Abstract

Detailed process understanding of powder systems is important for ensuring regulation compliant manufacturing of pharmaceutical solid-based drug products. However, this can get challenging due to the current limitations in experimental and computational approaches, constraining the available knowledge of critical quality attributes. To address this drawback, we propose the use of computationally efficient and mechanistically informed surrogate models developed using multi-zonal compartmentalization methodology. In this work, the proposed modelling strategy is demonstrated for continuous powder blenders, wherein, first principle-based discrete element simulation is used to obtain an inter-connected network of zones for detailed evaluation of mixing within the system. The obtained surrogate models are further validated using the original simulation, illustrating the accuracy of the proposed methodology.

Keywords: multi-zonal compartmentalization, continuous pharmaceutical manufacturing, surrogate modelling, continuous powder blender, radial mixing.

1. Introduction

Given the significance of ensuring product quality of pharmaceutical solid-based drug products, the regulatory agencies like U.S. Food and Drug Administration have proposed several initiatives to guide and regulate drug product manufacturing. Quality-by-Design (QbD) (Yu et al. 2014) is one such initiative focusing on designing the process such that end product quality is maintained. However, to successfully implement this initiative, it is important to obtain detailed mechanistic information of the overall process. Several research efforts (Ierapetritou et al. 2016) over the past years have contributed towards this goal of improving process understanding of pharmaceutical unit operations through use of experimental and simulation techniques. However, for some unit operations like continuous powder blender, the experimental techniques like particle tracking (Portillo et al. 2010) can get very expensive to capture powder mixing within the blender. Furthermore, researchers (Muzzio et al. 1997) have observed difficulties like disruption of powder bed and identification of adequate number of samples while using experimental technique for measurement of powder

mixing through use of sampling probes. These challenges hinder the accurate assessment of radial mixing and blend uniformity which is a critical quality attribute. On the other hand, first principle-based simulation techniques like discrete element modelling (Cundall and Strack 1980) can get computationally intensive as it involves evaluation of particle contacts and contact forces for all particles at each time step. To address the above challenges for acquiring assessment of powder mixing within these systems in reasonable computation time, we propose the use of surrogate model using multi-zonal compartmentalization methodology for modelling pharmaceutical unit operations. In this work, the proposed methodology is demonstrated for continuous powder blender. The following sections highlight the details of the different techniques utilized in this work, followed by results of the compartmentalization methodology and model validation. Lastly, section 6 focuses on the conclusions of the proposed work.

2. Discrete element modelling

Discrete element modelling (DEM) is a first principle-based technique to simulate particle dynamics in powder systems using Newton's laws of motion and contact laws based on discrete particle physics. Details of the equations involved in DEM are described in literature (Dubey et al. 2011; Bhalode and Ierapetritou 2020b) and has been widely applied for powder systems (Ketterhagen et al. 2009). Following the construction of the desired geometry and addition of particles within DEM, this method involves detection of particle contacts, evaluation of contact forces and corresponding particle trajectories for all particles at each time step, thus making it computationally intensive. In this work, we implement DEM for simulation of continuous powder blender using Hertz-Mindlin contact model, wherein, we simulate a periodic section (Gao, Yijie et al. 2012; Bhalode and Ierapetritou 2020a) of the blender. Here, a central section of the blender is used with periodic boundaries to replicate the powder behaviour as observed in the blender. In this work, two types of spherical, cohesionless particles are added to the periodic section at the start of the simulation, with a total of 3000 particles for each particle type, and the periodic section is simulated for 20 seconds with a blade speed of 100 RPM.

3. Multi-zonal compartmentalization methodology for surrogate modelling

Multi-zonal compartmentalization methodology is a hybrid technique to model complex systems. This method captures multi-scale information using computationally efficient and mechanistically informed surrogate models, while combining systemic or global and local process information (Jourdan et al. 2019). It is widely used in literature for different applications like bioreactors, fluidized columns and crystallizers. Multi-zonal compartmentalization transforms a high-fidelity simulation like DEM model of a process unit into an inter-connected network of compartments, where individual DEM grids are classified into compartments, such that the process variables of interest of each compartment are maintained within user-defined tolerance limits. This inter-connected network acts as a computationally efficient surrogate, while replicating the observed process behaviour. In this work, we implement this methodology for the continuous powder blender to develop surrogate representation of the DEM model, which can later be incorporated within process flowsheets. The proposed methodology is illustrated in Figure 1, where we simulate a periodic section of the blender in DEM. This section is

divided into 10 slices along the axial direction, and each slice is further divided into 20x20 grids along Y and Z directions. The averaged particle velocities are extracted for all grids in these slices and compartmentalized into multiple zones. These zones include the empty zone where no particles are present, and filled zone where particles are present. The filled zone is further divided into compartments corresponding to particle velocities being greater than 0, equal to 0, less than 0 and the dead zone. This zoning strategy when applied to Y and Z directions is termed as radial compartmentalization and when applied to the X direction, is termed as axial compartmentalization.

Figure 1: Modelling strategy for multi-zonal compartment modeling of periodic section of the continuous powder blender, illustrating axial and radial compartmentalization

4. Results

4.1. Radial compartmentalization

Based on the averaged velocities of individual grids extracted from DEM, the radial compartmentalization is developed for each slice along Y and Z directions. The individual grids are categorized into '+1', '0' and '-1' zones based on their averaged velocities and radial compartments are obtained as shown in Figure 2A.

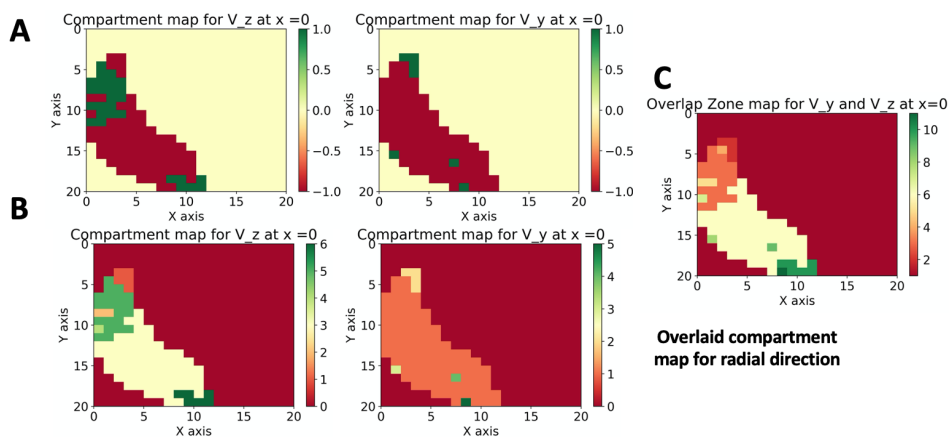

Figure 2: Radial compartment maps for slice $x = 0$. (A) the radial compartment maps for Y and Z directions, (B) corresponding distinct compartments for Y and Z directions, (C) the overlaid compartment map for radial direction.

Each compartment in the compartment maps is labelled separately to create distinct compartments as shown in Figure 2B. This is important for development of flowrates

(Delafosse et al. 2014) between the proposed inter-connected network of zones. The distinct compartments along Y and Z directions are combined to develop an overlaid compartment map (Tajsoleiman et al. 2019) for radial direction as shown in Figure 2, for slice corresponding to $x = 0$. Following the evaluation of overlaid compartment map, the inter-connection flowrates between compartments (F_{ij}) are evaluated using the interfacial area between compartments (A_{ij}) and averaged velocities of grids (v_i, v_j) along specific direction (k), as shown in Eq. (1) (Delafosse et al. 2014) where (i) and (j) correspond to different compartments. The flowrates are evaluated separately for Y and Z directions to convert the compartment map into an inter-connected network of zones.

$$F_{ij}(k) = A_{ij} * (v_i(k) - v_j(k)) \quad (1)$$

4.2. Axial compartmentalization

A similar strategy is implemented for axial compartmentalization of all slices along X direction in the periodic section. Here, the compartments are developed for each slice based on averaged velocities of grids along the X axis and categorized into compartments marked by '+1', '0', and '-1', as defined in section 3. The empty grids with no particles are classified into a separate section marked by '-2'. The axial compartment maps thus developed, are shown in Figure 3 for slices corresponding to $x = 0$ and $x = 1$. Following the axial compartmentalization, the inter-connection flowrates between these compartments are evaluated using Eq. (1), with interfacial area equal to the total area occupied by each compartment. The flowrates thus evaluated, provide forward and backward flows for each slice, resulting in a net forward flow of particles for the periodic section.

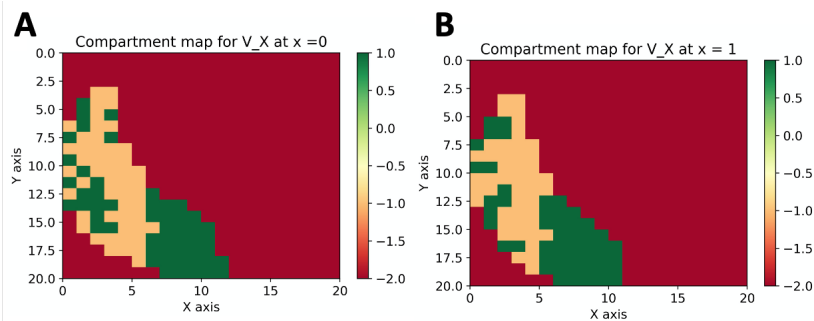

Figure 3: Axial compartments developed for slices $x = 0$ and $x = 1$ in the periodic section

Thus, combining the axial and radial compartmentalization strategies, we can obtain a surrogate model based on developing inter-connected network of zones, to simulate the powder flow as observed in original DEM model.

5. Validation of multi-zonal compartment model

5.1. Validation of radial compartmentalization

The proposed radial compartmentalization is validated based on the evaluation of powder mixing within the periodic section. In this study, a variance-based index,

relative standard deviation (RSD) (Gao, Yijie et al. 2012), is used to compare the surrogate model based on compartments with the original DEM model and evaluated using Eq. (2). For compartment model, C_i corresponds to the concentration of individual compartments, with C_{av} being the averaged concentration, and N equal to the total number of compartments. This equation is also applied to evaluate the RSD for DEM model where, C_i is the concentration of individual grids, with N being the total number of grids. Following the evaluation of RSD, T_{95} mixing time (Bhalode and Ierapetritou 2020a) is evaluated to obtain a quantitative comparison of the two models. This corresponds to the time it takes for the system to reach 95% of total mixing in the system, shown in Eq. (2).

$$RSD = \left(\frac{1}{C_{av}} * \sqrt{\frac{\sum_{i=1}^N (C_i - C_{av})^2}{N-1}} \right), T_{95} = \left(-\frac{1}{\gamma} \right) * \ln \ln \left(\frac{1-0.95}{A} \right) \quad (2)$$

Here, the mixing index profile is normalized, and the parameter estimation is performed to obtain A and γ . Following this, the T_{95} mixing time is calculated, as shown in Table 1, evaluated for different blade speeds. The low error margins validate the proposed strategy for radial compartmentalization.

Table 1: T_{95} mixing times for DEM and CM model

Blade speed	T 95 from DEM	T 95 from CM	Absolute relative error
50 RPM	14.812	14.5485	0.0178
75 RPM	12.366	12.129	0.0191
100 RPM	8.911	9.2684	0.0401

5.2. Validation of axial compartmentalization

The axial compartmentalization is validated based on residence time distribution (RTD) profiles (Gao, Yijie et al. 2012). The residence time profiles obtained from DEM correspond to the time it takes for all particles to travel from one end of the periodic section to another, calculated separately for both particle types (P1_DEM, P2_DEM), whereas the residence time for the surrogate model (RT_CM) corresponds to the time it takes for the particles to travel the length of the section based on averaged velocities extracted from the developed compartments. The obtained profiles shown in Figure 4 illustrate that the residence time of the surrogate model is fairly close to that obtained from DEM models, thus, validating the proposed axial compartmentalization strategy for surrogate models.

Figure 4: Residence time distribution profiles for validation of axial compartmentalization.

6. Conclusions

We propose the use of multi-zonal compartmentalization methodology for surrogate modelling of pharmaceutical continuous powder blender using periodic sections. A computationally efficient surrogate model consisting of inter-connected network of zones is developed for the DEM simulation, to quantify powder mixing within the system and validated with the original DEM using radial mixing time and axial residence time profiles. Thus, the proposed methodology is shown to capture axial and radial mixing of powder blender in a computationally efficient manner. For future work, we aim to integrate the proposed surrogate model within process flowsheets for integration of overall manufacturing lines.

Abstract

The description of materials in the context of thermodynamics is an essential part of the chemical engineer's models. The representation of thermodynamic relations is the objective of this study. By making use of ProMo variable/equation builder, we construct all the thermodynamics quantities based on the configuration space of contact geometry. The configuration space builds on the quantities internal energy (U), entropy (S), Volume (V) and mass species (n) adding the equations of state being the derivatives yielding the temperature, the negative pressure and the chemical potential.

ProMo expert domain provides the facilities to construct variable/equation sets from the conserved basic physical quantities, namely the ones defined above. It follows the strict rule of defining new variables as a function of existing variables. This ProMo building regulation is an excellent match to the contact geometry's fundamental approach to define thermodynamics. It generates a consistent set of variables and equations and provides a formal description that builds on pure mathematical terms. This mathematical representation also facilitates and simplifies automatic multiscale simulation modelling.

The use of well-defined variables and equations for the base ontologies system domain, facilitate an integrating factor for the application domain both for chemical engineers as well as the material multidisciplinary modelling community.

Keywords: Multidisciplinary and multi-scale simulations, Ontology-based framework, ProMovariable/equation builder

1. Introduction

Nowadays, having a generic stand-alone software for modelling and simulation (digital twin), data-driven reasoning, and knowledge-guided decision making are considered a significant success which will bring a digital revolution into industrial science and technology. Such platform optimises the dependence on trial and error based experimentation cycles for implementation in products and for manufacturing chemical processes development. Besides, it will accelerate and facilitate the integration of process and material design which is leading to plant and product design. However, the automation and industrialisation of this approach have many challenges to master.

Models are usually used to mimic and map the behaviours of a system into objects. It also gives freedom to the mind, allows tampering and testing, playing with what could become

real before it has real-world consequences beyond the use of modelling and simulation time. Models are thus central to any exploratory work that has the objective to exploit the object's behaviour.

However, the modelling term is highly knowledge-intensive activities (nearly all engineering and science activities) which covers a wide range of contexts from chemical engineering and more specifically, process systems engineering to manufacturing materials engineering. Models are multi-scale, and multi-dimensional capturing a variety of physical phenomena from classical mechanics and thermodynamics to quantum mechanics. Therefore for the integration of process and material design, selecting the right physical domain, scale, dimension, and parameter, besides, to guarantee the interoperability proper linking across the multi-scale models is not an easy task. Latter raises also the question of interoperability when realising the computational code.

There also exists a gap in modelling and simulation, which demands the representation and coupling of knowledge. Recently digitalisation of the industries increases the need for multidisciplinary simulation, thereby generating a demand for an extension towards the integration of different disciplines. Ontologies provide a perfect vehicle for the representation and coupling of knowledge. So the first important step is to introduce ontologies on all levels of the broader domain of simulation software systems, and to construct a generic simulation ontology-based framework. Because the used models and relations are mathematical descriptions of reality, the theoretical concepts of such frameworks are captured in the discipline-specific ontologies. In this respect, the use of well-defined variables and equations for the base ontologies system domain, facilitate an integrating factor for the application domain both for chemical engineers as well as the material multidisciplinary modelling community [6, 3].

ProMo, which is overarching the above concepts, is the focus of this paper. It is a software suite that realises an ontology-based computational engineering environment. It has a capability to provides the modelling and simulation of large and complex, multi-scale, multidisciplinary, and dynamic processes.

In this letter, the representation of thermodynamic relations by making use of **ProMo** is studied in detail. We also will see the correlation between the **ProMo** expert domain and the **ProMo** building domain.

- Section. 2 introduces a general review on **ProMo** and its objective. Moreover, an overview of the different parts of **ProMo** is provided.
- Section. 3 provides a brief explanation of the **ProMo** base ontology editor.
- Section. 4 illustrates how we construct all the thermodynamics quantities based on the configuration space of contact geometry by making use of the **ProMo** variable/equation builder.
- Section. 5 wraps up this manuscript with some concluding remarks.

2. The ProMo process modelling suite – an overview

ProMo is constructed on a series of modules, each of which considers as separate tasks (executable program, App, or application). Its design enforces a context-free approach,

which means, there is no loop in the definition space, but knowledge is built in a strict sequence: "Things" are put strictly on top of each other requiring a tiny set of fundamental "things". Besides, **ProMo** consists of three sets of tools, **expert**, **translator**, and **user**, which stay in contact with each other due to the transformation of information via directed graph structure.

ProMo consists of three sections, namely a section for generating the ProMo ontology, a section dedicated to generating process models, and a section that aims at the simulation and its utilisation [7, 8, 9]. **ProMo** not only create simulation code, but it also provides the base models as an extension to the EMMO (European Materials Modelling Ontology) in Ontology Web Language OWL form. It, in turn, can be fed into the Semantic Network providing the information to construct the software components automatically realising inter-task interoperability.

The **expert**'s section first constructs the ProMo base ontology. Then, in the second stage, adds the variable/equation system to the ontology-defined domain spaces to capture the mathematical behaviour of the disciplines' base entities. The third module links the now-defined entity models to graphical elements, which the **translator** uses with the graph-based visual editor of ProMo's second section.

The second section aims at the **translator** assists with the assembly of a process/material model given the set of base building blocks. Any composed model can be made part of the model library thereby extending the library of basic entity behaviours with composite models, and the task-building process generating the application simulating the modelled process. The instantiation tool adds the numerical information specifying a case, thereby defining a mathematical/numerical problem.

The third is for the **user** who will finally map the model into an executable code by **ProMo**'s task factory producing the digital twin. The user can then change the simulation conditions, but not the process structure.

3. ProMo's ontology builder

It is essential to structure the ontology hierarchically so that the knowledge is inherited down into the branches. In this way, domain ontology act as a vehicle to capture the knowledge of the interested domain. This is only possible when the ontology structure has the right form in a specific domain. The right design here means domain tree structure, as discussed above. Figure. 1 shows a hierarchical domain structure generated by the ProMo ontology editor. With this design, we make sure that integration and exchanging of the information is controlled [9].

It is the domain **experts producing** who produce the entity blocks for the different disciplines. It starts with the definition of the taxonomy and the structure captured in the **ProMo** base-ontology (see fig. 1) thus defines the syntax for the **ProMo** suite.

ProMo two global types of variable classes: (i) one of the type port variables, (ii) one that derives from port variables. The set of port variables is the base set of the fundamental variables, including constants, in the specific area of physics, which allows the expert to build all of the physics equations as a function of these variables. We build our entity-behaviour ontology for physical process based on classical mechanics, thermodynamics,

Figure 1: A graphical representation of the domain tree

particle physics, and quantum mechanics.

ProMo's ontology editor also generates all the containers for the variable/equation multi-bipartite graph and the indices. Indices play a main role in the **ProMo**. We define indices for nodes and arcs as well as for the tokens, which in the case of physics, are the conserved quantities. Further, indices capture the existing conversions and species. Product sets are used where variable-length index sets appear, like for species in nodes or arcs, etc [5].

From this perspective, by making use of ProMo variable/equation builder, we can now take a look at the construction of all the thermodynamics quantities based on the configuration space of contact geometry.

4. ProMo's equation editor

ProMo's **expert** section provides the facilities to construct variable/equation sets from the conserved basic physical quantities. The equation editor implements the strict rule of defining new variables as a function of existing variables based on a (minimal) set of defined port variables. The result is a consistent set of variables and equations that provide a formal description that builds on pure mathematical terms. The ProMo building regulations are an excellent match to the contact geometry's fundamental approach to define thermodynamics.

To construct the variables and equations, one first has to choose the domain in the ProMo domain tree. The ProMo ontology implements an inheriting policy: each variable defined on the selected level is inherited into the branch below. The process starts with the definition of the port variables. For each of them, the physical units and the dimensionality inform of index sets are defined. The expert defines a new variable as a function of existing variables. The editor disables the use of not-existing variables. Each operator is designed to compute the units and the dimensionalities following a rule defined for each

operator. This construction rules impose a lower-triagonal variable/equation structure with consistent variable dimensions and units. Some mathematical entity models require the solution of implicit equations. ProMo sets the rule that the expert has to define first an explicit expression for the new variable. Only in a second stage, a second equation can be added for this variable, which is a solution to a root computation. This approach resolves the problem of keeping consistency for both the units and the dimensionality of the variable.

4.1. Thermodynamics configuration space

There exist an analogy between classical mechanics and thermodynamics. Such that the equations of state are first-order partial differential equations, which are defining the thermodynamics mathematical models of the system and they are pretty similar to Hamilton's equations. Therefore classical mechanics and thermodynamics have both symplectic structures. With this resemblance in mind, we can construct the thermodynamics configuration space on the quantities internal energy (U), entropy (S), Volume (V) and mass species (n) adding the equations of state being the derivatives yielding the temperature, the negative pressure and the chemical potential [4, 2, 1]. By making use of the contact geometry concept, one can write the configuration space as:

$$U = (S, V, n, T, -p, \mu) \quad (1)$$

where $T = \frac{\partial U}{\partial S}$, $p = -\frac{\partial U}{\partial V}$, and $\mu = \frac{\partial U}{\partial n}$ indicate temperature, pressure, and chemical potential respectively. With this in mind, we can define the thermodynamics potentials as follows.

Enthalpy is obtained as:

$$H = U + pV \quad (2)$$

Helmholtz free energy is written as:

$$F = U - TS \quad (3)$$

Gibbs free energy is defined as:

$$G = H - TS \quad (4)$$

Grand potential is obtained as:

$$\phi = F - \mu n \quad (5)$$

Maxwell relations are given by:

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V, \quad \left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p \quad (6)$$

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial S}{\partial V}\right)_T, \quad \left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial S}{\partial p}\right)_T \quad (7)$$

In this way, we can describe the thermodynamics behaviour of materials and processes in details by generating the variable/relation (equation) system based on the port. In this

letter, the thermodynamics port variables are (U, S, V, n) , which we declare as of class "state variables". Next we generate the equations for $(T, -p, \mu)$ as a function of the just-defined state variables and port variables and declare them belonging to the class effort variables¹. Once we defined state variables and their units and indices, we cannot change them as the whole equation system will build on them. Once we have defined the right-hand-side expression defining the declared variable, it will be compiled. The compiler computes the units and indices. If compilation fails, the expression is rejected and the user is informed about the detected problem. With this sophisticated method, we can build all thermodynamics equations based on the minimum set of port variables.

ProMo compiler can compile all variables and equations into Matlab, python, C++, as well as generating OWL file for variables and relations. Besides, it compiles a Latex file to show the documented results.

5. Concluding remarks

In this letter, we have studied how to build and modify the thermodynamics variable/equation system based on configuration space methodology. In the physics domain, the port variables are the base variables for defining the configuration spaces of the mechanical and thermodynamic systems. The former is governed by the Hamiltonians and the latter by Contact Geometry. The construct will provide a solid fundamental framework of variables and equations. The approach guarantees proper propagation of physical units and dimensionality of the mathematical object. It also defines for each variable an input/output representation, which we allow to be substituted by any alternative model, thereby enabling surrogate models.

Multi-scenario Design Optimization using ADMM of a Thermal Energy Storage System

Sandeep Prakash,^a Dinesh Krishnamoorthy,^a Johannes Jäschke^{a*}

^a*Norwegian University of Science and Technology, Trondheim 7050, Norway*

johannes.jaschke@ntnu.no

Abstract

Using nonlinear models to represent multi-scenario design optimization problems can lead to very large NLPs that can become intractable to be solved centrally due to the available memory in the computing device used. In this paper, we consider a simple but general approach for partitioning the large problem into smaller NLPs by adding consensus constraints. A distributed algorithm is then developed by applying the Alternating Direction Method of Multipliers (ADMM) to solve the partition problems separately and overcome this memory limitations. The approach is demonstrated using a simple case study and compared against the solution obtained by solving the problem centrally.

Keywords: ADMM, thermal energy storage, optimal design.

1. Introduction

Thermal energy storage (TES) systems help manage the asynchronous behaviour between supply and demand of thermal energy that occur in many industrial processes. They store excess energy during off-peak periods and discharge it during peak demand, thus reducing reliance on external utilities and decrease operating costs. During the design stage, the profiles for the supply and demand for energy under which the system is expected to operate in are uncertain and needs to be accounted for. This uncertainty can

be represented by a set of discrete scenarios $S := \{1, \dots, S\}$ with cost weights ω_s to represent the likelihood of scenario s being realized. Stochastic programming approaches can be used to cast the optimal design problem as a two-stage optimization problem where

the design variables w^{des} are first-stage (here and now) decisions while the operations variables w_s^{oper} are second stage (wait and see) decisions for each scenario (Thombre et al., 2020).

The dynamics of the system in each scenario can be discretized into N equally spaced sampling intervals represented by the set $K := \{0, \dots, N-1\}$ and the optimal design problem cast as an NLP in the centralized form as ()

$$\min_{w^{des}, w^{oper}} \phi^{capex}(w^{des}) + \sum_{s \in S} \omega_s \left[\sum_{k \in K} l(x_{k,s}, u_{k,s}) \right] \quad (a)$$

$$s.t \quad g(x_{k,s}, u_{k,s}, \theta_{k,s}, w^{des}) \leq 0 \quad \forall k \in K, \forall s \in S \quad (b)$$

$$x_{k+1,s} = h(x_{k,s}, u_{k,s}, \theta_{k,s}, w^{des}) \quad \forall k \in K, \forall s \in S \quad (c)$$

$$x_{0,s} = x_0 \quad \forall s \in S \quad (d)$$

The vectors x , u and θ represent the differential states, control inputs applied to the plant during operations, and time-varying parameters respectively. The subscript $(\cdot)_{k,s}$ is used to represent the s^{th} scenario at timestep k while the initial condition for all scenarios is x_0 . We define the operations variable for scenario s built by stacking the vectors in each timestep k as, $(w_s^{oper})^T := [(x_{0,s})^T, \dots, (x_{N,s})^T, (u_{0,s})^T, \dots, (u_{N-1,s})^T]$. Functions $\phi^{capex}(\cdot)$ and $l(\cdot)$ represent the capital costs and operating costs. The function $g(\cdot)$ represents inequality constraints and function $h(\cdot)$ is used to represent the dynamics of the system. When considering many scenarios and longer time horizons, solving the optimal design problem in the central form as in (b) can become computationally intractable due to the limited memory available in the computing device used. In this paper, we explore the option of dividing this problem into smaller partition problems which can be solved separately by multiple smaller machines to overcome the memory limitations. The partition problems are then solved iteratively with a coordination step in between to reach a solution to the central problem.

2. Methodology

2.1. Reformulating the design problem as a general form consensus optimization problem

We can divide the two-stage dynamic optimization problem into P partitions denoted by the set $P := \{1, \dots, P\}$ in a very flexible manner. For example, besides considering each scenario as a partition, we could also form partitions within the prediction horizon of a particular scenario, or bundle together similar parts from multiple scenarios into a partition. Each partition p then is a separate optimization problem with its own local variables for design (w_p^{des}) and operations (w_p^{oper}) and can be solved separately. An illustration of a problem with 2 scenarios divided into 6 partitions is shown in Figure 1.

Figure 1: Illustration of dividing the optimal design problem with 2 scenarios into 6 partitions.

The solutions from the individual partitions put together is a solution to the centralized problem () when,

- All the partitions achieve consensus between their local design variables
- Adjacent partitions achieve consensus of the differential state variables shared between them (at the edge of the partitions)

We introduce a global copy of all the variables that must reach consensus into a vector ν and the consensus requirements can then be imposed as a constraint in each partition p . We can thus write the optimal design problem as a sum of smaller partition problems that are linked with consensus constraints as,

$$\min_{w_p, \nu} \sum_{p \in P} \Phi_p^{capex}(w_p^{des}) + \Phi_p^{oper}(w_p^{oper}) \quad (a)$$

$$s.t \quad g_p(w_p^{oper}, \theta_p, w_p^{des}) \leq 0 \quad \forall p \in P \quad (b)$$

$$h_p(w_p^{oper}, \theta_p, w_p^{des}) = 0 \quad \forall p \in P \quad (c)$$

$$w_p^{des} - \nu^{des} = 0 \quad \forall p \in P \quad (d)$$

$$A_p w_p^{oper} - B_p \nu^{oper} = 0 \quad \forall p \in P \quad (e)$$

$$w_p^T = \left[(w_p^{des})^T, (w_p^{oper})^T \right] \quad \forall p \in P \quad (f)$$

A_p and B_p are selection matrices used to link a subset of the local variables of partition p to the corresponding sections in the global copy ν . The objective function terms in the partition problems are chosen appropriately to add up to the original objective in ().

2.2. Applying ADMM to get a distributed algorithm

The individual partition problems in () are not trivially separable due to the presence of constraints that enforce the consensus condition. We can solve this problem in a distributed approach using ADMM as described below. The primal residual of the constraints (d) and (e) can be denoted using the vector r_p as,

$$r_p = \begin{bmatrix} w_p^{des} - v^{des} \\ A_p w_p^{oper} - B_p v^{oper} \end{bmatrix} \quad \forall p \in \mathbf{P}$$

The partial augmented Lagrangian (AL) function of () can be formed by relaxing these constraints and adding it to the objective as,

$$L_R(w_p, v, \lambda_p) = \sum_{p \in \mathbf{P}} \Phi^{capex}(w_p^{des}) + \Phi_p^{oper} + (\lambda_p)^T r_p + \frac{1}{2} (r_p)^T R (r_p) \quad ()$$

The vector $(\lambda_p)^T := \left[(\lambda_p^{des})^T, (\lambda_p^{oper})^T \right]$ is built by stacking lagrange multipliers associated with the consensus constraints and R is a symmetric positive definite matrix. The AL function is additively separable except for the quadratic penalty terms. The

ADMM algorithm involves solving the partition problems while keeping v and λ fixed and then updating them by keeping the local variables w_p fixed in an alternating fashion until convergence. The i^{th} iteration of the ADMM algorithm thus takes the form

$$(w_p)^{i+1} = \arg \min_{w_p \in W_p} L_R(w_p, v^i, \lambda_p^i) \quad \forall p \in \mathbf{P} \quad (a)$$

$$(v)^{i+1} = \arg \min_v L_R(w_p^{i+1}, v, \lambda_p^i) \quad (b)$$

$$(\lambda_p)^{i+1} = (\lambda_p)^i + R (r_p)^i \quad \forall p \in \mathbf{P} \quad (c)$$

Step (a) involves solving an optimization problem for each partition while the global variable is kept constant. This is the computationally expensive step in the approach but can be solved using separate machines and in parallel to speed up convergence. Step (b) is the minimization of the AL function while the local variables in partitions are kept constant. This step for consensus problems reduces to finding the minimum of a quadratic function and can be shown to be the averaging operator (Rodriguez et al., 2018) as,

$$v^{j+1}(j) = \frac{1}{|\mathbf{P}_j|} \sum_{p \in \mathbf{P}} w_p^{j+1}(j)$$

where $\mathbf{P}_j \subseteq \mathbf{P}$ denotes the set of partitions connected to the j^{th} element of the global variable. Step (c) is the update to the lagrange multipliers of consensus constraints and can be carried out in each partition separately. The termination criteria for ADMM

iterations are that primal residual (r^{i+1}) and the dual residuals $(s_p^{i+1} = (\lambda_p)^{i+1} - (\lambda_p)^i)$ be reasonably close to zero as explained in Boyd et al. (2010).

3. The TES Design problem

We use flowsheet in Figure 2 to represent the heating section of a district heating network, where water is used in a closed-loop to satisfy the heating requirement in an area.

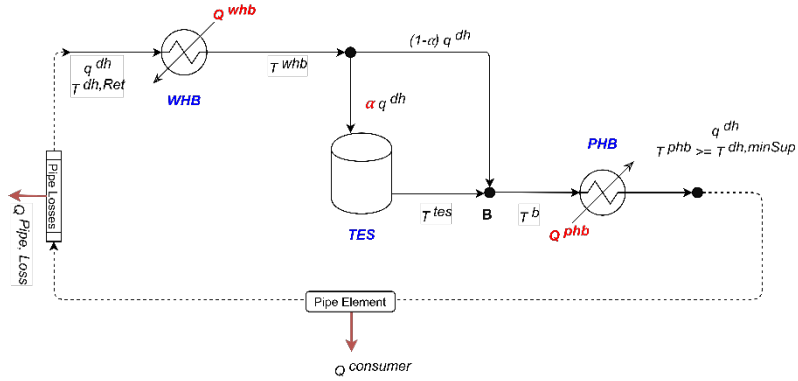

Figure 2: Simplified flowsheet of a district heating system.

The volumetric flow rate of water in the loop is q^{dh} which is determined by the number of consumers and their heating demands at any time. The temperature of water returned is $T^{dh,Ret}$ and determined by the heat losses in the system and is assumed to be correlated to ambient weather conditions. The operational objective of the heating system is to heat this water to a temperature T^{phb} that must be above a contractually specified temperature $T^{dh,minSup}$. A cheap source of heat is available from a process stream in an industrial process that needs to be cooled. It transfers heat to the district heating system using the heat exchanger WHB. Any additional heating required in the district heating side is met by using the peak heat boiler PHB. There is a temporal mismatch in the supply of heat from the process stream and the demand for heating from the consumers. To better manage this mismatch and decrease the reliance on external utilities, a thermal energy storage system in the form of a simple buffer tank is being considered. This simple TES system can charge/ discharge by raising/ lowering the temperature of the tank by manipulating the flow split α .

Mass and energy balance equations can be written out to model the dynamics of the system, details of which and the parameters used can be found in Prakash (2020). The differential states are $x^T = [T^{whb}, T^{tes}, T^{phb}]$ and the control inputs $u^T = [\alpha, Q^{phb}, Q^{dc}]$ and the uncertain parameters at each time step k are $\theta_k^T = [q_k^{dh}, T_k^{dh,Ret}, Q^{whb}]$. The design

problem is then to find the optimal volume of the TES tank (V^{tes}) that must be installed, given the uncertain profiles of future supply and demand of thermal energy.

4. Results and Discussions

We present a simulation study to demonstrate the distributed approach and compare it against solving the design problem as a single NLP centrally. Two equally likely scenarios are used to represent future operations (with $N = 60$). The profiles for Q^{whb} has a step change at timesteps $k = 20$ and $k = 40$, while all other parameters are held constant.

Quadratic functions are used to represent capital cost $\phi^{capex} = 0.001(V^{tes})^2$ and the operating cost $l = (Q^{phb})^2$. The design variables and operations variables were all scaled to be within zero and one while formulating the optimization problem. Scaling facilitated selecting the AL penalty parameters in R to tune the convergence in our distributed approach more easily. The penalty parameter influences the convergence speed of ADMM when applied to convex problems. In the case of nonconvex problems, poorly chosen values of this penalty parameter can make convergence harder or can even prevent convergence altogether. We use a diagonal matrix for R (with values 0.001 and 0.1 corresponding to the design and operation variables respectively) to roughly balance the magnitudes of the original objective and the added penalization term at the initial guess.

Figure 3: Results from solving the design problem centrally vs distributed approach.

In Figure 3, we can see that the primal and dual residuals become sufficiently small in the ADMM algorithm, indicating the convergence in our distributed approach. The optimal design variables can be seen to converge to the same solution as found by solving the problem centrally. An important point to note is that this behavior is not guaranteed by ADMM in the case of nonconvex problems. When applied to nonconvex problems, ADMM need not converge and even when it does converge, it need not converge to an optimal point and must be hence considered just as another local optimization method (Boyd et al., 2010). Although the convergence guarantees for ADMM in the case of complex nonconvex NLPs are poorly understood, it has been shown to perform satisfactorily in practice (Rodriguez et al., 2018). Three snapshots of the optimal differential state trajectory T^{tes} in the partitions of scenario 1 are shown in Figure 4.

Figure 4: Snapshots at ADMM iterations ($i = 1, 10, 100$) in the partition problems.

An interesting observation in our approach is that all partitions apart from the leftmost partition has the initial condition of the dynamic optimization problem as a variable. Thus in Figure 4, we can see that during the initial iterations (left subplot), the optimal solution is to initialize the TES tank at a high temperature. The penalization terms added are then

updated to close the gap between the partitions and achieve consensus (middle and right subplots). In this aspect our approach shares similarities to the multiple shooting (MS) approach in dynamic optimization. The key difference is that MS is solved centrally and the state continuity (consensus constraint) is enforced explicitly as an equality constraint by the solver. We solve it in a distributed way where the consensus constraint is relaxed by forming the AL. The ADMM iterations are then able to enforce this constraint implicitly by minimizing the AL.

5. Conclusion

In this paper, we presented the optimal design of a simple TES system under uncertainty as a two-stage nonlinear dynamic optimization problem. Due to limitations in memory of solving the problem centrally in a single machine, an approach for forming smaller partition problems in a general fashion was shown. The ADMM algorithm was applied to coordinate between the subproblems which could be solved separately and in parallel. A simple simulation exercise was used to demonstrate the approach.

Abstract

Calibration of the wastewater treatment plant (WWTP) models is a challenging task, because reliable collection of measured data and good process knowledge are required in each particular case. This research presents the case study of a Romanian municipal WWTP with the Anaerobic-Anoxic-Oxic (A²O) configuration. Activated Sludge Model No. 3 (ASM3) is the core of the developed WWTP model. The proposed WWTP model calibration methodology assumes the selection and computation of a set of influent variables, associated to a group of process and settler parameters, such as they fit the model predictions to the plant measurements. The objective function used for calibration consists in the absolute difference between the measured and model predicted effluent data and its constrained minimization finds the decision variables as calibration targets. Three optimization approaches were selected and investigated: genetic, genetic-hybrid and multiobjective Pareto algorithms. The calibration performance of the different optimization methods was evaluated and compared. The genetic-hybrid optimization method showed the best performance as the model predicted data approximates well the effluent measured data both in steady and dynamic state. The properly calibrated WWTP model was complemented with nitrification and denitrification control loops, aimed to improve the municipal WWTP operation by enhancing the effluent quality and reducing the aeration and pumping energy.

Keywords: wastewater treatment, ASM3 modelling, calibration, optimization algorithms, control.

1. Introduction

Activated sludge technology is one of the most reliable and efficient purification methods used at the municipal wastewater treatment plants. This technology requires the presence of heterotrophic and autotrophic microorganisms for achieving the removal of carbon, nitrogen and phosphorus pollutants emerged from the household and industrial activities. The demands of the continuously stricter effluent regulation limits

and the need of reducing the operation costs ask for the development of efficient operating solutions. They are effectively investigated by complex modelling tools and new solutions are implemented by efficient control systems (Hauduc et al., 2013). Mathematical models support the understanding of the complex processes occurring at the wastewater treatment plants, the operators training and the elaboration of the control strategies (Ostace et al., 2011). Activated Sludge Models (ASMs) describe the bio-chemical process, while the Benchmark Simulation Models (BSMs) complement the physical separation processes taking place at the municipal WWTPs (Rieger et al., 2013). Activated Sludge Model No. 3 (ASM3) describes the organic carbon removal, the nitrification and denitrification processes, rectifying some weak points of the Activated Sludge Model No. 1 (ASM1). According to the ASM3, the growth of heterotrophic biomass is achieved in two steps: in the first step biodegradable substrate is stored as internal storage products and in the second step these internal cellular storage products are consumed for the growth of heterotrophic microorganisms (Gujer et al. 1999). The WWTP models need to be calibrated, because the influent wastewater concentration and flow rate profiles, associated to the geometrical characteristics of the purification units, vary from one WWTP to another (Mannina et al., 2011). Various nitrification and denitrification control configurations are investigated and applied at the municipal WWTPs (Várhelyi et al., 2019). Two main control loops are considered to control the dissolved oxygen (DO) concentration in the biodegradation tanks, by manipulating the air flow rate, and to control the nitrates-nitrites concentration in the anoxic basin, by acting on the flow rate of nitrate recirculation from the aeration tanks (Gernaey et al., 2014). This paper presents the calibration of the Anaerobic-Anoxic-Oxic (A²O) ASM3-based WWTP model by comparing the performance of three optimization methods: genetic, genetic-hybrid and Pareto multiobjective algorithms. They are followed by the implementation of the nitrification and denitrification the control system.

