/2}$ are unknown grid boundaries (histogram bins); but they satisfy $\zeta_{j-1/2} < \zeta_j < \zeta_{j+1/2}$. If f(x,.) is normalized, then the vector (w) is composed of true probabilities that are satisfying the natural constraint ($\sum w_j = 1$). The problem now can be posed as follows: Given an accurate value of the true probability (w_j) at a characteristic point ζ_j , then invert Eq.(4) to find an estimate of f(ζ_j ;:). This is an inverse problem where a unique solution is required with sufficient accuracy to approximate f(ζ_j ;:) from the available information. The integral in Eq.(4) can be approximated using the one-point Gauss-Legendre quadrature or the midpoint rule which results in the following normalized discrete probability density approximation of f(x,.) at each characteristic point ζ_j :

$$f^*(\zeta_j;:) = \frac{1}{\Delta\zeta_j} \frac{w_j}{\sum_j w_j} + O(\Delta\zeta_j^2), \quad j = 0, 1, \dots, N_q - 1 \quad (5)$$

where $\Delta\zeta_j = \zeta_{j+1} - \zeta_{j-1}$ with the constraint $\zeta_{j-1} < \zeta_{j-1/2} < \zeta_j$ and $\zeta_j < \zeta_{j+1/2} < \zeta_{j+1}$. Eq.(5) provides a complete theoretical inversion of the latent probability density function $f^*(x,;) = f(x,;)/m_0$. The order of convergence is proportional to the square of the distance between the (j-1) and (j+1) characteristic curves of the particle size.

$$F^*(\zeta_{j+1/2};:) = \frac{1}{m_0} \sum_{j=0}^j w_j + O(\Delta\zeta_j^3), \quad j = 0, 1, \dots, N_q - 1 \quad (6)$$

Moreover, the cumulative distribution of f(x;:) can be easily derived from Eq.(5) and is presented in Eq.(6), where m_0 is the zero moment of f(x,.) and $\zeta_{j+1/2} = 0.5[\zeta_j + \zeta_{j+1}]$. It is clear by comparing the order of errors in Eq.(5) and (6) that the inversion of cumulative distribution function from the available QMOM information (ζ_j, w_j) is more accurate than the recovery of the pointwise values of f(x;:). The two normalized pointwise and cumulative densities given by Eqs.(5) and (6) are formally the two inversion formulas for the QMOM and are named the “InvQMOM”.

Results and discussion

In this section we present sample results of using the proposed InvQMOM. The method is validated intensively including analytical cases where exact solution is available, cases of fluid hydrodynamics due to droplet breakage in continuous industrial stirred tank, uncertainty propagation in smoke height prediction in fire system design and uncertainty of the reproduction number of the SIR (Susceptible, Infectious and Recovered) model used in the prediction of COVID-19 dynamics. Due to the limited space, two practical and intensive case studies are presented below.

Droplet breakage in industrial scale vessel

As an example of our inversion results, Figure (1-Left) shows a sample from 26 low-order moments as function of time for the population balance equation describing the dynamics of a continuous industrial scale vessel with 10 m³ volume (Alopaeus et al., 1999).

Figure (1): **Left:** Comparison between the first three low-order moments (m_0 , m_2 , m_3 starting from origin) using Chebyshev-QMOM and the OPOSPM-Weibull corrected method for liquid droplet breakage in a continuous industrial stirred tank (x-axis is time). **Right:** Reconstructed pdf using InvQMOM with 13 quadrature nodes at final time of 250 s (x-axis is dimensionless droplet diameter) as compared to OPOSPM-Weibull method (solid line).

The continuous red lines are calculated by the Chebyshev-QMOM while the blue diamonds are based on the pointwise evolution of the probability density function using the OPOSPM-Weibull corrected method (Attarakih and Bart, 2020). The accuracies of the two methods are extremely high; however, the Chebyshev-QMOM method requires CPU time around 50 percent less than that of the OPOSPM-Weibull corrected method at the expense of lost distribution. Now having a set of accurate moments at hand, the pdf is reconstructed from the available nodes and weights using the InvQMOM method (Eq.(5)) as shown in Figure (1-Right). The accuracy of the inverted pdf as compared to the continuous one as predicted by the OPOSPM-Weibull corrected method (solid line) is remarkable (Attarakih & Bart (2020)). Note that the InvQMOM is a post processing step where the pdf and cdf can be reconstructed. The only limitation that might arise is the difficulty to calculate a number of nodes more than 10 by the Chebyshev-QMOM. However, it is found that this limitation is not a problem for pure particle growth as described by the population balance equation. Since InvQMOM is a post processing step, it has no profound effect on the CPU time of QMOM where the inversion step has negligible CPU time and does not depends on the original QMOM complexity.

Uncertainty propagation of smoke layer height

The model that we used here is the Available Safe Egress Time (ASET) model (Upadhyay & Ezekoye, 2008). This is a deterministic fire model with input parameters (area of enclosure and ventilation, height and location of events) that are assumed to be known

with no random components. However, the heat release rate is considered to be uncertain variable and is sampled from the historical data of known distribution. Here the beta distribution is used with two shape parameters and a scaling factor to model the heat release rate.

Figure (2): **Left:** Comparison between beta cdf used to model uncertainty in the input heat release rate (solid line) and the inverted cdf using InvQMOM (filled diamonds) with Chebyshev-QMOM ($N_q = 12$, x-axis is R). **Right:** Comparison between inverted smoke layer height cdf using InvQMOM (filled diamonds) at $t_c = 120$ s (x-axis is smoke layer height) with the reconstructed cdf (solid line) using the Differential Maximum Entropy Method (Attarakih & Bart, 2014).

Mathematically, let the stochastic heat release rate be (R) with a pdf $\beta(R/b, s_1, s_2)$ where $s_1 = 1$ and $s_2 = 4$ are shape factors and $b = 200$ is scaling parameter (case I in Upadhyay & Ezekoye (2008)). This input stochastic uncertainty is propagated as an output of the ASET model with pdf $f(z, t)$. For a given critical time (t_c) at which $z(t_c)$ is the smoke layer height from the ground, the input uncertainty is propagated by the equivalence principle between the two pdf's: $\beta(R, t_0)dR = f(z, t_c)dz$ where the propagated information is conserved between $t = t_0$ to $t = t_c$. The smoke layer height $z(t)$ is obtained by the dynamic solution of ASET model with p parameters (Upadhyay & Ezekoye, 2008):

$$\frac{dz(R, t)}{dt} = G(p, R), z(0) = z_0 \tag{7}$$

$$m_r = \int_0^\infty Z(t_c)^r f(z) dz = \int_0^\infty Z(t_c)^r m(R) dR = \sum_{j=0}^{N_q-1} w_j Z_j(t_c)^r \tag{8}$$

The classical way to propagate the uncertainty in the heat release rate is to use the Monte Carlo (MC) simulation by sampling the random variable (R) from its known distribution ($\beta(R)$). Then the fire model is integrated using a given random sample (R) up to $t = t_c$. Repeating this procedure sufficient number of times will produce the required cdf of the propagated uncertainty of $z(R, t_c)$. If the model is sufficiently complex, then the MC method will be computationally expensive. To circumvent this, we follow the same idea presented by Upadhyay & Ezekoye (2008) where the characteristic values (ζ_j) are used as samples of the random variable (R). Keeping in mind that the propagated information is conserved, then the low order moments of $f(z, t_c)$ are calculated from those of the pdf of the input uncertainty as given by Eq.(8). To this end, the output uncertainty cdf is required to provide all the statistical information required for risk assessments. With the QMOM nodes and weights at hand, the InvQMOM is used to reconstruct the cdf of smoke layer height at given time (t_c) where the results of this case study are shown in Figure (2). In Figure (2-Right), the cdf of the propagated input uncertainty (Left) is extracted from the moments of Eq.(8) using InvQMOM (Eq.(6) with 12 nodes) which is compared to the

inverted cdf (solid line) using the DMaxEntM (Attarakih & Bart (2014)). This cdf is useful for risk assessments since the probability of the layer being below any given value is immediately available from the inverted cdf as shown in Figure (2-Right). Note that 12 quadrature nodes were used to sample the input uncertainty from the cdf of beta distribution as shown in Figure (2-Left) (case I in Upadhyay and Ezekoye (2008)).

Conclusions

The InvQMOM is a post processing method which can be used in complex computational environment such as CFD and online real time simulations. As a main conclusion, the InvQMOM is a universal distribution reconstruction method when the QMOM and its variants are used. It needs only a sufficient number of nodes and weights to work with negligible computational cost. Using different analytical and practical case studies, it is found that five to ten nodes were sufficient to reconstruct the pdf and cdf with an accuracy of $O(h^2)$ and $O(h^3)$ respectively.

A Dual-Layer Attention-Based LSTM Network for Fed-batch Fermentation Process Modelling

Kai Liu, Jie Zhang

jie.zhang@newcastle.ac.uk

Abstract

Recurrent neural network (RNN) is a dynamic neural network where the current network output is related to the previous outputs. Long short-term memory network (LSTM) has emerged as a high-performance RNN. However, the original LSTM does not consider variable and sample relevance for process modelling. To overcome this problem, the paper proposes a Dual-layer Attention-based LSTM (DA-LSTM) network to model a fed-batch fermentation process. In the proposed DA-LSTM, LSTM is used to extract features of the input data and multiple time series results of the hidden layer, an encoder input attention mechanism is to select relevant driving series in the input data sequence, and a temporal decoder attention mechanism is used to measure the importance of encoder hidden states. The model with this deep architecture for high-level representations can learn very complex dynamic systems. To demonstrate the effectiveness of the proposed method, a comparative study with the original LSTM, signal attention-based LSTM is carried out. It is shown that the proposed method gives better modelling performance than others.

Keywords: LSTM, attention mechanism, machine learning, fed-batch processes, encoder-decoder

1. Introduction

Batch processes are suitable for the responsive manufacturing of high value-added products such as pharmaceuticals, polymers and semiconductors. In recent years, due to the increasing demand for high value-added products and the high variety of such products, the proportion of batch processes in modern industry has increased rapidly. In batch processes, maximising the yield while satisfying the quality and operation constraints is the main objective, but it is hard to achieve because of the process characteristics including non-steady-state condition, batch-to-batch variations and strong nonlinearity. Process optimisation based on detailed mechanistic models for responsive manufacturing using batch processes is infeasible or very difficult to implement in practice. To overcome this difficulty, data-driven modelling and optimisation using statistical and machine learning techniques should be capitalised for batch processes.

In order to analyze and mine the information from monitoring data, several data-driven modelling methods can be utilized for modelling complex batch processes, such as principal component analysis, principal component regression, and partial least squares.

Compared with these data-driven modelling methods, artificial neural networks which also known as machine learning have attracted an increased attention in data-driven nonlinear modelling. However, due to complex physical and chemical reaction mechanisms, industrial processes, especially batch processes, have inherently complex nonlinear dynamic behavior. To model highly nonlinear processes, recurrent neural networks (RNN) are widely used. In contrast with feedforward neural networks, some neuron outputs are feedback to the neurons themselves or other neurons in the previous layer, so the basic characteristic of RNN is to exhibit dynamic temporal behavior and process arbitrary sequences of inputs by its internal memory. The traditional RNNs suffer gradient vanishing and/or exploding problems when computing the gradients of network outputs with respect to network weights (Pascanu et al., 2013).

To overcome gradient vanishing or exploding, the gated recurrent neural networks have been established, including long short-term memory (LSTM) and gated recurrent units (GRU) (Schmidhuber et al., 1997). LSTM and GRU networks allow creating gradient paths that neither disappear nor explode along time. Although LSTM is very useful in capturing long-term dependencies, it cannot focus on different variables in different time steps. To solve this problem, a well-constructed autoencoder network which is also named as encoder-decoder network is developed (Cho et al., 2014). Based on the gated RNN units, the sequence-to-sequence problems can be solved by encoder-decoder network. Through the encoder part, the input sequence is converted into a fixed-length vector, and then the decoder converts the generated fixed-length vector into an output sequence. However, as the length of the input sequence increases, the performance of the encoder-decoder network will rapidly decline. Moreover, due to the quality variables are usually predicted based on long lagged input sequences, this problem is more serious when applied to product quality prediction in batch processes. Attention-based encoder-decoder architecture attempts to distinguish hidden states with different attention weights among all time steps of a prediction window and could be a solution to this problem.

To address the above issues, a new multiple-stage attention-based LSTM network is proposed in this paper. It is inspired by the theory of human attention that the human attention is modelled by multiple-stage attention mechanism. In the first attention stage, attention mechanism is used to adaptively extract the relevant information in the input series at each time step by referring to previous encoder hidden state. In the second attention stage, a temporal attention mechanism is proposed to select high correlation encoder output. Both attention mechanisms are integrated with double layers long short-term memory networks and can be trained by back-propagation.

2. Methodology

2.1. Long Short-Term Memory Network

Long short-term memory network is an advanced recurrent neural network (Hochreiter and Schmidhuber, 1997) and provides a well-constructed structure by establishing “gates” in its basic unit which is named as “cell”. These gates can capture both the long-term memory and short-term memory along the time steps and avoid gradient exploding and/or vanishing in standard RNNs. The gates are named as “forget gate”, “input gate”, and “output gate”. The detail structure of LSTM is presented in Figure 1.

The operation of an LSTM unit can be summarized as:

$$\mathbf{i}_t = \sigma_g(\mathbf{W}_i \cdot \mathbf{x}_t + \mathbf{U}_i \cdot \mathbf{h}_{t-1} + \mathbf{b}_i) \quad (1)$$

$$\mathbf{f}_t = \sigma_g(\mathbf{W}_f \cdot \mathbf{x}_t + \mathbf{U}_f \cdot \mathbf{h}_{t-1} + \mathbf{b}_f) \quad (2)$$

$$\tilde{\mathbf{c}}_t = \tanh(\mathbf{W}_c \cdot \mathbf{x}_t + \mathbf{U}_c \cdot \mathbf{h}_{t-1} + \mathbf{b}_c) \quad (3)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \quad (4)$$

$$\mathbf{o}_t = \sigma_g(\mathbf{W}_o \cdot \mathbf{x}_t + \mathbf{U}_o \cdot \mathbf{h}_{t-1} + \mathbf{b}_o) \quad (5)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \quad (6)$$

where the activation functions are $\sigma_g(x) = \frac{1}{(1+e^{-x})}$ and $\sigma_g(x) = \frac{1}{(1+e^{-x})}$ and $\tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}$, W_i W and U_i U are weight parameters and \mathbf{b} b_i is bias, $e \odot$ denotes the pointwise multiplication.

Figure 1. Graphical illustration of the long short-term memory network

2.2. Attention-based Encoder-Decoder Networks

An encoder-decoder is a popular framework in deep learning, especially in sequence-to-sequence modelling. The key idea is to encode the input sequences into the hidden state sequence and then the hidden state sequence is converted into a fix-length vector. After that, the decoder generates a target output with the pervious fix-length vector. However, there is an obvious drawback of encoder-decoder framework that, with the increase in the length of the input sequence, the context vector will lose long-term information from input sequence and this will lead to rapid reduction in prediction performance. Due to this issue, the attention mechanism is a novel addition of encoder-decoder networks. In attention mechanism, an approved context vector \mathbf{c} , \mathbf{c}_t is better than a fixed context vector \mathbf{c} , an individual attention weight w_i , W_i of each encoder hidden state \mathbf{h}_i , h_i is calculated, and the approved context vector \mathbf{c}_t , \mathbf{c}_t is defined as (Bahdanau et al., 2015)

$$\mathbf{c}_t = \sum_{i=1}^T \mathbf{w}_i \mathbf{h}_i \quad (7)$$

In order to optimize the attention-based encoder-decoder network performance in industrial application and inspired by some theories of human attention (Hübner et al., 2010), a new Dual-layer Attention-based LSTM network (DA-LSTM) is proposed. In the first attention stage, attention mechanism is used to adaptively extract the relevant information in input series at each time step by referring to previous encoder hidden state. In the second attention stage, a temporal attention mechanism is proposed to select high correlation encoder output.

The input attention mechanism can be achieved as follow:

$$e_t^i = \mathbf{V}_e \tanh(\mathbf{W}_e \cdot \mathbf{h}_{t-1} + \mathbf{U}_e \cdot \mathbf{s}_{t-1} + \mathbf{Z}_e \cdot \mathbf{x}_t^i + \mathbf{b}_e) \quad (8)$$

and

$$\alpha_t^i = \frac{\exp(e_t^i)}{\sum_{i=1}^n \exp(e_t^i)} \quad (9)$$

where \mathbf{h}_t is hidden state and \mathbf{s}_t is cell state in the encoder LSTM unit.

When the input attention weights are obtained, the input sequence can be converted to

$$\tilde{\mathbf{x}}_t = (\alpha_t^1 x_t^1, \alpha_t^2 x_t^2, \dots, \alpha_t^n x_t^n)^T \quad (10)$$

The decoder with temporal attention can be calculated by:

$$r_t^i = \mathbf{V}_d \tanh(\mathbf{W}_d \cdot \mathbf{d}_{t-1} + \mathbf{U}_d \cdot \mathbf{s}_{t-1}^d + \mathbf{Z}_d \cdot \mathbf{h}_t + \mathbf{b}_d) \quad 1 < i < T \quad (11)$$

and

$$\beta_t^i = \frac{\exp(r_t^i)}{\sum_{j=1}^T \exp(r_t^j)} \quad (12)$$

where \mathbf{d}_t is the decoder hidden state and \mathbf{s}_t is the cell state in the decoder LSTM unit.

When the temporal weights are obtained, the approved context vector $\tilde{\mathbf{c}}_t$ can be achieved by

$$\tilde{\mathbf{c}}_t = \sum_{i=1}^T \beta_t^i \mathbf{h}_i \quad (13)$$

2.3. Proposed modelling strategy

The model is trained by a mini-batch stochastic gradient descent optimization called Adam optimizer (Kingma and Ba, 2015), which is a widely used optimization algorithm

for training neural networks and has advantages such as fast convergence and good adaptation to local minima issue. Moreover, in the training procedure, two training methods, which are teacher forcing method and non-teacher forcing method, are used together. Figure 2 shows the flowchart of the proposed model.

The mean squared error (MSE) is used as the loss function in this paper which can be defined as:

$$MSE = E((y - y_p)^2) \tag{14}$$

Where y and y_p are the target value and model prediction respectively.

Figure 2. Flowchart for proposed model framework

3. Results and discussions

The benchmark industrial penicillin fermentation simulator, IndPenSim (Goldrick et al., 2015), is used to produce simulated process operation data. Ten benches of data generated by IndPensim are used in model development. Eight batches are used as training data, one batch is used as validation data, and the remaining batch is used as the unseen testing data.

To investigate the effectiveness of DA-LSTM, it is compared with other two baseline methods which are attention-based encoder-decoder network (Encoder-Decoder) and long short-term memory network. The comparison between DA-LSTM and encoder-decoder is to evaluate the input attention mechanism effectiveness on complex bio-processes. With all these LSTM-based methods, 30 controllable and monitoring variables are taken as input variables, and the penicillin concentration is taken as the target output. In all these three models, the number of hidden units is 50, the maximum training epochs are 500, the initial learning rate is 0.005, and the dropout factor is 0.2.

Figure 3. Predictions of penicillin concentration

For visual comparison, the penicillin concentration prediction result is shown in Figure 3 with the MSE of each method shown in the legend. Figure 4 shows the corresponding prediction error. From Figures 3 and 4, it can be seen that comparing to the normal LSTM prediction result, the prediction of DA-LSTM and encoder-decoder are more accurate, especially when the slope starts to get steep. From Figure 3, it can also be seen that the prediction error increases when penicillin starts to ferment. At this period, the input variables are changed rapidly to control the fermentation process. This shows the encoder-decoder framework are more robust against the noise in input data. On the other hand, the prediction accuracy of DA-LSTM outperforms Encoder-Decoder because adaptively extracting driving series by input attention mechanism can provide more reliable input features to make accurate predictions. Overall, the DA-LSTM integrating the input attention mechanism as well as temporal attention mechanism achieves the lowest MSE among all three methods.

4. Conclusions

In this paper, a new dual-layer attention-based LSTM network is proposed and it integrates an input attention mechanism and a temporal hidden state attention mechanism. The encoder input attention mechanism is for selecting relevant driving series in the input data sequence, and a temporal decoder attention mechanism is used to measure the importance of encoder hidden states. Based on the preliminary results, the DA-LSTM can improve the performance of LSTM on modelling complex bioprocesses, especially with multiple input variables. The developed model will be used in process optimisation and control in the future.

Abstract

Pandemic-induced lockdowns, restrictions on commercial activities, or natural disasters can disrupt a supply chain for prolonged time periods. These disruptions significantly impact network connectivity and consumer demands which in turn affect the capacity and profitability of a supply network. In this work, we address the resilience and economic survivability of interconnected networks during connectivity disruptions. Resilience is the ability to defend against and recover from potential disruptions. Economic survivability (ES) is the ability to maintain positive cash flows. We introduce optimization-based metrics to quantify the resilience and ES in supply chain design and operation. We also develop multi-scenario and multi-period models and systematic approaches which lead to supply chains with maximum profitability for desired resilience and ES.

Keywords: Network Resilience, Supply Chain Survivability, Interconnected Supply Chains

1. Introduction

Disruption events can impair the economic performance of supply chains, and negatively impact the social welfare since demands cannot always be met. Graph-theoretic resilience quantification (Latora and Marchiori, 2001; Yazdani et al. 2011), connectivity reinforcing, installing additional capacity and emergency supplies (Turnquist and Vugrin, 2013; Zhang et al., 2020) and other approaches have been proposed to tackle network disruptions. However, pandemic-induced lockdowns (e.g., COVID-19), geo-political conflicts, sanctions and restrictions on commercial activities, and sudden natural disasters give rise to new challenges (Ivanov and Dolgui, 2020; El-Halwagi et al., 2020). Some of these lead to remote employment, productivity reduction, loss of connectivity links and sudden changes in product demands. These disruptions often continue for prolonged time periods, which may eventually lead to partially or completely shutting down a supply chain.

In this work, we first address the resilience of interconnected networks against connectivity disruptions. We use resilience quantification metrics to analyze the system performance against single-connectivity failures. We also propose a mixed-integer linear program (MILP) to design resilient systems with minimum overdesign for interconnected supply chains (Chapter 2). Next, we introduce the concept of economical survivability (ES) to express the sensitivity of a supply chain network to demand decreases (Chapter 3). A case study is presented to illustrate the concepts in Chapter 4.

2. Resilience Analysis of Interconnected Networks

We address the resilience analysis of interconnected supply chains with multiple products. A representative example is the Water-Energy Nexus (WEN) (Tsolas et al., 2018), where the energy and water networks act upon shared energy and water sources, acting as water and energy sinks respectively (Fig. 1). First, we analyze WEN resilience by quantifying the performance of interconnected supply chains after single-edge failures. Specifically, we measure the impact of removing one designed connection, and repeat it for the rest of a given infrastructure. The impact is measured using the following metrics: (i) network structural robustness ρ , which is the fraction of single-connectivity removals, after which the rest of the network is still feasible; (ii) operational resilience θ , which is the average fraction of demand satisfaction across all removals; and (iii) excess nexus capacity ζ , defined as the excess consumer demands that can be satisfied in nominal operation without disruptions.

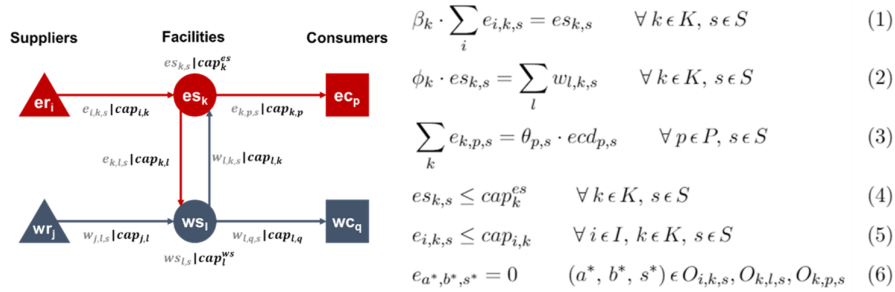

Figure 1: Water-energy nexus design and operation model

Over-designing improves the ability to operate after connections fail, but also increases the cost. One can avoid over-designing by paying a penalty if demand violation occurs. To capture this trade-off, we introduce the concept of minimum cost of resilience (*MCOR*), which is defined as $MCOR = \frac{\text{Resilient Design Cost} - \text{Nominal Design Cost}}{\text{Nominal Design Cost}}$. *MCOR* is the normalized cost difference between an overdesigned WEN (improved resilience) and the nominal design network (no disruptions).

Consider a WEN with the I, J energy and water resources, P, Q energy and water consumers, and K, L potential energy and water sources. To account for supply chain resilience in the design phase and ensure minimum overdesign (*MCOR*) we introduce disruption scenarios, equal to the number of potential connections to be designed. In each scenario, one connecting flow is imposed to be zero. The operating variables (generation, connecting supplies) and all operating balances are expanded for every scenario $s \in S$. Representative operating scenario-dependent balances are shown in Eqs. (1)-(6). Eq. (1) calculates the generation of energy from the energy sources k at every scenario s , based on the total input and a conversion factor β_k . Eq. (2) captures the dependence of energy generation from the water network via the intensity factor ϕ_k . Eq. (3) ensures that the demands of energy consumer p are satisfied for every scenario s . Also, operational resilience θ is a decision variable, as unsatisfied demands are penalized as cost. Eqs. (4) and (5) connect the scenario-dependent operating variables with the maximum design capacities. Finally, Equation (6) fix the operating flow rates of the missing links to zero, for each scenario-connection combination O_{a^*,b^*,s^*} . These combined with the operating equations ensure that balances hold across all disruption scenarios. Finally, the optimizer

will determine the cost-minimum common maximum capacities ($cap_k^{gen}, cap_{i,j}, \dots$) that will bound the scenario-dependent operating variables. The objective is to minimize the total WEN infrastructure cost, which is comprised of the fixed investment, capital, and scenario-dependent operating expenditures.

3. Economic Survivability of Supply Chains

In this section, we consider geographically interdependent supply chains with the same product. The interdependence arises from the raw material and product flows between supply chains from different regions. We consider the multi-period design and operation of a 5-echelon supply chain with raw material suppliers I , warehouse storage facilities J , processing facilities K , distribution centers L , and consumer centers M . In the design problem, given are consumer center demands that need to be satisfied in multiple regions. The objective is to determine the optimal connectivity and combination of storage and processing facilities to be designed, which will lead to minimum total network cost.

The supply chain design gives rise to an MINLP formulation, governed by operating balances to determine the time-dependent generation $gen_{k,t}$, flow rates $f_{i,j,t}$, and inventory levels of storage facilities $stor_{j,t}^{wh}$, to satisfy the consumer demands $d_{m,t}$. Representative operational constraints are depicted below. Eq. (7) ensures the availability of the raw material suppliers $a_{i,t}$ is respected. Eq. (8) and (11) calculate the inventory levels of warehouses J, L across the periods t . Eq. (9) expresses the product generation balance at processing facilities K , given by the total input from warehouses J and a conversion factor β_k . Finally, equation (12) ensures that the total flows reaching the demand centers from the distributors L will satisfy the consumer demands.

$$\sum_j f_{i,j,t} \leq a_{i,t} \quad \forall i \in I, t \in T \quad (7)$$

$$stor_{j,t}^{wh} = stor_{j,t-1}^{wh} + \sum_i f_{i,j,t} - \sum_k f_{j,k,t} \quad \forall j \in J, t \in T \quad (8)$$

$$\beta_k \cdot \left(\sum_j f_{j,k,t} \right) = gen_{k,t} \quad \forall k \in K, t \in T \quad (9)$$

$$gen_{k,t} = \sum_l f_{k,l,t} \quad \forall k \in K, t \in T \quad (10)$$

$$stor_{l,t}^{dc} = stor_{l,t-1}^{dc} + \sum_k f_{k,l,t} - \sum_m f_{l,m,t} \quad \forall l \in L, t \in T \quad (11)$$

$$\sum_l f_{l,m,t} = d_{m,t} \quad \forall m \in M, t \in T \quad (12)$$

We now address the survivability-aware design of supply chains in the event of lockdown-induced demand fluctuations. Our objective is to ensure that multi-regional supply chains maintain positive cash flows during disruption events. We express this by introducing economic survivability (ES). Disruption-induced demand decreases create negative cash flows since existing systems are designed for nominal higher demands. We define ES as the threshold of demand fraction for which the total profit of the supply chain remains non-negative. We define λ_t as this demand decrease fraction with lower values corresponding to higher survivability. The total profit $P(D_0)$ is given by the total sales revenue $REV(D_0)$ minus the capital cost of investment $FC(D_0)$ and the total operating cost $OC(D_0)$: $P(D_0) = REV(D_0) - FC(D_0) - OC(D_0)$.

The expression is calculated so that the network is designed to satisfy nominal demands

D_0 . If there is a demand reduction $D_t = \lambda_t \cdot D_0$, the capital cost of investment is not affected since it is a function of the capacity variables, and the original network was constructed for nominal demands $FC(D_0)$. However, the total revenue $REV(D_t)$ and operating cost $OC(D_t)$ are reduced by λ_t , hence $REV(D_t) = \lambda_t \cdot REV(D_0)$ and $OC(D_t) = \lambda_t \cdot OC(D_0)$. So, we can calculate or impose the economic survivability threshold of a supply chain using the following expression:

$$P(D_t = \lambda_t \cdot D_0) = \lambda_t \cdot REV(D_0) - FC(D_0) - \lambda_t \cdot OC(D_0) \geq 0 \quad (13)$$

$$\lambda_t \geq \frac{FC(D_0)}{REV(D_0) - OC(D_0)} \quad (14)$$

Our objective is to minimize this demand threshold to make supply chains more survivable.

4. Results

4.1. Resilience-aware Design

In the first part of the results we demonstrate the resilience-aware design of a WEN. We utilize the MILP multi-scenario formulation to obtain the resilient grass-root design for a given initial superstructure. For parametric values of external grid purchasing cost, which is the λ parameter that penalizes the unsatisfied demands, we derive the resulting resilience indices and the *MCOR*.

The distribution of the performance metrics is demonstrated in **Fig. 2a**. For low penalties λ , a network is not required to satisfy the demands, since the nexus relies solely on external supply purchasing. The metrics in that region are equal to zero. As λ increases, the network's size and contribution to the demands (Operational resilience θ) increase as well. Interestingly, for very high penalty λ , the network is 100% self-sufficient in terms of demand satisfaction and 100% resilient against single-connectivity disruptions ($\theta = \rho = 100\%$). Finally, the excess demand satisfaction ζ is almost 50% in that region. This entails that the nexus can satisfy 50% increased demands in the absence of disruptions.

In **Fig. 2b** the *MCOR* distribution is presented. In the low penalty region, the multi-scenario formulation provides the same solution as the non-resilient economical optimization of the same initial superstructure. Also, since there is no network to satisfy the demands, no connectivity disruptions can be observed. For higher penalties, the network is created to contribute to the demand satisfaction, increasing the *MCOR* until its maximum value. The last region corresponds to the maximum investment increase to fortify the supply chain with provisions to satisfy all demands against all disruption

Figure 2: Resulting resilience metrics (a) and *MCOR* (b) for parametric penalty λ .

scenarios. However, this investment cost increase ($MCOR$) corresponds to the minimum possible that can achieve 100% resilience. That is compared to heuristic-based resilience improvements and over-design strategies.

4.2. Survivability-aware Design

Finally, we explore the effect of economic survivability in the design of multi-regional supply chains. We consider a supply chain spanning across two regions $R=2$, with suppliers $I=2$, warehouses $J=3$, facilities $K=4$, distribution $L=3$, and consumer centers $M=2$. The distribution of the initial nodes across the corresponding regions is demonstrated in **Fig. 3**.

For the first part of the results, we maximize the global economic survivability ES_{tot} , by minimizing the threshold λ_{tot} , for the whole supply chain. The resulting network (**Fig. 3b**), leaves region 2 without any warehouses allocated and receives the required flows from region 1. The total profit is 219, and the total survivability threshold is $\lambda_{tot} = 0.652$. However, the calculated individual thresholds are $\lambda_{r=1} = 0.929, \lambda_{r=2} = 0.426$. This entails that the first region can handle smaller demand decreases and still maintain positive cash flows. This can be explained by the additional investments of the warehouse that operates in region 1 and supplies to region 2.

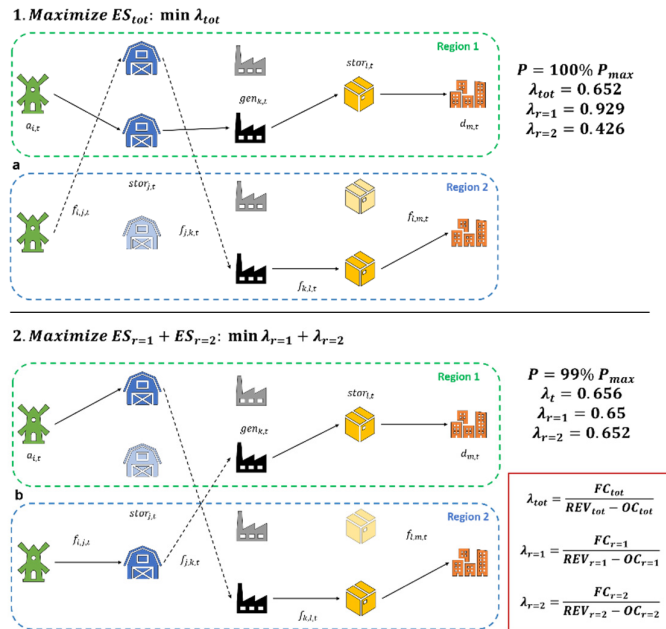

Figure 3: Comparison between optimizing a two-region supply chain for (a) global and (b) local survivability.

In the second part, we minimize the summation of the individual regional thresholds $\lambda_{r=1}, \lambda_{r=2}$. The resulting network (**Fig. 3b**) has total profit of 217 units, total survivability threshold $\lambda_{tot} = 0.656$, and $\lambda_{r=1} = 0.65, \lambda_{r=2} = 0.652$. In this case, the optimizer still allows inter-regional supplies, but now allocates each region with its required facilities. We have assumed that the capital investments and operating expenditures of inter-

regional supplies are compensated in the source region's total cost. As a result, the profit of the whole supply chain decreases and obtains 99% of the maximum potential profit. The total survivability is almost equal to the first case, but the individual thresholds are more balanced and closer to the average. The fixed investment of the facilities is also shared across the different regions more evenly.

We can conclude with the following remarks: (i) There is a strong positive correlation between return on investment (*ROI*) and economic survivability (*ES*). (ii) Maximizing global economic survivability (*ES*) leads to higher profitability of the whole supply chain. (iii) Maximizing local economic survivability $ES_{r=1} + ES_{r=1} + \dots$ ensures that investments on storage and generation facilities is more evenly distributed across multiple regions, in the expense of lower profit.

5. Conclusions

We have introduced two key concepts for the resilience- and survivability-aware analysis and design of interconnected supply chain networks. The first concept is the minimum cost of resilience (*MCOR*) and allows us to analyze and compare different network configurations for safe-guarding interconnected networks in the events of potential transportation link failures. The second key concept is the economic survivability condition, which ensures that a supply chain is immune to sudden changes in demands due to prolonged lockdowns or restrictions on inter-regional flows. We found that there is a strong correlation between economic survivability and return-on-investment, both at the global and local supply chain levels. Therefore, it is important to evenly allocate infrastructure to ensure the survivability of individual local regions that constitute a global chain. While this may reduce the profit, it ensures the sustainability of the overall supply chain in the long run.

Abstract

Liquid entrainment fraction is a key parameter for designing and optimizing downstream oil and gas production equipment and needs to be reliably estimated. In this study, a hybrid modeling (HM) approach, which combines existing mechanistic and semi-mechanistic (white-box) models and data-driven (black-box) models, is introduced for estimating entrainment fraction and its uncertainty. The hybrid model incorporates six white-box models and discrepancy models developed using Gaussian Process Modeling (GPM) trained with 1,562 experimental data. The average root-mean-square-error (RMSE) of the hybrid model is 0.06, which is a 61% reduction compared to the RMSE of the white box models (0.17).

Keywords: Hybrid Modeling, Entrainment Fraction, Gaussian Process Modeling

1. Introduction

In two-phase annular flow, the liquid forms a thin film around the pipe while the gas flows in the core of the pipe. Some portion of the liquid is entrained from the liquid film to the gas core. The ratio of the entrained liquid droplets mass flow rate to the total liquid mass flow rate in the pipeline is defined as the liquid entrainment fraction (Cioncolini and Thome, 2010). The liquid entrainment fraction is an essential parameter for the estimation of pressure drop, flow rate, liquid holdup, dry-out in annular flow, as well as for designing and optimizing separation facilities (Al-Sarkhi et al., 2012). Although mechanistic and semi-mechanistic models have been developed for predicting the liquid entrainment fraction, this is a complicated process, and none of the models capture all relevant phenomena, nor can they be applied over a wide range of operating conditions.

Hybrid modeling (HM), where part of a model can be formulated using first principles (white-box), and part of the model has to be inferred from data because of a lack of understanding of the mechanistic details (black-box) (Marquardt, 2002), is a good approach for estimating liquid entrainment fraction in two-phase flows. There are numerous hybrid modeling applications in chemical engineering, e.g., Zahedi et al. (2011) developed an ethylene oxide (EO) fixed bed reactor model with reaction kinetics estimated by an artificial neural network (ANN). In a more recent example, Bangi and Kwon (2020) integrated first principles models with a deep neural network (DNN), and applied it to a hydraulic fracturing process.

In this paper, a hybrid model is developed to estimate the liquid entrainment fraction. A database composed of entrainment fraction measurements and six semi-mechanistic models for predicting liquid entrainment fraction (white-box models) is constructed. The black-box models were then built for predicting the model discrepancy, which is defined

as the difference between the experimental and predicted entrainment fraction. The black-box models were trained using the Gaussian Process Modeling (GPM) (Williams and Rasmussen, 2006). The GPM outputs are the mean and variance of the model discrepancy, which were used to estimate confidence intervals. To obtain a more robust and accurate prediction, the bootstrap aggregating (bagging) technique is applied.

A brief overview of the six white-box models and the database used to build the black-box model is given in Section 2. Section 3 gives the details of the hybrid modeling approach. The result and discussion are given in Section 4. Finally, conclusions are summarized in Section 5.

2. Liquid Entrainment Fraction Database

We selected three widely-used models for predicting liquid entrainment fraction in different flow orientations, namely horizontal and vertical pipelines, as flow orientation significantly changes the underlying entrainment phenomena. The white-box models selected are Oliemans et al. (1986), Zhang et al. (2003), and Cioncolini & Thome (2010) for vertical pipeline orientation; and Pan & Hanratty (2002b), Mantilla (2008), and Nakazatomi & Sekoguchi (1996) for horizontal orientation.

The database contains 1,562 liquid entrainment fraction measurements at different experimental conditions, which are collected from open sources. Classified by the pipeline orientation, the number of measurements in vertical and horizontal orientations are 1,083 and 479, respectively. Nine experimental conditions (pipe diameter, inclination angle, gas density, liquid density, gas viscosity, liquid viscosity, gas-liquid surface tension, superficial gas velocity, and superficial liquid velocity) are the input variables that are relevant for entrainment fraction.

3. Hybrid Model Development Methodology

The liquid entrainment fraction measurement (y^e) at an operating condition can be decomposed and expressed by Eq. (1) (Jiang et al. 2013).

$$y^e = y^m + \delta \quad (1)$$

In Eq. (1), y^m is the entrainment fraction prediction of the white-box model, and δ is the model discrepancy, which is the difference between the entrainment fraction measurement and white-box model prediction. Here, we develop GPM-based black-box models (Jiang et al., 2013) to estimate the model discrepancy.

The training and validation data for developing the black-box models are obtained using the liquid entrainment measurements and the corresponding white-box model predictions for each pipeline orientation. For example, Oliemans et al. (1986) model is employed to calculate entrainment fractions and the model discrepancies for all 1,083 experimental conditions corresponding to the vertical pipeline orientation. These conditions are the inputs (X), and the calculated model discrepancy is the output (δ) for training the discrepancy model for Oliemans et al. (1986) model. This process resulted in six training and validation data sets.

3.1. Gaussian Process Modeling (GPM) Development with Bagging

The Gaussian Process (GP) algorithm is a supervised learning method with a theoretical basis in statistics. A GP is characterized by its mean function and covariance function or kernel function (Williams and Rasmussen, 2006). A constant mean function and square exponential kernel function with different length scales for each input dimension is utilized. Then, the GP prior is represented in Eq. (2):

$$f \sim \mathcal{GP}(m, k)$$

$$m(x) = a, \text{ and } k(x_p, x_q) = \sigma_f^2 \exp\left(-\sum_{h=1}^d \frac{(x_p - x_q)^2}{2l_h^2}\right) + \sigma_n^2 \Delta_{pq} \quad (2)$$

In Eq. (2), f represents the underlying function value at the input x , $m(x)$ is the mean function of the GP, and $k(x_p, x_q)$ is the covariance function representing the spatial covariance between any two points (x_p and x_q) at the process. In the covariance function, d is the dimension of input x , l_h represents the characteristic length scale corresponding to the h^{th} dimension of input x , σ_n^2 is the output variance, and the parameter σ_f^2 is output-scale amplitude. Δ_{pq} is Kronecker delta, which is one if $p = q$ and zero otherwise. The hyperparameters for the GP in Eq. (2) are $\theta = \{a, \sigma_f, \sigma_n, l_1, l_2, \dots, l_d\}$, and they are estimated by the Maximum Likelihood Estimation (MLE) (Rasmussen, 2003) using a Python-based package, GPy (GPy, 2012).

As shown in Eq. (3), the value of the mean function and its variance for the unseen test location X^* are inferred by calculating the posterior distribution using the training data set (X, δ) via Eq. (3).

$$f_* | X, \delta, X_* \sim \mathcal{N}(\bar{f}_*, \text{cov}(f_*))$$

$$\bar{f}_* = K(X_*, X) [K(X, X) + \sigma_n^2 I]^{-1} \delta \quad (3)$$

$$\text{cov}(f_*) = K(X_*, X_*) - K(X_*, X) [K(X, X) + \sigma_n^2 I]^{-1} K(X, X_*)$$

where f_* is the outputs of the test data given the inputs X and outputs δ of the training data and the inputs of the test data X^* . K is the covariance matrix. I is the identity matrix. Eq. (4) is employed to estimate model discrepancy $\hat{\delta}$ and its variance $\sigma_{\hat{\delta}}^2$ using the GPM at an unseen experimental condition.

$$\hat{\delta} = \bar{f}_*$$

$$\sigma_{\hat{\delta}}^2 = \text{cov}(f_*) \quad (4)$$

In this study, bootstrap aggregating (bagging) is utilized to obtain more robust and accurate predictions. In bootstrap aggregating, a set of models are developed to characterize the same relationship between input and output variables. One hundred training data sets are generated with replacement and used to train one hundred models for predicting model discrepancy that corresponds to each white-box model. To test the model's generalizability, for each model, only data that is not included in the training data set is used as testing data. The averaged predictive mean and variance from each model developed using bagging is calculated based on the property of the Gaussian mixture model shown in Eq. (5) and Eq. (6) (Chen and Ren, 2009):

$$E(\hat{\delta}) = \frac{1}{C} \sum_{c=1}^C \hat{\delta}(c) \quad (5)$$

$$\text{Var}(\hat{\delta}) = \frac{1}{C} \sum_{c=1}^C \sigma_{\hat{\delta}}^2(c) + \frac{1}{C} \sum_{c=1}^C (\hat{\delta}(c) - E(\hat{\delta}))^2 \quad (6)$$

where $E(\hat{\delta})$ is the averaged model discrepancy, $\text{Var}(\hat{\delta})$ is the averaged variance from one hundred GP models. Variable C represents the number of single GP models, which is

equal to 100 in this work. The final form of the predicted entrainment fraction from bagging GPM is shown in Eq. (7).

$$\hat{y}^e = y^m + E(\hat{\delta}) \quad (7)$$

$$95\% \text{ Confidence Interval} = \hat{y}^e \pm 1.96\sqrt{\text{Var}(\hat{\delta})}$$

3.2. Metrics to Evaluate the Hybrid Model Performance

To assess the prediction performance of the hybrid model, three quantitative metrics, Root-Mean-Square-Error (RMSE), Area Metric (AM), and Calibration Score (CS), are adopted. The RMSE is a widely used metric to measure the overall difference between prediction and measurement. The definition of RMSE is shown in Figure 1, where J is the number of predicted points. A lower RMSE value indicates a smaller difference between prediction and actual value, which represents a better model accuracy.

The AM compares both the mean and the variance of measurement and prediction (Ferson and Oberkampf, 2009). In Figure 1, the AM is the shaded area between the cumulative probability distributions of y^e and \hat{y}^e . A lower AM value represents a more accurate prediction. An AM value higher than the RMSE indicates that the experimental measurement is covered by the predicted confidence interval.

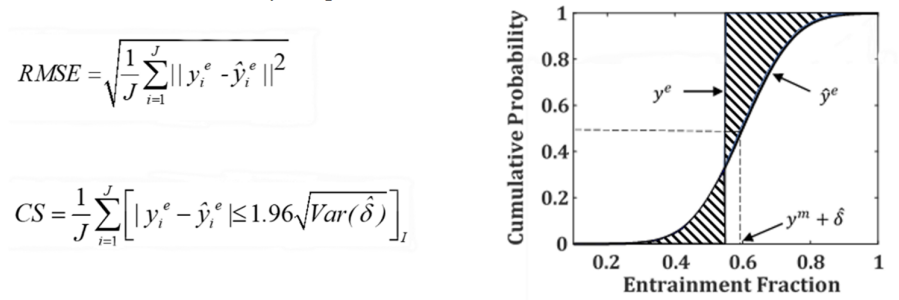

Figure 1. Definition of RMSE, AM and CS

The CS is the fraction of experimental measurements that are covered within a selected confidence interval (Richardson et al., 2019). In Figure 1, $[]_I$ represents the Iverson bracket. In our study, the 95% confidence interval is used. This metric is used as a minimum requirement check.

4. Results and Discussion

The performance metrics for the hybrid models are compiled in Figure 2. The RMSE and AM results are shown in Fig. 2(a), while the CS result is shown in Fig. 2(b). The AM for the white-box model is equal to the RMSE as there is no variance information. As can be seen from Fig. 2(s), there is a 60% reduction in both the average RMSE and AM with the introduction of hybrid models. If the results for vertical (Fig. 2(a) left of the dotted line) and horizontal pipeline (Fig. 2(a) right of the dotted line) orientations are compared, the RMSE and AM of models for the vertical orientation is lower (better) compared with the models for the horizontal orientation. Figure 2(a) reveals that the bagging technique reduced the RMSE and AM for all models compared to using a single GP model and improves the hybrid model prediction accuracy. The lower AM values and CS being closer to 0.95 for the bagging GP models indicate that bagging provides a more moderate and reliable confidence interval.