2. Municipal WWTP model

The developed municipal WWTP model comprises a nonreactive primary settler relying on Otterpohl primary clarifier model equations, five bioreactors (anaerobic, anoxic and three aerobic units) incorporating the biological equations of ASM3 and a nonreactive secondary settler described by the double-exponential velocity function settling model of Takács. The A²O layout of the municipal WWTP, with its anaerobic and anoxic reactors, is considered with the particular position of nitrate recirculation flow rate for transporting nitrates and nitrites from the aerobic zone into the anoxic bioreactor. The WWTP model was built in Matlab software and the Simulink graphical extension. For reducing the simulation time, the process equations were written in C programming language and were incorporated as compiled C files in Simulink S-function blocks.

3. Methods

3.1. Proposed calibration approach

The proposed calibration approach consists in five main steps: i) defining the calibration goals, targeted model variables and parameters, ii) collecting and analysing the construction and process measured data, iii) developing and software implementing the ASM3-based WWTP model, iv) calibrating the model in steady state, using different optimization methods, v) evaluating the calibration performance in steady and dynamic

state. The main calibration goal was to fit the model predicted effluent data to the effluent data measured at the municipal WWTP. The main pollutant components concentration in the influent and effluent streams, associated to the influent stream, recirculation and air flow rates, were measured with online sensors and were reconciled with laboratory measurements. The measured data was collected during May 2016 and the data set of the first 22 days of the month was considered for the WWTP model calibration (Simon-Várhelyi et al., 2020). In the calibration step the optimization problem was formulated and 10 decision variables containing four influent variables concentration (denoted as x_1 to x_4), three process parameters (x_5 to x_7) and three settler parameters (x_8 to x_{10}) were chosen in order to be calibrated. They were: readily biodegradable organic substrates (S_S , x_1), inert particulate organic material (X_I , x_2), heterotrophic biomass (X_H , x_3), nitrifying biomass (X_A , x_4), storage rate constant (k_{STO} , x_5), dissolved oxygen saturation constant (K_{O_2} , x_6), autotrophic maximum growth of the nitrifying organisms (μ_A , x_7), hindered zone settling parameter (r_h , x_8), flocculent zone settling parameter (r_p , x_9) and non-settleable fraction (f_{ns} , x_{10}). As objective function ($objfunc_{total}$) it was considered the weighted sum of the absolute differences between the effluent measured data and effluent model predicted data for: soluble part of the chemical oxygen demand (COD_{sol}), nitrates and nitrites (S_{NOX}), free and saline ammonia (S_{NH_4}) and total suspended solids (X_{SS}) concentrations. The lower (LB) and upper bounds (UB) of the decision variables were defined based on literature-scrutinized values. Equations (1-8) describe the proposed optimization problem, as they were formulated for the WWTP model calibration.

$$\min_X [objfunc_{total}(x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9, x_{10})] \quad (1)$$

$$X = [x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9, x_{10}] \quad (2)$$

$$objfunc_{total} = objfunc_{COD_{sol}} + objfunc_{NOX} + 10 \cdot objfunc_{NH_4} + objfunc_{SS} \quad (3)$$

$$objfunc_{COD_{sol}} = abs(COD_{sol,eff,measured} - COD_{sol,eff,simulated}) \quad (4)$$

$$objfunc_{NOX} = abs(NOX_{eff,measured} - NOX_{eff,simulated}) \quad (5)$$

$$objfunc_{NH_4} = abs(NH_4_{eff,measured} - NH_4_{eff,simulated}) \quad (6)$$

$$objfunc_{SS} = abs(SS_{eff,measured} - SS_{eff,simulated}) \quad (7)$$

$$LB \leq X \leq UB \quad (8)$$

The calibration was performed using three different optimization algorithms. The genetic algorithm optimization approach was the first tested method. It was based on the *ga* Matlab function. The second considered method was the genetic-hybrid algorithm, as it combines two optimization methods, i.e. the genetic algorithm and the classical algorithm. The *hybrid* Matlab function was used for its implementation. The third investigated optimization method was the multiobjective optimization, which finds the Pareto solutions using the genetic algorithm. The *gamultiobj* function of Matlab was implemented. For each of the three optimization methods, the calibration was performed in steady state using the same objective function and constraints. The best calibration results were selected, implemented in the model and further tested by performing dynamic simulations. The WWTP dynamic model behaviour was compared with process measured data, based on a 10 minutes sampling time evaluation approach.

3.2. Proposed control approach

The calibrated ASM3-based WWTP model was complemented with two feedback control loops having Proportional-Integral controllers, as presented in Figure 1. The first one is intended for the nitrification (aeration) control, while the second one is implemented for the denitrification control. This control design also achieves the removal of carbon and phosphorous pollutants. Control of the aeration is based on the DO concentration control in the last aerated bioreactor. The manipulated variable is the air flow rate introduced in the aerobic bioreactors. The second control loop aims the control of nitrates and nitrites concentration (S_{NOx}) in the anoxic bioreactor by manipulating the nitrate recirculation flow rate.

Figure 1. The proposed and investigated control loops.

Different setpoint values for the DO concentration in the last aerobic bioreactor and for the nitrates and nitrites concentration in the anoxic bioreactor were proposed and tested. The aeration energy (AE), pumping energy (PE) and effluent quality (EQ) were calculated based on the Eqs. (9-11) and compared to the actual performance of the municipal WWTP. The investigated control cases are presented in Table 1.

$$AE = C_{AE} \cdot \frac{SO_{sat}}{T \cdot 1.8 \cdot 1000} \int_0^T \sum_{\text{aerated bioreactor}} [V^{\text{bioreactor}} \cdot K_L a_i(t)] dt \quad (9)$$

$$PE = C_{PE} \cdot \frac{1}{T} \int_0^T [0.004 \cdot Q_{NR}(t) + 0.008 \cdot Q_{RAS}(t) + 0.05 \cdot Q_{waste}(t)] dt \quad (10)$$

$$EQ = \frac{1}{T \cdot 1000} \int_0^T [PU_{TSS}(t) + PU_{COD}(t) + PU_{BOD}(t) + PU_{TKN}(t) + PU_{No}(t)] Q_{effluent}(t) dt \quad (11)$$

Table 1. Investigated cases of the control loops with different setpoint values.

Case	Description
Case 0	WWTP actual operation (predominant manual control)
Case 1	DO setpoint value: 3 g O ₂ /m ³ , S _{NOx} setpoint value: 0.1 g N/m ³
Case 2	DO setpoint value: 3 g O ₂ /m ³ , S _{NOx} setpoint value: 0.05 g N/m ³
Case 3	DO setpoint value: 3 g O ₂ /m ³ , S _{NOx} setpoint value: 0.01 g N/m ³
Case 4	DO setpoint value: 2 g O ₂ /m ³ , S _{NOx} setpoint value: 0.1 g N/m ³
Case 5	DO setpoint value: 2 g O ₂ /m ³ , S _{NOx} setpoint value: 0.05 g N/m ³
Case 6	DO setpoint value: 2 g O ₂ /m ³ , S _{NOx} setpoint value: 0.01 g N/m ³

4. Results and discussion

4.1. Steady state calibration results

The steady state calibration results are presented in Tables 2-4, for all three considered optimization algorithms. Table 2 presents the calibrated decision variables, Table 3 comparatively shows the measured effluent data associated to the calibrated model predictions and Table 4 reveals the values of the optimization index. The calibrated decision variables show a good agreement with the values reported in the literature. The effluent simulated data approximates well the effluent measured data in steady state. The best results were achieved by the hybrid optimization method, as the overall objective function demonstrated the minimum value of 0.025. The calibrated decision variables obtained using hybrid optimization were used in the subsequent dynamic simulations.

Table 2. Calibrated values of the influent variables, process and settler parameters obtained with the different optimization methods.

Decision variable	Notation	Genetic algorithm	Hybrid method	Multiobjective method	Unit
Readily biodeg. organic substrates	S_s	49.02	15.37	74.2	g COD/m ³
Inert particulate organic material	X_i	36.21	62.86	32.81	g COD/m ³
Heterotrophic organisms	X_H	3.61	0.463	2.54	g COD/m ³
Nitrifying organisms	X_A	3.42	2.84	8.97	g COD/m ³
Storage rate constant	k_{STO}	2.24	3.35	0.91	g COD _{XS} / (g COD _{XH} day)
Saturation constant for DO	K_{O_2}	0.46	0.492	1.09	g O ₂ /m ³
Autotrophic maximum growth of the nitrifying organisms	μ_A	8.93	4.74	6.69	1/day
Hindered zone settling parameter	r_h	0.000799	0.00113	0.000687	m ³ /g SS
Flocculant zone settling parameter	r_p	0.00794	0.0125	0.0114	m ³ /g SS
Non-settleable fraction	f_{ns}	0.00449	0.006	0.00329	-

Table 3. Comparison between the average measured effluent data and the average simulated effluent data obtained by the calibration with different optimization methods.

Effluent variable	Notation	Measured data	Genetic algorithm	Hybrid method	Multiobjective method	Unit
Soluble chem. oxig. demand	COD_{sol}	4.84	4.84	4.84	4.84	g COD/m ³
Nitrates and nitrites	S_{NOX}	3.76	3.554	3.782	3.686	g N/m ³
Free and saline ammonia	S_{NH4}	0.17	0.1699	0.1698	0.0151	g N/m ³
Suspended solids	X_{SS}	12.00	12.00	12.00	11.83	g SS/m ³

Table 4. Comparison between the overall objective function values of the calibration results obtained by the different optimization methods.

	Genetic algorithm	Hybrid method	Multiobjective method
Overall objective function	0.211	0.025	1.797

The calibration based on the genetic algorithm optimization method also shows very good calibration performance, as only the reduced difference of 5 % for the effluent nitrates and nitrites concentration was observed. Results of the multiobjective optimization method show dissimilarities at the free and saline ammonia effluent concentration, but the simulated effluent soluble COD, nitrates and nitrites, suspended solids concentrations also fit to the measured effluent data.

4.2. Calibrated model results for the dynamic state

Dynamic simulations were performed using the fitted values obtained by the hybrid optimization method. Figures 2 and 3 show the comparison between the measured

effluent WWTP data and model predicted effluent data, for the concentration of the soluble COD and nitrates and nitrites (S_{NOX}) main variables.

Figure 2. Measured vs model predicted effluent data for soluble COD.

Figure 3. Measured vs model predicted effluent data for nitrates and nitrites concentrations.

Predictions of the calibrated model for the WWTP effluent approximates well the measured effluent data, both in steady and dynamic state.

4.3. Results of the WWTP control

Table 5 shows the values of the performance indices obtained by dynamic simulations using the calibrated model for the proposed control cases.

Table 5. Performance indices of the calibrated WWTP model with the control strategies.

Case	Aeration energy [kWh/day]	Pumping energy [kWh/day]	Effluent Quality [kg. P.U./day]
Case 0	13,720.03	8,793.29	20,440.06
Case 1	11,904.58	10,248.65	18,474.86
Case 2	11,680.42	7,942.05	18,768.56
Case 3	11,441.55	5,799.24	19,068.96
Case 4	10,357.93	14,138.25	16,694.57
Case 5	10,165.38	9,984.21	16,900.63
Case 6	9,940.05	6,260.02	17,138.97

As revealed by Table 5, the implementation of the proposed control improves the actual municipal WWTP operation when aeration energy and effluent quality are considered. However, depending on the case, pumping energy may be affected. The overall best performance among the investigated control cases was obtained for Case 6, i.e. by setting the DO setpoint value to 2 g O₂/m³ and the S_{NOX} setpoint value to 0.01 g N/m³. For this favourable control case, the aeration energy was reduced by 27.5 %, the pumping energy was diminished by 28.8 % and the effluent quality was improved by 16.1 %, when comparison was made to the actual WWTP operation.

5. Conclusions

The calibration of the municipal WWTP model based on the Activated Sludge Model No. 3 was accomplished using different optimization algorithms and their performance was comparatively presented. The hybrid optimization method demonstrated the best calibration performance. The calibrated model was used to implement control loops with different setpoint values, aimed to WWTP performance improvement. The most favourable case was presented and proposed for WWTP implementation as it showed energy reduction of about 28 % and effluent quality improvement of about 16 %.

Abstract

This study demonstrates the development of three modeling approaches for predicting thermophysical property with the ability to quantify the uncertainty in the prediction. The modeling approaches consist of a classical non-linear group-contribution (GC) model (GCM), Gaussian-Process regression (GPR), and a deep neural network (DNN) all applied to the first-order groups defined by Marrero and Gani as the molecular descriptor. The uncertainty was quantified using different methods: linear error propagation using the parameter covariance matrix for the GCM, the inherent uncertainty quantification of GPR models, and using a probabilistic layer able to learn the distribution of model outputs in DNN. The models have been applied to the lower flammability limit (LFL) at 298K. The model performance was evaluated using 5 folds cross-validation to ensure the models were exposed to all data and to detect potential overfitting,—a procedure frequently used within machine learning. The models obtained produce a good fit to the experimental data when applied to all available data with a coefficient of determination (R²) above 0.9 for all models, a maximum mean absolute error of 0.39 [%-vol], and a maximum mean squared error of 0.51.

Keywords: QSPR, Deep-Learning, Property Prediction, Uncertainty Analysis

1. Introduction

Thermophysical properties such as critical constants, enthalpic, and flammability properties play a vital role in many chemical engineering applications, e.g., phase equilibria calculations, process simulation, and risk assessment (Frutiger et al., 2016a). Predicting these properties in a fast yet computationally efficient way is therefore of paramount importance for many applications, especially in the absence or scarcity of experimental data and since it is impractical to perform measurements whenever the need arises. Traditionally, quantitative structure-property relationships (QSPRs) type models are employed to predict such properties from structural information of the chemical compounds (Austin et al., 2016). Recently, efforts have also been invested in applying emerging machine learning techniques as the new predictive tool in QSPRs (Zhang et al., 2018). Among them, deep neural networks (DNN) have drawn the utmost attention due to their ability to extract hidden features in large datasets and approximate the behavior of any function. This allows such models to compare, if not outperform, traditional QSPR

models. Some of the recent applications are the prediction of the perceived odor of molecules (Zhang et al., 2018) and critical properties of halogenated olefins (Mondejar et al., 2017). Few have however addressed the uncertainty of the predictions made by the models. This could potentially hinder the broader use of these models, especially in applications involving engineering decision-making. In this work, we develop and compare property prediction models with uncertainty quantification based on three modeling approaches: a GC-based non-linear regression (GCM), a machine learning-based Gaussian process regression (GPR), and a deep learning-based neural network (DNN) applied to the lower flammability limit property (LFL) of organic compounds.

2. Methodology

In developing QSPR models, two key modeling decisions must be addressed: how to describe the structural information of the chemical and how to relate the structure to the property of interest. The selection of these is discussed in the following.

2.1. Molecular Descriptor

The structural information of the molecule is transformed into a machine-readable molecular descriptor to be used as input to a mathematical model. One example of such expert-crafted descriptors is the segmentation in GC, where the molecule is described through the occurrence of specific predetermined atomic arrangements. The groups are defined to reflect a series of feature subsets of the molecule that are frequently occurring in the chemical design space (Marrero and Gani, 2001). Hukkerikar et al. (2012) developed a widely used GCM, where the molecule is described through three levels of increasing complexity to capture larger atomic arrangements. In this study, only the first-order groups defined by Marrero and Gani (2001) were used as input to all models. The exclusion of higher-order groups is to reduce the model complexity and because they do not always result in a reduction in the prediction error (Frutiger et al., 2016b).

2.2. Property data

The Lower Flammability Limit (LFL) was chosen to benchmark the models. The LFL is used in quantitative risk assessment and is defined as the lowest concentration of a chemical for which a flammable mixture with air is formed. The LFL is measured at 298K and 1 atm and is expressed in [%-vol]. The LFL was obtained from the AIChE DIPPR 801® database considering only experimental and accepted data (Rowley et al., 2019). A

Figure 1: Histogram of the LFL

2.3. Non-linear regression

A GCM for predicting the LFL of organic molecules has previously been developed in (Frutiger et al., 2016a) and can be seen in Eq. (1).

$$f(LFL) = \log \left(\frac{LFL}{LFL_{const}} \right) = T\theta \quad (1)$$

Where T is the group occurrence matrix and θ are the group contributions. The contributions and the model constant are determined by minimizing the sum of squared error (SSE) between the prediction and the experimental value. The model uncertainty is determined by linear error propagation using the parameter covariance matrix as described in (Frutiger et al., 2016b).

2.4. Machine-learning model: Gaussian Process Regression (GPR)

Gaussian process regression (GPR) is a probabilistic machine learning (ML) algorithm that, unlike many other ML models, allows prediction of the underlying uncertainties in its predictions. It does so by using kernels to explain a given model response as a realization of a random function of the following shape:

$$y^{GPR} = \beta f(x) + \sigma^2 z(x, w) \quad (2)$$

where the first term models the mean, σ^2 the variance and $Z(x)$ is a zero-mean, unit-variance stochastic Gaussian process. β denotes regressed coefficients and $f(x)$ a set of basis functions. The stochastic part $Z(w, x)$ introduces latent variables w to correlate observations x and new points x' in the input space using kernel functions, for which a variety of alternatives exist in both literature and available software packages. The most commonly used kernel types include squared exponential kernel, exponential kernel, “matern 3/2”, “matern 5/2” and rational quadratic kernel. In this work, we use MATLAB’s GPR fitter (`fitrgp`), which additionally provides model prediction error uncertainty and confidence intervals.

2.5. Deep-learning model

Deep neural networks (DNN) is a class of machine learning algorithms similar to the artificial neural network and aims to mimic the information processing of the brain. DNNs have more than one hidden layer (l) situated between the input and output layers (Goodfellow et al., 2016). Each layer contains a given number of units (neurons) that apply a certain functional transformation to the input. These types of models can approximate the behavior of any function (universal approximation theorem). The output (y) of a unit (i) in layer (l) is related to the output (x) of the earlier layer (k) with J outputs through a set of weights ($w_{i,k}$), a bias (b) and a non-linear activation function f.

$$y_i^l = f \left(\sum_{k=1}^J (w_{i,k} x_k + b_i) \right) \quad (3)$$

To fairly compare the various models in this work, only feed-forward layers were used. Despite the considerable interest, DNNs have gained in regression applications, few have dealt with the uncertainty in the prediction. This could be due to the complexity required to perform such an analysis. In this work, we use a probabilistic machine learning technique by introducing a probabilistic layer after the dense layers that can learn the distribution over the weights in the network. This layer learns the probability distribution of the outputs (y) related to the inputs (x) through weights (w). This makes it possible to model the loss function as the negative log-likelihood. The DNN was implemented using

the TensorFlow framework along with the TensorFlow distributions to model the probabilistic layer (Dillon et al., 2017). Grid-search was used to optimize the DNN hyperparameter systematically by varying the number of neurons, and dropout rate between [8,16,32,64], and [0.2-0.6] respectively. This resulted in a DNN comprised of: three dense layers (64) separated by three dropout layers (0.5) with a learning rate of $1e^{-4}$ and using the “Adam” optimizer and the “ReLU” activation function. The architecture was determined using an 80:10:10 training, validation, and testing split.

2.6. Training, validation, and model uncertainty

To validate the model performance and its ability to generalize to unseen data, 5-fold cross-validation was performed. The mean-squared-error (MSE), mean absolute error (MAE), and coefficient of determination (R^2) are reported as an average with a standard deviation across all folds. The uncertainty quantification of GCM and GPR is done using all data for the fitting following the approach in (Frutiger et al., 2016b; Hukkerikar et al., 2012), while for the DNN the average across folds was used.

3. Results

The model predictions and the 95% confidence intervals (CI) have been determined for the best performing model for each approach and are visualized in Figure 1. The average performance metrics across all folds and using all data can be seen in Table 1.

Table 1: Average statistical performance across all folds using all data

Model	MSE			MAE			R^2		
	train	test	total	train	test	total	train	test	total
GCM	0.33	1.60	0.51	0.33	0.70	0.39	0.95	0.74	0.90
GPR	0.00	1.23	0.25	0.01	0.57	0.12	0.99	0.73	0.94
DNN	0.10	1.10	0.26	0.12	0.59	0.20	0.98	0.78	0.94

All obtained models conform well to the experimental data when considering all available data for the evaluation (test and training data). Depending on the metric chosen, the models show different ability to generalize to unseen data. The DNN shows the highest R^2 and the highest MSE for the test data, however, it shows a higher MAE compared to GPR. And while the GCM shows a better R^2 score for the test data than GPR, it produces the highest MAE and MSE among all models. To produce a common ground for comparison and to evaluate the models' ability to characterize the chemical design space, the metrics have also been evaluated using all available data. Based on this, the GPR had the highest R^2 , alongside the DNN and the lowest MAE, and MSE. Although none of the models presented match the performance of the model produced in (Frutiger et al., 2016a) ($R^2=0.99$), it is important to note that the previous work used all Marrero Gani group orders and performed outlier treatment. Besides, all data were used for the training of the model resulting in the high R^2 value (Frutiger et al., 2016a). In this study we are applying an established cross-validation methodology for testing models and therefore assess the ability of the models to *predict* the property of interest, this is quite different from earlier approaches where all the data is used for GCM building. Using the k-fold cross validation also ensures that the model has been exposed to all available groups at least once. This is an effort to overcome the fact that not all groups appear with the same frequency. The alternative would be to select a training set that has all available groups at least once. However, this approach might produce a model that is biased towards one class of

compounds. In general, it seems the machine-learning and deep-learning approaches generalize better to unseen data.

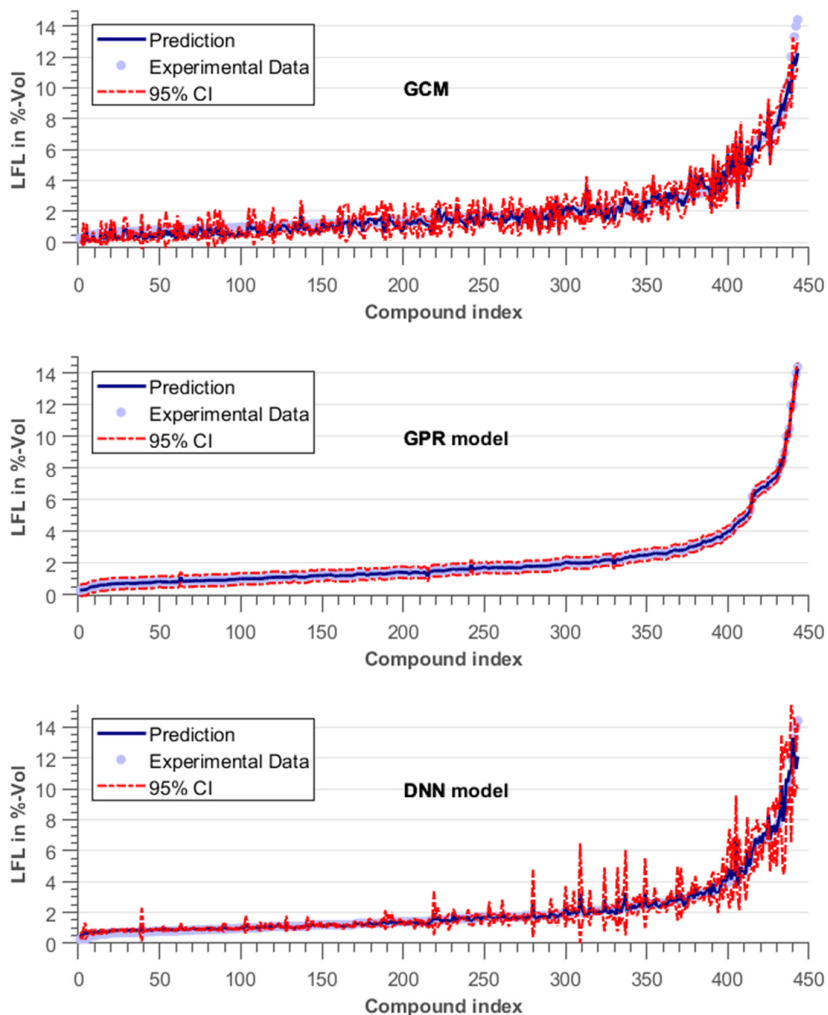

Figure 2: LFL model predictions and the 95% lower and upper CI interval

While the GCM underpredicts the LFL values in the lower end (lower than 0.5%), the DNN model is overpredicting these values. The GPR model does not show any of these tendencies. The uncertainty bounds resulting from the GPR model are very smooth in comparison to the ones produced by the GCM and the DNN model. The uncertainty bounds produced by the covariance matrix for the GCM provides more noisy confidence bounds compared to the two other models. The DNN model seems to struggle for predicting the uncertainty bounds for the data points at the higher end of the LFL spectrum (above 4%) and the confidence bounds are larger for these values and noisier. This could be due to the amount of data in these regions being much lower than for LFL values below 4%. The skewness of the data at the larger values of LFL could be the reason some of

the models struggle in predicting values in this region. From practical applications, the GCM approach with an asymptotic approximation of prediction uncertainty as well as the GPR approach seems in agreement with each other and could be used in process safety analysis, while further refinement of the DNN approach is needed. Moreover, assessing further the quality of the uncertainty predictions from different approaches would require the availability of a comprehensive measurement of the uncertainty of experimental data points. While qualitative information is provided in the DIPPR database, a quantitative analysis of the measured data uncertainty is particularly needed.

4. Conclusions

The uncertainty quantification has been illustrated for a thermo-physical property prediction model to predict the LFL through three different modeling approaches. All approaches are not only capable of providing the point prediction of the property but can also provide meaningful information about the models' confidence in its prediction. The uncertainty quantification using the covariance matrix for the GCM provides more noisy confidence bounds compared to the smooth prediction for the GPR model. The confidence of the DNN in the prediction suffers greatly for higher LFL values.

Abstract

Developing Industrial Symbiosis (IS) networks is a knowledge-intensive practice, where information is of crucial importance in order to discover the potential of IS connections between facilities engaging in exchange of materials and/or energy. In this work, we provide methods and tools that assist modelling and systemic use of existing IS knowledge to analyse potential IS networks and synergies.

Keywords: industrial symbiosis, knowledge graphs, graph databases.

1. Introduction

Industrial Symbiosis (IS) is an innovative approach to create industrial networks (Isenmann and Chernykh, 2009) for economic, environmental and social benefits. IS brings together companies from all business sectors through material trading and sharing assets to add value, reduce costs and benefit the environment (Lehtoranta et al., 2011). Developing IS networks is a knowledge-intensive practice, where information is necessary to discover potential IS connections between flows of materials, waste and/or other resources related to industrial facilities. Therefore, the efficiency of ICT solutions for facilitating IS depends heavily on collecting, analysing and integrating highly-diverse quantitative and qualitative data (Grant et al., 2010). The key objective of our work in the SYMBIOICT project (co-financed by the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call RESEARCH-CREATE-INNOVATE) is to overcome two major barriers for detecting large-scale IS networks such as: (a) focus on “1-1” connections, (b) lack of modelling and systemic use of existing knowledge. By applying data analytics technologies we produced a knowledge graph of existing and potential IS connections, matching input/output flows of industrial facilities. Each connection can be weighted using parameters such as the distance of the facilities (transport cost), the facility size and the cost savings from the proposed waste prevention. We demonstrate how knowledge graphs can be effectively used for matching (a) material to process, (b) material to company, (c) company to company. Using the knowledge graph we accomplished an effective analysis of potential IS networks and synergies that would otherwise be extremely difficult to identify. These results were also visualized on a map, displaying “hot spots” of existing IS synergies as well as cases with high potential of forming new IS connections.

2. Background

2.1. Knowledge Graphs

A knowledge graph captures the semantics of a domain using a set of definitions of concepts, their properties, and the relations between them. Knowledge graph has become a term that is recently ubiquitously used yet does not have a well-established definition. Typically, a knowledge graph: (i) mainly describes real world entities and their interrelations, organized in a graph, (ii) defines possible classes and relations of entities in a schema, (iii) allows for potentially interrelating arbitrary entities with each other, and (iv) covers various topical domains (Paulheim, 2017).

Since its inception by Google in 2012 (powered in part by the Freebase knowledge base) and until today knowledge graphs have been an intrinsic part of organizing knowledge in a distributed way for web applications, especially after the “second wave” of the Semantic Web with the introduction of Linked Data and the adoption of Resource Description Framework for information modelling on the web (Ji et al., 2020).

2.2. Industrial Symbiosis facilitation

In EU countries, the promotion of IS is usually supported by teams of experts or practitioners that engage in networking sessions with industries and other stakeholders for the purpose of the development of IS projects (Artola et al., 2018). In these sessions, brokers usually apply straightforward techniques (without the use of ICT tools) to detect the possibility of resource (raw materials, waste, energy) exchange among the participating stakeholders. This approach can be restrictive, leading to serendipitous discovery of cooperation opportunities and IS networks of limited scale and complexity. The success of such efforts relies heavily on the skills and experience of each mediator and not on a systemic use of information and knowledge. Other efforts, such as the SMILE Resource Exchange platform launched in 2010 in Ireland as a waste trading system to promote IS, have later transitioned towards a more hands-on facilitated approach focusing on “1 on 1” solutions before utterly coming to a close in 2018.

In recent years, a few digital services have been developed focusing on supporting decision making for waste valorisation and reduction. For example, International Synergies (www.international-synergies.com) has developed SYNERGie, a proprietary ICT resource management database and platform, enabling organizations to identify resource reuse opportunities. Even though these digital solutions incorporate knowledge of best practices for waste valorisation, they often follow the same approach of searching for “1 on 1” connections. In this way they fail to take into consideration data on raw materials, waste and industrial processes, the analysis of which can highlight new possibilities for establishing more complex and less obvious IS networks.

3. Dataset and Model

3.1. Description

We adopt a data-driven approach for the facilitation of IS, proposing knowledge graphs as the tool for incorporating IS related data, such as industrial processes combined with flows of materials, waste and other resources related to industrial facilities. With this representation, the user can model large and complex IS networks involving heterogeneous industries and a wide range of by-products exchanged. Logic built into knowledge graphs allows us to reason about the information contained within, and to make implicit information in the graph explicitly accessible.

The challenge of creating a knowledge graph for waste valorization solutions lies in the fact that the necessary information is usually fragmented and located in many

heterogeneous sources. Therefore our first step was the extraction of the data related to IS from various sources, and then we moved on to the transformation and interconnection of them. In this way we managed to construct a knowledge graph and perform further analysis on the data.

In particular, the knowledge graph can be used for matching waste to process, waste to company, company to company or querying using only desired properties. We can demonstrate examples in agricultural activities, rural and municipal communities and ports, with reliable results. The graph can be enriched as more technologies are developed. Connections can be either implemented or potential, depending on the development stage. Furthermore quantitative data can be used for evaluating possible synergies with mathematical optimization techniques.

3.2. Data Collection

Data used for the development of the graph database were mainly mined from official repositories of IS best practices as well as research papers and news items. In particular, our main sources were best practices implemented in Sweden: (industrialsymbiosis.se), Finland: (www.industrialsymbiosis.fi/home-en-gb/) and Denmark (Kalundborg Eco-industrial Park). The Nordic countries have a long tradition in sustainable development and thus they offer a breadth of available data and best practises, which could be replicated in other less circular countries. Other novel examples we took into consideration include Guitang group in China as well as IS networks established in Greece (symbiosisproject.eu), which proves that even in countries where circular economy initiatives are still at an early stage, IS networks can be developed, given that the necessary knowledge is available.

4. Methodology

4.1. Knowledge Graph Model

Nodes and edges (or relationships) were used in order to represent entities involved and their in between connections. In the proposed model nodes can have one of three different labels: Company, Material or Process which connect to each other with relationships (edges) having one of the following three labels: Is_Input, Has_Output or Has_Process. The nodes, the edges and the attributes are presented below in more detail. Regarding nodes, three different labels were used.

- Set of Companies C: {c|c company} Nodes with label: “Company” represent the geographic location where the various processes take place.
- Set of Materials M : {m|m material} Nodes with label: “Material” represent materials in any state (solid, gaseous, liquid) and can be waste materials, raw materials, byproducts etc.
- Set of Processes P : {p|p process} Nodes with label: “Process” describes actual industrial processes that transform raw materials into useful products, but also activities such as farming etc.

Regarding edges, three different labels were used.

- Set of Is_Input : {i|i Is_Input} Relationships with type: “Is_Input” relate Material nodes with Process nodes.
- Set of Has_Output: O : {o|o Has_Output} Relationships with type: “Has_Output” relate Process nodes with Material nodes.
- Set of Has_Process H: {h|h Has_Process} Relationships with type: “Has_Process” relate Company nodes with Process nodes.

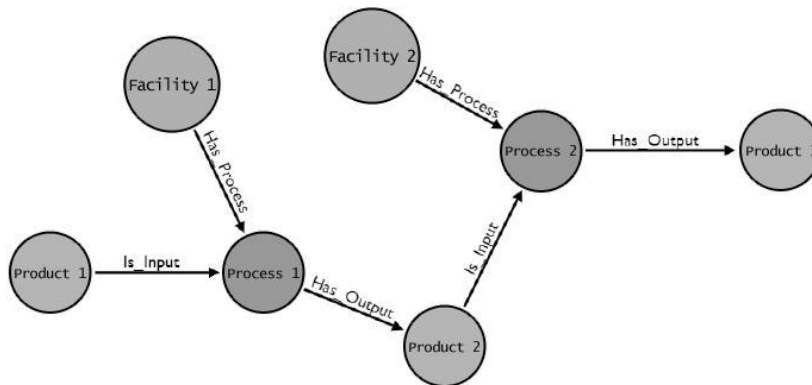

Figure 1. Sample graph with the three different types of nodes and three different types of edges

The node labeled Company is connected with the node labeled Process through the edge labeled Has_Process, whereas the node Process and Material can connect with edges labeled Is_Input or Has_Output depending on the direction. Both edges and nodes have attributes which vary depending on the label. Properties regarding materials can be physical, chemical, biological etc. whereas properties regarding processes can be CAPEX, OPEX etc. In the next section we demonstrate how the knowledge graph is used to suggest connections between companies, waste and processing technologies.

5. Results

5.1. Implementation

In our approach we utilize the neo4j platform (neo4j.com), a native graph database built from the ground up to leverage data and also data relationships. Using neo4j we created a graph database for storage, automation and visualization of IS networks. Using the data collected we created a Knowledge Graph containing: 49 industrial facilities, 99 industrial processes, and 154 different materials. The resulting Knowledge Graph can suggest connections between companies, waste and processing technologies.

5.2. Query Example

Using our graph we can perform a variety of queries for facilitating IS planning and networking, offering matches between (a) materials to process, (b) materials to company, (c) company to company. E.g., a question such as: "My facility produces Ethanol by Fermentation of Molasses. Which other materials can be used instead of Molasses in my Fermentation process to produce Ethanol?" is expressed as follows in neo4j:

```

match p=(n:Material)-[*]->(a:Material)
where any(node_on_p in NODES(p)
  where node_on_p.ProcessName='Fermentation' ) and n.MaterialName <>
'Molasses' and a.MaterialName='Ethanol' and n.MaterialRole
in['final','exchange']
return p
  
```

By executing the above query, neo4j presents a result set with materials that can lead to the production of Ethanol by Fermentation, based on the data of the Knowledge Graph. We also get the corresponding paths for the chain of processes in order to achieve it. In

this example we get: Bread Residues (through Hydrolysis), Sugar Beet (directly), Wheat Waste (directly), Starch (directly), and Municipal Solid Waste (through Gasification).

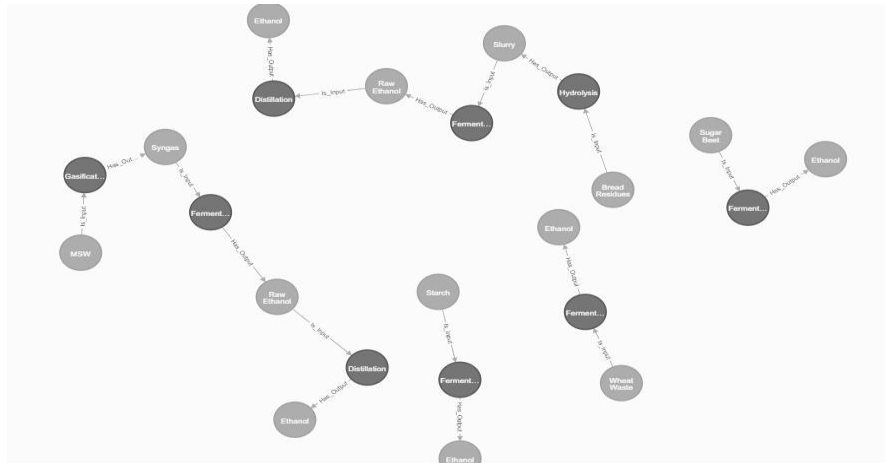

Figure 2. Result set of query on Knowledge Graph.

5.3. Visualization of IS potential

Combining information extracted from the knowledge graph with data regarding location and activity of industrial facilities in Greece (e.g., location, magnitude, industrial NACE codes), we were able to detect cases with high potential of forming successful new IS connections. We visualized these proposed IS connections on a digital platform (snf-252687.vm.okeanos.grnet.gr), where industrial facilities are connected based on the potential exchange of materials and/or other resources. Each IS connection is weighted based on the distance between the industrial facilities involved combined with the facility magnitude. Results are visualised on an interactive map, indicating proposed IS connections as well as “hot spots” with high potential of IS regional synergies.

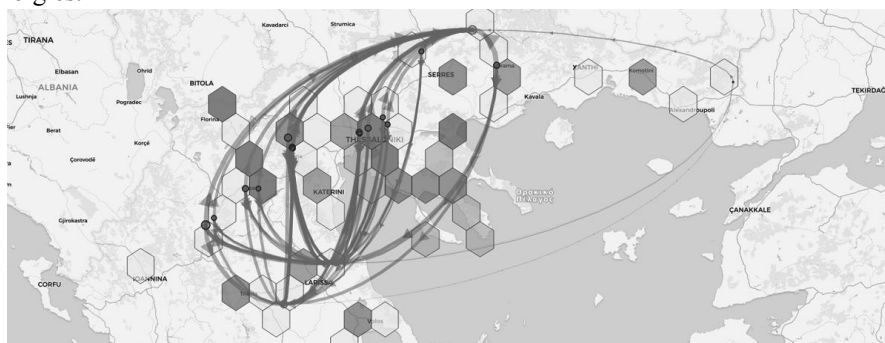

Figure 3. Map of proposed IS connections and “hot-spots” using the Knowledge Graph.

6. Conclusions

In conclusion, the developed model allows real time analysis about potential IS networks which include several different partners and synergies that would otherwise be

extremely difficult to identify. In this way, a user of the knowledge graph can use even limited information as parameters in order to obtain suggestions on relative applied industrial symbiosis practices, proposed technologies that can process their waste, and generally identify possible IS opportunities. Finally, we demonstrate a digital platform that exploits IS knowledge graphs present IS hotspots and potential new connections.

Limitations of this methodology, which actually will be taken into consideration in our future work plans to improve our methods, include the data collection process, which is not automated, as well as the lack of data regarding the economic value of the exchanges. Also, the graph cannot prioritize potential matches or compare them with regard to their economic or environmental performance. Finally, at this stage, we do not provide narrow searches involving constraints in equipment and processes, or even involving company location information, but such type of data has already been collected (see also Figure 3) and will be soon exploited to provide such type of searches.

Abstract

In this work, we present a software prototype for the generation of Process Intensification (PI) systems integrated with safety, flexibility, and control analysis. The prototype comprises three major suites: (i) Synthesis Suite - which systematically generates promising PI configurations based on a phenomenological process synthesis approach (i.e. Generalized Modular Representative Framework), (ii) Simulation Suite - which is integrated with a PI model library to translate the PI synthesis results into corresponding equipment-based process alternatives, and (iii) Operability Suite - which performs model-based safety, flexibility, and controllability analysis to ensure the actual operational performance of the resulting PI systems under varying conditions. A user interface has been built to coordinate the functionalities of the suites, allowing them to work in tandem to create an environment that generates safe and operable PI flowsheets without pre-postulation of potential process schemes. A case study on the metathesis reaction of pentene is presented to demonstrate the potential of the prototype in deriving safe and operable PI systems.