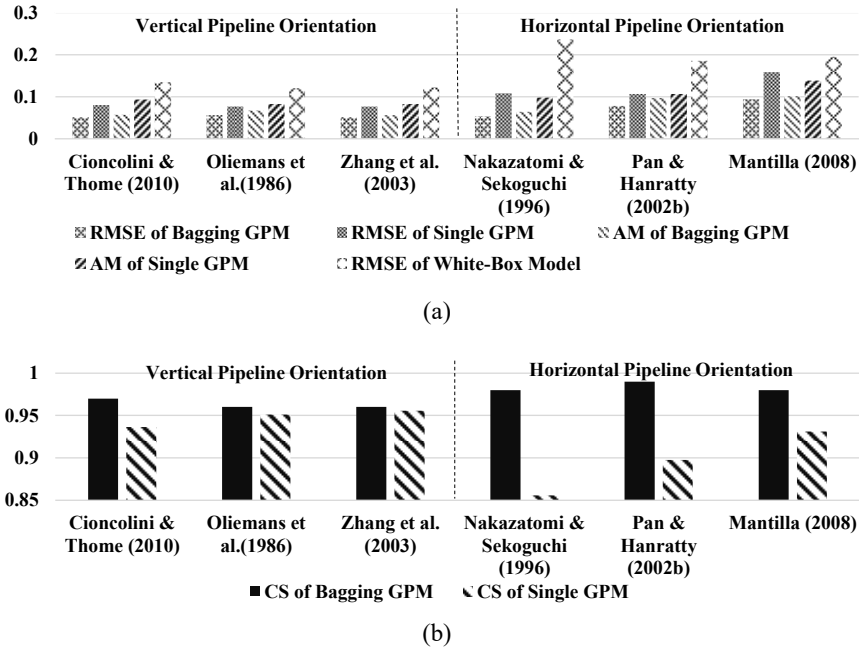

Figure 2. Entrainment Fraction Prediction Result

5. Conclusions

In this study, a hybrid modeling approach, which combines white-box models and GPM-based black-box models, is developed to estimate the liquid entrainment fraction in two-phase flow. Six mechanistic and semi-mechanistic models explaining the underlying physical phenomena are employed as white-box models to predict entrainment fraction, while the GPM is used as a black-box model to estimate the difference between experimental measurements and white-box model predictions. The bagging technique is added to obtain a more robust and accurate black-box model. The results reveal that the hybrid modeling approach yields models that have lower RMSE than the white-box models. Furthermore, the GPM-based hybrid model provides an estimate of the prediction uncertainty, which is not possible to obtain with the white-box models. Future work will investigate approaches to increase the hybrid model prediction accuracy and shrink the confidence interval, such as data clustering and input and output transformations prior to hybrid model training.

joao.manzi@ufcg.edu.br

Abstract

This paper makes a detailed investigation of the construction of the balances of mass, energy and entropy, aiming at a comprehensive analysis of the behavior of tubular reactors (Plug Flow Reactors - PFRs). The correlation between the physical base (space-time) and thermodynamic concepts was also explored with a view to making the relationship between the physical and thermodynamic quantities clearer. While doing so, new insights were obtained which led to showing that these balances can be used to improve the performance of tubular reactors in a simple and inexpensive way. A typical case study is discussed in order to demonstrate that the contribution of this paper is to put forward a model that can also be applied to PFRs and improve their performance.

Keywords: balances, entropy production, energy saving, cost.

1. Introduction

From statements made at conferences or even from comments in reviews of papers, it seems clear to us that there is a gap in understanding the main concepts of thermodynamics and in how best to apply them in the context of chemical processes. This has generated a wide array of misunderstandings, particularly when applied to models for plug flow reactors (PFRs).

When our thoughts turn to process analysis, simulations, balances, building models, and some other techniques, the excellent textbooks by Thomas Edgar and David Himmelblau (Edgar et al., 2001; Himmelblau and Bischoff, 1968), though first published more than 20 years ago, still come to mind today. However, some details are not focused on in much depth and it can therefore make an exploration of the concepts that underpin them difficult, especially for beginners.

The classical case is concerned with saving energy for which the First Law of Thermodynamics is the major reference to establish the procedures. However, using only this Law does not appropriately solve such issue, because it does not deal with the nature constraints imposed on the processes. A quick analysis, carried out when the Gibbs function $\Delta G = \Delta H - T\Delta S$ is taken into account, reveals that when the process occurs (ΔG negative) and since ΔS is always increasing, then on minimizing energy (ΔH), ΔG becomes more negative and this can seem to be good for the process, because it becomes more spontaneous. However, this occurs at the expense of an increase in the level of entropy, thus indicating a loss of the level of organization of the reactive system, which may indicate a higher production of by-products has taken place. Hence, the Second Law of Thermodynamics should also be used to deal appropriately the system, so as to generate

a more realistic scenario, taking into account a trade-off between energy and entropy (Andresen,2011; Bispo et al.2013). For these reasons, this paper tackles and explores the constructive details of these balances, as a result of which new insights were obtained.

2. Theoretical basis

Figure 1: Outline representation of a PFR

In dealing with mass balance, the following equation can be derived as a function of time (t), length (l), angle (θ) and radius (ϕ).

$$\frac{\partial m_i}{\partial t} \frac{dt}{dt} + \frac{\partial m_i}{\partial l} \frac{dl}{dt} + \frac{\partial m_i}{\partial \theta} \frac{d\theta}{dt} + \frac{\partial m_i}{\partial \phi} \frac{d\phi}{dt} = [\text{generation or consumption of } i] + \text{mass. dif} \quad (1)$$

Given that $\frac{dC_i}{dt} = \frac{1}{V} \frac{dn_i}{dt} = \frac{1}{VM_i} \frac{dm_i}{dt}$ results in $\frac{dm_i}{dt} = \mp r_i VM_i$, then Equation 1 can be rewritten as:

$$\frac{\partial m_i}{\partial t} + \frac{\partial m_i}{\partial l} \frac{dl}{dt} + \frac{\partial m_i}{\partial \theta} \frac{d\theta}{dt} + \frac{\partial m_i}{\partial \phi} \frac{d\phi}{dt} = \mp r_i VM_i + [\text{mass diffusion}] \quad (2)$$

r_i is the reaction rate of generation or consumption of the component i while M_i is its molecular mass. Since $m_i = C_i VM_i$ and the transport by mass diffusion can be given by $J_m = D_{ij} \left[\frac{\partial^2 C_i}{\partial l^2} + \frac{1}{\phi^2} \frac{\partial^2 C_i}{\partial \theta^2} + \frac{1}{\phi} \frac{\partial}{\partial \phi} \left(\phi \frac{\partial C_i}{\partial \phi} \right) \right]$, where D_{ij} denotes the diffusion coefficient, Eq. 2 does not seem to meet the needs of analysis, because the working variables, i.e., those normally used, have not been adequately inserted. Consequently, the working variable as concentration should be introduced. Therefore, Equation 2 can be rewritten as:

$$\frac{\partial C_i}{\partial t} + \frac{\partial C_i}{\partial l} \frac{dl}{dt} + \frac{\partial C_i}{\partial \theta} \frac{d\theta}{dt} + \frac{\partial C_i}{\partial \phi} \frac{d\phi}{dt} = \mp r_i + D_{ij} \left[\frac{\partial^2 C_i}{\partial l^2} + \frac{1}{\phi^2} \frac{\partial^2 C_i}{\partial \theta^2} + \frac{1}{\phi} \frac{\partial}{\partial \phi} \left(\phi \frac{\partial C_i}{\partial \phi} \right) \right] \quad (3)$$

Having in mind the general formulation applied to the energy balance, the following Equation can be derived in which energy expresses E (total) with regard to the kinetic (E_k), potential (E_p) and internal energy (U). Given that $H = U + PV$ which can be rewritten as $H = U + E_p$, it is easy to note that total energy can be replaced by H , enthalpy, since kinetic energy can be neglected. Thus, the energy balance can be given by the following Equation:

$$\frac{dH(t,l,\theta,\phi)}{dt} = \frac{\partial H}{\partial t} + \frac{\partial H}{\partial l} \frac{dl}{dt} + \frac{\partial H}{\partial \theta} \frac{d\theta}{dt} + \frac{\partial H}{\partial \phi} \frac{d\phi}{dt} = \pm \dot{Q} \pm \dot{W} + \text{ther. diffusion} \quad (4)$$

It should be pointed out that Eq. 4 represents the state variable H as a function of space and time. However, in order to explore the thermodynamic behavior of the system, what is needed is to make this Equation appropriate, by introducing the state variable H as a function of $H(T, P, n_i)$, where T , P and n_i denote temperature, pressure and moles of component i , given by:

$$dH = \frac{\partial H}{\partial T} dT + \frac{\partial H}{\partial P} dP + \sum_i \bar{H}_i dn_i \quad (5)$$

where \bar{H}_i represents the partial molar enthalpy. By placing Eq. 5 into Eq. 4, Eq. 6 can be obtained:

$$\begin{aligned} & \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{dt} \right] + \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{dt} \right] \frac{dl}{dt} + \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{d\theta} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{d\theta} \right] \frac{d\theta}{dt} + \\ & \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{d\phi} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{d\phi} \right] \frac{d\phi}{dt} = \pm \dot{Q} \pm \dot{W} + [\text{heat generated by the reactive system}] + \\ & [\text{thermal diffusion}] \end{aligned} \quad (6)$$

or rewritten as:

$$\begin{aligned} & \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{dt} \right] + \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{dt} \right] \frac{dl}{dt} + \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{d\theta} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{d\theta} \right] \frac{d\theta}{dt} + \\ & \left[\left(\frac{\partial H}{\partial T} \right)_P \frac{dT}{d\phi} + \left(\frac{\partial H}{\partial P} \right)_T \frac{dP}{d\phi} \right] \frac{d\phi}{dt} = \pm \dot{Q} \pm \dot{W} + \Delta H_R(-r.V) + K \left[\frac{\partial^2 T}{\partial l^2} + \frac{1}{\phi^2} \frac{\partial^2 T}{\partial \theta^2} + \frac{1}{\phi} \frac{\partial}{\partial \phi} \left(\phi \frac{\partial T}{\partial \phi} \right) \right] \end{aligned} \quad (7)$$

It should also be noted that Eq. 4 does not contain such a heat generated by the reactive system. It is important to emphasize that the heat generated by the reactive system arose in Eq. 6 due to the difference between the partial molar enthalpy between reagents and products. The dependence relationships between H and T or P are well known and they can be easily found by means of the Maxwell equations.

Since the heat generated by the chemical reaction is given by $\Delta H_R(-r.V)$ and considering the mass balance besides the thermal diffusion given by (J_Q) , then Eq. 6 can be rewritten as shown in Eq.7.

To make the in-depth analysis of the process, which was mentioned in the introduction, the entropy balance must be introduced to meet analytical needs. Therefore, the Second Law of Thermodynamics should be used.

$$\frac{dS(t, l, \theta, \phi)}{dt} = \frac{\partial S}{\partial t} + \frac{\partial S}{\partial l} \frac{dl}{dt} + \frac{\partial S}{\partial \theta} \frac{d\theta}{dt} + \frac{\partial S}{\partial \phi} \frac{d\phi}{dt} = \frac{\delta \dot{Q}}{T} + \delta \dot{\sigma} + \text{entro. diffusion} \quad (8)$$

where \dot{Q} denotes the heat flow through the surface and $\dot{\sigma}$ represents the entropy production rate while Equation 8 expresses entropy change as a function of space and time. In the same way that was followed for previous balances, the entropy change must be expressed as a function of T , P and n_i to give thermodynamic sense to the analysis. The entropy change can be given by:

$$dS = \frac{\partial S}{\partial T} dT + \frac{\partial S}{\partial P} dP + \sum_i \bar{S}_i dn_i \quad (9)$$

By introducing Eq.9 into Eq. 8, the following equation can be obtained:

$$\begin{aligned} & \left[\left(\frac{\partial S}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial S}{\partial P} \right)_T \frac{dP}{dt} \right] + \left[\left(\frac{\partial S}{\partial T} \right)_P \frac{dT}{dt} + \left(\frac{\partial S}{\partial P} \right)_T \frac{dP}{dt} \right] \frac{dl}{dt} \\ & + \left[\left(\frac{\partial S}{\partial T} \right)_P \frac{dT}{d\theta} + \left(\frac{\partial S}{\partial P} \right)_T \frac{dP}{d\theta} \right] \frac{d\theta}{dt} + \left[\left(\frac{\partial S}{\partial T} \right)_P \frac{dT}{d\phi} + \left(\frac{\partial S}{\partial P} \right)_T \frac{dP}{d\phi} \right] \frac{d\phi}{dt} \\ & = \frac{\delta \dot{Q}}{T} + \delta \dot{\sigma} - \Delta S_R(-rV) + [\text{entropy diffusion}] \end{aligned} \quad (10)$$

where $\dot{\sigma}$ denotes the entropy production rate. Entropy diffusion (J_s) is given by $J_s = \frac{J_Q}{T}$ (Umpierre, 2015).

REDUCING THE DIMENSIONALITY OF THE SYSTEM

In practice, it is always important to make some simplifications. Thus, it is not difficult to verify for most practical cases that the following conditions can be assumed:

- There is no shaft work, the fluid properties are constant, the velocity of the fluid is sufficiently high to neglect the effects of diffusions, the external temperature is maintained constant, only the effects and interactions along the length are considered and the drop in pressure is negligible.
- In addition, another substantially significant one can be assumed, namely: the steady state.

As the objective is to bring the system as close as possible to reversibility, which corresponds to a particular steady state and since the above conditions are easy to verify in practice, considering also that $v_l = \frac{dl}{dt}$ and $\Delta S = \frac{\Delta H}{T}$, because $\Delta G=0$ when the system goes towards reversibility, then Eqs. 3, 7 and 10 can be reduced to:

$$\begin{aligned} \frac{\partial c_i}{\partial t} v_l &= \mp r_i ; \quad \left[\left(\frac{\partial H}{\partial T} \right)_p \frac{dT}{dt} \right] v_l = \pm \dot{Q} + \Delta H_R (-r \cdot V) ; \\ \left[\left(\frac{\partial S}{\partial T} \right)_p \frac{dT}{dt} \right] v_l &= \frac{\delta \dot{Q}}{T} + \delta \dot{\sigma} - \Delta S_R (-rV) \end{aligned} \quad (11)$$

Thus, by rearranging Equations in (11), it is easy to conclude the following:

$$\dot{\sigma} = 2 \frac{\Delta H_R}{T} (-rV) \quad (12)$$

Eq. 12 expresses the rate of entropy production for a PFR, which satisfies the restrictions aforementioned. For more complex cases and with reduced restrictions, the complete structure previously formulated should be used. The resulting set of couple differential Equations can be easily solved by means of one of several numerical methods widely cited in the literature (Fogler, 2016).

3. Results and Discussion

A simple but significant case has been used as a case study, for which the reduction of the dimensionality of the system has been taken into account. The classical tubular reactor presented by Bilous (Bilous and Amundson, 1956) also addressed by Himmelblau (Himmelblau and Bischoff, 1968) considers a simple reaction $A \rightarrow B$, irreversible, first order, for which the data sheet, extracted from Bilous and Amundson (1956). By using such data, jointly with the balance model established, the behavior of the concentration of the reagents and the system temperature are shown below. Additionally, since the 2nd Law of Thermodynamics plays a pivotal role in the optimization of results, then the entropy production rate and the entropy production for two wall temperatures are also depicted below (Jaynes, 1980). It should be emphasized that the model with the aforementioned restrictions fully reproduces the results obtained by Bilous and Amundson.

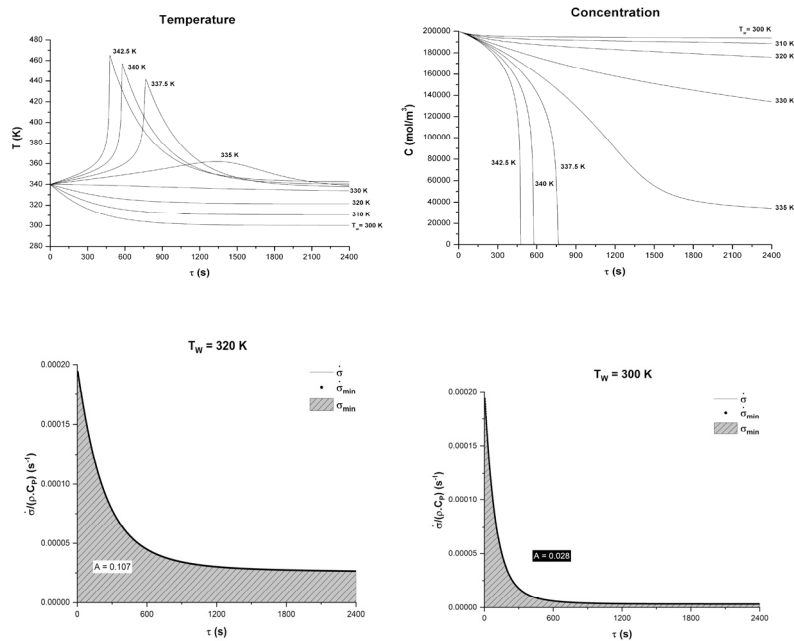

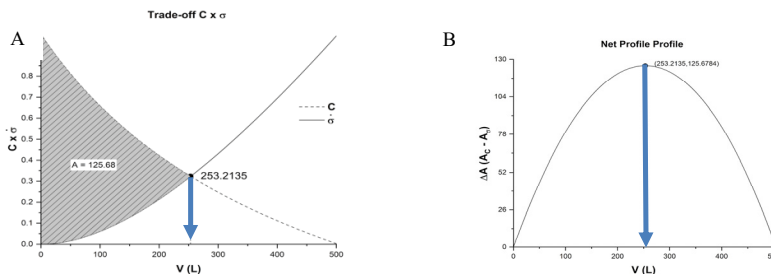

Figure 2: Concentration profile, temperature and the entropy production. The rate of entropy production and its maximum value are also shown for two wall temperatures (T_w). From graphical results presented above it is noted an increase in the conversion as too in the production of entropy, with probably the generation of by-products, which can energetically overload the separation section. Thus, the global energy saving may not meet the initial expected savings.

Additional insights derived from entropy analysis

The idea to develop a relation between concentration and entropy comes from cost analysis that it seems to be direct and very relevant, with a view to determining the optimum length of the reactor. This can be done by establishing a trade-off between conversion and the entropy production. The graph below shows the quantities, concentration and the entropy production, with data normalized on a scale from 0 (zero) to 1 (one) and plotted on the Cartesian plane.

The area under the concentration curve in Figure 3 A shown below can be viewed as income because it generates the product of economic interest while the area under the entropy production curve in the same Figure can be regarded as the entropic cost (variable cost). Thus, the shaded region can be considered as an indicator of net profit because it is the result of the difference between the revenue and the cost. Note also from the intersection point of the two curves, that the area between the concentration and the entropy production may indicate a monetary loss because the operating costs denoted by the production of entropy is higher than the revenue represented by the concentration.

Figure 3 B shows a difference ΔA between the area (A_C) of concentration (profit) and the area (A_σ) of entropy production (cost), as a measure of the net profit or loss. Another relevant feature of the graph shown in Figure 3 B is the maximum point of the curve that represents the difference ΔA between the areas of concentration less entropy production that is, the maximum profit. If $\Delta A < \Delta A_{max}$, this would generate a smaller profit.

Figures. 3 A: Trade-off between concentration and the entropy production. 3 B: Difference ΔA between the area (A_c) of concentration (profit) and the area (A_σ) of entropy production (cost), as a measure of the net profit or loss.

Concluding Remarks

This paper showed the development in detail of the balances of mass, energy and additionally the entropy balance applied to PFR with a view to bridging the conceptual gaps that the literature has discussed over the last 20 years.

The results also showed the behavior of the system in relation to conversion, temperature and the entropy production rate, in addition to the entropy production. It should be noted that the result for conversion and temperature of the system reveal the same behavior obtained by Bilous (Bilous and Amundson, 1956). It was also shown that from the economic point of view, the intersection of the curves, conversion and the entropy production, establishes the optimal point, which denotes economic efficiency. Taking into account the optimal point and since there is a strong relationship between it and the length of the reactor, then it is possible directly to determine the optimal length of the reactor for producing the best economic results, mainly regarding the saving of energy due to reduced overloading of by-products for separation section.

Finally, the methodology has proved to be a feasible strategy, easy to apply and of low operating cost.

Abstract

Data-driven operation monitoring and optimization of chemical plants can be performed using Digital Twin, along with intelligent algorithms. This study proposed a sequence-to-sequence rolling training algorithm to overcome the challenge of rolling predictions. The data were generated through dynamic simulation of the vapor-recompression C3 process using Aspen Plus. Studies showed that StS with rolling training could better fit the real data than the StS model. Moreover, StS with rolling training was able to present efficient long-term predictions as Digital Twin.

Keywords: Digital Twin, sequence-to-sequence model, rolling training, long-term prediction.

1. Introduction

Digital twin (DT) defines the application of holistic simulations to virtually mirror the physical systems. Adopting digital twins can assist engineers to monitor productions, evaluate the benefits and safety of the control in an isolated virtual environment, and operation strategies by interacting with the twin model before going online (Rosen et al. 2015; Eckhart and Ekelhart, 2018; He et al. 2019).

A digital twin can be developed through the first principle models (FPMs) and data-driven models (DDMs) (Chou et al. 2019). Commercial DT solutions for chemical plants are generally based on data-driven models improved purely from the measured data of the targeted industrial plants (Brenner and Hummel, 2017; Magargle et al. 2017). DTs based on data-driven methods depend on the black-box models created to attain correlations between the inputs and outputs of the plant (Pantelides and Renfro, 2013). These systems are applied to find specific production anomalies or to achieve production forecasts. However, they cannot be used to predict abnormal plant operation situations not covered by the available collected data because they are based only on measurement data attained from the plant. Moreover, they need proficient interpretation and are thus complicated to scale up (Eckhart and Ekelhart, 2018). Data-driven DT application depends on the automation and the monitoring systems to provide information about the plant state (Pantelides and Renfro, 2013). In contrast, the advantage of the first principle model can be ensuring that a physical process response

is correct. The drawbacks are including a lot of domain knowledge is required, a lot of information may not be readily available, the model development life cycle will be a very long-time, the accuracy of the model may be limited and restricted by the use of commercial software (Boschert and Rosen, 2016; Martínez 2018). Some researchers have studied the application of DT in engineering optimization (Rosen et al. 2015; Gabor et al. 2016). There is no guarantee that the data-driven method can extrapolate beyond existing data because very little domain information about the process is used. Therefore, there are always doubts about whether such models can serve as true DTs. Sequence-to-Sequence (StS) model is the closest approach as a DT, but the prediction is not long enough (Chou et al. 2019).

This study proposes a novel training algorithm to ensure that the StS model is able to generate infinite long-term rolling predictions as a DT. The paper combines the research within the dynamic simulation and rolling prediction. DT is developed and used for the quality and process control of a chemical plant. The procedure not only minimizes the output errors but also errors in the prediction of the hidden state as a rolling prediction without new sensor input is performed.

2. Methodology

2.1. Process Description

Aspen Plus was employed for dynamic process simulation of the vapor-recompression C3 (propane-propylene) distillation column, and about 10^6 data were generated with random disturbances of the inlet compositions and flow rate. The vapor-recompression C3 flowsheet is shown in Figure 1.

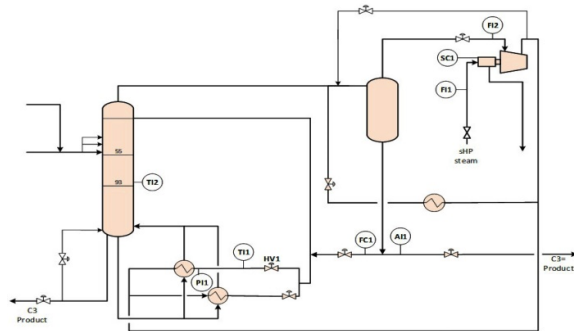

Figure 1. VRC C3 process schematic.

Data of three manipulated variables (u_t), five sensor variables (sv_t) such as flows, pressures, temperatures, and one quality variable (qv) were available every minute, as Table 1 presents. 10^6 data of variables were collected by averaging every 10 minutes, in 2~3 years. The manipulated variables were adjusted in the process, but the sensor variables were measured. The StS model was trained for the rolling prediction. Then, the results of StS model and StS with rolling training for quality and sensor variables were compared for one day and eight days of rolling predictions. The coefficient of determination (R^2), a statistical measure of the goodness of fit with respect to variations, of test data predictions was used as an indicator of the prediction accuracy of the model. The higher coefficients are indicators of better goodness of fit for the observations.

Figure 2 shows StS rolling prediction of the quality variable for one day. The model could only predict well for the first nine hours while the error increased along with the

rolling. R^2 was calculated 0.217 for this case and it confirmed that horizontal prediction is not equal to the rolling prediction. Therefore, the StS model was trained for the rolling based on the algorithm mentioned in Figure 3.

Table 1. Variables of the process

Variables		
u_1	SC1	Compressor speed control
u_2	FC1	Reflux rate control
u_3	HV1	Valve control
qv_1	AI1	Bottom composition measurement
sv_1	FI1	Steam rate measurement
sv_2	FI2	Flow of top vessel measurement
sv_3	TI1	Temperature of major reflux measurement
sv_4	TI2	Temperature of distillation measurement
sv_5	PI1	Pressure of major reflux measurement

Figure 2. StS Rolling prediction of one day for the quality variable.

2.2. Rolling training algorithm

The new procedure designs rolling training for the StS model in each epoch (Figure 3). The StS model is composed of two sections comprising an encoder (En) and a decoder (De), each of which is a chain of cells corresponding to different time steps. The encoder is an observer, and the decoder is a predictor. Based on Figure 3, when

$$\begin{aligned} \text{Rolling} = 1 & \quad h_{En,r,t} = h_{De,r0,t} & r = 0, \dots, W \\ \text{Rolling} = 2 & \quad h_{En,r,t+1} = h_{De,r0,t+1} & r = 0, \dots, W \\ \text{Rolling} = W-1 & \quad h_{En,r,t+(W-1)} = h_{De,r0,t+(W-1)} & r = 0, \dots, W-1 \end{aligned}$$

$r = 0$ is defined as horizontal prediction.

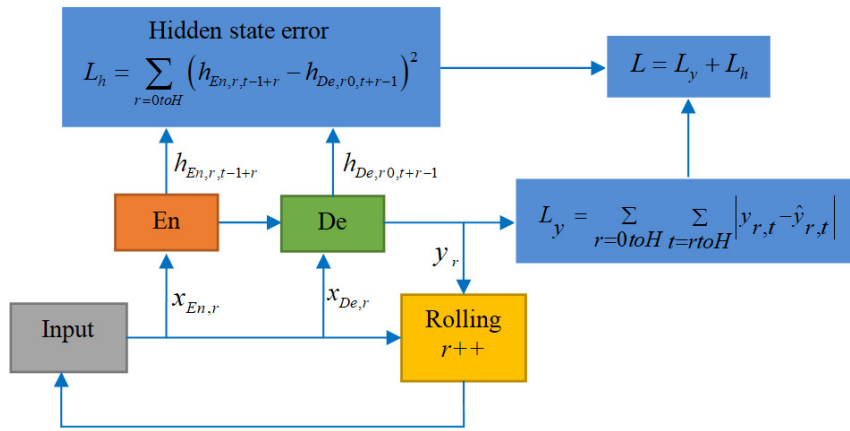

Figure 3. Architecture of StS network with rolling training

3. Result and discussion

3.1. Rolling prediction of quality variable

Figure 4. Rolling prediction for one day using the StS model.

Figure 5. Rolling prediction for one day using StS with rolling training.

Figure 6. Rolling prediction for eight days using the StS model.

Figure 7. Rolling prediction for eight days using StS with rolling training.

Table 2. Comparison of R^2 for variables predictions

	R^2			
	StS (1 day)	StS with rolling training (1 day)	StS (8 days)	StS with rolling training (8 days)
qv ₁	0.217	0.975	0.170	0.972
sv ₁	0.433	0.950	0.370	0.975
sv ₂	0.906	0.990	0.956	0.996
sv ₃	-6.703	0.734	-2.088	0.895
sv ₄	0.911	0.985	0.877	0.994
sv ₅	0.906	0.985	0.868	0.993

A comparison study of the StS model and StS with rolling training is shown in Figures 4–7 and Table 2. As shown in Figure 5, the rolling prediction of the quality variable for one day was able to closely follow the real data, and R^2 improved by 0.76 compared with the StS model (Figure 4). According to Figures 6 and 7, rolling prediction of the quality variable for eight days did not match the real data for the StS model but, for long-term rolling prediction, StS with rolling training could show good performance and R^2 improved by 0.80. Table 2 confirms the superiority of StS with rolling training

compared with the StS model. For all variables, the errors for StS with rolling training are less than the StS model, especially for qv_1 , sv_1 , and sv_3 that the difference is considerable. Rolling training on the StS model could significantly improve sv_3 because R^2 increased by 7.43 and 2.98 for one day and eight days predictions, respectively. Moreover, the determination coefficients of StS with rolling training for eight days could better fit the real data compared with one-day rolling training. Besides, sv_3 could present an improvement of 21.93% in the long-term prediction.

4. Conclusions

In this study, the rolling training algorithm could enhance the performance of long-term StS rolling predictions in the process of vapor-recompression C3. The model could predict dynamic responses over a near infinite horizon using various manipulation sequences that were not included in the training data, with only a short window of observed data. StS model with long-term rolling predictions could better fit the real data than the StS model. Therefore, the StS model with rolling training was concluded as a true data-driven digital twin of a physical simulator in this study.

Abstract

Model-based approaches are essential for the operation, optimization, and control of applications in the process industry. Different structures are often investigated to build representative and robust models, and a set of parameters with the same attributes are required to utilize them effectively. Parameter estimation gets arduous with the increasing complexity of the process, the model, and the size of the parameter space. In this work, a parameter-estimation problem based on a steady-state model of diesel hydrodesulfurization is investigated using gradient-based and gradient-free optimizers. The optimal parameter sets obtained are then assessed in terms of performance and computational time for the different optimizers. Furthermore, the sensitivity of the various parameters is also investigated. Due to the catalytic reactions in this process, some parameters have to be updated depending on the catalyst activity. In addition to the initial estimation, the updated parameters are also studied, and instead of a time-based one, a tolerance-based recalculation schedule is suggested. Finally, the robustness of the final model is analyzed by giving different operating conditions and feed characteristics. The adaptive parameter approach proved better data fitting capabilities by improving the coefficient of determination for temperature predictions.

Keywords: parameter estimation, optimization, sensitivity analysis.

1. Introduction

Environmental regulations to decrease the land and sea vehicles' SO_x emissions have urged refiners to produce low sulfur fuels. For the production of ultra-low-sulfur diesel, ultra-low-sulfur gasoline, and low-sulfur marine grade fuels, to meet the most recent Emission Control Area (also known as global sulfur cap) regulations (IMO, 2016), hydrodesulfurization (HDS) systems are used at various locations in a refinery, i.e., pretreatment of naphtha isomerization, reforming, and heavy-oil cracking feedstock, post-treatment of fluid catalytic cracking product. HDS reactors generally consist of a series of fixed catalyst beds at 300 – 400 °C and 30 – 130 bar (Jiménez et al., 2007).

Tasks of design, simulation, optimization, and control of HDS are aided by mathematical models of the system akin to other refinery operations, which differ from most chemical process models by the number of compounds and chemical reactions involved. There are different approaches to model such systems used for these tasks, some more convenient than the others reflecting the behavior of high numbers of compounds and reactions. To describe the kinetics of the HDS reactions, power-law (Dorneles de Mello et al., 2018) and Langmuir - Hinshelwood (Borgna et al., 2004; Jarullah et al., 2011) models are widely used in the available literature. While the power-law models are simpler with fewer parameters involved, Langmuir – Hinshelwood models are more informative on

the surface-catalyzed reactions. Furthermore, a lumping methodology is commonly used for HDS models. Discrete lumping (Yang et al., 2017), continuous lumping (Aydin et al., 2015; Elizalde & Ancheyta, 2012), and structure-oriented lumping (Ghosh et al., 2009) offer varying levels of fidelity, and these methods are previously discussed according to the required input data and computational effort (Iplik et al., 2020).

Discrete lumping and continuous lumping models are often used for simulation and optimization studies due to their simplicity compared to structure-oriented lumping. During the commercial process with fixed bed reactors, catalyst loses its activity due to coke and metal deposition in the porous structure (Maity et al., 2013). Although this phenomenon is studied and modeled (Takatsuka et al., 1996), and it causes an increase in the operational temperature, it is rarely included in the simple power-law models. If the deactivation is not included in the model, an optimization with a final sulfur concentration constraint will fail to estimate optimal operating conditions as the catalyst activity decreases.

A continuous lumping model for a hydrocracker, by Elizalde and Ancheyta (2014), is an example considering catalyst deactivation with an additional time-dependent model equation for activity decay that has a constant parameter dependent on the operating conditions and feed. As useful as it is for single crude processing refineries, most refineries operate with varying feedstock; therefore, it is hard to assume a constant decay. In this work, we suggest a reaction rate constant update schedule based on the difference between the model predictions and the process measurements.

2. Methods

Continuous lumping models are based on the assumption of the liquid mixture being a continuum with respect to a selected attribute (e.g., true boiling point, carbon number, reactivity) (Becker et al., 2015). This type of model is found useful for petrochemical applications due to its ability to represent the complexity of the mixture with a few parameters. The model used for this work consists of 1D differential mass and energy balances (Eq. 1 and 2) and a correlation of true boiling point to reactivity derived by Sau et al. (1997) (Eq. 3). True boiling point (TBP) is normalized by equation 4, and the distribution of the sulfur species is shown by equation 5. The term N represents the number of species in the mixture, and as $D(k)$ is their distribution function, equation 6 ensures the conservation of species (Chou & Ho, 1988). First-order kinetics was considered for all the reactions. Details of the model can be found in Elizalde and Ancheyta's work (2012) that used the same mass balance equation.

$$\frac{dc(k, z)}{dz} = -\frac{1}{\vartheta} k e^{-Ea/R(1/T-1/T_0)} c(k, z) \quad (1)$$

$$\frac{dT}{dz} = \frac{1}{\vartheta \cdot c_p} \int_0^{k_{max}} k e^{-Ea/R(1/T-1/T_0)} c(k, z) D(k) (-\Delta H(k)) dk \quad (2)$$

$$k = k_{min} - k_{max} \ln(e^{-1} - 1) \theta^{1/\beta} \quad (3)$$

$$\theta = \frac{TBP - \min(TBP)}{\max(TBP) - \min(TBP)} \quad (4)$$

$$D(k) = \frac{di}{d\theta} \frac{d\theta}{dk} = N \frac{d\theta}{dk} \quad (5)$$

$$\frac{1}{N} \int_0^{k_{\max}} D(k) dk = 1 \quad (6)$$

The model with the given equations has five parameters, k_{\min} , k_{\max} , β , E_a , and ΔH . While k_{\min} and k_{\max} represent the reactivities of the highest and the lowest boiling point compounds that consist of a sulfur atom, respectively, β is the exponential correlation coefficient. E_a and ΔH are the activation energy and the heat of reaction; however, rather than belonging to a single reaction, these values represent all the reactions of the continuous mixture.

The initialization of the concentration distribution on the TBP curve was formulated as a constrained optimization (Govindhakannan & Riggs, 2007) and solved with a sequential quadratic programming algorithm. The sulfur compounds are normally distributed on the same TBP curve. Differential material and energy balance equations were solved with a 5th order Runge – Kutta method. The parameter estimation problem was structured as a sum of temperature and sulfur residuals given in equation 7.

$$\min_p \left(\sum_{n=1}^3 ((T_{data,n} - T_{pred,n}(p))^2) + \sum (s_{data} - s_{pred}(p))^2 \right) \quad (7)$$

Two methods were tested to solve the problem, gradient-based optimization and gradient-free optimization. Both solvers were given constraints to prevent impractical results such as negative activation energy. Multiple initial points were randomly distributed by Latin hypercube sampling, and in total, 190 initialization sets were employed for the gradient-based solution. Matlab fmincon solver with an interior point algorithm was used as the gradient-based method, and simulated annealing was used as the gradient-free method. Unlike the gradient-based solution, simulated annealing was initialized only once due to its ability to avoid local minima.

The data was collected from a real HDS plant with three catalyst beds; therefore, all the parameters were estimated for each bed. The resulting parameter sets were evaluated on test data. A sensitivity analysis was applied to the best fitting parameter set by perturbation of $\pm 10\%$ on each parameter. Finally, an update schedule for the reaction rate constant was tested, recalculating the parameters within $\pm 10\%$ constraints of their latest value, when any temperature prediction has an error over 2 K. While updating the deviating bed's parameters, activation energy and specific heat of reaction were not recalculated. The cost function of the update included only the relevant bed's temperature residual and the final sulfur residual.

3. Results and Discussion

Using the temperature and the sulfur measurements of the process, the parameter estimation problem was solved with two different algorithms. Within the analysis of the

190 resulting parameter sets of the gradient-based algorithm, 62% of them were found in local minima, compensating the temperature residual with the sulfur residual or vice versa. The feasible parameter sets, together with the one obtained from the simulated annealing algorithm, were tested by using a data set that was not included in the solution of the parameter estimation problem. Consecutive data sets were selected for the parameter estimation and the test case to eliminate the effect of catalyst deactivation on the reaction constants. The best-fitting parameter set was found by the gradient-based optimization, given in Table 1.

Table 1: Estimated best-fitting parameters.

1 st bed		2 nd bed		3 rd bed	
$k_{\min 1}$ [h^{-1}]	0.89	$k_{\min 2}$ [h^{-1}]	1.49	$k_{\min 3}$ [h^{-1}]	1.49
$k_{\max 1}$ [h^{-1}]	2.45	$k_{\max 2}$ [h^{-1}]	9.95	$k_{\max 3}$ [h^{-1}]	1.51
β_1 [-]	9.96	β_2 [-]	1.00	β_3 [-]	5.79
E_{a1} [kJ/kmol]	65500	E_{a2} [kJ/kmol]	66500	E_{a3} [kJ/kmol]	51800
ΔH_1 [$\text{kJ/kg}_{\text{sulfur}}$]	-7555	ΔH_2 [$\text{kJ/kg}_{\text{sulfur}}$]	-5230	ΔH_3 [$\text{kJ/kg}_{\text{sulfur}}$]	-8278

One point to keep in mind is the time needed to estimate these parameters. The gradient-free algorithm took roughly 48 hours to calculate a single set of parameters, which was not the best fit. The gradient-based algorithm estimated a set of parameters, on average, every 15 minutes that resulted in 190 parameter sets taking the same time. With the increasing number of dimensions and the nonlinearity of the models, parameter estimation requires high computational time, and the fast gradient-based algorithms might fail to calculate a feasible set. However, with a simple set up, the design space can be investigated thoroughly, and a useful set of parameters can be estimated.

Perturbation of the parameters given in Table 1 by $\pm 10\%$ showed that the changes in E_a and ΔH do not have a considerable effect on the temperature or sulfur concentration predictions of the model. On the other hand, k_{\min} , k_{\max} , and β changes affected the model outputs significantly. The extent of the changes is given in Figure 1 for some parameters of the first bed. Since the sulfur measurement is only available for the final product, the right-hand side axes of all the graphs show the effect of each parameter on the final value, whereas the left-hand side axes demonstrate the impact on the given bed temperature.

Figure 1: Sensitivity analysis results of some parameters. (\square - Temperature, \diamond - Sulfur)

Based on the sensitivity of the parameters, k_{\min} , k_{\max} and β were selected for the update procedure to explain the catalyst deactivation, therefore, to predict the relevant values better. Temperature measurements were chosen to set the update threshold, and each catalyst bed was evaluated separately. When the bed temperature prediction failed to stay in the 2 K error threshold region, k_{\min} , k_{\max} , and β of the related bed were recalculated by using the last measurements as explained in the previous section.

As expected, the first bed parameters were updated more often due to faster deactivation. None of the updates were periodic; the time passed between the updates varied between

two to eight weeks. Lacking a regular trend shows the benefit of the error threshold based parameter updates. The difference in the feed characteristics causes a difference in the deactivation pattern.

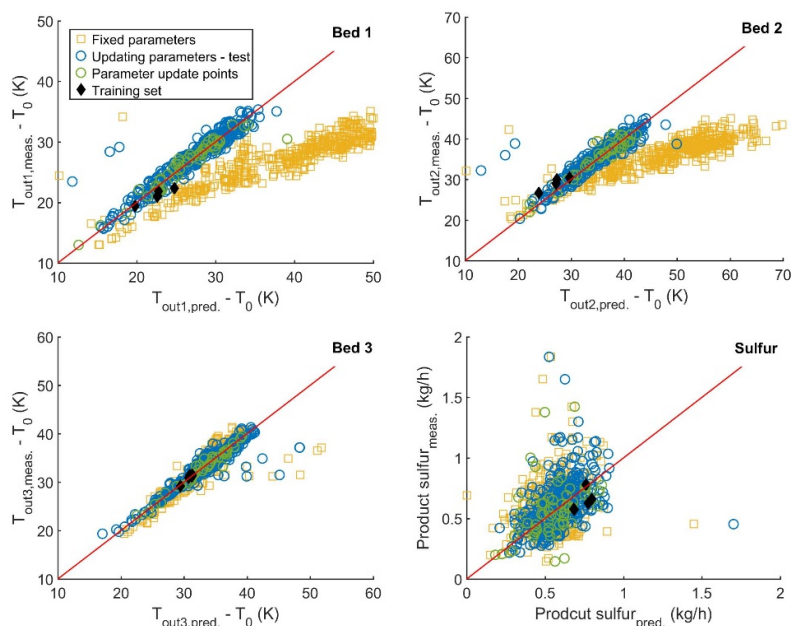

Figure 2: Model outputs with and without the parameter update schedule

The difference between the temperature measurements and the model predictions are given for bed temperatures and sulfur content in Figure 2. The improvements in the model prediction capabilities can be seen from the graphs. Especially in the first two catalyst beds, the fixed parameter set fails to give reasonable estimates as the temperature increases. The update procedure prevents this significant deviation that indeed occurs due to lower catalyst activity. The final sulfur content prediction has a higher error than the other model outputs and, its coefficient of determination increased to 0.65 from 0.45 after the updates.

4. Conclusion

A steady-state continuous lumping model was used to explain real data of an HDS reactor with three catalyst beds. The parameter estimation problem was solved with a gradient-based and a gradient-free algorithm. The best fit was chosen, and the sensitivity of the parameters was checked in the $\pm 10\%$ region. The parameters related to the reaction rate constants were found to be more sensitive than the activation energy and the heat of reaction values. The sensitive parameters were selected to be recalculated when the model failed to predict the temperature with a greater error than 2 K, assuming that the reason was the deactivation of the catalyst over time. The model predicted the bed temperatures better with the update schedule. The deactivation is compensated with a temperature increase, and a high temperature causes a premature deactivation. Therefore, it is crucial to update the models to predict the desired process values correctly; an outdated model cannot be used for optimization or control. The refineries using changing feed should

consider a check of prediction deviations as the deactivation will differ according to the processed mixture.

Abstract

In this study, we developed a model of amine regeneration process with electrodialysis reclamation unit based on the removal of heat stable amine salt (HSAS) and conducted techno-economic analysis (TEA) by applying the developed model. The HSAS produced in the amine regeneration process acted as a corrosive factor and reduced the efficiency of heat exchanger and the amount of amine available. During development, the model was divided into the amine gas sweetening process and amine regeneration unit construction. The thermodynamic equation considered electrolyte phase equilibrium using the electrolyte nonrandom two liquid model. A RadFrac model was used for regeneration, the removal process of H₂S, and the HSAS removal unit considered the reaction with the sodium hydroxide solution by utilizing the RCSTR model. According to TEA, the total capital investment increased by \$1,823,530, but the total plant cost decreased by \$485,994; therefore, the payback period was calculated at 3.75 y. We believe that the model could provide a guideline for process application if implemented for the optimization of other variables, such as the consumption of raw materials.

Keywords: heat stable amine salt, amine regeneration process, electrodialysis reclamation unit

1. Introduction

Recently, sulfur compounds, such as H₂S, which occur in the refinement of crude oil, are considered the main cause of air pollution. Unlike other air pollutants, they account for about 80% of the emissions generated during the combustion of plants and factories. In addition, they have a fatal effect on the human body and act as a corrosion factor in the process. Hence, many factories focus on the removal of these compounds, with most of them following the amine gas sweetening process for this purpose. This process involves the absorption and removal of H₂S generated during the combustion of crude oil using amine. After the absorption of H₂S, the amine is regenerated from the stripper and reused; this process is called amine regeneration. The absorption and regeneration mechanism of the amine is due to the pK_a difference from H₂S. In the absorber of the amine gas sweetening process, the pK_a difference is greater than one, and thus, the amine is

absorbed from H_2S because it operates at relatively low temperature and high pressure. Subsequently, the regeneration of amine occurring in the pKa difference is smaller than one by creating relatively high and low pressure conditions in the stripper of the amine regeneration process. However, if the amine reacts with relatively strong acids, such as formate, acetate in the acid gas, and even strippers under high and low pressure conditions, heat stable amine salt (HSAS) is produced because the pKa difference is greater than one. Because the HSAS remains in the process and acts as a corrosion factor, reducing the efficiency of the heat exchanger, it should be removed through additional processes. Among the various methods, electro dialysis reclamation is a method of the selective elimination of HSAS through a negative ion and positive ion permeability membrane via a reaction with a basic solution, such as NaOH, which has high electricity consumption and device cost. Therefore, when practically implementing the electro dialysis reclamation units, we must compare them with conventional processes through techno-economic analysis. Here, we developed a model of the amine regeneration process with electro dialysis reclamation unit and validated the model with the real data of the commercial plant. We carried out the economic assessment by applying the developed model, calculated the net present value (NPV) through the annual cash flow considering depreciation and inflation rate, and estimated the payback period (PBP) for annual total plant cost (TPC) reduction in comparison with the increased total capital investment (TCI).

2. Process description

Figure 1 depicts a simple workflow for the amine gas sweetening process. First, to remove the H_2S generated during the refinement of crude oil from sour gas, the gas enters the sour gas absorber. The sour gas absorber typically uses a tray column, and the bubble cap on each plate is deployed to facilitate the contact between gas and liquid. The H_2S is afterward absorbed and removed through an exothermic reaction under relatively low-temperature and high-pressure conditions by contacting with amine (Eq. (1)).

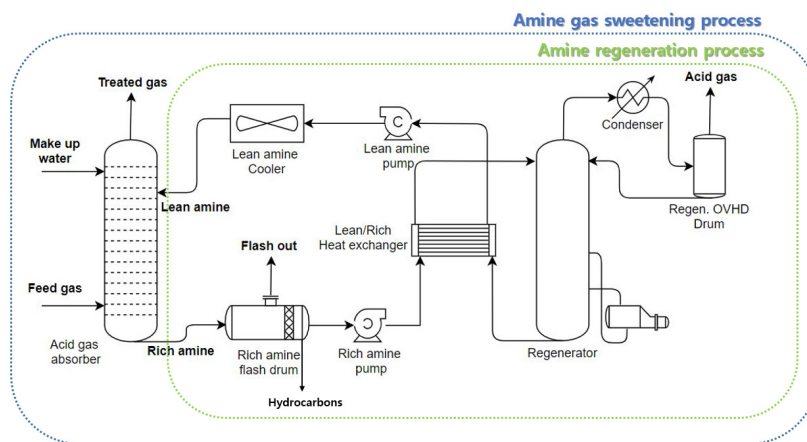

Figure 1 - Schematic diagram of amine gas sweetening process.

The amine that absorbs H₂S, called rich amine, is discharged into the lower part of the absorber and undergoes the amine regeneration process.

The hydrocarbons in rich amine are removed by weight difference in rich amine flash drum, which operates at low pressure to maintain the amine flow to the regenerator. To reduce the heat load of the reboiler in the regenerator and remove H₂S, the rich amine is preheated through the Lean/Rich heat exchanger before entering the regenerator. Subsequently, it enters the regenerator for regeneration. The regenerator utilizes the tray column like sour gas absorber. The steam produced in the reboiler applies sufficient heat to the amine solution to aid the removal reaction. After the regeneration, acid gas is cooled through the condenser and released via the treatment process. Thereafter, the regenerated amine circulates in the lower part for reuse. The amine that removed the H₂S can be reused through the removal process and is called lean amine. The regenerated lean amine is reused by reducing the temperature using the Lean/Rich heat exchanger, thereby entering the absorber through Lean amine cooler and filter. In addition to H₂S, the sour gas produced during the combustion of crude oil contains relatively acidic substances, such as acetic acid and formic acid, which generate HSAS when reacted with amine. The typical HSAS contains acetate and formate, and the salt-producing reaction formula is as follows (Eq. (2), (3)).

3. Model development

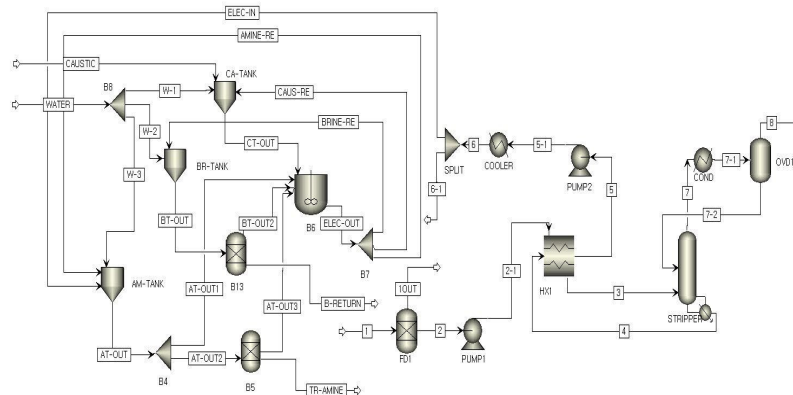

Figure 2 - Schematic diagram of amine gas sweetening process.