Keywords: Process Intensification, Process Synthesis & Optimization, Process Control, Software Prototype.

1. Introduction

Process Intensification (PI) has attracted an emerging interest in the chemical engineering research community and the chemical process industry owing to its potential ability to drastically increase process profitability and efficiency (Moulijn et al., 2008; Tian et al., 2018). The past few decades have witnessed significant advances in the field of PI (Keil, 2018; Segovia-Hernández and Bonilla-Petriciolet, 2016). However, a widely used process intensification commercial software is still lacking (Tula et al., 2019; Skiborowski, 2018). Driven by several recent national initiatives such as the RAPID Institute (Bielenberg and Palou-Rivera, 2019), the academic community has initiated attempts to develop software prototypes for computer-aided process design, synthesis, and intensification leveraging state-of-the-art process systems engineering approaches (Tula et al., 2017; Demirel et al., 2017; Chen et al., 2018; Miller et al., 2018).

In this paper, we present the development towards a software prototype based on our recently proposed framework for the synthesis of operable process intensification systems (Tian et al., 2020). The prototype systematically generates intensified process systems by utilizing a novel phenomenological synthesis approach with embedded process operability, safety, and explicit model predictive control analysis criterion. Section 2 of the paper elucidates the prototype architecture and the function of embedded suites. In section 3, a case study of a reactive separation system is presented to demonstrate the working of the prototype. The remaining section covers conclusions and future directions.

2. Software Prototype

The prototype platform consists of three suites, namely: (i) Synthesis Suite, (ii) Simulation Suite, and (iii) Operability & Control Suite. As illustrated in Figure 1, the user interface (UI) built on Python brings these suites together in a seamless manner to provide a consolidated environment while allowing user input and interaction. The different functional suites take advantage of various commercially available software packages, such as GAMS[®] for process synthesis and optimization, ASPEN PLUS[®] for steady-state process simulation, and gPROMS[®] for dynamic modeling and control analysis. These suites work in tandem to provide key insights to the user and are coordinated through the UI as detailed below.

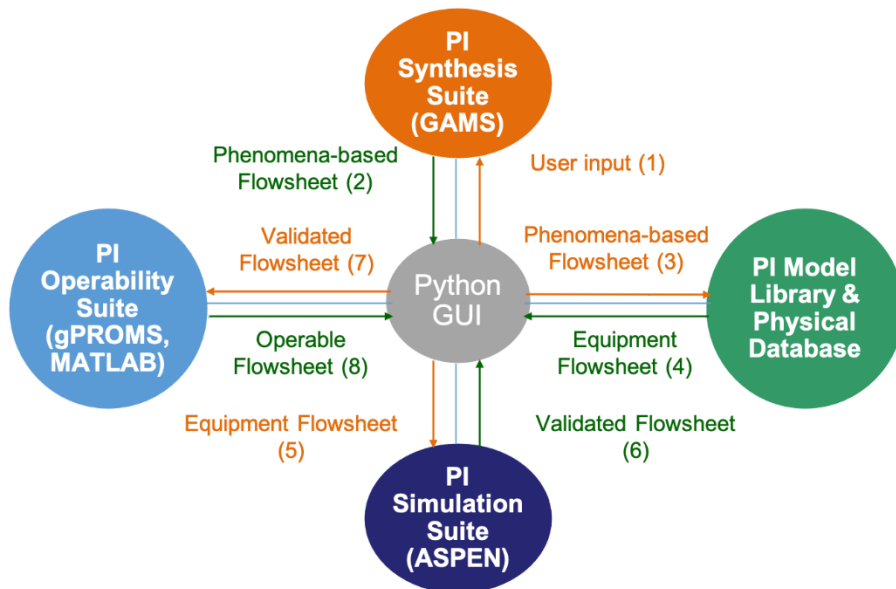

Figure 1: Information flow chart for the software prototype platform

2.1. User Interface

The interface is programmed to facilitate communication and the transfer of data between the suites of the software prototype. Through the UI, users can select individual suites for targeted equipment/flowsheet intensification, design, or analysis. However, the UI can also guide users to navigate between different suites in a step-by-step manner

for integrated design with operability, safety, and/or control. To this end, the UI acts as a central node for information flow as shown in Figure 1 and provides key input and output information to the user at every stage.

2.2. *Synthesis Suite*

The synthesis suite provides the tools required for the systematic generation of optimal and intensified process solutions. The technical foundation of the suite is laid by the Generalized Modular Representative Framework (GMF) (Papalexandri and Pistikopoulos, 1996). To characterize various chemical processes, GMF employs two phenomenological modules, namely, the pure heat exchange module and the multi-functional mass/heat exchange module. Interlinked configurations of these modules, generated as a result of solving an optimization problem, can form the basis for the creation of conventional and/or novel unit operations. The optimization problem is formulated as a mixed-integer nonlinear programming problem (MINLP) and solved using the Generalized Benders Decomposition algorithm in GAMS[®]. The parameters of the model are assumed to be deterministic and provided by the user through the UI. To exchange information between the UI and the synthesis suite, Python Application Programming Interface (API) is used. More detail on GMF modular representation and model formulation can be found in Tian and Pistikopoulos (2020).

2.3. *Simulation Suite*

To validate the resulting configuration, the GMF module based flowsheet is converted to the corresponding equipment based flowsheet. This translation is achieved through a model library which comprises of information pertaining to various process equipment, and a set of rules governing the assignment of equipment to a module or a group of modules. The user can avail from a library of models and suggestions provided by the database to choose the equipment. This allows the prototype to account for equipment constraints and lends the flexibility to generate alternative flowsheets. It is imperative to note that the accuracy of translation will depend on the extensiveness of the library database. Novel equipment will have to be appended to the library in prior to achieve the desired translation. Subsequently, the equipment based flowsheet is simulated using ASPEN PLUS[®] to perform steady-state validation. Furthermore, high fidelity models are developed to fully capture and analyze the process dynamics.

2.4. *Operability Suite*

Model-based analyses are currently enabled for the following PI operational considerations: (i) flexibility analysis to ensure feasible operation under process uncertainty, (ii) risk analysis to evaluate the inherent safety performance of the resulting process configuration at the conceptual design stage, and (iii) explicit/multi-parametric model predictive control to deliver optimal dynamic operation strategies under disturbances following the PAROC (PARAMetric Optimisation and Control) framework (Pistikopoulos et al., 2015). These operability analysis approaches can also be integrated with the above Synthesis Suite and Simulation Suite to simultaneously generate optimal and intensified process designs with guaranteed operability, safety, and control performance (Tian et al., 2020).

3. Case Study: Pentene Metathesis Reaction

3.1. Problem Statement

In this section, we revisit the problem of 2-Pentene (C_5H_{10}) metathesis to form 2-Butene (C_4H_8) and 2-Hexene (C_6H_{12}) which is an equilibrium limited reaction adapted from Tian and Pistikopoulos (2020). At atmospheric pressure, the reaction takes place in the liquid phase and can be described by ideal vapor-liquid equilibrium (VLE). The production target is to obtain 50 kmol/h of 98% butene and 50 kmol/h of 98% hexene from a saturated liquid feed stream of 100 kmol/h pure pentene at atmospheric pressure. The objective is to design a process with the minimum utility cost.

3.2. User Input

The UI window is built on Python with the help of the *Tkinter* package. It allows the creation and management of window attributes like panels, buttons, and entry fields. The UI window comprises of dedicated panels for showing input/output data, run time data, superstructure layout, and comparison between alternatives of the generated flowsheet. To allow for the dynamic updates of UI panels, they are created as objects of python defined classes. Users can access all functionalities of the prototype with the help of the button attribute. For the case study, the required input information includes physical properties like molecular weight and molar mass, thermodynamic information such as Antoine and heat capacity coefficients, reaction information such as stoichiometry and standard Gibbs energy of formation, utility costs, and input feed conditions.

3.3. Process Synthesis

To generate the module based flowsheet, the maximum number of modules was set to 5. This number can be increased to acquire more information about the identified unit operations or decreased to reduce the computational time. The optimal MINLP solution includes values for the number of pure heat and mass/heat exchanger modules (integer variables), the presence of connections between stream and modules (binary variables), and the operating conditions (continuous variables). The results are exported to a database file (.db) to create modular structures using Python scripts. To visualize the solution, conditional statements are used to read the binary values and create their corresponding module or stream. For example, a module exists if the associated binary variable is assigned the value of 1, or 0 otherwise.

The resulting graphical module based flowsheet with the information on the constituent phenomena is shown in Figure 2. The modules and text in the flowsheet are sized according to the number of modules, and the size of the allocated window. Additionally, the python scripts account for the optimal layout to display process streams without over-lapping with the modules. The red and blue lines show hot and cold stream conditions respectively. The pure heat exchange module represented by white blocks, at the top and bottom can be translated into condenser and reboiler respectively. The mass/heat exchange modules can be translated into trays of a reactive distillation column.

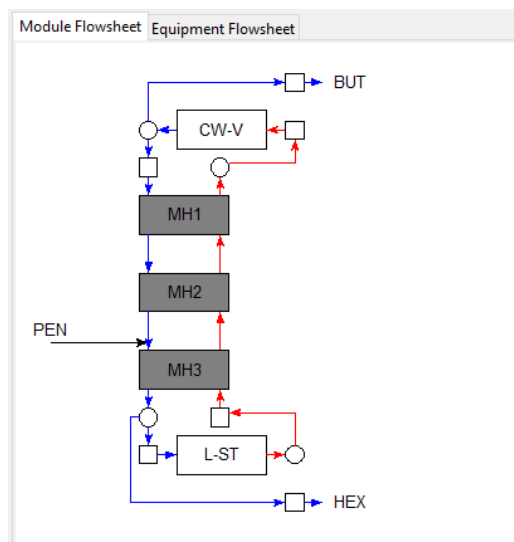

Figure 2: Module flowsheet for the pentene metathesis reaction

3.4. Remarks

The resulting GMF modular solutions are then identified and translated to equipment-based process alternatives with the help of a specialized PI model library developed as part of the SYNOPSIS Project (Pistikopoulos et al., 2020). The model library consists of validated rigorous and short-cut models for various intensified reaction and/or separation systems, including but not limited to, advanced distillation columns and reactive distillation columns. Moreover, the model library integrates different commercial software platforms (e.g., Aspen, gPROMS, Python) to leverage the existing unit operation models as well as to enable the flexible use of models for different computational purposes (e.g., simulation, optimization, control) in a platform-independent manner.

The safety, operability, and control performance of the PI systems can be further analyzed using the model-based metrics introduced in Section 2.4. This can be achieved either via posterior operational analysis for a given intensified process design, or via integrated process design optimization with operability, safety, and control considerations to systematically generate optimal process structures with desired operational performances.

4. Conclusion and Future Work

In this paper, we have presented our work towards the development of a software prototype to integrate process synthesis and process simulation with process operability, safety, and control analysis of the PI design to deliver validated operable PI system flowsheets. The connection of different parts of the prototype is explained and demonstrated using a pentene metathesis reaction example. Ongoing work addresses

the creation of the model library and establishing a connection of the UI with the simulation and operability suites.

Data-driven modelling of choke valve erosion using data simulated from a first principles model

Jan Henrik Jahren^a, Jose Matias^a and Johannes Jäschke^{a*}

^aDepartment of Chemical Engineering, Norwegian University of Science and Technology, Sem Sælands vei 4, 7034 Trondheim Norway

Abstract

Maintenance of subsea operating equipment is a significant part of the operational costs of running an oil production system. For instance, on the Norwegian continental shelf, it amounts to 60 billion NOK in operational expenses. One of the principal mechanisms of degradation in subsea process equipment is erosion by sand, which is a very complex process and, thus, difficult to model using physical domain knowledge. Because of this difficulty, we propose in this paper the use of data-driven approaches for modelling erosion in critical equipment of a subsea oil production rig. In such systems, a multitude of available process measurements such as flowrates, gas lift injection rates, pressures etc. can be combined to a soft sensor for component degradation. This approach could save significant amounts of resources by allowing fewer cost intensive inspections and monitoring schemes. A soft-sensor approach was tested with simulated data of the sand degradation of a choke valve in a gas lifted oil production system with three wells. In this paper, we present results from soft-sensor methods like multiple linear regression, regression trees, ensembles methods and kernel methods. The approaches were tested and compared in two case studies, the first with constant sand outflow from the reservoir for initial exploration of the data driven approaches, and the second with a more realistic profile in which the sand rate is increasing. In both cases, we compare the soft sensor modelling techniques in terms of their basic requirements of accuracy as well as transparency and interpretability.

Keywords: equipment degradation, data-driven modelling, machine learning

1. Main Text

Failure to detect faults in large scale, expensive or critical equipment can have immense consequences. Both financial and in the most extreme cases, loss of life. One of the main mechanisms in equipment degradation in subsea oil extraction, is sand erosion. Accurately modelling this process is vital for monitoring of equipment health (Si et al. (2012)). Erosion by sand is a very complex process and, thus, difficult to model using physical domain knowledge. Because of this difficulty, we propose in this paper the use of data driven approaches for modelling erosion in critical equipment of a subsea oil production rig. In such systems, a multitude of available process measurements, such as flowrates and pressures, can be combined to a soft sensor for component degradation. This approach could save significant amounts of resources by allowing fewer cost intensive inspections and monitoring schemes as well as improving safety. To investigate the usability of such a data-driven modelling approach models will be tested on simulated data using the subsea gas lifted oil well network model proposed by Krishnamoorthy et al. (2016) and adapted by Verheyleweghen and Jäschke (2018).

2. Gas lifted oil well network

In some cases, oil wells do not have sufficient reservoir pressure to lift fluids to the topside facility. Gas lift, the injection of compressed gas through the annulus, can be used to overcome this. The annulus is the void between the well piping and the casing. This leads to a reduction in the fluid mixture density. That, in turn reduces the hydrostatic pressure loss in the well. Consequently, the pressure at the well bottom decreases, compensating for the low reservoir pressure.

Figure 1: Illustration of a gas lifted oil production system with three wells showing how production goes from reservoir to topside facility (Verheyleweghen and Jäschke (2018)).

In Figure 1 the different parts of a gas lifted oil well network is shown. The oil flows, from a single reservoir into three wells, then, into a manifold before the riser takes the fluid mixture to the surface. Maturing fields experience a significant increase over time in sand production, which can be approximated by an exponential function (Hettema et al. (2006)).

3. Method

3.1. Simulations

A small additional adaption to the model was made to incorporate a varying sand production rate (SPR). For each case study datasets of 200 time series of 500 days were simulated containing the total erosion length of the wells choke valves. The gas lift rate was varied randomly every 50 days within a given range:

Figure 2: Illustrative plot of cumulative erosion [mm] (right axis) and flowrate [kg/s] (leftaxis) from one 500 day time series.

Constant sand production rate yielding a greatly simplified model, but a good starting point for initial exploration of the data-driven methods. This is equivalent to: $m_{\text{sand}}(t) = m_{\text{sand}}(0)$.

Exponential sand production rate yielding a more realistic model of a field increasing sand production as it matures. An exponential function, $m_{\text{sand}}(t) = m_{\text{sand}}(0)e^{0.05t}$, was chosen to emulate a qualitative description of the sand production rate in a field over time (Hetteema et al. (2006)). Figure 2 shows the cumulative erosion of the choke valve for one simulated time series in addition to the total well production flowrate. Note that the choke valve erosion is a function of the well production flowrate, as expected, but the dominating force is the sand production flowrate. The more sand produced by the well, the faster the choke valves erode.

Process variables were measured every time step (day), with added noise to process measurements. Erosion, gas lift injection rate and sand production rate were recorded directly without noise. The pressure is measured in the annulus, well head (top of each well), riser head (top of the riser) and in the manifold connecting the wells. The production rates of gas and oil in the top of the riser as well as the top of each individual well are also measured. In addition to the process measurements, the sand production rate of the reservoir and the gas lift injection rate (control input of the optimisation) are used to simulate the erosion in the choke valves atop each well. The simulated data is then split in two parts of equal size, a training set and an independent test set. Due to the large availability of data for validation, since simulated data is used, we choose to use holdout validation, holding out 30% of the training set for model selection and validation. The final data sets contained 100 time series for training and validation and 100 time series for an independent test set.

3.2. Pre-processing

The gradient of the simulated cumulative erosion is used as response variable (i.e., the erosion rate), this is chosen as the response variable as the cumulative erosion has significant autocorrelation and is a time series, while the erosion rate at any given point only depends on the process variables at that point in time. Sand production rate is usually.

not a constantly monitored variable, as such it was supplied to the models with a realistic sampling interval of 50 days, but the impact of lowering this to 30 days is also studied. Models were tested on normalized data with unit variance and mean zero. Tests were also done using principal component (PC) scores as predictors, in this case PC's explaining > 95% variance.

3.3. Data-driven models

For obtaining the soft sensor for erosion degradation, multiple traditional statistical learning methods are implemented and compared for the use cases, a brief introduction is given below but the interested reader is referred to Friedman et al. (2017). All models were implemented in MATLAB using the Statistics and Machine Learning toolbox (The MathWorks (2020)).

Multiple linear regressions (MLR) are the simplest of all statistical models, where we assume a linear relationship between predictors (or combinations of predictors when including interactions). When such a relationship exists, these models yield good interpretability and room for extrapolation. For the linear regression models, least squares loss is used, and a stepwise approach (Stepwise MLR) is applied for model selection, with iterative addition of predictors (linear terms and interaction terms) to a null model until additional predictors no longer lead to significant reduction in loss.

Ensemble methods essentially aggregate several simple models, in this case regression trees to yield a better prediction than individual models can. In this work bootstrap aggregation (Bagged trees) and gradient boosting (Boosted trees) were used. Ensemble methods can provide very good models of linear and non-linear phenomena, but this comes at a significant cost in transparency as interpreting relationships from these methods is very difficult.

Support vector regression (SVR), which is a kernel method adapted from the famous classification algorithm support vector machines, was used. This method uses the support vector machine (SVM) algorithm to create a separating hyperplane in the data space which will allow prediction on new data samples. SVM's are particularly suited for high dimensional data and are robust against outliers (Drucker et al. (2003)). The reported results are from Cubic kernel SVR, which had the strongest overall performance.

In this work the loss function for parameter optimisation, model selection and model validation is always the mean square error of prediction (MSE). Hyperparameters of the ensemble and kernel methods were tuned using Bayesian optimization, using the expected improvement as acquisition function.

4. Results and discussion

Learning methods were tested on both the data simulated from constant sand production rate and exponential sand production rate. The performance of the methods is measured by independent test set mean squared error of prediction (MSE). The performance results are given in Table 1, where the first two columns give results for the first case study and the last for the second case study. There are some considerations outside of model performance to be taken into account when selecting a model for actual applications. There are significant differences in model training time, with the outlier being cubic kernel SVR, requiring significantly more training than bagged trees, boosted trees and

stepwise MLR. When dealing with safety critical equipment and infrastructure we are not only interested in a high accuracy, but also a high level of trust in the model predictions which in turn means that transparent and interpretable models are preferred. None of the models considered here are completely black box, in general models with transparent coefficients showing how a prediction is made are easier to interpret. Linear regressions are a class of such methods, allowing easy analysis of coefficients and, consequently its predictions. As such, when performance is close the preferred methods will be MLR models due to fast training times and superior interpretability.

Method	Const. SPR	Const. w/ PCA	Exp. SPR	Exp. w/ PCA
Stepwise MLR	0.0096	0.0166	0.0182	0.0191
Bagged trees	0.0091	0.0162	0.0184	0.0192
Boosted trees	0.0125	0.0320	0.0184	0.0239
Cubic kernel SVR	0.0120	0.0129	0.0164	0.0169
30 Day Sampling Rate				
Stepwise MLR	<i>N/A</i>	<i>N/A</i>	0.00740	0.00946
Bagged trees	<i>N/A</i>	<i>N/A</i>	0.00537	0.0134
SVR	<i>N/A</i>	<i>N/A</i>	0.00687	0.00879

4.1. Constant sand production rate

All the methods show a small MSE value when tested on unseen data. Since the underlying phenomenon of erosion behaves linearly when sand production rate is held constant as in this test case. Very good fit is, thus, expected. The usefulness of this test case was primarily for initial exploration on a very simplified system. Additionally, we note that the performance of all models is degraded when principal components analysis (PCA) pre-processing is applied. This could be because the overall degrees of freedom afforded to the model is lowered. If multiple variables are mainly represented in one principal component, the interactions between them cannot be properly modelled by the interaction terms in a linear regression model, similar arguments hold for the other methods.

4.2. Exponential sand production rate

For the data simulated with exponential sand production rate, a significant decrease in the performance was observed for all methods, as expected with a more complex phenomenon being emulated. Similarly, to the initial test case, there is a drop in performance when PCA is applied, but this effect is relatively weaker for the exponential data. In this case cubic kernel SVR proved to have the strongest performance, but in general bagged trees, boosted trees and Stepwise MLR all provided accurate predictions of the erosion rate. The sampling rate of the sand production rate measurement as expected has a very significant impact on the model accuracy with exponential distribution, increasing sampling to once every 30 days instead of 50 for example reduces the MSE of an optimised bagged ensemble from 0.0066 to 0.0184. Similar trends are seen in the other methods as well, with model performance improving significantly when

sampling rate is increased. Such an effect is expected, as the models are working with more accurate data.

5. Conclusion

It is observed that for constant sand production rate, very accurate predictions of the erosion rates are made. Additionally, a significant degradation of accuracy is seen for all the constant sand production rate models except for the kernel methods when PCA is used. This could be due to a lower reliance on variable interactions which to some extent is hidden when PCA is applied. This provided a useful initial exploration and foundation for the second case study. On the data simulated from an exponential sand production rate the performance is overall worse, which is expected since the phenomenon that the models are attempting to reproduce is more complex. The methods are still relatively accurate with under 0.02 MSE on normalised unseen test data. However, when the slope of the sand production rate profile gets very steep (i.e time increases) the models suffer quite significantly from the sampling rate. With current model performance there is a strong case to be made for selecting linear regression-based methods as they provide superior model transparency and interpretability. Having observed that simulated data can be predicted well using statistical models, further investigation on real world data is merited to ascertain applicability to real industrial facilities.

A Metamodelling Approach for Air Pollution Source Estimation

Kuang Cheng^a, Yi Cao^{a,b}, Shuanghua Yang^{a,b}

^a*Zhejiang University, Hangzhou, Zhejiang Province, China 310027*

^b*Institute of Zhejiang University-Quzhou, Quzhou, Zhejiang Province, China 324000*

Abstract

The fast and accurate identification of air pollutant release effectively improved the emergency management for fine chemical industrial parks. The pollutant emission parameters could be estimated with the observed pollutant and meteorology data using an air dispersion model. Most of the fast response source term estimation methods are based on the Gaussian plume model for the low computation complexity. The concentration profile estimated by the Gaussian plume model can hardly represent the observation result affected by the complicated terrain with buildings in dense industrial area. Besides, the dispersion models with well characterized building profile like computation fluid dynamic (CFD) are time consuming.

In this paper, a metamodelling method with downwash effect of buildings in the domain to estimate the air pollutant emission is proposed. The dispersion model (Aermod) with combined plume rise and building downwash (PRIME) model preferred by U.S. Environmental Protection Agency is used to establish an emission inventory which covers most possible release scenarios in a dedicated area such as a chemical industrial park. The initial emission inventory is then fed to a neural network. The emission inventory will be updated as well as the neural network with an increasing number of scenarios until the trained neural network meets the pre-set criteria. The well-trained neural network is then used to predict the source emissions with observed data collected in a fine chemical industrial park.

A case study is performed with a localized Aermod model with geometry and surface character data collected from an industrial park. The results show that the building down wash effect in the industrial parks is responsible for some source estimating error produced by the inverse Gaussian dispersion model. It shows the advance of time consumption and competitive prediction accuracy compared to typical least square inversion methods.

Keywords: Source Term Estimation, Metamodelling, Aermod, Air Pollution, Emergency Management

1. Introduction

Chemical industrial parks gather a large number of industrial enterprises in limited space, challenging daily and emergency management for air pollution control. The development of emission determining has attracted great attention recently.

There are two major types of source tracing methods for chemical industrial parks: (1) the receptor-based model source tracing such as chemical mass balance (CBM) and molecular markers (MM) and (2) the source-based model source tracing such as least square (LS) technique and Bayesian inference-based methods e.g. Markov chain Monte Carlo (MCMC). CMB and MM have been proved with a better performance for source

tracing via studies implemented in a number of locations in USA (Schauer and Cass, 2000), while the prior knowledge of the source profile required by CBM and MM is hardly to be satisfied due to the complexity of pollutant composition and confidentiality (Jaeckels et al., 2007). The source-based model source tracing method such as LS has an important role in various of scenarios. Concentration measurements from sensors can be used for source terms estimation (STE). With the application of sensors measuring the concentration of relative pollutant the source term in the dispersion model can be estimated with the measured data from sensors with regard to source term estimation (STE) (Xu and Xu, 2017). Issartel (2003) used an inverse dispersion model to address the reconstruction of space-time geometry without statistical frame. An experiment data with released tracing gas measured with 14 stations in a characteristic spacing of 500 km was used for evaluation purposes. Lushi and Stockie (2010) developed a STE method based on the inverse Gaussian plume dispersion model. With the meteorology and deposition data from a lead-zinc smelting operation they estimated the total emission and produced a reasonable result. Other than optimization based methods, the Bayesian inference based methods of STE provide the probabilistic considerations for uncertainty analysis with not only one solution but a probability density function (Xu and Xu, 2017).

Apart from the algorithms used for STE problems, the performance of dispersion model is critical for source tracing. Yee et al. (2014) addressed the STE problems with Bayesian inference framework using different dispersion models indicating the significance of model errors caused by the difference between the dispersion model and the fact in real situation (Yee et al., 2014). A limitation of the Gaussian dispersion model (Wawrzynczak et al., 2014) is that Gaussian dispersion model can hardly estimate the source strength simulated by a Gaussian puff model (SCIPUGG).

American Meteorological Society (AMS) and U.S. Environmental Protection Agency (EPA) Regulatory Model (Aermod) enhanced the performance of Gaussian model not only by characterizing the vertical structure of wind profile but also describing the effect of building downwash with incorporated plume rise enhancement (PRIME) algorithms (Perry et al., 2005; Schulman et al., 2000). Although the model performance has been evaluated by many researchers, there are rare applications to STE problems due to the relative high computation load compared with Gaussian dispersion model.

Artificial neural network (ANN) based metamodel has been widely used for nonlinear mapping for the ability to quickly learn from data while limited applications in air pollution source tracing are proposed. In this paper, to overcome the problem of Aermod to be used for STE, an ANN based metamodel is adopted to allow the STE problems to be solved with less computation time but maintaining a reasonable degree of accuracy. The rest of the paper is organized as follows, Section 2 describes the problems and methods used in this paper in detail, Section 3 introduces the numerical experiment setup followed by Section 4 and 5 with result discussions and conclusions respectively.

2. Methodology

2.1. Problem description

Based on the advection-diffusion equation, a point source in location $\mathbf{x}(x, y)$ with releasing rate q produces concentrations measurement c at receptors with coefficient

$a(\mathbf{x})$. Considering n sources with unknown emission rates $\mathbf{q} \in \sim^n$, the concentration measurements at m receptors $\mathbf{c} \in \sim^m$ are dependent on emission rate linearly as follows:

$$\mathbf{c} = \mathbf{A}\mathbf{q} + \boldsymbol{\varepsilon} \tag{1}$$

$$\mathbf{c} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_m \end{bmatrix}, \quad \mathbf{q} = \begin{bmatrix} q_1 \\ q_2 \\ \vdots \\ q_n \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \quad \boldsymbol{\varepsilon} = \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_m \end{bmatrix}$$

Where matrix $\mathbf{A} \in \sim^{m \times n}$ is a sensitive matrix and its value is related to \mathbf{x} . The vector $\boldsymbol{\varepsilon} \in \sim^m$ represents noise and model errors. The problem is now to estimate \mathbf{q} and \mathbf{x} to minimize Euclidean norm:

$$J = \frac{1}{2} \sum_{i=1}^m \varepsilon_i^2 = \frac{1}{2} \sum_{i=1}^m (c_i - \sum_{j=1}^n a_{ij} q_j)^2 = \frac{1}{2} (\mathbf{c} - \mathbf{A}\mathbf{q})^T (\mathbf{c} - \mathbf{A}\mathbf{q}) \tag{2}$$

For source locations \mathbf{x}_k , with fixed unit emission rate \mathbf{q}_k , coefficient matrix \mathbf{A}_k can be calculated with an atmospheric dispersion model. Source strength \mathbf{q}_k and $\boldsymbol{\varepsilon}_k$ can be estimated with calculated \mathbf{A}_k and concentration measurement \mathbf{c} .

$$\mathbf{q}_k = \mathbf{A}_k^+ \mathbf{c}, \quad \boldsymbol{\varepsilon}_k = (\mathbf{I} - \mathbf{A}_k \mathbf{A}_k^+) \mathbf{c} \tag{3}$$

To minimize $J_k = \frac{1}{2} \boldsymbol{\varepsilon}_k^T \boldsymbol{\varepsilon}_k$, a necessary condition is satisfied for a stationary point:

$$\frac{\partial J_k}{\partial \Delta \mathbf{x}_k^T} = \left(\frac{\partial \boldsymbol{\varepsilon}_k}{\partial \Delta \mathbf{x}_k} \right)^T \boldsymbol{\varepsilon}_k = 0 \tag{4}$$

The location \mathbf{x}_k at stationary point indicates the locations of the unknown sources.

After the estimation of source location, the sensitive matrix \mathbf{A} is available and the source strength \mathbf{q} for unknown source can be estimated according to Eq. (3).

There are a number of optimization algorithms in the literature to estimate the variable \mathbf{q} and \mathbf{x} such as Levenberg-Marquardt (Marquardt, 1963) and Newton-Raphson (Loke and Barker, 1996). These methods are diverse with iterative techniques and initial values of target parameters.

The iterative techniques may be time consuming. One of reasons that the Gaussian model is widely used for STE problems is the balanced performance and computation cost. Different from Gaussian model based least square method, the iteration of Aermოდ model is extraordinarily time consuming that hardly to be used for STE problems, particularly for emergency emission source tracing. To overcome this deficit, an Aermოდ model-based ANN metamodelling (ANN-Aermოდ) approach is proposed.

2.2. Source terms estimation using ANN

This metamodelling approach is not simply to replace Aermოდ to make the computation fast, but actually to solve it as an inverse model, hence to replace the LS optimization as well.

The methodology is essentially realized in three steps. In the first step, a dedicated industrial area, the Aermოდ model localized with parameters like albedo, Bowen ratio, surface roughness and terrain elevation, is used to generate emission scenario inventory. The inventory contains full cross design samples to cover the entire domain dimension by dimension.

In the second step, the samples in the inventory are passed to a typical neural network. In terms of the input and output of the ANN, the input includes:

(1) a set of concentration \mathbf{c} simulated to represent the values recorded by the measurement system which dimension is depends on the number of sensors in the industrial park (2) wind speed v and wind direction d (3) sources emission rate q (4) ambient temperature T . Other than these variables, the Aermოდ model requires more to process the data, namely, location of measurement system, albedo, Bowen ratio and surface roughness. These variables are typically unchanged, therefore, we do not need to consider these parameters in the ANN model. The output of the ANN is three-dimensional set $\{x, y, q_n\}$ corresponding to the source locations in x and y -axis coordinate and source emission rate q_n . The input dataset IN and output dataset OU are described as:

$$IN = \{c_m, v_m, d_m, T_m\}_{m=1}^{M_i}, \quad OU = \{x_n, y_n, q_n\}_{n=1}^{N_i} \quad (5)$$

Where M_i is number of concentration measurements and N_i is number of source locations.

The third step is to estimate the source locations and emission rate with ANN. The sampled measurements dataset $D_i = \{c_i, v_i, d_i, T_i\}_{i=1}^{M_i}$ is the input of the ANN and the output is source locations and emission rate: $D_o = \{x_\tau, y_\tau, q_\tau\}_{\tau=1}^{N_i}$.

Table 1 Range of variation of variables considered in source emission inventory

x_n, y_n	q_m	u_m	d_m	T_m
2 sources	min: 0[g/s]	min: 1[m/s]	min: 10°	min: 0°C
	max: 1[g/s]	max: 3[m/s]	max: 360°	max: 30°C

3. Experimental study

A numerical experiment is undertaken to evaluate the performance of features of the proposed method. The Aermოდ model is localized with building geometry, measurement locations, terrain elevation and surface roughness data collected from a chemical industrial park in Shangyu, China whose layout is demonstrated in Figure 1.

There are 11 receptors around the industrial park denoted by triangles in Figure 1. The circles are potential two source locations corresponding to the highly risk area. Other variables used to generate the inventory and their value are shown in .

Table 1. In this work, a scenario inventory with the total 1.3×10^5 records is processed for training. A back propagation neural network with three hidden layers is used to correlate the input and output. For performance evaluation purposes, a numerical

simulation is undertaken using the least square method with either Gaussian model (LS-Gaussian) or Aermod model (LS-Aermod). Addition to the test data for three methods, initial guess is required for LS-Gaussian and LS-Aermod method.

4. Results and discussion

The numerical simulation is implemented using Aermod (version 19191) running on a computer with Intel Core i5 (3.00GHz), 24.0GB RAM. The emission scenario data collection used for performance evaluation is not included in the training data. The prediction results are shown in Table 2. The test data simulated an emission in location (-

Figure 1 The geometry of an industrial park in Shangyu

175.00, 640.00), denoted by the circle in the south of the industrial park in Figure 1, is implemented. In Table 2, the computation time 0.402s indicating the advance of metamodelling method compared to 29.157s (LS-Gaussian) and 4123.617s (LS-Aermod). The location error of LS-Gaussian is 801.22 m, 3.50 m for LS-Aermod and 9.48 m for the ANN-Aermod method. The details of true and estimated source locations are shown in fourth and fifth column in Table 2. The results of LS-Gaussian and LS-Aermod indicated the Aermod model provided a different concentration profile in building complexity area compared to the Gaussian model. The building downwash effect plays an important role in chemical industrial parks.

Although the LS-Aermod method demonstrated less retrieval error, the relatively high time consumption is hardly to be accepted for emergency emission estimation. The LS-Gaussian method costs a ratio of 0.7% computation time of LS-Aermod, while the high estimation error of location is away of the region of high-risk area shown as circles in Figure 1. The ANN-Aermod model comparing with others methods, cost a ratio of 0.001% computation time of LS-Aermod method, with an estimation error ratio of 1.18% of LS-Gaussian method, could process a valuable result with the least time consumption.

Table 2 Numerical experiment using test data simulated with Aermod model. The first column shows the source tracing method. The second column is total computation time for all trials. The third column is Euclidian distance E_L corresponding to location estimation error. The fourth and fifth column show the true release location and retrieved location respectively.

Method	Computation Time(s)	E_L (m)	Release Location	Retrieval Location
LS-Gaussian	29.157	801.22	(-175.00, 640.00)	(-157.12, -161.02)
LS-Aermod	4123.617	3.50	(-175.00, 640.00)	(-171.50, 640.00)
ANN-Aermod	0.402	9.48	(-175.00, 640.00)	(-175.00, 647.32)

5. Conclusion

This paper proposed an efficient and accurate source term estimation technique for chemical industrial parks. The prediction error ratio is 1.18% to Gaussian model based least square method and the computation time ratio is 0.7% of Aermod model-based method. The accurate prediction of source location shows the competitive performance of source tracing in industrial parks with complex constructions. Thus, accurate predictions can be made in a limited time, providing plenty of valuable time for emergency responses.

This source tracing method runs free of initial guess of source locations and therefore provides a more practical solution for source tracing in emergencies.

Abstract

This paper presents a methodology for combining foreground and background uncertainty in the life-cycle assessment (LCA) of processes and products at a low technology-readiness level. We compare the LCA of two ionic liquids, 1-butyl-3-methyl-imidazolium tetrafluoroborate [bmim][BF₄] and 1-butyl-3-methyl-imidazolium hexafluorophosphate [bmim][PF₆]. The nominal scenario predicts that [bmim][BF₄] generates lower end-point environmental impacts than [bmim][PF₆]. However, the uncertainty ranges around these nominal predictions overlap significantly, with [bmim][BF₄] causing higher impacts than those of [bmim][PF₆] in up to 30% of the uncertainty scenarios. On top of this, accounting for uncertainty in the foreground data more than doubles the estimated impact ranges in several damage categories. This case study, therefore, demonstrates the need for combining foreground and background data uncertainty for more reliable life-cycle assessments.

Keywords: uncertainty analysis, life cycle assessment, ionic liquids, process simulation

1. Introduction

Life-cycle assessment (LCA) is a popular methodology to quantify the environmental impacts of products and processes throughout their life cycle (Guinée and Heijungs, 2017). It entails the collection of so-called inventory data on mass and energy flows, from raw material extraction to process emissions and wastes. In many applications, however, these data may be lacking because of confidentiality or low technology readiness (Skoronski et al., 2020).

Various approaches have been proposed to bridge the gap in inventory data. One such approach entails the development of detailed process models in order to predict the performance at scale of processes at a low technology-readiness level (TRL), for which industrial process data are yet unavailable (Hetherington et al., 2014). However, these process models can themselves be subject to large uncertainty (Van der Spek et al., 2017). It is important, therefore, to quantify these uncertainties and propagate them into the predicted inventories, and ultimately the predicted impacts. Despite this, most LCA studies based on process simulation simply omit the effect of uncertainty, or consider only the uncertainty in the background data which comprise energy and material flows

delivered to the foreground system as aggregated data sets whereby individual plants and operations are not identified (Baaqel et al., 2020; Llantoy et al., 2020). A more rigorous uncertainty analysis calls for including uncertainty on the foreground data alongside background uncertainty, that is, uncertainty from the system of primary concern to the analysis including process operating conditions and thermophysical properties. This is especially important when comparing processes with similar performance indicators where the corresponding uncertainty ranges could indeed overlap significantly.

This paper presents a methodology for combining foreground and background uncertainty in the LCA of such processes and products at a low TRL. The approach is illustrated with the case study of two dialkylimidazolium ionic liquids (ILs), 1-butyl-3-methylimidazolium tetrafluoroborate [bmim][BF₄] and 1-butyl-3-methylimidazolium-hexafluorophosphate [bmim][PF₆]. Both ILs find many applications, for instance as physical separation media (Riisagera et al., 2006; Shiflett and Yokozeki, 2010) where their separation solvating capacity and negligible vapor pressure are advantageous. The current low TRL of ILs justifies the use of process flowsheeting to simulate their production at scale and, therefore, the consideration of foreground data uncertainty. The methodology is described next (Section 2), before introducing the case study (Section 3) and presenting some results (Section 4) and conclusions (Section 5).

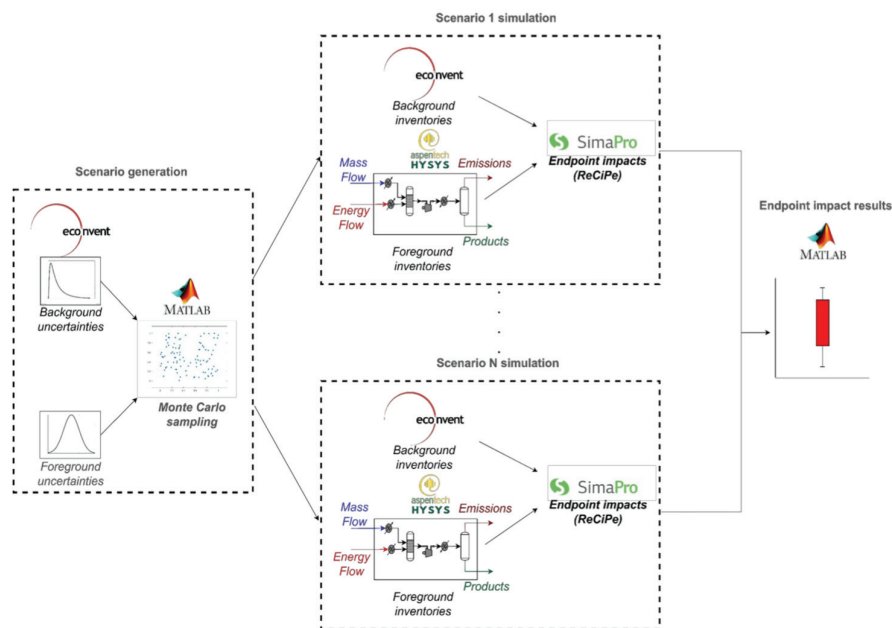

Figure 1: Methodological framework for uncertainty analysis in LCA.