In this study, Aspen plus V10 was used to simulate the amine regeneration process. Figure 2 presents a schematic diagram of the amine gas sweetening process. The electrolyte nonrandom two-liquid model was used as the thermodynamic model for considering the gas phase and the chemical reaction mechanism of the absorption and regeneration of H₂S in the amine regeneration process using the Redlich–Kwon equation. The equilibrium constant of absorption, regeneration, and HSAS removal reactions was obtained by minimizing the Gibbs free energy. In process modeling, SEP1 was simulated using the Separator model as rich amine flash drum, which input the split fraction as much as the emission flow from the actual process. Afterward, the rich amine entered the Lean/Rich Heat Exchanger, which was HX1, and heat exchange occurred. HX1 used MHeatX model and entered the outlet temperature of the actual condition. The regenerator was simulated using the RadFrac model and referenced the operating condition in the actual process, such as feed stream to stage, reboiler type. It is also reflected in the model considering the reaction of the regeneration of H₂S. Finally, EL-STACK was simulated using the RCSTR model as the electro dialysis stack. Operation conditions were set to 40 °C and 5 atm, assuming equal temperature and pressure, and the reactor volume was entered referring to design basis. The design conditions are based on those of a commercially operated electro dialysis reclaiming unit with a capacity of 0.5 kg-mol/day.

Table 1 lists the validation results for design. These results indicate that the composition was mostly consistent with the simulation results; however, there was a difference in the amount of HSAS and H₂S removed. This is because the difference of the values was calculated using the equilibrium constant obtained by minimizing the Gibbs energy, which was influenced by other factors in the actual process, such as temperature and pressure. However, factors that affect the equilibrium constant must be derived through experimental study. Therefore, in the future, the model could be modified considering other factors that affect the reaction.

4. TEA

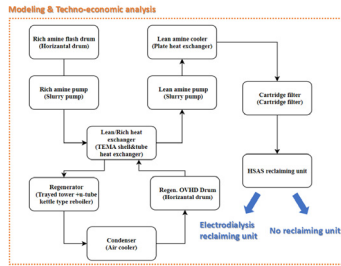

Figure 3 - TEA diagram of the process.

Figure 4 - Cash flow of the process

Techno-economic analysis (TEA) is performed to determine the potential for investment by reviewing economic feasibility in advance. Figure 3 presents the TEA diagram of the process. Here, we conducted TEA with existing processes to determine their economic feasibility with electrolysis reclamation unit using the developed model. The NPV was calculated based on the 20-year recovery period and PBP was estimated using the decreased annual TPC. Table 2 lists the equipment costs and Table 3 the utility costs of the reclamation unit obtained from the Aspen Process Economic Analyzer software.

Table 2 - Equipment cost of the process.

Category	Equipment Cost [\$]
Flash drum	74,400
Rich amine pump	9,044.53
Heat exchanger	1,374,600
Stripper	463,500
Condenser	352,900
Lean amine pump	8,711.29
Cooler	16,100
Filter	50,600
Overhead drum	14,600
Electrodialysis reclaiming unit	1,550,000

Table 3 - Utility cost of the process.

Category	Usage	Unit
Cooling water	134,942.0	\$/y
Steam	4,937,273	\$/y
Electricity	73,937.60	\$/y
Makeup water	22.44294	\$/y

The TCI includes equipment, labor, and land costs necessary for the construction and installation of the initial process. Generally, it includes the fixed capital cost (FCI), startup cost, and working capital. The TPC is the cost incurred by the production or service of a product. Tables 4 and 5 list the TCI and TPC of each process, respectively.

Table 4 - TCI of each process.

Classification	Conventional process	Improved process	Unit
FCI	11,916,857	11,916,857	\$
Startup cost	1,191,685.7	1,191,685.7	\$
Working capital	2,313,272.3	2,586,801.7	\$
TCI	15,421,815	17,245,345	\$

Table 5 - Total plant cost (TPC) of each process.

Classification	Conventional process	Improved process	Unit
Manufacturing cost	10,591,552	10,004,559	\$
General expense	0.000000	0.000000	\$
Reclamation unit cost	-	101,000	\$
TPC	10,591,552	10,105,558	\$

The NPV is the conversion of annual cash flows throughout the investment period into the present value (Eq. (4)). If the NPV has a positive value, it is considered a reasonable investment. However, because the amine regeneration process covered in this study is not a profitable process, the NPV always has a negative value when costs are converted according to current prices. The NPV of the two processes were calculated, and units with lower absolute values were determined to be economical. Table 6 lists the NPV of each process.

Table 6 - NPV of each process.

Category	NPV	Unit
Conventional process	-2,539,231	\$/kg HSAS reclaimed
Improved process	-2,531,225	\$/kg HSAS reclaimed

The NPV calculations revealed that the installation of additional processes increased TCI, but NPV had smaller values owing to low raw material and maintenance costs, thereby making the improved process economical. In addition, PBP was calculated at approximately 3.75 y in comparison with increased TCI.

5. Conclusions

In this study, we developed a model of the amine regeneration process with electro dialysis reclamation unit. The simulation results using the developed model were validated against the data of the actual commercial process. In TEA, TCI increased by approximately \$1,823,530, while the annual TPC decreased by \$485,994. Hence, the cost per kilogram of HSAS reclaimed decreased by approximately \$8,006. We believe that this model could be a guideline for further optimization of real processes

Abstract

The fundamental process step within the production of SNG from biomass is methane production. In the present work, methanation is considered to be carried out in a series of adiabatic fixed bed reactors with inter-cooling and product recycle. A robust mathematical model for the considered configuration has been developed that would essentially capture the fundamental operations of the methanation process and help to provide optimal guidelines for industrial operations. In detail, several CO/CO₂ feed ratio compositions and recycle ratios were analyzed.

Keywords: Methanation, Adiabatic Packed Bed Reactors, Power-to-Methane, Dynamical Model.

1. Introduction

The reduction of CO₂ emissions and, more in general, the sustainable production of adequate amounts of energy are unescapable challenges that our societies have to tackle. In this context Power-to-Methane (PtM) is a very interesting technology, for the role that it can play in the storage and distribution of electric energy produced by renewable sources, overcoming their intrinsic uncertainty (Bareschino et al. (2020)). Actually, methane is widely used in the industry, energy, and transportation sectors worldwide and its already developed grid distribution network makes its production preferable when compared to other gaseous fuels. Relying on the features of Chemical Looping Combustion (CLC) residual biomasses can be used as source of heat and CO₂ (Bareschino et al. (2020), Diglio et al. (2017a)). Indeed, in this process the combustion of a fuel is carried out in such a way as to reach an inherent separation of CO₂ and water from the combustion flue gas, leading to a gaseous stream that is ready to be fed to the methanation reactor (Adanez et al. (2012), Diglio et al. (2018)). Furthermore, high purity CO₂ streams may also be obtained from integration of Calcium Looping (CaL) with concentrated solar power (Tregambi et al. (2021)). The conversion of CO₂ to SNG needs hydrogen, which in real applications is usually produced from excess renewable energy (solar and/or wind) (Rönsch et al. (2015)). Carbon dioxide methanation is a highly exothermic and reversible reaction favored at low temperature and high pressure. The catalysts are easily deactivated due to the thermal stress and the methane yield is limited because of the exothermic reaction approaching the chemical equilibrium. The design and development of a methanation reactor is therefore complex owing to both the large amount of heat produced at high pressure and mass transfer and equilibrium

limitations. Several reactor concepts have been consequently proposed and investigated in literature to control the temperature rise associated to the highly exothermic Sabatier reaction so to avoid catalyst sintering while approaching the best thermodynamic condition for the process (Kopyscinski et al (2010)), ranging from multiple adiabatic layers fixed beds with inter-cooling and optional product recycle (e.g. TREMP or Lurgi methanation) to fluidized bed reactors. The reactor configuration studied in the present work consists of three adiabatic fixed bed reactors with gas recycle and inter-stage cooling to displace the gas temperature in the direction of higher equilibrium conversion. A recycle loop is adopted to decrease the hot spot temperature by diluting the inlet reactants concentration. In this background, the main goal is to develop a robust mathematical model for the proposed configuration. Such a model would essentially capture the fundamental operations of the methanation process and help to provide optimal guidelines for industrial operations. In particular, by assuming a production scenario, several recycle ratio and feed composition have been studied.

2. Kinetic scheme and mathematical model

The reported methanation process is carried out in a series of adiabatic fixed bed reactors with nickel-based catalysts and inter-cooling between each stage. In Fig. 1 a schematic layout scheme of the reported methanation process is depicted. After entering the reactor, the temperature of the gas mixture rises to values between 300 and 700 °C because of the exothermicity of the methanation reaction. At the exit of each reactor stage, cooling and water condensing occurs so to partially remove water and adjust the dew point of the gas, in this way the equilibrium is shifted towards the products.

Figure 1 – Adiabatic fixed bed methanation with inter-cooling and recycle; H₁-H₂: heater, C₁-C₄: cooler, HP₁-HP₂ high-pressure boiler and 3 adiabatic methanation reactors, see (Kopyscinski et al., 2010) for more details.

Methanation unit inlet pressure was set to 20 bar, according to Rönisch et al. (2015), so to achieve high conversion degree. The recycle ratio (molar gas flow rate of the recycle stream divided by that of the stream leaving the reactor) was varied between 0.5 and 2.0 both to shift the balance towards the formation of methane and to limit reactor temperature below 700 °C in order to avoid catalyst sintering and carbon deposition (Diglio et al. 2107b).

To describe axial temperature and concentration profiles in each fixed bed methanation reactor, a numerical 1D model has been used. In the model it is assumed that the reactor is adiabatic and pseudo-homogeneous, hence neglecting the heat and mass transfer resistances between the phases and within the catalyst. Therefore, the model complexity is considerably lower in comparison to heterogeneous models (Kopyscinski et al. (2010)). Finally, homogeneous properties are considered, and catalyst surface is

assumed to be completely exposed to the bulk fluid conditions, so fluid-to-particle heat and mass transfer resistances are neglected. An analogous model for CO methanation has been developed and validated by Er-rbib and Bouallou (2014).

The material balance for each gas component ($i=CH_4, CO, CO_2, H_2, H_2O$) was written as:

$$\varepsilon_g \frac{\partial C_i}{\partial t} = -u_{sg} \frac{\partial C_i}{\partial x} - (1 - \varepsilon_g) \rho_c r_i \quad (1)$$

where x is the dimensionless axial position along each reactor belonging in $[0,1]$, ε_g represent the bed porosity, C (kmol.m^{-3}) the gas concentration, ρ_c (kg.m^{-3}) the packed-bed density, and r_i ($\text{kmol.kgcat}^{-1}.\text{s}^{-1}$) the rate of consumption or formation of i -species ($i=CH_4, CO, CO_2, H_2, H_2O$); this latter is determined by summing up the reaction rates of that species in all the reactions R_j (see Table 1) according to the stoichiometric coefficient as follow:

$$r_i = \sum_{j=1}^3 (v_{i,j} R_j) \quad (2)$$

The gas superficial velocity (u_{sg} (m.s^{-1})) has been calculated as follow:

$$u_{sg}(x, t) = \frac{PM_{in}}{PM} T(x, t) u_{sg, in} \quad (3)$$

where PM is the molecular weight (kg.kmol^{-1}) and the subscript in represents the inlet conditions. Finally, the energy balances were written as:

$$(\varepsilon_g \rho_g c_{pg} + (1 - \varepsilon_g) \rho_c c_{pc}) \frac{\partial T}{\partial t} = -(\varepsilon_g \rho_g c_{pg}) \frac{\partial T}{\partial x} - \rho_c \sum_{j=1}^3 (\Delta H_{R_j}) R_j \quad (4)$$

where ρ and c_p ($\text{J.kg}^{-1}.\text{K}^{-1}$) represent the density and heat capacity for gas (g) and solid (c), respectively, while ΔH_{R_j} (kJ.kmol^{-1}) is the reaction enthalpy for R_j reaction. The complete CO/CO₂ methanation reaction scheme is reported in Table 1.

Table 1 – Reactions scheme and associated standard enthalpies of reactions.

Reaction	ΔH_{298} (kJ.kmol^{-1})	
$CO + 3H_2 \Leftrightarrow CH_4 + H_2O$	-206	R1
$CO_2 + H_2 \Leftrightarrow CO + H_2O$	41	R2
$CO_2 + 4H_2 \Leftrightarrow CH_4 + 2H_2O$	-165	R3

The detailed kinetic model for Ni-based catalyst and the reaction rate constants can be found in Xu and Froment (1989).

The mathematical model Eqs. (1)-(4) is completed with the following boundary and initial conditions:

$$C_i(0, t) = C_{i, in}, C_i(x, 0) = 0 \quad (5)$$

$$T(0, t) = T_{in}, T(x, 0) = T_0 \quad (6)$$

The operating conditions, reactor volumes, and catalyst properties used in the simulations are reported in Table 2.

Partial differential equations governing reactor dynamics were reduced to a set of ordinary differential equations by the application of finite differences over a uniform grid of 200 discretization nodes. The reduced set of ordinary differential equations has been numerically solved by making use of the Fortran library DLSODES (e.g. (Altimari et al., 2012)). Both reactions R1 and R3 (Table 1) are exothermic and characterized by a substantial volume contraction.

Table 2 – Parameters used in the simulations.

Parameter	Value	Parameter	Value
P, bar	20.0	V_3, m^3	35
$T_{in1}, ^\circ C$	300	$c_{pc}, J.kg^{-1}.K^{-1}$	1100
$T_0, ^\circ C$	400	$\rho_c, kg.m^{-3}$	2350
V_1, m^3	7	ϵ_g	0.4
V_2, m^3	16	$u_{sg0}, m.s^{-1}$	1

The high reaction enthalpy associated with the above reactions, reported in Table 1, results in large potential adiabatic temperature increase that may cause catalyst sintering and possibly leads to carbon particles formation. To avoid catalyst loss and carbon deposition it is therefore recommended to operate at a temperature below 700 °C (Rönsch et al. (2015)). Accordingly, the reactor can be cooled with the help of product recirculation, this being state-of-the-art for adiabatic methanation reactors during steady-state operation. The recycle ratio is typically chosen in a range between 0.5 and 3.0 for methanation reactors (Matthischke et al. (2018)).

3. Results

Several types of feed stream were considered as feed for the above described reactors network. Namely, a CO₂ pure stream leaving a CLC process and two different syngases coming from PW (poultry waste) and PE (polyethylene) CLC-gasification (Qingyu et al. (2019)) are considered. For the synthesis of methane, the additional hydrogen required for the methanation process comes from an array of high-pressure polymer electrolyte membrane cells (HP-PEM) (Bareschino et al. 2020). According to reactions' stoichiometries (R1 and R3 in Table 1), the stoichiometric number (SN) for the composition of the feed is:

$$SN = \frac{mol_{H_2} - mol_{CO_2}}{mol_{CO} + mol_{CO_2}} \quad (7)$$

The SN value is 3 and according to this value, the hydrogen demand by HP-PEM unit has been defined.

In Fig. 2 are shown methane molar fraction and temperature time series at reactors exit. The methane molar fraction increases moving along the reactor series and at the exit of the last reactor a H₂ and CO₂ conversion degree of 0.97 and 0.96 is respectively observed, corresponding to a $y_{CH_4}=0.96$ on a dry basis. Under the same operating conditions, the time series of the temperature at the exit of each reactor are depicted in

Fig. 3. The adiabatic temperature rise in the first, second and last reactor is 280 °C, 200 °C, and 45 °C, respectively.

Figure 2 – Methane molar fraction and temperature at the exit of each reactor according to the legend for $y_{CO_2in}=0.2$ and $y_{H_2in}=0.8$, and recycle ratio equal to 1 (other parameters are those reported in Table 2).

To gain insight about the effectiveness of the displacement of gas temperature in the direction of higher equilibrium conversion by intermediate cooling (Fig. 2), the evolution of the H₂ conversion is illustrated in Fig. 3 for 3 methanation reactors as well as the adiabatic temperature effect. Each diagonal line represents an adiabatic reactor (inlet and outlet conditions), and each horizontal line represents an intermediate cooling.

Figure 3 – H₂ conversion vs temperature

When the syngas is produced by CLC-Gasification the following feed composition are considered, $y_{CO}=0.14$, $y_{CO_2}=0.09$ and $y_{H_2}=0.77$ for PW and $y_{CO}=0.21$, $y_{CO_2}=0.04$ and $y_{H_2}=0.77$ for PE gasification. As previously discussed for SN=3 in the fed the required hydrogen is produced by HP-PEM system. Due to the higher exothermicity of R1 respect to R3 (Table 1), increasing the CO/CO₂ ratio in the feed increases the maximum temperature reachable. Therefore, to guarantee that the maximum temperature does not exceed 700 °C, a higher recycle ratio (RR) is required. In particular, for the GCL output by PW a $RR=2$ is used while for GDC output by PE a $RR=2.5$ is considered.

It is important to underline that the concentration of methane on the dry basis obtained in this scheme matches in all the considered cases the level required for its direct supply in the natural gas grid (see Table 3) wherever the minimum required threshold is set by special regulations for the injections of SNG at > 95% methane content.

Table 3 – Methanation unit results on dry basis.

	PW	PE
CH ₄	95.5	95.3
X _{H2}	97.4	98.1

4. Conclusions

The performance of the methanation unit was evaluated by using a series of adiabatic fixed bed reactors filled with Ni supported on alumina, with inter-cooling, water condensation at the exit of each reactor, and product recycle. Several feed compositions and recycle ratio has been investigated to achieve high reactor performances while limiting temperature increase so to avoid catalyst sintering. The results show that in all the investigated cases the methane concentration on the dry basis is high enough to be injected in the methane grid without the necessity of further upgrade processes.

Abstract

Hybrid modelling has caught renewed attention in many fields of engineering in the last two decades. By combining machine learning with first principles modelling, hybrid modelling is in many cases a more pragmatic modelling approach compared to first principles modelling, and at the same time a more robust alternative to data-driven modelling. However, quantifying uncertainty associated with hybrid models has not been investigated in detail thus far. Thereby, in practice, some models fail to reliably provide information for their performance under uncertainty. In this work, an integrated probabilistic modelling approach is presented for simultaneous modelling and uncertainty quantification using a hybrid model structure. The approach accounts for three types of uncertainty, including training data uncertainty, process stochasticity and model structure uncertainty. To demonstrate the advantages of this approach, the modelling strategy is highlighted through the modelling of a flocculation process. Here, mass and population balance models are combined with a probabilistic machine learning based kinetic model for estimating the particle phenomena kinetics. The model predictions are compared to predictions from a deterministic hybrid model counterpart.

Keywords: Hybrid modelling, Probabilistic modelling, Machine learning.

1. Introduction

With the increasing demand for fast process development alongside the requirement of a transition to sustainable productions, there has never been more focus on generating and utilizing mathematical models for chemical and biochemical processes. Modelling of these processes based on traditional first principles is in many cases not a trivial task and may easily require a significant number of time-consuming experiments. In some cases, the cost of developing a process model is even assessed not to be commensurate with the benefits of having a process model in the first place. This results in process models not being applied to the extent possible, even though they could facilitate a faster process development and secure a more sustainable production.

To reduce the time and efforts spent on modelling a chemical/biochemical process, various machine learning approaches have been proposed. The application of

data-driven modelling has been accelerated in the last two decades by the significant improvements in various sensor techniques, advancements in systems engineering and digitalization of data collection, and the development of highly efficient computational techniques for training data-driven models. Especially the combination of first principles modelling of fundamental phenomena and machine learning, also known as hybrid modelling, has caught renewed attention in the past few years. Application of first principles modelling here ensures that model predictions obey chemical and/or physical laws, which make the machine learning more robust and requires less training data. Hybrid modelling has been applied for modelling of various chemical and biochemical processes showing good predictive capabilities (Glasse and Von Stosch, 2018). More advanced hybrid model structures have also been proposed recently, where one example is the integration of computational chemistry into hybrid modelling, which may facilitate multi-scale modelling (Nazemzadeh, 2020). Recently, Nielsen et al. (2020a) have demonstrated how even complex hybrid models can be trained in real-time by utilizing automatic differentiation and backpropagation.

Many of the hybrid models suggested in literature are lacking a quantification of the prediction uncertainty, which makes it difficult to assess whether the model prediction is supported by the training data or it is a result of an uncertain extrapolation. Knowing about this uncertainty is crucial in the development of new processes where data may be scarce, but also when a hybrid model is used for process control. For instance, it was recently shown by Nielsen et al. (2020b) that a hybrid model based predictive control may suffer from the lack of uncertainty quantification, as it may converge to a solution that is based on a highly uncertain prediction.

With a part of the hybrid model being data-driven, the model accuracy and uncertainty will heavily depend on the data quantity and data quality used for training. This also means that the model uncertainty will change, when hybrid models are used for adaptive learning, where data is continuously acquired from a process and used for training the process model. Therefore, it is necessary to re-estimate this uncertainty continuously based on the current training dataset.

In this work, a hybrid modelling approach is presented, which integrates the quantification of model uncertainty into the model training. The uncertainty quantification includes the training data uncertainty, the uncertainty due to process stochasticity and the model structure uncertainty. The uncertainty of the training data is here estimated based on prior knowledge of the sensor precision, whereas the process stochasticity and the model structure uncertainty are estimated based on the training data. The modelling approach is subsequently applied for modelling of a flocculation process and compared to a deterministic hybrid model.

2. Probabilistic hybrid model

In this work, a hybrid model structure presented by Nielsen et al. (2020a) will be used, where a set of mechanistic models based on first principles are supplemented with a machine learning model that predicts a number of hidden process variables, \bar{y} . The machine learning model estimates the hidden process variables using the current measured process variables, \bar{x} , and control actions, \bar{z} . The mechanistic models are here formulated as a system of differential equations for the measured process variables, \bar{x} . To train the hybrid model, a set of time-series data is required for the measured process

variables, where the hybrid model is trained to predict the process dynamics between pairs of measurements that are distanced with a small time-horizon Δt .

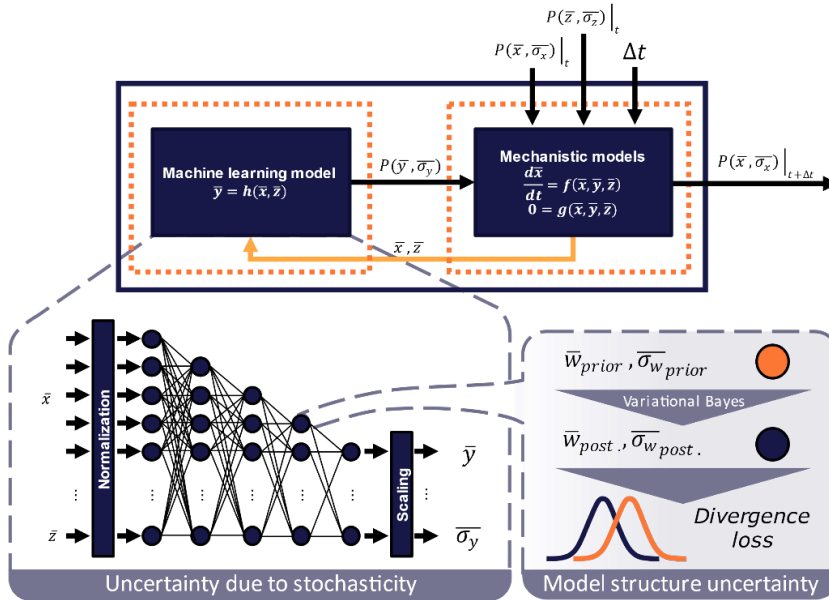

Figure 1: Probabilistic hybrid model structure, based on the hybrid model structure suggested by Nielsen et al. (2020a)

In this work, the sources of model prediction uncertainty in the hybrid model are divided into three, addressing the training data, the process stochasticity, and the model structure uncertainty respectively. The three types of uncertainty will be treated slightly differently, and will be summarized in the following sub-sections, followed by a procedure for training the probabilistic model. A schematic overview of the probabilistic hybrid model structure can be found in Figure 1. To simplify the uncertainty quantification in this work, we assume that structural model uncertainty of the mechanistic models can be neglected, and that the only source of model uncertainty is within the machine learning model.

2.1. Training data uncertainty

To estimate the uncertainty of the training data, prior sensor/sampling knowledge is required. A probability distribution must be specified for each measured process variable to estimate the uncertainty due to sensor precision. Furthermore, the standard deviation for each individual process sensor reading must be estimated. This is done based on prior knowledge of the specific sensor resolution and/or by estimating the uncertainty due to sampling.

2.2. Process stochasticity

To estimate the process stochasticity, the machine learning model is expanded to not only predict the mean value of the process variables, \bar{y} , but also to estimate the standard deviation of these process variables, $\bar{\sigma}_y$, corresponding to their stochasticity. This means that the output size of the machine learning model is doubled compared to a

deterministic hybrid model counterpart. A probability distribution must here be selected for each hidden process variable.

2.3. Model structure uncertainty

To estimate the model structural uncertainty, a probabilistic machine learning model is used as the data-driven model. Compared to a traditional deterministic machine learning model, this type of machine learning model will not only give a prediction, but also quantify the uncertainty of the prediction. This is done by treating the machine learning weights, \bar{w} , as statistical parameters. The mean values of the weights, \bar{w} , and their corresponding standard deviations, $\bar{\sigma}_w$, are here estimated using variational inference, based on the training data. To carry out the variational inference, a prior probability distribution needs to be specified. In this work, the prior probability distribution is set to have a trainable mean value and a fixed standard deviation, corresponding to Empirical Bayes. To carry out the variational inference in this work, the stochastic variational inference method by Kingma and Welling (Kingma, 2014) is used.

After model training, for each model prediction, a new set of weights is sampled from the inferred probability distributions, and thereby estimates the uncertainty of the model. This does not differ significantly from a parameter-based uncertainty analysis of a conventional model. However, as the weights, \bar{w} , in a machine learning model can have much greater impact on the model structure compared to parameters in a conventional first principles model, this uncertainty quantification will not only estimate the parameter uncertainty but also the overall model structure uncertainty.

2.4. Model training

The presented probabilistic hybrid model is trained using a gradient descent method, where the gradient is calculated using automatic differentiation. The loss function that needs to be minimized (see Equation 1 and 2) is the negative log-likelihood, based on the mean and standard deviation of the model predictions of the future measured process variables, \bar{x} , after the various model uncertainties have been propagated through the hybrid model. An additional term in the loss function is furthermore added, consisting of the divergence between the prior probability distribution and the posterior probability distribution of the model weights, which allows for training the prior mean.

$$loss = -\log(\mathcal{L}(\bar{w}, \bar{\sigma}_w | \bar{x}_{data})) + \sum D_f(p_{w,posterior} || p_{w,prior}) \quad (1)$$

$$\min_{\bar{w}, \bar{\sigma}_w} loss \quad (2)$$

When training the probabilistic hybrid model, for each training epoch, a number of samples, n_s , are drawn from the probability distributions for the measured process variables, \bar{x} , with the measured mean and their corresponding estimated standard deviation, $\bar{\sigma}_x$. These samples are then used as inputs to the machine learning model, where the model weights have been sampled from the posterior probability distribution. For each sample, the predicted mean, \bar{y} , and standard deviation, $\bar{\sigma}_y$, are used to sample the stochastic hidden variables. The hidden stochastic variables are then propagated through the set of mechanistic models alongside the sampled initial process variables, \bar{x} ,

resulting in n sample predictions for each training entry, which can be transformed into probability distributions where the likelihood of a given outcome can be calculated. Note that the samples from the various probability distributions are only drawn once for one training entry as it is here assumed that the hidden process variables will remain constant for short time-horizons Δt , which is used during model training.

3. Case study: A lab-scale flocculation of silica

In this section, the presented probabilistic hybrid model will be applied for modelling of a lab-scale flocculation process of silica particles in water, using experimental data that was obtained from a 200 mL stirred glass reactor. The particle size distribution and pH were monitored for in total 11 batch operations, with varying pH. The particle size distribution was here monitored by at-line image analysis using the ParticleTech solution (ParticleTech ApS, Farum, Denmark). pH was monitored using an in-line pH probe. A low pH was observed to promote agglomeration of the silica particles and stirring would result in breakage of particles. This process has previously been examined and modelled using a hybrid machine-learning assisted model by Nielsen et al. (2020a), using the same dataset for training the model, and will here be used for comparison to the predictions from the probabilistic hybrid model. To allow for comparison, the same non-linear discretization scheme has been applied.

As for the previously demonstrated deterministic hybrid model (Nielsen et al., 2020a), the mechanistic models here consist of a discretized population balance model that accounts for the mass balances involved in the agglomeration and breakage phenomena. pH is assumed to be perfectly controlled, meaning that it is possible to model the future pH using the control action z . The machine learning model used in the probabilistic hybrid model is here a deep Bayesian neural network (BNN) with in total 4 layers, where the prior probability distributions are normal distributions for all model weights. The BNN estimates the bin-specific rate of effective agglomerations, the bin-specific rate of breakage and the bin-specific daughter-particle distribution coming from breakage. The stochasticity of the predicted rates is assumed to follow normal distributions.

The estimated standard deviation for the pH measurements was estimated based on the resolution of the sensor, which was 0.01. The estimated standard deviation for the discretized particle size distribution was done based on the sensor resolution and the sampling uncertainty. First, the uncertainty due to the image analysis sensor resolution was introduced. As the image resolution of the ParticleTech solution is 0.5 $\mu\text{m}/\text{pixel}$, this was used as the standard deviation. For each detected particle, gaussian noise with a mean of zero and a standard deviation of 0.5 μm was added to the detected particle diameter. This was done for 100 samples, where each result was discretized based on a non-linear discretization scheme. For each discretized result, the standard error of sampling was estimated, giving a mean and standard deviation of the discretized particle size distribution.

The probabilistic hybrid model structure was trained using TensorFlow and TensorFlow Probability by Abadi et al. (2014), where both the Bayesian neural network and the set of mechanistic models were implemented as custom models. For training the model, 20 samples were used for each training entry, resulting in a roughly 20 times longer training time compared to the corresponding deterministic hybrid model (Nielsen et al., 2020a). End-of-batch predictions from the probabilistic hybrid model and the

deterministic hybrid model counterpart can be seen in Figure 2. The predictions are based on a set of test data coming from a low-pH batch, where the time-horizon of the prediction is one hour.

When comparing the mean prediction of the probabilistic hybrid model and the single-point predictions from the deterministic hybrid model, both models can be seen to succeed in capturing the agglomeration kinetics to an acceptable degree. The probabilistic hybrid model does however offer more information, in the form of reasonable estimations of the prediction uncertainty. It is here evident that the predictions are quite uncertain, especially

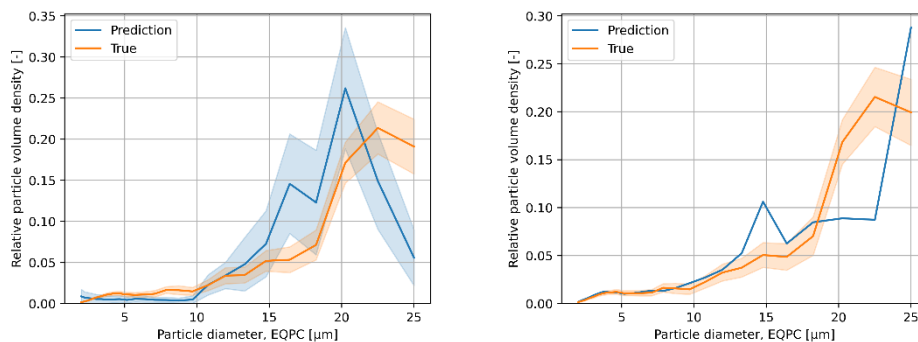

Figure 2: End-of-batch predictions from the probabilistic hybrid model (left) and the deterministic hybrid model counterpart by Nielsen et al. (2020a) (right)

for the agglomeration phenomenon, which cannot be seen easily from the deterministic hybrid model. Further studies are however needed to confirm the reliability of these uncertainty predictions, and the methodology must be tested for varying sets of training data to check its ability to adapt the uncertainty quantification accordingly.

4. Conclusions

In this work, a hybrid model structure and training procedure has been proposed where prediction uncertainty is integrated into the modelling process. This approach could allow for quantifying the model uncertainty for a given set of training data, by addressing uncertainty related to training data, process stochasticity and model structure uncertainty. At the cost of an increased computational time for training, the probabilistic hybrid model has been shown capable of giving a reasonable quantification of the model prediction uncertainties. Additional studies are however needed to confirm these findings.

Abstract

Beer production is an elaborate process, where, from the same critical ingredients, a greatly complex mixture of compounds is obtained depending on the operating conditions. The different combinations of these species, also called off- and on-flavors, are responsible for each beer's distinctive taste.

Improving any step of the beer production process will significantly influence the success of a brewery. Therefore, it is essential to carefully describe the beer production process's different stages to optimize process conditions and beer flavor. To do so, in this work, a comprehensive fermentation model and optimization problem were formulated to determine how an up-to-date industrial beer production should optimally operate. To achieve this, a dynamic optimization problem using a Genetic Algorithm is formulated and implemented to maximize the conversion of substrate to ethanol and minimize fermentation time while setting the final acceptable concentrations of the by-products as strict constraints. Results show that each by-product affects beer flavor as well as process performance in a unique manner.

Therefore, we believe that this work contributes to a comprehensive understanding of the impact of different off- and on-flavors on the optimal beer flavor profile and optimizing process conditions.

Keywords: fermentation, modelling, optimization, beer flavor

1. Introduction

Brewing is one of the oldest processes in which biotechnology has been used to produce alcoholic beverages. The main production steps in beer brewing are: (i) wort production, alcoholic fermentation and maturation, further processing, and stabilization. Fermentation and maturation are the lengthiest steps in the brewing process; fermentation takes three to six days, and the maturation stage takes up to two weeks (Vassilev et al., 2013). Wort, a sugar-rich intermediate, is produced from a starch source such as malted barley (Rodman and Gerogiorgis, 2017). The fermentation occurs through the yeast's enzymatic activity, where sugar is converted to pyruvate, and, in anaerobic conditions, the yeast then converts pyruvate to ethanol and CO₂. Off- and on-flavor compounds, being by-products, are produced during fermentation and maturation (Bosse and Griewank, 2014). Thus, beer flavor is highly dependent on the

yeast's metabolism. There are over 800 compounds present in the final beer, and they are categorized as follows: higher alcohols, esters, fatty acids, vicinal diketones (VDKs), aldehydes, and sulfidic compounds. However, not all of these species have the same impact on the final beer flavor. Higher alcohols, esters, and VDKs are the strongest flavor impacting compounds produced by yeast. Higher alcohols and esters are desirable volatile constituents of a pleasant beer (on-flavor), while VDKs and sulfidic compounds are considered off-flavors. The main sulfidic compounds are H_2S and SO_2 which are highly related to the yeast activity during fermentation. The concentration profile of all the flavor-active species must be under control in order to keep some compounds from dominating and destroying the delicate flavor balance.

Therefore, this work's primary goal is to model and optimize the beer fermentation process to provide the breweries with a competitive edge by improving beer flavor and decreasing costs. To achieve this, the following steps are taken: (i) a comprehensive fermentation model is developed based upon kinetic models, including a yeast growth model, ethanol and by-products production (fusel alcohols, esters, vicinal diketones, acetaldehyde, and sulfidic compounds); (ii) a sensitivity analysis is performed on the initial variables of fermentation model; and, (iii) a dynamic optimization problem is formulated and implemented based upon the genetic algorithm strategy to optimize the flavor profile and operation.

2. Methods

2.1. *Fermentation model scope, development & implementation*

The model developed and implemented in this work is built upon the lager beer fermentation model presented in (Ramirez and Maciejowski, 2007), including the biomass growth model, amino acids uptake, ethanol formation, and flavor model. In this model, there are twelve yield parameters that relate the yeast growth and nutrients uptake to the production of flavor compounds, and these are assumed to be constant (except the growth and amino acids uptake rate). They are obtained by averaging the values given in (Gee and Ramirez, 1994). Thus, in this study, an important modification to the model has been made to account that the enzymatic activity involved in the production mechanisms varies with temperature. Therefore, not only the kinetic rates should change with temperature, but the yield coefficients should also be temperature-dependent. For this reason, instead of assuming that the production yields remain constant during the fermentation, we have introduced temperature dependence on said yields by using a 2nd order polynomial equation. This has shown to be a good option, but the details of such adjustments are not presented here due to the space limitations.

Furthermore, to the best of our knowledge, there is no more freely available data on the production of the remaining flavor compounds. Since the current work aimed not to perform experiments, only ten flavor species have been included in the final model. The model has been implemented in MATLAB and is available upon request.

2.2. *Sensitivity analysis*

A sensitivity analysis is performed on the initial variables to test the effects of upstream processing conditions and different raw materials. To do this, one-factor-at-a-time (OAT) sensitivity analysis is applied. It is one of the most common methods to perform sensitivity analysis since it is simple and easy to implement. The OAT approach

modifies one input variable at-a-time, keeping the remaining parameters at their baseline (Saltelli and Annoni, 2010). Any change observed in the output will unambiguously be due to the changes in the input. However, one disadvantage is that OAT does not account for the effect of simultaneous variation of input variables; thus, it doesn't spot correlations between inputs.

In this work, as presented in Section 3, we assess the impact on the final concentrations of the biomass, ethanol, and by-products when having a 25 % variation in the initial variables (e.g., G_0 , M_0 , X_0).

2.3. *Dynamic optimization*

Several model parameters influence the yeast metabolism and thus final beer flavor profile. Among these parameters, in order to reach optimal flavor and operation, fermentation time and the temperature were selected as the variables to be optimized. The reactor's operating temperature has a significant impact on the resulting beer flavor and aroma by affecting the yeast growth and reaction rates as well as the yield coefficients. To increase the profit margin, breweries continuously try to minimize the fermentation time. However, a minimum time is required to consume all the sugars, produce enough ethanol, and allow the re-assimilation of VDKs to occur successfully (Smart, 2003). Moreover, these parameters are two of the few easily adjustable parameters in an existing fermentation process.

The genetic algorithm (GA) was chosen as the optimization strategy to optimize time and the temperature profile. Genetic algorithms are stochastic search algorithms based on natural selection and natural genetics principles. GA has been chosen since it avoids getting trapped in local optima like other traditional optimization methods. This is due to the fact that being a population-based algorithm, it leads to a better exploration of the search space. For more details on GA and its implementation, please refer to (Potgieter and Engelbrecht, 2007).

3. **Results & Discussion**

3.1. *OAT Sensitivity Analysis*

As previously stated in Section 2.2, a 25 % variation (uncertainty range) is applied to the initial variables to test their impact on the concentrations of substrate (Table 1) during the fermentation and on the biomass, ethanol, and by-products concentration (Table 2).

As observed in Table 1, the initial concentration of glucose and the initial yeast concentration are undoubtedly the initial concentrations with a greater influence on sugars and amino acids' consumption rates. This is due to the compounding effect given by the fact that the presence of sugars boosts yeast growth. In contrast, once the initial concentration of one amino acid is changed, only the corresponding amino acid consumption rate is impacted.

The maximum variations observed regarding the final concentrations of biomass, ethanol, and by-products (flavor species) are presented in Table 2.

Changes in the initial maltose and yeast concentration are highly influenced by the concentration of acetaldehyde, VDKs, ethyl caproate, and ethyl acetate. Furthermore, the initial concentrations of amino acids seem to be the most influential parameters in the production of all fusel alcohols and isoamyl acetate (directly related to the formation of isoamyl alcohol). Furthermore, the relationship between ethyl acetate's final concentration is also affected by changes in the initial concentration of maltose. This is

because ethyl acetate is directly linked to sugar metabolism. Thus, higher initial concentrations of maltose lead to a higher final concentration of ethyl acetate.

3.2. Dynamic optimization: time and temperature

As stated in Section 2.3, GA is the optimization strategy chosen to perform the dynamic optimization of the beer fermentation process (time and temperature profile). Four fitness functions (Eqs. 1 to 4) have been designed to test and analyze the following objectives.

To minimize: the concentration of off-flavors (fusel alcohols, VDKs, acetaldehyde) and fermentation time; *To maximize:* concentration of on-flavors (ethanol and esters).

$$FF(O1) = Q_{IB} + Q_{IA} + Q_{MB} + Q_P + Q_{EA} + Q_{EC} + Q_{IAc} + Q_{VDK} + Q_{AAI} + Q_{EtOH} + Q_t \quad (1)$$

$$FF(O2) = Q_{EtOH} + Q_t \quad (2)$$

$$FF(O3) = Q_{EA} + Q_{EC} + Q_{IAc} + Q_{EtOH} + Q_t \quad (3)$$

$$FF(O4) = Q_{IB} + Q_{IA} + Q_{MB} + Q_P + Q_{VDK} + Q_{AAI} + Q_t \quad (4)$$

The fitness function penalizes low concentrations of esters, ethanol and fermentation time as well as high concentrations of fusel alcohols, VDKs, and acetaldehyde. The fitness function will only consider penalties above (off-flavors + time) or below (on-flavors) the extreme values. If the variables are above the minimum population value (off-flavors + time) or below the maximum population value (on-flavors), the penalization is given by the squared difference to the extreme value. Besides, the fermentation time is considered as a penalization factor for all the fitness functions. This is due to the fact that the targeted minimum fermentation time is reached after 120 hours. In Eqs. 1 to 4, all variables have the same importance. Thus all penalties have been normalized for time and all the flavor species. Due to space limitations, the penalization functions, Q_i , are not described here.

The optimal temperature profiles obtained with the four fitness functions are presented in Figure 1. In O2, where the goal is to maximize the ethanol concentration (while minimizing the fermentation time), the optimal profile keeps the temperature at its maximum value (287.65 K). In contrast, when the aim is to minimize the off-flavor species and fermentation time (O4), the optimal profile maintains the temperature at the minimum acceptable value (283.65 K). In O3, the optimal profile is consistently close to the maximum temperature value; however, the temperature declines marginally in the fermentation's early stages. Finally, when all the variables are included in the optimization problem (O1), the optimal profile starts at the maximum temperature (287.65 K) and, after 15 hours, drops to the minimum temperature (283.65 K) and, after 60 hours, the temperature rises and reaches 287.65 K once again.

Figure 1: Optimal temperature profiles for optimization scenarios O1 to O4.

In scenarios O2 and O3, the penalization values of isobutanol, isoamyl alcohol, and 2-methyl-1-butanol are relatively high. That means that when the fermentation temperatures are close to the maximum value during the entire fermentation (O2 and O3), the fusel alcohols' production increases significantly, leading to undesired levels. Similar behavior is observed in scenario O4, where the low optimal temperature leads to low values of esters and ethanol production (also undesired). Hence, these low final

concentrations lead to the high penalization values for ethanol and esters in run O4. As mentioned above, due to space constraints, the values of all the penalization factors for the four optimal temperature profiles are not presented.

4. Conclusions

This fermentation model has been carefully examined and improved, as well as tested through a sensitivity analysis. The model is able to assess the trade-off between time-minimization and the final states of the fermentation process, and it has been designed to include all temperature effects. Finally, an optimization problem is solved based on the GA method, which has been applied in order to obtain an optimal flavour profile and within the minimum fermentation time possible. The results obtained from the optimization study show that low temperatures keep the production of the undesired compounds low and high temperatures are required to maximize the ethanol production. Due to the model challenges presented before, it is audacious to claim that the exact optimal profile obtained with the optimization O1 is the best temperature profile for the studied beer fermentation. However, we are confident to affirm that the temperature must be kept low during the first days of the fermentation to avoid over-production of off-flavour species, and afterwards it must be increased to enhance the ethanol and esters production in a minimal time. Future work is two-fold, the authors want to explore the effect of variables like pitching rate and wort composition and also expand the fermentation model to include other flavor compounds and for that we are planning experiments.

Nomenclature

G_0 - Glucose concentration for $t=0$	IB - Isobutanol	IAC - Isoamyl acetate
M_0 - Maltose concentration	IA - Isoamyl alcohol	VDK - Vicinal diketones
N_0 - Maltotriose concentration for $t=0$	MB - 2-methyl-1-butanol	AAI
X_0 - Biomass concentration for $t=0$	P - 2,3-Pentadione	EtOH - ethanol
I_0 - Isoleucine concentration for $t=0$	EA - Ethyl acetate	t - time
V_0 - Valine concentration for $t=0$	EC - Ethyl caproate

Abstract

The maximum likelihood estimate is a method for fitting failure models to lifetime data. In the literature, a commonly used practice is to find a combination of model parameter values where the partial derivatives of the log-likelihood are zero. We show that greater log-likelihood values can be found by using the Nelder-Mead optimization algorithm with adaptive parameters. We demonstrate that the improved fitting has a significant impact on the decision-making on a selective maintenance optimization problem, defined using the failure model by Sarhan and Apaloo (Reliab Eng & Syst Saf, 2013, 112, 137-144).

Keywords: model fitting, reliability, optimization, decision-making.

1. Introduction

The components of an industrial production plant degrade over time, reducing the overall reliability. An unexpected failure in a critical component may cause significant production losses. In order to improve the reliability of the plant, the operators plan maintenance shutdowns, during which degraded components are either replaced or repaired. However, as modern production plants often comprise thousands of replaceable/repairable components, the operators are rarely able to maintain all the components. Identifying the best subset of maintenance actions, subject to time and cost, is referred to as selective maintenance optimization. In the corresponding literature, the component lifetimes are typically assumed to follow either the Weibull or exponential distribution with given parameters without directly considering any lifetime data (Cao et al., 2018). Thus, we recently performed a selective maintenance optimization study that links lifetime data into selective maintenance optimization with the focus on the bathtub-shaped failure rates (Ikonen et al., 2020).

The bathtub-shaped failure rate is a combination of three contemporaneous failure modes: a decreasing infant mortality rate, a constant random failure rate, and an increasing failure rate due to degradation. The literature is fairly established in terms of failure distributions of such models. However, the fitting of model parameters to lifetime data is often performed inadequately. While some authors explicitly maximize the log-likelihood function (e.g. by PROC NLMIXED in SAS or MaxBFGS in the Ox language), a commonly used approach is to find a point in the parameter space where the partial derivatives of the log-likelihood are zero. This approach is, for example, performed by Xie et al. (2002), El-Gohary et al. (2013), and Sarhan and Apaloo (2013) when fitting their failure models to the widely studied lifetime dataset by Aarset (1987). As the log-

likelihood functions of the models are non-convex, the resulting fitting may well correspond to a local optimum, or even a saddle point.

In this paper, we first show that better fits, i.e., greater log-likelihoods, can be found to the lifetime dataset by Aarset (1987) for the failure models proposed in the three abovementioned studies by using the Nelder-Mead algorithm with adaptive parameters (Gao and Han, 2012). Second, we demonstrate how the improved fitting of the failure model by Sarhan and Apaloo (2013) affects the decision-making on a selective maintenance optimization problem.