2. Methodology

The proposed methodological framework (Figure 1) combines uncertainty modeling, Monte Carlo sampling, process simulation, and environmental assessment. For each uncertainty realization, the uncertainty is propagated through both the background and

foreground inventories, and ultimately to the environmental damages. These activities are conducted with the state-of-the-art tools Aspen-HYSYS and SimaPro and coordinated using Matlab. They are further detailed below.

2.1. Environmental assessment

The LCA follows the four phases defined in the ISO 14040 standards: (i) goal and scope, (ii) inventory analysis, (iii) impact assessment, and (iv) interpretation. Choices about the system, including the scope, the boundaries of the foreground system and the functional unit, are made in the first phase. Environmental flows corresponding to the system inputs and outputs are collected during the inventory phase, including raw materials, energy streams, emissions and wastes. Inventories for the background processes can rely on databases, such as ecoinvent or GaBi. In contrast, the foreground processes may not be found in such databases due to confidentiality or low technology readiness, but they may instead be predicted using detailed process flowsheeting, such as Aspen-HYSYS or gPROMS. Both the foreground and background inventories are finally translated into environmental impacts during the impact assessment phase through a characterization method.

2.2. Background and foreground uncertainty modeling

A common approach to quantifying the uncertainty in background inventories involves the so-called Pedigree matrix (Weidema and Wesnæs, 1996). Scores between 1–5 are assigned to the inventory data based on five criteria: reliability, completeness, temporal, geographical and technological differences. These scores are combined with a basic uncertainty factor to determine the standard deviation of a log-normal distribution for each environmental flow. In contrast, the foreground uncertainty corresponds to uncertain process parameters, including operating conditions such as pressures and temperatures, reaction rates and conversions, and thermophysical properties such as boiling point and density. These uncertain process parameters can be propagated to the mass and energy flows using the process flowsheet model.

Unlike the background uncertainty which can be retrieved from LCA databases, the main sources of uncertainty in the foreground processes need to be characterized. These may be related to experimental errors in lab-scale procedures, or else inferred from expert opinions when process scale-up is involved. Such uncertainty may furthermore be expressed as parameter ranges or probability distributions.

2.3. Uncertainty propagation

Monte Carlo sampling is used to construct a set of scenarios from the combined foreground and background uncertainty. The number of scenarios is determined automatically based on a user-defined error tolerance between the sample mean and the actual uncertainty mean value (Law and Kelton, 2000). The foreground and background inventory flows for each uncertainty realization are computed using the process model and the inventory database, respectively. In turn, the inventory flows for each scenario are converted to environmental impacts, after normalization by the functional unit and application of a characterization method:

$$C_j = \sum_{i=1}^N f_i b_{ij}$$

where C_j is the predicted endpoint impact j of the scenario in units of environmental damage; f_i is the foreground output in the form of mass and energy flow i under a given uncertainty scenario in units of mass or energy; and b_{ij} is the characterized normalized

background output under a given uncertainty scenario in units of environmental damage of endpoint impact j per unit of mass or energy of flow i with N the number of flows into and out of the process. The scenario generation and evaluation, and the final aggregation into impact uncertainty ranges, are orchestrated in Matlab.

3. Case Study Definition

3.1. Synthesis of Ionic Liquids

Our case study compares the performance of two dialkyl-imidazolium ionic liquids: 1-butyl-3-methylimidazolium tetrafluoroborate [bmim][BF₄] and 1-butyl-3-methylimidazolium hexafluorophosphate [bmim][PF₆]. Both ILs are produced using the same process, for which we developed process models using Aspen-HYSYS to scale-up experimental synthesis procedures.

The synthesis proceeds via the exchange of ions between 1-butyl-3-methylimidazoliumchloride [bmim][Cl] and the corresponding salt. The salt used for [bmim][BF₄] is sodium tetrafluoroborate and for [bmim][PF₆], lithium hexafluorophosphate. The products are the ionic liquid and the chloride salt. The scaled-up process starts by reacting a solution of [bmim][Cl] with excess salt under atmospheric conditions. The mixture is then separated into (i) an upper phase containing the separated IL with some impurities and (ii) a lower phase containing solid chloride salt. The upper phase is washed using the corresponding fluorinated salt to remove impurities before removing excess water from the IL in a vacuum distillation column.

3.2. Life-Cycle Assessment and Uncertainty Analysis

We adopt a cradle-to-gate scope that encompasses all stages from raw material extraction to the final product synthesis. The geographic location for the assessment is Europe. Since chemicals are commonly sold by weight and because the scope of our work is limited to the production phase only, the functional unit is set to “1 kg of ionic liquid”. Background inventory data are collected from the ecoinvent v3.5 database (Wernet et al., 2016) interfaced through SimaPro v9.0. The foreground production processes for both ILs and their precursors are unavailable in ecoinvent and thus modeled using Aspen-HYSYS v9. Thermophysical properties such as density and critical properties are obtained from experiments or from the literature. Other properties such as heat of formation are estimated using group contribution methods (Valderrama and Rojas, 2009). The rest of the properties are estimated from the molecular structure using the Property Constant Estimation System (PCES) in Aspen-HYSYS. The predicted background and foreground inventories in each uncertainty scenario are converted into 17 mid-point impacts using the ReCiPe 2016 characterization method (Huijbregts et al., 2016). Then, they are further combined into 3 damage categories (end-points): human health, ecosystems quality and resources.

We consider a total of 9 uncertain parameters in the (foreground) process model, 5 of which correspond to unit operating conditions (e.g., temperature, pressure) and the other 4 are thermophysical properties (e.g., density, heat of formation). All of these parameters are assumed to follow a normal distribution, with standard deviations estimated based on literature data or from experience. The number of foreground uncertainty scenarios was in the range between 3,000–5,000 for the various runs.

4. Results and Discussions

Figure 2 shows the box plots for each end-point indicator, where [bmim][BF₄] and [bmim][PF₆] are compared under the following scenarios: (A) combined foreground and

background uncertainty, (B) foreground uncertainty only, and (C) background uncertainty only. The central line inside each box represents the median scenario; the upper and lower ends of the box represent the 75% and 25% quartiles, respectively; and the lower and upper extended lines represent the minimum and maximum values, respectively.

Comparing both ILs in terms of their median scenarios only, one could conclude that the production of [bmim][BF₄] presents lower environmental impacts than [bmim][PF₆] in all damage areas. But the box plots show a different reality, whereby the range of impacts of both ILs overlap significantly. All uncertainty considered (scenario A), the damages caused by [bmim][BF₄] on human health (left plot), ecosystems quality (middle plot), and resources (right plot) are higher than those caused by [bmim][PF₆] in 20%, 15% and 30% of the uncertainty scenarios, respectively. This overlap is significantly larger than under the traditional approach of considering solely the background uncertainty (scenario C), where the damages caused by [bmim][BF₄] on human health, ecosystems quality and resources are higher than those of [bmim][PF₆] in 8%, 5% and 20% of the scenarios. Therefore, adding the foreground uncertainty to the background uncertainty (scenario A) is necessary for a more reliable comparative assessment of these two ionic liquids.

Notice that [bmim][BF₄] presents lower impacts on human health, ecosystems quality and resources in nearly all of the scenarios when considering the foreground uncertainty alone (scenario B). But even though these contributions could appear low in comparison to their background uncertainty counterparts, they result in 2 to 3-times larger interquartile ranges for the environmental impacts under combined foreground/background uncertainty propagation. This is mainly due to the multiplicative effect of the foreground and background uncertainty which are linked via the mass and energy flow inventories.

Figure 2: Comparison of end-point indicators under combined foreground/background uncertainty (A), foreground uncertainty only (B), and background uncertainty only (C).

5. Conclusions

A methodology was proposed for the environmental assessment of emerging technologies that combines process flowsheeting with LCA and propagates the uncertainty in both

background and foreground processes to the predicted environmental impacts. This methodology was illustrated with the case study of two dialkyl-imidazolium ILs, [bmim][BF₄] and [bmim][PF₆]. Accounting for the foreground uncertainty was found to increase the uncertainty ranges around all three end-point impact indicators significantly, in comparison with a classical assessment that would only consider the background uncertainty. Future research should, therefore, consider the potential effect of foreground uncertainty more carefully, especially in the comparative LCA of early-stage processes and products, in order to enable more robust decision making.

Abstract

Modeling of energy recovery systems, Heat Exchanger Networks (HEN) as an example, are complex processes due to many parameters involved and the lack of knowledge on the impact of operational variables on the response. These variables are often affected by different types of uncertainty as to measurement errors, computation errors, or imprecision related to the underlying method. The uncertainty in the data may be treated by considering, rather than a single value for each variable, the interval of values in which it may fall, histograms, or other multivalued data: symbolic data. This work aims to use, when possible, the symbolic data analysis to adapt the classical mathematical HEN models. It deals with the study of continuous interval data through suitable Principal Component Analyses and Regression for two purposes: clustering exchanges (i) classification of exchangers to detect those impacted by uncertainty factors and (ii) evaluation of the relationship between the different process parameters (inlet temperature, heat transfer coefficient, etc.) on interval data. The new method has been tested on a real data set and the numerical results are reported. The symbolic approach provides a simple way to study a great number of scenarios.

Keywords: Machine Learning for Symbolic Data, Interval-valued data, Flexibility and Robustness, Heat Exchanger Networks (HEN)

1. Introduction

Energy saving is an important issue for both industries and society. In the industrial chemical process, Heat Exchanger Networks (HEN) are widely used techniques for reducing external heating and cooling utilities. Data generated by those complex systems has increased drastically over the past few years. Suppose we have 20 Heat Exchangers (Hx) on which 4 variables are measured (2 input and 2 output hot and cold input streams). If we assume that we have hourly values of these variables for 1 year, then each exchanger is described by 35040 values. If, on the other hand, certain characteristics of the exchangers (let's say 3) vary over time, then the 3D array representation conventionally used in data analysis is then $8760(\text{hours}) \times 20(\text{Hx}) \times 7$ (parameters). This is not very large compared to what could be provided by the industry in real-time.

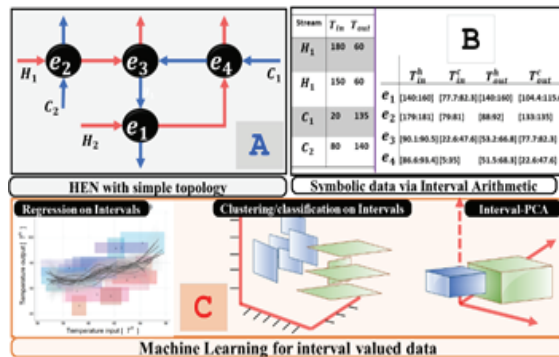

Even such data is ubiquitous for a larger scale of HEN systems, data-oriented based approaches are often analyzed with simplified models by aggregating data. During this operation, some information on the variability aspects is lost. The robustness assessment of HEN is therefore affected since its flexibility is conditioned by the variability of the uncertain parameters. When the size n of entries (exchangers) and p number of variables (features) are very large, classical analysis can be problematic.

To address this problem, we use a more complex object description to capture the variability of measured parameters on each exchanger. When dealing with quantitative variables, complete information can be achieved by describing a set of statistical units in terms of interval data, histogram, rather than a single-valued variable. Mathematically, interval-valued data with measurements on p random variables, are p -dimensional hyperrectangles in R^p . Such data need to be visualized, synthesized, and compared on factor spaces.

This paper is in a complementary perspective to Floquet et al's work (Floquet et al., 2016). They have initiated the robustness analysis of a simple exchange networks using interval arithmetic. They pointed out the "butterfly effect" of the alteration of characteristics of some Hx on the operation of the HEN. Indeed, a maintenance operation of an exchanger, alter the variability of the other parameters of the network. Reducing fouling would imply variations in pressure and shift flows between parallel branches, all changing over time in a way that is difficult to predict (Macchietto et al., 2018). The purpose of this paper is to check whether there are groups of exchangers characterized by the same properties in terms of their responses to external fluctuations. Following the same idea (interval-valued data), the Symbolic Data Analysis (SDA) (Billard & Diday, 2006; Bock & Diday, 2012) is used to study how uncertainty in the output of a model can be apportioned to different sources of uncertainty.

2. Machine Learning for symbolic data

Figure 1 outlines the design and methodological scheme of the proposed method. This methodology draws on two main components: (B) Symbolic data through interval arithmetic, and (C) machine learning for symbolic data. Part A corresponds to the HEN model to be studied or simulated. The interval-valued data is then constructed in part (B). The core function of the

proposed method included in this paper is part (C). The originality of this research lies in the combination of a traditional robustness analysis of HEN with SDA.

2.1. Symbolic Data and statistics of interval-valued variables

In classical statistics, $n \times p$ data matrix $X = X_{ij}$ is defined between n individuals and p variables, where each

cell (i, j) contains a unique value x_{ij} . The symbolic objects are more complex than a simple valued variable description, symbolic data can contain internal variation of the features representing *imprecise knowledge* and can be structured. The symbolic analysis generalizes the classical data analysis, e.g. $x = c$, $c \in R$ is equivalent to the symbolic interval $\xi = [c, c]$. A full conceptualization of symbolic objects can be found in (Bock & Diday, 2012). Let Ω be a set of individuals, D containing the descriptions of individuals and the descriptions of classes of individuals, a , a mapping defined from Ω into D which associates to each $\omega \in \Omega$ a description $d \in D$ by using intervals, histograms, etc. More formally, symbolic object is a triplet $s = (a, R, d)$ where R is a relation between

descriptions, d is a description, and a is a mapping defined from Ω in L depending on R and d . For instance $L = true, false$ or $L = [0,1]$ and R may be one of the relations in $=, \equiv, \Rightarrow, \leq, \subseteq, \in$. To illustrate this point with a simple HEN example, if the outlet temperature of two exchangers ω_1, ω_2 is given by $T_{out}(\omega_1) = 90^\circ C, T_{out}(\omega_2) = 120^\circ C$ the description of the class $D = (\omega_1, \omega_2)$ obtained by a generalization process can be $[90,120]$. The symbolic object s is defined by a triple $s = (a, R, d)$ where $d = [90,120]$, $R = ' \in '$ and a is the mapping: $\Omega \rightarrow true, false$ such that a is the true value of $T_{out}(\omega)Rd$ written $a(\omega) = T_{out}(\omega) \in [90,120]$. An individual ω is in the extent of s if and only if $a(\omega) = true$. Simple statistical descriptions (mean, variance, ...) for interval-valued variables have been defined in (Bertrand & Goupil, 2000). Let consider $Y_j \equiv Z$ be the j^{th} interval-valued random variable, and $Z(\omega_u) = [a_u, b_u]$ is a realization of Z for the observation ω_u over the observed interval $[a_u, b_u]$. The empirical distribution function, $F_Z(\xi)$, is the distribution function of a mixture of m distributions $Z(\omega_u), u = 1, 2, \dots, m$. The central and dispersion parameters of a variable all derived from a strong assumption: the inherent fluctuation within random intervals and rectangles is uniformly distributed: $f(\xi) = \frac{1}{m} \sum_{u: \xi \in Z(u)} \left(\frac{1}{(b_u - a_u)} \right)$. The symbolic sample mean for interval-valued data is given by:

$$\underline{z} = \frac{1}{m} \sum_u \left(\frac{1}{(b_u - a_u)} \right) \quad (1)$$

and the sample variance is given by

$$S^2 = \frac{1}{3m} \sum_u (b_u^2 + a_u^2 + b_u a_u) \frac{1}{4m} \left[\sum_u (b_u + a_u) \right]^2 \quad (2)$$

2.2. PCA for interval-valued data

A principal component analysis is designed to reduce p -dimensional observations into s -dimensional components (where $s \ll p$) in an interpretable way, such that most of the information in the data is preserved. Let $i = 1, 2, \dots, m$ denote n objects (exchangers) described by p features (or variable) Y_1, Y_2, \dots, Y_p (temperatures, ...). The symbolic data matrix used for interval PCA is given by $\underline{X} = (\xi_{11} \dots \xi_{1p} \vdots \dots \xi_{n1} \dots \xi_{np})$ where $\xi_{ij} = [x_{ij}, x_{ij}]$ is the interval of possible values of variable j for the exchanger i , and the symbolic data vector can be denoted by $x_i = (\xi_{i1}, \dots, \xi_{ip}) = ([x_{i1}, x_{i1}], \dots, [x_{ip}, x_{ip}])$. The data point is represented in R^p space by hyperrectangles R_i with 2^p vertices. There are mainly two methods to solve the algebraic mapping to lower dimension: Vertices and Centers methods. To find the factorial axes for Centers method, a classical PCA is applied to the centers $c_i \in R^p$ of the n hyperrectangles R_i . The coordinates of i^{th} center c_i is denoted by x_{ij}^c , where x_{ij}^c is computed for $i = 1, \dots, n$ and $j = 1, \dots, p$. From that case, the centers of hyperrectangles in its rows is an $n \times p$ data matrix, denoted by X and the j^{th} column of X is denoted by the feature Y_j^c . The interval principal components values are obtained by computing first the v^{th} principal component of the center c_i is given by:

$$\psi_{iv}^c = \sum_{j=1}^p (x_{ij}^c - \underline{x}_{ij}^c) \cdot \eta_{iv} \quad (3)$$

where $\eta_{jv} = (\eta_{1v}, \dots, \eta_{pv})$ is the v^{th} of S (sample covariance matrix associated with the dataset). It is possible to find an $[\underline{\psi}_{iv}, \overline{\psi}_{iv}]$ of the possible values of v^{th} principal component ψ_{iv}^c of c_i (Cazes et al., 1997).

For the object i

$$\underline{\psi}_{iv} = \sum_{j=1}^p \max(x_{ij}^r - x_j^c) \cdot \eta_{jv} \quad \text{for} \quad \underline{x}_{ij} \leq x_{ij}^r \leq \overline{x}_{ij} \quad (4)$$

$$\underline{\psi}_{iv} = \sum_{j=1}^p \max(x_{ij}^r - x_j^c) \cdot \eta_{iv} \quad \text{for} \quad \underline{x}_{ij} \leq x_{ij}^r \leq \overline{x}_{ij} \quad (5)$$

3. Application to HEN data

3.1. Data simulation design and preliminary analysis

The starting point for this application is the data table from step B in Figure 1, which is the result of HEN model analysis by interval arithmetic. In order to evaluate the behavior of the exchanges on a more complex network, simulated data on the initial table were undertaken and the simulation procedure is as follows:

- For each variable $(T_{in}^h[\min_{in}^h, \max_{in}^h], T_{in}^c[\min_{in}^c, \max_{in}^c], T_{out}^h[\min_{out}^h, \max_{out}^h], T_{out}^c[\min_{out}^c, \max_{out}^c])$, and for all exchangers, we look for the minimum and the maximum.
- Simulate 40 points (exchanges) using random variable from the uniform distribution. For example, for the exchanger No. 30 (E30), the minimum input temperature for the cold stream is obtained by the following probabilistic simulation scheme: $T_{in}^c(E30) \sim U(\min(\min_{in}^h), \max(\max_{in}^h))$. Retrieve the interval matrix of the 4 variables: $T_{in}^h, T_{in}^c, T_{out}^h$, and T_{out}^c .

Statistical description for the interval-valued data of the initial matrix and the simulated one, using equations 1 and 2, is presented in the following Table:

Tableau 1 Descriptive statistics (mean and standard deviation s:d) for the interval-valued

		T_{in}^h	T_{in}^c	T_{out}^h	T_{out}^c
Initial data	Mean	[124.20:131.42]	[46.32:61.30]	[70.32:84.30]	[84.68:94.95]
	sd	[44.47:45.42]	[38.25:23.67]	[20.81:12.03]	[47.34:38.20]
Simulation	Mean	[112.14:134.02]	[45.34:42.93]	[68.95:81.42]	[76.98:97.71]
	sd	[20.77:28.33]	[22.91:23.85]	[11.38:9.02]	[33.34:25.32]

3.2. Principal Component Analysis for interval-valued data

The interpretation of the position of the interval-valued data in the principal plane is the same as in the classical principal component analysis situation. In Figure 2, we show the results with respect to the first three axes, achieved by the Symbolic PCA using 4 and 5 (centers method). Notice that the 61% of the total inertia is explained by the first two axes in the case of simulation (40 exchangers), and 98.5% of in the case of initial data (4 exchangers). In Figure 2, closeness among clusters exchanger mainly influenced by the

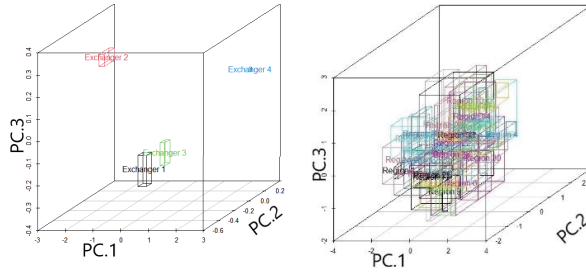

Figure 2 Principal 3D-space with data of interval type of HEN. Factorial for 4 Exchangers (left) and for 40 Exchangers (right).

same descriptors. Only one group consisting of exchangers 1 and 3 can be identified. The constituent elements of this cluster are influenced by the same main factors. Exchangers 2 and 4 are detached from the cluster from a 3D perspective. This observation is in line with the conclusions of the initial study (Floquet et al., 2016). For simulated data, the same analysis can be achieved using additional information, and at this stage, it is also difficult to give an interpretation of the similarity in size and shape among exchangers. In order to shed new light on the variability of outlet temperatures as a function of input streams, we propose a linear regression on interval values.

3.3. Regression and prediction for interval-valued data

Tableau 2 Results of interval-valued data regression

	Dependent variable	
	$T_{out}^h [min_{out}^h, max_{out}^h]$	$T_{out}^c [min_{out}^c, max_{out}^c]$
$\widehat{\beta}_0$	63.22	37.46
$\widehat{\beta}_1$	0.0046	0.17
$\widehat{\beta}_2$	0.244	0.6

The model proposed here is based on the classical formation of HEN models. However, a notable difference lies in the integration of symbolic objects in the model. To understand how the input (cold and hot) temperature stream affects the output temperature, we propose a regression model for interval-valued temperature. For a hot stream:

$$T_{out}^h [min_{out}^h, max_{out}^h] = \beta_0 + \beta_1 \cdot T_{in}^h [min_{in}^h, max_{in}^h] + \beta_2 T_{in}^c [min_{in}^c, max_{in}^c] + \epsilon \quad (6)$$

The following results are obtained using the simulated data in the Table. To evaluate this approach, two datasets were used: (i) *training dataset*, which is a set of the first 35 exchangers used to fit the parameters of the model 6 and (ii) *test dataset*, which is a set of the rest 5 exchangers used to provide an unbiased evaluation of the

Table 3 The prediction results

Hx	Predictions		Test	
	$[\widehat{T}_{out}^h]$	$[\widehat{T}_{out}^c]$	$[T_{out}^h]$	$[T_{out}^c]$
E36	[64.21:75.01]	[61.41:80.81]	[73.61:67.64]	[39.89:119.97]
E37	[73.25:82.21]	[76.12:104.68]	[69.72:89.61]	[115.31:89.80]
E38	[68.06:76.77]	[63.75:87.63]	[57.47:91.65]	[46.96:104.48]
E39	[64.73:77.73]	[69.71:80.77]	[88.25:85.72]	[113.54:66.64]
E40	[60.93:72.54]	[52.76:75.85]	[52.70:88.04]	[83.85:100.02]

estimated model. The Table 3 shows the results of the predictions using the fitted model and corresponding data test. The size of the coefficient for each independent variable $T_{in}^h [min_{in}^h, max_{in}^h]$ and $T_{in}^c [min_{in}^c, max_{in}^c]$

gives the size of the effect that variable is having on the dependent variable T_{out}^h and T_{out}^c . The estimated coefficients tell how much the output stream is expected to increase when that inputs streams (hot and cold) increases by one. For example the coefficients for the model 6, T_{in}^h differed by 1°C (and T_{in}^c did not differ) T_{out}^h will differ by 0.17°C units, on average. The estimated intercept $\widehat{\beta}_0$, is the expected mean value of T_{out}^h and T_{out}^c when all inputs are 0. In our experiments, the T_{in}^h and T_{out}^c never comes close to 0, then intercept has no meaningful interpretation.

4. Conclusion

Symbolic Data Analysis (SDA) extends statistics and multivariate data analysis to deal with data structured in a distributional form with complex internal variations. In this paper, comprehensive modeling via SDA has been presented that moves substantially beyond the traditional modeling in HEN robustness analysis. It proposed some new approaches which intended to redefine the robustness of HEN based on interval data. First, the detection of Exchangers cluster which would be affected by common factors has been modeled by Symbolic Principal Component Analysis. Second, the relation between inherent variation, expressed by intervals, of input and output temperature has been modeled using the linear regression method for interval-valued variables. Future research should include histogram valued-data.

Rules for Predicting Benefits in Simultaneous versus Sequential Heat Integration

Abstract

Applying simultaneous process optimization and heat integration (SIM) on a process can lead to an increased Net Present Value (NPV) compared to applying a sequential approach (SEQ) to the same process. These benefits do not always arise, but the computational effort is significantly higher. In this paper, three heuristic rules are proposed that predict whether applying SIM will improve a specific process over applying SEQ. These rules are to be applied once the results of SEQ are available and can be used to decide if SIM should be applied or not. The proposed rules are subsequently verified with two test cases.

Keywords: Simultaneous Heat Integration, Sequential Heat Integration, Process Optimization, Non-Linear Programs (NLPs), Trade-Off-Section (TOS)

1. Introduction

Multiple optimization strategies can be applied to ensure that a newly developed chemical process is energy efficient. The traditional way to perform energy optimization is sequential process design and heat integration (SEQ), which consists of two steps. In the first step, the operating conditions of the background process are optimized, assuming that all heating and cooling demands are satisfied by external utilities. In the second step, the heat integration scheme is optimized to derive the lowest possible external utility demand for this process. It follows that the sequential approach leads to a process where the operating conditions are determined without considering the scope for improved heat recovery. An alternative to SEQ is simultaneous process optimization and heat integration (SIM), where the process and the heat integration are optimized in one step. Duran and Grossmann (1986) proposed an NLP formulation for applying SIM to a process. This formulation was used in several publications as a basis for further research. Examples are Dowling and Biegler (2015), who modified the formulation for large scale flowsheet optimization, and Kamath et al. (2012), who proposed a modification that allows for taking phase changes into account. An alternative MINLP formulation was proposed by Kong and Maravelias (2018). However, to avoid the higher computational costs with MINLP problems, this paper focuses on the NLP formulation by Duran and Grossmann (1986).

The benefit of applying SIM instead of SEQ is that the external utility costs can be decreased. In addition, better process parameters can be found than the ones obtained by

applying SEQ. One potential downside of SIM is that the computational costs are significantly higher, because the size of the resulting NLP is larger with increased degree of non-linearity. It follows that the complexity of the optimization model increases, which can lead to reduced robustness, i.e. the optimizer may fail to find the global optimum or even a feasible solution. Hence, the resulting higher effort is justifiable only if applying SIM leads to significant improvements compared to applying SEQ. However, these benefits do not occur for every process; a counter example can be found in Pötting (2020).

In this paper, three heuristic rules are proposed. These heuristics allow for predicting whether applying SIM instead of SEQ can lead to benefits for a specific process. As the rules are to be applied after performing SEQ, they allow the engineer to decide whether SIM should be applied or if an application of SIM would lead to similar results as already obtained from the SEQ approach. The proposed rules are applied to two test cases and optimization with both SEQ and SIM are performed to verify the predictions made.

2. Methodology

The proposed heuristics are derived based on the following reasoning: The process optimization performed by applying SEQ leads to the highest possible net present value (NPV) for the background process. By definition of optimality, any change in operating conditions for applying SIM from the optimum given by applying SEQ would lead to the same or a lower NPV for the background process. Thus, the lower NPV has to be compensated for by providing more heating capacity. The rules proposed in this paper are explained for the case of an increase in the utilized heating capacities. An analogous set of rules can be derived for the case of increasing utilized cooling capacities. The utilized heating capacity of a process can be increased if three different conditions are met:

- Heuristic 1: There needs to exist a Trade-Off-Section in the process which is described in more detail in Section 2.1.
- Heuristic 2: The process needs to be able to utilize the additional heat. This can be done by either reducing the usage of external heating utilities or by using the heat to produce additional products, such as steam or electricity. The use of additional heat to reduce the feedstock consumption is beyond the scope of this paper. Heuristic 2 is explained in Section 2.2.
- Heuristic 3: The creation and utilization of additional heating capacity needs to be cost efficient. Heuristic 3 is discussed in Section 2.3.

2.1. *Heuristic 1: Existence of a Trade-Off-Section*

To be able to increase the amount of provided heating capacity by applying SIM, a process needs to have at least one Trade-Off-Section (TOS). A Trade-Off-Section can be defined as a section of the process which allows for adjusting the operating conditions such that the profitability of the background process is lowered in order to generate additional heating capacity. A section is a TOS if it satisfies the following two conditions:

- At least one of the section's operating parameters has to influence both the heat exchange with the rest of the process and at least one outlet flow of the section.

This influenced effluent heat or material flow is denoted $f_{Infl}^{TOS,out}$ and the operating parameter is referred to as decision variable x . The identified section can have several additional effluent flows that may be influenced by the independent variable as well. If the considered process section has several independent variables or influenced flows, each combination of process section, independent variable and influenced flow has to be evaluated separately. For the process section to be a TOS, only one of these combinations needs to meet the second condition.

- The second condition is that perturbing the decision variable x from its optimal value determined after applying SEQ has an opposite effect on the NPV of the background process compared to the quantity of additional heating capacity generated. This opposite effect allows for compensating the lower NPV of the background process by additional heating capacity. However, the NPV is determined by the entire background process and not only the particular TOS studied. To relate the local behavior of the TOS to the plantwide performance that determines NPV, it is assumed that the influenced effluent flow $f_{Infl}^{TOS,out}$ correlates positively with the plant wide NPV.

Heuristic 1 is formalized in Equation (1). $Q^{TOS,out}$ denotes the heating capacity that is provided by the TOS, and x_{SEQ} is the optimal value of x after applying SEQ.

$$\left. \frac{\partial f_{Infl}^{TOS,out}}{\partial x} \right|_{x=x_{SEQ}} * \left. \frac{\partial Q^{TOS,out}}{\partial x} \right|_{x=x_{SEQ}} \leq 0 \quad (1)$$

2.2. Heuristic 2: Existence of a Suitable Heat Sink

To improve a process by applying SIM instead of SEQ, the additional heating capacity provided by the TOS needs to be utilized by a Heat Sink. Here, it is essential to define two types of Heat Sinks: Natural and Created Heat Sinks. A Natural Heat Sink is a process section that still has a demand for external heating utilities after applying SEQ. It follows that the use of the additional heating capacity to satisfy Natural Heat Sinks leads to a decrease in the cost of external utilities. A Created Heat Sink arises if certain background process parameters change compared to the sequentially optimized process, with two consequences: First, the heating demand of the process increases and second, this additional heat results in an increase in the yield of a product. The process section with the increased heating demand is denoted as Created Heat Sink. An example is a steam turbine that can be increased in size compared to the results of SEQ to use the additional heat for increased power production.

A Heat Sink is denoted as a Suitable Heat Sink if the additional heat can be transferred to the Heat Sink with respect to the minimum temperature difference. To determine whether heat transfer to a Natural Heat Sink is possible, the additional heat source (obtained from changing the operating parameters of the TOS) can be included in the Grand Composite Curve (GCC) of the process. The Natural Heat Sink is suitable if the additional heat can be used in the process. To evaluate if a Created Heat Sink is suitable, only the hot and cold streams forming the Created Heat Sink are of interest. Using these streams only, a reduced GCC diagram can be derived. The Created Heat Sink is suitable

if an increase in the heating demand of the section allows more heat to be transferred from the TOS.

2.3. Heuristic 3: Economic Profitability

The availability of both a TOS and a Suitable Heat Sink is a requirement for potential benefits from applying SIM instead of SEQ. In addition, it must be profitable to accept a sub-optimal operating point of the background process to improve the heat integration. The evaluation of this profitability needs to be done separately for processes with a Natural Heat Sink and those with a Created Heat Sink as they have different types of revenues: Created Heat Sinks are only used if there are no suitable Natural Heat Sinks. The reason is that in the sequentially optimized process, external utilities would have been used to produce the additional product, if that would have been more profitable. As this is not the case, it follows that the earnings from selling the additional product are lower than the costs for the additional external utilities. Accordingly, it is more cost efficient to reduce the amount of external heating utilities than to increase the amount of a product.

For a process with a Suitable Natural Heat Sink, the reduced use of external utilities has to lead to larger savings than the losses from sub-optimal operation of the background process. The rules are meant to exclude processes from being subject to SIM. Therefore, a sufficient but not necessary assumption is that all costs that are not related to revenues or utility costs do not decrease when applying SIM instead of SEQ. In addition, the earnings from products whose flow rates are independent of $f_{Infl}^{TOS,out}$ are assumed not to decrease. With these assumptions, there needs to be at least one $x = x_{SIM}$ for which the process satisfies the condition stated in Equation 2.

$$\left(Q^{TOS,out} \Big|_{x=x_{SIM}} - Q^{TOS,out} \Big|_{x=x_{SEQ}} \right) * c_{heating} + \left(f_{Infl}^{TOS,out} \Big|_{x=x_{SIM}} - f_{Infl}^{TOS,out} \Big|_{x=x_{SEQ}} \right) * \quad (2)$$

Equation 2 consists of two terms: The first term stands for the reduced costs for external heating utilities due to the satisfaction of heating demand with the additional heat. The second term denotes the losses in the production due to the changes in the background process. Pr is the set of all sold products. The fraction $f_p / f_{Infl}^{TOS,out}$ stands for the ratio between the flow rate of the product f_p and the flow rate of the influenced effluent material or heat flow of the TOS, $f_{Infl}^{TOS,out}$, which is assumed to be constant. This assumption holds if the downstream process units always operate in the same optimal operating point and a change in $f_{Infl}^{TOS,out}$ just leads to a linear rescaling of the downstream process units. As this paper deals with grassroots design, it is justifiable to assume that rescaling would be preferred over a non-optimal operating point. The unit cost for the heating utility is denoted as $c_{heating}$ and the specific earnings of a product p is c_p .

The condition stated in Equation (2) is also a conservative estimate for the profitability of a process with a Created Heat Sink. The reason is that satisfying a Created Heat Sink is always less cost-efficient than satisfying a Natural Heat Sink, as explained in Section 2.2. As a consequence, if the condition for a Natural Heat Sink to be cost-efficient does not hold, a process with only Created Heat Sinks is not cost-efficient either.

3. Case Studies

The application of the proposed rules is illustrated with two case studies. The first case study is the example process discussed by Duran and Grossmann (1986). The flowsheet is shown in Figure 1. Following the proposed rules, the first step is to identify a process section that can be a TOS. This process section is chosen to be the steam generation part of the reactor and the following heat exchanger, excluding the reactor itself. The effluent steam flow $f_{Steam}^{TOS,out}$ is both the decision variable x and the influenced outlet flow $f_{Infl}^{TOS,out}$. A decrease in the steam production leads to a higher temperature of the stream entering heat exchanger H1 and therefore to more available heat. As this satisfies the condition stated in Equation 1, the steam generation part is confirmed to be a TOS.

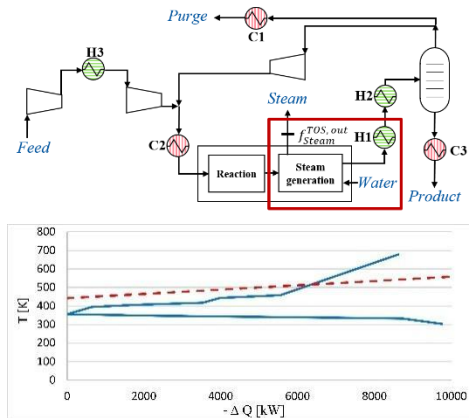

Figure 1: Flowsheet and GCC with additional heating capacity of the example process by Duran and Grossmann (1986). The red box marks the TOS.

The availability of a Suitable Heat Sink is evaluated with the GCC of the process, which is shown in Figure 1 as the blue solid line. The additional heating capacity provided by the TOS is shown as the red dashed line. As heat transfer from the TOS to the process is thermodynamically feasible, it follows that the process has a Suitable Natural Heat Sink. Next, the profitability of applying SIM has to be evaluated. With steam as the sold product, the technical and economic parameters used by Duran and Grossmann (1986) lead to $c_p < c_{heating}$. As it is assumed that applying SEQ always lead to maximum production, it follows that $Q_{Steam,SIM} < Q_{Steam,SEQ}$. Also, the steam flow $f_{Steam}^{TOS,out} = f_{Infl}^{TOS,out}$ does not pass any downstream unit after the TOS. It follows that $f_p = f_{Infl}^{TOS,out}$ and therefore $f_p / f_{Infl}^{TOS,out}$ is constant. Accordingly, Equation 2 holds and the application of SIM is therefore recommended. This recommendation is confirmed

by the results of Duran and Grossmann (1986) as they achieve a 90 % higher annual profit by applying SIM instead of SEQ.

Figure 2: Flowsheet and Reformer behavior of the example process by Pötting (2020). The red box marks the TOS.

The second case study is the process studied by Pötting (2020), which is a simplification of the process proposed by Subramanian et al. (2021). The flowsheet of this process is shown in Figure 2. The reformer and the heat exchanger after the reformer are identified as a TOS candidate. The decision variable x is the oxygen-to-natural-gas ratio $ONGR$ at the reformer inlet. The influenced outlet flow $f_{Infl}^{TOS,out}$ is the molar flow of H_2 $n_{H_2}^{TOS,out}$.

The right part of Figure 2 shows the temperature and the molar flow of H_2 at the reformer outlet, which are modeled to be linear functions of the $ONGR$. With $n_{H_2}^{TOS,out} = n_{H_2}^{TOS,out,max}$ at $x = x_{SEQ}$ and the assumption of constant specific heat capacities, the condition stated in Equation 1 holds. Accordingly, this section is proven to be a TOS.

As the SEQ approach to process optimization results in a threshold problem, there is no Natural Heat Sink in the process. It follows that a Heat Sink needs to be created. This can be done by increasing the size of the steam turbines, which leads to an increased power production. Figure 3 shows the streams of the steam turbine section after applying SEQ as the blue solid line. The red dashed line indicates the additional heating capacity. This dashed line starts to the right of the solid line because it is not replacing already available heat sources, but it can be used as a heat source for the additional Created Heat Sink. An increase of the steam mass flow leads to a horizontal stretch of the solid line. The result is shown by the grey dotted line. As this dotted line allows more heat transfer from the dashed line than to the solid line, the Heat Sink is Suitable.

To evaluate the profitability, it is assumed that the blended syngas flow always contains enough CO to run a stoichiometric methanization and that the specific heat capacity of the effluent stream of the TOS is constant. As $ONGR_{SEQ}$ is $ONGR_{min}$, it follows that $ONGR_{SIM} > ONGR_{SEQ}$. Using the parameters of Pötting (2020), Equation 2 can be shown not to hold. Accordingly,

Figure 3: Evaluation of the usability of a Created Heat Sink, Pötting (2020)

applying SIM will not lead to an improvement compared to SEQ. Pötting (2020) also obtained this result.