2. Model fitting

The failure rate $h(t)$ and the reliability function $R(t)$ of the failure model by Sarhan and Apaloo (2013)¹ are defined as

$$\left\{ \begin{array}{l} h(t) = \frac{\lambda\beta\gamma \left(\frac{t}{\alpha}\right)^{\beta-1} e^{(t/\alpha)^\beta + \lambda\alpha(1-e^{(t/\alpha)^\beta})}}{\left[1 - e^{\lambda\alpha(1-e^{(t/\alpha)^\beta})}\right]^{1-\gamma} + e^{\lambda\alpha(1-e^{(t/\alpha)^\beta})} - 1} \\ R(t) = 1 - \left[1 - e^{\lambda\alpha(1-e^{(t/\alpha)^\beta})}\right]^\gamma \end{array} \right. \quad (1)$$

where $\lambda, \alpha, \beta, \gamma > 0$ are the parameters of the model and $t \geq 0$ is time. The likelihood function is defined as

$$\mathcal{L}(\theta) = \prod_{i=1}^n h(t_i)^{d_i} R(t_i), \quad (3)$$

where θ is an array of the model parameters, n is the number of samples in the lifetime dataset, t_i is the service time of component i and d_i indicates whether the component has failed ($d_i = 1$) or is still functioning, i.e., a right-censored sample ($d_i = 0$). In the dataset by Aarset (1987), all components were operated until failure, so let us assume here that $d_i = 1, \forall i \in \{1 \dots n\}$. Substituting Eqs. (1) and (2) into Eq. (3), and taking the natural logarithm from both sides, yields the log-likelihood function

$$\begin{aligned} \ln \mathcal{L}(\theta) = & n[\alpha\lambda + (1 - \beta) \ln\alpha + \ln\beta + \ln\lambda + \ln\gamma] \\ & - \alpha\lambda \sum_{i=1}^n e^{\left(\frac{t_i}{\alpha}\right)^\beta} + \frac{1}{\alpha\beta} \sum_{i=1}^n t_i^\beta + (\beta - 1) \sum_{i=1}^n \ln t_i \\ & + (\gamma - 1) \sum_{i=1}^n \ln \left(1 - \exp\left\{\lambda\alpha \left(1 - e^{(t_i/\alpha)^\beta}\right)\right\}\right). \end{aligned} \quad (4)$$

Sarhan and Apaloo (2013) maximize the log-likelihood function, $\ln \mathcal{L}(\theta)$ (Eq. (4)), by solving numerically a system of four non-linear equations. These equations are defined by setting the partial derivative of $\ln \mathcal{L}(\theta)$ with respect to the four model parameters $\theta = \{\alpha, \beta, \gamma, \lambda\}$ to zero. The same approach is used by Xie et al. (2002) and El-Gohary et al. (2013).

¹ For brevity, we do not include the correspondents of Eqs. (1), (2) and (4) for the models by Xie et al. (2002) and El-Gohary et al. (2013). The equations are available in the papers in question.

In this paper, we maximize $\ln \mathcal{L}(\theta)$ (Eq. 4), by the Nelder-Mead algorithm with adaptive parameters (Gao and Han, 2012), which we implemented using the SciPy.minimize library (Harris et al., 2020). Further, in order to avoid local maxima, we perform a multi-start of 100 optimization procedures with randomized starting points. The function evaluations are implemented using NumPy (Virtanen et al., 2020).

The dataset by Aarset (1987) contains the lifetimes of 50 components (Table 1). We fitted the model by Sarhan and Apaloo (2013), as well as the models by Xie et al. (2002) and El-Gohary et al. (2013), to this dataset using the above described approach. The resulting log-likelihoods $\ln \mathcal{L}(\theta)$ and the model parameters are listed in Table 2. Our approach yields log-likelihoods greater than those reported in the references for all three models.

Table 1: Lifetime dataset by Aarset (1987). The dataset consists of failure times of 50 components, reported here on multiple lines.

0.1	0.2	1	1	1	1	1	2	3	6	7	11	12	18	18	18	18

Table 2: Log-likelihoods $\ln \mathcal{L}(\theta)$ and parameters of the trained models.

model	method	$\ln \mathcal{L}(\theta)$	parameters
Sarhan and Apaloo (2013)	Nelder-Mead	-203.6972	$\alpha = 79.3949, \beta = 39.0646, \gamma = 1.4040e-2, \lambda = 1.1116e-12$
	reference	-213.858	$\alpha = 49.05, \beta = 3.148, \gamma = 0.145, \lambda = 7.181e-5$
Xie et al. (2002)	Nelder-Mead	-231.6466	$\alpha = 13.7467, \beta = 0.5877, \lambda = 8.7597e-3$
	reference	-236.247	$\alpha = 110.0909, \beta = 0.8408, \lambda = 1.41e-2$
El-Gohary et al. (2013)	Nelder-Mead	-222.2441	$\lambda = 8.9592e-5, c = 8.2786e-2, \theta = 0.2625$
	reference	-224.080	$\lambda = 1.43e-3, c = 4.4e-2, \theta = 0.421$

Figure 1: Probability distributions of the model by Sarhan and Apaloo (2013) with the tuned (by the Nelder-Mead algorithm with adaptive parameters) and the reference parameters.

Figure 1 shows the reliability function $R(t)$, failure rate $h(t)$, and probability density function $f(t)$ of the model by Sarhan and Apaloo (2013) with the tuned parameters,

obtained by the Nelder-Mead algorithm, and the reference parameters. The distributions are clearly different. First, the reliability function with the tuned parameters is steeper in the time period of $t = 80 \dots 90$ than that with the reference parameters, capturing the frequent occurrences of failures at the end of time in the dataset (c.f the empirical reliability function). Second, the failure rate $h(t)$ remains nearly constant longer with the tuned parameters (until around $t = 75$) than with the reference parameters (until around $t = 50$). In other words, the ‘bottom of the bathtub’ is wider with the tuned parameters than with the reference parameters, indicating that the failures due to degradation appear later.

3. Selective maintenance optimization

In our earlier work (Ikonen et al., 2020), we derived a variable describing the change in the component-specific reliability ΔR^y , if it is replaced, and presented a contour plot of ΔR^y in the space of component age a and the length of the next operation window t_w . The change in reliability is defined as

$$\Delta R^y = R^y - R^0 = R(t_w|0) - R(a + t_w|a)F \quad (5)$$

where F is a parameter indicating whether the component is functioning before the maintenance break, and R^y and R^0 are the reliabilities if the component is replaced or left untouched, respectively. The conditional reliabilities in Eq. (5) are

$$\begin{cases} R(a + t_w|a) = \frac{R(a + t_w)}{R(a)} \\ R(t_w|0) = R(t_w). \end{cases} \quad (6)$$

$$(7)$$

Figure 2(a) and Figure 2(b) show the contour plots of ΔR^y for the model by Sarhan and Apaloo (2013) with the reference and tuned parameters, respectively. In the earlier work, we pointed out that, if the component is functioning before the maintenance break and the hazard rate is bathtub-shaped, a region exists in the contour plot where the reliability is negative (indicated by the white region in Figure 2(a) and Figure 2(b)). The replacement of a functioning component lying in this region is not sensible.

Figure 2: The improvement in reliability, ΔR^y , if a functioning component is replaced, based on the model by Sarhan and Apaloo (2013) with the reference (Subfigure a) and tuned parameters (Subfigure b).

In the earlier work (Ikonen et al., 2020), we studied a small-scale bi-objective selective maintenance optimization problem as an illustrative example. The two conflicting objectives are to maximize the overall reliability of the system, R_{sys} , and to minimize the maintenance cost c_{tot} . The system consists of 18 components with various levels of criticality. The reliabilities of all components in the system are assumed to be equivalent to that used in generating the dataset by Aarset (1987). The decision variables define whether individual components are repaired, replaced, or left untouched, and the number of maintenance personnel, p , invited to perform the maintenance actions. The next planned operation window has a length of $t_w = 10$. For more details of the optimization model and the selective maintenance optimization problem the reader is referred to Sections 3.2 and 4, respectively, of the paper by Ikonen et al. (2020).

Let us now return to this optimization problem and solve its Pareto front using the failure model by Sarhan and Apaloo (2013) with the tuned and reference parameters². We transform the bi-objective optimization problem into a series of single-objective optimization problems by ϵ -constraint method (Haimes et al., 1971), and solve them using the global optimization solver BARON 20.4.14 (Kılınç and Sahinidis, 2018). Figure 3 shows the obtained Pareto fronts, as well as representative solutions. Each grid element in the representative solutions corresponds to a single component, the age of which has been indicated by its color.

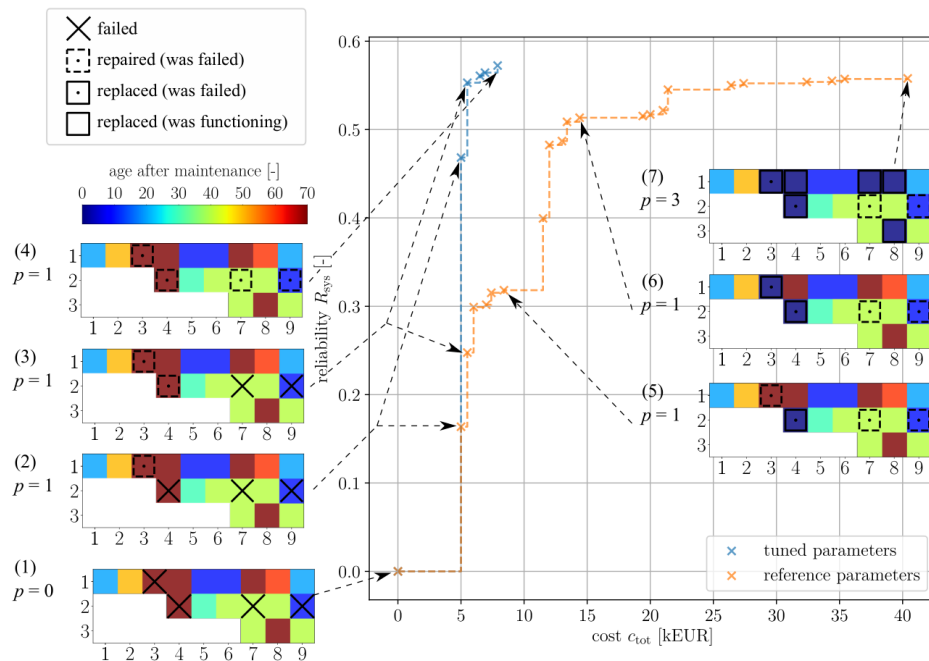

Figure 3: Pareto fronts of the selective maintenance optimization problem, in which the component-specific reliabilities are determined using the model by Sarhan and Apaloo (2013) with the tuned and reference parameters.

² The results obtained with the reference parameters have already been reported in Ikonen et al. (2020).

Starting from the bottom left corner of the Pareto fronts, the first three solutions are the same with both parameters. However, the modeled system reliabilities, as well as the following solutions on the Pareto front are drastically different. The reason is that with the tuned parameters, all components lie in the region of Figure 2(b), where the replacement of a functioning component is not sensible. Thus, even at the top right corner of the corresponding Pareto front, only the failed components are repaired (see Representative solution (4)). The use of reference parameters would result in unnecessary (and costly) component replacements, which would not improve the overall reliability of the system.

4. Conclusions

Fitting a failure model to lifetime data by maximizing the log-likelihood requires solving a non-linear, and often non-convex, optimization problem. We show that performing a multi-start of the Nelder-Mead optimization algorithm with adaptive parameters (Gao and Han, 2012) yields greater log-likelihoods for the models by Xie et al. (2002), El-Gohary et al. (2013) and Sarhan and Apaloo (2013) than the reported reference parameters. We demonstrate that the improved fitting of the model has a significant impact on the decision-making of maintenance actions on an optimization problem, defined using the failure model by Sarhan and Apaloo (2013).

Abstract

Simulation times of complex chemical processes are often too long for real-time applications, especially when first principles nonlinear dynamic models are used. Data-driven surrogate models of those first principles models trained with simulation data offer a competitive alternative for advanced process control (APC) applications. When sampled with standard methods, processes with a narrow feasible dynamic input space generate datasets with scarce feasible samples. As a representative example, the startup, operation and shutdown of a vacuum batch distillation process separating a binary methanol-water mixture was simulated using a rigorous dynamic pressure-driven model in Aspen Plus dynamics. Expert knowledge was introduced in the form of operation recipes to reduce the vast dynamic input space to a time independent parameter sampling. Using the generated datasets in the form of timeseries, nonlinear ARX and RNN systems were identified. The prediction accuracies of both data-driven models were compared, taking into account their model complexity.

Keywords: data-driven modelling, batch distillation, dynamic simulation, sampling

1. Introduction

In general, it is prohibitive to conduct the minimum amount of experiments necessary for process optimization in real chemical plants. Therefore, process modelling and simulation is used to generate those predictions. Even so, simulation times are often too long for real-time applications, especially when first principles models are used. To counter this, data-driven surrogate models of those mechanistic models are trained with simulation data to reduce computation time during online operation, sacrificing prediction accuracy (Caballero and Grossmann (2008)). One important challenge arises when processes with a narrow feasible input space are sampled with standard methods (such as amplitude-modulated pseudorandom binary sequences (APRBS), among others. See Isermann and Münchhof (2011)), generating datasets with scarce feasible samples.

As a descriptive example, in this contribution a batch distillation process consisting of a vacuum column separating a binary methanol-water mixture is simulated using a rigorous dynamic pressure-driven model in Aspen Plus dynamics (APD) from cold and empty start-up and subsequent shutdown with nitrogen purge. Optimization of the startup of reactive distillation processes has been performed by Reepmeyer et al. (2004); Forner et al. (2006); Lukacs et al. (2006) and Carmona (2011), but using computationally expensive first principles models. Startup strategies for pressure swing distillation were also developed by Klein and Repke (2007), and distillation of three-phase mixtures was also

analysed by Tran et al. (2003), yet based also on first-principles models. Complex dynamic processes like these show a narrow feasible input domain, where standard nonlinear dynamic sampling methods either generate input-output data in a non-representative domain, or more often sample over a hypercubic domain defined by input upper and lower bounds which leads to mostly non-converging simulations. To tackle this, expert knowledge is introduced in the form of operation recipes (Löwe (2001)) to reduce the vast dynamic input space to a time independent parameter sampling.

To test the usability of this sampling method in real-time applications, data-driven models are trained and tested. As a benchmark, the prediction accuracy of a more conventional nonlinear autoregressive model with exogenous variables (NARX) with a tree partition nonlinearity is compared to a recurrent neuronal network (RNN) with two long short-term memory (LSTM) layers with a similar amount of trainable parameters.

2. Methods

2.1. Simulated batch distillation process

A batch distillation process for the separation of a water-methanol mixture shown in Fig. 1 was modelled in APD, with geometric dimensions and specifications shown in Tab. 1. Pressure changers (valves and pumps) had to be placed at every material stream. NRTL was chosen as thermodynamic activity coefficient model with N_2 as Henry component. Phase equilibrium efficiency was chosen as 100%.

Figure 1: Screenshot of the model implemented in APD, including control loops, inertization stream (N_2) and non-condensable gases (NCG). The distillate tank was simulated as a cumulative distillate flow.

Table 1 Operating conditions and plant specifications for a sieve tray column

parameter	value	units	description
$w_{F,MeOH}$	0.5	kg/kg	feed mass fraction of methanol (rest is water)
T_F	21.0	$^{\circ}C$	feed temperature
h	8.0	m	column height
D	80.0	mm	column inner diameter
V_B	0.08	m^3	max. volume of sump
h_{weir}	0.08	m	weir height
n_{st}	10		number of equilibrium stages
S_F	5		feed stage
UA^{Cond}	1.0	kW/K	overall heat transfer coeff. times area of condenser
$c_{p,Cond}^{med}$	4.187	$kJ/(kg \cdot K)$	cooling medium specific heat capacity
UA^{Reb}	1.635	kW/K	overall heat transfer coeff. times area of reboiler
$c_{p,Reb}^{med}$	1.670	$kJ/(kg \cdot K)$	heating medium specific heat capacity

2.2. Dynamic sampling through recipes

Batch distillation processes are inherently dynamic. Since in this contribution the scope is to generate surrogate models capable of predicting whole operation cycles, this process was simulated starting from a cold and empty state at ambient pressure, with all valves closed, pumps off and heating and cooling mediums at 21°C. Subsequent shutdown with nitrogen inertization was also simulated. The developed first principles model was set up to have 12 inputs (see Tab. 2) and 26 outputs (although an arbitrary amount can be selected from the flowsheet simulator). Since performing classical nonparametric input samplings would lead to mostly non converging simulations (due to nonphysical behaviours with strong nonlinearities like pumping out empty trays), process knowledge is introduced to constrain the dynamic input sampling space using operation recipes. Different recipes are described in Löwe (2001) and Wang et al. (2003), among others. Here the “conventional strategy” (according to Löwe) described in Tab. 3 will be adopted. A time independent parameter sampling on the parameter set $\Theta = \{\theta_1 \dots \theta_{20}\}$ is translated to dynamic input signals. Hammersley sampling over a hypercubic domain of $[-10\%, +10\%]$ from nominal values with normal sampling distribution was chosen.

Table 2 Selected plant inputs

ID	variable	description
1	x_{VN2}	nitrogen valve position
2	PC^{SP}	pressure controller setpoint
3	x_{VF}	feed valve position
4	RRC^{SP}	reflux ratio controller setpoint
5	$T_{Reb}^{med,in}$	reboiler heating medium inlet temperature
6	LC_D^{MODE}	level controller mode ($\in \{0 = auto, 1 = manual\}$)
7	LC_D^{SP}	condenser level controller setpoint
8	LC_D^{OP}	condenser level controller output
9	PC^{MODE}	pressure controller mode ($\in \{0 = auto, 1 = manual\}$)
10	PC^{OP}	pressure controller output
11	LC_B^{MODE}	sump level controller mode ($\in \{0 = auto, 1 = manual\}$)
12	LC_B^{OP}	sump level controller output

Table 3 “Conventional strategy” starting from an empty and cold column

step	description
1	wait for time θ_1 with system cold and empty
2	generate vacuum ramping down PC^{SP} to θ_2 during a period of θ_3
3	start filling sump with feed ramping up x^{VF} to θ_4 during a period of θ_5
4	wait until sump level reaches θ_6 and close feed valve ($x^{VF} = 0$)
5	heat up reboiler ramping up $T_{med,in}^{Reb}$ to θ_7 during a period of θ_8
6	wait until condenser level reaches θ_9
7	start extracting distillate shrinking RRC^{SP} from ∞ to θ_{10}
8	turn on condenser level controller ($LC_D^{MODE} = 0, LC_D^{SP} = \theta_{11}$)
9	rise reboiler temperature (ramp up $T_{med,in}^{Reb}$ to θ_{12} during a period of θ_{13})
10	wait until achieving cumulative distillate composition θ_{14}
11	stop distillate extraction ($LC_D^{MODE} = 1, RRC^{SP} = 0$)
12	stop generating vacuum ($PC^{MODE} = 1, PC^{OP} = 0$)
13	cool down reboiler ramping down $T_{med,in}^{Reb}$ to θ_{15} during a period of θ_{16}
14	wait until reaching a reboiler temperature of θ_{17}
15	start inertization ramping up x_{VN2} to θ_{18} during a period of θ_{19}
16	empty bottoms ($LC_B^{MODE} = 0, LC_B^{OP} = \theta_{20}$)
17	stop inertization ($x_{VN2} = 0$)

2.3. Design and training of data-driven models

In this contribution, the more classical NARX and newer RNN models are analysed in terms of prediction accuracy over a testing dataset. As an extension of linear time-invariant polynomial models to the nonlinear case, NARX extends ARX models by a nonlinear block (Schoukens and Ljung (2019)). Here, a tree partition nonlinearity was chosen. The amount of tree partition units of the NARX model was set to generate a model with a similar complexity as the RNN (in terms of trainable parameters n_p). The architecture of both data-driven models is specified in Tab. 4. If not specified, default settings of the corresponding toolboxes were used.

The prediction accuracies can be analysed comparing the mean squared errors (MSE) between min-max normalized testing (y_{stc}) and predicted (\hat{y}_{stc}) data for each model, according to:

$$MSE = (n_s n_t n_y + 1)^{-1} \sum_{s=1}^{n_s} \sum_{t=1}^{n_t} \sum_{c=1}^{n_y} (y_{stc} - \hat{y}_{stc})^2$$

where s, t, c are sample, timestep and channel indexes with cardinalities n_s, n_t and n_y .

Table 4 Chosen data-driven model architectures and number of trainable parameters n_p

model	NARX	RNN
architecture	1 input regressor with input delay of 1 timestep for each output. Nonlinearity: tree partition with 231 units. focus: prediction method: PEM	sequence of layers: <input type="checkbox"/> LSTM (64 units), returning sequences <input type="checkbox"/> LSTM (64 units), returning sequences off <input type="checkbox"/> dense layer solver: adam loss function: MSE
toolbox	Matlab/System Identification Toolbox version 9.13	tensorflow 2.1.0/Keras
n_p	729,456	730,426

3. Results and discussion

A total of 1000 Hammersley parameter samples were generated. 645 of these led to converging simulations, shown in Fig. 2. Each complete batch cycle consists of $n_t = 401$ timesteps with a sample time of $T_s = 0.01$ h.

Figure 2: Simulated mass flow of MeOH in the distillate for converged runs in APD. One sample is highlighted in **black**, others are shaded. Visible batch phases: (1) cold phase, (2) first distillate production, (3) further heating and (4) distillate depletion and shutdown.

The input time series \mathbf{X} generated by the recipe in Tab. 3 as well as the output time series \mathbf{Y} from APD were collected in a 3D data structure in the form: $\dim(\mathbf{X}) = (n_s, n_t, n_x)$ with $n_x = 12$ input channels, and $\dim(\mathbf{Y}) = (n_s, n_t, n_y)$ with $n_y = 26$ output channels. A training/testing data ratio of 3/1 was selected to split the converged samples ($n_s = 645$) into sample sizes $n_s^{train} = 483$ and $n_s^{test} = 162$. The resulting training and testing datasets were min-max normalized for each corresponding channel in the training set.

For similar complexity (in terms of trainable parameters), the MSE over all testing samples was $5.24 \cdot 10^{-3}$ for the NARX model and $9.83 \cdot 10^{-3}$ for the RNN model. Fig. 3 shows one testing sample example and the predictions of both data-driven models.

Although higher, the MSE achieved by the RNN model and its lack of unexpected peaks makes this combination of recipe sampling and RNN as surrogate model a promising strategy for APC applications. The peaks observed in the NARX prediction might be consequence of overfitting by forcing its number of parameters n_p to equal those used in the RNN. To tackle this issue, alternative model architectures and their hyperparameters must be studied in more depth.

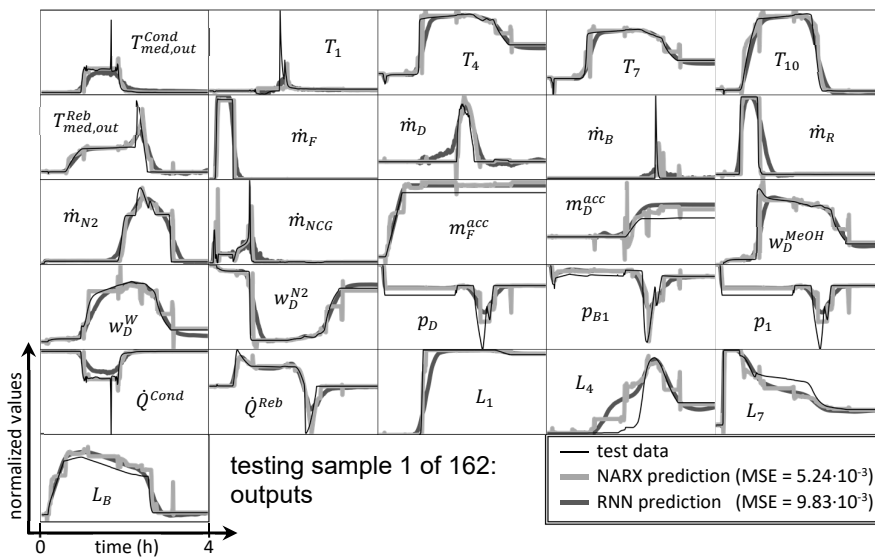

Figure 3: Outputs predicted by NARX and RNN models for one of 162 testing samples

4. Conclusion and outlook

A dataset for the identification of data-driven models was generated from a pressure-driven dynamic batch distillation column simulation in Aspen Plus Dynamics. Even though expert knowledge in the form of operation recipes was introduced to reduce the dynamic sampling space to a time invariant parameter space, 35.6% of the Hammersley samples led to non-converging APD simulations. NARX and RNN models were identified using data from converged simulations, where the NARX model achieved a higher prediction accuracy on a testing dataset than the RNN model in terms of its MSE with a similar number of trainable parameters, although showing unexpected peaks in its

prediction. Therefore, the combination of recipe sampling and RNN as surrogate model shows promising properties for APC applications.

The methodology of dynamic sampling through recipes may be applied to other complex dynamic processes where the feasible sampling domain is highly constrained. Adaptive sampling strategies might decrease the amount of non-converging simulations and enhance prediction accuracies of data-driven models. Since data from non-converged simulations carry information about operation constraints, in future works those trajectories will be included in the training dataset. Furthermore, the architecture of NARX and RNN models may also be studied in more depth to avoid overfitting by varying the amount of regressors and trainable model parameters.

Batch operation may be optimized based on data-driven models, and these models may be adapted for their use in real-time applications.

On the acceleration of global optimization algorithms using a cutting plane decomposition and machine learning

Asimina Marousi, Antonis Kokossis,*

School of Chemical Engineering, National Technical University of Athens, Zografou Campus, 9, Iroon Polytechniou Str. GR-15780, Athens, Greece

akokossis@mail.ntua.gr

Abstract

The paper presents an accelerated approach for global optimization that is applied on quadratic programming problems. The global optimization is based on a decomposition method using cutting planes that are generated, analysed, and screened using advanced analytics. The work capitalizes and builds on innovations by Baltean-Lugojan et al. (2019) who recently presented a generic and effective outer approximation method suitable for semidefinite relaxations. The use of data analytics is applied in populations (P) of cutting planes, experimenting with different metrics and clustering methods. The proposed approach achieves a reduction in the integrality gap by 18-30% with the largest reductions in relation to larger problems (jumbo problems: 100 variables, 75% density).

Keywords: global optimization, outer- approximation, cutting planes, quadratic programming, machine-learning

1. Introduction

Global optimization is a dynamic and thriving area of research with several powerful methods already in place. The effectiveness of algorithms varies with the particular form of the objective function and constraints, the number and type of variables and constraints, and/or the problem sparsity/structure. Even for smooth objective functions and constraints (e.g. polynomials), the optimization problem is generally difficult to solve while providing proper guaranties for the optimum and solution at acceptable times. State-of-the-art (SoA) solvers in global optimization rely on iterative algorithms that establish progress through local optimization steps or, in the case of decomposition methods, in the successive optimization of sub-problems. Cutting plane approximation methods classify among the most promising algorithms of that sort. As a general remark, algorithms generate data that are not fully turned to account. Emerging technologies in machine learning and advanced data analytics can be deployed to exploit such data streams as they are generated and produced internally. Data populations may relate to individual iterations or relate to the entire sequence of iterations. Open challenges include means to translate interim data into exploitable populations, methods to map data analytics with decisions, and techniques to formulate approximations suitable to improve optimization efficiency and speed. In this paper we examine the potential of embedding data analytics in conjunction with SoA optimization methods, specifically advances in quadratic programming featuring outer-approximation methods and cutting planes following the work by Baltean-Lugojan et al. (2019). The new approach leads to a new

class of separation problem and is particularly amenable to the data-driven approach studied in the paper. The purpose of the research has been to particularly examine the correlation of the cutting planes as they are selected by the algorithm in the QP problems and to formulate selection criteria appropriate for each individual iteration. In Section 2, the approximation of the original QP and the decomposition of the cutting planes are presented. Section 3 demonstrates the methodology establishing data metrics and analytics. The emphasis in the research experiments has been to improve the solution quality. Results are presented in Section 4. They consider a wide range of examples and rather encouraging evidence.

2. Problem description and background

The optimization problem is considered a nonconvex quadratic problem that is box and linearly constrained, i.e.

$$z_{qp} = \min_x \{x^T Q x + c^T x \mid Ax \leq b, x \in [0,1]^N\} \quad (1)$$

with an N -variable vector x , $A \in \mathbb{R}^{p \times N}$ and $Q \in \mathbb{R}^{N \times N}$ assumed to be an indefinite matrix. For the problem to be solved a series of reformulations and relaxations are taking place as proposed in Sherali and Fraticelli (2002). Each quadratic term $x_i x_j$ is replaced by a new variable X_{ij} . Let the lifted variables $X_{ij} \forall i, j$ form the symmetric matrix $X = xx^T$ and let $Q \cdot X = \text{Tr}(Q^T X) = \sum_{i,j} Q_{ij} X_{ij}$, representing the Forbenius inner product. Then z_{qp} is lower bounded by,

$$z_{qp}(\mathcal{B}) := \min_{x,X} \{Q \cdot X + c^T x \mid Ax \leq b, x \in [0,1]^N \text{ and } (x, X) \in \mathcal{B}\} \quad (2)$$

parametric on any convex set \mathcal{B} that adds valid constraints to the basic lifted formulation of the quadratic problem.

The relaxation of the nonconvex $X = xx^T$ to $X \succcurlyeq xx^T$, or equivalently $\begin{bmatrix} 1 & x^T \\ x & X \end{bmatrix} \succcurlyeq 0$ results in the semidefinite relaxation (SDP) of the quadratic problem with a positive semidefinite (PSD) restriction Sherali and Fraticelli (2002); Qualizza et al. (2012). The SDP relaxation is augmented by the reformulation-linearization technique (RLT), Anstreicher (2009), for $0 \geq x_i, x_j \leq 1$.

In the initial round of optimization, the PSD constraint is omitted. Let the solution of the initial round be X^*, x^* , to evaluate if the PSD constraint is guaranteed, eigendecomposition is performed on $\begin{bmatrix} 1 & x^{*T} \\ x^* & X^* \end{bmatrix}$, with t the negative eigenvalues of the matrix. If $t = 0$ then PSD is met, if $t \geq 1$ then PSD is violated. For every t the corresponding eigenvector v_k is used to generate the violated cutting planes $v_k^T \begin{bmatrix} 1 & x^T \\ x & X \end{bmatrix} v_k \geq 0, \forall k \in 1, \dots, t$ which are used as PSD constraints in the following round.

Qualizza et al. (2012), observed that the generated cuts are few, one cut per negative eigenvalue, and also very dense, i.e., almost all entries in v_k are nonzero, causing the reoptimization of the linear relaxation to slow down. For that reason, they introduced a heuristic for the sparcification of the PSD cuts. To overcome the

problem of few dense cuts, Baltean-Lugojan et al. (2019), introduced low-dimensional approach leading to lighter linear relaxations.

With \mathcal{P} denoting the power set of the vertex $V: \{1, \dots, N\}$ and $\rho \in \mathcal{P} (\rho \subseteq V)$ any arbitrary index subset, let $x_\rho \in \mathbb{R}^{|\rho|}$ the vector slice of x and $X_\rho \in \mathbb{R}^{|\rho| \times |\rho|}$ the submatrix slice of X . For any subset of \mathcal{P} the following semidefinite relaxation is introduced,

$$(\forall \mathcal{F} \subseteq \mathcal{P}) \mathcal{P}(\mathcal{F}) := \left\{ (x, X) \mid \forall \rho \in \mathcal{F} : \begin{bmatrix} 1 & x_\rho^T \\ x_\rho & X_\rho \end{bmatrix} \geq 0, X_{ii} \leq x_i \forall i \in \rho \right\} \quad (3)$$

A fixed cardinality $n (1 \leq n \leq N)$ is imposed on \mathcal{P} such that:

$$\mathcal{P}_n := \{ \rho \in \mathcal{P} \mid |\rho| = n \}, \text{ with } |\mathcal{P}_n| = \binom{N}{n} \quad (4)$$

A separation problem arises since there are $\binom{N}{n}$ available inequalities to create cutting planes. In Baltean-Lugojan et al. (2019), the separation problem is addressed with one of the following strategies: feasibility, or optimality and combined selection. In feasibility strategy cutting planes are selected based on most negative eigenvalues of the SDP relaxations. Optimality strategy represents the improvement of the objective function resulted by the selection of a specific cut and is calculated by an artificial neural network. Combined strategy selects optimality cuts with negative eigenvalues.

In order to make the Master problem efficient we need to find the best underestimators which will allow faster convergence of the optimization algorithm. We are imposing an extra sorting criterion for the inequality constraints added in the Master problem by Baltean-Lugojan et al. (2019). The cutting planes should not only be highly ranked based on eigenvalues(feasibility) or the improvement of the objective function (combined) but they should also be independent to each other. They rationale here is that if one cutting plane is selected, there must be a guarantee that any additional selected cutting plane added to the list of constraints provides new information for the problem. Both may be informative enough however the information they provide may be overlapping.

3. Proposed acceleration methodology and machine learning experiments

The proposed algorithm consists of 3 main steps that involve:

- Step 1: Solution of $z_{qp}(\mathcal{B})$ from Eq. (2)
- Step 2: Creation and evaluation of ordered sets of cutting plane populations
- Step 3: Screening and selection of cutting planes

The convex set \mathcal{B} initially consists of RLT constraints. Each solution of Eq. (2) is attained by the Branch and Cut algorithm (Step 1). For each on-going solution the decomposition provides for the low-dimensional PSD constraints. Each constraint is examined regarding the selected measure/condition for feasibility (Baltean-Lugojan et al., 2019); all PSD sub-problems satisfying the condition (e.g., $\lambda_\rho < 0$) enter the population (P) used for analysis. (P) consists of N-D vectors with $\frac{n}{N} \cdot 100\%$ density and its population is ordered in descending feasibility. The analysis uses both Euclidean metrics and alternative metrics introduced by means of an *affinity distance*, $d_a(x, y)$, that is formally introduced

thereafter. The complementarity within (P) is determined by clustering techniques (Step 2) such as k-means and agglomerative clustering that are deployed using fixed and/or variable numbers of clusters. Hybrid methods explored sequential implementations of Euclidean and affinity metrics.

The affinity metric $d_a(x, y)$ holds similarities to the Hamming distance and was used to evaluate differences between vectors for each sub-problem population. For $x, y \in \mathbb{R}^N$, the affinity metric is defined by,

$$d_a(x, y) := \sum_i^N [1 - g(x_i, y_i)], \text{ where } g(x_i, y_i) = \begin{cases} 1, & \text{if } x_i = y_i \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

In Step 2 the Euclidean and/or the affinity distance are applied to analyse the population of (P). In the case of the affinity metric defined by Eq (5), the distance between the vector, \tilde{x}_1 , that is corresponding to $|\lambda|_{max}$, is first computed against all other vectors in P. Vectors featuring $d_a(\tilde{x}_1, \tilde{y}) = 2$ are declared similar and subsequently removed from (P) into a cluster. The analysis proceeds with the next vector \tilde{x}_2 ; the process terminates once the full population is clustered. In Step 3, vectors are selected from the created clusters to suggest cutting planes and to update the convex hull \mathcal{B} . Within each cluster, a shortcut criterion (C1) can be used to select the highest-in-rank vector ($max|\lambda_\rho|$) while other criteria may also be applied featuring additional levels of sophistication. A mixed use of metrics has also been applied where clustering is implemented twice in Step 2 and 3: clustering using the Euclidean distance and selecting cutting planes using the affinity norm (Hybrid1) or with the use of the affinity metric first and the Euclidean next (Hybrid2).

4. Results

Machine learning experiments are performed over the test set of BoxQP studied by Baltean-Lugojan et al. (2019). For all computational experiments $n = 3$, namely the dimensionality of the cutting planes. The feasibility is the cut selection measure. The number of rounds and cuts are dictated by literature so that to compare the proposed approach with reference work (Rf1). The number of iterations in the optimization algorithm is 20; the added cuts for each round (e.g. the selection size) are set to 100. Following Baltean-Lugojan et al. (2019), the convergence limit and the final solution is achieved when cut rounds are 40 and cut/round are set to 5% of the available sub-problems. Results are evaluated based on the convergence of the algorithm and the final solution. The computational experiments are carried in python 3.5 using cplex 12.8 python API solver and scikit-learn v0.2 (Pedregosa et al., 2011) package for k-means and agglomerative clustering.

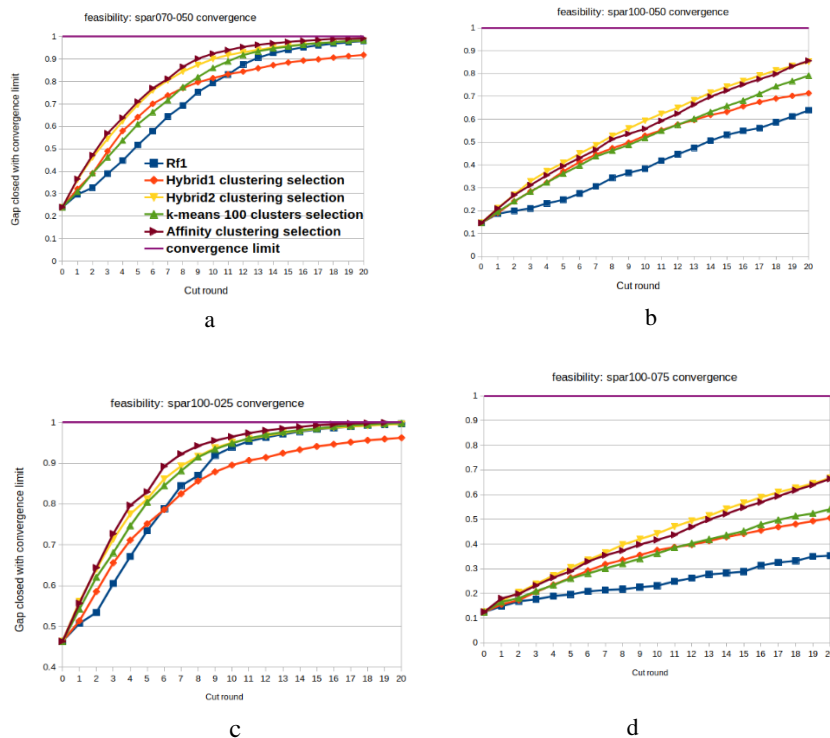

Figure 1 Gap closure between $z_{qp}(\mathcal{B})$ and the convergence limit targeted by the outer-approximation using the feasibility measure to rank the population P. The different clustering methods are embedded in the reference algorithm (Rf1) resulting in an extra sorting of P

As a general remark, the proposed approach achieves significant gap closures that are especially evident in problems of higher complexity as shown in Fig.(1b) (15-21% gap decrease) and Fig.(1d) (18-31% gap decrease). Accordingly, the approach proves particularly useful in cases where conventional methods feature large convergence gaps. To a lesser degree, improvements are achieved in the lower-density and lower-dimensionality problems shown in Fig.(1a) and Fig.(1c). The convergence performance in using the affinity metric in Step 2 performs with similar trends to Hybrid2. The use of affinity in Step 3 performs with similar trends to Hybrid1 and proves an inferior option suggesting that the use of the affinity metric is a much stronger choice when applied in earlier stages of analysis. The shortcut criterion (C1) is generally found to outperform other sophisticated options studied in this work.

Clustering based on $d_a(x, y)$ provides remarkable improvements not only over the reference algorithm but also over the conventional clustering method of k-means. Furthermore, the convergence of the optimization solution follows a consistent trendline in all cases, demonstrating that the $d_a(x, y)$ is a suitable metric for a wide range of QP instances. The emphasis of the paper has been to exclusively reduce the integrality gap. The reduction has subsequently affected CPU times with an increase reported either in the use of the affinity metric or, primarily, the use of clustering algorithms. The affinity metric used for clustering increased CPU times by 5-60 times. The largest delays are observed in small complexity instances where the original algorithm has fast convergence. Over-the-self clustering algorithms delayed the algorithm by 7-25 times with computational time increasing with problem complexity. Given the current emphasis of the paper, there is significant scope to improve such times in future developments.

5. Conclusions

The use of data analytics by cutting plane algorithms has proved an essential drive for improvements in global optimization. The conclusion is demonstrated with a study of a wide range of optimization problems. Results demonstrate significant room to reduce the cutting plane populations generated by the conventional algorithms. The affinity metric introduced in Eq (5) proved a promising approach to handle cutting plane redundancies and to support clustering. Reinforcing the methodology by selection criteria biased on both feasibility and complementarity performance has enabled improvements in the original algorithm. The use of the affinity metric has generally outperformed general-purpose clustering (e.g. k-means, agglomerative clustering) while in hybridized forms the metric led to better results though without impressive improvements. Remarkably, the clustering approach has a greater impact in high-dimensional & medium-to-high density problems indicating a promising and encouraging scope to improve existing algorithms.

6. Acknowledgement

The authors are grateful to generous assistance and collaboration with Dr Ruth Misener and Radu Baltean-Lugojan from Imperial College. The sharing exchanges have been instrumental to test developments for several problems also to compare the proposed algorithms with established benchmarks and the state-of-the-art. None of that would be possible without their assistance. The authors acknowledge financial support by the H2020-EU.1.3.3. Grant RENESING II (H2020-778332).

Abstract

Industrial scale bio-manufacturing processes are transitioning towards Industry 4.0, which promises to change the competitive landscape. As part of this (r)evolution, there is an increased focus on developing digital twins of critical operations, such as fermentation processes. A key economic driver for the enthusiastic embrace of digital twins by this industry is the promise of increased process efficiencies and resource utilization, mainly through improved plant operations. However, for digital twins to move from the “current hype” to a beneficial solution in the industry, some challenges must be overcome. This manuscript attempts to identify these challenges and opportunities by developing a Digital Model of a Pilot Scale Bioreactor producing Green Fluorescent Protein (GFP) currently used for Teaching purposes.

Keywords: Digital Twins, Validated models, Bioreactors, Fermentation.

1. Introduction

The digitalization movement in bio-manufacturing promises improved process operations through informed decision-making (Udugama, Gargalo, et al., 2020). One key pillar in the discussion of digitalization is the concept of Digital Twins. Digital Twins, through the creation of virtual plants, accurately represent the behavior, including the “look and feel” of a physical plant (Lukowski et al., 2019).

In Process Systems engineering, the development of mathematical/process models has been a standard practice for decades. There are remarkable examples of benchmark simulations such as the MIT-Novartis Continuous pharmaceutical production process (Benyahia et al., 2012) and the Benchmark Simulation Model (BSM) for wastewater treatment plants (Rosen et al., 2006) being amongst a countless number of mathematical models. In the bio-manufacturing industry, mathematical models have also been used for decades and continue to be a popular alternative to physical experiments when it comes to design and optimization of different processes and unit operations (Mears et al., 2017; Narayanan et al., 2020). Today, these mathematical models are often referred to as Digital Model and make up the core “prediction engine” of a Digital Twin (Lopez et al., 2020).

The Accelerated Innovation in Manufacturing Biologics (AIM-Bio) project is a joint initiative between North Carolina State University and the Technical University of Denmark (DTU) established to create a “world-class program in bioprocess research and development and workforce training that focuses on products and technologies for the future of biopharmaceutical manufacturing”. As a part of this initiative, the (PROSYS) center at DTU collaborates with BTEC at North Carolina State University to develop digital models of their pilot scale bio-manufacturing facility, primarily used for education purposes. The overall goal of this endeavor is to develop Validated Digital models that can be in the form of Operator Trainer Simulators to enhance students' learning.

As in many bio-manufacturing processes, fermentation is a central part of the pilot scale bio-manufacturing operations. BTEC produces GFP as a model protein through an *E. coli* based fermentation process. More specifically, the process employs an induced fermentation batch using *E. coli* (BL21(DE3)) with a plasmid pET17-b to produce GFPuv with a T7 promoter (IPTG) in a Sartorius Stedim 300-L Bioreactor. This bioreactor is equipped with a standard set of sensors such as temperature, pressure, pH, and off-gas measurements. An industrial distributed control system (DCS) is used to operate the reactor, while a process historian is used for logging the available process data. Moreover, advanced analytical equipment is used for off-line monitoring of the batch's progression, similar to standard industrial practice.

This contribution aims to understand the level of detail and the necessary auxiliary elements (e.g., GUI) that a mathematical model of a fermentation process needs to have in order to fulfill the role of being a standalone Virtual Plant. Furthermore, this work will also enable us to better understand the level of detail/fidelity, and additional complexity that a mathematic model must incorporate so as to become a Digital Twin.

2. Digital Model Development

As an initial push towards developing a fully-fledged digital model, a macro-kinetic process model that accounts for overflow metabolism and the associated acetate excretion and substrate consumption inhibition was set up in Matlab Simulink. The ordinary differential equations describing the mass balances were set up in accordance with earlier models reported by Xu et al. (Xu et al., 1999), Anane et al. (Anane et al., 2017) and Pham et al. (Pham et al., 1998).

2.1. Macro kinetic model formulation

The set of ordinary differential equations uses five inputs and a set of auxiliary algebraic equations describing the intracellular kinetics: biomass formation and oxygen consumption, substrate, and acetate consumption. The substrate is primarily glucose and is modded accordingly, while 15 g of ampicillin are added as antibiotics are added at BTEC reactor to control unwanted bacteria growth, this is not modelled in the digital model. There are six output/state variables, which are: volume, biomass concentration, extracellular substrate concentration, acetate concentration, dissolved oxygen, and mass of GFP produced.

The inputs used in the model were chosen due to the fact that they are important and manipulatable physical variables: feed flow rate (L/h), feed glucose concentration (g/L), temperature (C), headspace pressure (atm), volumetric mass transfer coefficient. The Matlab model developed by Anane et al. (2017) was used as the starting point for developing a Digital Model. And the temperature was kept at a constant 30 °C.

2.2. Structural Modifications to the Model

Two main structural changes were carried out in this work. First and foremost, the model was converted into a Matlab Simulink operated model. This allows the model to be run similar to a prediction engine, where outputs and inputs can be altered externally in real time, lending it to be used as a Digital Model. Secondly, along with the process variables, the model was extended to also have other key state variables as output, in case that they can be monitored at the pilot plant in the future.

2.3. Introduction of GFP

The mechanistic model of the GFP production after the induction with IPTG has been developed using standard biochemical yield kinetics (Figure 1). The kinetics are based on how much substrate is available for product formation and given as total mass because GFP is formed intercellularly with minor extracellular concentration as a result of lysis and only being sampled after harvesting the batch. After induction, the cell production is also reduced, assuming that all induced cells only produce GFP and do not reproduce. The switch from the growth phase to the production phase is modeled based on mixing experiments performed at BTEC on the actual reactor. This results in a nearly instantaneous switch from growth to production due to the reactor's short mixing times. IPTG can be toxic to cells when used at high concentrations causing cell stress. However, the concentration used at BTEC is optimized so that this problem is negated.

Figure 1. Current modeled GFP increase with IPTG induction at 5.8 hours (dotted line).

3. Challenges and Opportunities

3.1. Modelling the Cell line

A key learning from the initial endeavor was that an accurate digital representation of the process requires us to go beyond the standard mathematical modeling and explore the cell factory. To this end, a digital model of the process seems to require a multi-scale approach. Of particular interest was to understand how IPTG influences the cell behavior so that the cell is induced to produce GFP. From a chemical engineering perspective, this type of process behaviour can be modeled using a kinetic equation activated when IPTG is introduced into the reactor. However, based on BTEC's observations, this concept of a hard production switch is incorrect. Instead, the observations suggest that the cell growth rate is significantly reduced at that induction time point. Even before induction, some "minor" GFP production rate is expected. Moreover, the reduction in growth rate is a

function of the concentration of IPTG introduced into the reactor. Considering all these aspects, efforts are underway to model the cell itself, where parameters such as reduced growth rate and GFP production rate present in the mechanistic model will be determined by solving the cell model at appropriate time intervals during a batch.

3.2. Lack of Process Data

A critical limitation that had to be overcome in the development of the digital model was the lack of process data that was initially available for parameter estimation and model validation purposes. This is another key aspect in transitioning a mathematical process model into a digital model.

The main benefit of adopting the *E. coli* growth model developed by Anane et al. (Anane et al., 2017) is that the process parameters related to biomass growth have been validated against an actual fermentation process, although in a lab-scale setup. To identify if the process parameters suggested in (Anane et al., 2017) yield an accurate digital representation of the fermentation process at BTEC, a Monte-Carlo analysis on the process model was performed, where key process parameters including qS_{max} and Y_{em} were varied. The results of this analysis were plotted together with the single process data set that was available. They are displayed in Figure 2 (a) and (b).

Figure 2 shows that the data points and the process model have a similar but slightly shifted growth curve when only varying a single parameter from values based on lab-scale data (Anane et al., 2017). Note however that a lack of data points during regular periods of operation means that further process data is required to make a definitive conclusion. Compared to biomass growth rate data, only a final value of GFP produced is available for GFP production. This is due to the fact that GFP is stored intracellularly, and by following the current standard operating procedure (SOP), the amount of GFP produced in a bio-reactor is measured by processing the biomass into cell paste using a sample taken at the end of the process.

A clear plan has been put in place to improve the quality of the data to be gathered in the future. Firstly, the volume of data gathered will be improved, as multiple experimental runs are currently planned and protocols in place to collect the process data generated. Specific experiments are also designed to capture the GFP production rate through running trial experiments where batches are not induced. This will allow for substrate consumption ratio for biomass production vs. protein yield to be calculated throughout a batch.

3.3. Validation vs. Complexity

Based on the current trends and interpretation of digital models, which, in short, need to be a virtual representation of the physical process, only a multi-scale model that integrates the “cell factory” and the reaction kinetics would be sufficiently complex and accurate. To achieve this, a digital model of such a process should include this multi-scale phenomenon and even consider fluid dynamic dependencies due to the potential heterogeneity present within a 300 L bioreactor. Such a multi-scale model is more complicated than the current *off-the-shelf* solution that employs a set of Ordinary Differential Equations to describe a bioreactor's time-dependent behavior. If the necessary process data is available, such a multi-scale model would potentially be much more accurate in mimicking an actual bioreactor's behavior.

However, from a practical standpoint, there are significant limitations in gathering process data. For example, other than temperature, pH, and flow information, BTEC currently requires manual operator intervention to collect and analyse off-line measurements to determine dissolved oxygen and glucose concentration. Furthermore, capturing effects such as pH gradients is impractical as only a single pH sensor is present

in the reactor. Another important consideration is the data preprocessing (e.g., GFP concentration measurements), which is tedious and time-consuming. All in all, a decision needs to be made regarding the level of detail to be included in the final digital model. There are two alternatives: (i) go back to the current approach (ODEs representing the reactor); or (ii) gather the necessary data at the cell level, as well as potentially other aspects (e.g., bioreactor fluid dynamics), and integrate them into the model. In pursuing the second approach, concepts such as high-throughput screening can be used to generate data related to the cell model, which then can be used for validation purposes at the cell level. Novel measurement technology such as free following sensors (Gargalo et al., 2020) can potentially be used to gather information on the bioreactor's fluid dynamics. Moreover, fluorescence spectroscopy can be used to track GFP production in real-time, which would enable the validation of both cell and reactor models.

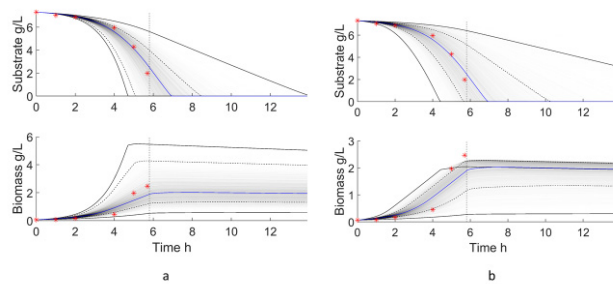

Figure 2. Monte-Carlo simulation: 2000 samples varying (a) Y_{em} (b) qS_{max} with induction time. 95% confidence interval (CI) is shown as dotted lines. Outermost incident (solid line), process data (*).

3.4. The role of a Graphical User Interface (GUI)

A GUI plays a crucial role in transitioning a mathematical process model into a digital model. This is because a GUI makes a mathematical process model have the “look and feel” of a physical process. In practice, many physical processes in the bio-manufacturing industry are often controlled through a controller GUI. To this end, the development of a graphical user interface allows students to explore a mathematical model's behavior in a similar way to operating a real process (Udugama, Germaey, et al., 2020).

4. Conclusions

A Digital Model of the BTEC Pilot Scale Bioreactor producing Green Fluorescent Protein (GFP) has been developed and implemented in Matlab Simulink. Furthermore, by analyzing the GFP production details, it was concluded to develop a multi-scale approach to increase the digital model's fidelity. To this end, data on different scales, e.g., at the cell level and bioreactor fluid dynamics, will be collected and reflected in the model. In summary, this contribution laid the foundation in developing a detailed mathematical model with the necessary auxiliary elements (such as a GUI) to fulfill the role of being a standalone virtual plant both for in education and in industrial scale bio-manufacturing processes.

Abstract

Developing forecasting models that incorporate that external parameters in addition to past data for crude oil and derivatives are a challenging task since it is highly dependent on economic, geographical, and political issues. However, forecasting the prices is very important for strategic planning and oil refineries' operational decisions. This paper presents an automated tool to predict crude oil prices and their main products by applying Box-Jenkins methodology for the next two months at the beginning of each month in a rolling horizon manner. The resulting forecast is shared with related departments to develop their production plans accordingly. We show that improved accuracy with this forecasting approach is beneficial in any planning and decision-making process and increases profit.

Keywords: price forecasting, crude oil, Cox-Jenkins, SARIMA

1. Introduction

Refineries are continuous-flow manufacturing facilities that have a considerable effect on the global economy. In concise terms, petroleum refineries can be summarized as processing crude oil into a more valuable product by using chemical and physical operations. Production planning and process scheduling are among the most important activities of refineries for maximizing profit. Several software packages optimize the refinery operations; these tools need various data such as feedstock prices and products, demands for all products and byproducts, and supply limits [1]. Since the usual planning period covers the next two months, forecasting the future prices of products is critical.

Linear programming-based planning systems determine the production plans for all units in the refinery. The general approach for the production and scheduling process has two phases: (i) Determining monthly rolling plans for crude selection and conducting refinery operations in line with forecasting demands. (ii) based on the monthly plans, implementing short-term plans for finding operational strategies regarding crude availability, product delivery, operational and logistic constraints, and economic issues. [2]

As well as the price of the products itself, the price bracket between related products is a key parameter for making decisions on production planning. For example, the price difference between the naphtha and gasoline shows the refineries how to add value to the upper distillate; either produce gasoline or sell naphtha and reformat separately. The price range of diesel and aviation fuel has a strong impact on the refinery's profitability. The price bracket between low and high sulfur diesel determines the refineries'

profitability of desulphurization units. Furthermore, the prices of low and high sulfur fuel oils are important for determining the quantities of additives during the blends of different types of marine fuels.

This paper presents an automated approach to generate price data forecasting by applying Box-Jenkins methodology to historical price data. As an industrial implementation, the objective is that this monthly-generated data set becomes an input to planning activities in operations of a refinery operated by Tüpraş. The improved accuracy of forecasted data allows us to improve robustness in scheduling.

2. Methodology

Box Jenkins ARIMA methodology refers to a set of procedures for identifying, fitting, and checking ARIMA models with time-series data [3]. Although there are many works related to Box-Jenkins ARIMA methodology, a completely automated Box-Jenkins SARIMA tool does not exist. The objective is to create an automated and comprehensive forecasting approach that generates price predictions for an oil company.

There are two different approaches to monitoring crude oil and derivatives' price: Ratio and crack margin. The ratio is the division of a product price by the crude oil price, whereas crack margin is the price difference of the product and crude oil. Instead of the ratio, monitoring a product's crack margin is much more meaningful because it does not fluctuate rapidly as the crude oil price changes.

In this study, crack margin data is used for modeling because its variance is lower than the ratio. Also, crack margin is a function of both Brent crude oil price and each product's price.

2.1 Data Preprocessing

We start by identifying whether the data is stationary or not [4]. The most usual approach is to analyze the series plots and ACF plots [5]. Since the aim is to develop a full-automated system, we use various tests based on the definition of stationarity.

The corresponding tests and their stopping criterion conditions are as follows:

- (i) Stationary test: Count the number of ACF lags out of the critical level. If the result is more than $(0.2) \times (\text{total number of lags})$, the series is not stationary,
- (ii) Trend stationary test: We use KPSS (Kwiatkowski, Phillips, Schmidt, and Shin) test for this purpose. If the data is stationary, it should not contain trend. [6]
- (iii) Mean stationary test: We divide the data into two pieces, and by using t-test, we check whether the mean of the series of time-dependent or not.
- (iv) Randomness test: We use the Ljung-Box Q test over the ACF of the series. The aim is to check whether series have autocorrelation for a fixed number of lags.
- (v) Augmented Dickey-Fuller Test: We use the test to check whether time series data are stochastically stationary or not.

The algorithm executes the tests mentioned above automatically, and if there is at least one test that shows data is nonstationary, then we take the first derivative of data, namely order of differencing is increased by one (by default, it is zero). These comprehensive tests can easily catch nonstationary data. Nevertheless, we still want to use graphical analyses to inform the user.

At the end of this section, the algorithm determines whether the data is stationary or not. If the data is nonstationary, then it calculates the order of differencing. Original data, box plot of monthly divided data, historical data around the desired month, monthly average data, ACF and PACF plots of monthly data, and normality plots will be shown to the user to justify the findings.

2.2 Model Identification and Diagnostic Checking

To increase the selection process's robustness, we model all possible combinations. We use the fact that orders of AR and MA are usually less than and equal to two. We also increased the upper limit of the AR limit to 7. However, model results do not become more desirable than increasing model complexity. Thereby, we chose to go over all 972 combinations of SARIMA models (nonseasonal differencing order is fixed in the first step, so 972 is the number of all different combinations).

For all 972 different SARIMA models, values of coefficients are calculated by using maximum likelihood estimation. The estimated parameters for the current model is forced to satisfy the following conditions:

- (i) Parameter estimation should converge
- (ii) MA coefficients should be invertible
- (iii) AR coefficients should be stationary

If one model fails to meet these conditions, we drop this model and do not further investigate or use it in the forecasting.

Having estimated coefficients, we check goodness of the fit for each model. This part is diagnostic checking of all available SARIMA models and particularly vital in the Box-Jenkins method. All available SARIMA models are assessed with the following tests:

- Significance of parameters: All the estimated parameters should be significantly different from zero. We use p values for each parameter of a model for this purpose. If the corresponding model has at least one parameter with a higher p -value than 0.1, we diagnose it as having an insignificant parameter.
- Testing heteroscedasticity: The standard deviation of standardized residuals should be varying at a fixed level. If it is not non-constant, then there is a heteroscedasticity issue. In order to detect this issue, we applied the Goldfeld-Quandt test. We tested whether the sum of squares in the first third of the sample is significantly different from the sum of squares in the last third of the sample.
- Testing normality: We tested for the normality of standardized residuals. For this purpose, we used the Jarque-Bera normality test. Standardized residuals should have an approximately normal distribution. Otherwise, it violates one of the Box-Jenkins assumptions.
- Testing serial correlation: We tested whether there is a statistically significant correlation between standardized residuals. The residuals should pose no autocorrelation. Otherwise, there is room for improvement. We applied Ljung and Box and Durbin-Watson tests to check whether residuals are uncorrelated.

When a model passes all these tests, it goes to the next stage, which is the final stage for selecting the best model.

2.3 The Best Model Selection

This section presents each product's best model and is used for forecasting. For this purpose, we take the first 85% of the data as training data and the rest of it as the test data.

We have approximately 120 data points, so the test data window is around 12 data points, namely one year. The best model should capture the trend of last year with minimum error. There are many statistics to check this model accuracy; we used mean squared error for this purpose.

After splitting the dataset into training and test sets, we train all candidate models with training data, and new models are obtained. Then, each time step of the test set is iterated. Namely, candidate models predict one period ahead, and after that, the actual value of the predicted time is given to the model. While preserving the model parameters, new coefficients are estimated with this new value, and again one period ahead prediction is carried out. "The iterative approach allows a new ARIMA model to be trained each time step. Prediction is made each iteration and stored so that all prediction can be compared to actual values at the end of the test set, and an error score is calculated. In this case, a mean squared error score is calculated". The best model has the least error score among the candidate models.

We implemented all steps of the model in python 3.6. Built-in Python libraries carry out some statistical tests. Anyone can use this comprehensive and complete automated tool for any time series data. However, the users must consider the prediction horizons, i.e., daily, weekly, monthly, etc. After this specification, the tool provides forecasting values for the desired prediction horizon

The accuracy of the forecast is tested between January 2017 and May 2018. The approach in testing is quite similar to selecting the best model. First, only the data between January 2009 and December 2016 is given to the model. It selects the best model as discussed in the previous sections. After it predicts the next month, we calculate the monthly average of that predicted month. In the next iteration, the algorithm has data between January 2009 and January 2017, and the code again carries out all stages. The program in any iteration might identify a completely different SARIMA model. We calculate all prediction errors for all months and all products by using the mean average percent error

3. Results and Discussion

To test the forecasting tool's accuracy, we used the actual oil and its derivatives price data published every day. We gather the data daily; however, we used monthly average data since the aim is to predict prices monthly. Moreover, a daily variation of prices is too high to predict, and the autocorrelation function decays so slowly that even after many differencing, it is not stationary. In this study, seven major products and Brent crude oil prices are forecasted for sixteen months ranging from January 2017 to June 2018. At the beginning of every month, the prices are predicted for the next month and the two months ahead. Table 1 shows the average forecasting accuracy for each product and Brent crude oil. As a general conclusion, the prediction for $n+1^{\text{th}}$ month is better than the one for $n+2^{\text{th}}$ as expected since the forecasting power decreases as the time period increases. The prediction accuracy of gasoline is around 90% for both periods. When middle distillate products of aviation fuel, low and high sulfur diesel, are considered, the accuracy ranges from 91% to 95%. The application has some development areas when the bottom products are considered since the accuracy is between 68% and 86%. Although Brent crude oil price is hard to forecast due to factors that cannot be modeled easily, the tool performs well, ranging from 93% to 96%. The forecast means absolute error for naphtha is 1.2. These calculations are done using mean absolute error (MAE) except naphtha because

mean average percentage error (MAPE) is used for naphtha since the magnitude of error is small.

Moreover, to compare our SARIMA Box Jenkins methodology, we implement Single Exponential Smoothing, Double Exponential Smoothing, and Triple Exponential Smoothing (Holt-Winters Method) for one period ahead prediction. The performance measure is the same. Mean absolute average error and the same iteration method are applied (first the model predicts, then the corresponding data is introduced). The following models' optimal parameters are found by using a similar grid search algorithm.

Table 1. Average Forecasting Accuracy for 16 Months by Stepwise Modeling for SARIMA Box Jenkins

	(n+1)th Month Accuracy	(n+2)th Month Accuracy
Gasoline 10 ppm	91,1%	90,3%
Aviation Fuel	95,0%	92,4%
High Sulphur Diesel	93,8%	93,4%
Diesel 10 ppm	93,6%	91,2%
Fuel Oil 1%	78,7%	68,3%
Fuel Oil 3.5%	85,9%	75,0%
Brent Crude Oil	95,9%	93,1%

Table 2. Average Forecasting Accuracy for 16 Months by Stepwise Modeling with Other Models

	Single Exponential Smoothing	Double Exponential Smoothing	Holt-Winters	ARIMA	SARIMA
Gasoline 10 ppm	89.9%	89.1%	88.1%	90.8%	91.1%
Aviation Fuel	93%	93.2%	92.7%	92.2%	95.0%
High Sulphur Diesel	93.8%	93.5%	91.0%	93.2%	93.8%
Diesel 10 ppm	93.4%	93.4%	93.2%	91.7%	93.6%
Fuel Oil 1%	73.7%	73.9%	78.3%	73.3%	78.7%
Fuel Oil 3.5%	84.8%	84.1%	85.8%	84.7%	85.9%
Brent Crude Oil	94.9%	95.2%	93.5%	95.2%	95.9%

Comparisons of actual and forecasted prices are displayed to the user as shown in the following figure:

Figure 1 Predicted Price (red) vs Actual Price (blue).

4. Conclusions

This study proposes a new approach to achieve more profitable production planning. We extended the Box-Jenkins method by adding a fully automated and comprehensive grid search algorithm. This approach substitutes human judgment with statistical tests and trying all combinations without giving up any critical stage of Box-Jenkins methodology. This tool provides the numbers and very powerful graphs that justify those numbers. Since it is an interactive tool, the user may accept or reject the proposed results, mainly based on the graphs. We implemented using python 3.6 and made an easy to use interface. The tool only needs the original data, time window, and predicted values. To test model accuracy, we applied it to forecasting petroleum products' price and Brent crude oil price. Generally, our forecasting accuracy is between 90-98%, with one exception, the accuracy of Fuel Oil forecasts is close to 75-85%. When we compare the Box-Jenkins Full Automated SARIMA model to other well-established model types, it is seen that our model has better forecasting accuracy than the other types. This fully automated tool is deployed in Tüpraş Foreign Trading Department. Price prediction dedicated from this tool is one of the critical import inputs they use during the crude selection and planning processes

Abstract

This paper discusses the implementation of interfacial transport in the systematic modelling methodology by Preisig (2012) and how to lecture the approach as well as its implications to engineering students. We first elaborate on the theoretical concept of interfaces before abstracting them into topologies that allow for comprehensible as well as precise mathematical assessments of the transport processes involved. Thereby, any interfacial transfer is rooted in its fundamental parts of transport towards, across and away from the interface. These steps can be assessed by only a handful of algebraic equations from an ontology, which covers the entirety of physical concepts, state derivatives, and conservation principles. Due to this, interfacial transport can rapidly be implemented in process models, significantly aiding subsequent model simplification as well as model fitting.

Keywords: process modelling, ontology, topology, dynamics, diffusion

1. Motivation

Many processes like extraction, adsorption and membrane filtration depend on mass, momentum and energy transfer across interfaces. As shown by Preisig (2014b), these processes can conveniently be abstracted into a topology that is a network of capacities; non-overlapping, finite volumes that only interact with each other by the means of directed arcs. Arcs that are flows of extensive quantities (like mass) driven by gradients of intensive properties like concentration, temperature or pressure.

The convenience of topology modelling can further be intensified by providing an expert ontology - a comprehensive collection of fundamental definitions and relations taken from the application-relevant scientific roots, and by implementing all of this in the highly automatised modelling suite *ProMo* [Elve and Preisig (2019); Preisig (2020)]. However, from lecturing engineering students it transpired that further emphasis has to be placed on the concept of interfaces and its realization within the methodology.

Consider the case one is asked to model an adsorption column: Most likely, the initial process topology drawn would be similar to the one depicted in Figure 1. A feed F enters column C , in which the adsorption of component i on adsorbent A proceeds before leaving the unit as the processed product P . The process is defined by the conditions at its boundaries to the environment. Since we assume for now that the environment is infinitely large compared to our process plant, thus not affected by the process, we depict both the feed F and the product tank P as reservoirs (semi-circles)

that are infinite volumes of constant properties. On the other hand, C and A are depicted as finite, distributed capacities (ellipses), indicating that in these volumes intensive properties are dependent on the location of observation. The process of adsorption is implemented by flows of mass (black arcs), heat (dotted red arcs) and volume work (dashed blue arcs) across a boundary (black bar) between C and A . Boundaries are surfaces without any extensive quantity. Usually, they indicate discrete changes between two capacities, like fluid | solid interphases in the sketched adsorption process. Despite its low granularity and abstract nature, this topology appropriately outlines the process in question. However, as we noticed when lecturing students, most people tend to stick with their first, rather rough topology when continuing with the mathematical modelling, not realising that such a low degree of granularity will cause complications in further modelling. In the example of Figure 1, students would often go on to try implementing all transport terms in capacity C , while A is only contributing the adsorption kinetics. Meanwhile, the boundary is just left as a shallow symbol of intent in the topology, not contributing to any mathematical modelling despite being the most-important part of the process; the process-limiting interphase. This approach usually ends in the numerical bottleneck that the system in C will be a partial-differential equation with at least three dependencies:

Figure 1: A first topology for any arbitrary adsorption process

The time t , the radial coordinate x and the axial coordinate y . Furthermore, transport processes from C to A are compressed into one misleading term in this approach, neglecting the potentially different nature of connected transports in the direction of x and neither providing nor showing any understanding of the inner workings at hand.

Therefore, we strongly advocate for a systematic approach when modelling processes that exceed interfaces. By expanding on the discussions in Pujan and Preisig (2020), this paper presents the proposed methodology while discussing its implications and contributions to the design and communication of comprehensive but comprehensible process models.

2. Transport processes across all sorts of interfaces

In the following, we refer in our terminology to *interphases* for interfaces between two discrete phases, whereas *intraphases* denominate interfaces without any phase change, like the discrete difference between a flowing fluid in a pipe and its almost-stagnant fluid film at the pipe walls.

When an interphase is introduced to a system, fluids form sub-systems on both sides. These adhere considerably different regimes than the fluid bulks. Those sub-systems are conventionally called films. However, as we will discuss later, the term *film* can be misleading in this context. For now, we define as film the volume that manifests an explicit change of properties on the interphase's normal coordinate, as depicted in the examples of Figure 2. We limit the scope of our remarks on material transport, although the analogy to heat transfer is often self-evident. As the films in Figure 2 indicate, diffusion is in them commonly the predominant mode of transportation, always in a gradient-successive direction. This film diffusion gets slower the further it departs from the interphase. Until it measurably dies out at the level of the bulk fluid. At this point, an intraphase indicates the discrete change between both, the considerably lumped bulk and the distributed film.

Figure 2: Generic profiles of an adsorption column (left) and a membrane unit (right)

Though it shall be placed emphasis on the fact that the concentration gradient is never actually zero, what would wrongly imply an absence of transport from the bulk to the film. In actuality, the gradient inclines towards zero in infinity and the intraphase is only placed on a x from where on the effective diffusion is conventionally considered to be negligible.

The two examples in Figure 2 splendidly exhibit most kinds of interfaces: *a*) bulk | film intraphases; *b*) fluid | solid interphases; *c*) fluid | pores intraphases, and *d*) fluid | membrane interphases. The first two we discussed already, but further discussion is advisable for the cases of *c* and *d* since, in contrast to *a* and *b*, they strongly rely on the scale of model design. Picture that the plots in Figure 2 would be zoomed out for the adsorption process and zoomed in for the membrane. The film | pores intraphase would turn into a film | adsorbent interphase, whereas the film | membrane interphase would transform to a film | membrane pores intraphase. The implication is clear: Pores may be formed by a solid phase but their contents clearly belong to the fluid phase, thus, a film | pores intraphase is placed if considered to be constructive. A membrane is fundamentally nothing more than an elaborate porous material. Accordingly, defining a membrane as another phase than the fluid may be the conventional as well as constructive approach, but a fluid | membrane "interphase" remains nothing similar to an actual interphase in a fluid | fluid system. The interphase-specific concentration jump may occur in the right plot of Figure 2 just as it would across a water | hexane interphase, however, this effect is not due to phase saturation but sieve stochastics.

Estimating concentrations at interphases is tricky due to discrete jumps. Thus, no approximations can be made on one side of the interface just from the concentration on the other. Fortunately, the chemical potential μ_i does not exhibit jumps so that we can approximate the concentrations with the aid of Equation (1), where μ_i° is the standard, μ_i^{ideal} the ideal and μ_i^{excess} the excess chemical potential. Keep in mind though, even there is no jump in μ_i , functions of intensive properties are *never* continuous across interfaces and we can only approximate interfacial conditions via close-quarter estimations on both sides.

$$\mu_i = \mu_i^\circ + \mu_i^{ideal} + \mu_i^{excess} = \mu_i^\circ + RT \ln(x_i) + \mu_i^{excess} \quad (1)$$

3. Derivation of topology capacities

From the elaborations in the previous section it transpires that interface-exceeding processes have to be modelled with the impact of the interface in mind. To stick with the examples in Figure 2, an adsorption model has to expand a system of bulk - film - pores - adsorbent, while a membrane model should expand bulk 1 - film 1 - membrane - film 2 - bulk 2. Supposedly, these are the lowest granularities for the associated topologies, which we can construct solely from six different capacities: *I*) lumped (circle), *II*) dynamic distributed (ellipse), *III*) steady-state distributed (rectangle), *IV*) boundary (black bar), *V*) point capacity (black dot), and *VI*) reservoirs (semi-circles). According to Preisig (2012), this is enough to define basic operations as elements of a process and to construct complete plant models by generating different combinations of them.

Each capacity inherits the fundamentals of any physics ontology, namely the conservation principles of mass, energy and momentum. Therefore, Equation (2) is part of every capacity, where \dot{n}_i denotes the accumulation of compound i over time and \hat{n}_i the compound flow. In our example, the state variable transformations in Equations (3) and (4) are also amenable to all, with dr_j being the place-in for the coordinate expansion normal to A .

$$\dot{n}_i = \sum \hat{n}_i \quad (2)$$

$$\hat{n}_i = c_i \hat{V} \quad (3)$$

$$V = A dr_j \quad (4)$$

The distinction between capacities results from additional definitions like Equation (5) added to the lumped *I* and *IV-VI* (the distributed capacities are left out since c_i is not constant), and the requirement for some kind of transport mechanism in the distributed systems *II* and *III*. For films and pores, the transport mechanism is the link between molecular flux and flow in Equation (6), and Fick's 1st law in Equation (7). Although we limit our discussion to interface-exceeding processes, note that different transport mechanisms would have to be selected for the membrane, and transport outside of films would have to consider not only diffusional but also convective fluxes. The event-dynamic capacities *III-VI* are set with the constraint $\frac{\partial}{\partial t} = 0$. Additionally, the surface nature of *IV* constrains its amount of extensive quantities to zero while connecting flows only on the boundary's normal coordinate.

$$\dot{n}_i = c_i \dot{V} \quad (5)$$

$$\hat{n}_i = J_{i,r_j} A \quad (6)$$

$$J_{i,r_j} = -D_{i,r_j} \frac{\partial c_i}{\partial r_j} \quad (7)$$

That leaves us with six distinct capacities to build our process on. In the following, we locate vectors normal to membrane or adsorbent on the x coordinate, whereas the perpendicular flows along the process unit are located on y . We further assume processes on other coordinates than x and y , and the distribution of compounds in films, pores and the membrane along y as well as between the adsorbent particles, to be negligible. We know from Figure 2 that at any discrete y , films and pores inhibit diffusion-induced distributions in the direction of x , separated by interfaces. Accordingly, we set dynamic, distributed capacities in the dynamic time-scale of Figure 3, perpendicular to the convective bulk flows and connected via boundaries. Preisig (2014a) explains in detail how topologies are

Figure 3: Dynamic topology for any discretionary stage in an adsorption column (left) and a membrane unit (right)

easily translated into an incidence matrix in order to mathematically assess the model. The topologies in Figure 3 depict one theoretical stage for each process, thus a discretization over y . Given an appropriate number of stages - so that $dy \rightarrow 0$ applies - the bulk flow can be reduced to a linear function of the boundary conditions at the respective stage. Furthermore, the input conditions for processes in x -direction do not need to be formulated as a function of y but adhere to the homogeneity assumption. Effectively relieving the numerics from y as one of the model's dependent variables.

$$\int_V \dot{n}_i \, dv = \int_A (\hat{n}_{i,x_0} - \hat{n}_{i,(x_0+dx)}) \, da \quad \Rightarrow \dots \Rightarrow \quad \dot{n}_i \, dx = \hat{n}_{i,x_0} - \hat{n}_{i,(x_0+dx)} \quad (8)$$

$$\hat{n}_{i,(x_0+dx)} = T(x; x_0) = f(x_0) + f'(x_0) \frac{(x-x_0)}{1!} + f''(x_0) \frac{(x-x_0)^2}{2!} + \dots \quad (9)$$

$$\dot{n}_i \, dx = \hat{n}_{i,x_0} - \hat{n}_{i,x_0} - \frac{\partial \hat{n}_i}{\partial x} \, dx - \frac{\partial^2 \hat{n}_i}{\partial x^2} \frac{dx^2}{2} + \dots \quad \Rightarrow \dots \Rightarrow \quad \dot{n}_i = - \frac{\partial \hat{n}_i}{\partial x} \quad (10)$$

$$\dot{c}_i = \frac{D_{i,x}}{dx} \frac{\partial^2 c_i}{\partial x^2} = k_{i,I} \frac{\partial^2 c_i}{\partial x^2} \quad (11)$$

Every diffusional flow in Figure 3 has one input at an arbitrary x_0 and one output at $x_0 + dx$. By recalling that the accumulation in a capacity \dot{n}_i is estimated over the capacity's volume V while connected flows \hat{n}_i are estimated over the capacity's surface A , we derive Equation (8) from Equations (2) and (4). Substituting Equation (5) into (8) yields the balance of a generic lumped capacity. For the distributed capacities in our example however, we have to expand the unknown $\hat{n}_{i,(x_0+dx)}$ in Equation (9) over x_0 by means of a Taylor series $T(x; x_0)$. This, together with $dx \rightarrow 0$, formulates the balance of an arbitrary distributed capacity in Equation (10). The substitution of (10) by the selected transport mechanism and the common assumption that A and the diffusion coefficient $D_{i,x}$ are independent of x , closes with Equation (11) - Fick's 2nd law in disguise.

4. Concluding remarks of advisory

We reason that lecturing process modelling with the presented methodology in mind not only significantly aids comprehensibility but also trains engineering students in compartmentalizing complex processes into their fundamental parts and to design appropriately comprehensive models that always satisfy the conservation principles. As was shown, limiting the topology design to the six introduced capacities together with their respective parts of a fundamental equation ontology enables rapid model design while offering easy mathematical accessibility as well as pacing options in terms of discretization. This easing of numerics also significantly reduces computing times, thus empowering the crafted

models to be utilized in online process control applications.

Since we arranged flows on different coordinates in separate capacities, solving the resulting equations is no longer a problem of numerics but of parameters only. If no $D_{i,x}$ are handily available, multiple interfacial transport concepts like the two-film, penetration or surface-renewal theory are applicable to solve Equation (11) via the mass transfer coefficient $k_{i,l}$ at each side of the interface. Furthermore, different kinds of transport limitations, as depicted in Figure 2, can be realized by means of time-scale based model simplifications in the respective capacities. However, the material diffusion coefficient $D_{i,x}$ must not be confused with the effective diffusion coefficient applied by Nernst (1904). As sketched in Figure 4, the effective film thickness δ is derived from the intensive gradient's tangent at the interface, whereas the film thickness dx in Equation (11) - and therefore the dedicated capacity - denotes the range of measurable distribution.

In this paper, we only discussed the dynamic process depiction. The reason is that dynamic and steady-state processes are two clearly distinct problems in process simulation. In a dynamic process, the knowledge of the conditions on one side of an interface suffices the estimations on the other side. In contrast, steady-state estimations are in their nature boundary-condition problems - Equation (11) with the constraint $\frac{\partial}{\partial t} = 0$ results in a gradient of its boundary conditions. Thus, steady-state interfacial processes have to be assessed from both sides. That raises one particular question, not to be answered within the scope of this paper but still worth considering: Is it actually constructive to lecture process modelling with focus on steady-state as the reputedly easy starting point?

Abstract

This contribution presents a kinetic study for the identification of the complex reaction mechanism occurring during the ABE upgrading, and the development of a kinetic model. Employing graph theory analysis, a directed bipartite graph is constructed to reduce the complexity of the reaction network, and the reaction rate constants and reaction orders are calculated using the initial rate method, followed by the calculation of the activation energy and frequency factor for an Arrhenius-type law. Subsequently, using general mass balancing a proposed mathematical model is produced to determine the apparent reaction rates, which are successfully in line with the experimental results.

Keywords: reaction mechanism, kinetic modelling, ABE upgrading.

1. Introduction

The increase in global energy consumption, correlated with the increase in greenhouse gas emissions has prompted interest in the “green” production of fuels and chemicals. Biomass conversion, such as sugar fermentation using the bacteria genus *Clostridium* (Qureshi et al., 2010) to produce an acetone, butanol and ethanol (ABE) mixture is a well-recognised “drop-in” fuel option, and one of the first commercial biofuel production methods. Following upgrading and conversion, the products from the ABE mixture are compatible with fuel or chemicals sourced from other means, making the process an attractive option for the transportation or chemical industry. This opens an avenue for the integration of a bio-refinery with an oil refinery, with the aim of moving towards sustainable fuels and chemicals production.

An important aspect of ABE upgrading requiring understanding is the determination of the very complex reaction network, which could facilitate the conceptualisation of a realistic model of the process. Although various studies regarding the production of long-chain hydrocarbons from ABE are available (Onyestyák et al., 2015; Sreekumar et al., 2015), there is little work concerning the kinetic modelling of the involved reactions.

The following sections present the identification of a reaction network for the ABE upgrading based on literature and experimental data (Ketabchi et al., 2020a; Ketabchi

et al., 2020b). This network is used as a basis for calculating the kinetic parameters and a mathematical model of the process. Finally, the obtained model is compared to experimental data to investigate its accuracy.

2. Acetone, butanol and ethanol catalytic upgrade towards long-chain hydrocarbons

Following upgrading and conversion, the ABE mixture's products are attractive fuels or chemicals for transportation and chemical industry. Despite the complexity of the reaction network, it is necessary to identify a starting point so that the kinetics of this reaction can be calculated to produce a preliminary model. Even though various studies regarding the production of long-chain hydrocarbons from ABE are available (Onyestyák et al., 2015; Sreekumar et al., 2015), there is little work concerning the kinetic study and modelling of the reactions.

Starting from these studies, a network of the main reactions taking place during the ABE upgrading is proposed in Equations (1) – (11).

Due to the complexity, with 16 components involved, (A = acetone, B = butanol, E = ethanol, D = isopropyl alcohol, F = 2-pentanone, G = 2-heptanone, I = 4-nonanone, J = 6-undecanone, K = 6-undecanol, L = 4-heptanol, M = 1-butanone, N = mesityl oxide, P = isophorone, plus O₂, H₂O and H₂) including equilibrium, series, reversible, and other type of reactions occurring at once, this network requires further simplification for the scope of this work.

3. Kinetic modelling of the ABE upgrading

Using the reactions in equations (1) – (11), as well as their interrelations, a mathematical modelling theory is applied using three main algebraic parameters. These parameters are: the set of chemical reactions R_i , with i = the number of finite sets of reactions occurring; the set of chemical species S_j , with j = the corresponding species involved in reaction; and lastly, the nonnegative integer stoichiometric coefficient of each component β_{ij} . Altogether, the model is represented as:

$$R_i = \sum_{j=1}^n \beta_{ij} S_j \quad i = 1, \dots, m \quad j = 1, \dots, n \quad (12)$$

Given that these parameters are defined, the kinetic rate equation can be defined as a nonlinear function of the concentration of chemical species S_j , $f_i (C_s(\text{mol/L}))$:

$$r_i = k_i f_i(C_s) \quad i = 1, \dots, m \quad (13)$$

Where r_i is the reaction rate, and k_i is the reaction rate constant.

The reactions are considered to take place in a batch reactor with constant volume. Applying a mass balance on this batch system, a lumped kinetic model in the form of ordinary differential equations (ODEs) is obtained. These equations demonstrate the change of concentration against time in the following way:

$$\frac{dC_i}{dt} = r_i \cdot \beta_{ij} \quad (14)$$

To simplify the kinetic reaction network, the concept of graph theory analysis (Gupta et al., 2016) can be applied. This concept is based on the evaluation of unnecessary reactions and components that are eliminated as a result of the interpolation of complete conversion or quasi-equilibrium reactions.

3.1. Identification of chemical reaction network

In order to identify the connection between the species in the proposed reaction network in Equations (1) – (11), a directed bipartite graph is defined (Figure 1), which is dependent on the components, S , the reactions, R , and a set of direct links.

The application of this approach decreases the numbers of reactions in the network from 14 (due to the reversible reactions (9) – (11) considered each as two separate reactions) to only 7 (or 9, as R4X and R5 are reversible):

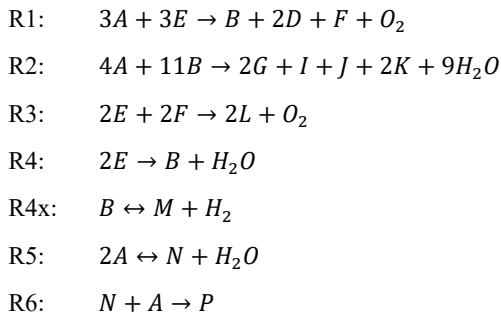

Figure 1. Bipartite graph for the ABE upgrading reaction network

For simplicity in future calculations, the reverse reactions of R4x and R5 are denoted as R-4x and R-5, respectively.

3.2. Kinetic calculations of the chemical reaction network

Considering the chemical reaction network identified in the previous section, the mass balance of the system represented by Equation (14) can be written. The following kinetic law, from which the order (x, y) and the reaction rate (k_i) are determined is used:

$$r_i = k_i c_a^x c_b^y \quad (15)$$

These are calculated based on the initial rate method, in which the rate of reaction at the instant that the reactants are first mixed is considered. This initial rate is assumed to be equal to the average rate of reaction.

Subsequently, the different activation energies and pre-exponential factors associated with each reaction are determined using an Arrhenius-type equation, by fitting experimental data at various temperatures.

Due to the assumption of equating the initial rate to the average rate, the values obtained will be, to some extent, inaccurate. On the other hand, some species will appear halfway through the reaction, making the calculated rates underestimated. Therefore, to reduce these errors, a parameter optimisation is performed using MATLAB R2019a, in an iterative procedure, using the calculated kinetic constants as first guess and optimising their value such that the mathematical model fits the experimental data.

3.3. Experimental procedure

Four experiments of ABE upgrading are performed in a pressure vessel/Parr reactor (Parr Series 5500 HPCL Reactor and a 4848 Reactor Controller) with the volume of 300 mL, at autogenous 80 bar pressure and 300 °C (Ketabchi et al., 2020b).

Table 1. Conversion of reactants and yield of products having the highest concentration at different temperatures using Fe catalyst

Temperature (°C)		200	250	300
Conversion (%)	A	99.0	99.6	99.6
	B	-	-	95.9
	E	95.5	95.9	95.2
Yield (%)	D	6.45	10	6
	G	3.40	3.40	3.80
	L	-	0.60	0.64
	P	-	-	0.34
	J	-	-	0.40

The reactor is purged with N₂ to ensure an oxygen-free atmosphere, and filled with 0.5 g of reduced Fe catalysts and 83.5 mL of anhydrous ABE mixture (Sigma-Aldrich) with the mole ratio 3:6:1. After 18 hours, the catalysts are recovered through filtration and the liquid products analysed in a gas chromatograph through the SIM mode (Agilent HP6890 GC), using a DB-5 Capillary Analytical column and a flame ionisation detector (FID). Quantification of the reaction products is performed by establishing GC response

factors of the main products identified, by injection of samples with known concentrations prepared using standards. The results for the four experiments are shown in Tables 1 and 2.

Table 2. Experimental data used for obtaining kinetic data

<i>Experiment</i>	<i>Acetone (moles)</i>	<i>Butanol (moles)</i>	<i>Ethanol (moles)</i>
<i>K1</i>	0.306	0.601	0.2054
<i>K2</i>	0.153	0.601	0.1027
<i>K3</i>	0.306	0.300	0.1027
<i>Original</i>	0.306	0.601	0.1027

4. Results and discussion

Using the approach described in Section 3.2, the order and reaction rate constants summarised in Table 3 are calculated.

Table 3. Reaction rate parameters for the ABE upgrading network

<i>Reaction number</i>	<i>Total reaction order</i>	<i>Reaction rate value ($\times 10^{-6}$)</i>	<i>Unit</i>	<i>E_a (kJ/mole)</i>	<i>A</i>
<i>R1</i>	2	2200	<i>L/mole · s</i>	7.656.3626	17.16590×10^{-5}
<i>R2</i>	2	2500	<i>L/mole · s</i>	647.1950	66.21620×10^{-5}
<i>R3</i>	1.4	330	<i>L/mole · s</i>	284,122.6360	1.94199×10^{21}
<i>R4</i>	0	0.01300	<i>mole/L · s</i>	146,193.3760	16.09740×10^4
<i>R4x</i>	0	0.00310	<i>mole/L · s</i>	317,262.2400	2.03707×10^{-6}
<i>R-4x</i>	0	0.00135	<i>mole/L · s</i>		
<i>R5</i>	1	0.15300	<i>1/s</i>	89,358.8720	4.00504×10^{-30}
<i>R-5</i>	1.028	0.18600	<i>1/s</i>		
<i>R6</i>	1	0.15400	<i>1/s</i>	63,375.1278	9.46455×10^{-30}

It can be observed that at constant temperature the slowest reaction is R4x, as it has the lowest reaction rate and the highest activation energy, which is in good agreement with the observations by Narayanan et al. (1998) that Fe is not well suited for aldol condensation reactions involving hydrogen transfer. Interestingly, R2 has the highest reaction rate constant, showing that the Fe catalyst favours it. The model data is subsequently compared to the experiments, in concentration vs. time graphs (Figure 2), to assert the model accuracy. The expected trend of decreasing concentration with time can be seen with the reactants, while an increase is observed for the remaining components regarding the modelled data. However, one limitation of the model simplification should be discussed regarding components (such as Ethanol), which are both produced and consumed in the ABE upgrading. Production occurs also in

irreversible reactions, not considered in the final model. Therefore, for such cases, the model is only able to predict the overall trend.

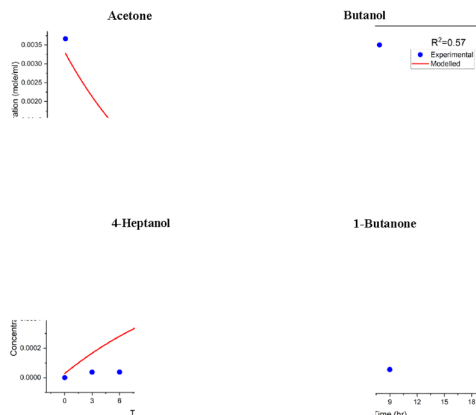

Figure 2. Comparison between experimental and modelled data

5. Conclusions

This contribution identifies a reaction network for the ABE upgrading using graph theory analysis, based on previous literature, as well as experimental data. Following this, the kinetic model parameters are determined and optimised for Arrhenius law-type of equations. The resulting model is compared with the experimental data through concentration-time graphs, demonstrating a decent degree of accuracy, despite a few components displaying abnormal behaviour. More experiments should be performed to obtain more data for these and for additional products to further improve the model and its accuracy.

Abstract

In this work, we present a new stochastic black-box optimizer—named MOSKopt—for optimization under uncertainty problems involving expensive-to-evaluate and arbitrarily complex simulation models subject to severe uncertainties and multiple design constraints. The optimizer relies on a novel surrogate-assisted, simulation-based, and data-driven optimization algorithm developed in our earlier work for multiple-constrained optimization of stochastic black-box systems using a stochastic Kriging (SK) type surrogate model, which has shown its promising potential in stochastic simulation optimization studies. MOSKopt replaces simulation replications with parallelized Monte Carlo simulations to characterize the resulting error distributions of the optimization objective and constraints in a more generalized way. In doing so, it broadly extends the applicability of SK-based frameworks to other optimization problems exposed to uncertain input data or model parameters—a commonly encountered paradigm in process simulations driving the digital twins. We benchmark the optimizer and its algorithms on three case studies with increasing complexity. The first two are benchmark test problems taken from simulation optimization literature, whereas the third optimizes the design and operations of a wastewater treatment plant (WWTP) subject to effluent quality constraints using a detailed plant-wide simulation model—the closest case to a digital twin—consisting of several high-fidelity bioprocess models (e.g., activated sludge and anaerobic digestion) calibrated for data obtained from full-scale wastewater treatment plants under uncertain influent scenarios. The results from case studies quantitatively demonstrate the superior efficacy of the MOSKopt algorithm over the literature methods not only in maintaining feasibility under multiple stochastic constraints but also in returning better objective function values. The results also show the potential of the MOSKopt’s entirely non-intrusive workflow, which makes it a suitable optimizer for applications involving digital twin projects with non-negligible uncertainties.

Keywords: simulation-based optimization, digital twins, optimization under uncertainty

1. Introduction

Industry is invested in building digital twins that are aimed at mirroring every facet of their physical counterparts (e.g., a pharmaceutical manufacturing process) as accurately as possible. At the core of this ambition lie high fidelity simulations driven by an integrated set of first principles/mechanistic, multiscale, and machine learning models that are continually kept up-to-date using data collected from sensors in real-time. There

is much to be done to realize the full potential of such ambitious projects. For instance, optimizing the design and operations of a physical twin requires a simulation-based and data-driven optimization engine that can interface with its virtual replica. To this end, simulation-based optimization algorithms hold an appealing promise due to their non-intrusive ability to seek a near-optimal set of decisions to arbitrarily complex process models along with the ability to incorporate stochastic objectives and constraints, thereby allowing for the quantification of uncertainties surrounding the decisions made from the use of the digital twin technology. In this work, we consider optimization under uncertainty problems whose objective and constraints are surrounded by uncertainties and can only be estimated by performing high fidelity simulations. For these problems, we comparatively evaluate sampling and simulation-based optimization methods.

2. Methods

2.1. Benchmark method: Exhaustive sampling

The exhaustive sampling method represents the standard Monte Carlo sampling-based approach to uncertain design space exploration problems. In this method, both the design space of the process parameters and the uncertainty space of uncertain input parameters are discretized using sampling [1]. At each design sample (x_i) the probability of satisfying active constraints under uncertainty is computed via Monte Carlo simulations performed within the uncertainty space. Table 1 shows several statistical metrics (e.g., mean, upper confidence interval of the mean, etc.) that can be used for hedging against the uncertainties. Despite being effective, this method often requires a large number of model evaluations, making it extremely intensive (computationally), if not prohibitive, especially for real practical applications, where the computational cost of running the simulation model can be very high. To reduce the required number of simulations and also to increase the efficacy of this method, simulation-based methods described next employ surrogate models that assist with performing a more informed exploration within the design space.

Table 1: Uncertainty hedging strategies used in this work for satisfying stochastic constraints.

Identifier	Explanation MCS: Monte Carlo simulations, cl : constraint limit
Mean	$\text{mean}(\text{MCS}) < cl$ for each constraint
UCI95	Upper confidence interval of $\text{MCS} < cl$ for each constraint
PF80	The probability of the feasibility of the $\text{MCS} > 80\%$ for each constraint
MeanPlusSigma	$\text{mean}(\text{MCS}) + \text{standard deviation}(\text{MCS}) < cl$ for each constraint

2.2. Simulation-based optimization

In our earlier work [2], we described the simulation-based optimization approach which employs stochastic Kriging [3] type surrogate models that are constructed from a dataset of initial observations of optimization objective and constraints. A Monte Carlo-based uncertainty analysis is also performed on each design sample in the initial dataset. The surrogate models are then used to find the next best candidate design points in an adaptive sampling stage, which performs an internal optimization using infill criteria. The designs proposed by this stage are validated by performing rigorous simulations, and the data obtained from these simulations are used to improve surrogate models of the objective, constraints, and their uncertainties. Lastly, after a certain computational budget is exhausted, the best feasible design among the simulated design points is returned as the near-optimal design. Since this design is obtained by taking into account the effects of uncertainties on the optimization objective and constraints, it is also the near-optimal

design under uncertainty. This workflow has been implemented in the solver MOSKopt with two infill criteria: feasibility enhanced expected improvement (FEI) [4] and multiple constrained FEI (mcFEI) [2]. Further details can be found in the original work [2].

3. Case studies

3.1. Case study 1: An illustrative test problem — Sasena

To demonstrate the benefits of the simulation-based approach, we first consider a widely-studied illustrative test problem named Sasena from literature [5]. With its two design variables and three active design constraints, Sasena readily allows for design space visualization and provides a case well representative of actual engineering design optimization problems subject to multiple stochastic constraints. To make this problem an optimization under uncertainty problem, we arbitrarily introduce four uncertain parameters entering the expressions of both the objective and the constraints as follows:

$$\begin{aligned}
 \min_x \quad & f(x) = -u_1(x_1 - 1)^2 - (x_2 - 0.5)^2 \\
 \text{s.t.} \quad & g(x) = [g_1(x), g_2(x), g_3(x)] \leq 0 \\
 & g_1(x) = (u_2(x_1 - 3)^2 + (x_2 + 2)^2)e^{-x_1^2} - 12 \\
 & g_2(x) = 10u_3x_1 + x_2 - 7 \\
 & g_3(x) = (x_1 - 0.5)^2 + u_4(x_2 - 0.5)^2 - 0.2
 \end{aligned} \tag{1}$$

$$0 \leq x_i \leq 1 \text{ for } i = 1, 2 \text{ and } u_j \approx \mathcal{N}(\mu, \sigma) \text{ for } j = 1, \dots, 4 \text{ and } \mu = 1, \sigma = 0.5$$

We solve this problem using the benchmark method. First, the two-dimensional design space of the problem is sampled using Latin hypercube sampling (LHS) with a varying number of samples—from a very coarse (10) to a very fine (10^5) design. Each sample in the sampling design is a candidate design for which an uncertainty analysis is performed using vectorized Monte Carlo simulations with 10^3 samples taken from the normally distributed input uncertainty space. The results are repeated 50 different times so as to alleviate the effects of the randomness in the initial sample locations. Table 2 shows the averaged (over 50 repetitions) results of the optimum found and its location. Expectedly, increasing the number of design samples results in improved objective values as the finer sampling cover the design space more rigorously. A design sample is declared feasible if the mean plus the standard deviations (obtained from Monte Carlo simulations) of each constraint satisfies the corresponding constraint limits. Similarly, the other hedging strategies, as was tabulated in Table 1, are also computed, and the obtained results are shown in Figure 1. Using only the mean for uncertainty hedging yields lower optimum values (-0.549 for 10^5 design samples), whereas more conservative approaches uplift the

Figure 1: Uncertainty hedging strategies are compared along with the increasing number of design samples. The returned optimum shifts upwards for more conservative strategies.

optimum towards the positive axis. The same problem is also solved with the simulation-based optimizer (MOSKopt) using the two infill criteria (FEI and mcFEI) with a total of 100 samples in the design space (10 initial, 90 adaptive iteration samples). Table 2 shows the good agreement obtained among the methods.