4. Conclusion and future work

This paper proposes three heuristic rules for evaluating the benefits of applying simultaneous over sequential process optimization and heat integration. The first rule determines if the background process contains a Trade-Off-Section that can provide additional heating capacity by sacrificing product flow rate. The second rule evaluates if this additional heat capacity can be feasibly transferred and used by the rest of the process. The third rule focuses on the economics of generating this additional heating capacity at the expense of profitability of the background process. Two example processes verified these rules. In future work, it is possible to derive a similar set of rules for benefits due to a reduced feedstock consumption.

Abstract

The resilience of a system is defined as the system's capability of recovering from failures. Traditionally, only predictable aspects are considered when designing processing systems. Evaluation of these aspects is performed via assessment of exact indicators and enumeration of all cause-effect options. However, such evaluation is not appropriate for determining the resilience of processing systems, since resilience is based on unexpected events in addition to the expected ones. Consequently, the cause part of the cause-effect relation is not known or not effective. In the current work, the general formula for determining resilience of a system is embedded into a P-graph based process synthesis algorithm. Thus, the resilience can be considered when selecting the most preferred process during its synthesis. The result is illustrated by synthesizing a process of adipic acid production by nitric acid oxidation of KA oil.

Keywords: Resilience, Process design, P-graph.

1. Introduction

A system is generally evaluated considering several aspects, e.g., profitability, reliability, and sustainability. In addition, since there are a lot of interconnections between the operating units that comprise engineering systems, structural indicators are also important. Agility, resilience, and supportability are just three examples for such indicators (Bernus et al., 2020), they are all highly dependent of the system's structure. The current work focuses on resilience, which expresses the persistence of the system, and also its capability to absorb change, and recover from it (Holling, 1973).

In most cases, resilience is derived from other metrics of the system, more than 20 alternatives for such derivation were listed by Trimintzios (2011). For engineering systems, the main considerations for resilience are controllability (Morari, 1983) and flexibility (Grossmann et al, 2014). Another possible metric for resilience is the system performance level after a disturbance (Bhamra et al., 2011). The repair or replacement times of the system's components can also be taken into account (Gong and You, 2018). Since systems resilience has no general definition, there are a large number of different specific definitions for the different areas of application. A thorough review of these was given by Hosseini et al. (2016), whereas a general overview of resilience theory has been provided by Linkov and Trump (2019).

In a processing system, the disturbances or changes, referred by resilience definitions, mostly involve failures of equipment units. The failures in a processing system can be predictable or unpredictable/unexpected, as well as internal or external. Traditionally, in designing processing systems, the predictable, known aspects are taken into account. On the basis of that, exact indicators, such as cost or systems reliability, can be determined.

However, resilience also needs to contemplate unexpected events. The prediction of these events is either impossible, or would require enumerating an enormous amount of possibilities, requiring a significant computational effort. To overcome this philosophical issue, one solution is to enumerate all possible “effects”. Since the enumeration can conveniently be based on the P-graph framework, it is a firm foundation of a new formulation of resilience.

Formally, a processing system is considered resilient if after any failures it is

- able to perform its designated job in full or on a pre-specified partial level;
- able to return to its original state.

Designing a resilient processing system requires either, or both of these goals to be considered. The first goal, i.e., maintaining operation after failures, can be achieved via redundancies in the system. Two different types of redundancies can be distinguished. *Unit-level* redundancy incorporates identical or similar equipment units (or simply: units) to be built in parallel to critical units in the system. When a unit fails, one of its redundant counterparts can immediately, or with some delay take over the operation. On the other hand, *process-level* redundancy contains multiple separate production paths for one of more materials in the process. In case of a failure, a part of the process (containing multiple units) is turned off and a different production path is utilized. This redundant path may even contain different technologies which are more convenient for the short time interval while the main production path is repaired. Naturally, the two redundancy strategies can be combined in a processing system for the best result. The second goal when designing resilient systems, i.e., returning to the original state, is related to maintenance and repair. Units with shorter repair time can be preferred to reduce the off-time of the system.

The current work proposes a method to perform synthesis of processing systems with redundancies, considering resilience based on the above-mentioned enumeration of “effects”. The resilience indicator incorporates both the redundancies in the system, and the repair times of the failed units. The goal is to generate all processing systems that satisfy the requirement on resilience, and rank them according to their cost of operation (i.e. annualized capital cost and operating cost of units). Generating a ranked list is more practical than generating just one option, as it provides the opportunity for selecting a more convenient solution, in light of additional constraints.

The generation of multiple solutions, and the enumeration of the effects are both combinatorial in nature, and cannot be properly incorporated into standard mathematical optimization; i.e. an appropriate tool is required. For this reason, the proposed method is based on the P-graph framework (Friedler et. al., 1992a), which is an axiom-based combinatorial tool for process network synthesis (PNS). The framework represents a PNS problem as a bipartite graph of materials and operating units, and provides several algorithms, such as algorithm MSG (Friedler et. al., 1993) for generating the maximal structure (superstructure), and algorithm SSG (Friedler et. al., 1992b) for generating all potential solution structures. In addition, any mathematical model can be integrated to ensure that only feasible processing systems are generated.

2. Synthesis of processing systems considering resilience

The method described here is a combination of two algorithms: generating processing systems for process synthesis and determining the resilience of the generated processing systems. The generation of the processing systems is performed by the combinatorial

algorithms provided by the P-graph framework. To determine the resilience of a processing system based on the enumeration of the effects, a proper formula is needed.

The number of products of a processing system is not limited, however, first, systems of single product will be examined. This product has a minimum accepted production flowrate (γ), which is specified in the problem definition. This is the flowrate that the production must reach to be considered as fully operational, anything less is considered as partial operation. It is common in processing systems to halt the operation if the production goes below a certain level (because of technical and/or economic reasons), this minimum production flowrate (δ) is also defined.

In a processing system with redundancies, it is important to distinguish the normal operation, i.e., the operating units that are active when the system functions as planned. The remaining operating units are the backup units; these are employed if some failures happen in the normal operation.

Let K denote the number of units in the normal operation, it is assumed that these units are subject to failures. Let S_n^f denote the set of all combinations of at most failures among the units of the normal operation. Let N_n^f be the cardinality of set S_n^f . To uniformly measure the capability of recovering through repairs, time horizon is introduced as a constant value throughout the synthesis.

Let s be an element of S_n^f . The production flowrate over time of the system as a consequence of failures in s is denoted by function $F(s, t)$, where $t \in [0, h]$. To plot the resilience uniformly on the $[0, 1]$ scale, this production flow rate is normalized to $p(s, t)$ as given in Eq. (1).

$$p(s, t) = \begin{cases} 1, & \gamma < F(s, t) \\ \frac{F(s, t)}{\gamma}, & \delta \leq F(s, t) \end{cases} \quad (1)$$

Eq. (2) defines the relative production of the system during time horizon h after the failures defined by s occur (at time 0).

$$q(s) = \frac{\int_0^h p(s, t) dt}{h} \quad (2)$$

The resilience of the system to at most n simultaneous failures is given by enumerating over all possible sets of failures in S_n^f , and taking the average of the relative production rates, see Eq. (3). If the number of failures is not limited (or limited to the number of units in the normal operation, i.e. K), the result given by the formula is the resilience of the system to any set of failures (Eq. (4)).

$$R_n = \frac{\sum_{s \in S_n^f} q(s)}{N_n^f} \quad (3)$$

$$R = R_K \quad (4)$$

By combining the described resilience analysis method with the synthesis tools of the P-graph framework, the following algorithm is proposed to perform PNS with resilience consideration.

Input of the algorithm:

- Information needed for the PNS problem
- γ and δ flowrates
- The repair times of the units
- h time horizon
- Lower bound for resilience (0 if not specified)

Main steps:

- Algorithm SSG of the P-graph framework generates all potentially useful processing systems
 - Only feasible processing systems are generated, as described by the mathematical model given in the problem formulation
- For each generated processing system
 - Normal operation of the process is determined so that the operating cost is minimal
 - Resilience analysis is performed with the proposed formulas
 - If the resilience of the processing system is below the lower bound, it is discarded
- The list of potential processing systems is ranked based on their cost of operation, it is the output of the algorithm

Selecting the desired processing system from the ranked list is up to the designer or decision maker. A simple choice is to select the one with the lowest cost of operation. Another option is to plot the processing systems on a chart showing the cost of operation against the resilience, i.e., to determine the Pareto front, and make a decision based on that.

3. Case study

This work contemplates process synthesis for a continuous process for adipic acid from KA oil (mixture cyclohexanol/cyclohexanone) and HNO_3 . The problem structure is depicted in Figure 1. Low temperature oxidation of KA oil can be performed in two different reactors. Reactor A handles heat with recirculation, whereas reactor B employs a coolant. Oxidation is enhanced in a second reactor at high temperature. Nitrogen oxides can be recovered as nitric acid by means of a bleacher, where they are oxidized. Alternatively, they can be to recover in a membrane process and oxidized in a separated reactor. Oxidized gases are absorbed in water and returned into the process. Separation of water is performed by evaporation in one or more stages. Adipic acid is recovered by crystallization followed by a solid separation stage. Different sequences of these operations are considered for the synthesis problem. Crystals of adipic acid are recrystallized to improve purity of the product. The liquid effluents from the separation stages are recycled into the process, nonetheless a fraction is purged out from the system to avoid accumulation of by-products. These byproducts are employed in another process in the plant; therefore, catalyst is recovered from the purged stream, and sent to a treatment process previous its final destiny.

The case study was solved to generate all possible designs for the processing system providing that the cost of operation of the system does not exceed 2,560,000 USD/y, and

the resilience is at least 0.4. All 4068 generated processing systems are represented in Figure 2 as cost against resilience. The Pareto front of the solutions is indicated by the red dots. .

One of the processing systems in Pareto front is selected as an example (indicated with a larger green circle on Figure 2) and is presented on Figure 4. Its cost of operation is 1,728,408 USD/y, and its resilience is 0.57. The designed or normal operation is shown with bold lines on Figure 4, the redundant units are shown with gray lines.

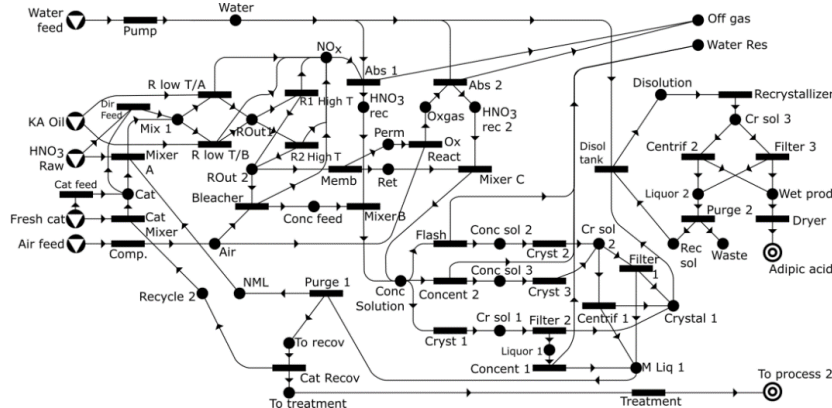

Figure 1. P-graph representation of the superstructure of the case study

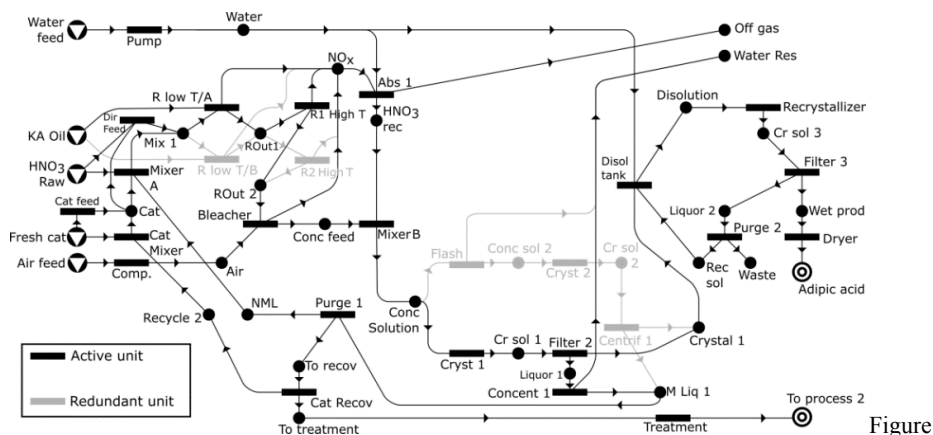

Figure 2. Generated processing systems for the case study, red dots indicate the Pareto front, green circle identifies the process shown on Figure

4. Conclusions

A process synthesis method has been proposed that considers resilience to unpredictable events by combinatorial enumeration of the effects. The method generates all, or n-best potential processes that satisfy the requirement for the resilience, and rank them according to their cost of operation. The capabilities of the method were illustrated through a case study of adipic acid production, where the algorithm generated 4068 potential solutions; 25 of them formed the Pareto front.

3. One of the generated processing systems of the Pareto front

jonathan.maedler@tu-dresden.de

Abstract

Smart equipment as a cyber-physical system can be envisioned to support owner/operators with model-based assistance systems. In fluctuating process scenarios, which are expected within modular plants, frequent adaptation of the required simulation models to changing conditions will be necessary. Therefore, automated functional quality assessment for simulation models would provide a significant added value for the owner/operator. Currently, quality assessment of simulation models is dominated by the verification and validation methods developed by Sargent and co-authors (Sargent and Balci, 2017). Although these methods provide a wide spectrum of assessment methods, they base on a rather narrow view on quality of simulation models. In addition, quality and quality advancement are typically not measured continuously. To overcome these obstacles, the authors discuss the applicability of central quality assurance methods from the field of software development to simulation model assessment. These are the principle of test-driven development and the application of quality models to measure quality and quality advancement. A framework and a workflow for test-driven development of simulation models are proposed and evaluated in a case study on a soft sensor for a fermentation process. It was found, that in principle, the framework provides transparent and continuous quality assessment in a semi-automated manner and lays the foundation for guidance strategies during model development.

Keywords: smart equipment, quality assessment, validation, soft sensor

1. Introduction

As a cyber-physical system, smart equipment can be envisioned to support owner/operators with model-based assistance systems. The importance of concepts and technologies like design space, soft sensors or model predictive controllers in plant operation is rapidly growing. Unfortunately, the setup of these systems is highly dependent on the concrete process running within the plant. This is especially a challenge for modular plants (c.f. VDI, 2020), which are to be used within fluctuating process scenarios for various chemical or biochemical applications. Therefore, simulation models require frequent adaptation to the changing conditions. Since these simulation models become core part of the functionality of smart equipment and the modelling process will become an important part of the user experience, an automated quality assessment methodology must capture a broad view on functional quality and quality attributes. Quality assessment should promote a transparent and continuous view on functional quality and quality advancement during the modelling process. To optimally support the

owner/operator, the quality assessment must be as efficient as possible and run automated. Since several model-based assistance systems applying different modelling approaches should be supported, the methodology has to be flexibly applicable to different model classes and allow the simple integration of additional requirements.

In this paper, the authors discuss the applicability of quality assurance concepts from software development to simulation models. A framework for automated functional quality assessment for simulation models is presented. This lays the foundation for further development of a fully guided assessment framework for smart equipment. The remainder of this paper is organized as follows: section 2 introduces and discusses standard methods for quality assessment of simulation models and highlights the gap in research. Following, in section 3 the authors discuss quality models and methodologies from the area of software development and present a concept to apply these methodologies to the area of simulation models. In section 4 a case study is conducted to evaluate the suggested methodology. Lastly, section 5 provides a conclusion and suggests further research.

2. State of the art in quality assessment of simulation models

Today's quality assessment of simulation models is dominated by the verification and validation (V&V) methods (Sargent and Balci, 2017). Sargent (2013) describes four distinct steps in the model development process. Firstly, in the center of the modelling process is the data validation, which represents the process of ensuring the correctness and appropriateness of the data for model building, evaluation, testing and simulation experiments. Conceptual model validation is utilized in determining the correctness of the underlying assumptions of the conceptual model and the applicability of the model for the intended purpose. Computerized model verification describes the process of assuring the correctness of the implementation of the conceptual model and the computer programming. Lastly and most importantly, Sargent (2013) defines the operational validation as the assurance of model accuracy over a domain of validity. Even though a substantial number of V&V methods exists in literature, the most commonly used ones rely on graphical inspection (Roungas et al., 2018), which is not suitable for automated model quality assessment. Roungas et al. (2018) propose a framework that classifies existing methods according to their suitability for certain simulation models and their characteristics. One example is the use of face validation during operational validation for simulation models without access to the source code but available data from the real system. Sargent and Balci (2017) find that many studies do not apply V&V consequently or even neglect it.

In conclusion, the recent methods are not able to meet the requirements for functional quality assessment of simulation models in smart equipment according to the introduction. These cyber-physical systems will rely heavily on continuous integration and continuous deployment strategies (CI/CD) (c.f. Bruckner et al., 2020). Although the V&V methods provide a wide spectrum of assessment methods, they mainly focus on model accuracy as quality property. Other quality attributes like reliability or efficiency are considered as boundary conditions only. This approach reduces the overall transparency of simulation model quality. Another important drawback of the current approach is that usually quality specification and testing is exclusively addressed at the end of each model development phase like conceptual modelling or implementation. This limits the transparency of quality advancement within the modelling process. In addition, many V&V methods rely on expert evaluation of graphical representations. This is not appropriate for automated quality assessment.

Therefore, for this paper the authors aim to resolve the issues with the state of the art in quality assessment for simulation models by transferring quality assurance concepts from software development to simulation models. The next section outlines the concepts of test-driven development and quality models and presents a new framework for quality assessment of simulation models.

3. State of the art in quality assessment of simulation models

3.1. Test-driven software development

According to the test-driven development concept (c.f. Beck, 2003), requirements for software parts have to be translated into tests. Developers are forced to formulate the requirements and implement the tests before starting the actual development of the software. Afterwards, these tests are used to check the progress of software development and the advancement of software quality continuously. This approach increases the transparency of the overall quality of software.

3.2. Quality models in software development

For an assessment of software quality, attributes that characterize good software quality must be determined (Wagner, 2013). The abstract term of quality needs to be made tangible. To accurately assess the quality of software, one needs to differentiate between structural and functional quality (Balci, 1998). Structural quality relates to the source code and architecture of software. Functional quality describes the execution of software (Balci, 1998). Quality models are an approach to defining requirements for perceived quality. A widespread approach for structuring quality models in software development are so-called FCM models (Cavano and McCall, 1978). Factors (F) describe the desired attributes of the software. Criteria (C) are allocated to those factors and are tested by metrics (M). Figure 1 depicts the hierarchal structure of FCM models. The metrics provide a quantitative measure that weighs attributes against requirements (Cavano and McCall, 1978). Quality models exist for different types of software applications and aspects. The QUAMOCO framework or the ISO/IEC 9126 are used to assess software product quality (Wagner, 2013). A widely used quality model for software product quality is the ISO/IEC 25010. This standard is derived from the software quality model of McCall and Cavano, which was one of the first approaches to assess software quality (Cavano and McCall, 1978, ISO/IEC, 2011). The quality model of ISO/IEC 25010 for product quality consists of eight quality factors: functional suitability, reliability, performance efficiency, operability, security, compatibility, portability and maintainability.

3.3. A test-driven approach to quality assurance for simulation models

In summary, some important lessons can be learned from software quality assurance. Firstly, the concept of test-driven development provides an approach to increasing the transparency of quality advancement. Secondly, quality models define what good quality

Figure 1: Taxonomy of FCM (Factor-Criteria-Metrics) models

attributes are. Those can be represented by quality factors and criteria and become measurable by metrics. The definition of quality needs to be expandable because quality expectations evolve with time.

Based on these lessons and the requirements in the introduction, a new framework for the assessment of functional quality in smart equipment is developed. Figure 2 presents the suggested workflow. The specification of the purpose of the simulation model should always be the first step within model development. Afterwards, a generic FCM model must be adapted based on the specified purpose. The factors and criteria within ISO/IEC 25010 provide the frame for a set of metrics to achieve transparent quality assessment. The user decides which factors, criteria and metrics will be included. The next step is to determine the target range or target value for each metric that can be used to calculate a quality rating. Afterwards, a standard modelling approach applying first principles modelling, data driven modelling or a combination of both can be taken. The advancement is then tested using the specified FCM model continuously. If the simulation model sufficiently fulfills the target, the user can exit model development successfully. If this is not the case, the smart equipment can provide recommendations of action to the user for further development based on the various criteria analyzed applying the FCM model.

4. Case Study

4.1. Study design

The authors conduct an initial evaluation of the proposed new framework for functional quality assessment using a case study. The use case for the quality assessment is a soft sensor for process monitoring. A simulated first principles model for yeast fermentation provides the raw data (Nagy, 2007). The soft sensor is used for online estimation of biomass concentration during the fermentation. The data-driven soft sensor is a feed forward neural network (FFNN) and is trained through Levenberg-Marquardt backpropagation. Inputs for the soft sensor are reactor temperature, dissolved oxygen concentration, yeast concentration and ethanol concentration. A quality model based on ISO/IEC 25010 was adapted to the use case. The quality factors functional suitability, reliability, performance efficiency and maintainability were considered. The quality factors performance efficiency and maintainability were not separately examined in the evaluation due to the study design without a real process plant. Metrics were matched to the quality factors functional suitability and reliability for the quality assessment. The equations for those metrics are shown in Table 1. Important metrics for soft sensors are the difference between estimated and measured values, which covers the criterion functional appropriateness, and the coverage of the targeted area of validity of the soft

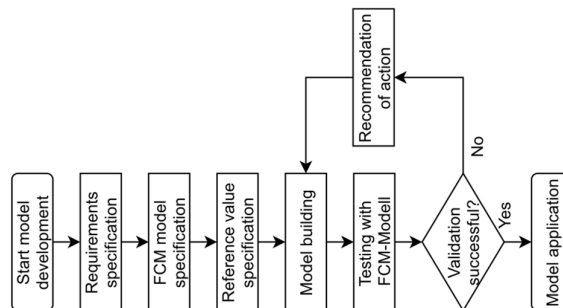

Figure 2: Workflow for functional quality assessment for simulation models in smart equipment

Table 1: Metrics overview for quality assessment

Metric	Equation	Source
Coverage	$\frac{\text{NumberOfInputs} \sqrt{V_{\text{FittingData}}}}{\sqrt{V_{\text{Specified}}}}$	(Marquardt, 2007)
R ²	$1 - \frac{SSE}{SST}$	(Roungas et al., 2018)
RMSE _{test}	$\sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2}$	(Montgomery & Runger, 2010)
Violation _{output}	$\frac{\sum \text{Violation}_{\text{Boundary,Output}}}{\sum \text{Data}_{\text{Output}}}$ with process limit violation	(Marquardt, 2007)
Outlier _{frequency}	$\frac{\sum \text{Outlier}_{\text{Output}}}{\sum \text{Data}_{\text{Output}}}$ with MAD filter	(Liu et al., 2004, Roungas et al., 2008)

sensor with model fitting data, which relates to the quality criterion of functional completeness. The case study consists of seven cases and is designed to emulate quality differences in the soft sensor model to evaluate the method. The cases differentiate between model fitting data (Case 1 – 3), model structure (Case 4) and input data for online estimation (Case 5 – 7). Soft sensors for online prediction use measured online data for the estimation of the output.

4.2. Study results

The quality assessment is able to distinguish between the designed quality differences in the case study. For some cases, like Case 7, almost every metric requires an action to further develop the simulation model, while in other cases, like Case 1, only certain metrics require an action because the targets are not met. For example, if the target range for the outlier frequency is not met, the quality assessment recommends adding a pre-processing layer into the soft sensor to filter out incorrect data points. In case of output violations of the process limits, the quality assessment recommends different actions depending on the severity of the error. Actions range from simple retraining of the model to replacing the entire modelling approach. The high coverage for Case 3 shows that the

Table 2: Results for the different quality metrics

Factor	Functional Suitability			Reliability	
	Correctness	Appropriateness	Completeness	Fault tolerance (Robustness)	
Metric	R ²	RMSE _{test}	Coverage	Violation _{Output}	Outlier _{frequency}
Case 1	0.82	0.0893	0.3904	0.0488	0.0
Case 2	0.77	0.0891	0.3451	0.0487	0.0
Case 3	0.37	0.0888	0.9347	0.0488	0.0
Case 4	0.85	0.0896	0.3904	0.0491	0.0
Case 5	0.55	0.0893	0.3904	0.0976	0.0741
Case 6	0.53	0.0826	0.3904	0.1707	0.0667
Case 7	0.53	0.1343	0.3904	0.5366	0.0167

coverage metric cannot be regarded in isolation, as the high coverage is due to noise increase in the model fitting data. Simply comparing the volumes of the convex hulls does not entirely capture the correctness of the data. One future approach will be to also assess the position of the volumes in space.

5. Conclusion

In this paper, a new approach to quality assessment of simulation models based on the test-driven development concept and FCM models from software development was presented. The framework allows transparent and continuous quality assessment of simulation models within the modelling process. The determination of requirements before the start of model building allows an early linkage of requirements and tests during the planning phase of the tests. This framework lays the foundation for guidance strategies during model development. The structure of the quality model enables only a semi-automated quality assessment because the generic quality model must be adapted manually beforehand but, therefore, allows easy adjustment and extension of the quality model. Future work will explore the applicability of the method to other types of soft sensors and use cases of simulation models like design space models. Additional factors, criteria and metrics should be introduced into the framework. Furthermore, new metrics must be developed if no universally accepted ones are available. Finally, the method should be tested in real world applications.

Abstract

Detection of abnormal behaviors (faults) in chemical process systems is a challenging task due to the high amount of data collected through measurements associated with distributed sensor networks. In these multivariate systems, gaining insight into the inner structure of collected high-dimensional data is essential for exploring and discovering paths to assist big data technologies. This exploration is facilitated by the use of many tools, such as dimension reduction techniques and clustering methods. In the present paper, the synergy between dimension reduction techniques and clustering methods has been studied to help discovering methods which complement each other in the field of fault detection and to demonstrate the performance of a fault detection strategy which is tested on the data from the well-known Tennessee Eastman Process simulator. The outcomes can be substantially improved by judiciously pairing the dimension reduction approach with a method from the appropriate group of clustering methods.

Keywords: Data mining, Dimension reduction, Data clustering, Fault detection, High-dimensional data

1. Introduction

Control systems of chemical processes require constant monitoring of different variables throughout the system. The historical data obtained from different plant sections and system variables are high-dimensional and complex, yet they are an extremely useful resource for discovering patterns and behaviors, thereby facilitating the detection of faults and other anomalies. Many fault detection methods utilizing high-dimensional historical data have been developed throughout the years and benefit from the use of data science tools such as dimension reduction techniques and clustering methods, or both. Each of these tools have separately been studied in the context of various applications and evaluated based on their success in class representation. Applying a dimension reduction technique helps to extract the most important features of a high-dimensional dataset and represent them using lower dimensions, and a clustering method is used to identify groups and classes containing those features. It should be pointed out that the attributes of dimension reduction and clustering methods have a direct effect on the outcomes. Therefore, a study on such attributes will help discovering how dimension reduction techniques and a common unsupervised learning tool, clustering, can complement each other in the field of fault detection. Utilizing combinations which complement each other

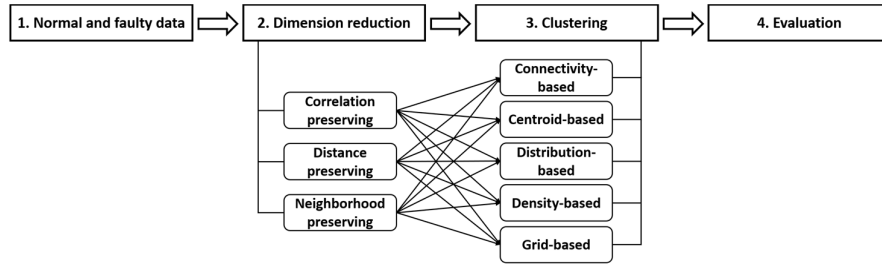

Figure 1: A step-wise summary of the presented approach

improves information extraction from the data and the fault detection process. There have been previous studies such as the work done by Thomas et al. (2018) demonstrating some methods are more compatible with each other. The reason of such observations is explored and discussed in the current paper by studying a wider range of methods.

The dimension reduction techniques in this work are classified as correlation-preserving methods, distance-preserving methods and neighborhood-preserving methods while the clustering methods are categorized as connectivity-based, centroid-based, distribution-based, density-based and grid-based techniques. As shown in Figure 1, the proposed approach consists of a first step where the data containing different states are normalized, followed by a dimension reduction step then a clustering step, ending with the evaluation of the results. Different combinations of categories are tested and characteristics of each group of methods is taken into account to match each class of dimension reduction technique with one or more groups of clustering methods to achieve the best overall functionality of the fault detection process. Each of the methods are briefly explained in Sections 2 and 3 with a focus on their definitive attributes. Evaluation criteria is explained in Section 3. The proposed approach is tested on a dataset containing three different types of faults from the Tennessee Eastman Process simulator mentioned in Section 4. The discussion of the results is available in Section 5.

2. Dimension reduction techniques

The techniques utilized in this study for dimension reduction and visualization purposes are categorized into three groups based on their approach to map the original high-dimensional data onto the low-dimensional space. The considered attributes leading to choose these categories are the input type of the methods, meaning whether they use a distance matrix or the data points for projection, and their examined neighborhood, meaning whether local points are taken into account or they are examined globally (Espadoto et al., 2019).

In the first category, correlation-preserving methods include the ones that consider and preserve the correlation between the samples, whether in a global scale or a local scale. Examples of this category are Principal Component Analysis (PCA) and its variants. PCA is a linear transformation for dimension reduction with the objective of preserving the maximum variance within the data which is performed on a global scale.

Techniques in the second category, distance-preserving methods, preserve distances between samples in a global scale to map the data onto a lower number of dimensions. The methods chosen for this category are Multidimensional Scaling (MDS) and Isometric mapping (Isomap). MDS is a nonlinear method which represents the distances of the data points as similarities between them and Isomap is a nonlinear embedding method which

constructs a neighborhood graph of the samples to find the shortest path between two nodes.

Third category of dimension reduction techniques is neighborhood-preserving methods. Dimension reduction techniques such as t-Stochastic Neighborhood Embedding (t-SNE) and Uniform Manifold Approximation and Projection (UMAP) preserve the distance between data at a local scale. t-SNE is a nonlinear technique which represents local structures of a dataset by considering the affinities of its data points as probabilities. UMAP is also a nonlinear method similar to t-SNE with assumption of uniformly distributed data.

3. Clustering methods

Clustering methods differ in defining the similarity criteria for identifying classes (clusters). Therefore, considered methods in this study fall into one of the five aforementioned categories. The approach towards clustering in each category along with a representative example is briefly explained in this section (Han et al., 2012).

3.1. Clustering categories

The methods in the connectivity-based category take the distance between data points into account to assign cluster memberships. Closer data points are assumed to be in similar clusters as opposed to further data points. The most well-known method in this category is agglomerative hierarchical clustering, using a number of possible closeness measures (linkages).

Methods in the centroid-based category find centroids in order to partition the data into a specific number of clusters. This is done by minimizing the distance of points from their closest centroid. The examples chosen for this category are *k*-Means and *k*-Medoids. The main difference between these two methods is their selection of the centroid.

The main idea exploited in the third category, distribution-based clustering, is the assumption that members of a cluster most likely belong to the same distribution. Points are assigned to clusters based on their probability of belonging to a distribution; Gaussian mixture models (GMM) is an example that assumes that the data is constructed of multiple Gaussian distributions (Reynolds, 2015).

In the fourth category, which includes density-based methods, clusters are defined as areas of high density separated by areas of low density. Higher density is defined as smaller regions with higher number of samples. Density-Based Spatial Clustering of Applications with Noise (DBSCAN) and Ordering Points To Identify the Clustering Structure (OPTICS) are two examples in this category. Both methods assign points to clusters based on a density criterion, while their difference can be simply expressed that OPTICS orders the points to prioritize the memberships.

Methods in the last category divide the space into grids and calculate the density of each grid to find the clusters. These methods are called grid-based clustering methods. An example is CLustering In QUest (CLIQUE). This method partitions high-dimensional data into non-overlapping subspaces and uses these subspaces to identify clusters.

3.2. Cluster evaluation criteria

Multiple metrics have been defined to assess the performance of a clustering algorithm. Metrics used in this study utilize the ground truth class assignments of the data points for evaluation. *Adjusted Rand Index* (ARI) (Rand, 1971) and *Adjusted Mutual Information* (AMI) (Vinh et al., 2009) measure the similarity of the true labelling and the clustering labelling, while ignoring the permutations and with chance normalization, meaning random assignments will have a score close to zero. ARI is bounded between -1 and 1, and AMI has an upper bound of 1, while 1 being the perfect score for both. *Homogeneity*

is a measure of clusters being pure, and *Completeness* measures if all members of a class have been assigned to the same cluster. *V-measure* is their harmonic mean, and all three scores are bounded between 0 and 1, 1 being the perfect score (Rosenberg and Hirschberg, 2007).

4. Case study

In order to study the synergy between categories of dimension reduction techniques and clustering methods, all the methods mentioned above were tested on a dataset generated using the Tennessee Eastman Process (TEP) simulator in MATLAB (Bathelt et al., 2015). This benchmark chemical plant consists of five major units (a reactor, a product condenser, a recycle compressor, a vapor-liquid separator, and a product stripper) and eight components in total and has been the reference for testing many data-driven fault detection methods in chemical engineering. The simulation has 41 measured variables and 12 manipulated variables. The original simulation has 20 predefined faults of different types that can be introduced to the system. For this study, three different faults of varying types were selected; Fault 2 which is a step change in a component's composition, Fault 13 which is a slow drift in the reaction kinetics, and Fault 14 which is the sticking of reactor cooling water valve. Each of these faults were separately active for a constant 20 minutes, and then turned off right before the next period started.

The generated dataset consisting of these three faults and 20 minutes of normal operation (without any faults) was first preprocessed by removing the constant variables and normalizing to a zero mean and unit variance. A dimension reduction technique was applied to the dataset followed by a clustering method. All the dimension reduction techniques were used to obtain two-dimensional data, and the parameters for each clustering method were searched for based on the scores described in Section 3.2. They were selected such that the clustering would result in the highest possible scores for maximum number of metrics; In other words, the clustering assignments would match the true labels of the four different states as much as possible. Hence, better scores (closer to 1) do not necessarily correspond to correct number of clusters, but they may contain some extra clusters or some combined clusters. Every combination of mentioned dimension reduction techniques and clustering methods were tested as mentioned to find the categories that complement each other more successfully in isolating the different faults.

5. Results and discussion

The ability of a clustering method to accurately detect different states and faults as separate clusters in this case is highly dependent on the ability of the dimension reduction technique to extract the inner structure and information from the original high-dimensional data. Therefore, if some states are not distinguished from each other after the first step of dimension reduction, complete fault isolation in clustering is almost impossible. For example, in the visualization of the two-dimensional data, it was observed that data points of Fault 14 were close to those of the normal state or even were indistinguishable in most of the cases.

The results of the case study are summarized in Table 1. For ease of comprehension and to satisfy the space restrictions, only the AMI scores for different cluster assignments are shown for each dimension reduction technique. The best score for each dimensional reduction technique is highlighted.

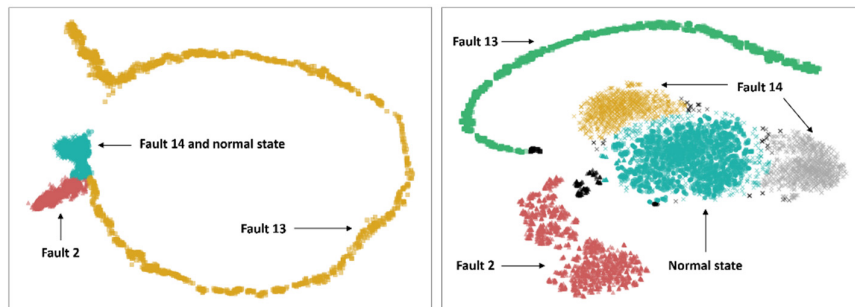

As presented in Table 1, for the correlation-preserving category (e.g., PCA), a density-based clustering had the best performance, and the distribution-based clustering was the

Table 1: AMI Scores for Cluster Assignments After Dimension Reduction

	Hierarchical	k-Means	k-Medoids	GMM	DBSCAN	OPTICS	CLIQUE
PCA	0.511	0.513	0.455	0.630	0.645	0.683	0.373
MDS	0.539	0.510	0.427	0.553	0.600	0.501	0.433
ISO	0.655	0.589	0.573	0.440	0.707	0.700	0.426
t-SNE	0.766	0.610	0.716	0.642	0.785	0.668	0.766
UMAP	0.685	0.595	0.575	0.628	0.704	0.673	0.433

method with the second-best performance. For the distance-preserving category (e.g., MDS and Isomap), DBSCAN achieved the highest AMI score for both techniques. The best clustering result for the neighborhood-preserving category was also DBSCAN. For both methods in this category, hierarchical clustering also produced results which were relatively close to the highest scores. Other evaluation scores demonstrated same results, confirming the most compatible clustering methods and dimension reduction techniques represented in Table 1 for each category. Also, it can be seen the lowest performance for PCA, Isomap and UMAP was obtained with the grid-based clustering method (e.g., CLIQUE), and the lowest performance for MDS and t-SNE were from the centroid-based clustering methods. These two categories of clustering methods do not work well with elongated clusters and tend to separate a long cluster into several smaller ones and as demonstrated later in this section, Fault 13 has such a feature. This fault is a slow drift in the reaction kinetics, and this is well-reflected in the elongated shape of its cluster in the low-dimensional space.

In total, for all five dimension reduction techniques, a density-based clustering method achieved the best performance in accurately isolating the faults, and distance-based clustering was amongst one of the methods with a relatively high score for two of the three categories of dimension reduction techniques. Overall consideration of the results demonstrates that density-based clustering methods lead to higher AMI scores in general, therefore more accurate cluster assignments. Most of the tested dimension reduction techniques represent similarity of data points in terms of their closeness in the lower dimensions, therefore the clusters can be found using a method which searches for areas with high density or clusters them based on the relative distance of data points more easily. An additional observation can be made by comparison of dimension reduction techniques, stating that the clustering results obtained after t-SNE demonstrate better performance compared to all other techniques for the dataset at hand.

(a) Isomap Dimension Reduction

(b) t-SNE Dimension Reduction

Figure 2: DBSCAN clustering applied on (a) Isomap and (b) t-SNE results

Highest AMI scores were achieved using t-SNE followed by DBSCAN clustering and using Isomap followed by DBSCAN. These results are presented in Figure 2. Different colors represent different clusters found through the mentioned steps and the arrows pointing to each cluster show the true categories of the present states on the figures. Three obtained clusters can be seen in Figure 2(a). Two faults (2 and 13) were detected successfully and two of the states (Fault 14 and no fault) were almost overlapping and combined into a single cluster in color blue. Figure 2(b) shows five different clusters in addition to outliers (in black) found by DBSCAN. All four different states were detected almost perfectly, with the exception of the yellow and gray clusters which are labeled separately but both are Fault 14. It can be seen that Fault 14 is mapped very closely to the normal state with no faults.

6. Conclusions

This presented work focused on studying the performance of categories of clustering methods when used in conjunction with categories of dimension reduction techniques to enhance the fault detection process. The tests were carried out on a case study from the TEP simulator to find the dimension reduction techniques and clustering methods that complement each other. Different combinations of dimension reduction techniques followed by clustering methods were applied to the dataset to obtain the highest similarity in cluster assignments to true data labels. The study shows that different categories of dimension reduction tend to produce results with specific characteristics leading to their higher compatibility with some categories of clustering methods. More specifically, the results show that the density-based and distance-based clustering categories have a promising performance in identifying isolated states and possible faults used along with all dimension reduction categories.

Abstract

Catalytic wet-air oxidation is an attractive solution to treating refractory wastewater. The process has been demonstrated at laboratory scale over a low-cost pillared clay catalyst in a trickle-bed reactor. However, complex interaction of fluid dynamics and reaction kinetics makes scaling up of laboratory reactors to industrial reactors very difficult. Changes in hydrodynamic parameters are significant when laboratory reactors are scaled up to commercial reactors. To understand the behaviour of fluids inside a trickle-bed reactor, a computational fluid dynamics model was developed from experimental data using an Euler–Euler model. A commercial software Fluent was used to study hydrodynamic behaviour, temperature distribution and oxidation process. The model indicated that a hot spot was formed near the centre of the reactor due to liquid mal-distribution. Moreover, incorporating monolithic structure in a reactor packing material helped to lower pressure drop due to low velocities inside monolith channels. Furthermore, when the reactor was modelled at 160 °C and 10 bar, phenol was completely oxidized to CO₂.

Keywords: Advanced Oxidation Processes, CFD modeling, Reactor Scale-Up, Eulerian Model.

1. Introduction

Phenolic wastewaters originate from several industrial processes making them a model pollutant for bio-toxic and non-biodegradable organic pollutants. Moreover, phenol is an intermediate product found in the oxidation of aromatic hydrocarbons (Makatsa et al, 2020). It is also listed as a priority pollutant by the United States Environmental

Protection Agency (Lal and Garg, 2014). The use of phenol in petroleum, petrochemical, pharmaceutical, paint, pulp and paper, plastic and refinery industries is common (Zhang et al, 2019). There are different wastewater treatment methods available and catalytic wet-air oxidation (CWAO) is gaining a lot of interest due to developments in heterogeneous catalysis (Baloyi et al, 2019). The reactor choice is very important in this process (CWAO) since it can affect the reaction mechanism, which might result in the formation of undesired products like polymers. These by-products are known to be responsible for catalyst deactivation by blocking access to active sites (Pintar and Levec, 1992).

Trickle-bed reactor (TBR) is widely used in many industrial processes. However, there are few challenges associated with this type of reactors such as measuring the interaction between gas, liquid, and solid flows including high-pressure losses. The reactor flow regime is dependent on superficial mass velocity, fluid properties (density, viscosity, etc.), and design parameters. In most instances, the reactor is operated between a low interaction regime (trickle flow regime) and a high interaction regime (pulse, spray, and bubble regime).

Ranade et al (2011) suggested that the scale of the reactor affects the performance of a TBR. Also, these authors listed several factors that are directly affected during reactor scale-up as follows; reactor to particle diameter ratio, reactor volume, bed porosity, wetting, channeling, liquid mal-distribution, dispersion and reactor operating mode (isothermal/adiabatic). After thorough investigation, these researchers concluded that the wall effect is predominant in laboratory TBR whereas flow mal-distribution is common in industrial TBR due to large bed diameter. On the other hand, when CFD model is developed correctly, the scale of the reactor can be taken into consideration. CFD models are based on conservation of mass, energy and momentum; and provide a time saving and cost-effective approach in the reactor design (Kapfunde et al, 2018).

The purpose of this study is to validate the results obtained in our previous work (Makatsa et al, 2019) using a 3D multiphase Eulerian model of phenol oxidation in a trickle bed reactor. To the best of our knowledge, this is the first study to simulate CWAO of phenol using a novel Al/Zr-PILC catalyst supported on a cordierite monolith.

2. Governing equations

A multiphase Eulerian CFD model of phenol oxidation in a TBR was developed using commercial software ANSYS Fluent 2019R2 and 2020R2. The following sets of mathematical equations are incorporated into a CFD code solver.

Mass conservation equation:

$$\frac{\partial (\varepsilon_k \rho_k)}{\partial t} + \nabla \cdot (\varepsilon_k \rho_k U_k) = 0 \quad (1)$$

Momentum conservation equation:

$$\frac{\partial (\varepsilon_k \rho_k U_k)}{\partial t} + \nabla \cdot (\varepsilon_k \rho_k U_k U_k) = -\varepsilon_k \nabla P_k + \nabla \cdot (\varepsilon_k \mu \nabla U) + \varepsilon_k \rho_k g + F_{K,R} (U_k - U_r) \quad (2)$$

Where ε_k is volume fraction for each phase, ρ_k is the density of the k-th phase, U_k is the cell velocity of the k-th phase and $F_{K,R}$ is an interphase momentum exchange (Ranade et al, 2011). The interface coupling term $F_{K,R}$ can be expressed as follow

$$F_{GL} = \varepsilon_G \left(\frac{E_1 \mu_G (1 - \varepsilon_G)^2}{\varepsilon_G^2 d_p^2} \left[\frac{\varepsilon_s}{(1 - \varepsilon_G)} \right]^{0.667} + \frac{E_2 \rho_G (U_G - U_L) (1 - \varepsilon_G)}{\varepsilon_G d_p} \left[\frac{\varepsilon_s}{1 - \varepsilon_G} \right]^{0.333} \right) \quad (3)$$

$$F_{GL} = \varepsilon_G \left(\frac{E_1 \mu_G (1 - \varepsilon_G)^2}{\varepsilon_G^2 d_p^2} \left[\frac{\varepsilon_s}{(1 - \varepsilon_G)} \right]^{0.667} + \frac{E_2 \rho_G U_G (1 - \varepsilon_G)}{\varepsilon_G d_p} \left[\frac{\varepsilon_s}{1 - \varepsilon_G} \right]^{0.333} \right) \quad (4)$$

$$F_{LS} = \varepsilon_L \left(\frac{E_1 \mu_G \varepsilon_S^2}{\varepsilon_G^2 d_p^2} + \frac{E_2 \rho_L U_G \varepsilon_S}{\varepsilon_L d_p} \right) \quad (5)$$

Where F_{GL} , F_{GS} , F_{LS} are gas-liquid, gas-solid and liquid-solid momentum exchange terms. To understand turbulence inside the reactor, a standard k- ε model was chosen and the software solved the following mathematical equations (Lopes and Quinta-Ferreira, 2010);

$$\mu_{t,L} = \rho_L C_\mu \frac{k_L^2}{\varepsilon_L} \quad (6)$$

The liquid viscosity turbulence $\mu_{t,L}$ is calculated from the transport equations by determining kinetic (k_L) and dissipation energy (ε_L) from the following equations (Lopes and Quinta-Ferreira, 2007)

$$\frac{\partial}{\partial t} (\rho_L \alpha_L k_L) + \nabla \cdot (\rho_L \alpha_L \vec{u}_L k_L) = \nabla \cdot \left(\alpha_L \frac{u_{t,L}}{\sigma_k} \nabla k_L \right) + \alpha_L G_{k,L} - \alpha_L \rho_L \varepsilon_L + \alpha_L \rho_L \Pi_{k,L}$$

$$\frac{\partial(\rho_L \alpha_L k_L)}{\partial t} + \nabla \cdot (\rho_L \alpha_L \bar{u}_L k_L) = \nabla \cdot \left(\alpha_L \frac{u_{t,L} \nabla k_L}{\sigma_k} \right) + \alpha_L G_{k,L} - \alpha_L \rho_L \Pi_{k,L} \quad (7)$$

$$\frac{\partial(\rho_L \alpha_L \varepsilon_L)}{\partial t} + \nabla \cdot (\rho_L \alpha_L \bar{u}_L \varepsilon_L) = \nabla \cdot \left(\alpha_L \frac{u_{t,L} \nabla \varepsilon_L}{\sigma_k} \right) + \alpha_L \frac{\varepsilon_L}{k_L} \times (C_{1\varepsilon} G_{k,L} + C_{2\varepsilon} \rho_L \varepsilon_L) + \alpha_L \rho_L \Pi_{\varepsilon,L} \quad (8)$$

The following parameters were taken as constants C_μ , $C_{1\varepsilon}$, $C_{2\varepsilon}$, σ_k , σ_ε and assigned the following values 0.09, 1.44, 1.92, 1.0 and 1.3, respectively. Enthalpy was calculated from the conservation of energy in a multiphase Eulerian model as follows (Manoharan and Buwa, 2019; Lopes and Quinta-Ferreira, 2007).

$$\frac{\partial(\rho_q \alpha_q h_q)}{\partial t} + \nabla \cdot (\rho_q \alpha_q \bar{u}_q h_q) = -\alpha_q \frac{\partial p_q}{\partial t} + \bar{\tau}_q : \nabla \bar{u}_q - \nabla \cdot \bar{q}_q + S_q + \sum_{p=1}^n (\bar{Q}_{p,q} + \dot{m}_{pq} h_{pq} - \dot{m}_{qp} h_{qp}) \quad (9)$$

The specific enthalpy of phase q is represented by h_q and \bar{q}_q is a heat flux. The heat exchange intensity between the q and p phases is represented by \bar{Q}_{pq} whereas interphase enthalpy is represented by h_{pq} and S_q is the source term. By activating species transport the solver modeled volumetric reaction using the following equation (Lopes and Quinta-Ferreira, 2010):

$$\frac{\partial \alpha_q \rho_q C_{q,i}}{\partial t} + \nabla \cdot (\alpha_q \rho_q u_q C_{q,i}) = \nabla \cdot (\alpha_q \rho_q D_{q,i} \nabla C_{q,i}) + \alpha_q \rho_q S_{q,i} \quad (10)$$

The kinetic parameters for Al/Zr-PILC catalyst were derived from our previous work (Makatsa et al, 2019). The term in eq. (10) includes the reaction rate as;

$$-r_{ph} = k_{ob} \cdot C_{ph}^\alpha \quad (11)$$

And K_{ob} can be expressed as follow,

$$k_{ob} = k_o \cdot \exp\left(\frac{-E_{ob}}{RT}\right) \cdot P_{O_2}^\beta \quad (12)$$

By assuming ideal plug flow and first order with respect to phenol, K_{ob} can be expressed as follow,

$$k_{ob} = -\left(\frac{1}{\tau}\right) \ln(1 - x_{ph}) \quad (13)$$

3. Results

A mixture of phenol (C_6H_5OH) and oxygen (O_2) was fed to the isothermal-isobaric reactor operated at 160 °C and 10 bar. The gas and liquid inlet velocities were kept constant at 0.012 and 0.00007 m/s, respectively. As shown in Figure 1, the concentration profile of phenol inside the reactor is close to zero along the reactor bed. This is due to increased residence time and improved kinetics. These results are supported by Figure 2(a), which shows the contours of phenol mass fraction inside the reactor. The results show that the pollutant is highly concentrated at the top half of the reactor. However, the concentration is sharply decreased as the stream moves through the reactor, and phenol is completely oxidized to form carbon dioxide (CO_2) as shown in Figure 2(b). From these findings, it can be concluded that C_6H_5OH was completely mineralized to CO_2 and water. Our results are consistent with the findings of (Lopes and Quinta-Ferreira, 2010), in their study phenolic acid was oxidized in a TBR and simulated using the Euler-Euler method at 160 and 200 °C. They concluded that 82% of total organic carbon (TOC) was converted at 160 °C whereas only 84.8% was converted at 200 °C.

Figure 1: Mass fraction of phenol inside the reactor bed.

Figure 2: Contours of phenol mass fraction (a) and CO₂ profile inside the reactor (b).

4. Conclusions

A computational fluid dynamics model of a trickle-bed reactor was developed to simulate catalytic wet air oxidation of phenol and experimental results were used to validate the model. A multiphase Eulerian model coupled with energy and species transport equations was used to model the phases. The reactor model was simulated at 160 °C, 10 bar and CFD results showed that phenol was completely removed leaving a significant amount of CO₂.

Abstract

Stage-wise superstructure (SWS) is one of the most widely used methods for Heat Exchanger Network (HEN) synthesis. Approaches to obtain optimal HEN solution can be based on the deterministic algorithm, but it is difficult for solving a large-scale problem since the complexities arisen from nonlinearities of SWS. Several methods which employed stochastic algorithms and meta-heuristic approaches have been proposed to tackle the problem. However, it determines a near-optimal HEN configuration from a series of stochastic solutions which are obtained by the execution of many computational operations, thus it is time consuming and a global optimum will not be achieved from only randomly generated results. In this study, an enhanced SWS is presented, in which new constraints and variables are added to avoid conflicted calculation of non-isothermal mixing energy balance and reduce the redundant combinations. Moreover, the present model is extended to allow a flexible requirement of stream splitting for practical application. Then, a deterministic-based global solver (GAMS/BARON) is applied in solving three case studies, operated on computer: I7-8565U. The results showed that the proposed approach can provide a cost-efficient HEN solution with a lower TAC than that obtained from existing stochastic and deterministic algorithms.

Keywords: Heat exchanger network synthesis, Deterministic approach, Optimization, Process synthesis, Mathematical programming

1. Introduction

Heat exchanger networks are important for the process industries, since it can reduce energy consumption and pollutant emissions by heat integration of process streams. The benefit can be attributed into HENs for achieving energy saving, but heat exchangers bring significant capital investment at the same time. To increase economic benefits, HEN optimization has been widely studied. The approaches used in HEN synthesis can be divided into pinch method and automated method. Pinch Technology has been widely applied and can provide a cost-efficient solution, but it requires experienced designers and may lead to missing promising solutions.

Mathematical programming has been developed to achieve automated HEN synthesis. It generally formulates the design problem through a superstructure. One of the widely used superstructures has been proposed by [Yee and Grossmann \(1990\)](#). Based on the use of stage-wise superstructure (SWS), the HEN synthesis is formulated as an MINLP problem, as targeting the minimum total cost. Due to non-linearity, non-convexity and raised problem sizes for large-scale HEN optimization problems, it is a challenge to find an

optimal HEN solution at accepted time. Several approaches have been reported to solve the HEN synthesis problem by using different algorithms.

Stochastic algorithms treat the HEN design with randomization, not limited by model non-convexity and discontinuity. Some papers have applied these methods in solving HEN synthesis, such as: Genetic Algorithms (GA) (Holland, 1992), Simulated Annealing (SA) (Kirkpatrick, 1983), Particle Swarm Optimization (PSO) (Kennedy and Eberhart, 1995). Based on these, a number of papers have been published to use hybrid-approach with developed stochastic algorithms. Recently, GA-PSO and SA-RFO methods have been applied to solve the models (Pavão et al., 2016; Pavão et al., 2018) respectively, in which parallel processing techniques and streams with phase change were considered.

However, for employing stochastic algorithms, extensive computational efforts are required to determine near-optimal solutions. Deterministic approaches have been widely employed to solve HEN synthesis problems, such as Branch and Bound (BB) and Outer Approximation (OA) (Zamora and Grossmann, 1997). In recent years, study (Huang et al., 2012) reported a modified superstructure to consider non-isothermal mixing, and solved by commercial solver BARON/GAMS. Faria et al. (2015) developed the Bound Contraction method to solve the HEN synthesis problem, in which variables are partitioned to construct a linear or convex lower bound. Kim et al. (2017) presented a deterministic-based global optimization, which extended the works (Faria et al., 2015). However, large time-resource is necessary according to their approach, and industrial-scale problems have not been investigated by the use their method.

In this work, based on the SWS developed by Huang et al. (2012) and Pavão et al. (2017), an enhanced non-isothermal mixing superstructure is proposed. A global solver, BARON/GAMS is employed as the deterministic approach. Additional variables and constraints are defined to improve the model performance and achieve flexible splitting requirement.

2. Mathematical Model

The mathematical formulation is based on the well-known stage-wise superstructure (SWS) proposed by Yee and Grossmann (1990), and stages are introduced in which all possible matches between hot streams and cold streams are optimized. In this formulation, the iso-thermal mixing assumed in the original SWS method is removed, and some logical constraints are adopted to improve the non-isothermal mixing model. Basically, the set of hot process streams ($i; i \in HP$), cold process streams ($j; j \in CP$), and stages ($k; k \in ST$) are considered. The number of stages is assumed as $ST = \max[i, j]$. Some following assumptions are described below:

- a. Constant stream flow rate, heat transfer coefficients and thermodynamic properties.
- b. Split stream pass exchangers in series and by-pass are not considered.
- c. Utility inlet and outlet temperatures are given.

2.1. Objective function, stage and overall energy balances

The objective function, stage and overall heat balances can be founded in the literature (Yee and Grossmann, 1990). The objective function is to minimize the total annual cost (TAC), which consists of the total capital cost related to the heat exchangers and utility cost. Stage and overall energy balances are required to achieve feasible heat transfer in each stage and each stream with heaters or coolers.

2.2. Non-isothermal mixing (NIM)

Different from the iso-thermal mixing, exchanger energy balance is applied to express the NIM heat transfer. For a hot stream (cold stream), the inlet temperature of a split stream enters the heat exchanger is the same as the stage inlet temperature $Th_{i,k}$ ($Tc_{j,k+1}$). The outlet temperature for each split stream can be different according to the varying heat capacities and heat duties. Continue variables $fh_{i,j,k}$ and $fc_{i,j,k}$ ($0 \leq fh_{i,j,k} \leq 1$; $0 \leq fc_{i,j,k} \leq 1$) are defined as split fractions of hot stream i and cold stream j . The true outlet temperatures of exchangers can be calculated by exchanger energy balance, as formulated:

$$(Th_{i,k} - Thout_{i,j,k+1})Cp_h fh_{i,j,k} \geq q_{i,j,k} \quad i \in HP, j \in CP, k \in ST \quad (1)$$

$$(Tcout_{i,j,k} - Tc_{j,k+1})Cp_c fc_{i,j,k} \geq q_{i,j,k} \quad i \in HP, j \in CP, k \in ST \quad (2)$$

Where $Thout_{i,j,k}$ and $Tcout_{i,j,k}$ are the actual outlet temperatures of exchangers. In addition, the model allows the stream to fully bypass a stage if no exchangers are required. Two continuous variables are defined as:

$$yh_{i,k} \begin{cases} 1 & \text{if hot stream } i \text{ bypass the stage } k \\ 0 & \text{Otherwise} \end{cases} \quad i \in HP, k \in ST \quad (3)$$

$$yc_{j,k} \begin{cases} 1 & \text{If cold stream bypass the stage } k \\ 0 & \text{Otherwise} \end{cases} \quad j \in CP, k \in ST \quad (4)$$

Based on Eq. (3) and Eq. (4), the constraints to direct feasible stream split fraction have been reported by Huang et al. (2012).

2.3. Feasibility constraints

To conduct a feasible HEN configuration, some process constraints reported by Yee and Grossmann (1990), and Huang et al. (2012) are used in this model, which targets the basic feasibilities of temperatures, assessments of temperatures, and feasible minimum approach temperature difference (MATD). Furthermore, the stage inlet temperature of hot stream i must be no less than the split stream temperature that enters the next stage $k + 1$. Similarly, the split stream temperatures of cold stream j as it leaves the stage k must be equal to or larger than the stage inlet temperature. Hence, some new assessments and constraints of temperatures are presented as follows:

$$Thin_i = Thout_{i,j,firstk} \quad i \in HP, j \in CP, k \in ST \quad (5)$$

$$Tcin_j = Tcout_{i,j,lastk} \quad i \in HP, j \in CP, k \in ST \quad (6)$$

$$Th_{i,k} \geq Thout_{i,j,k+1} \quad i \in HP, j \in CP, k \in ST \quad (7)$$

$$Tc_{j,k+1} \leq Tcout_{i,j,k} \quad i \in HP, j \in CP, k \in ST \quad (8)$$

For heat transfer in split streams, the temperature change must be 0 if the match does not exist. Upper bound of temperature change is required to formulate these constraints. The relevant correlation has been proposed by Huang et al. (2012).

3. Optimization

In this study, the proposed model is formulated as a non-convex MINLP problem, as applying global solver BARON to target a near global optimal solution under specified iteration or time-resource. Figure 1 illustrates the optimization procedures. If a feasible upper bound solution cannot be found within acceptable time, the required stage number k can be reduced gradually to decrease the number of binary variables. Additionally, LMTD equation is employed at the last step to avoid overestimated exchanger area obtained by using LMTD approximation.

Figure 1. Block diagram of optimization approach

4. Case study

In this section, this case is a crude oil fractionation process originally studied by Kim et al. (2017) by a deterministic-based bounded method. In order to satisfy the practicality with industrial crude oil units, the total split numbers for crude oil stream, C1 and C2 should not exceed four respectively. Pavão et al. (2018) applied the SA-RFO method to solve this problem, and they noted that the solution obtained by the SA-RFO method is better than that reported by Kim et al. (2017). Nevertheless, in their work (Pavão et al., 2018), they ignored the split limitation and the split streams of C2 are larger than four, which becomes impractical for industrial crude oil systems. Hence, in order to evaluate the performance of the proposed method, two cases are conducted and compared with the results of Kim et al. (2017) and Pavão et al. (2018), respectively. The first case is based on limited splitting streams while introducing new constraints. The second case is obtained through the present method directly. To conduct HEN with limited branch number, Eqs (9) and (10) are formulated to achieve required splitting number (splitting number ≤ 4 for C1 and C2 respectively):

$$\sum_{i \in H P} z_{i,j,k} \leq 4 \quad j \in C P, k \in S T \quad (9)$$

$$\sum_{i \in H P} \sum_{k \in S T} z_{i,j,k} - \left(\text{stage number} - \sum_{k \in S T} y_{j,k} \right) + 1 \leq 4 \quad j \in C P \quad (10)$$

This problem is then solved with 11 stages and the MATD is set to 10 °C to be consistent with the literature (Kim et al., 2017). To find a high-quality solution at accepted computational time, maximum computation time is set (4 h in the case study). Furthermore, iteration numbers are recorded with the maximum value of 2500. For computational operations, GAMS 24.6 with BARON is used as the global MINLP solver. The computer model is a Dell Intel ® Core™, I7-8565U CPU, 1.99 GHz with 8 GB RAM.

Figure 2 and Table 1 show the optimal HEN configuration and results comparison with limited branch number, respectively. From the results, a better HEN solution is obtained as a lower TAC (3,455,358 \$/yr) and time-resource (98 % time-resource saving) than previous paper (Kim et al., 2017). Next, Figure 3 presents the optimal HEN solution without split limitation. According to Table 1, the total 3,379,651 \$/y TAC is obtained, which is lower than the best solution so far (3,391,066 \$/y), with 79 % computation time reduction.

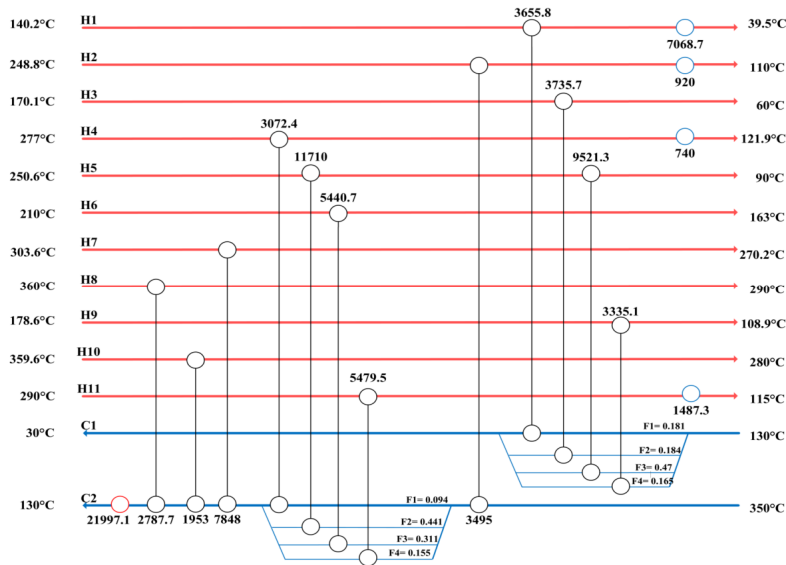

Figure 2. Optimal HEN solution while limiting split streams

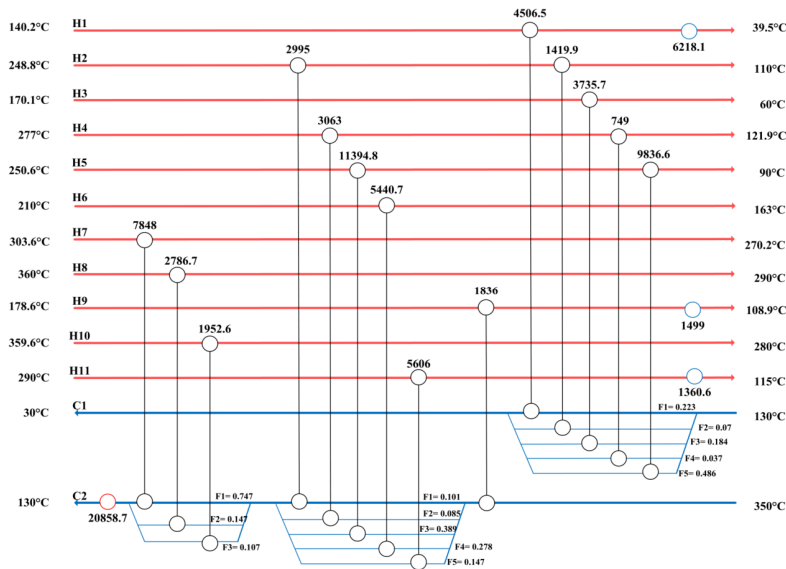

Figure 3. Optimal HEN solution without limiting split streams

Table 1: Results comparison

Reference	TAC (\$/y)	CPU (s)	Units	QH (kW)	QC (kW)	Total Area (m ²)
Kim et al.	3,456,649	47,783	17	23,566	11,783	10131.1
This work	3,455,358	534	17	21,997	10,216	13245.2
Pavao et al.	3,391,066	22,630	18	20,891	9108	13835.1
This work	3,379,651	4564	18	20,858	9077	13690.9

5. Conclusions

Consequently, the proposed method shows better performance than the previous approaches. A cost-efficient HEN solution can be obtained by the enhanced deterministic approach with acceptable time. Different from the existing stochastic algorithms that may have inconsistent solutions in different executions, the deterministic approach applied in proposed method can give better solutions, shown with cost-efficient HEN solutions with a lower TAC and computation time than that obtained from the existing stochastic (0.34 % TAC saving, 79 % computation time reduction) and deterministic algorithms (0.04 % TAC saving, 98 % computation time reduction).

Modelling Biogas and H₂S in Anaerobic Digestion

Bozzano Giulia Luisa, Moretta Federico, Rizzo Eleonora and Manenti Flavio
Politecnico di Milano, piazza Leonardo da Vinci, 32, Milan (MI) – 20133, Italy
giulia.bozzano@polimi.it

Abstract

Green Economy is the key word of the last two decades. In this context, an important role is covered by anaerobic digestion (AD), treating organic waste fractions to recover both fertilizing elements and energy. Countless biochemical reactions lead to substrate degradation and biogas development. Despite AD has been used for many years, its study from an engineering point of view is quite recent. The reference model ADM1 (Anaerobic Digestion Model No.1), proposed in the late 90's by IWA (Batstone et al., 2002) to describe and simulate the steady-state digestion of sewage sludges from Wastewater Treatment (WWT) plants, has gone through several adjustments during time. The aim of this work is to improve and extend ADM1 by means of coefficients and equations optimization to better fit various contexts such co-digestion processes. Moreover, provide a description of the complete biokinetic of H₂S, main biogas impurity, through the homologation of Fedorovich and Kalyuzhnyi studies (1998), which perfectly address its production from the organic feedstock reduction by means of Sulphur Reducing Bacteria (SRB) bacteria. Introducing the novelty of H₂S biological abatement process, whose mechanism spontaneously occurs under microaeration condition, also requires the implementation of an inhibition function since O₂ will affect methane production. Python™ is the coding language chosen in order to solve a highly stiff ODE system and earlier literatures are the roots of this new model, that has been validated on real data resulting in 0.2%vol. H₂S and 2%vol. unreacted O₂ release.

Keywords: AD Process, H₂S Biokinetics, Python™, Mathematical Modelling.

1. Introduction

Anaerobic digestion consists in the molecular cleavage of organic matter, carried out by many different families of microorganisms, living in an oxygen free environment defined as anaerobic condition. The final products of this biological transformations are biogas, a gaseous mixture mainly composed by CH₄ (50-60 %vol.), CO₂ (25-50 %vol.), H₂ (0-1 %vol.) and digestate, the semi-solid residue that can be converted into fertilizer and used for rural applications. The feedstock, characterized in terms of carbohydrates, lipids, proteins, and inert materials, undergoes four reaction stages in which the substrate is exploited by bacteria as source of nutrients. The hydrolysis reaction converts carbohydrates, lipids and proteins into their respective monomers i.e. sugars, fatty acids and amino acids by adding a molecule of water to break their polymeric chains. This reaction represents the Rate Determining Step of the entire process. Then, Acidogenesis follows. This is responsible for the production of several short acid molecules (e.g. valeric, butyric and propionic acid and CO₂) accompanied by high pH reduction to around 4.5~5.5. These acids are converted into CH₃COOH and H₂ during Acetogenesis, but however the latter has a strong inhibition effect over some microorganisms, it's quickly consumed during the last step of Methanogenesis. In this way they can grow, duplicate,

and generate other chemicals as their intake wastes. Hydrogenotrophic bacteria convert CO_2 into CH_4 consuming H_2 (Eq. 1) while Acetoclastic bacteria produce CH_4 from CH_3COOH (Eq. 2). So, the overall reactive step stabilizes the final pH level inside the digester at a value about 6–8 (this strictly relies upon feedstock characteristics).

In order to simply represent the trends of these elements, the used kinetic model is a non-structured and non-segregated one, meaning that all the bacterial cells are equivalent in terms of age, size and metabolism abilities, so the reactions are not influenced by the intracellular structure itself but only depends on operative conditions. All these concepts were applied for the construction of Anaerobic Digestion Model No.1 (ADM1), that is a complex Monod-type kinetic created by IWA in 1997. The process described is a wet AD (total solid content < 10 %wt.) performed in a CSTR constant volume in mesophilic conditions (i.e., 35 °C). It consists in an ensemble of 35 differential equations representing the mass balances for all the substrates and bacteria families involved into the process (Batstone et al., 2002). Then, eight additional algebraic equations are needed for pH computation, balance closure and biogas partial pressure evaluations. General equations are functions of ρ , the production term summarizing the reaction rates expressed through 1st order or Monod kinetics, accounting also for different inhibition functions (e.g., low pH value, H_2 , NH_3), moreover acid-base ions dissolution equilibrium and liquid-gas mass transfer expressions ρT_i appear in ADM1 equations.

2. Model improvements

As reported in the previous paragraph, ADM1 was firstly developed for digestion processes which treat principally wastewater. In the last decades, different authors proposed extensions and modifications to the model in order to adapt it to the digestion of different substrates. In H. Li et. al (2019) a mathematical model is proposed to simulate manure mono-digestion in order to get the dynamics of carbon, phosphorus and nitrogen components in wet condition and high total-solid content and it was found valid to describe a high total-solid inhibition. Rivas-Garcia et al. (2020), in their studies, have tried to extend ADM1 to co-digestion proposing different values for kinetic parameters through regression of experimental data. In summary, to properly run a real-case simulation, ADM1 has to be adapted to the anaerobic digestion of various feedstocks, other than sewage sludges. Being the model based on default parameters, these have been investigated to better fit meaningful different dynamics behavior of all the species through iterative approximations starting from previous studies (Rivas-Garcia et al., 2020; Heng Li et al., 2019; F. Blumensaat et al., 2003). New values for parameters are reported in Table 1 as optimized parameters. This allows the adaptation of ADM1 to process different types of substrates, becoming more suitable in industrial applications where not only wastewater AD is performed. So, the ADM1 extension proposed in this paper makes it more suitable for a wider range of substrates than the previous thanks to the new found kinetic constant values, which open the doors to the possibility to describe different feedstock AD with great results. This aspect is further confirmed directly with real data comparison (section 3) and by reproducing the results of the works aforementioned, meaning that the new model is so capable to describe also specific situation with good approximation. A second contribution addresses equations, CSTR mass balances become different for macromolecules and intermediate molecules. For the former, the normal shape of the equation is used, for the latter the inlet term $S_{in,i}$ has to be removed since

only macromolecules, such as carbohydrates, lipids, proteins, and inert materials, are directly introduced with feed stream (Eq. 3-4). Then, a clear distinction between influent initial conditions and starter initial conditions is required: the former is defined by the inlet concentration of the macromolecules derived by their influent flowrate value, the latter is referred to the bacteria amount initially present inside the reactor necessary to start the digestion process (Eq. 5). To further specify, the starter composition can be defined as inoculum, if only bacteria are present, or as fresh digestate if it consists in an already treated digestate recirculated to the feed stream or taken from another reactor. Another novelty brought by this work addresses hydrogen sulfide release and its biological abatement together inside the digestion chamber. Developed from sulfur rich substrate by means of sulfur reducing bacteria (SRB), H₂S, a toxic acid responsible for serious units' corrosion, has to be reduced to few ppm to be harmless. Its typical value ranges between 0.2~2 %vol. of the final biogas amount. This small percentage makes the acid treatment suitable with Sulfur Oxidizing Bacteria (SOB), that being aerobic bacteria, have to be activated by low amount of oxygen. As normal industrial practice, the oxygen is injected in the headspace, in order to directly encounter the SOB and reducing the inhibition effect on methanogens.

Table 1. Optimized kinetic constants and misc. coefficients.

Constant type	Reference compound	Default value	Optimized value
Hydrolysis $k_{hyd,i}$ [d ⁻¹]	Carbohydrates	10	1.25
	Proteins	10	0.525
	Lipids	10	0.8
Semi-Saturation $K_{S,i}$ [kgCOD m ⁻³]	Sugar	0.5	0.3
	Fats	0.4	0.8
	Propionate	0.1	0.2
	Acetic Acid	0.15	0.2
	Hydrogen	0.000007	0.0000099
Michealis-Menten $k_{m,i}$ [kgCOD kgCOD ⁻¹ d ⁻¹]	Sugar	30	20
	Amino Acids	50	45
	Propionate	13	15
	Hydrogen	35	55
Degradation $k_{dec,i}$ [kgCOD kgCOD ⁻¹ d ⁻¹]	Sugar	0.02	0.05
	Fats	0.02	0.05
	Acetic Acid	0.02	0.05
	Hydrogen	0.02	0.09
Inhibition $K_{I,i}$ [kmol m ⁻³]	Ammonia Inhibition	0.0018	0.003

In order to treat sulfur compounds in the reactive mixture the model proposed by Flores-Alsina (2016) properly works but requires several input information concerning feedstock characterization that is quite impossible to have without expensive and time-consuming laboratory analysis, because its aim concerns modelling also phosphorous and iron ions interaction in AD processes. Treating claimed micronutrients such as P, Fe and Ca makes the model too complex for industrial purposes, so the homologation of Kalyuzhnyi and Fedorovich (1998), a simpler but complete work about these topics, allows to mathematically account for H₂S development during digestion. Reaction rates for SO₄²⁻ and H₂S (Eq. 6) follow Monod kinetics and three more bacteria families are added (i.e., Acetogenic SRB, Acetoclastic SRB and Hydrogenotrophic SRB). On the other hand, the chemical oxidation of the acid to solid elemental S_x (that typically accumulates in the reactor ceil) is described trough the incorporation of Sharma et al. (2014) kinetic expression adapted to anaerobic conditions.

$$dS_i/dt = HRT(S_i^{in} - S_i) + \sum_j^{NR} \rho_i v_{i,j} \quad (3)$$

$$dS_i/dt = HRT(-S_i) + \sum_j^{NR} \rho_i v_{i,j} \quad (4)$$

$$dX_i/dt = HRT(-X_i) + \sum_j^{NR} \rho_i v_{i,j} - k_{dec} X_i \quad (5)$$

$$\rho_i = \frac{k_{m_i} (S_i S_{SO_4^{2-}}) (1 - H_2 S_{dis}/K_{I_i})}{(K_{S_i} + S_i) (K_n + S_{SO_4^{2-}})} X_i \quad (6)$$

Where for the symbology of Eq. 3-5 refer to Batstone et al. (2002), and for Eq. 6 refer to Kalyuzhnyi and Fedorovich (1998). As introduced, this new model for AD process description, brings dissolved oxygen reactant S_{O_2} (since methanogenesis happens in liquid phase) and its mass balance (Eq. 7) for the first time, whose principal task is the biological abatement of H_2S . However, it is also responsible for the inhibition of the Methanogenic bacteria (MPB). Because these latter work in liquid phase, it is crucial to evaluate the right amount of oxygen to insert, since it will penetrate in the substrate by natural diffusion. To reduce inhibition, SOBs are often placed on wood frameworks installed in the headspace, so all the O_2 injected will be captured from them as nutrient. To be complete and reliable, the model has to account also for these phenomena introducing a new function that relates the content of oxygen dissolved S_{O_2} into liquid phase to the methane production balance, actually, multiplying it in dissolved methane mass balance. The inhibition function (Eq. 8) is then tuned properly by a constant whose value was set be $K_{I,O_2} = 0.00035 \text{ kgCOD/m}^3$, in order to fit a case study, later presented. The shape of the function is kept similar to the other inhibition functions, already present in the original ADM1 model, not to impact on the stiffness of the model itself. I_{O_2} , then, is present as multiplication factor in liquid phase methane mass balance (Eq.9). Again, for the symbology of Eq. 9 refer to Batstone et al. (2002).

$$dS_{O_2}/dt = HRT(S_{O_2}^{in} - S_{O_2}) - \rho T_{O_2} - k_{m_{O_2}} \frac{S_{O_2}}{K_{S_{O_2}} + S_{O_2}} S_{H_2S}^{\alpha} \quad (7)$$

$$I_{O_2} = \frac{1}{1 + S_{O_2} / K_{I,O_2}} \quad (8)$$

$$dS_{CH_4}/dt = HRT(-S_{CH_4}) + (1 + Y_{ac})\rho_{11}I_{O_2} + (1 - Y_{H_2})\rho_{12}I_{O_2} - \rho T_{CH_4} \quad (9)$$

Another improvement concerns the characterization of the feedstock. Specifically, the introduction of a pseudo-component covering all the charged substrates. This is defined as a weight average of the bio-composition of all the inlets and result as percentages of the macromolecules in the feedstock. These values are then converted in kgCOD/m^3 in order to fit the model's unit of measures. Specific analysis for compounds such as phosphorus, calcium or metals are not necessary. Finally, the model so defined can be easily supported by the generation of a detailed database collecting all the aforementioned values of a huge variety of possible substrates, simplifying the usability of the model itself and spreading its simulation range to different industrial applications.

3. Case Study

To validate the developed model, the simulation of a local CSTR, with a Hydraulic Retention Time (HRT) of 35 days, is employed to test the new mathematical model. The plant is designed to discharge around $28 \text{ m}^3/\text{d}$ of digestate and produces $3 \text{ m}^3/\text{d}$ of biogas

from the co-digestion of different origins feedstock (Table 2). The amount of air used for microaeration treatment corresponds to the 5 %vol. of the headspace volume (i.e. 0.0315 m³/d of O₂ injected). The code implementation in Python™ requires a time span of 35 days divided into 10,000 subintervals and an absolute and relative tolerance of 10⁻¹⁰ and 10⁻¹¹ respectively. The effluent biogas is not only composed of methane, carbon dioxide and hydrogen, but contains also small amounts of hydrogen sulfide that has been previously developed from sulfur containing compounds and in part biologically oxidized. Table 3 shows the final composition of the model simulation in terms of volumetric percentages of biogas main components and allows to quickly compare them with the real plant outlet biogas composition (Unit effluent) provided. Oxygen is responsible for H₂S abatement and its excess leaves the headspace unreacted. From the trends reported below it is possible to see the reaching of a stationary phase within the canonical 30 days for AD processes. Picks in the biogas production (Fig. 1a) refer to different degradation times for the hydrolysis products from the substrate. It is also possible to notice as the trend showed by the original ADM1 does not depict properly the biogas trend. This due to the lack of evaluation of H₂S and other aforesaid compounds present in the feedstock and especially the methanogenesis oxygen induced inhibition in liquid phase. However, both the trends seem to be really similar at the steady-states. It's necessary to say that these trends represent the instantaneous value of biogas produced, so at the end the total biogas production refers to the area under these curves. Finally, it is clear from the Figure 1a that this kind of substrate, in this condition, is not suitable to be simulated from the original model. Furthermore, the dynamic trend of the sulfur compounds is analyzed (Fig 1b) from the new balances added, showing the sulfur present in the feed quickly reduced to H₂S before undergoing to degradation due to SOB_s.