Table 2: The average results of the optimum value of the objective and its location obtained using different methods. The uncertainty hedge is set to MeanPlusSigma.

Method	# of LHS design samples	Total # of calls to the model	Optimum value (f)	Location of the optimum (x)
Exhaustive	10^1	10^4	-0.395	[0.310, 0.662]
Exhaustive	10^2	10^5	-0.452	[0.204, 0.376]
Exhaustive	10^3	10^6	-0.464	[0.197, 0.465]
Exhaustive	10^4	10^7	-0.467	[0.202, 0.447]
Exhaustive	10^5	10^8	-0.468	[0.200, 0.453]
FEI	10^2	10^5	-0.451	[0.275, 0.932]
mcFEI	10^2	10^5	-0.458	[0.247, 0.445]

3.2. Case study 2: A high dimensional test problem — Rosen Suzuki

In order to both investigate the reliability and also compare the performance of both infill criteria in higher-dimensional problems, we solve the Rosen Suzuki test problem from literature [5]. Similar to the previous case, we introduce uncertain parameters in the expressions of both the objective and the constraints as follows:

$$\begin{aligned}
 \min_x \quad & f(x) = x_1^2 + x_2^2 + 2u_1x_3^2 + x_4^2 - 5x_1 - 5x_2 - 21x_3 + 7x_4 \\
 \text{s.t.} \quad & g(x) = [g_1(x), 100g_2(x), 1000g_3(x)] \leq 0 \\
 & g_1(x) = x_1^2 + u_2x_2^2 + x_3^2 + x_4^2 + x_1 - x_2 + x_3 - x_4 - 8 \\
 & g_2(x) = x_1^2 + 2x_2^2 + x_3^2 + 2u_3x_4^2 - x_1 - x_4 - 10 \\
 & g_3(x) = 2x_1^2 + u_4x_2^2 + x_3^2 + 2x_1 - x_2 - x_4 - 5
 \end{aligned} \tag{2}$$

$$-3 \leq x_i \leq 3 \text{ for } i = 1, \dots, 4 \text{ and } u_j \approx \mathcal{N}(\mu, \sigma) \text{ for } j = 1, \dots, 4 \text{ and } \mu = 1, \sigma = 0.25$$

Table 3 tabulates the results obtained from 50 different repetitions. The benchmark method used 10^5 design samples, whereas the MOSKopt solver used only 50 design samples (20 initial plus 30 infills) to locate the optimum, with the MeanPlusSigma

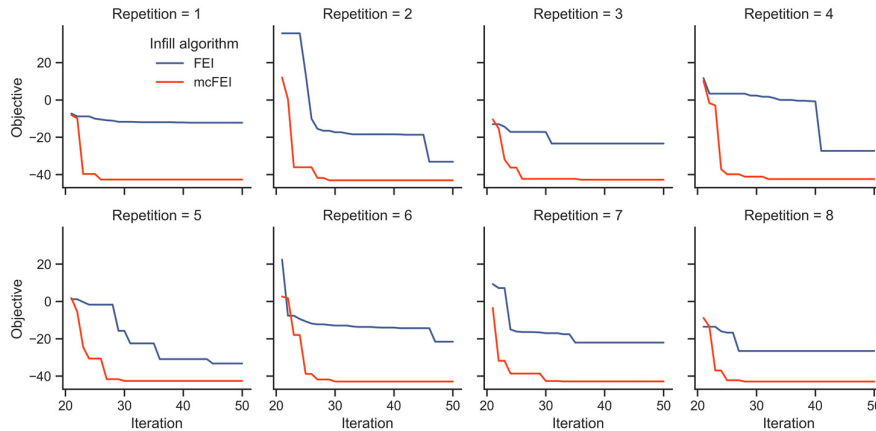

Figure 2: Comparison of FEI and mcFEI infill criteria for the Rosen Suzuki test problem. The multiple constraint modeling of the mcFEI criterion leads to better convergence.

hedging. Comparing the two infill criteria, Figure 2 shows convergences where the mcFEI criterion consistently outperforms the FEI criterion in returning better optimum solutions satisfying the stochastic constraints. This can be explained with the separate modeling of each constraint response and their uncertainty, as implemented in the mcFEI criterion, as opposed to the lumped approach of the FEI criterion. As each constraint has different scales, separate modeling helps to better identify the uncertain characteristics of the problem’s output space and hence leads to the better performance of the mcFEI criterion. The solver’s GitHub repository (<https://github.com/resulal/MOSKopt>) contains the working code examples of Sasena and Rosen Suzuki case studies.

Table 3: Results of simulation-based optimization for the uncertain Rosen Suzuki problem.

Method	# of LHS samples	Total # of calls to the model	Optimum value (f)	Location of the optimum (x)
Exhaustive	10^5	10^8	-42.152	[-0.026, 0.841, 1.951, -0.914]

mcFEI	50	50×10^3	-42.701	[0.028, 0.608, 1.996, -0.996]

3.3. Case study 3: WWTP plant optimization under influent uncertainty

After demonstrating the motivations behind the simulation-based approach with the simple test problems, we now turn to the engineering design under uncertainty problems subject to multiple constraints. To this end, we build on the results of our earlier work [6], where we presented a Monte Carlo sampling-based design space exploration for two full-scale WWTPs: Avedøre (Denmark) and Valladolid (Spain). Both plants employ an activated sludge process-based wastewater treatment with anaerobic digestion of the sludge line. Four influent fractionations, namely soluble inert (*SI*), readily biodegradable substrate (*SS*), particulate inert organic matter (*XI*), and active heterotrophic biomass (*XBH*), are allowed to be uncertain around their nominal values with a coefficient of variation (σ/μ) of 10 %. The design objective is to minimize a plant-wide operational cost index (OCI) while the active design constraints are the regulated effluent quality metrics, e.g., chemical oxygen demand (COD), total nitrogen (TN), and ammonia (NH_4). A more detailed description of the mathematical models, plant-wide simulation strategy, and the calculation of plant performance indicators can be found in our earlier work [6]. The MOSKopt solver is called with the mcFEI criterion along with the MeanPlusSigma hedging and the plants are simulated to a steady-state. Figure 3 shows the progress of the objective value in both plants using 150 design samples (60 initial + 90 adaptive), whereas Table 4 shows the values of the decision variables obtained at the returned optimum. Compared to our earlier work [6], the results obtained here using the simulation-based solver show improvement in the returned best objective values, reducing the operational costs in both plants under uncertain influent scenarios.

Figure 3: Results of simulation-based design space optimization in full-scale WWTPs.

Table 4: Optimization results for the WWTP design optimization case study.

Design and operational decision variables	Lower bound	Value at optimum Avedøre	Value at optimum Valladolid	Upper bound
Hydraulic residence time (HRT) [day]	0.125	0.125	0.125	0.5
Volume ratio of anoxic/aerobic tanks (VR)	0.2	0.49	0.52	0.8
Solids retention time (SRT) [day]	5	8.32	5.20	15
Dissolved oxygen setpoint (DO) [g/m ³]	0.7	0.70	0.89	1.5
Surface overflow rate (SOR) [m ³ m ⁻² day ⁻¹]	16	33	31.22	33
Internal recycle ratio (RRi)	1	2.75	2.78	3

4. Conclusions

This work has presented a novel generic stochastic black-box solver designed to meet a growing need from industry involved in optimization-based decision making coupled with the complex digital twin simulations. The objective was to showcase use cases for the solver by also comparing its performance to other literature methods. Results from three case studies highlight the importance of integrated uncertainty considerations in multiple design constraints in order to increase flexibility and resilience in the face of uncertainty. Using an embedded Monte Carlo simulations, the solver makes it possible to quantify uncertainties surrounding design constraints and thereby robustify design and operational decisions against the effects of possible variations in the influent wastewater compositions. The solver's entirely non-intrusive workflow makes it possible to plug in complex simulation models (e.g., via COM interfaces to CFD codes) without the further need for model modification and facilitates its wider adoption by non-specialist practitioners in other domains.

Global Optimization of Mixed-Integer Polynomial Programs via Quadratic Reformulation

Tanuj Karia^a, Claire S. Adjiman^a and Benoît Chachuat^{a,*}

^a *Centre for Process Systems Engineering, Department of Chemical Engineering, Imperial College London, London SW7 2AZ, United Kingdom*

Abstract

Mixed-integer polynomial programs (MIPOPs) frequently arise in chemical engineering applications such as pooling, blending and operations planning. Many global optimization solvers rely on mixed-integer linear (MIP) relaxations of MIPOPs and solve them repeatedly as part of a branch-and-bound algorithm using commercial MIP solvers. GUROBI, one of the prominent MIP solvers, recently added the capability to solve mixed-integer quadratically-constrained quadratic programs (MIQCQPs). This paper investigates global optimization of MIPOPs via their reformulation as MIQCQPs followed by their solution to global optimality using GUROBI. The effectiveness of this approach is tested on 60 instances of MIPOPs selected from the library MINLPLib. The performance of the MIQCQP reformulation approach is compared to the state-of-the-art global solvers BARON, ANTIGONE and SCIP in GAMS. For the case of single threading, a reduction of 28% and 42% compared to SCIP and ANTIGONE respectively is observed. This approach, therefore, holds promise for integration into existing global solvers to handle MIPOPs.

Keywords: Deterministic global optimization, Polynomial programming, Mixed-integer nonlinear programming, MINLPLib

1. Introduction

Mixed-integer polynomial programs (MIPOPs) are a special case of mixed-integer nonlinear programs (MINLPs), whereby the objective and constraint functions are polynomial in the continuous and discrete variables. They are frequently encountered in chemical engineering applications, such as pooling & blending (Teles et al., 2013b), optimal scheduling of multiproduct plants (Castro and Novais, 2009), and short-term planning of integrated refinery-petrochemical complexes (Uribe-Rodriguez et al., 2020). Significant research effort has thus been devoted to solving MIPOPs to guaranteed global optimality. Generic global solvers based on spatial branch-and-bound search such as BARON (Kılınç and Sahinidis, 2018), ANTIGONE (Misener and Floudas, 2014) and SCIP (Gamrath et al., 2020), can all handle MIPOPs as special cases. Other algorithms include the reformulation-linearization technique (RLT) (Sherali and Tuncbilek, 1992), and the piecewise-linear relaxation approach (Teles et al., 2013a; Nagarajan et al., 2019). All of the aforementioned algorithms rely on linear (LP) or mixed-integer linear (MIP) relaxations of non-convex sub-expressions, which are solved using commercial MIP solvers. Recently, the capability to solve non-convex mixed-integer quadratically-constrained quadratic programs (MIQCQPs) was added to the GUROBI MIP solver (Gurobi Optimization LLC, 2020). In this paper, therefore, we investigate a novel solution approach, whereby MIPOPs are first reformulated as MIQCQPs and then

solved using GUROBI to global optimality. The performance of the reformulation approach is compared to the state-of-the-art global solvers BARON, ANTIGONE and SCIP. The rest of the paper is organized as follows: in Section 2 a brief description of the theory behind the reformulation, its implementation, and the test instances used is provided; the performance of our approach and comparisons with the aforementioned global solvers is analyzed in Section 3; finally, conclusions are drawn in Section 4.

2. Methodology

We consider MIPOPs in the form:

$$p_0(x, y) \tag{1}$$

$$s.t. \quad p_i(x, y) = 0, \quad i = 1, \dots, m_c \tag{2}$$

$$p_i(x, y) = 0, \quad i = m_c + 1, \dots, m \tag{3}$$

$$x \in [x^L, x^U] \subset R^{n_x}, \quad y \in [y^L, y^U] \subset Z^{n_y} \tag{4}$$

where x and y denote, respectively, the continuous and discrete variables; and the functions $p_i: R^{n_x} \times R^{n_y} \rightarrow R$, $i = 0, \dots, m$ are all polynomial in their arguments:

$$p_i(x, y) := \sum_{j=1}^{J_i} a_{i,j} q_{i,j}(x, y) \tag{5}$$

$$q_{i,j}(x, y) := x_1^{\alpha_{1,i,j}} \dots x_{n_x}^{\alpha_{n_x,i,j}} y_1^{\beta_{1,i,j}} \dots y_{n_y}^{\beta_{n_y,i,j}}, \quad j = 1, \dots, J_i \tag{6}$$

with real coefficients $a_{i,j} \in R$ and positive exponents $\alpha_{k,i,j}, \beta_{l,i,j} \in Z_0^+$, $k = 1, \dots, n_x$, $l = 1, \dots, n_y$.

2.1. Quadratic Reformulation

The main idea behind reformulating MIPOPs as MIQCQPs is that any polynomial function can be transformed into a quadratic function via the introduction of auxiliary variables. The reformulation proceeds by constructing a list B of monomials in the variables x and y , with the following properties (Rumschinski et al., 2010):

1. For every monomial q in Eqn. (6), there exists $b_1, b_2 \in B$ such that $q = b_1 b_2$
2. For every monomial $q \in B$ of degree higher than 1, there exists $b_1, b_2 \in B$ such that $q = b_1 b_2$
3. $1 \in B$

Notice that the list B is not unique in general.

From Property 1, the polynomial functions p_i in Eqn. (5) can be rewritten as quadratic forms:

$$p_i(x, y) = \xi^\top Q_i \xi, \quad i = 0, \dots, m \quad (7)$$

where the variable vectors ξ correspond to the elements of B ; and for suitable real symmetric matrices $Q_i \in S_+^{n_\xi}$ with $n_\xi = |B|$ obtained using Eqn. (7).

From Property 2, decomposing the elements in B with degree higher than 1 into products of lower-order monomials also in B gives rise to auxiliary quadratic constraints:

$$\xi^\top R_i \xi = 0, \quad i = 0, \dots, n_d \quad (8)$$

for suitable real symmetric matrices $R_i \in S_+^{n_\xi}$ and n_d is number of such decompositions.

Lastly, bounds on the variables ξ can easily be inferred, e.g., using interval calculations from the original variable bounds in Eqn. (4). These bounds can be represented by a set of linear constraints

$$A\xi \leq 0 \quad (9)$$

for a suitable real matrix $A_i \in R^{2n_\xi \times n_\xi}$.

Overall, an equivalent MIQCQP to the MIPOP in Eqns. (1) – (4) can be written in the form:

$$\min_{\xi \in R^{n_\xi}} \xi^\top Q_0 \xi \quad (10)$$

$$s. t. \quad \xi^\top Q_i \xi = 0, \quad i = 1, \dots, m_e \quad (11)$$

$$\xi^\top Q_i \xi \leq 0, \quad i = m_e + 1, \dots, m \quad (12)$$

$$\xi^\top R_i \xi = 0, \quad i = 0, \dots, n_d \quad (13)$$

$$SEQ \text{ Equation } \setminus * \text{ ARABIC } 13) \\ A\xi \leq 0, \quad \xi_1 = 1 \quad (14)$$

2.2. Implementation

A script was written in Python v3.7 that reads a GAMS scalar model and imports the list of all variables and variable bounds, the objective function, and the constraints. The quadratic reformulation described in Section 2.1 is automated in the library MC++ (Chachuat et al., 2015) by defining expression trees (DAG) from the problem information in Python. A dedicated class in MC++ returns the vector of monomials, sparse quadratic forms for all the polynomial objective and constraint functions (7), and sparse quadratic forms for the auxiliary constraints (8). Bounds on the auxiliary DAG variables are furthermore inferred using the verified interval library PROFIL (Knüppel, 1994). Ultimately, all of this information is collected by a C++ script that generates a lp file for the MIQCQP (10) – (14) and passes it to GUROBI (v9.0.3) for global optimization. This workflow is summarized in Fig. 1.

Figure 1: Workflow for reformulation of MIPOP as MIQCQP and solution using GUROBI

2.3. Testing

In order to test the effectiveness of this approach, 60 test instances of MIPOPs from MINLPLib (GAMS Development Corp., 2018) are considered, which correspond to a wide variety of applications. These instances comprise between 3--961 variables and 0--5329 constraints and have a degree ranging between 2--8. All of the computations are performed on a dual 12-core Intel® Xeon® CPU E5-2650 v4 @2.20GHz with 196GB of RAM and running Centos 7.8. The list of all instances used for testing and the corresponding '.lp' files can be accessed from https://github.com/tk3016/Test_instances_ESCAPE31.git.

In solving the reformulated MIQCQPs using GUROBI, only 1 thread is exploited, denoted as 'Gur-1'. This is to allow for a more transparent comparison with the state-of-the-art global solvers BARON (v20.4.14), ANTIGONE (v1.1) and SCIP (v7.0) in GAMS (v32.2) that only take advantage of multi-threading in solving the MIP relaxations. In this study, multi-threading is not exploited in state-of-the-art global solvers. For all the solvers considered, *Absolute termination tolerance* is set at 10^{-9} , *Relative termination tolerance* is set at 10^{-4} , *Feasibility tolerance* is set at 10^{-5} and a *Time limit* of 3600s or 1 hour is imposed.

Performance is assessed using performance profiles (Dolan and Moré, 2002). The shifted geometric mean (SGM) (Mittelmann, 2020) over all the test instances is also calculated for each solver based on the wall-time:

$$SGM = \exp\left(\frac{\sum_{i=1}^n \ln \ln((1, v_i + s_h))}{n}\right) - s_h, \quad (15)$$

where v_i is the wall-time taken to solve instance i , n is the total number of instances considered and s_h is a non-negative shift parameter, set to 5 in this paper.

3. Results and Discussion

As outlined in the previous section, first all the GAMS models are read using a Python script such that all relevant information about the problem can be collected and passed to MC++ for reformulation. It is noted that the time taken to process the reformulation is < 1 s for all instances except *transswitch0030r* (1.222 s), *transswitch0039r* (1.805 s) and *unitcommit2* (17.234 s). For *unitcommit2*, the time is unusually high because it

comprises 960 variables, 5329 linear constraints and a polynomial objective with 480 monomials of degree ≥ 2 and 720 monomials of degree 1. Since the time taken to process the re-formulation is negligible for majority of the instances, it is excluded from the discussion henceforth. Based on the performance profiles in Fig. 2, it is observed that the largest proportion of problems is solved within 1s in Gur-1, with the second largest proportion achieved with BARON. Within the maximum time limit of 1 hour, BARON solves 68% of the instances, with Gur-1 a close second at 65%. Similar behaviour is observed when considering the SGM in absolute and relative terms (Table 1), with the best performance achieved with BARON, followed by Gur-1, SCIP and ANTIGONE. Focusing on specific problem types, Gur-1 is found to perform worse than current state-of-the-art solvers for periodic scheduling of continuous multiproduct plants problems. Among solved instances of this type, BARON and SCIP can solve *multiplants_mtg1a* in approximately 1300s whereas Gur-1 and ANTIGONE are unable to solve the instance within 1 hour. BARON, ANTIGONE and SCIP can solve *multiplants_mtg2* in 1703s, 24s and 1375s respectively which is significantly faster than Gur-1 which solves it in 3573s. For unsolved instances of this type (*mtg1b*, *mtg1c*, *mtg5*, *mtg6*),

Figure 2: Performance profile for the test set showing proportion of instances solved as a function of wall-time on a log₂ scale

Solver	BARON	SCIP	ANTIGONE	Gur - 1
Shifted Geometric Mean	2.01	3.25	4.04	2.34
% reduction (Gur-1)	-16	28	42	-

Table 1: Shifted Geometric Mean of wall-time (s) over the test set for the five runs. % reduction (Gur-x) refers to the percentage change in SGM between Gur-x and the algorithm indicated in the relevant column, relative to that algorithm.

the relative gap ($|(Primal\ Bound - Dual\ Bound)/Primal\ Bound| \times 100$) is significantly larger for Gur-1 when compared to other global solvers. This can be attributed to weaker root node relaxations obtained by GUROBI than for other global solvers. The spatial branch and bound-based global solvers exploit several pre-processing techniques that reduce the bounds on variables significantly. Consequently, this leads to tighter relaxations and stronger cutting planes. Such pre-processing strategies are not employed with the reformulation approach, nor is an incumbent solution made available at the root node or at the start of the B&B tree. Despite this, the reformulation process is found to perform more effectively in most cases than direct solution of the MIPOP with state-of-the-art solvers. This demonstrates the merit of using this approach.

4. Conclusion

A reformulation of MIPOPs into MIQCQPs and their solution with a specialized algorithm has been proposed and tested for a varied set of problems. Comparison with direct solution of the MIPOPs indicates that the reformulation approach is a promising strategy. For the case of single-threading (Gur-1), the performance is better than ANTIGONE and SCIP but marginally worse than BARON. There is potential to further improve its effectiveness by incorporating pre-processing strategies. The approach can be further developed by automating the workflow and using pre-processing strategies will be investigated. Finally, this approach can potentially be integrated within global solvers used to solve MIPOPs since reformulation can generally be carried out quickly and efficiently.

A data-based approach for the development of asynchronous and distributed optimization algorithms in complex engineering applications

Ioannis Geroulis, Georgios Panayiotou, Antonis C. Kokossis,*

School of Chemical Engineering, National Technical University of Athens, Zografou, Athens 15772, Greece

Abstract

The paper outlines a generic optimization approach with extensive capabilities to distribute the computational work in the optimization, also to explore interim data generated by the optimization algorithms without penalizing search times and effort. The approach postulates a network of autonomous computing nodes and data pools (data repositories); nodes and pools respectively generate and host interim solutions that are redistributed in the network with a parallel use of data analytics that constitute asynchronous tasks. The approach is demonstrated in complex problems of (single and multiphase) reactor network synthesis. The algorithm is implemented using an infrastructure of multiple CPU cores. Results confirm significant reductions of computing times due to parallelization, also the benefit to explore cost-free analytics over data generated internally. Future work includes a more systematic and extensive use of machine learning, also the use of dynamic networks of nodes and pools.

Keywords: optimization, parallel and asynchronous search, data analysis, reactor networks.

1. Introduction and background

Optimization methods remain in the core of process systems engineering addressing a wide range of problems in process and product design (synthesis and process development, process integration and intensification) as well as in operations and process dynamics. Rather than relying on over-the-self algorithms, chemical engineering has pioneered novel optimization technology featuring advanced methods that reach out to the wider systems community. Floudas and Gounaris, 2009 offer an extensive list of methods presenting strong evidence that chemical engineering contributions have been major and lasting. Optimization algorithms include stochastic optimization algorithms invariably applied by means of Simulated Annealing, Tabu Search, Genetic algorithms and/or hybrid methods. The latter algorithms face the difficulty to choose parameter values so that convergence is guaranteed while deterministic algorithms face the challenge to transcend local optima and to ensure that the solution is globally optimum. Optimization problems in chemical reactor design rank among the hardest to tackle due to the complexity and nonlinearity of their state space as well as the numerous degrees of freedom to fathom (types of reactors, macro and micro-mixing, multiple processing paths and kinetics, trade-offs between mass transfer and chemical reactions etc.). Accordingly, reactor design sets up an excellent background to benchmark optimization methods especially as both deterministic (Achenie and Biegler, 1986) and stochastic methods (Ashley and Linke, 2004) are available to compare and test efficiency.

Most optimization algorithms, whether deterministic or stochastic, typically involve sequences of internal (local search) steps, namely tasks that repeat and iterate before convergence is pulled off once they meet appropriately selected criteria (e.g. KKT conditions and integrality gaps in deterministic methods; statistical targets in standard deviation for stochastic methods). Local search tasks generate significant volumes of interim data. Those are hardly explored by conventional algorithms notwithstanding an apparent potential for acceleration and efficiency: data can be explored to tune local search parameters (that are usually set by heuristics), share interpretation of the state space (that could be complex), and/or improve confidence in the solution quality. However, efficiency gains are debatable as any meaningful use of data analytics entails the introduction of expensive and interruptive steps, possibly more demanding than the standard local search tasks. Accordingly, reported efforts are so far restricted to offline analysis with a view to extract rules and knowledge from solution sets of stochastic optimization experiments (Ashley and Linke, 2004) or to merely reduce degrees of freedom in synthesis problems (Kokossis et al., 2016). Separate work has pointed out into better prospects to explore data structures in optimization (Cecelja et al, 2014) by completely reformulating the algorithm to the purpose. The paper responds to the challenge by presenting an algorithm based on a network of autonomous units that includes data pools and computing nodes. Numbers of pools and computing nodes are design parameters of the algorithm. Units generate, host, and redistribute interim solutions. Computing nodes are asynchronous and operate in parallel to generate interim solutions stored in data pools. Pools supply initial points for each local search while interim solutions may transfer across different pools based on their statistical properties and their solution quality. The algorithm is possible to demonstrate advantages provided there is access to a distributed network of CPUs, also on the assumption that the optimization problem to solve is reasonable complex or large. The following sections include the presentation of the methodological approach, the steps of its implementation and results in the application of the algorithm to optimize complex reactor networks and multiphase reaction systems.

2. Methodological Approach

The optimization problem is addressed in a general form:

$$\max f(x, y), \quad s. t. \{ \mathcal{H}(x, y) = 0, \mathcal{G}(x, y) \leq 0, x \in \mathbb{R}^n, y \in \{0,1\}^n \} \quad (1)$$

The set in Eq. (1) defines its feasible region

$$\mathcal{S} = \{(x, y) | \mathcal{H}(x, y) = 0, \mathcal{G}(x, y) \leq 0, x \in \mathbb{R}^n, y \in \{0,1\}^n\} \quad (2)$$

Let us further introduce

- a set $J = \{j\}$ of P_j computing nodes

$$\tilde{P} = \{P_j\}, \quad j = 1, 2, \dots, n_m \quad (3)$$

- a set $I = \{i\}$ of data pools \tilde{S}_i containing elements $s_{i,k}$ in \mathcal{S} so that

$$\tilde{S}_i = \{s_{i,k} \in \mathcal{S}, i \in I, k = 1, 2, \dots, n_L^p\} \quad (4)$$

where $n_L^p = \text{card}(\tilde{S}_i)$ is the maximum population of solutions in each pool and n_p and n_m are respectively the total number of pools and computing nodes. The nodes assigned to each pool \tilde{S}_i are denoted by $N_{i,l}$, $i = 1, \dots, n_p$ & $l = 1, \dots, n_c$, n_c is the total number of nodes corresponding to a single pool. Let $h_j: \mathcal{S} \rightarrow \mathcal{S}$ be a (local) search function assigned

at each computing node P_j . The application of h_j on a $s_{i,k} \in \tilde{S}_i$ yields a new element in \tilde{S}_i , namely

$$h_j: s_{i,k} \in \tilde{S}_i \xrightarrow{P_j} h_j(s_{i,k}) \in \tilde{S}_i \quad (5)$$

The successive application of h_j constitutes a Markov chain g^{L_j} with length L_j . Given the P_j , h_j and $s_{i,k} \in \tilde{S}_i$ the inclusion of $s'_{i,k}(\tilde{S}_i)$ will k -expand each pool \tilde{S}_i (Fig. 1) to

$$\tilde{S}'_i = \tilde{S}_i U\{h_j(s_{i,k})\} = \tilde{S}_i \quad (6)$$

Each element $s_{i,k,0} \in \tilde{S}_i$ is a candidate to process through available nodes P_j where successive applications of h_j yield new internal solutions along the lines:

$$g^{L_j}_{i,j,t}(s_{i,k,0}) = s_{i,k,0} \rightarrow s_{i,k,1} \rightarrow s_{i,k,2} \rightarrow \dots \rightarrow s_{i,k,L_j}, \quad t = 1, 2, \dots, L_j \quad (7)$$

The new interim solutions s_{i,k,L_j} are assessed by the Metropolis criteria (Metropolis et al, 1953).

Figure 1: The k – expansion of pool \tilde{S}_i through a computing node and a Markov chain.

Each pool constitutes an autonomous system that can be connected to each other and it is also connected to a particular number of the available computing nodes. Local searches can be carried out in parallel and are asynchronous as there is no need to stall and wait for any other tasks to complete or start. Indeed, additional parallel tasks can be assigned to explore clustering, sorting, reduction, or any other type of data analytics. The analysis constitutes an asynchronous and independent step from the pool population expansion and the search for additional interim data. A clustering approach on \tilde{S}_i will partition the pool population into disjoint clusters

$$\tilde{S}_i = U_l \tilde{S}^P_{i,l} \quad (8)$$

$\tilde{S}^P_{i,l}$ denotes the disjoint partitions in \tilde{S}_i . For pools connected with each other partitions can be transferred across pools. Let two pools \tilde{S}_i , \tilde{S}_n with $i, n \in I$, which are connected through a path $(i, n) \in C_{i,n}$. Let the path $C_{i,n}$ indicates all permissible directions partitions can follow, essentially controlling data traffic from each pool \tilde{S}_i to \tilde{S}_n . Assuming a clustering approach is applied on \tilde{S}_i , a disjoint partition $\tilde{S}^P_{i,n}$ is termed as an *inflection* of \tilde{S}_i on \tilde{S}_n . A general formulation for the k -inflection is accordingly,

$$\tilde{S}'_i = U_l \tilde{S}^P_{i,l} - \tilde{S}^P_{i,n}, \quad \tilde{S}'_n = \tilde{S}_n U_l \tilde{S}^P_{i,n}, \quad l \neq n \quad (9)$$

Network connections are degree of freedom of the approach but is defaulted to serial connections in the illustrations that follow. A design parameter T_i is assigned to account for the level of acceptance allowed for new entries in each pool. The network structure of

Figure 2 is accordingly the default network tested in all illustrations and is defined by \mathbb{C} as

$$\mathbb{C} = \{\mathcal{S}_1, \mathcal{S}_2, \dots, \mathcal{S}_{n_p}\}, \quad T_i < T_l, \quad \forall i > l \quad (10)$$

Figure 2: Mapping between autonomous units of the network \mathbb{C} .

3. Implementation, illustration and results

Design parameters for the optimization algorithm included

- The number of pools and nodes: the algorithm used 5-10 pools assigning 1-16 cores per pool. Markov chains ranged from 30-100 iterations.
- Pool parameters (mainly T_i): assignments ranged from 10^3 down to 10^{-4} (using logarithmic scales between successive assignments)
- Type and frequency of sorting and clustering tasks: solutions were sorted and partitioned discarding the lower 10% and transferring the top 20% over to pools with lower T_i
- Upper and lower bounds for the population in the pool: 15-100 solutions
- Parameters associated with convergence criteria

Figure 3: Computational time vs number of cores

The algorithm is implemented on python 2.7 using SQLite3 to create a local database (refraining the need for an internet connection) while computations relied on the National Infrastructures for Research and Technology (GRNET). GRNET operates ARIS (Advanced Research Information System), a high-performance system to support that

offers 80 cores with Intel Xeon E5-2680v2 10C 2.8GHz processors. Termination criteria included upper limits on the computational time, upper and lower limits on the number of tasks, progress in the objective function overall and individually at each pool (best stored and average). The method has been tested against complex problems in reactor network design (Mehta and Kokossis, 1997) using a superstructure approach. The engineering problem features multiphase chemical reactors, mass exchange units, mixers, and splitters. The set of equations consists of nonlinear equations with few discrete options. The domain addresses both single-phase and multi-phase applications and can be extended to reactive separations systems. The algorithm has been compared with standard annealing algorithm that is unable to parallelize but is empowered to allocate up to ~10,000 stages of calculation stages with fixed acceptance criteria (e.g. equivalent to the pools proposed in the algorithm).

Illustration 1. The purpose has been to test the efficiency of the algorithm to converge but also the parallelization that can be achieved. The reaction system included the following reactions and initial feed concentrations: $A \rightarrow B$ (1), $r_1 = k_1 C_A$, $k_1 = 0.05 \text{ s}^{-1}$, $A_{in,(l)} = 1 \frac{\text{kmol}}{\text{h}}$; $B \rightarrow C$ (2), $r_2 = k_2 C_B$, $k_2 = 0.03 \text{ s}^{-1}$, $B_{in,(l)} = 0 \frac{\text{kmol}}{\text{h}}$; $C \rightarrow A$ (3), $r_3 = k_3 C_C$, $k_3 = 2 \text{ s}^{-1}$, $C_{in,(l)} = 10 \frac{\text{kmol}}{\text{h}}$. The algorithm managed to converge with only 10 improvements per pool (while results of the parallelization are summarized in Fig. 3. The reason behind the faster performance has been the significant number of unsuccessful simulations for both algorithms. The computational time drops as more cores are added, sharper initially (as 2 and 3 cores are assigned per pool) and continuing to decrease, almost linearly to the point in which 10 cores are assigned per pool (e.g. at a level equal to the maximum number of iterations) and decreasing further even as the bound is surpassed. The distribution of internal solutions is presented in Figure 4. Markov chains ranged from 30-100: in shorter Markov chains (L=30) the new algorithm matched standard annealing but proved 5-6 times slower; it has been faster for higher chains (L=100) where it also converged to consistently better solutions.

Figure 4: Population of internal solutions for Illustration 1

Illustration 2. The purpose of the illustration has been to test the algorithm in a much more demanding problem from the literature that involved two phases: (g)-gas and (l)-liquid. The reaction system included the following reactions and initial feed concentrations: $A + F \xrightarrow{k_1} B + H$ (1), $r_1 = k_1 C_A C_F$, $k_1 = 10 \frac{\text{m}^3}{\text{kmol h}}$; $A + 2F \xrightarrow{k_2} D + 2H$ (2), $r_2 = k_2 C_A C_F^2$, $k_2 = 5 \frac{\text{m}^3}{\text{kmol h}}$; $B + F \xrightarrow{k_3} C + H$ (3), $r_3 = k_3 C_B C_F$, $k_3 = 2 \frac{\text{m}^3}{\text{kmol h}}$; $B + 2F \xrightarrow{k_4} E + 2H$ (4), $r_4 = k_4 C_B C_F^2$, $k_4 = 1 \frac{\text{m}^3}{\text{kmol h}}$; $F_{in,(g)} = 200 \frac{\text{kmol}}{\text{h}}$, $A_{in,(l)} = 100 \frac{\text{kmol}}{\text{h}}$.

The distribution of internal solutions is presented in Figure 5. As in all other examples, a higher concentration of solutions is observed in the lower pools. Markov chains ranged from 40-100: in all Markov chains the new algorithm has been slower but consistently producing 5-20% better solutions than those reported in the literature.

Figure 5: Distribution of internal solutions in Illustration 2

4. Conclusions

In all examples the analysis of the interim data produced in the pools remained largely unexplored. By a similar token, the options to connect the pools with computer nodes in all-inclusive networks has not been researched. The level of analytics employed has remained basic and could benefit from machine learning methods available to cluster solutions, extract problem features and/or adjust the algorithm in a dynamic fashion. Even at its basic form, the algorithm managed to outperform over-the-self developments and improve literature results. Its advantages include a significant degree of parallelization and its potential to invite data analytics without essential penalties on the search.

Julien.deBeer@aveva.com

Abstract

The chemicals industry is facing a highly dynamic environment. Demand is continually fluctuating, and the pressure for new sustainable processes and products is rising. New environmental regulations are always expanding and becoming less harmonized globally, and customers are demanding sustainable products that are friendly to the environment. To follow all the market changes and remain competitive, companies need to invest in capital projects to develop new processes and products. However, since it's a capital-intensive industry, new investments in capital projects need to be carefully managed.

Today, companies need to find ways to be more efficient in the execution of the engineering projects. One way is to compress engineering cycles and adapt processes and products to comply with sustainable KPIs and new demands. The Unified Engineering methodology is one option enabled by the latest technologies and tools available. For decades, engineering to design and build industrial plants has been developed through projects with a complex and highly iterative workflow, using siloed solutions. The entire process is very time consuming, and the final deliverable to the owner of the operation is a set of documents (P&IDs, datasheets, 3D model, etc.) with disperse data, with no guarantee of consistency.

In order to compress engineering cycles, a data-centric approach must be used. With this approach, documents and applications are always kept up to date with the latest validated data. The data-centric approach is the first step to apply the Unified Engineering methodology, which will evolve later to the plant Digital Twin. The Unified Engineering methodology uses a single source of information that is available for all the teams involved in the project. Drawings, steady-state and dynamic process simulations, line lists, datasheets, 3D models, and isometrics, among others, are regularly updated with the data available in the unified source of information. Engineers become more efficient and work with reliable information as documents and models are updated in a controlled way as soon as any change is made. For even greater sustainability and effectiveness, the best way is to use the Unified Engineering methodology in the cloud. The cloud enables higher degrees of flexibility and collaboration among people working from different locations, which means that always the most appropriate resources can be allocated for each part of the project.

Unified Engineering reduces capital project costs, risks, and delays enabling shorter engineering cycles required to deliver new sustainable projects. By minimizing engineering errors and accelerating project execution, companies can get 50% faster FEED stage, 30% increase in engineering efficiency, and 5% reduction in TIC (Total Installed Cost).

Keywords: sustainable products, compressed engineering cycles, unified engineering

1. Introduction

As an industrial software provider we support chemical companies achieve superior performance in their quest to make sustainable products, align with the circular economy and demonstrate product stewardship throughout the product life cycle. By digitally connecting assets, process, and people, our solutions empower companies to run safe and responsible operations, mitigating EHS risks, and moving toward more circular systems, while remaining profitable.

With more than 50 years of industrial software innovation, AVEVA enables 13 of top 15 chemical companies and most of the world's petrochemical crackers, with the most comprehensive portfolio that ties profitability to sustainability goals.

Research typically identifies the following Critical Sustainability Drivers:

- Demand higher transparency on a company's environmental, social & governance (ESG) performance by stakeholders
- Manage a complex environment and provide safety to employees, processes, products and local communities.
- Minimize energy and utilities consumption, so as emissions.
- Manage liquid effluents, waste and suppliers, seeking the circular economy.
- Commitments to global and local regulations
- Portfolio management towards innovation and sustainable products

Today's technology allows suppliers to develop better solutions to those markets that are in constant change. The Digital Twin technologies, initially adopted mainly by the automotive and aerospace industries, are now promoting big changes in how chemical plants are operated and managed. This type of technology can change the decision-making process since more reliable information is available in real time.

Significant step was taken recently in terms of process simulation driven by two major sustainability industry trends. For the circular economy industry trend, chemical companies are developing new chemical processes that yield materials that can be recycled rather than used one time. For the hydrogen economy industry trend, companies will substitute hydrogen fuels to reduce CO₂ emission into the atmosphere. Both the chemical and hydrogen economy trends lead to corresponding advancement in process simulation including modeling and thermodynamics.

Now it is possible for the engineering and operating companies to build the Digital Twin of the process plant. The Digital Twin is built on a simulation platform that will support the entire plant lifecycle, from design to operation, while also addressing new hydrogen and circular economy requirements.

2. The Digital Twin

The new generation of process simulation uses a platform approach that evolves the simulation model from the conceptual engineering to the operation optimization. It allows a new approach to be implemented so companies can transition from the conventional scenario to the use of the process simulation Digital Twin, expanding benefits to the entire plant lifecycle. The same platform is used for process simulation and process utilities (cooling water, flare, steam and others), allowing engineers to further evaluate how each system impacts the other. Heat and material balances can be re-evaluated after equipment and pipeline sizing, since that information is in the simulation from

the beginning, as a result, little or no extra engineering effort is required. Once sizing is validated, the simulation is switched to dynamic mode, in which control loops are included to the simulation model to validate the process control strategy. As it is easier to shift the simulation to dynamic mode, rather than build a completely new model using the conventional approach or converting a model that cannot be taken back to the steady state mode, dynamic studies are performed earlier in the project lifecycle. This promotes savings in equipment acquisition and in operating costs, since control logic responses are evaluated in earlier stages. Plus, when something doesn't respond as expected, simulation is taken back to steady state mode, for re-evaluation of heat and material balance and re-sizing. The ability to go back and forth between steady state and dynamic modes is critical to increase efficiency in the project lifecycle, leading to huge savings in engineering effort. Table 1 summarizes how the new platform approach affects the plant lifecycle and its results.

Lifecycle Phase	Model	Benefits
Conceptual Engineering	The Digital Twin for the process plant is "first born"	<ul style="list-style-type: none"> • Fast evaluation of design alternatives due to continuously solved and flexible specifications • A native cloud application that protects IP to reduce IT costs • Open modeling for first-of-a-kind processes and equipment
Front End Engineering and Design (FEED)	The Digital Twin further develops to represent all process equipment	<ul style="list-style-type: none"> • One product with one learning curve for multiple applications, such as process, process utilities, and relief and flare • Integrated Asset Modeling of interacting but separate systems, such as, an oil field gathering and topsides processing, or the process and its flare system • Automated population of an engineering database • Automated creation of FEED engineering deliverables • Multi-user collaboration of a single simulation
Detailed Engineering	Simulation-Driven Engineering: The Digital Twin grows to also represent the mechanical design and the control strategy	<ul style="list-style-type: none"> • Other disciplines, such as controls, mechanical, piping, all contribute to the engineering database • Simulation takes information from the engineering database to test the Digital Twin continuously as it is designed • Process engineering trends towards new agile software engineering practices with a test-driven development now made possible because of the existence of the Digital Twin

Lifecycle Phase	Model	Benefits
Startup and Commissioning	The Digital Twin is used for Operator Training and Controls Checkout	<ul style="list-style-type: none"> • The actual DCS logic can be integrated to the Digital Twin • Operators are trained without a separate operator training simulator investment
Operations	The Digital Twin is a master simulation model for process improvement, equipment monitoring, optimization, and more	<ul style="list-style-type: none"> • One master Digital Twin model can be spawned to many applications, such as, training, equipment monitoring, and real time optimization to reduce the sustainment costs associated with separate point solutions • No longer need to maintain several process simulation models for a plant – design model, operator training simulator (OTS) model, unit performance monitoring and real-time optimization (RTO)
Revamp	The Digital Twin is used for new evaluations since it is always up to date.	<ul style="list-style-type: none"> • When a modernization or performance improvement is required the Digital Twin has current information and allows calculations and analysis without the need of re-engineering for an up to date simulation.

Table 1 – How a maturing Digital Twin develops and provides benefits for each phase

3. Unified Engineering

Companies are beginning to make progress on their digitalization journey, finding the right applications for digital transformation and seeing increasingly better returns on their investment. While the age-old market environment challenges (such as supply and demand, cost and price) haven't gone away, competitive pressures are making the digital transformation opportunity more pressing than ever. Many have already started to leverage the latest data-centric technology and work processes for their workforce to collaborate and take control of their data, reducing the risk for errors, delays and increased project cost throughout the asset lifecycle. By doing so they are in a stronger position to become more competitive, increase their margins and win new business.

Unified Engineering is a new proposition to break down the silos between FEED and Detailed Design to minimize risk and maximize return on Capital Investment.

Unified Engineering enables global multi-discipline teams to work concurrently in a common data-centric environment, controlling and managing change across the entire project. This breaks down the silos between FEED and detailed design. The simulation data created in FEED is readily available for use in detailed design and is checked and validated in real-time, increasing efficiency, minimizing risk, and maximizing return on investment on your Capital Projects.

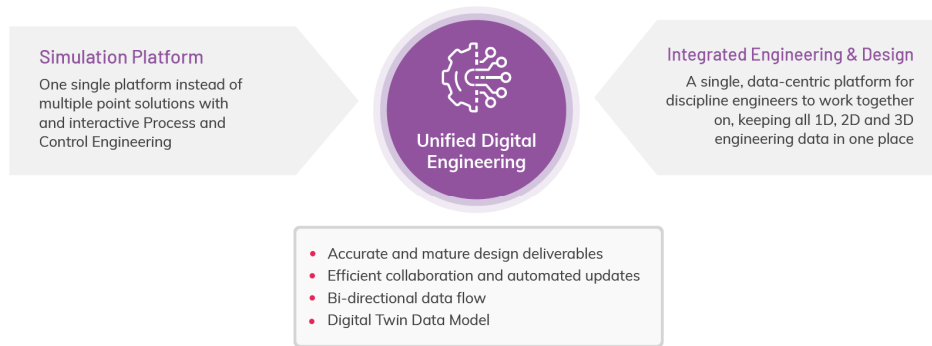

Never have the stakes been higher for companies when it comes to making improvements to their engineering work processes to maximize ROI on Capital Projects. Productivity has not developed in decades – the average Capital Project schedule lags by 20 months and goes over budget by 80%¹.

In many of today's Capital Projects, there is a disconnect between FEED and Detailed Design. In response, AVEVA are the first industrial software provider to pioneer a new solution to break down the silos between these engineering disciplines.

Unified Engineering consists of two main components, the Unified Lifecycle Simulation Platform (one model), and Integrated Engineering and Design (one database). The two are combined to form a robust process model and an engineering database that is able to synchronize through bi-directional flow of all 1D, 2D and 3D data on one platform. The bi-directional integration of a steady state and dynamic process model with an engineering database makes the process seamless and eliminates the need for MS Excel or other intermediate steps to transfer information between tools.

With the Unified Engineering model you can have:

- Verification that the plant will operate as expected, and that controls are properly configured
- Verification that equipment and piping are properly sized
- One single version of the truth that remains up-to date

The process model and the engineering database synchronizes through bi-directional flow from a single platform

Figure 1 - Unified Engineering principles

4. Process Simulation lifecycle

Process simulators are irreplaceable tools for every process engineer. Since the nineteen seventies, process simulators have found widespread adoption within operating companies in oil & gas, refining and chemical industries, as well as the engineering companies and equipment manufacturers that service these industries. The tools available in the market today have incrementally improved over the years to provide more features and functionality. However, they

trace their origins to legacy architectures, operating systems and aftermarket user interfaces, which create inherent limitations:

- They cannot support the full plant lifecycle as they are limited by their single-purpose architecture such as steady state process simulation, dynamic simulation, optimization, or flow network analysis for which they were originally designed
- Extending their functionality can be performed by a very small number of software developers with chemical engineering knowledge, software programming skills, and/or knowledge of that particular specialized program
- They are often based on decades old programming code that cannot leverage the more recent technological developments within the software industry

Today's simulators typically only support a single phase of the lifecycle and are often based on thermodynamics of different simulation vendors and different calculation methods. This not only leads to lack of trust in the results, but causes substantial rework by having to build a new simulation model in each new tool. And the results are hard to compare.

The technological limitations of incumbent process simulation tools forestall improvements in engineering workflows. Collaboration only occurs outside the simulation, because the software cannot accommodate it. Engineering departments send analysis and optimization questions to outside specialists because they cannot easily perform advanced simulations with their in-house tools and software expertise. These complications trap engineering workflows in a waterfall project management paradigm where development is forced into a linear process. Iteration is to be avoided because legacy software makes it cumbersome, error-prone, and tedious.

Global competition, pricing pressure and energy alternatives are now driving the need for a new approach. The oil & gas industry has seen high volatility and the lower price level of today is seen as the "new normal". The chemicals industry has a continuous need to innovate for greater agility and lower costs.

The next generation of workers also expects a modern, scalable and easy to use solution with technology they now take for granted – high speed internet access, mobile devices, touch screens and virtual reality. New concepts like the Industrial Internet of Things (IIoT), Industry 4.0, and Artificial Intelligence have created greater opportunities with a new next generation platform that provides a "Digital Twin" of the plant through the process lifecycle that cannot be provided with today's tools.

A next generation process simulation platform means that one process model is extended throughout the entire lifecycle of the plant, from concept through to operations. This requires a process design mode, a fluid flow/rating mode and a dynamic mode, in combination with the ability to toggle back and forth between modes. Optimization may be provided to any mode. Table 1 describes each phase of the project lifecycle, and how a maturing Digital Twin develops and provides benefits for each phase.

A single, easy-to-use simulation platform will allow engineers to move seamlessly between questions of design, analysis, and optimization. Engineers will be able to assess the impact of design and specification changes quickly and with a holistic view of multiple disciplines. Intensive collaboration becomes commonplace. In this environment, organizations will be able

to adopt agile engineering workflows based on smaller pieces of work with continuous integrated testing to reduce development cost while eliminating surprises at the end of the project.

5. Process Simulations for Sustainable Technology

Physics-based, first-principles models are a critical component of the asset digital twin. As industry develop new process technologies to serve sustainable industry trends such as the circular economy and the hydrogen economy, process simulation programs must adapt to become useful tools for process engineers to design sustainable processes. While academia research how to simulate model reactions or chemical thermodynamics, this modeling and thermodynamics must be integrated within industrial simulation products so that the unified engineering workflow may be applied to develop the digital twin of plants as they are engineered.

There are many Hydrogen-based projects under consideration around the world. Blue, Green, and Gray Hydrogen projects need common process simulation advancement that need to be modeled in processes that support the hydrogen economy.

Green hydrogen is produced by the electrolysis of water. Process simulators will include new electrolyzer equipment models. The Digital Twin for the operation of these plants may use an integrated model to optimize the use of wind and solar power generation for electrolysis.

Blue and gray hydrogen is produced by splitting the methane in natural gas into Hydrogen and CO₂ by steam methane reforming or auto thermal reforming. Development of integrated process plant simulation is required for removal of the CO₂ for capture and storage to produce blue hydrogen. New membrane adsorption models will separate hydrogen for greater purity for blending with natural gas. The carbon dioxide created must be removed using new generation of amines thermodynamics for CO₂ capture by companies that manufacture the amines and companies that use the amines for the separation of CO₂ for carbon capture.

Due to the low volumetric energy density of gaseous hydrogen when used as a fuel, plants must liquify the hydrogen to use it as a transportation fuel. Process simulators will include thermodynamic models appropriate for cryogenic hydrogen. In addition, ammonia is used as a transition fuel with models and thermodynamics required for ammonia pipelines and hydrogen conversion.

Circular economy trends are driving chemical companies to produce materials that may be recycled more readily. This drives the development of new thermodynamic methods and component data to study new process simulation. Chemical and energy companies are replacing fossil based raw materials with renewable feedstocks driving research and development of new reaction technology.

Finally, to make all processes more sustainability by reducing their energy consumption footprint, new simulation products will include the ability to calculate the cost of utilities such as steam, cooling water, and electricity, to minimize operating costs.

6. Conclusion

Lifecycle process simulation has been a vision for process simulation providers and their customers for a long time. Today's simulators cannot leverage the rapid developments occurring in the software industry due to legacy architecture.

Looking at the industry's increasing demand for higher transparency, this can only be achieved using a data-centric Digital Twin approach. This data-centricity enables an ideal platform for new product and process development to create new models and include the management of complex environments bringing together both steady-state and dynamic simulation with constant iteration and constant solving capabilities.

The integration of the process analysis and simulation with other disciplines also allows to breakdown the silos that were typically existing previously. Connecting and remotely controlling previously unconnected processes will increase sustainable operations and improve business efficiency in a sustainable environment. Over the long term the impact will drive resilience and sustainable performance through technologies.

A homotopy continuation-based branch and bound algorithm for process synthesis and design using rigorous unit operation models

Yingjie Ma, Nan Zhang, Jie Li*

Centre for Process Integration, Department of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK

jie.li-2@manchester.ac.uk

Abstract

Synthesizing chemical processes using rigorous unit operation models often leads to a large-scale strongly nonconvex mixed-integer nonlinear programming problem, which is difficult to solve. In this work, we propose a homotopy continuation-based branch and bound (HCBB) algorithm in which an adaptive variable-step length HC method is used to navigate the NLP subproblem to gradually approach a feasible solution. The computational results indicate that the proposed HCBB algorithm provides a robust convergence to a higher-quality locally optimal solution from different initial points for an example of process synthesis compared to existing general MINLP solvers.

Keywords: Process synthesis, homotopy continuation, branch and bound algorithm, rigorous models

1. Introduction

Optimisation-based chemical process synthesis and design problem using rigorous models usually leads to a large-scale strongly nonconvex mixed integer nonlinear programming (MINLP) problem, which is rather difficult to solve (Biegler et al., 1997). It is known that the global solvers such as BARON (Tawarmalani & Sahinidis, 2005) and ANTIGONE (Misener & Floudas, 2014) often cannot converge or even fail to provide a feasible solution for such MINLP problems within acceptable computational effort (Gopinath et al., 2016). The branch and bound (B&B) algorithm (Land & Doig, 1960) and the outer approximation (OA) algorithm (Duran & Grossmann, 1986) are often used to find a locally optimal solution within acceptable computational time (Viswanathan & Grossmann, 1993; Zhang et al., 2018). As both OA and B&B algorithms require to solve a series of strongly non-convex NLP subproblems, which are vulnerable to divergence. Therefore, they also often fail or converge to a locally optimal solution with low quality.

In this work, we propose a homotopy continuation-based B&B (HCBB) algorithm to solve the strongly nonconvex MINLP problem resulting from a superstructure-based synthesis of reaction-separation-recycle processes using rigorous models (Ma et al., 2019). The homotopy continuation (HC) method (Ficken, 1951) is used to improve the performance of the B&B algorithm. At each node, the generalised reduced gradient (GRG) algorithm (Drud, 1985) is first employed to find a feasible solution for the NLP subproblem using the solution from the previous node as the initial point. Once it fails, an adaptive variable-step length HC method is used to gradually approach a feasible

solution, which is then used to initialise the GRG algorithm to generate a locally optimum. The synthesis and design of a hydrodealkylation (HDA) process (Douglas, 1985) is solved to illustrate the capability of the proposed HCBB algorithm. It is shown that the HCBB algorithm is able to always converge to the same local optimum of 4.959 M\$ y⁻¹ in 5 minutes even from different initial points, whilst BARON, ANTIGONE and DICOPT solvers in GAMS (GAMS Development Corporation, 2014) fail in 1 h. The SBB/GAMS solver and the successive relaxed MINLP (SRMINLP) algorithm (Ma et al., 2019) converged to a worse solution of 4.713 M\$ y⁻¹ from some initial points.

2. Problem statement

The problem is stated as follows: for given raw material, product and production requirements (e.g., production rates and product purities), we want to get the optimal flowsheet structure and reactor types, optimal operating conditions, optimal sizes of reactors, distillation columns and heat exchangers. The objective is to minimize total annualised cost (TAC) or maximize profit. This is realised through a superstructure-based method. The superstructure is composed of a reactor network and a separation network for ternary separation. The superstructure for reactor network is from (Lakshmanan & Biegler, 1996). There are several stages in the reactor network. At each stage, different types of reactors can be used. At most one reactor can be selected at each stage. Distillation is assumed to be the only separation technology considered in the separation network since it is widely used for separation. The separation network is represented using the state equipment network (SEN) representation (Yeomans & Grossmann, 1999). The distillation columns are modelled by rigorous equilibrium stage model. The detailed model of the whole process synthesis problem can be found in (Ma et al., 2019).

3. Homotopy continuation-based branch and bound algorithm

3.1. Overall framework of the proposed HCBB algorithm

The proposed HCBB algorithm is shown in Fig. 1. It is based on the classical B&B algorithm. At each node, an NLP subproblem requires to be solved using the GRG algorithm due to its good convergence. However, the GRG algorithm requires a feasible solution before entering optimisation phase, which is difficult to provide (Drud, 1985). In the proposed algorithm, the homotopy-continuation method is used to get a feasible solution to initialise the GRG algorithm, which is shown in the following section.

3.2. Homotopy continuation method for the derivation of a feasible solution

In the B&B algorithm, \mathbf{x} denotes continuous variables and \mathbf{y} denotes binary variables. At a node i , there are \mathbf{S} ($s = 0, 1, 2, \dots, S$) binary variables in total including \mathbf{S}_F^i fixed binary variables and \mathbf{S}_R^i relaxed binary variables. That is $\mathbf{S}_F^i \cup \mathbf{S}_R^i = \mathbf{S}$. Then all binary variables at this node i are denoted as $\mathbf{y} = \{y_s | s \in \mathbf{S}\}$ with $\mathbf{y}_F^i = \{y_s | s \in \mathbf{S}_F^i\}$ to denote the fixed binary variables and $\mathbf{y}_R^i = \{y_s | s \in \mathbf{S}_R^i\}$ to denote the relaxed binary variables. Based on these notations, an NLP subproblem at a node i can be denoted as $P^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$. All the NLP subproblems $P^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$ have the same constraints and objective function but differ in \mathbf{y}_R^i and \mathbf{y}_F^i .

To get a feasible solution of $P^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$, we need to solve a corresponding feasibility

problem, which is denoted as $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$. Note that $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$ has the same constraints as $P^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$, but its objective function is a constant (e.g., 0). We take the optimal solution or a feasible solution from the previous node (e.g., the parent node of the current node) as an initial point in which we use \mathbf{x}^0 and \mathbf{y}^0 to represent the values of continuous variables and binary variables, respectively. In other words, $\mathbf{y}_R^{i,0} = \{y_s^0 | s \in \mathcal{S}_R^i\}$, and $\mathbf{y}_F^{i,0} = \{y_s^0 | s \in \mathcal{S}_F^i\}$. Since the initial point is an optimal solution from a previous node, $(\mathbf{x}^0, \mathbf{y}_R^{i,0})$ must be a solution of $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$ where \mathbf{y}_F^i is fixed to $\mathbf{y}_F^{i,0}$. To gradually reach to the solution of $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$ from the solution of $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^{i,0})$, i.e. the initial point, we can sequentially solve a series of feasibility problems, $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^{i,m})$ ($m = 0, 1, 2, \dots$) with $\mathbf{y}_F^{i,m}$ gradually approaching \mathbf{y}_F^i from $\mathbf{y}_F^{i,0}$, which is the HC process. For \mathbf{y}_F^i and $\mathbf{y}_F^{i,0}$, some of their components may be equal, while the other components are different. Thus, we only need to change the components that are different, which we call homotopy variables, and are notated as \mathbf{y}_{FH}^i and $\mathbf{y}_{FH}^{i,0}$, respectively. The common components are notated as \mathbf{y}_{FC}^i . Following this, the feasibility problems during homotopy can be represented by $FP^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_{FH}^{i,m}, \mathbf{y}_{FC}^i)$ ($m = 0, 1, 2, \dots$) with $\mathbf{y}_{FH}^{i,m}$ changing from $\mathbf{y}_{FH}^{i,0}$ to \mathbf{y}_{FH}^i . For convenience, we introduce a homotopy parameter t ($0 \leq t \leq 1$), and set $\mathbf{y}_{FH}^{i,m} = t \cdot \mathbf{y}_{FH}^i + (1-t) \cdot \mathbf{y}_{FH}^{i,0}$. Thus, the feasibility problems during homotopy can be represented as $FP^i(\mathbf{x}, \mathbf{y}_R^i; t^m, \mathbf{y}_{FH}^{i,0}, \mathbf{y}_{FH}^i, \mathbf{y}_{FC}^i)$ with t^m changing from 0 to 1. During HC, t^m is updated by the step length Δt^m though applying $t^{m-1} + \Delta t^m$ or $t^{m-2} + \Delta t^m$. To improve both convergence and efficiency, Δt^m is allowed to vary adaptively in the following rules:

Algorithm 1. Update Δt^m and t^{m+1} according to solution history during homotopy.

- 1 **Input:** convergence status of a solution \mathbf{Z}^f , Δt^{m-1} , Δt^{m-2} , t^{m-1} and t^m .
- 2 **If** \mathbf{Z}^f is infeasible then
- 3 $\Delta t^m = 0.5 \cdot \Delta t^{m-1}$
- 4 $t^{m+1} = t^{m-1} + \Delta t^m$
- 5 **Else if** $m = 1$ or $\Delta t^{m-2} \neq \Delta t^{m-1}$ then
- 6 $\Delta t^m = \Delta t^{m-1}$
- 7 $t^{m+1} = t^m + \Delta t^m$
- 8 **Else**
- 9 $\Delta t^m = 2 \cdot \Delta t^{m-1}$
- 10 $t^{m+1} = t^m + \Delta t^m$
- 11 **End if**

With above discussion, the HC method for solving NLP subproblems is as followings:

Algorithm 2. Solve an NLP subproblem using the homotopy continuation method.

- 1 **Input:** Select the solution of a previous NLP subproblem as an initial point \mathbf{Z}^0 , set $\mathbf{y}_{FH}^{i,0}$ and \mathbf{y}_{FH}^i , set $0 < \Delta t^0 < 1$, $0 < t^1 < 1$, $0 < \Delta t^{min} < 1$, and $M > 0$.
- 2 **For** $m = 1, 2, 3, \dots$
- 3 Solve $FP^i(\mathbf{x}, \mathbf{y}_R^i; t^m, \mathbf{y}_{FH}^{i,0}, \mathbf{y}_{FH}^i, \mathbf{y}_{FC}^i)$ from \mathbf{Z}^0 and get the solution \mathbf{Z}^f .
- 4 **If** \mathbf{Z}^f is optimal and $t^m = 1$ then
- 5 Solve $P^i(\mathbf{x}, \mathbf{y}_R^i; \mathbf{y}_F^i)$ using \mathbf{Z}^f as an initial point and get the solution \mathbf{Z}^* .
- 6 Break #Get the optimal solution of the NLP subproblem
- 7 **Else if** $m \leq M$ then

```

8       Update  $\Delta t^m$  and  $t^{m+1}$  according to Algorithm 1.
9       If  $\Delta t^m < \Delta t^{min}$  then
10          Break #Fail to find a solution
11       End if
12     Else
13       Break #Fail to find a solution
14     End if
15 End for

```

In this work, $\Delta t^0 = 0.5$, $t^1 = 0.5$, $\Delta t^{min} = 0.01$ and $M = 20$. The HCBB algorithm is implemented in Python (Python Software Foundation, 2016) through interfacing CONOPT solver (Drud, 1985) in GAMS for NLP solution.

Figure 1. Homotopy-continuation-based branch and bound algorithm.

4. Case study

The HDA process using toluene and hydrogen to produce benzene and by-product diphenyl from (Douglas, 1985) is used to illustrate the capability of the proposed HCBB algorithm. The superstructure is given in Fig. 2, where the reactor can be either adiabatic or isothermal and there are three distillation columns. The required benzene molar purity is 99.97% with a production rate of 124.8 kmol h⁻¹. The objective is to maximize economic profit which is calculated by the revenue of benzene and diphenyl minus annualised capital cost and operating cost. All parameters for chemical reaction, thermodynamic calculation and economic evaluation are from (Kocis & Grossmann, 1989). While (Kocis & Grossmann, 1989) used short-cut models (i.e., Fenske-Underwood-Gilliland method for distillation columns), we use rigorous equilibrium stage model for distillation columns. There are 8142 constraints, 8643 continuous variables, and 13 binary variables.

Besides the HCBB algorithm, five other algorithms are also used, including DICOPT implementing OA algorithm (Duran & Grossmann, 1986), SBB implementing conventional B&B algorithm (GAMS Development Corporation, 2014), SRMINLP algorithm from (Ma et al., 2019), BARON (Tawarmalani & Sahinidis, 2005) and ANTIGONE (Misener & Floudas, 2014). The maximum computational time is set as 1 hour. We generate five different initial points, with which two local optima are found at the root using CONOPT. These two optima are used to initialize the six algorithms. While SBB, SRMINLP and HCBB can solve the problem from both initial points with the results

provided in Table 1, BARON, ANTIGONE and DICOPT fail in 1 h. From Table 1, SBB find a worse local optimum of 4.713 M\$ y⁻¹ from the root node 2 than HCBB. This is because around half of the NLP subproblems are infeasible as shown in Table 1, which misses the better optimal solution. Similarly, SRMINLP also finds a worse local optimum with TAC of 4.711 M\$ y⁻¹ from the root node 2 because it is easy to be trapped in the local optimum. This is because the initial point at root node 2 is close to the worse local optimum and the subproblem becomes more and more ill-conditioned and isolated with the tightness of the relaxed parameters. HCBB finds nearly the same optimal solution from both initial points because it significantly improves the success rate of solving NLP subproblems. The HC calculation has been invoked for 3 and 5 NLP subproblems respectively due to normal GRG algorithm fails when starting from root nodes 1 and 2. The optimal design of HDA process from the HCBB is presented in Fig. 3.

Figure 2. The superstructure for the HDA process.

Table 1. Comparative design results and computational times of different algorithms

	Profit (M\$ y ⁻¹)		Computational Time (s)		No. infeasible NLP/total No. of NLP	
	Init 1	Init 2	Init 1	Init 2	Init 1	Init 2
SBB	4.959	4.713	63	51	3/10	3/7
SRMINLP	4.956	4.711	120	63	0/2	0/2
HCBB	4.958	4.957	101	126	0/8	1/9

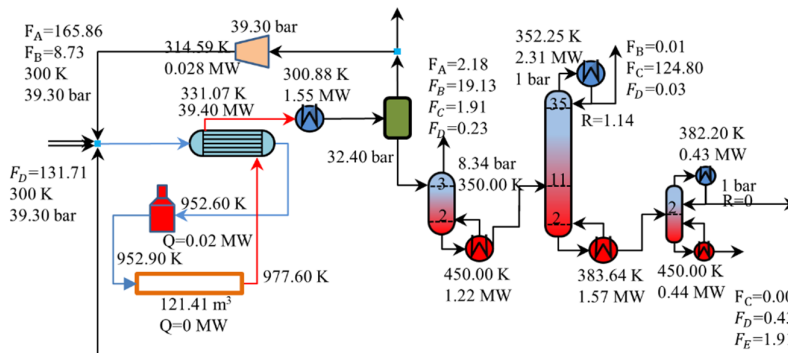

Figure 3. Optimal design of HDA process where the unit of flow rate is kmol h⁻¹ and A, B, C, D and E represent H₂, CH₄, C₆H₆, C₇H₈ and C₁₂H₁₀ respectively.

5. Conclusions

In this work, we proposed a HCBB algorithm to solve strongly nonconvex MINLP problems resulting from process synthesis and design problems using rigorous models. In this HCBB algorithm, an adaptive variable-step length HC method was used to navigate the NLP subproblem to approach a feasible solution. The computational results demonstrate that the proposed HCBB algorithm is able to converge to the same local optimum with a profit of 4.959 M\$ y⁻¹ in 5 minutes from different initial points, whilst BARON, ANTIGONE and DICOPT fails to find a feasible solution in 1 h. SBB and SRMINLP converged to a worse solution with 5% less profit.

ROmodel: A Python Robust Optimization Modeling Toolbox

Johannes Wiebe,^a Ruth Misener,^a

a Imperial College London, London, UK

j.wiebe@imperial.ac.uk

Abstract

We introduce ROmodel, a Python package that extends the modeling capabilities of the popular modeling language Pyomo to robust optimization problems. ROmodel contains a library of commonly used uncertainty sets which can be generated using their matrix representations, but it also allows the definition of custom uncertainty sets using Pyomo constraints. The resulting models can be solved using ROmodels solvers which implement both the robust reformulation and cutting plane approach. We apply the problem to a number of instances of three case studies and show some results.

Keywords: robust optimization, optimization under uncertainty, software tools

1. Introduction

Robust optimization has become a method of choice for optimization under uncertainty in process systems engineering with applications ranging from production scheduling to flexible chemical process design (Janak and Floudas, 2005; Li and Ierapetritou, 2008; Zhang et al., 2015; Ning and You, 2017; Shang and You, 2018; Grossmann et al., 2016). This has been accompanied by considerable development of new techniques: distributionally and adjustable robust optimization can reduce solution conservatism (Grossmann et al., 2016), data-driven robust optimization designs application specific uncertainty sets based on available data (Bertsimas et al., 2018), and approximate robust optimization bridges the gap between classic robust optimization and semi-infinite programming, making non-linear problems more tractable (Houska and Diehl, 2013). While this is undoubtedly a positive development, the large number of approaches and the required domain knowledge can discourage practitioners from making the transition from deterministic optimization to optimization under uncertainty. Furthermore, the lack of a platform that allows the easy implementation and application of new algorithms means that it is difficult to compare different approaches (Marc and Schöbel, 2016)

In this paper, we introduce ROmodel, a python package that extends the popular, Pythonbased modeling language Pyomo (Hart et al., 2017) to facilitate modeling of robust optimization problems and implementation of robust optimization algorithms. ROmodel combines intuitive modeling of robust optimization problems with the richness of Pyomo's solver interfaces and methods for model transformations and Python's data processing capabilities. It supports both automatic reformulation and cutting plane algorithms and can be extended to incorporate other approaches. Uncertainty sets can be chosen from a library of common geometries, or custom defined using Pyomo constraints. A number of similar software packages for modeling robust optimization problems have been introduced in the past: JumPeR extends Julia's modeling language Jump to robust optimization problems (Dunning, 2016), ROME provides a matlab interface (Goh and Sim, 2011), and Vayanos et al. (2020) recently proposed the C++ robust optimization

solver ROC++. AIMMS also has some capabilities for modeling robust optimization problems. One advantage of ROmodel is that it is based on Python and Pyomo. Python is becoming increasingly popular in many fields and particularly in data analytics and machine learning. ROmodel allows these techniques to be integrated seamlessly with robust optimization methods. Pyomo is a very powerful modeling environment and is also open source. Because ROmodel is entirely based on Pyomo, it can take advantage of many of its solver interfaces, model transformations, and more. ROmodel is open source and available on Github (Wiebe and Misener, 2020).

The rest of this paper is structured as follows. In Section 2 we introduce the new modeling objects which ROmodel provides and show how they can be used to easily model robust optimization problems. Section 3 introduces the three solvers which ROmodel contains: a reformulation based solver, a cutting plane solver, and a nominal solver for obtaining nominal solutions of robust problems. Section 4 introduces the three case studies we use to evaluate ROmodel and presents a number of results.

2. Modeling

In order to model robust optimization problems within Pyomo, we introduce two new modeling objects:

1. `UncSet`: A class based on Pyomo's `Block` class used to model uncertainty sets.
2. `UncParam`: A class similar to Pyomo's `Param` and `Var` class used to model uncertain parameters.

The two new modeling objects are sufficient for modeling quite generic robust optimization problems. Uncertainty sets can be defined in two ways: using Pyomo constraints or, for common types of geometries, using their matrix representation.

2.1. Generic uncertainty sets

The `UncSet` class inherits from Pyomo's `Block` class and can be used largely in the same way. One can use this property to construct generic uncertainty sets by adding Pyomo constraints to the `UncSet` object. The following example shows how a polyhedral set can be modeled using this approach:

```
# Define uncertainty set
m.U = UncSet()
m.w = UncParam(range(2), uncset=m.U, nominal=[0, 0])
# Add constraints
m.cons1 = Constraint(expr=m.w[0] + m.w[1] <= 1)
m.cons2 = Constraint(expr=m.w[0] - m.w[1] <= 1)
...
```

This way of modeling uncertainty sets is very flexible, however not every set that can be modeled using this approach can necessarily also be solved. We discuss which types of uncertainty sets can be solved in Section 3.

2.2. Library uncertainty sets

For standard uncertainty sets which are commonly used, the above approach is unnecessarily complicated. Instead we have implemented custom classes which can be used to define them using their matrix representation. Polyhedral sets of the form $U =$

$\{w: Pw \leq b\}$ can be constructed by passing the matrix P and the right hand side b to the `PolyhedralSet` class, e.g.:

```
# Polyhedral set
m.U = PolyhedralSet(mat=[[ 1,  1],
                        [ 1, -1],
                        [-1,  1],
                        [-1, -1]],
                    rhs=[1, 1, 1, 1])
```

Ellipsoidal sets of the form $(w - \mu)^T \Sigma^{-1} (w - \mu) \leq 1$ can be constructed using the `EllipsoidalSet` class, the covariance matrix Σ and the mean vector μ , e.g.:

```
# Ellipsoidal set
m.U = EllipsoidalSet(cov=[[1, 0, 0],
                        [0, 1, 0],
                        [0, 0, 1]],
                    mean=[0, 0, 0])
```

Implementing additional sets simply requires a new Python class collecting the necessary data and a function which, given a Pyomo constraint and an uncertainty set returns its robust counterpart as a Pyomo block.

2.3. Uncertain parameters

Once an uncertainty set is defined, we can utilize the `UncParam` class to easily construct uncertain constraints. Consider the following deterministic Pyomo constraint:

```
# deterministic
m.x = Var(range(3))
c = [0.1, 0.2, 0.3]
m.cons = Constraint(expr=sum(c[i]*m.x[i] for i in m.x) <= 0)
```

If the coefficients c are uncertain, we can model the robust constraint $c^T x \leq 0 \forall c \in U$ as:

```
# robust
m.x = Var(range(3))
m.c = UncParam(range(3), nominal=[0.1, 0.2, 0.3], uncset=m.U)
m.cons = Constraint(expr=sum(m.c[i]*m.x[i] for i in m.x) <= 0)
```

2.4 Swapping uncertainty sets

One of the advantages of ROmodel is, that it makes trying different uncertainty sets very easy. A robust model can simply be resolved with a different uncertainty set:

```
# Uncertain parameter
m.c = UncParam(range(3), nominal = [...], uncset = m.U1)
# Solving the model with m.U1
solver = SolverFactory('romodel.cuts')
solver.solve(m)
```

```
# Swapping uncertainty sets and resolving with m.U2
m.coef.uncset = m.U2
solver.solve(m)
```

3. Solvers

We implement three solvers within RModel: A robust reformulation based solver, a cutting plane based solver, and a nominal solver.

3.1 Reformulation

The reformulation-based solver implements standard duality based techniques for reformulating robust optimization problems into deterministic counterparts (Bertsimas and Sim, 2004). The solver is illustrated in Fig. 1. It essentially consists of a pre-processing:

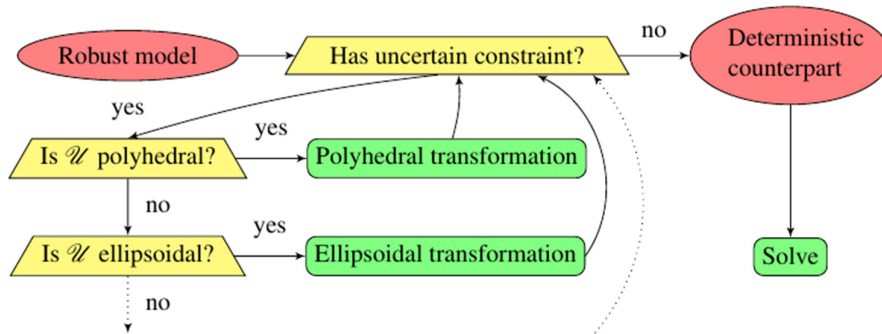

Figure 1: Schematic of reformulation solver

First, it detects every constraint containing uncertain parameters. Second, it checks the structure of each uncertain constraint and the corresponding uncertainty set to determine if a known reformulation is applicable. Finally, it applies a model transformation and solves the resulting problem using one of the available solvers in Pyomo.

RModel currently implements standard reformulations for ellipsoidal and polyhedral uncertainty sets and linear uncertain constraints, but it can easily be extended to include other reformulations. Adding new reformulations requires two Python functions: a function which detects whether a constraint and uncertainty set have the required structure and a function which generates the robust counterpart.

3.2 Cutting planes

The cutting plane solver, outlined in Fig. 2, implements an iterative strategy for solving robust optimization problems (Mutapcic and Boyd, 2009). It replaces each uncertain constraint by a `CutGenerator` object which initially just contains the nominal constraint. The solver then iteratively solves the master problem and generates cuts to cut off solutions which are not robustly feasible. RModel's cutting plane solver can generally be applied to any convex uncertainty set.

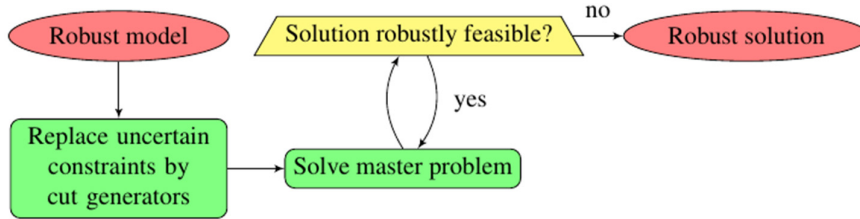

Figure 2: Schematic of cutting plane solver

3.3 Nominal

ROmodel also includes a nominal solver. This solver replaces all occurrences of the uncertain parameters by their nominal values and solves the resulting deterministic problem. The advantage of this is that it is not necessary to have separate implementations of the nominal and robust problem. An implementation of the robust model can easily be used to obtain the solution of the nominal problem:

4. Results

We use ROmodel to model and solve robust versions of three literature problems: a portfolio problem (Bertsimas and Sim, 2004), a knapsack problem, and a pooling problem instance (Adhya et al., 1999). We solve each problem with both the reformulation and cutting plane solver for ellipsoidal and polyhedral uncertainty sets and using both the library approach to generating uncertainty sets as well as the generic, Pyomo constraint-based approach. We solve each instance for 30 different uncertainty set sizes.

		Reformulation	Cuts	Overall
Knapsack	Polyhedral	71	365	84
	Ellipsoidal	65	248	83
Pooling	Polyhedral	99	469	119
	Ellipsoidal	60171	607	712
Portfolio	Polyhedral	69	402	92
	Ellipsoidal	65	40927	81
Overall		71	406	244

Table 1: Median time in milliseconds taken to solve the three example problems with different uncertainty set geometries using the reformulation and cutting plane solvers

Table 1 shows the median time in milliseconds taken to solve each problem for a given uncertainty set geometry and solver. The reformulation solver generally outperforms the iterative cutting solver. An exception is the the non-linear, non-convex pooling problem with an ellipsoidal set. For this instance, the cutting plane solver achieves significantly better results, which is in line with previous research (Wiebe et al., 2019).

5. Conclusion

ROmodel can be used to easily formulate robust versions of common optimization problems. The modeling environment it provides makes robust optimization methods more readily available to practitioners and makes trying different solution approaches and uncertainty sets very easy. ROmodel is open source and available free of charge and could play a vital role as a platform for prototyping novel robust optimization algorithms and comparing them to existing approaches.

Modelling – Mechanistic reductionism extended with holistic empirical components

Heinz A Preisig

*Norwegian University of Science and Technology
Department of Chemical Engineering
NO-7491 Trondheim, Norway
heinz.preisig@chemeng.ntnu.no*

Abstract

We discuss the underlying aspects of our computational engineering suite, implementing application-specific reductionism. Our Process Modelling suite (ProMo) supports complex multi-discipline and multi-scale models using discipline-specific basic building blocks. An application-domain-specific ontology captures the involved disciplines and their respective basic entities being the smallest granulates in each field. Each basic entity is primarily equipped with a mechanistic mathematical input/output representation. We augment this mechanistic approach with a holistic component by allowing multiple definitions of these behaviour descriptions, thereby enabling empirical models. ProMo's ontology reasoner handles the resulting multi-directed variable/equation graphs representing the entity models. The discipline-related model components are linked together over two mechanisms depending on the nature of their interaction. The concept of "tokens" provides the necessary abstraction, allowing for a network of networks description of multi-disciplinary models.

Keywords: Ontology, multidisciplinary, multi-scale, simulations, digital twin.

1. Mathematical models – modelling

If one takes modelling at its face value, it is omnipresent, and people use the term *model* in many different contexts. The term *model* is "loaded" with many different meanings and interpretations. In experimental work, one often plays with geometrical scales: one works on a small model process instead of the "real" process. In process systems engineering, we mainly focus on mimicking the process' input/output behaviour through mathematical modelling and simulation. Computational engineering is the primary activity of a process engineer, and while one also "plays" with *scales*, the term has different interpretations.

For process engineers, *models* are mathematical representations of systems' input/output behaviours. One applies reductionism, and the general idea is to describe the process as a conglomerate of interacting parts. In physics-related science subjects, one typically proclaims the applicability of the reductionism paradigm. In contrast, one also accepts that one does not always have enough knowledge or insight that enables one to provide all fundamental parts or the ability to describe all interactions required to capture the observed behaviour and one has to resort to a holistic approach.

Here we explore the possibility of combining the two approaches.

2. The Science Viewpoint

We are careful in defining "science" as the fundamental approach characterised by reductionism's ultimate application. Careful, because this view constitutes the belief that nature builds on fundamental entities. Physics, as theoretical and fundamental science, does have the objective to find those fundamental entities. The approach is to break the object of interest recursively down into smaller and smaller bits until no smaller "bits" can be identified or detected. Once in a dead-end, one declares the finest-grained entities as the current fundamental entities, and one continues the search on the next lower scale.

Models must only be good enough for the application and no better – a saying which well-known and lesser-known people have repeated many times. People construct models for a *purpose* (Apostel (1960)). The quality of the model one defines indirectly, namely in the context of the *application*. The process of generating a model is therefore recursive and ranges over design, realisation and application. Based on this consideration, one defines the termination points of the granularisation on the *appropriate* level in the break-down process, which, in a first instance, is a matter of judgment, making modelling to be seen as an art.

Once one has identified the smallest required entities, one *declares* them as the fundamental entities, and builds the models using them as building blocks.

3. Different complexities

Following those lines of thought, one distinguishes different kinds of complexities:

Many-complexity: The first is on a given level of granularity; the process behaviour consists of many items. Examples are easy to find. One requires many molecules to represent a material's behaviour appropriately. Sand piles consist of many sand particles, and catalytic beds have many active sites, many surfaces, etc. In these cases, one looks into thousands to millions of separate objects.

Structur-complexity: In contrast, the second type of complexity is about several scales. Here just a hand full is considered "many".

Discipline-complexity: Having elements from different disciplines is yet another type of complexity and again "many" is in the order of a hand full.

4. Scales

The "frame" in which a physical process lives, is defined by the four-dimensional space-time and we distinguish between two types of scales, namely time scales and length scales. Material science is the home of length scales: macro, meso, micro and nano are used in this context. Not without discussion though, as particularly meso is only defined as the scales between micro and macro or nano and macro.

Time scales are not often put into the limelight of modelling discussions. The reason may be that they are linked to the length scales. Obviously, a smaller part of a whole reacts quicker to a change on its boundary than the larger of the same kind. Though if one views the modelling process again from the point of not getting too detailed, it is useful to consider the time-scales.

Figure 1: Time-scale motivated model reduction: Shrinking and expanding time scales

We claim that each physical process model assumes splitting the time scale into three sections: constant, dynamic and event-dynamic. The constant part divides into a set of reservoirs providing the driving forces for the embedded dynamic process, which is a Carnot-type of view for a process' operations. The event part is considered to "just happen" in the time-scale of the dynamic process. Typical chemical engineering example is the pressure wave propagation in a plant. Some model reduction methods operate on time scales. Keywords are singular perturbation with perturbation parameters being assumed small, which results in merging fast parts of the dynamic system into the event-dynamic domain. At the same time, on the other end of the dynamic spectrum, large capacities may be merged into the constant environment, see Figure 1.

5. Disciplines & Interactions

Let us first define *discipline* in the context of modelling. Here we use the term for a *domain* in which the same "things" are being handled, exchanged, processed ... The term is thus circularly defined with interactions. The declared basic entities process the *tokens* are exchanged between the entities. It is these *tokens* that indirectly represent the domain of the discipline. To give an example: declaring mass, energy and momentum as the *tokens* define a class of physical systems. One may classify further into particulate and continuous systems. Thus *tokens* are per se not the only criteria for the declaration of a discipline, but we may use it to declare domains of entities that interact with a class of *tokens*.

Figure 2: The liquid and the gas exchange tokens, while the gas and the thermo domain exchange information.

Domains characterised by different classes of *tokens* may interact only by exchanging information. Examples are the interaction between the physical domain and the domain capturing control. Others may be associated with analysing the designed process such as life-cycle or techno-economical evaluations, optimisation or the like.

Two domains of different length scales do not interact by exchanging *tokens* but information. As an example: a macroscopic system may require information about the material properties. Using molecular simulation technology is one possible method to compute the necessary properties. The input provided by the macroscopic model is the vector of canonical variables, such as temperature, pressure and molar composition. The molecular code returns

the requested property. The macroscopic level provides state information, mostly in the form of intensive properties, and in return, it obtains the requested physical quantity information. Exchanging the molecular code by any empirical model or a database does not change the nature of information exchange.

6. On Boxes

The use of *boxes* is a typical thinking pattern when describing the behaviour of a system. Generically, a *box* represents the input/output behaviour of a modelled system. In the context of reductionism, this implies that a network of the smallest identified entities, the basic *boxes*, the basic building blocks, describes the modelled plant's behaviour. These networks may become very large, defining the *many-complexity*, which is approached using recursion and hierarchical representation of the model. Thus the picture is interacting *boxes* in *boxes* or networks in networks.

Boxes may be classified. The terminologies of using *white box* for mechanistic models and *black box* for empirical models are widely used in engineering and science¹. *Glass-box* is intuitively the better term for *white-box* models, as it expresses the fact that one can see what is inside thereby providing information about the internal state. While mechanistic models are classically based on the reductionism view, black-box models are not built on insight but represent only the input/output behaviour without considering the internal state. They are based on a holistic view.

Many will view the use of the terms *white box* and black box as traditional. Though things tend to change with time and the meaning of terms undergoes adaptation to new or non-traditional fields, like this is the case with the renewed emerging field of artificial intelligence. For example, in AI literature, one finds explanations like: *White-box models are the type of models which one can clearly explain how they behave, how they produce predictions and what the influencing variables are.* (see Tannam (2020), or SciForce (2020)).

7. ProMo's network of network approach

NTNU's Process Systems Engineering group's ProMo project is based on reductionisms. It constructs multi-disciplinary models from the different discipline's base entities, where base entities are defined in the context of the model and its granularity.

The European Commission financed the development of the European Materials & Modelling Ontology (EMMO) (EMMC (2020)) and processes are part of the EMMO. The extension of the EMMO with the respective entity behaviours is NTNU's PSE groups' contribution.

Our Process Modelling suite *ProMo* provides the ontology and simulation construction tools. It is designed to handle large models that may stretch over several scales and employ different disciplines. Thus *ProMo* handles all three types of complexities: *many-complexity*, *structure-complexity* and *discipline-complexity*. As a basis, we use a network of networks approach and recursion within the networks. The "networks" represent the domains with its interacting *boxes* with the *boxes* being the networks' nodes. The *boxes* may again contain networks thereby allowing for a hierarchical representation of domains with a large many-complexity on the corresponding granularity level Preisig (2010). The top network links different discipline-specific networks. One has typically macroscopic continuous physical systems, microscopic particulate systems, control systems, material models, and databases for chemical engineering processes. The *ProMo* ontology provides

¹A well-formulated definition can be found in Wiener (1961).

the information of what disciplines are involved by defining a discipline tree.

ProMo's ontology provides a set of fundamental *boxes*, a kind of Lego-set from which the user constructs more complex *boxes* and finally complete process models. It is *ProMo*'s expert section that provides the necessary tools to define the model building instruction and the basic boxes (Preisig (2020)). For physical systems, the fundamental behaviours are based on the conservation and the balancing principles. For mechanical systems, including the molecular level, the Hamiltonian framework serves as a basis. In contrast, it is the contact geometry that defines the configuration space for thermodynamic systems.

8. Need for Empirical Models

So let us take a step backwards: The underlying philosophical concept is reductionism. Its idea is to break the object recursively into smaller and smaller parts until a level is reached, which can be considered the smallest essential component. The relative "size" of the smallest elements defines the model's granularity, with the required details depending on the application. Latter implies that the nature of the entities is defined in the context of the application. However, this approach is often not feasible, simply because one has too little knowledge about what the lower-level entities are and how one can describe their functionality. Another reason is that one would require a myriad of elements to capture the system's behaviour appropriately. The way out is to use another approach, namely local *holistic* approach. The holistic approach replaces a (highly) detailed or ill-defined entity with a surrogate. Surrogates go under various names, but the term "black-box" does capture it quite well: one replaces a mechanistic description, in this terminology called a white-box or glass-box, with a set of interacting functions. This network of functions is then fitted to input/output data yielding a modelled physical unit's simulated behaviour. This idea is by no means new. These models were termed black-box or metamodels, neural nets, and symbolic regression models (Cozad and Sahinidis (2018)), to mention a few. They are all functional networks, and so are the mechanistic descriptions. The result is that one defines multiple representations of the same input/output behaviour.

9. *ProMo*'s Handling of Multiplicity of Representations

ProMo's expert section has the tools for defining the equations representing the entity input/output behaviour, allowing for a multiplicity of definitions. An application-tailored reasoner² to handle this task. The modeller, called the *translator*, does though want to have a unique behaviour description. *ProMo*'s reasoner allows selecting an alternative in each case. The MoDeNa platform (Karolius et al. (2016, 2017)), uses a dynamic allocation of alternative models. An approach that is new in the domain of what today is termed "Open System Platforms" adds a great degree of flexibility in computing multi-scale processes.

10. Conclusions

ProMo enables the construction of complex models using a few discipline-specific basic building blocks. By providing a basic set of building blocks, the art of modelling is

²Term reasoner is used in the computer-science's ontology domain - usually implementing a first-order logic analysis.

moved from the writing of the behaviour equations to defining the model's structure. So the user's main task is selecting the structure of the model, selecting the right level of granularity, and considering the time scale in which the model must represent the modelled object. Model structures are information-exchanging, discipline-specific networks, each characterised by transferring and processing *tokens*.

The base entities' definition is done by experts in the respective field, thus removing the need for the user to acquire the necessary knowledge. A mechanistic, deductive, description may not always appropriately capture all behaviours, but one may have to succumb to an empirical representation rich enough to capture the observed behaviour. Those models are holistic and mostly empirical or semi-empirical. The multiplicity of representing individual entities is not a problem to handle. *ProMo*'s reasoner is designed to process the resulting multi-bipartite variable/equation graphs.

The approach taken in the design of *ProMo* splits the modelling activity into sections, where experts are providing the behaviour description of the basic building blocks input/output behaviours. A problem translator constructs the complex models using these building blocks. All input/output relations are automatically compiled and processed internally, without the user's need for interaction. The approach eases the construction of complex models. The problem translator tasks focus on the model's structure and not the representation of the basic blocks. The overall result is a reduced time from problem formulation to simulation, thus increasing the ability to explore alternatives.

Abstract

Biomass proved promising outcomes as a sustainable alternative to fossil fuels for energy generation. With the mounting concerns on the environment and the increasing pressures on natural resources, there is an impetus to investigate new biomass feedstocks and further develop efficient biomass conversion processes and technologies. Gasification, amongst other thermochemical conversion processes, is considered as one of the most efficient and clean processes, generating syngas which can be fed to gas turbines for electricity production. To enhance the process' efficiency, the integrated gasification combined cycle is adopted which utilises the exhaust heat from the gas turbine to operate a joined steam turbine. In this study, a biomass based integrated gasification combined cycle (BIGCC) with CO₂ recovery is modelled, simulated and optimised. The carbon recovery segment consists of a post-combustion chemical absorption carbon capture from the exhaust flue of the BIGCC using potassium carbonate as solvent. The presented integrated system is able to produce electricity from date pits at a negative carbon credit. Thus, this system aims at recycling waste for the generation of valuable commodities, reducing GHG emissions and diversifying the energy portfolio, all feeding into the concept of sustainability. The proposed system is simulated as a thermodynamic equilibrium model for the BIGCC and a rate-based model for the carbon capture segment in Aspen Plus software. The energy and exergy efficiencies for the overall system are calculated and optimised. Several parametric studies were conducted to select impactful operating parameters and their ranges for the optimisation model. Outcomes of this study indicate that the proposed system generates 420 kW of electricity and captures 80% of the CO₂ emitted from the BIGCC. The integrated system achieves maximum energy and exergy efficiencies of 54% and 61% respectively.

Keywords: Biomass, BIGCC, Carbon capture, Potassium carbonate, Optimisation.

1. Introduction

The rapid population growth has led to increasing demand on energy, water and food. As a consequence, the use of fossil fuel resources for energy generation has grown, and is now posing significant concerns on the environment because of the high and cumulative greenhouse gas emissions (GHG) associated with burning these fuels (AlNouss et al., 2019). A major contributor to greenhouse gas emissions is CO₂, which has reached an amount of 33.1 Gt in 2018 amounting from energy generation activities (IEA, 2019). Mitigation efforts, and target plans have been set to keep the temperature rise below 1.5°C to 2°C, agreed upon during the Paris agreement and put towards actions plans in the national development goals. Pathways reflecting these efforts include as one of the priority scenarios the implementation of bioenergy with carbon capture and storage (BECCS) as a solution (IPCC, 2018). The integration of greenhouse gas control technologies has become a necessity to mitigate the ever increasing global GHG emissions while sustaining the population needs in terms of energy, water and food. A study integrated greenhouse gas control technologies with an energy, water and food nexus system with the aim of evaluating the corresponding environmental impact of different scenarios. The achievement of negative GHG emissions was proven in this study by using bioenergy with carbon capture and storage technology (Al-Ansari, 2017). The optimisation of BECCS technology can lead to less GHG emissions, and can make the technology less energy intensive and ready for commercialisation. The optimisation can be done at the different process levels of the integrated system. For example, a study conducted an optimisation of the syngas produced through determining the optimal biomass blend used as well as the optimal operating configurations for the gasifier (AlNouss, 2020). Others studied the efficient integration of biomass integrated gasification combined cycle (BIGCC) with the carbon capture segment, extracting heat from one system and feeding it to the other. For example, a study investigated the use of heat from the low pressure steam turbine to regenerate the solvent used for carbon capture Monoethanolamine, reaching an energy efficiency of 47.03% (Dinca, 2018). Others focused on studying the carbon capture process separately like Oyenekan and Rochelle (2009), where they investigated the use of piperazine promoted potassium carbonate for CO₂ removal using a rate-based model. In this study, an optimisation model is proposed for maximizing the energy and exergy efficiencies of a BIGCC with post combustion carbon capture using potassium carbonate (K₂CO₃) as a solvent. To run the optimisation, a prior rigorous sensitivity analysis is conducted to select the impactful operating parameters on the efficiencies and determine their ranges. In the next section, the proposed integrated system is described and baseline operating parameters are presented. Then, in the third section the analysis and optimisation model for the system are described.

2. Model development

In this study, a model is developed of a biomass based integrated gasification combined cycle with a post combustion carbon capture using potassium carbonate as a solvent. The system is able to generate power, and capture CO₂ while reutilising low value heat streams from the multiple subsystems for a better efficiency. Data points are chosen as a biomass and is fed to the gasification unit at a baseline rate of 100 kg/h. The ultimate and proximate analyses are presented in Table 1 (AlNouss, 2018).

Table 1: Ultimate and proximate analyses of date pit biomass

Proximate Analysis	Volatile matter	Fixed carbon	Ash	Moisture	Ultimate Analysis	C	H	O	N	S
	77.7	16.31	0.98	5.01		50.84	6.83	37.88	4.45	0

The gasifier operates at a temperature of 800°C and a pressure of 1 bar. The produced syngas is then sent to a heat recovery unit to cool the syngas before compression and combustion. The combusted gas is then expanded in a gas turbine for power generation, and is discharged at a pressure of 32 bar. The heat value of the syngas is utilised by the dual-pressure steam turbine along with the exhaust heat from the gas turbine for more power production. Superheated steam is fed to the high pressure turbine at 538°C and 124 bar, and to the low pressure turbine at 500°C and 32 bar. After utilising the heat from the gas turbine effluent, the stream is transferred to a carbon capture unit along with potassium carbonate. The gas from the BIGCC called EX-GAS is fed at the bottom stage of the absorber, and the solvent called LEANIN is fed to upper stage producing a countercurrent flow. The aqueous potassium carbonate solution (40 wt%) then absorbs CO₂ and exists the absorber as RICHOUT1 and goes through an expansion to decrease its pressure before entering the stripper at stage two with a pressure of 150 mbar. The stripper is set to a column pressure drop of 10 mbar. The CO₂ is removed from the rich solution and exits the stripper as ACIDGAS, while the remaining solvent exits from the bottom of the stripper as LEANOUT1 and is pumped for regeneration as shown in Figure 1.