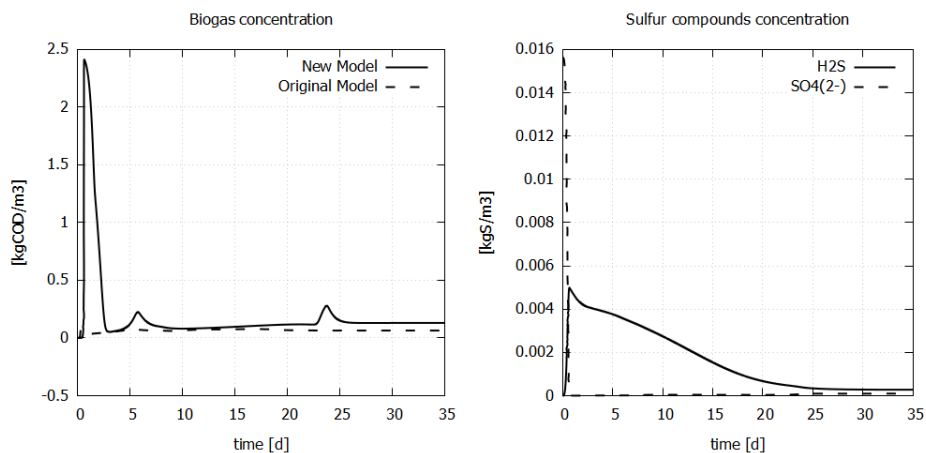

Figure 1. Trends of exiting biogas (a-left) and of dissolved H₂S and SO₄²⁻ (b-right).

Table 2. Feedstock composition.

Feed	m ³ /d
Cattle slurry	19
Bovine manure	7.4
Sorghum and Triticale silage	4.4

Table 3. Exiting composition of biogas compounds.

Component	Simulation [%vol.]	Unit effluent [%vol.]
CH ₄	70.7	50-75
CO ₂	27.06	25-45
H ₂	0.011	< 1
H ₂ S	0.2	0.02-2
O ₂	2	< 2

4. Conclusions

The presented model accounts for 43 differential equations, 35 original ones completed with the mass balances for SO_4^{2-} , H_2S and O_2 for both the liquid and gas phase and three new bacterial mass balances dedicated to SRBs. SOB's balances, instead, are not considered having a negligible contribution in the microbial environment. New kinetic constants have been proposed. Moreover, the new model greatly simplifies the simulation itself. In Flores-Alsina et al. studies (2016) the possibility to compute sulfur dynamics was presented with a mathematical model which needed several input information concerning feedstock characterization, which increases both the difficult availability of those data and the model complexity. The model here presented, requires a reduced number of input data that are summarized in the definition of a pseudo-component, which characteristics are defined by its percentages of macromolecules (carbohydrates, lipids, proteins), the amount of sulfur and inert materials coming from the feedstock charged to the digestion chamber and the air/oxygen feed to the headspace for biological H_2S abatement. A data base of biomasses and their characteristics has been also built for the pseudo-component definition. Original ADM1 has also other gaps that the presented model tries to fill with easy co-digestion simulation and complete H_2S dynamics. Case study results not only show realistic outlet values, provided in range percentages by the company, but also correct time depending on trends. Although this is a new work, it seems promising given the first results, and further studies, experiments and optimization processes will make the model complete and more effective.

Abstract

Machine learning algorithms are drawing attention for modelling processes in the chemical and biochemical industries. Due to a lack of fundamental understanding of complex processes and a lack of reliable real-time measurement methods in bio-based manufacturing, machine learning approaches have become more important. Hybrid modelling approaches that combine detailed process understanding with machine learning can provide an opportunity to integrate prior process knowledge with various measurement data for efficient modelling of the (bio)chemical processes. In this study, the application of a hybrid modelling framework that combines various first-principles models with machine learning algorithms is demonstrated through a laboratory-scale case of flocculation of silica particles in water. Since flocculation is a process that occurs across length- and time scales, an integrated hybrid multi-scale modelling framework can improve the phenomenological understanding of the process. The first-principles models utilized in this study are molecular scale particle surface interaction models such as Derjaguin-Landau-Verwey-Overbeek (DLVO) theory and interfacial tension predictions combined with a larger-scale population balance model.

Keywords: Hybrid modelling, Flocculation, Surface interactions, Interfacial tension energy

1. Introduction

The integration of machine learning and first-principles model in hybrid form can be achieved in different ways. For instance, a general hybrid model is proposed by Oliveira (2004) to model a stirred tank bioreactor. Another way of applying hybrid modelling approaches is represented in Psychogios and Ungar (1992), which provides interaction between a machine learning algorithm and a first-principles model of a fed-batch bioreactor. Based on the availability of first-principles models and prior process knowledge, one can apply a variety of different hybrid models. The hybrid modeling approach implemented in this study is represented in Figure 1. The model inputs are the data collected from experiments, which includes the pH measurements throughout each batch operation and the particle size distribution. According to the availability of first-principle models for the flocculation process, such hybrid modelling scheme (see Figure

1) is used, since a first-principles model does not exist to fully describe the process. Hence, a machine learning model (here artificial neural network) can be trained based on the model inputs and the first-principles models use the output of the machine learning algorithm and model inputs all together to predict a future particle size distribution.

Figure 1: Hybrid modelling schemes according to the availability of first-principles models

Various approaches have been used to model particle processes, including flocculation, by using a population balance model (PBM). In this study, a discretized PBM is implemented using the work of Nazemzadeh et al. (2019) to model the particle size distribution over time. The discretized PBM is represented in Eq. (1).

$$\frac{dN_i}{dt} = \sum_{\substack{j \geq k \\ v_{i-1} \leq (v_j + v_k) \leq v_{i+1}}} \left(1 - \frac{1}{2} \delta_{j,k}\right) \eta_i \alpha_{j,k} \beta_{j,k} N_j N_k - N_i \sum_k \alpha_{i,k} \beta_{i,k} N_k + \sum_k \gamma_{j,i} S_j N_j - S_i N_i \quad (1)$$

Where N_i is the number of particles in a size bin of the discretization scheme, $\delta_{j,k}$ is the Dirac delta function, η_i is the proportionality coefficient related to the discretization scheme, $\alpha_{j,k}$ is the collision efficiency of two colliding particles, $\beta_{j,k}$ denotes the collision frequency of particles, γ is the breakage distribution function, and S denotes the breakage rate of a particle. Collision efficiency of the two colliding particles is calculated by using DLVO theory (Yotsumoto and Yoon, 1993) as a first-principles model. This theory in combination with Fuch's stability ratio (W) (Ahmad et al. 2008) allows us to determine the collision efficiency from the interaction energies between two particles in the system (see Eq. (2)). The remaining parameters of the PBM are defined by the semi-empirical equations found in the literature (Li et al. 2019).

$$\frac{1}{\alpha_{i,j}} = W_{i,j} = \int_{r_i+r_j}^{+\infty} \frac{\exp(V_T/K_b T)}{s^2} ds \quad (2)$$

Where V_T is the total interaction energy between two particles with a surface-surface separation distance and radii r_i and r_j , K_b is the Boltzmann constant and T is temperature.

Moreover, a solid-liquid interfacial tension (IFT) prediction model by Andersson et al. (2020) is implemented to determine the surface interaction energy of two particles in contact with each other. In future studies, we plan to use the predicted IFT values as an additional soft sensor to the hybrid model to evaluate the unknown parameters in the first-principles model.

2. Modelling framework

In this study, the hybrid model uses the population balance model as the main first-principles model to represent the particle size evolution as a function of time. The prior knowledge of flocculation kinetic parameters alongside with DLVO theory is used as additional first-principles models on top of the PBM. The kinetic model contains parameters such as a velocity gradient, which is not measured during the process

operation. Moreover, the breakage term in the PBM contains parameters that cannot be correlated with the process variables. A modelling workflow related to the selected modelling approach is represented in Figure 2. This workflow is structured by extending the modelling framework developed by Nielsen et al. (2020). The difference between the framework in the present study and the one developed in Nielsen et al. (2020) is the utilization of first-principles models for the kinetic parameters in a PBM (i.e. DLVO theory and semi-empirical equations of other kinetic parameters). The machine learning algorithm (black box in Figure 1) is an artificial neural network consisting of three hidden layers with 34, 40, and 50 neurons respectively. The output of the neural network is the unknown/unmeasured parameters of the population balance model.

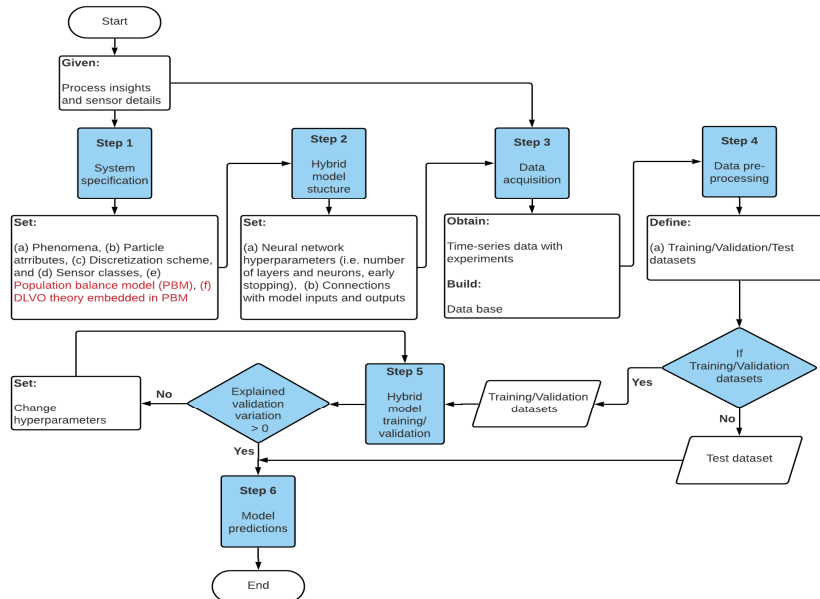

Figure 2: Overview of the hybrid multi-scale modelling workflow

3. Application example

The application of the proposed modelling framework is demonstrated through a laboratory-scale silica particle flocculation. To this end, an experimental setup is prepared that uses a dynamic image analysis sensor (Nielsen et al. 2019) to monitor the particle size distribution. The flocculation is stirred by an impeller to increase the chance of occurrence of particle collisions in the system. Moreover, an in-line pH probe is installed in the tank to measure the pH continuously. Several batches of experiments are carried out at different pH values. Variation of pH imposes a different surface charge density on the particles by protonation/deprotonation of the surface silanol groups on the silica. The experiments show that for the batches, in which pH is in the range of 2 to 3, agglomeration of particles takes place as shown in Figure 3 (a). However, at a higher pH value, the process is dominated by breakage phenomena and successful collisions of particles are less likely to happen (see Figure 3 (b)).

Silica nanoparticles have a point of zero charge (PZC) in the range of pH 2 to 3 (Cloarec et al. 2016). For a pH in the vicinity of the PZC, silica nanoparticles are neutral. Therefore, when two particles approach each other the attraction forces can overcome the repulsion forces and the particles collision will be more likely successful. However, for a pH

higher/lower than the PZC, the particles become deprotonated/protonated and negatively/positively charged. Hence, the repulsion forces of surfaces with the same charge can easily overcome the attraction forces and no agglomeration takes place.

Figure 3: End-of-batch representation of particles: (a) at $pH = 2.45$, (b) at $pH = 7.61$

To determine the interfacial tension energies of silica particles, a structure of a silica nanoparticle containing 54 Hydrogen, 121 Oxygen, and 47 Silicon atoms was constructed and then optimized by using density functional theory (DFT) calculations. The geometry optimization was carried out for a neutral and singly deprotonated molecular structure by using the BP functional (Becke 1988), the TZVP basis set (Schäfer et al. 1992) and the COSMO implicit solvent model (Klamt and Schüürmann, 1993) with infinite dielectric constant using TURBOMOLE, v 7.4 (Ahlrichs et al. 1989). The IFT calculations were carried out using a solid-liquid interfacial tension model in COSMO-RS (Klamt et al., 2010) by using the BP_TZVP_C30_1601 parameterization in COSMOtherm (Eckert and Klamt 2010). The IFT of singly deprotonated silica nanoparticle and water was approximately -16 mN/m . The negative value of IFT means that a deprotonated silica nanoparticle has a favorable interaction with water. In this study, the IFT energies are only used to characterize the process. However, in future studies these interaction energies are planned to be utilized directly in the hybrid model.

The hybrid multi-scale framework in §2 is applied to the experimental data collected from the laboratory-scale flocculation of silica particles in water. Figure 4 represents the end-of-batch predictions for two batches of experiments: (a,c) dominated by breakage and (b,d) dominated by agglomeration. In both cases, the hybrid multi-scale model quite accurately predicts the particle size distribution of the end time-point. The predictions are improved compared to the similar case study in Nielsen et al. (2020). In that study, PBM was the only first-principles model and all the kinetic parameters of the model were estimated by means of a neural network. The agglomeration end-of-batch predictions in that study showed that the relative volume density of large particles were not predicted quite accurately due to either lack of data for training, or the fact that a pH sensor was not sufficient to describe the process. However, for the agglomeration batch in the present study, the model predicted the relative volume density of particles more accurately even for larger size-bins. A pure machine learning approach is also utilized to model the flocculation process to compare the performance of a black-box model and the hybrid model. The black-box model uses Eq. (3) to predict the particle number concentration for each size-bin in a future time-point with the rate that is determined by the machine learning algorithm. Hence, no phenomenon is defined for the process and the future particle number concentration is predicted by a single rate at each time-point for each size-bin. The rest of the modelling components are chosen to be the same as the ones in §2 (see Figure 2). The end-of-batch predictions for the black-box model are represented in Figure 4 (c,d). The predictions show that for the breakage batch, the performance of

the hybrid and black-box models are reasonably comparable. We believe that the reason is the fact that the variations of relative volume densities in that experimental batch were not very high and both models can predict the end-of-batch distribution in a similar way. However, in the agglomeration batch, the hybrid model outperformed the machine learning model in end-of-batch predictions.

$$\frac{dN_i}{dt} = rate_{i,t} \quad (3)$$

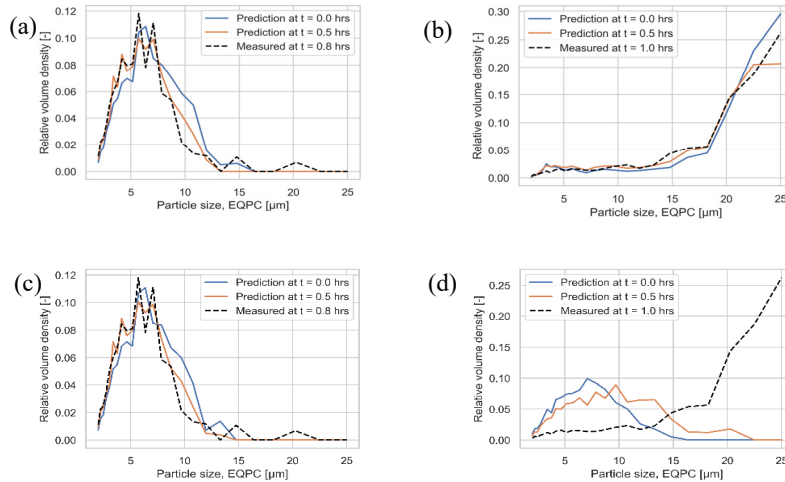

Figure 4: End-of-batch predictions of (a) agglomeration batch, (b) breakage batch for the hybrid model and (c) breakage batch, (d) agglomeration batch for the black-box model

4. Conclusion and future developments

In this study, the application of a hybrid multi-scale framework was demonstrated on a laboratory-scale case of silica particles flocculation by using a population balance model, DLVO theory, and semi-empirical equations of flocculation kinetics to model the process. The main reason that we used machine learning for modelling the flocculation process is that a prior process knowledge does not exist to fully describe the process. The end-of-batch predictions of two experimental batches have shown that such modelling approach can accurately estimate the evolution of particle sizes in the system in a future time horizon for both phenomena (agglomeration and breakage) involved in the flocculation process. Moreover, a pure black-box model was also used to perform the same end-of-batch predictions. Both modelling approaches showed similar predictions for the batch dominated by breakage due to the very small variations of the particle size distributions in the breakage batch. Nonetheless, the hybrid model outperformed the black-box model by accurately predicting the end-of-batch particle size distribution. We believe that the integration of machine learning algorithms and first-principles models helps us to model complex processes such as flocculation more accurately and predict the dynamics of the system in a future unknown time-horizon.

5. Acknowledgment

We would like to thank Novozymes A/S and Greater Copenhagen Food Innovation program (CPH-FOOD) for co-financing this research and also for their support during this project.

Abstract

Simulations of chemical processes require accurate physical properties, which are usually estimated from experiments. Experimental effort can be minimised by optimal experimental design (OED). OED tailors experimental measurements to minimise the expected uncertainty of the fitted parameters. However, in process design and optimisation, the primary purpose of an experiment is usually not to determine property parameters as accurately as possible but to enable most accurate process simulations. Therefore, in this work, we present OED of physical property measurements leading to optimal predictions of process simulations by the so-called *c*-optimal experimental design. A *c*-optimal design minimises the uncertainty of the simulation results by weighting parameters by their influence on the process model. The *c*-optimal OED is employed to design liquid-liquid equilibrium measurements as a basis for simulations of an extraction and a hybrid extraction-distillation process. For the same simulation accuracy, the *c*-optimal design can almost halve the number of experiments compared to state-of-the-art OED that neglects the process. Our work shows that *c*-optimal design can reduce experimental effort in chemical engineering successfully by tailoring experiments to their process application.

Keywords: model-based experimental design, parameter precision, *c*-optimal design, liquid-liquid-equilibrium, non-random two-liquid model, extraction-distillation.

1. Introduction

Accurate estimation of property parameters is crucial for the simulation of chemical processes (Mitsos et al., 2018). The basis for accurate parameter estimation is experimental data. If such data is not available, new experiments are required, usually consuming time and large volumes of material samples, leading to high costs. Therefore, experimental effort should be minimised by careful design of experiments. Optimal experiments minimise the uncertainty in the experimentally determined parameters. The systematic selection of optimal experiments is enabled by model-based optimal experimental design (OED) (Atkinson et al., 2006). OED analyses the

propagation of uncertainty from inaccuracies in experimental measures to estimated parameters. The propagation is used to optimise the experimental design, i.e., the settings and inputs of the experiments (Franceschini and Macchietto, 2008). However, for process systems engineering, the primary purpose of experiments is rarely the knowledge of parameters itself, but the use of these parameters in process simulation. An optimal experimental design minimising parameter variances does not necessarily lead to the most accurate process simulations. OED for process simulations needs to consider the use of the fitted parameters within the process models.

Recently, OED was applied to design plant experiments using a flowsheet simulator (Asprion et al., 2019). The authors designed experiments at the plant to measure property data capturing the parameter use in the process simulation. However, for this approach, challenging plant experiments need to be performed instead of lab-scale experiments. Recker et al. (2013) presented a pioneering approach considering the process model within OED of lab-scale experiments. In their work, state-of-the-art OED was extended by scaling the well-known A -criterion heuristically by process sensitivities to parameters. A similar OED objective was proposed by Lucia and Paulen (2014) for robust model predictive control. The authors tailored the modified E -criterion by the sensitivities of the optimal robust economic objective value with respect to the range of parametric uncertainty.

Although these approaches successfully integrated process sensitivities into OED, the OED objectives rely on heuristic scaling. However, full consideration of process information by systematic uncertainty propagation is enabled by established theory:

c -optimal experimental design. In c -optimal design, the objective is to minimise the variance of a linear combination of the parameters (Atkinson et al., 2006). By linear approximation of the variance propagation from the parameters through the process model, c -optimal design can be employed to minimise the uncertainty of process simulations.

So far, c -optimal OED has not been applied to chemical engineering problems. Therefore,

we adapt c -optimal design to experiments for the measurement of liquid-liquid-equilibria

to simulate extraction and extraction-distillation processes. We compare the c -optimal objective to state-of-the-art OED methods using the D -optimality criterion and an A -optimality criterion that is heuristically scaled by process sensitivities.

2. Method: Calculation of c -optimal experimental designs

To design optimal experiments, OED needs to link the uncertainties of experimental measures to the uncertainties of the model parameters. Mathematically, the uncertainties of the model parameters are expressed in the parameter variance-covariance matrix V_{θ} .

The parameter variance-covariance matrix is approximated by the product of the Fisher information matrix $F(\hat{\theta}, \xi)$ and the number of experiments N_{exp} .

$$V_{\theta} \approx \left[N_{exp} F(\hat{\theta}, \xi) \right]^{-1} \quad (1)$$

The Fisher information matrix $F(\hat{\theta}, \xi)$ depends only on the chosen experimental design ξ and an initial parameter guess $\hat{\theta}$. As the parameter variance-covariance matrix

is proportional to the inverse of $F(\hat{\theta}, \xi)$, OED mainly focuses on designing an optimal Fisher information matrix by selecting an optimal design ξ^* . The Fisher information matrix $F(\hat{\theta}, \xi)$ is obtained from the model $g(w, \theta)$. The model $g(w, \theta)$ describes the experiments by linking the uncertainties of experimental measurements V_w to the parameters θ . The Fisher information matrix $F(\hat{\theta}, \xi)$ is calculated for an experimental design ξ by taking the model sensitivity to experimental measures A_μ and the model sensitivity to parameters B_μ for each experiment μ of the experimental design.

$$F(\hat{\theta}, \xi) = \sum_{\mu=1}^{N_{exp}} v_\mu B_\mu^T \left(A_\mu V_w A_\mu^T \right)^{-1} B_\mu \quad \text{with} \quad A_\mu = \frac{\partial g}{\partial w} \Big|_{w_\mu, \hat{\theta}} \quad \text{and} \quad B_\mu = \frac{\partial g}{\partial \theta} \Big|_{w_\mu, \hat{\theta}} \quad (2)$$

State-of-the-art OED objective functions are based on the Fisher information matrix and aim to optimise a scalar measure of the Fisher information matrix. The c -optimal design additionally considers the use of the estimated parameters in the process model. Variance

propagation through the process model weights the parameter variances by the sensitivities of the process model result $h(\theta)$ to the parameters θ in the c -optimal design.

$$c(\hat{\theta})^T F(\hat{\theta}, \xi)^{-1} c(\hat{\theta}) \quad \text{with} \quad c(\hat{\theta}) = \frac{\partial h}{\partial \theta} \Big|_{\hat{\theta}} \quad (3)$$

We compare the c -optimal design with state-of-the-art OED objectives. The most popular

objective is D -optimal design. D -optimal design maximises the determinant of $F(\hat{\theta}, \xi)$ to minimise the volume of the confidence ellipsoid spanned by all parameters.

$$\log(\det F(\hat{\theta}, \xi)) \quad (4)$$

Inspired by Recker et al. (2013) and Lucia and Paulen (2014), we also investigate a heuristically scaled Fisher information matrix together with A -optimal experimental design. The A -optimal design maximises the trace of the Fisher information matrix. We scale the Fisher information matrix with a diagonal weighting matrix W . The weighting matrix W includes the sensitivities of the process model output $h(\theta)$ to the parameters θ .

$$\text{tr}\left(F_{heur}(\hat{\theta}, \xi)\right) = \text{tr}\left(W F(\hat{\theta}, \xi) W\right) \quad \text{with} \quad W = \text{diag}\left(\frac{\partial h}{\partial \theta} \Big|_{\hat{\theta}}\right) \quad (5)$$

All experimental designs are computed by a solution algorithm with monotonic global convergence from literature (Yu, 2010). Derivatives are obtained by numerical differentiation. The algorithm provides experimental designs with a continuous distribution of experimental effort, i.e., which share of the total experimental effort should be spent on which measurements. The results serve as targets for experiments in the laboratory. The identified experiments are optimal for the initial parameter set; thus, an iterative procedure might be required in practice. For comparison of the OED objectives, each experimental design ξ can be assessed by OED-efficiencies, e.g., c -efficiency $\zeta_c(\xi)$. The c -efficiency is the ratio of the objective values (Eq. (3)) of a

c -optimal design and of the design under consideration. The inverse of $\zeta_c(\xi)$ shows how many more experiments are needed for the same accuracy of the process simulation compared to a c -optimal design.

3. Case Study and Results

For two solvent-based processes, we apply c -optimal experimental design to tailor liquid-liquid-equilibrium (LLE) measurements: (1) the extraction of acetone from aqueous solution with toluene and (2) the extraction-distillation process for the same mixture including a distillation column to separate the extract. The extraction and distillation column are modelled using pinch-based process models (Bausa et al., 1998; Redepenning et al., 2017) employing the non-random two liquid (NRTL) model as an activity coefficient model. The liquid-liquid-equilibrium experiments are designed to estimate isothermal NRTL- t -parameters for the extraction and linearly temperature-dependent NRTL- t -parameters for the extraction-distillation process. We challenge the results of the c -optimal design by the D -optimal design and the heuristically scaled A -optimal design.

3.1. OED for the simulation of a pinch-based extraction column

For the extraction process, we determine at which concentrations which share of experimental effort should be invested in LLE-experiments for minimum uncertainty in the solvent demand of the process. For simplicity, we assume that LLE-experiments are performed with the overall composition of the components that corresponds to the centre of the tie lines. Therefore, an experiment is fully characterised by a scalar measure α which runs from 0 at the binary subsystem to 1 at the critical point of the two-phase region.

For each optimality criterion used, three distinct locations for measurements are sufficient

for an optimal design (Figure 1). As commonly found in OED, the optimal design suggests repeating measurements at these locations rather than to explore other locations. The locations and, in particular, the share of the total experimental effort differ for the three objectives: The c -optimal design shifts 80% of the experimental effort towards the operating range of the extraction column resulting in a c -efficiency ζ_c about 3 times higher than the D -optimal design (Table 1). Consequently, 3 times more D -optimal experiments would be required to obtain the same accuracy as the c -optimal experiments. Interestingly, the c -optimal design does not place any experiments in the operating range of the extraction column and still places about 20% of the experimental effort in the high-curvature region of the binodal curve.

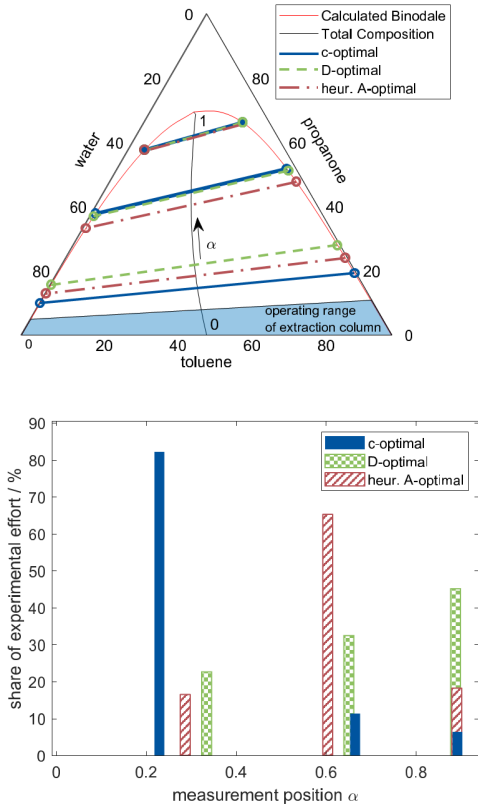

The D -optimal design places 75% of the experiments in the high-curvature region of the binodal curve, as already found by Dechambre et al. (2014). In the high-curvature region of the binodal curve, the phase equilibrium model is susceptible to the property parameters leading to low uncertainty in the parameter estimation.

The c -optimal design balances the parameter requirements: Experiments need to be linked

to the operating range of the process, but the exclusive focus on the process neglects that

accuracy can be increased by including experiments for high parameter precision. The heuristic A -optimal design achieves a c -efficiency ζ_c of only 0.28. The experimental design from the heuristic A -optimal design is closer to the c -optimal design. However,

the c-efficiency is lower than the c-efficiency of the D-optimal design, which shows that the similarity of designs is not necessarily correlated to the efficiency.

(a) Location of LLE experiment

(b) Share of experimental effort

Figure 1: Optimal designs for LLE experiments for the extraction process.

Table 1: c-efficiency ζ_C for the c- and D-optimal experimental designs ξ_C^* and ξ_D^* and the heuristically scaled A-optimal design $\xi_{A,heur}^*$ for the extraction and the extraction-distillation process

Experimental design ξ	c-efficiency ζ_C	
	Extraction	Extraction-Distillation
c-optimal ξ_C^*	1	1
D-optimal ξ_D^*	0.36	0.61
heuristically scaled A-optimal $\xi_{A,heur}^*$	0.28	0.57

3.2. OED for the simulation of an extraction-distillation process

For the extraction-distillation process, we design the location of the LLE-experiments within the miscibility gap as before and additionally, the temperature for each LLE-experiment to minimise the uncertainty of the reboiler energy demand. Other key performance indicators of the process could serve as targets as well by computing the corresponding sensitivities $c(\theta)$. For each design objective, the design mainly focuses on the boundaries of the design space (Figure 2). On the boundaries, the parameter sensitivity is highest leading to low parameter uncertainty. For the extraction-distillation process, parameter precision is more important for accurate process simulation than for the extraction only: The D -optimal design yields a c -efficiency ζ_c of about 0.6 (Table 1).

Still, the c -optimal design increases accuracy by 64%. The heuristic A -optimal design is comparable to the D -optimal design. However, the heuristic A -optimal design does not improve in c -efficiency ζ_c compared to the D -optimal design, despite the consideration of process sensitivities. In this case study, the heuristics are not only exceeded by the c -optimal design, but also by the conventional design that does not consider the process. Therefore, the selection of the right optimality criterion is crucial for process engineering problems. For the extraction and extraction-distillation process, only c -optimal design tailors experiments for the process simulations.

4. Conclusion

In this work, we investigate a method for optimal experimental design (OED) of lab-scale experiments that consider the use of the estimated parameters in a subsequent process simulation: c -optimal experimental design. The c -optimal design includes the propagation of uncertainties from measurements to the outputs of the process model. We compare

c -optimal design with state-of-the-art OED, i.e., D -optimal design and a heuristically scaled A -optimal design. The c -optimal design yields non-trivial experimental designs that outperform state-of-the-art OED by providing more accurate results of process simulation. The c -optimal design does not simply perform experiments in the operating region of the process but balances parameter precision with uncertainty propagation to the process model. Thereby, the experimental effort can be significantly reduced while maintaining the same accuracy.

On the practical identifiability of kinetic models of hydroxymethylfurfural hydrogenation in batch reaction systems

Philipp Deussen^a, Federico Galvanin^{a,*}

^a*Department of Chemical Engineering, University College London, Torrington Place, London WC1E 7JE, United Kingdom*

f.galvanin@ucl.ac.uk

Abstract

Hydroxymethylfurfural (HMF) is an organic compound that occurs in numerous foods and is used as feedstock in a variety of chemical processes. HMF can be hydrogenated to form 2,5-Dimethylfuran (DMF), which is an important component in biofuel production. Several kinetic models have been proposed in literature for this hydrogenation reaction, including power law and Langmuir-Hinshelwood-Hougen-Watson (LHHW) models based on reaction species. A critical aspect to address is the parametric identifiability in these models, i.e. the correct estimation of model parameters from experimental data. In this paper, a two-step identifiability approach is proposed exploiting model-based design of experiments (MBD_{oE}) techniques to assess the identifiability of candidate kinetic models of HMF hydrogenation at variable experimental conditions in a batch reaction system. Information maps indicate the most informative regions of the experimental design space to be used to precisely estimate the kinetic model parameters.

Keywords: identifiability analysis, model-based design of experiments, kinetics of HMF hydrogenation

1. Introduction

HMF is an organic compound that can be found naturally in many foods and is used industrially as a platform chemical in plastics, pharmaceuticals and agrochemicals. It can be hydrogenated to DMF - an alternative biofuel and additive for diesel or jet fuel. It significantly lowers pollution versus its fossil equivalents (van Putten et al., 2013). Proposed mechanisms for this hydrogenation reaction include power-laws (Grilic et al., 2014, Luo et al., 2015, Gyngazova et al., 2015), single-site LHHW (Jain and Vaidya, 2016) and dual-site LHHW (Gawade et al., 2016) kinetics. However, these models lack an explicit temperature dependence. Thus, an expansion of the power-law model to include temperature dependency is proposed and the estimability of the new set of kinetic parameters from experimental data (practical identifiability) assessed (Chis et al., 2016).

MBD_{oE} techniques (Franceschini and Macchietto, 2008) have been proposed in literature to design sets of experiments yielding the most informative data to be used for model identification. Experiments can be designed for discriminating between candidate kinetic models or, given a suitable model structure, to improve precision in parameter estimation

(Galvanin et al., 2016). A two-step identifiability approach is proposed in this paper using MBDoe techniques to assess the identifiability of three new candidate kinetic models of HMF hydrogenation in a batch reactor. Temperature, duration and initial concentrations of reagents are the decision variables defining the design space of the models. First, the design space is screened using Latin Hypercube Sampling (LHS) to generate conditions for running in-silico experiments under variable modelling/noise assumptions. Second, experiments are mapped using the Fisher information matrix (FIM) as information metric (Galvanin et al., 2016). Combined with a-posteriori statistics from parameter estimations using in-silico data, the analysis indicates the most informative regions for precise estimations of model parameters for experimentation without numerical optimisation.

2. Methodology

The proposed kinetic model (1) is written in terms of control variables, \mathbf{w} , state variables $\mathbf{x}(t)$ and parameters $\boldsymbol{\vartheta}$ to be determined. The function $\mathbf{h}(\mathbf{x}(t))$ (2) relates state variables and measured responses $\hat{\mathbf{y}}(t)$. The vector for the design of experiments $\boldsymbol{\varphi}$ (3) lies in the design space, ϕ , and contains \mathbf{w} , initial conditions \mathbf{y}^0 , duration τ and sampling times \mathbf{t}_{sp} .

$$\mathbf{f}(\mathbf{x}(t), \dot{\mathbf{x}}(t), \mathbf{w}, \boldsymbol{\vartheta}, \tau) = 0 \quad (1)$$

$$\hat{\mathbf{y}}(t) = \mathbf{h}(\mathbf{x}(t)) \quad (2)$$

$$\boldsymbol{\varphi} = (\mathbf{y}^0, \tau, \mathbf{w}, \mathbf{t}_{\text{sp}}) \quad (3)$$

In any experiment ($1, \dots, n_{\text{exp}}$) the sensitivities of the measurable outputs \hat{y}_i ($1, \dots, n_m$) to perturbations of the parameters $\boldsymbol{\vartheta}$ ($1, \dots, n_\theta$) are expressed in the sensitivity matrix \mathbf{Q} (4) and computed at sampling points \mathbf{t}_{sp} . The $n_\theta \times n_\theta$ -dimensional variance-covariance matrix \mathbf{V}^θ (5) is obtained from the standard deviation of measurement errors (σ) and \mathbf{Q} . Each kl -th element in the parameter correlation matrix \mathbf{C} (6) can be computed from \mathbf{V}^θ elements. Correlations scale from -1 (total anticorrelation), to 0 (no correlation) to 1 (total correlation). Critical correlation begins at 0.95. The Fisher information matrix (FIM) (7) approximates the Hessian matrix of the log-likelihood function of parameters $\boldsymbol{\vartheta}$ using the predicted outputs \hat{y}_i (Franceschini and Macchietto, 2008).

$$\mathbf{Q} = \begin{bmatrix} \frac{\partial \hat{y}_1}{\partial \vartheta_1} & \dots & \frac{\partial \hat{y}_1}{\partial \vartheta_{n_\theta}} \\ \dots & \dots & \dots \\ \frac{\partial \hat{y}_{n_m}}{\partial \vartheta_1} & \dots & \frac{\partial \hat{y}_{n_m}}{\partial \vartheta_{n_\theta}} \end{bmatrix} \quad (4)$$

$$\mathbf{V}^\theta = [\mathbf{Q}^T \sigma^{-2} \mathbf{Q}]^{-1} \quad (5)$$

$$C_{kl} = \frac{V_{kl}^\theta}{\sqrt{V_{kk}^\theta V_{ll}^\theta}} \quad (6)$$

$$\mathbf{H} = \sum_{i=1}^{n_{\text{exp}}} \sum_{j=1}^{n_m} \begin{bmatrix} 1 \\ \sigma_{ij}^{-2} q_{ij}^T q_{ij} \end{bmatrix} \quad (7)$$

Organic systems are often sloppy. Sloppiness (Chis et al., 2016) is identified if the eigenvalues of the FIMs of different parameters vary by three orders of magnitude or

more and is described by the ratio of the axes of the confidence area. Sloppiness occurs when under specific experimental conditions some parameters have very low impacts on the outputs (i.e. negligible sensitivity), but a set of experimental conditions to identify the full set of model parameters in ϕ does exist.

A two-step procedure is proposed to test the identifiability of selected models in ϕ :

Step 1: The sensitivity and information metrics rely on ϕ and \mathfrak{D} and are thus only locally valid. Since local optima are undesirable, the design space is screened by LHS. LHS is more efficient than randomly selecting points as the position of already generated points is considered before generating subsequent ones, avoiding local clusters (Montgomery, 2012). In-silico experiments are run using these points and the correlation matrix (6) is computed. Models are checked for sloppiness by testing whether critical correlations persist throughout ϕ even when a large number of samples is taken. If correlations persist, these models are practically unidentifiable and must be rejected or reparametrised.

• **Step 2:** A parameter estimation is carried out using a Student t-test to assess the precision of the estimates and a χ^2 test to assess the adequacy of model predictions. The model passes when the parameter t -values (8) are larger than the 95% confidence ($\alpha = 0.05$) reference t -value and the sum of weighted residuals (9) is less than a reference χ^2 value.

$$t_i = \frac{\hat{\vartheta}_i}{t \left(\frac{1-\alpha}{2} + \frac{1-\alpha}{2} n_{exp} n_m - n_{\theta} \right) \sigma_i} \quad i = 1, \dots, n_{\theta} \quad (8)$$

$$\chi^2 = \sum_{i=1}^{n_m} \sum_{j=1}^{n_{sp}} \frac{(y_{ij} - \hat{y}_{ij})^2}{\sigma_i^2} \quad (9)$$

The trace of the FIM (7) of the experiments is used as a scalar measure of information in ϕ . If plotted on a graph against conditions of ϕ it allows to identify the most informative regions of the design space to provide a ranking of experiments (Galvanin et al., 2016).

3. Case Study

3.1. Definition of experimental design space

The model by Gyngazova et al. (2017) (10-15) was developed for HMF hydrogenation in a lab-scale batch reactor (Figure 1) and was used as a basis for candidate kinetic models.

$$dC_{HMF}/dt = -k_1 C_{HMF} \quad (10)$$

$$dC_{BHMF}/dt = k_1 C_{HMF} - k_2 C_{BHMF} - k_5 C_{BHMF} \quad (11)$$

$$dC_{MFA}/dt = k_2 C_{BHMF} - k_3 C_{MFA} \quad (12)$$

$$dC_{DMF}/dt = k_3 C_{MFA} - k_4 C_{DMF} \quad (13)$$

$$dC_{DMTHF}/dt = k_4 C_{DMF} \quad (14)$$

$$dC_{DHMTHF}/dt = k_5 C_{BHMF} \quad (15)$$

$$\phi = [C_{HMF}(0), C_{DMF}(0), T, \tau] \quad (16)$$

Figure 1 – Proposed HMF hydrogenation mechanism in THF solvent using Ni/C catalyst

The design vector ϕ (16) is defined in the design space ϕ (Table 1). The experimental setup bounds temperature and duration. Ranges for reagents were obtained from literature (Gyngazova et al., 2017). In ϕ , 30 in-silico experiments were run assuming an even t_{sp} [min] distribution. Gaussian noise with $\sigma = 0.03$ M was used to perturb simulated concentrations; this value reflects the expected error in actual experiments (Bindwal and Vaidya, 2014). Matlab v.9.5 was used to generate in-silico measurements and LHS points (Khaled, 2020). gPROMS ProcessBuilder v.1.4.0 was used for MBD_{oE} (supporting A-, E- and D- optimality) and nonlinear parameter estimation using maximum likelihood.