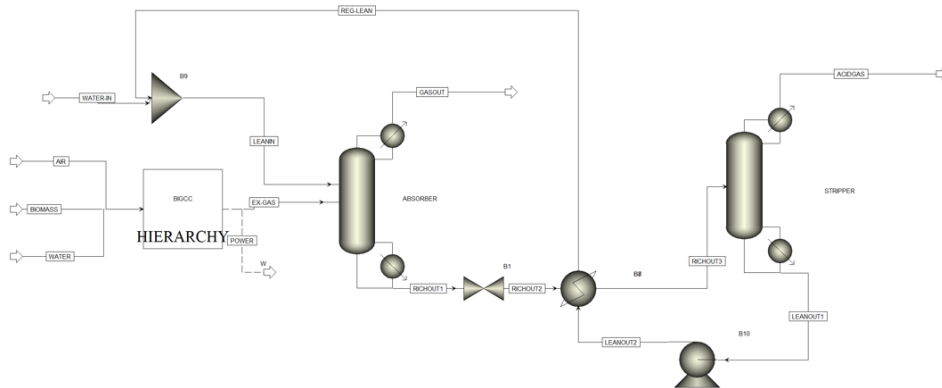

Figure 1: System's flowsheet in Aspen Plus

3. Analysis and optimisation

Aspen Plus software is used in simulating the above presented model for the BIGCC and carbon capture integrated processes. The BIGCC segment is simulated following a thermodynamic equilibrium model, while the carbon capture unit is simulated using a based model that takes into consideration the reaction kinetics for more accurate results. Assumptions taken in this simulation include steady state and steady flow conditions,

isothermal conditions for the decomposition and separation stages with atmospheric conditions taken as 25 °C and 1 bar, adiabatic conditions for the combustion, tar formation is neglected, and char is considered as 100% carbon. The Peng-Robinson equation of state with Boston-Mathias modifications is used for the BIGCC unit and the Electrolyte Non-Random Two Liquid (NRTL) property method is used for the carbon capture unit. The overall reaction of carbon capture by potassium carbonate is described in equation (1).

The kinetics of the reaction mechanisms are calculated using the Power Law as shown in equation (2).

$$Kinetic\ factor = kT^n \cdot e^{-E/RT} \quad (2)$$

The model is simulated initially for a baseline scenario following the operating parameters described in the model development section. The overall energy and exergy efficiencies are then calculated following equations (3) and (4) respectively. A sensitivity analysis is then run to see the effect of varying operating configurations on key parameters of the efficiencies such as the effect of gasification temperature on power and CO₂ mass flowrate, the effect of biomass flowrate on power production and CO₂ mass flowrate, the effect of solvent temperature and pressure and stripper pressure drop on reboiler heat duty and CO₂ captured. This sensitivity analysis works as a basis for defining a range to be studied for the operating parameters. The efficiencies are then optimised by changing the studied ranges of the operating parameters and determining simultaneous optimal values for these parameters that will maximise the energy and exergy efficiencies.

Variations in each operating parameter are studied through the simulation in Aspen plus. Results of the sensitivity analyses are transferred to Matlab to build regression models describing the energy and exergy efficiencies corresponding to changes in each operating parameter. Energy and exergy efficiency functions for each operating parameter are developed. The weighted average of these functions is computed to represent the objective functions of the proposed optimisation model. A pareto front is developed using Genetic Algorithm (GA) in Matlab to generate optimal solutions for the simultaneous computing objectives of energy and exergy efficiencies.

Variables:

\dot{W}_{net} : net power (W)

\dot{m}_{CO_2} : CO₂ flowrate in acid gas (kg/s)

h_{CO_2} : CO₂ enthalpy in acid gas (J/kg)

ex_{CO_2} : CO₂ total exergy in acid gas (J/kg)

$ex_{biomass}$: total exergy of biomass (J/kg)

$\dot{Q}_{heaters}$: heat duty of heaters in BIGCC (W)

$\dot{Q}_{reboiler}$: reboiler heat duty in stripper (W)

Decision variables:

$T_{gasification}$: gasification temperature (°C)

$\dot{m}_{biomass}$: biomass flowrate (kg/h)

$T_{solvent}$: lean solvent temperature (°C)

$\dot{m}_{solvent}$: lean solvent flowrate (m^3/h)

$\Delta P_{stripper}$: stripper pressure drop (mbar)

Objective function:

$$\text{Maximise: } \eta_{en} = \frac{\dot{W}_{net} + \dot{m}_{CO_2} h_{CO_2}}{\dot{m}_{biomass} LHV + \dot{Q}_{heaters} + \dot{Q}_{reboiler}} \quad (3)$$

$$\text{Maximise: } \eta_{ex} = \frac{\dot{W}_{net} + \dot{m}_{CO_2} ex_{CO_2}}{\dot{m}_{biomass} ex_{biomass} + \dot{Q}_{heaters} (1 - \frac{T_0}{T_s}) + \dot{Q}_{reboiler} (1 - \frac{T_0}{T_s})} \quad (4)$$

Constraints:

$$700^\circ\text{C} \leq T_{gasification} \leq 900^\circ\text{C}$$

$$100\text{kg/h} \leq \dot{m}_{biomass} \leq 1000\text{kg/h}$$

$$40^\circ\text{C} \leq T_{solvent} \leq 80^\circ\text{C}$$

$$5\text{ m}^3/\text{h} \leq \dot{m}_{solvent} \leq 30\text{ m}^3/\text{h}$$

$$3\text{ mbar} \leq \Delta P_{stripper} \leq 10\text{ mbar}$$

4. Results and discussion

The results of the sensitivity analyses are presented in Figures 2-6. The effect of gasification temperature on power and CO₂ mass flowrate presented in Figure 2 demonstrates an increasing trend for both energy and exergy efficiencies with the increase in gasification temperature. This is due to the increase in power output and the decrease in CO₂ generation and reboiler duty. Whereas, the increase in biomass flowrate presented in Figure 3 indicates an increase in exergy efficiency and a decrease in energy efficiency. This is linked to the important increase in power generation and that of the energetic heat of the reboiler, but the small increase in the exergetic reboiler heat.

Figure 2: Effect of gasification temperature

Figure 3: Effect of biomass flowrate

The effect of solvent flowrate presented in Figure 4 indicates a decreasing trend for both energy and exergy efficiencies with the increase in solvent flowrate until a certain point approximately at 14 m³/h where beyond it the trend starts to increase. This can be linked to the effective increase in CO₂ captured starting a solvent flowrate of 14 m³/h. Figure 5 illustrates the effect of solvent temperature where a decreasing trend in both energy and exergy efficiencies is demonstrated with the increase in solvent temperature due to the decrease in CO₂ capture.

Figure 4: Effect of solvent flowrate

Figure 5: effect of solvent temperature

The effect of stripper pressure drop presented in Figure 6 indicate a decreasing trend in both energy and exergy efficiencies with the increase in stripper pressure drop. This is due to the fact that the effectiveness of CO₂ capture process decreases with the increase in column pressure drop and the increase in reboiler duty requirement.

The results of the optimisation problem considering these five sensitive decision variables are illustrated in Figure 6. The optimisation suggests gasification temperature approximately at 900°C, lean temperature at 30°C, lean flowrate of around 20 m³/h and stripper pressure drop of 3 mbar for both maximisation cases of energy and exergy efficiencies. Whereas, the optimisation recommends two different biomass flowrates with 315 kg/h for exergy efficiency maximisation case and 100 kg/h for energy efficiency maximisation case. This is due to the distinct behaviour both showed with the increase in biomass flowrate.

Figure 6: Effect of stripper pressure drop

Figure 7: Optimisation results

5. Conclusions

BECCS technology is considered as a viable strategy and solution to reduce CO₂ concentration levels from the atmosphere. In efforts to make this technology applicable to large scale processes and economically profitable, it is necessary to improve its efficiency and comprehensively study the integration of all the subsystems. Hence, in this study a proposed model of a biomass integrated gasification combined cycle (BIGCC) with post combustion carbon capture using potassium carbonate is analysed and optimised thermodynamically in terms of energy and exergy efficiencies. The first step of this study consisted of modeling and simulating a baseline scenario of the integrated system. Then, a sensitivity analysis was conducted to see the effect of varying operating parameters on the efficiencies. The most impactful operating parameters were then selected and inputted as decision variables to the optimisation model. The objective of the optimisation was to maximise the energy and exergy efficiencies subject to some constraints defined by the allowable ranges of the operating parameters set in the sensitivity analysis. Results show that the maximum energy and exergy efficiencies achieved by this optimisation are 54% and 61% respectively.

The state of play towards modeling of air quality in the city of Rabat

Soraya EL HAMDOUNI,^a Essediya CHERKAOUI,^b Abderrahmane NOUNAH^c and Mohamed KHAMAR

Civil Engineering and Environment Laboratory (LGCE); Materials, Water and Environment Team; Higher School of Technology of Salé; Mohammed V University in Rabat, Morocco

Abstract

Rabat, the capital of Morocco, a green and sustainable city, a radiant city on a regional and national scale, faces a serious problem of air pollution caused by the daily flow of vehicles. Faced with the inaccessibility of the data on this issue, the study focuses on the quantification of the CO₂ emission rate by vehicles and their contributions to air pollution and the choice of station for monitoring CO₂ by a sensor. Once the database is completed, it will be shared through an application/website accessible to the population in order to make them aware of this problem.

Keywords: Pollution, treatment, modeling

Located in the extreme northwest of the African continent, Morocco is a country bordered by the Mediterranean Sea to the north and the Atlantic Ocean to the west. Inland, the Atlas mountain range runs through the center of the country, between which lie vast plateaus of grassland. The natural border in the south is the Sahara Desert. It covers an area of 446,550 km² with a population of 34 million inhabitants, this population is spread over 12 regions according to the new administrative division of 2015.

The prefecture of Rabat, the object of our study is the administrative capital of the Kingdom, it belongs to the region of Rabat Salé Kénitra and is the capital of its region. It covers an area of 118 km². The prefecture is bounded to the north by the prefecture of Salé, to the south by the prefecture of Skhirat-Témara, to the east by the two prefectures Salé and Skhirat-Témara, to the west by the Atlantic Ocean. Rabat is made up of two municipalities, the urban municipality of Rabat which includes five districts (Agdal-Riad, El Youssoufia, Hassan, Souissi, Yacoub El Mansour), and the urban municipality of Touarga where the royal palace is located. It benefits from a crossroads location (accessible to all the provinces in the region), as it represents an attractive hub on a regional and national scale given its administrative weight.

We produced a situation map of the prefecture of Rabat at the national, regional, and provincial levels using ArcGIS software on the basis of the new administrative division of 2015 (Figure 1).

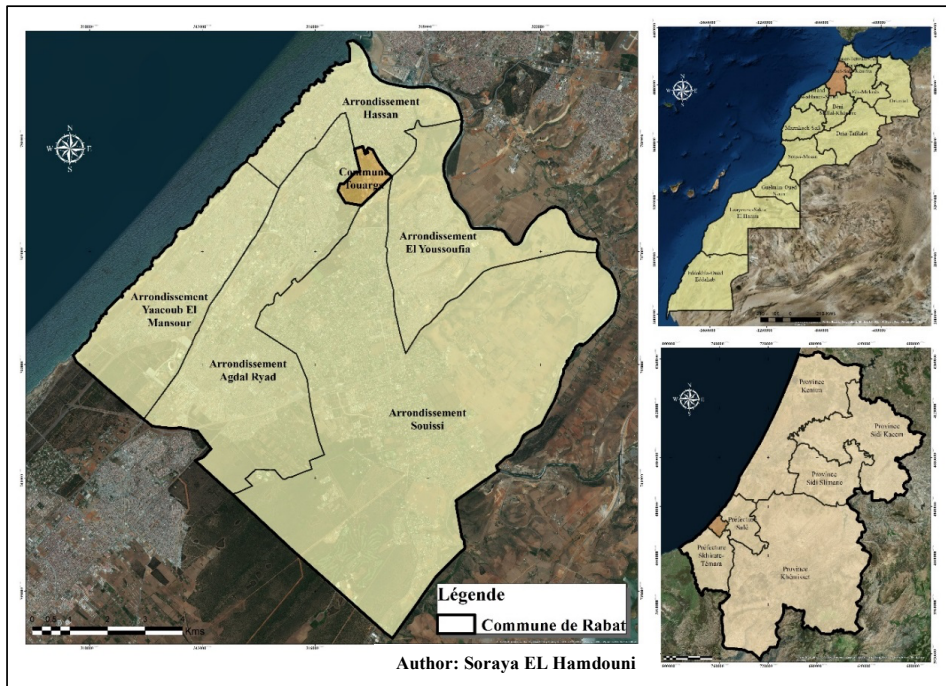

Figure 1: Situation map of the prefecture of Rabat

Demographically, Rabat is home to a population of 572,717 inhabitants, or 12.6% of its region and 1.7% of the whole country.

since 2004 the city of Rabat has been losing its population. This regression is due to several factors, including (Figure 2)

- The logic of social filtration following slum relocation operations (departure of a large demographic mass);
- Geographic constraints (the prefecture is bounded by the Bouregreg wadi, the Atlantic Ocean, and the green belt) which slow down urban sprawl;
- Land constraints that do not allow planned urbanization;
- A political will to keep the city of Rabat a lower town, less dense and elitist;
- A mismatch between supply and housing needs in terms of stock, price, and quantity offered;
- Lower and lower birth rate;
- High standard of living compared to neighboring municipalities;

Figure 2: Evolution of the population of the prefecture of Rabat

Regarding the economic aspect, precisely the branches of activity, Rabat knows a dominance of the tertiary sector with a percentage of 38%, this dominance is justified by the concentration of all the administrations and public and private services, this concentration is not other than the result of the centralization adopted previously in Morocco, followed by services (19%), trade occupies third place (14%) and lastly agriculture (1%) and the water branch, electricity, and energy (1%). (figure 3)

Figure 3: The branches of activity at the prefecture of Rabat

As for the industrial component which represents 11%, according to the Chamber of Commerce, Industry, and Service, Rabat has 3 industrial zones,

- The Takkadoum industrial zone with 37 companies in the field of Textile, IMM, Automotive, and Construction.
- The Al Fadila industrial zone with 24 companies in the field of Agri-food, Textile, IMME, Pharmaceuticals, and Construction.
- The Vita industrial zone with 4 companies in the chemicals sector, IMM and a Showroom (76% of units), and car dealerships.

Although Rabat is labeled a green city, thanks to the doubling of the global average of green spaces for each individual,) its industrial zones which do not really impact the quality of the air, its delegated management of solid and efficient waste with a collection is around 99%, a liquid waste management system by a WWTP which has been in operation since 2011.

The major problem that the capital faces on a daily basis and which has a direct impact on air quality is transportation. Being an elitist city, attractive and radiant at the national level, Rabat really suffers from this phenomenon in environmental and urban terms, this problem is strongly linked to the phenomenon of commuting between Rabat and the neighboring municipalities.

To respond to this problem, Rabat has opted for various solutions, such as the tramway, which is still not sufficient to speak of Rabat as a city free from air pollution.

In order to better understand the consequences of commuting, fieldwork was carried out (interrupted several times by COVID 19) at the level of the entrances and exits of the city of Rabat aiming at the quantification by category of vehicles in rush hour in order to show the contribution rate of vehicles to daily CO₂ emissions.

To do this, we opted for the quantification of vehicles on all the entrances and exits of Rabat on the side of the Salé prefecture to the north-east and on the side of the Skhirate Témara prefecture to the south-east which are the two prefectures that delimit Rabat.

the fieldwork was spread over 12 peak hour quantification stations from 7:30 am to 9:30 am and 3:30 pm to 5:30 pm. After the database was developed, it was processed using ArcGIS software in order to find the station with the most traffic (Figure 4).

We made the map at ArcGIS, to locate the 12 stations with the number of vehicles at peak hours.

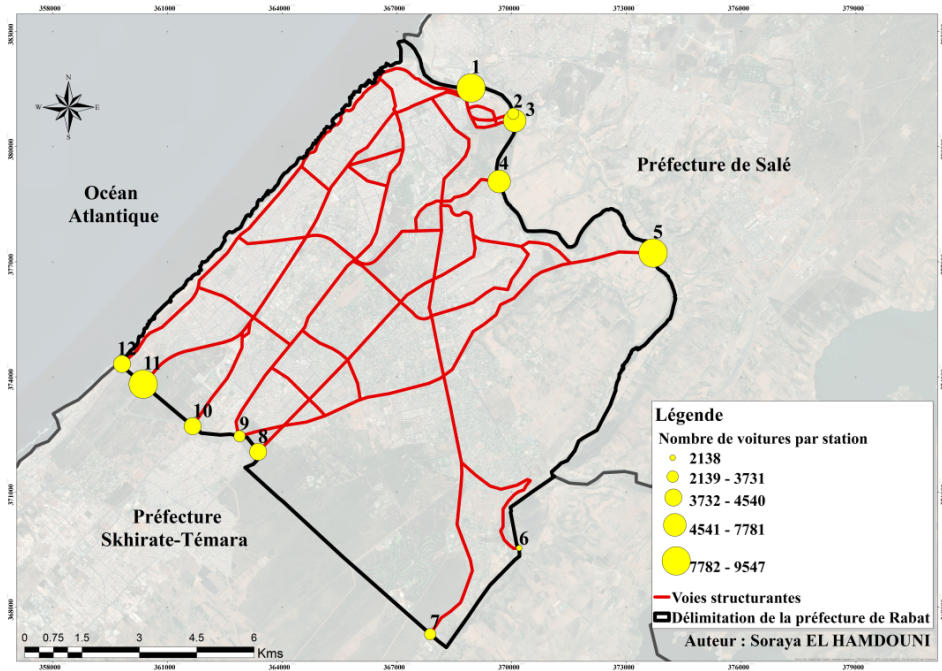

Figure 4: Location map of vehicle census stations

Based on the number of cars passing through each station and the quantity of CO₂ in g / km released by types of the car according to their technical datasheet, it was found that the maximum quantity is observed at station 1 and the minimum is at station level 6 (Table 1)

Station	1	2	3	4	5	6	7	8	9	10	11	12
CO ₂ g/km	1307	560	1167	1069	1279.5	321	548	634.5	960	681	1432	609

Station 1 (Hassan II Bridge) representing the north side of the prefecture and station number 11 on the south side representing Avenue Hassan II are the stations most marked on the one hand by the greatest flow of cars and other the CO₂ emission quite high.

This is why we chose the two stations which will be monitored by gas sensors of the quantities of CO₂ released by the means of transport into the air. In our case study, it is station 1 (Pont Hassan II) on the Salé side and station 11 (Avenue Hassan II) on the Témara side with the largest number of vehicles. (Figure 5)

Figure 5: Incoming and outgoing vehicles at the two stations under study

The quantification of vehicles at the entrances and exits of Rabat was accompanied in parallel with a study on the CO₂ emission rate of each brand of vehicle, to highlight the contribution rate of vehicles to pollution of air daily.

The graph below groups together all the vehicle brands with increasing order of CO₂ emissions. According to the figure, the least polluting brand is Citroën and the most polluting brand is Toyota. As for Morocco, the best-selling brand of vehicles is the Dacia, which is ranked 5th in terms of CO₂ emissions in the air. (Figure 6)

Figure 6: CO₂ emissions by vehicle brand

The data collected from the two sensors will be the subject of typical modeling and pilot for future sensors. As they will serve as a roadmap for the realization of an effective, real and achievable project.

It is in this logic that the present proposal relating to the creation of an application / Website accessible to the population and to the local authority of the city of Rabat is important and useful in the fight against pollution of the air caused by vehicles in a participatory approach.

Abstract

Estimating energy consumption in cement mills is critical for the cement industry. Following data science practices and adopting machine learning (ML) technologies, we developed energy consumption prediction models for a cement mill of TITAN SA plant in Kamari Viotia. The models exploit historical sensor measurements and operational data and give predictions for energy consumption with accuracy better than almost one order of magnitude compared to existing baseline methods.

Keywords: machine learning, energy consumption, prediction, cement industry

1. Introduction

Cement grinding is a key process in the cement industry. During this phase, gypsum and mineral or artificial raw materials (e.g., pozzolan, ash, limestone) are added to the clinker (basic raw material for cement production) and, then grinded in special mills until a very small grain size is achieved. During the grinding process, corrective actions are constantly taken, in both the quota of the ingredients of the recipe and the operating parameters of the mill in order to achieve the appropriate fineness of the mixture. Large amount of electrical energy is consumed for mill operation. Therefore, it is essential for a cement industry to estimate its energy consumption in its cement mills. Estimation of the energy consumption can be used in a number of processes, such as assisting in the process of compliance with the requirements of ISO 50001 for energy efficiency, detecting changes in the operating parameters of the mill to save energy and executing scenarios for the energy consumption footprint of new mixtures.

To this end, we propose a model that estimates the energy consumption of a cement mill. We followed a data-driven approach, utilizing historical data recorded during the grinding process, and we designed and implemented machine learning models for energy prediction. Our models have been applied in TITAN SA plant in Kamari Viotia. Results show that we achieved an improvement of accuracy for energy consumption prediction by one order of magnitude, based on baseline method.

2. Background

TITAN uses a proprietary methodology for creating a model for estimating energy consumption in the company's cement mills. This methodology takes into consideration a number of variables, such as the cement mix composition and the product's blaine. At the core of this modelling approach is a linear function with weighted fractions of clinker, gypsum, slag, fly ash, pozzolan, limestone and other components in the product. The weights assigned to each component of the mix are estimated for each of TITAN's cement mills using linear regression on past data. The methodology also adds to the model corrections for over-grinding of the softer components, and also takes into consideration the operational parameters for each type of cement mill (e.g., mill type, separator type etc). The model created by this methodology, calculates the estimation of power consumption for a standard blaine value, and then, using an adjustment formula, corrects it to the final estimation based on the product's blaine.

In our approach we were granted full access to the proprietary methodology adopted by TITAN (not to be disclosed in this paper), in order to use it as a baseline method and compare the results of our methodology.

3. Dataset

3.1. Description

We collected hourly operations data from TITAN Kamari cement plant, near Athens, from January 2018 to August 2019. The processing of the data resulted in a dataset with 15,592 records and 43 features. Data is comprised of features for cement mix composition (e.g., the percentage of, clinker, gypsum, fly ash, etc), and operational parameters (e.g, like separator speed, fan speed, etc). Furthermore, measurements from sensors (temperature in various stages of the mill process, etc), quantities of additives and qualitative characteristics of the mix (blaine, etc) are some extra sets of features that were included in the data.

3.2. Data Exploration and Feature Correlation

Using statistical methods and data visualization, we got a better understanding of the data. Specifically, the correlation table indicated that attributes did not have high correlation, so there was no need of dimensionality reduction. Regarding data preprocessing, we deleted records with zero running time of the mill, as well as zero production and real blaine. Records that were associated with incorrect measurements or outliers were also deleted. Further preprocessing involved One-Hot Encoding for categorical attribute cement type. The final dataset consisted of 5,010 records and 39 features.

4. Methodology

Our methodology consisted of the following three steps.

- We designated which prediction methods we will apply in our experiments and we came up with 7 models.
- We examined which methods will boost our predictions and we concluded that cross-validation and feature selection was those that we are going to study.
- We considered various metrics, which are used in the existing bibliography, in order to compute the performance of our regression models.

4.1. Prediction Methods

We implemented a group of models using 7 prediction methods, grouped in 3 major categories, (a) Multiple Linear Regression, (b) Ensemble Methods, and (c) Hyperplanes.

Multiple Linear Regression includes the classic form of linear regression that calculates the coefficients of a linear function by minimizing the mean square error between the predicted and the actual values. Furthermore, Ridge and Lasso regressions both are a convention of the linear regression which minimize the mean square error plus one regularization term to keep the coefficients at a low range. However, these regularization terms are different as the Lasso regularizer leads to more aggressive reduction of the range of coefficients. This often generates zero coefficients corresponding to characteristics that have a small effect on the target value. Practically, it performs a feature selection.

In the Ensemble Methods, AdaBoost Regression (Freund and Schapire, 1995) (Drucker, 1997) and XGBoost Regression (T. Hastie and Friedman, 2009) the estimation of the target is done by combining estimates of many individual prediction models based on decision trees. On the contrary, in the Random Forest Regression (Breiman, 2001) the estimation of the target value is done by combining average estimation values of several individual prediction models based on classifying decision trees for a number of subsets of the data set. The difference between AdaBoost Regression and XGBoost Regression is how the combination of the estimations is done. In AdaBoost Regression the combination of estimations is done serially, so each new model corrects the previous one and is trained giving more weight to the training data for which the previous model showed underfitting behaviors. On the other hand, in XGBoost Regression every new model is trained to estimate the prediction errors of the previous model, so that the prediction of the previous model is corrected based on the new one.

Finally, Hyperplanes included Support Vector Regression-SVR which is based on the support vector machine classification model, which has been modified to predict continuous values. The main difference between SVR and linear regression is that the latter aims to minimize the mean square error between the predicted values and the actual values of the target value, while the SVR aims to limit the error to a range of values.

4.2. Feature Selection and Cross-Validation

Feature selection serves three basic purposes. To start with, it makes model training faster, since the size of training set is reduced. Also, since it performs dimensionality reduction, the risk of overfitting is being overcome. Lastly, it increases the accuracy of the prediction since features that add noise are not taken into account. We followed the feature selection method implemented in Guyon et al. (2002). This approach ends up with a feature ranking through recursive feature elimination and cross-validated selection of the best number of features. More particularly, starting with a list of all features, the method recursively deletes one feature in every repetition. Finally, we came up with a list of features that returned the best results during the evaluation of the model based on the validation set. Table 1 shows the number of features recommended in every prediction model.

Prediction methods	Number of features selected
Linear Regression	30
Ridge Regression	28
Lasso Regression	25
AdaBoost Regression	22
XGBoost Regression	16
Random Forest Regressor	23
Support Vector Regression	22

Table 1. Number of features selected in each prediction method

Dataset records	Training set	Validation set	Folds	Testing set
5,010	4,008	1,002	4	1,002

Table 2. Dataset splits

A training set is a set of data with records that give us the target value along with the values of other attributes that affect it. Usually, such a set results from data files in which each record relates to the same reference period. Conventionally, for the implementation of machine learning projects the 70-80% of the whole dataset is used as the training set and the rest as testing set which is used for the evaluation of the model. This method often leads to overfitting, with the model performing extremely well in predicting values when the input belongs to the testing set, but it fails if the input is foreign to the testing set.

In our case, model implementation was performed with the method of cross-validation (T. Hastie and Friedman, 2009). Specifically, we applied K-Fold cross-validation. This method uses different parts of data to fit and test the model. In particular, the method consists of the following steps:

1. Data is splitted into K equal-sized folds.
2. For the k-th fold, the model is fitted to the other K-1 folds.
3. Prediction error of the fitted model is calculated when predicting the k-th fold.
4. The second and third step are repeated for all folds and the K estimates of prediction error are combined.

For the k-fold cross-validation, we have split the training set into 4 folds with suffling. Table 2 shows how we split the whole dataset in training, validation and testing sets.

4.3. Evaluation Metrics

For every dataset that we used in our methodology (training, validation and testing), we calculate evaluation metrics to understand the model's behavior and its' predictive ability.

Prediction methods	Datasets	R-squared	MAE	MSE	RMSE
Baseline	Training set	-0.1497	4.0933	43.3750	6.5859
	Validation set	-	-	-	-
	Testing set set	-0.1497	4.2088	48.6345	6.9738
AdaBoost Regression	Training set	0.6847	1.7114	11.9253	3.4533
	Validation set	0.6645	1.7218	12.997	3.6052
	Testing set	0.5775	1.7777	17.963	4.2383
Random Forest Regression	Training set	0.9429	0.4854	2.1615	1.4702
	Validation set	0.7251	0.8029	10.5898	3.2541
	Testing set	0.6282	0.8349	15.8105	3.9762
XGBoost Regression	Training set	0.9999	0.005	0.0001	0.0128
	Validation set	0.7370	0.671	10.1639	3.188
	Testing set	0.6564	0.6613	14.608	3.822

Table 3. Results in training, validation and testing sets for baseline and 3 best predictions methods

A simple metric is Mean Absolute Error (MAE) which is the sum of the average of the absolute difference between the predicted and actual values. Another metric used is the Mean Squared Error (MSE), which is the same as the MAE, but the difference is that it

squares the difference between actual and predicted values before summing them all. Root Mean Squared Error (RMSE) is taking the square root of MSE. Also, we used R2 which quantifies the quality of fit of a set of predicted output values to the actual output values.

5. Results

We performed our experiment on a Dell PowerEdge R430 Intel(R) Xeon(R) CPU E5-2609 v4 @ 1.70GHz with 14 cores and 16G RAM running Ubuntu 18.04 LTS, kernel 4.15.0-99. For model training, we used two open-source Python libraries, scikit-learn (Buitinck et al., 2013) which provides tools for model fitting, data preprocessing, model selection and evaluation, and XGBoost (Chen and Guestrin, 2016) which is an optimized distributed implementation of Gradient Boosting.

As mentioned above, in our experiment the K-Fold cross-validation we have split the training set into 4 folds with shuffling. Initially, we examined the evaluation metrics in a validation set. For Multiple Linear Regression methods, the R-squared and MSE in every fold of the validation set had high standard deviation, indicating poor performance of these methods. Hence, it was not worthwhile to check their evaluation metrics in the testing set. The same behavior was observed for Support Vector Regression. In contrast, Ensemble methods performed very well, so we continued by exploring the evaluation metrics, for those methods, in the testing set. Table 3 shows the results in training, validation and testing sets for Ensemble methods.

The baseline method had a poor performance, indicated by the negative R-squared, and high values of MAE, MSE and RMSE. Among Ensemble methods, AdaBoost Regression had the worst performance with an R-squared in the testing set not exceeding 0.6, and MAE almost 1.8. Concerning Random Forest Regression, even though the results of the method in the training set seemed promising, its performance in the validation and the testing sets wasn't as good as expected. However, we detected a significant improvement in the MAE which was reduced in half. Finally, XGBoost Regression delivered the best results among all methods, regarding all evaluation metrics, since the R-squared in the testing set fluctuated near 0.65, the MAE was reduced even more and the MSE was the lowest observed among all three methods. Comparing the results from the XG-Boost Regression to those from the baseline method, we observe a decrease both in MAE and MSE. In general, Ensemble methods delivered improved results according to the R-squared. To this end, as results demonstrate, the machine learning methods used in this study, outperformed the baseline method.

6. Conclusions and Future Work

Using data science practices and adopting machine learning (ML) technologies, we have developed energy consumption prediction models for a cement mill of TITAN SA plant featuring superior performance over conventional models used in the past. The models exploit historical sensor measurements and operational data and give predictions for energy consumption achieving an improvement of accuracy for energy consumption prediction by one order of magnitude, based on baseline method.

Specifically, the top three models reached MAE less than 1.77 (the existing baseline method has a MAE >4.00) and R2 more than 0.57 (the existing baseline method has a R2 <0.2). The models produced have so far exploited data streams, not first principles. Future work will exploit such principles to improve the performance towards the development of hybrid process engineering models, to generalize the approach, and to

enable the analysis with a potential to extract knowledge from the data and support decisions.

Abstract

Volatile Organic Compounds (VOCs) are a class of solvents extensively used for the production of Active Pharmaceutical Ingredients (APIs) in the pharmaceutical industry. To ensure adherence to environmental regulations, adsorption is widely implemented as an effective VOC emission abatement method. The present work relies on an adsorption model which accounts for mass transfer by advection-dispersion in the gas phase and pore diffusion in the solid phase. Kinetics are described via the Linear Driving Force (LDF) model with a lumped mass transfer coefficient; the adsorption equilibrium concentration is expressed via the Langmuir isotherm (single-component adsorption) and the Extended Langmuir Isotherm (binary mixture adsorption). Dynamic simulation results highlight the breakthrough behaviour of key VOCs and mixtures towards improved process efficiency.

Keywords: Process simulation, Volatile Organic Compound/VOC, emissions, adsorption

1. Introduction

Primary (upstream) pharmaceutical manufacturing is characterized by the consumption of large solvent volumes, key in reactions and separations: Volatile Organic Compounds (VOCs) are prominent but also problematic, as their high volatility at standard conditions has catastrophic effects on both human health and environment (Perez-Vega et al., 2013). Adsorption is an effective abatement method, exploiting the potential of porous materials for selective VOC capture (Yang et al., 2019); others (membranes, cryo-condensation, thermal/catalytic oxidation) can be costlier (Belaissaoui et al., 2016; Chung et al., 2019). Widely employed for high volumetric flows at low VOC concentrations (Das et al., 2004), adsorption offers high efficiency, low energy demand and easy installation/maintenance. However, adsorbent purchase and VOC-saturated bed regeneration costs pose challenges.

The present paper describes the use of a published fixed bed adsorption model to analyse the operation of an activated carbon bed for adsorption of VOCs from pharma emissions. The first-principles dynamic model is used to simulate adsorption of solvents and binary mixtures (methanol, ethanol, acetone, dichloromethane, chloroform, benzene, toluene). Specifically, the adsorbate mass balance describes the VOC concentration distribution between gas and solid phase in the fixed bed, the Linear Driving Force (LDF) kinetic model approximates VOC adsorption rate onto particles,

and the Langmuir isotherm is employed to quantify the adsorbate equilibrium distribution onto the solid carbon phase. Breakthrough curves for single-component and binary VOC system adsorption on various adsorbents can critically assist towards informed operational decisions in regard to raw feed handling (e.g. mixing, sequencing, conditions) to achieve OpEx cost minimization.

2. Dynamic Process Modelling: Assumptions and Structure

The mathematical model used in the present study relies on the following assumptions:

1. Isothermal conditions are ensured throughout the bed, with negligible pressure drop and constant fluid velocity due to low VOC concentrations considered (Das et al., 2004).
2. Radial concentration gradients and carrier gas adsorption are considered negligible.
3. The gas behaviour can be considered to obey the ideal gas law (Tefera et al., 2013).
4. The VOC mass transfer in the activated carbon bed considered for pharma emission treatment occurs by advection-dispersion in gas phase and by diffusion in solid phase.
5. The mass transfer rate in the solid phase is approximated by the LDF model which is characterized as “simple, analytical and physically consistent” (Sircar and Hufton, 2000).
6. Equilibrium obeys the Langmuir model for pure substances (Tefera et al., 2013) and the Extended Langmuir model (Jain & Snoeyink) for binary mixtures (Tefera et al., 2014).

$$q_{e,1} = \frac{(q_{m,1} - q_{m,2})b_1C_1}{1 + b_1C_1} + \frac{q_{m,2}b_1C_1}{1 + b_1C_1 + b_2C_2} \quad (13)$$

$$D_{ax,i} = \left(\alpha_0 + \frac{Sc_i Re_p}{2} \right) \frac{D_{AB,i}}{\varepsilon_b} \quad (14)$$

$$\varepsilon_b = 0.379 + \frac{0.078}{\left(\frac{D_b}{d_p} - 1.8 \right)} \quad (15)$$

$$D_{AB,i} = 10^{-3} T^{1.75} \frac{\sqrt{\frac{M_A + M_B}{M_A M_B}}}{P \left(\left(\sum \nu \right)_A^{0.33} + \left(\sum \nu \right)_B^{0.33} \right)^2} \quad (16)$$

$$-\Delta H_{ad,i} = 103.2 + 1.16a_i + 0.76\Delta H_{vap,i} - 3.87(IP_i) - 0.7\gamma_i - 26.19w_{mic} \quad (16)$$

$$\frac{\partial q_i}{\partial t} = k_{LDF,i} (\rho_p q_{e,i} - q_i) \quad (17)$$

$$C_i(z=0, t) = C_{0,i} \quad (17)$$

$$k_{LDF} = \frac{60\varepsilon_p C_{o,i} D_{eff,i}}{q_{o,i} \tau_p d_p^2} \quad (18)$$

$$C_i(z, t=0) = 0 \quad (18)$$

$$\varepsilon_p = V_{pore} \rho_p \quad (19)$$

$$q_i(z, t=0) = 0 \quad (19)$$

$$\tau_p = \frac{1}{\varepsilon_p^2} \quad (8) \quad \frac{\partial c_i}{\partial z}(z = L, t) = 0 \quad (20)$$

$$\rho_p = \frac{\rho_b}{1 - \varepsilon_b} \quad (9) \quad q_{o,i} = \rho_p q_{e,i} \quad (21)$$

$$\frac{1}{D_{eff,i}} = \frac{1}{D_{AB,i}} + \frac{1}{D_{k,i}} \quad (10) \quad Re_p = \frac{d_p V_s \rho_m}{\mu_m} \quad (22)$$

$$D_{k,i} = 97 r_p \sqrt{\frac{T}{M_A}} \quad (11) \quad Sc_i = \frac{\mu_m}{\rho_m D_{AB,i}} \quad (23)$$

$$q_e = \frac{q_m b C}{1 + b C} \quad (12) \quad V_s = \frac{4Q}{\pi D_b^2} \quad (24)$$

A short description follows: on Eq. (1) C , $D_{ax,i}$, u , ε_b , q are the gas phase VOC concentration (kg m^{-3}), axial dispersion coefficient ($\text{m}^2 \text{s}^{-1}$), interstitial velocity (m s^{-1}), bulk bed porosity and adsorbed phase VOC concentration (kg m^{-3}), respectively. Eq. (2) of Dantas et al. (2011) and Eq. (3) further introduce Sc_i , Re_p , $D_{AB,i}$, α_0 , D_b and d_p as the Schmidt number of component i , the Reynolds number (adsorbent particle), the molecular diffusivity ($\text{m}^2 \text{s}^{-1}$), the empirical mass diffusion correction factor (20), the internal bed diameter (m) and the (considered) unidisperse particle diameter (0.00075 m) respectively.

In Eq. (4), Σv is the atomic diffusion volume (A: VOC, B: air), T is temperature (K), P is pressure (atm) and M is molecular weight (g mol^{-1}). Eq. (5) features $k_{LDF,i}$ as LDF mass transfer coefficient (s^{-1}) and $q_{e,i}$ is the inlet PT adsorbent equilibrium capacity (kg kg^{-1}). In Eq. (6), ε_p , $C_{o,i}$, $D_{eff,i}$, $q_{o,i}$ and τ_p are the particle porosity, inlet concentration (kg m^{-3}) and effective diffusion coefficient of component i ($\text{m}^2 \text{s}^{-1}$), the concentration at the solid phase which is in equilibrium with C_o (kg m^{-3}), and the particle tortuosity, respectively. Eqs. (7)-(11) present ρ_p , ρ_b , V_{pore} , $D_{k,i}$ and r_p as particle/bed density (kg m^{-3}), pore volume ($\text{m}^3 \text{kg}^{-1}$), Knudsen diffusivity coefficient ($\text{m}^2 \text{s}^{-1}$) and particle radius (m) respectively.

Beyond the Eqs. addressing macroscopic phenomena, we need microscopic descriptions. Thus, Eqs. (12)-(15) introduce $q_{e,i}$, $q_{m,i}$, b_i , $b_{o,i}$, and $\Delta H_{ad,i}$ as the equilibrium and maximum adsorption capacity of component i (kg kg^{-1}), the Langmuir affinity coefficient ($\text{m}^3 \text{kg}^{-1}$), the pre-exponential constant ($\text{m}^3 \text{kg}^{-1}$) and the heat of adsorption (kJ mol^{-1}), respectively. Eq. (16) presents α_i , $\Delta H_{vap,i}$, IP_i , γ_i and w_{mic} as polarizability (10^{-24} cm^3), heat of vaporization (kJ mol^{-1}), ionization potential (eV), VOC surface tension (mN m^{-1}) and average micropore width (nm) respectively. Finally, Eqs. (22)-(24) provide dimensionless number definitions with V_s , ρ_m , μ_m and Q denoting the superficial velocity (m s^{-1}), system density (kg m^{-3}), system viscosity (Pa s) and volumetric flowrate ($\text{m}^3 \text{s}^{-1}$), respectively.

3. Dynamic Model Parameters for Adsorption Systems

The dynamic model is used to simulate VOC adsorption on activated carbon, as organic emissions from distillation and pressure filtration units occur during API manufacturing. The original set of PDEs is reduced to a set of ODEs using the Method of Lines for space (central finite difference) discretisation and subsequent solution in MATLAB v.

2020a. The adsorption of acetone, benzene and ethanol with air, as well as toluene with either air or N₂ as the carrier gas (Tefera et al., 2013; Delage et al., 2000) has been examined; we also explore adsorption of two binary mixtures (acetone-ethanol, toluene-ethanol) at the same (P = 1 atm, T = 300 K) conditions, on another (BAC) adsorbent (Tefera et al., 2014). Benzene and air are used for model validation purposes, not due to industrial relevance.

The system viscosities are determined through Wilke's equation (Dantas et al., 2011) for binary mixtures (air: T = 293 K, 300 K, VOCs: T = 293 K, 298 K, 300 K); moreover, system densities are computed from pure component data via mixing rules (NIST, 2020).

Air as a carrier is a binary mixture (N₂:O₂=79:21% v/v); x_{VOC} is the VOC molar fraction. Tables 1 and 2 summarise all essential parameter values for the determination of the axial dispersion coefficient ($D_{\text{ax},i}$) for all single components and binary mixtures, respectively.

Table 1: Parameters for axial dispersion coefficient calculation (single-component adsorption).

System	ρ_m (kg m ⁻³)	μ_m (Pa s)	Re	Sc	$D_{\text{AB},i}$ (m ² s ⁻¹)	x_{VOC}
Acetone–Air	1.95	$2.15 \cdot 10^{-5}$	62.17	1	$1.10 \cdot 10^{-5}$	0.001
Benzene–Air	2.04	$2.25 \cdot 10^{-5}$	62.15	1.19	$9.28 \cdot 10^{-6}$	0.001
Ethanol–Air	1.99	$7.62 \cdot 10^{-5}$	2.72	3.11	$1.23 \cdot 10^{-5}$	0.021
Toluene–Air	2.03	$2.25 \cdot 10^{-5}$	61.93	1.33	$8.35 \cdot 10^{-6}$	0.001

Toluene–Ethanol	0.0013	1	2.405	0.42	3412.18	0.38	0.00187	$1.87 \cdot 10^{-5}$
	0.0016	1	2.405	0.39	129.19	0.38	0.00094	$7.49 \cdot 10^{-4}$

4. Results and Discussion

Breakthrough curves of VOC components in all examined systems have been normalised by adsorbate inlet concentration and illustrated in Fig. 1, for acetone, benzene, ethanol, toluene (two carriers) and two binary mixtures (acetone-ethanol, toluene-ethanol). Dynamic model results have been validated vs. published experimental single-component breakthrough curves which dictated our inputs (Tefera et al., 2013; Delage et al., 2000). For all pure component adsorbates (air or N₂ carrier) and operating conditions considered, our computed breakthrough are found to be in great agreement with experimental data.

Benzene and toluene demonstrate similar adsorption (breakthrough onset and duration) behaviour, despite the differing LDF mass transfer coefficient values shown on Table 3; these observations are in excellent agreement with previous findings (Tefera et al. 2013).

Acetone, on the other hand, shows markedly earlier (and somewhat faster) adsorption. Ethanol also demonstrates fast adsorption (the fastest of all substances studied here), due to its high LDF mass transfer coefficient. The lower operating temperature (T = 293 K) used for comparison vs. experimental data (Delage et al., 2000) also affects breakthrough curve features, as adsorption is exothermic. Further investigating the magnitude of radial dispersion contributions but also the effect of non-isothermal operation for either pure or mixture feeds will provide significant benefits towards ensuring high VOC model fidelity. The carrier gas effect is examined by simulating toluene adsorption with N₂ vs. air: the axial dispersion coefficient is computed as 31% lower for the pure N₂ carrier gas case ($D_{ax}/N_2 = 0.0009$ vs. $D_{ax}/air = 0.0013$ m² s⁻¹), resulting in a steeper breakthrough curve.

Binary mixtures adsorbing on BAC appear very similar: ethanol breakthrough starts much faster than the other (acetone, toluene) component, as per its pure-component behaviour and due to favourable adsorption kinetics, and a likely weaker affinity for the adsorbent.

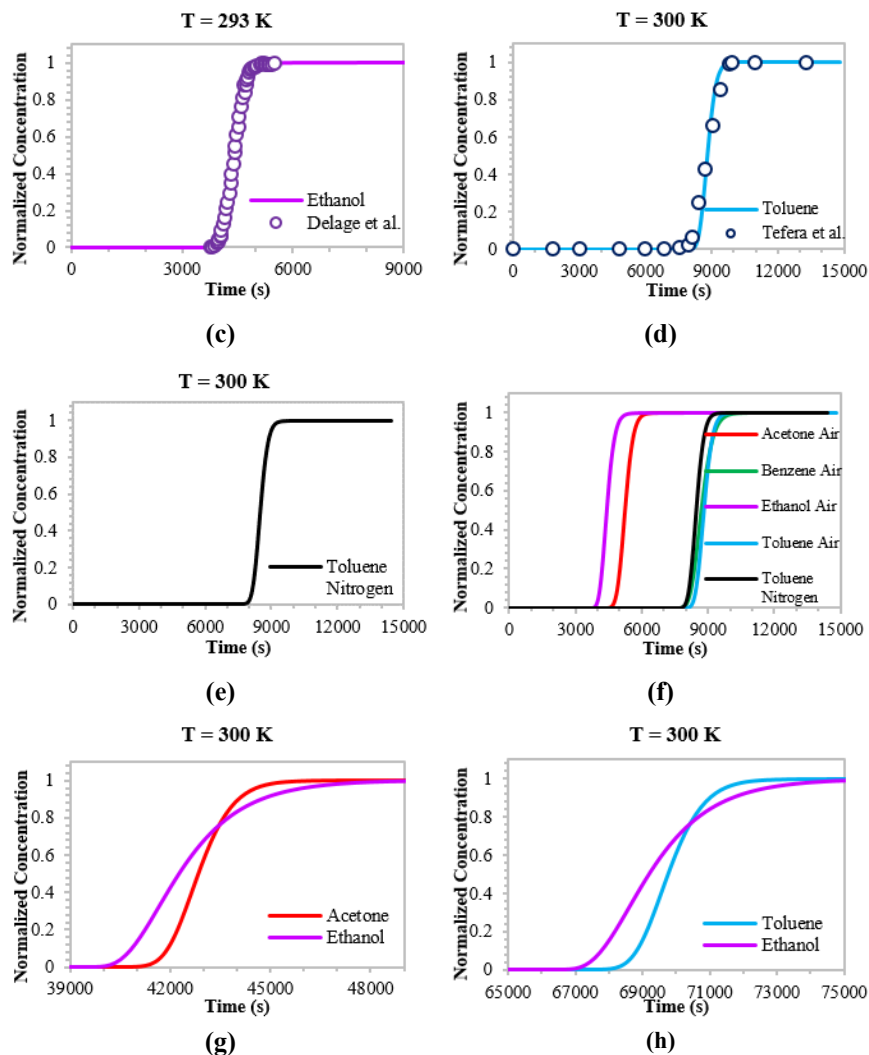

Figure 1. Breakthrough curves vs. published experiments (Tefera et al., 2013; Delage et al., 2000).

5. Conclusions

Upstream pharmaceutical manufacturing inevitably relies on significant solvent volumes for many (especially reaction/separation) uses, with great environmental repercussions. Efficiently capturing Volatile Organic Compounds (VOC) from pharma emission streams is a strategic priority for advanced manufacturing striving to embrace greener practices, hence inducing the research challenge of ensuring plant longevity and cost-effectiveness.

Adsorption of VOC pollutants on activated carbon beds is an industrially implemented solution for lowering emissions, so overcoming its efficiency limitations is a necessity. Modelling pharma solvent adsorption systems is tackled by many literature studies, yet without a concerted effort for a unified platform encompassing both technical (feed

variability, adsorption kinetics) and economic (maintenance, scheduling) problem vistas. This paper relies on an adsorption model for pharma VOC recovery, which considers axial dispersion and Linear Driving Force mass transport under isothermal conditions. Dynamic simulations of the adsorption behaviour of several VOC-air systems show clear differences between polar (acetone, ethanol) and non-polar (benzene, toluene) solvents. The binary systems examined demonstrated no competitive adsorption, which however may occur if multi-component raw organic streams are fed to the same adsorption bed. The vastly different breakthrough timescales (in the order of hours) vary by mixture composition but also by adsorbent (e.g. activated carbon vs. Picaktif vs. BAC) indicate that high-fidelity PDE models are critical for economically relevant process optimization.