Table 1 – Definition of design space ϕ

	Lower	Upper	Unit
$C_{HMF}(0)$	0.01	0.2	M
$C_{DMF}(0)$	0.01	0.2	M
T	300	600	K
τ	60	360	min

3.2. Candidate kinetic models

• **M1:** A temperature dependency is introduced into the original model (10-16) using Arrhenius equation (17). A_i [min^{-1}] and E_{Ai} [J mol^{-1}] are estimated instead of k_i [min^{-1}]. The new parameters are computed using experimental data from Gyngazova et al. (2017), which fit the reformulation in (18) with $R^2 > 0.91$.

$$k_i = A_i e^{-\frac{E_{Ai}}{RT}} \quad (17)$$

$$\ln(k_i) = -\frac{E_{Ai}}{RT} + \ln(A_i) \quad (18)$$

• **M2:** Buzzi-Ferraris and Manenti (2009) outline a reparametrisation (19) to reduce correlation. B_i [min^{-1}] and C_i [K] are new, re-balanced parameters to be estimated. Initial guesses are obtained by rearranging equations (20 & 21). The mean temperature, T_m [K], is fixed at a suitable average of experimental temperatures (Schwaab et al., 2008).

$$k_i = B_i e^{C_i \left(\frac{1}{T} - \frac{1}{T_m} \right)} \quad (19)$$

$$B_i = \exp \left(\ln(A_i) + \frac{C_i}{T_m} \right) \quad (20)$$

$$C_i = -E_{Ai}/R \quad (21)$$

• **M3:** this is a reduced model based on M1 that estimates parameters E_{Ai} and keeps A_i constant at the values obtained from fitting experimental data in (18); these are the values that would otherwise be used as an initial guess in the parameter estimation.

Table 2 - Correlation matrix for M1 obtained from 30 experiments generated using LHS

θ	A_1	A_2	A_3	A_4	A_5	E_{A1}	E_{A2}	E_{A3}	E_{A4}	E_{A5}

3.3. Simulation results for candidate kinetic models

- **M1:** Critical correlations (Table 2) exist between parameters E_{A_i} and A_i . The model passes the χ^2 test despite large residuals affecting individual experiments. The t-test was passed, however, the t-values for A_i were orders of magnitude higher than the ones for E_{A_i} . This was due to unrealistically large estimated values for A_i , passing the t-test only because, according to (8), the corresponding standard deviation σ was small in comparison. This makes the t-test untrustworthy and explains the good results obtained despite high correlations. The contribution to the overall information content (FIM) is also much higher for E_{A_i} than for A_i , underlining a low sensitivity to A_i in ϕ for M1.

- **M2:** First, the value of T_m was fixed at 450K (centre of the temperature design range). Then, using this value of T_m , the new parameters B_i and C_i were calculated from data points generated using M1, which reliably describes the original system at these conditions. The conditions suggested by the LHS were then used with these estimates for B_i and C_i . Correlations were significantly reduced and critical correlations appeared only between C_2 and C_5 . However, the deviation between M1 and M2 was so large that M2 no longer accurately represented the original system. The above estimation procedure was repeated fixing T_m at different values clustered around the centre of the design space to see if the choice of T_m affected the lack of fit. Parameter correlations were reduced but still the model was not adequate to represent the system in a large set of conditions in ϕ .

- **M3:** Using 30 experiments generated using LHS, there were no critical correlations between the estimated parameters for this reduced model. All parameters were estimated satisfactorily except E_{A3} (Table 3), which depends heavily on the MFA concentration (12-13). The χ^2 test was passed overall, but some experiments with low MFA concentrations deviated more in their predictions. MFA concentration may practically be too low to be detected at some experimental conditions, and this affects parameter estimation.

A FIM-based information analysis was then conducted on M3 to determine the most informative regions of the design space to explore in future experiments for a precise estimation of model parameters (Figure 2). The analysis identified two potential regions: 1) $C_{DMF}(0) = 0.19$ M and $C_{HMF}(0) = 0.10$ M in a $\tau = 230$ min long batch experiment at $T = 510$ K; 2) $C_{DMF}(0) = 0.09$ M and $C_{HMF}(0) = 0.17$ M in a $\tau = 280$ min long batch experiment at $T = 530$ K. The temperature in the reactor could thus be bounded between 450-550 K to improve parameter estimability.

(a) Initial HMF and DMF concentrations (b) Temperature and experiment duration
 Figure 2 – Information maps in terms of design variables obtained by plotting the trace of the FIM of all experiments using an information surface in model M3.

Table 3 – M3: confidence intervals after parameter estimation using LHS conditions

θ [kJ mol ⁻¹]	Final Value	Initial Guess	95% t-value (reference value = 1.65)
E_{A1}	66.99	58.79	1939.57
E_{A2}	66.49	64.48	676.13
E_{A3}^{**}	6.57**	42.00**	0.001**
E_{A4}	76.36	83.61	3772.45
E_{A5}	63.86	62.17	492.01

4. Conclusions

A two-step identifiability study was applied to three candidate kinetic models for HMF hydrogenation. M1 and M2 have been found unsatisfactory due to high correlation and low fidelity, respectively. The reduced model M3 showed satisfactory fitting performance but limitations on representing E_{A3} resulting from low and potentially undetectable MFA concentrations. Applying a FIM-based information analysis allowed to define the most informative regions of the experimental design space for a precise estimation of kinetic parameters. The most informative was at high DMF and lower HMF concentrations in a batch experiment lasting 230 min at 510 K. Future work will aim to confirm these results using robust MBDoE techniques to precisely estimate the full set of model parameters.

Abstract

Model-based design of experiments is a technique for accelerating the development of mathematical models. Through maximally informative experiments, time and resources for estimating uncertain model parameters are minimized. This article presents a method for computing effort-based experimental designs, whereby designs are akin to experimental recipes. As well as identifying which experiments are the most informative, the optimal experimental effort to dedicate to each experiment is also optimized. Upon discretizing the experimental design space and treating the efforts as continuous decision variables, this method leads to convex optimization problems regardless of the model structure, which is ideal for large, parallel experimental campaigns. The case study of a batch reactor model with four parameters is presented to illustrate the methodology.

Keywords: optimal experiment design, model-based design of experiments, experimental effort, information, parametric uncertainty

1. Introduction

Optimal experiment design (OED) has shown great success in accelerating the development of mathematical models through providing maximally informative experimental campaigns. The seminal example is its application to construct *statistical* models such as response surface models (RSM), where OED led to the discovery of the celebrated factorial designs and their derivatives (Box and Wilson, 1951; Box and Hunter, 1961). Although highly effective, this approach can still require significant resources and time to develop for problems with many experimental degrees of freedom. In addition, its applicability to dynamic systems remains limited (Georgakis, 2013).

When applied to a *mechanistic* modelling framework, this approach leads to a systematic, optimization-based methodology, for which the name model-based design of experiments (MBDoE) was coined (Franceschini and Macchietto, 2008). MBDoE is often applied to expedite the development of knowledge-driven or hybrid (static or dynamic) models, which have superior extrapolation capability compared to statistical models and may be transferable to other similar systems. Such system-tailored strategies can significantly reduce the experimental effort for large-scale design problems, but come at the price of a much higher complexity and computational burden.

Consequently, MBDoe has become almost synonymous with sequential design and experimentation, that is, one experiment designed and conducted at a time with parameter update in between each experiment. This seems to have caused the concept of *effort*-based experimental designs, which is widely used in classical OED for the simultaneous design of experiments (Nguyen and Miller, 1992; Fedorov and Leonov, 2014), to be somewhat forgotten in MBDoe.

This paper aims to reintroduce the concept of effort within MBDoe. The focus is on methods that (i) discretize the continuous experimental spaces into a finite set of experimental candidates then (ii) seek to determine optimal effort to dedicate to each candidate. Section 2 states the problem of interest, reviews some background material on OED, and presents the methodology. Then, Section 3 illustrates the methodology with the case study of a batch reactor with two experimental degrees-of-freedom and four model parameters.

2. Methodology

2.1. Experimental Designs

Consider an experimental system, whereby $x \in X \subset R^{n_x}$ denotes the vector of experimental variables or controls. An experimental campaign design, or simply experiment design, Ξ is often made up of repeated combinations of $N_c > 0$ unique candidate experiments. It may be formally defined as

$$\Xi := \left\{ x_1 \dots x_{N_c} p_1 \dots p_{N_c} \right\} \quad (1)$$

where $x_i \in X$ and $p_i \in [0, 1]$ refer to the experimental variables and effort associated with the i th candidate experiment, respectively. If r_i is the number of times the experiment x_i is repeated, and $N_t \geq N_c$ is the total number of experiments, then $p_i = r_i/N_t$.

Designs where p_i are only allowed to be multiples of the fraction $1/N_t$ are called discrete (effort) designs and require for the N_t to be specified a priori. In contrast, continuous (effort) designs allow p_i to vary continuously, subject to the convex combination constraints

$$\sum_{i=1}^{N_c} p_i = 1 \quad \text{and} \quad p_i \geq 0 \quad \forall i \quad (2)$$

thereby making them independent of N_t . For theoretical considerations, continuous designs may be regarded as discrete designs with $N_t = \infty$, justifying that the distinction between continuous and discrete designs become less relevant as N_t gets larger.

2.2. Optimal Experimental Design Formulations

Classical OED formulations are concerned with linear response models of the form

$$y = F(x) \theta \quad (3)$$

where $y \in R^{n_y}$ denotes the vector of responses, and $\theta \in R^{n_\theta}$ the vector of model parameters. The $n_y \times n_\theta$ matrix F is called the regressor matrix. It is comprised of

vertically stacked regression vectors f_j^T , which are user-chosen functions of x that should differ between responses.

Such mathematical models can be built using a data set $(x_1, \dots, y_1), \dots, (x_{N_t}, \dots, y_{N_t})$ collected during an experimental campaign. The root problem of OED, therefore, is to determine an experiment design that is maximally informative. One way of measuring such information content is by means of the (normalized) Fisher Information Matrix (FIM) which, for the experimental campaign (1) and the linear model (3), can be written as

Optimality Criterion	ϕ	
	Standard	Eigen-form
Determinant	$\log \log (\det \det (M))$	$\log \log \left(\prod_k \lambda_k\right)$
Average of trace	$-\left(M^{-1}\right)$	$-\sum_k \lambda_k^{-1}$
Extreme	$\lambda_{\min } (M)$	λ_k

Table 1: standard information criteria for parameter precision.

$$M(\Xi) = \sum_{i=1}^{N_c} p_i A_i, \text{ with } A_i = F\left(x_i\right)^T F\left(x_i\right), \tag{4}$$

where $A_i \in R^{n_\theta \times n_\theta}$ is the atomic information matrix associated to the i th candidate experiment. This expression clearly shows the FIM's dependence on Ξ , and takes advantage of the FIM's additivity property for independent experiments.

An *optimal* experiment design Ξ^* is a design that maximizes some scalar criterion ϕ of the FIM M

$$\Xi^* \in \arg \arg \phi(M(\Xi)) \tag{5}$$

Notice that this formulation is applicable to both discrete and continuous (effort) designs. Three classical scalar criteria of the FIM are reported in Table 1 – the focus in the remainder of this short paper is on D-optimal designs.

Now turning to generic nonlinear process models of the form

$$y = f(x, \theta) \tag{6}$$

Where the mapping f needs not be available in closed form, e.g. could be defined implicitly via the solution of algebraic and/or differential equations. The main challenge for computing optimal designs for nonlinear models is that the FIM for a nonlinear model becomes a function of the model parameters θ , making the optimal designs also a function of θ . A popular approach in MBDoe entails linearizing the model (6) around a nominal model parameter value θ^n ,

$$y \approx f\left(x, \theta^n\right) + \frac{\partial f}{\partial \theta}\left(x, \theta^n\right)\left[\theta - \theta^n\right] \tag{7}$$

After rearrangement, the linearized model (7) may be recast into the form of (3), with a linearized response $\tilde{y}:=y - f\left(\cdot, \theta^n\right)$, model parameter $\tilde{\theta}:=\theta - \theta^n$, and regressor matrix

$\tilde{F} := \frac{\partial f}{\partial \theta}(\cdot, \theta^n)$. In turn, the latter can be substituted in Equation (4) to compute a linearized FIM, so standard methods can then be applied to compute an optimal design for the linearized model. Such a design is said to be *locally-optimal* around θ^n for the original nonlinear model (6).

2.3. Continuous-Effort Approach to MBDoe

Searching over Ξ in Problem (5) is particularly challenging as it entails determining the optimal number of candidates $N_c \in Z^+$, the optimal experimental variables $x_i \in R^{n \times N_c}$, and the optimal experimental efforts $p \in [0, 1]^c$, all together (see, e.g., De Castro et al., 2019). Consequently, existing MBDoe techniques rely on approximations.

In the traditional MBDoe setting (Franceschini and Macchietto, 2008), the number of experiments and associated efforts are usually fixed so the search proceeds over the experimental variables only. Yet a limitation is that these problems are typically riddled with local optima. In contrast, we propose to discretize the continuous experimental variable space X into a sampling set X_s comprising $N_s \gg N_c$ experimental candidates. This reduces the problem (5) to searching over the experimental efforts for the N_s candidates,

$$\left(p_1^*, \dots, p_{N_s}^* \right) \in \arg \arg \left\{ \phi \left(\sum_{i=1}^{N_s} p_i A_i \right) : \sum_{i=1}^{N_s} p_i = 1, p_i \geq 0 \forall i \right\} \quad (8)$$

When computing continuous-effort designs, $p_i \in [0, 1]$, the problem formulation (8) is convex insofar as the function ϕ is concave. And all three standard criteria listed in Table 1 are indeed concave functions. In addition to precluding locally suboptimal designs, this property thereby enables the use of powerful convex optimization solvers to solve large-scale experimental design problems efficiently—the size of the problem being directly proportional to the number of sample design candidates N_s but independent of the total number of experiments N_t to be designed. Notice also that the complexity associated with the chosen model structure is moved away to a prior step, which involves precomputing the atomic information matrices A_i , $i = 1 \dots N_s$ of each design candidate. Although costly, these atomic information matrices are independent of the experimental efforts and could thus be precomputed in parallel to save time.

Lastly, it is worth mentioning that the methodology is by no means restricted to a specific discretization strategy. Though without an effective discretization scheme, computation of the atomic matrices could quickly become intractable as the number of experimental variables n_x increases. We thus see much potential in developing smart discretization strategies tailored to continuous-effort MBDoe approaches, as part of future work.

3. Case Study

Consider an experimenter developing a model of a batch reactor running the reaction $A \rightarrow \nu B$. The proposed model is given by

$$\frac{dc_A}{dt} = -r, \quad \frac{dc_B}{dt} = \nu r, \quad r = kc_A^\alpha, \quad k = \exp \exp \left(\theta_0 + \theta_1 \left(\frac{T - T_{ref}}{T} \right) \right) \quad (9)$$

where the order of the reaction α , the stoichiometric ratio ν , the (transformed) pre-exponential constant θ_0 , and the (transformed) activation energy θ_1 of the reaction are the unknown model parameters to be estimated from experimental data. The reaction rate r is modelled to be temperature-dependent, with a reaction constant k that follows Arrhenius-type kinetics. The experimental variables of the system are the sampling times $t_{sp} \in [0, 200]$ in minutes, the initial A concentration $c_A^0 \in [1, 5]$ in moles/L, and temperature $T \in [273.15, 323.15]$ in K. The nominal model parameter values are $\theta_0 = -4.50$, $\theta_1 = 2.20$, $\alpha = 1$, and $\nu = 0.5$. The setup measures c_A and c_B at a unique sampling time t_{sp} during each batch. It is decided to compute a D-optimal experimental design, and all the results are obtained using the open-source python library Pydex (<https://github.com/KennedyPutraKusumo/pydex/>).

Figure 1: D-optimal continuous-effort experimental design. The effort of each candidate equals the sum of efforts allocated to each sampling time variant.

Using the discretization approach, 25 candidate experiments are enumerated from a 5×5 mesh-centered grid of c_A^0 and T . For each candidate, 11 sampling times are enumerated from an equally-spaced time grid. The atomic information matrices are computed, with the linearization via finite differences using numdifftools (Brodtkorb and D’Errico, 2015) taking a total of 2.40 CPU-sec, followed by solution of (8), taking 0.25 CPU-sec using MOSEK (MOSEK ApS, 2020) through CVXPY (Diamond and Boyd, 2016).

The computed optimal non-zero efforts are presented in Figure 1. Out of the 25 candidate experiments, only two are part of the optimal design: Candidates 21 and 25.

They correspond to experiments with $\left[c_A^0, T \right]$ of [5.00, 273.15] and [5.00, 323.15], respectively. The optimal effort for Candidate 21 is 49.85%, with three sampling time variants. 9.71% samples at $t_{sp} = 60$, 14.67% samples at $t_{sp} = 80$, and the remaining 25.48% samples at $t_{sp} = 200$. Notice that $t_{sp} = 60$ and $t_{sp} = 80$ are adjacent sampling times, which suggests that the "true" optimal sampling time could lie between 60 and 80 minutes, with an optimal effort of $9.71 + 14.67 = 24.38\%$. Furthermore, one may reasonably guess that the true sampling time is closer to 80 minutes as the effort allocated there is larger, although this is difficult to ascertain. Candidate 25 is allocated 50.15%, a near equal split with Candidate 21. There are two different sampling time variants, 26.40% samples at $t_{sp} = 60$, whilst the other 23.75% will sample later at $t_{sp} = 160$. Candidates 21 and 25 tell us that an informative experimental campaign involves running experiments with c_A^0 as high as possible, and alternating between the highest and lowest temperatures. The pattern followed by the optimal sampling times comprises a measurement early during the batch and a second measurement near the end of the batch.

In practice, using a continuous design requires a rounding procedure in order to convert the optimal fractional efforts to integers. Out of existing rounding procedures, Adam's method of apportionment is probably superior (Pukelsheim and Rieder, 1992). A multiplier v is set equal to N_t initially. Each effort p_i is multiplied by v , and rounded up to the nearest integer; the result is called the apportionment of each candidate a_i . If $\sum a_i > N_t$, v is reduced using a heuristic, e.g. multiplied by 0.90. If $\sum a_i < N_t$, v is increased, again by a heuristic. This is done iteratively until $\sum a_i = N_t$. The final apportionment a_i 's are the desired rounding.

4. Conclusion

The success of model-based experimental design in process systems engineering is accompanied by challenges that still needs to be addressed. We introduced a methodology that brings the concept of continuous efforts into model-based experimental designs, ideal for designing parallel experimental campaigns. The methodology involves discretizing the continuous experimental variables into a set of experimental candidates. This approximation brings advantages over a standard model-based experimental design, including a guaranteed convex optimization, and a problem size that does not scale with the number of experiments. Although effective, efficiency of the methodology hinges upon effective discretization procedures. Even without an effective discretization procedure (gridding), we demonstrated the tractability and efficiency of the method in designing an experiment for a batch reactor. There is a wealth of unexplored areas that follow up from this work. Studies into the different attitudes an experimenter can have towards sampling times, various robustification strategies against model-parametric uncertainties, and constrained experimental designs are amongst the most promising directions.

Abstract

The design space (DS) is defined as the combination of materials and process conditions which provides assurance of quality for a pharmaceutical. A model-based approach to identify a probability-based DS requires costly simulations across the entire process parameter space (certain) and the uncertain model parameter space (e.g. material properties). We demonstrate that application of metamodel-based filters and global sensitivity analysis (GSA) can significantly reduce model complexity and reduce computational time for identifying and quantifying DS. Once DS is identified it is necessary to present it graphically. The output of identification of DS is a multi-dimensional probability map. The projection of the multi-dimensional DS to a 2D representation is still unavoidable irrespectively of the method used to reach such probability mapping. We showed that application of constraint GSA can dramatically reduce the number of required for visualization 2D projections.

Keywords: Design Space, probability map, Sobol' sensitivity indices, global sensitivity analysis

1. Problem Setting

Pharmaceutical products should be approved by a regulatory body to be manufactured on the condition that there is enough evidence to demonstrate the safety and efficacy of the drug product, and that the manufacturing process has “controls” to assure the quality of it. These “controls” represent a set of “admissible operating conditions” that provide an assurance of quality, accounting for variations in the materials and manufacturing processes. They are commonly referred to as the Design Space (DS) (U.S. Department of Health and Human Services, 2006).

Identification of probabilistic DS is a demanding task and for a typical practical problem the traditional approach based on exhausting sampling requires costly computations (García-Muñoz et al, 2015). A novel theoretical and numerical framework for determining probabilistic DS using metamodeling and adaptive sampling was proposed in Kucherenko et al, 2020. It was based on the multi-step adaptive technique using a metamodel for a probability map as an acceptance-rejection criterion to optimize sampling to identify the DS.

Consider a model $f(\vec{x}; \vec{\theta})$, and the vector of constraint functions $\vec{g}(\vec{x}; \vec{\theta})$, where \vec{x} is a vector of process parameters defined in the box domain H^d , $\vec{\theta}$ is a vector of uncertain model parameters defined in m -dimensional real space R^m with a given pdf $\varphi(\vec{\theta})$. Define probability $p(\vec{x})$ of occurrence of an undesirable (reliability estimation analysis) or desirable (pharmaceutical/chemical engineering) event as

$$p(\vec{x}) = P\left(\vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^*\right) = \int_{\Omega(\vec{x})} \varphi(\vec{\theta}) d\vec{\theta} \quad (1)$$

Here \vec{g}^* is a vector of given thresholds, domain $\Omega(\vec{x})$ is defined as $\Omega(\vec{x}) = \left\{ \vec{\theta}: \vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^* \right\}$. Probability (1) can be presented in a convenient form as:

$$p(\vec{x}) = \int_{R^m} I(\vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^*) \varphi(\vec{\theta}) d\vec{\theta} = E_{\vec{\theta}} \left[I(\vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^*) \right], \quad (2)$$

where I is an indicator function. Define design space (DS) as $DS(\vec{x}; p(\vec{x}) \geq p^*)$, where p^* is a critical (acceptable) value of probability of meeting constraints. A brute force numerical estimation of $p(\vec{x})$ requires $N_x \times N_{\theta}$ model runs, where N_x is the number of points in the space of the process parameters \vec{x} , N_{θ} is the number of sampled points in the $\vec{\theta}$ - space. For a typical practical problem this number can be very large which results in costly computations. For such models, global sensitivity analysis (GSA) is an efficient practical tool which can dramatically reduce computational costs and provide useful additional information about importance of parameters and model structure.

GSA is a widely used tool for identification of key parameters whose uncertainty most affects model output. In the context of DS identification GSA can be applied to identify uncertain parameters contributing to the acceptance of imposed constraints with potential further model reduction. This problem is linked to the problem of identification of critical regions of inputs $\vec{\theta}$ responsible for "extreme" values (values for which constraints are satisfied) of model response. It is known as a factor mapping setting of GSA. It typically requires rather complex techniques such as Monte Carlo Filtering. We propose an efficient GSA formulation using an indicator function $I(\vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^*)$ as a "model output" which allows the application of a well-developed GSA method of Sobol' indices.

In order to illustrate the developed approach a single-stage batch reactor problem was considered, with two "bounded" variables. This system was introduced in Samsatli et al. 1999 and used in Kucherenko et al., 2020. It is assumed that the following reactions take place in a fixed volume vessel with a given initial charge of solution A (1 m³ of solution A with a concentration 2000mol/m³): $2A \xrightarrow{k_1} B \xrightarrow{k_2} C$. The processing time and temperature profiles may be adjusted to maintain the purity and production rate of the desired product B above certain levels (representing constraints of the form

$\vec{g}(\vec{x}; \vec{\theta}) \geq \vec{g}^*$. The kinetic parameters of this model $\vec{\theta}$ (two activation energies E and two pre-exponential factors k) are considered to be uncertain.

2. Machine Learning and Global Sensitivity Analysis

As a first step we applied a framework for determining probabilistic DS using metamodeling and adaptive sampling developed in Kucherenko et al, 2020. The (Q)RS-HDMR method developed in Zuniga et al., 2013 was used to build metamodels. Consider the ANOVA-HDMR decomposition of an integrable function $f(x) \equiv f(x_1, x_2, \dots, x_n)$ defined in the unit hypercube H^n

Figure 1. Contour plots of the probability map. DS results with 3 non important uncertainty parameters fixed. Broken line is DS corresponding to $p^*=0.68$.

$$f(x) = f_0 + \sum_i f_i(x_i) + \sum_{i < j} f_{ij}(x_i, x_j) + \dots + f_{12\dots k}(x_1, \dots, x_n) \quad (3)$$

It is known that this decomposition is unique if the mean value of each term with respect to integration from the set of any variable it depends on is equal to zero, in which case pairs of component terms are orthogonal with respect to integration. (Q)RS-HDMR method exploits the fact that for many practical problems only low order interactions of the input variables are important. This assumption can dramatically reduce the computational effort for building metamodels.

Assuming that component functions in (3) are piecewise smooth and continuous, they can be decomposed using a complete basis set of orthonormal polynomials:

$$f_i(x_i) = \sum_{r=1}^{\infty} \alpha_r^i \varphi_r(x_i), \quad f_{ij}(x_i, x_j) = \sum_{p=1}^{\infty} \sum_{q=1}^{\infty} \beta_{pq}^{ij} \varphi_{pq}(x_i, x_j), \quad \dots \quad (4)$$

Here $\varphi_r(x_i)$, $\varphi_{pq}(x_i, x_j)$ are sets of one- and two-dimensional basis functions and α_r^i and β_{pq}^{ij} are the coefficients of decomposition. From the orthogonality of the basis functions it follows that:

$$\alpha_r^i = \int_0^1 f_i(x_i) \varphi_r(x_i) dx_i, \quad r = 1, \dots, k, \quad (5)$$

$$\beta_{pq}^{ij} = \int_0^1 \int_0^1 f_i(x_i) \varphi_p(x_i) \varphi_q(x_j) dx_i dx_j, \quad p = 1, \dots, l, \quad q = 1, \dots, l'.$$

The choice of the basis functions depends on the probability distributions of the inputs.

For practical purposes the summation in (4) and (5) is limited to some maximum orders k, l, l'

$$f_i(x_i) \approx \sum_{r=1}^k \alpha_r^i \varphi_r(x_i), \quad f_{ij}(x_i, x_j) \approx \sum_{p=1}^l \sum_{q=1}^{l'} \beta_{pq}^{ij} \varphi_p(x_i) \varphi_q(x_j) \quad (6)$$

Hence, the HDMR approximation function up to the second order interaction can be constructed as

$$\tilde{f}(x) = f_o + \sum_{r=1}^k \alpha_r^i \varphi_r(x_i) + \sum_{p=1}^l \sum_{q=1}^{l'} \beta_{pq}^{ij} \varphi_p(x_i) \varphi_q(x_j) \quad (7)$$

There is a similarity between this method and the surrogate-based feasibility analysis (Bhosekar. and Ierapetritou, 2018). However, feasibility analysis relates to the ability of a process to satisfy all relevant constraints and it is formulated in deterministic setting, while we are dealing with a probabilistic problem setting (1). In our approach metamodels were built to approximate a probability map and then use them as an acceptance-rejection criterion to optimize sampling to identify the DS, while the surrogate-based feasibility analysis aims at finding a surface defining the boundary of the feasible space within the box bounded design space as accurately as possible using only built surrogate.

At the second step we applied GSA which revealed that only one parameter out of four, namely k_{j2} is important. These results were used for complexity reduction, namely by fixing (E_{j1}, E_{j2}, k_{j1}) parameters to their nominal values and computing the DS. In this case results identical to the benchmark results were obtained with a much lower number of points in the process parameters space (Figure 1). Complexity reduction after application of GSA resulted in a 16 times speed-up. The SobolGSA software (Kucherenko et al., 2019) was used for building metamodels and computing Sobol' sensitivity indices.

3. Visualization of Design Space

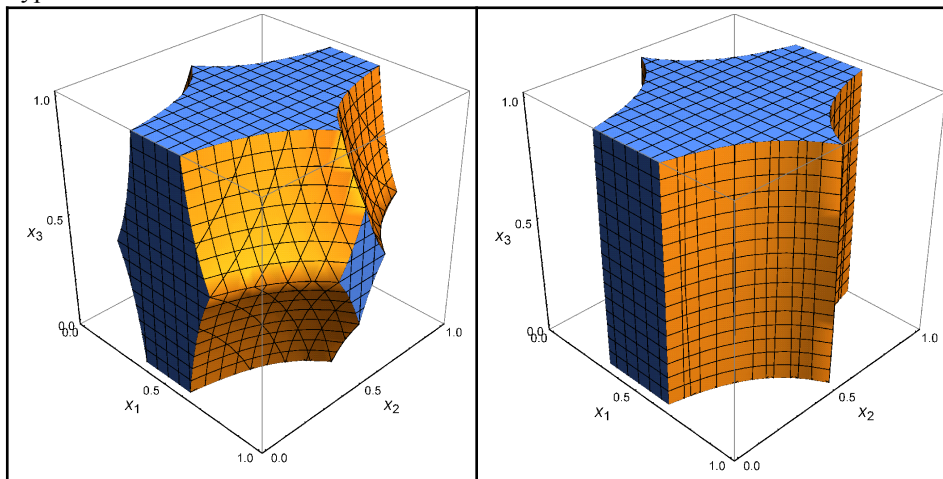

A challenge remains in the visualization of DS needed to communicate higher dimensionality probability maps and the inclusion of this information into the formal documentation required for the approval of DS by a government agency. For more than three parameters process parameters visualization of DS is a challenging task. Guidance for Industry, Q8(R2) Pharmaceutical Development (2009) has the following recommendations: "When multiple parameters are involved, the design space can be presented for two parameters, at different values (e.g., high, middle, low) within the range of the third parameter, the fourth parameter, and so on." Considering DS in d -dimensional process parameters space, a graphical presentation of DS via 2D plots prescribed in [3] would result in $N_p = \frac{d(d-1)}{2} 3^{d-2}$ 2D plots.

GSA can be applied for visualization of DS. This problem belongs to a class of models with constraints. Most existing GSA techniques were designed under the hypothesis that model inputs are independent. However, in many cases there are dependencies among inputs, which may have significant impact on the results. A constraint GSA (cGSA) as an extension of variance based Sobol' sensitivity indices that was developed in Kucherenko et al, 2017.

Consider DS in d -dimensional process parameters space and assume that GSA revealed that parameter x_i is unimportant. It means that any 2D projections corresponding to different values of x_i will be the same. Hence instead of three values ("high", "middle", "low") for this parameter only one is sufficient for the graphical presentation, which would result in the reduction of N_p to $\frac{(d+4)(d-1)}{2} 3^{d-3}$ 2D plots. In the case of s non-important parameters N_p will be reduced to $[(d - s)(d + 5s - 1) + 9s(s - 1)]3^{d-s-2}/2$. For illustration we consider a 3D Sobol' "g-function":

$$f(x) = \prod_{i=1}^3 \frac{|4x_i - 2| + a_i}{1 + a_i} \tag{8}$$

with three different sets of parameters a_i and x_i uniformly distributed in the unit hypercube H^3 .

(a)

(b)

Figure 2. 3D DS shape. (a) $a = \{0; 1; 2\}$; $SI = \{0.706; 0.0818; 0.0234\}$, $SIT = \{0.856; 0.229; 0.104\}$; (b) $a = \{0; 1; 99\}$; $SI = \{0.761; 0.0957; 0.002\}$, $SIT = \{0.887; 0.238; 0.003\}$; (c) $a = \{0; 49; 99\}$; $SI = \{0.996; 0.0004; 0.0005\}$, $SIT = \{0.996; 0.0005; 0.0006\}$. SI and SI^T are the values of the main effect and total Sobol' sensitivity indices respectively.

A synthetic DS is defined as $DS(\vec{x}; f(\vec{x}) \geq 1)$ where f acts as “probability $p(\vec{x})$ ”. Its shape for different sets of parameters a_i is shown in Figure. 1. In the first case (Figure 2, a) all three 2D projections are important and the prescription given above requires plotting $N_p = \frac{d(d-1)}{2} 3^{d-2} = 9$ 2D projections. GSA reveals that in this case all three input parameters are important. In the second case (Figure 2, b) although all 2D projections onto the planes (x_1, x_2) , (x_1, x_3) and (x_2, x_3) are important, 2D projections on the plane (x_1, x_2) are independent of parameter x_3 . Hence only $N_p = \frac{(d+4)(d-1)}{2} 3^{d-3} = 7$ 2D projections are required for the visualization of DS. GSA shows that in this case parameter x_3 is not important. In the third case (Figure 2, c) only 1D projection to the x_1 axis is important while for two other parameters DS shape is defined in the whole domain of their change $[0,1]$ hence no 2D projections are of any interest. GSA shows that in this case only parameter x_1 is important.

4. Conclusions

We showed on a typical problem from the chemical industry that application of metamodel-based filters can significantly reduce model complexity and computational costs for identification of DS. GSA provides important information about the importance of uncertain parameters and can further reduce computational costs. We propose formulations via indicator functions which allow transformation of constrained problem into a class of problems with independent variables and enabled application of a well-developed variance-based method of Sobol' indices. Our approach is applicable to a wide range of process designs where the operational aspects are treated in terms of ranges rather than fixed points and where system models include uncertain parameters.

Graphical presentation of multidimensional DS is challenging task. The projection of the multi-dimensional DS to a 2D representation is required by the industry regulatory bodies. We showed that constraint GSA can be applied to dramatically reduce the number of required for visualization 2D projections.

Abstract

The combined use of Advanced Oxidation Processes (AOP) and conventional bio-processes has been suggested for the efficient treatment of wastewaters with a significant presence of recalcitrant contaminants. However, no models have been proposed to describe such combined processes, which prevents further design and operational optimization. Thus, by combining models previously reported this work contributes a first model integrating AOPs and bio-processes. Mass balances were reformulated by consistently linking the variables used in each model. The model was implemented using Simulink® and it was tested and analyzed using several process configurations (photo-Fenton processes followed by a biological treatment as well as a biological treatment followed by a photo-Fenton process). The outlet concentrations of total organic carbon (TOC) and substrate (S) were monitored for various wastewater compositions, which allowed analyzing the performance of the integrated system and suggesting suitable treatment arrangements. Different treatment options were discussed and the capability of the integrated bio/AOP and AOP/bio models was shown to allow a systematic approach to design, operation, and control of integrated wastewater treatment plants in the future. Further research will be oriented to improve the understanding of the potential key parameters as well as their inclusion in the model.

Keywords: Hybrid Model, AOP, Biological process, Wastewater treatment.

1. Introduction

Wastewaters contain an increasing number of persistent contaminants. Pollutants with high chemical stability and/or low biodegradability (e.g. emerging contaminants: pharmaceuticals, cosmetics, and personal care products) cannot be efficiently addressed by common wastewater treatment processes (WWTP). Conversely, Advanced Oxidation Processes (AOPs), in particular, the photo-Fenton process, can oxidize a broad range of non-biodegradable from wastewaters by means of a catalytic reaction of ferrous iron and hydrogen peroxide (H_2O_2) in an acidic or circumneutral pH under UV-VIS radiation yields highly oxidant hydroxyl radicals. However, such chemical oxidation for complete mineralization is much more expensive, which limits large-scale applications.

Hence, combining AOPs with biological treatments has been reported as an opportunity to reduce design and operating costs (Huang et al., 2017; Oller et al., 2011). Several configurations of hybrid AOPs as pretreatment or post-treatment with bioremediation for wastewater treatment have been experimentally studied (Nidheesh et al., 2021). However, the design and operation of such a hybrid process require suitable models. A great deal of mathematical models for WWTP have been developed and reported, while not many works have addressed the modeling of AOPs. Models combining AOPs and bio-processes have hardly been discussed. The modeling needs, and perspectives of AOPs and WWTP are different, as well as it is the nomenclature and the lumped parameters selected to characterize the system. This may explain the divergence of the research efforts of both areas, as well as the problems that converging them to a unique hybrid model entail. Therefore, a first and key step is consistently linking the variables used in both modeling approaches (biological and chemical) in a pilot coupled model. Consequently, this study consisted on selecting kinetic models for WWTP and AOP, standardizing nomenclature, mapping lumped parameters, and finally extending the models to incorporate those essential aspects considered by only one model. This has been applied to the combination of photo-Fenton processes followed by a biological treatment as well as a biological treatment followed by a photo-Fenton process. Particularly, new equations for non-biodegradable contents in the WWTP needed to be introduced, as well as equations discriminating biodegradable and non-biodegradable matter in the AOP model. Hence, simulation examples are discussed in regard of the expected results, achievements, and limitations of the model.

2. Methodology

The main problem to be addressed is the identification of the significant parameters and reactions in each subsystem and appropriately linking kinetic expressions and material balances in a consistent model of the resulting hybrid system. The integration strategy consists on preparing two configurations: AOPs as a pre-treatment followed by biological treatment (plan AB), also in the opposite direction, considering the post-treatment of AOPs (plan BA). Three case studies will be used to test the model: wastewater with only non-biodegradable contaminants (W1), partially biodegradable wastewater (W2), and completely biodegradable wastewater (W3). The schematic diagram of the proposed approach is illustrated in Figure 1.

Figure 1. Schematic diagram of the proposed integrated modeling

The mathematical models already proposed for the photo-Fenton process and the activated sludge biodegradation (ASM1) were first selected and adapted, and later, the models were coupled by linking of the associated variables. The coupled ordinary differential equations (ODEs) were solved simultaneously concerning the conceptual consistency of the related parameters using Simulink®.

2.1. Biological treatment kinetic model

There is abundant literature developing reliable models for WWTPs with formulations fully elaborated and complicated. However, reduced versions are still required for quickly analyzing design trade-offs and layouts, which is the purpose at this stage.

Furthermore, in the preliminary steps of developing a model, using simplified models may speed up the model evolution with consistent results and later, the model can be enriched with more complex concepts. Thus, the biological wastewater treatment model selected was the Activated Sludge Model No.1, ASM1, consisting of four non-linear differential equations (Vlad et al., 2011). The mass balance equations were adopted for modeling of the active sludge biomass (X) at the level of the aeration tank, the mass balance of the substrate (S), the mass balance of the oxygen in the water mass (DO), and the balance of the recycled biomass (X_r) at the level of the settling tank. The biomass growth rate (μ), was modeled by the Monod law.

2.2. Modeling of the AOP (photo-Fenton process)

Cabrera Reina et al. (2012) proposed and validated a photo-Fenton process model for batch operation and then the model was re-written by Audino et al. (2019) to describe the continuous operation. The model did not consider biodegradability, although it should be taken into account to apply integrated treatment processes including Fenton-based processes and biological treatment (Huang et al., 2017).

Thus, the model by Audino et al. (2019) was adapted by separating the biodegradable (subscripted by b) and non-biodegradable (subscripted by nb) parts of the organic matter to enable biodegradability footprint tracking in the combined model. To do that, the equations and subsequently related mass balances were replicated for non-biodegradable contents. The proposed model includes the two ferric species, hydrogen peroxide, the radicals formed from peroxide (R), the dissolved oxygen, three states accounting for the biodegradable organic matter (two kinds of partially oxidized organics (MX_{1b} , MX_{2b}) plus the parent compound (M_b) present at the beginning of the reaction) which are responsible for the lumped parameter measured as TOC_b .

Three complementary states for the non-biodegradable organic matter were introduced to the model including two kinds of partially non-bio oxidized organics (MX_{1nb} , MX_{2nb}) plus the parent non-bio compound (M_{nb}) present at the beginning of the reaction, aggregated as TOC_{nb} (i.e. $TOC = TOC_b + TOC_{nb}$). The values of the kinetic constants of the new reactions were also replicated at this stage.

3. Development of the integrated models

The two simulation schemes are next presented. The AOP pre-treatment followed by WWTP is designated as AB, while using AOP as a post-treatment is designated as BA.

3.1. Combined modeling: configuration AB

The biodegradability of wastewaters can be improved in a combined AOPs system, which is favorable to WWTPs, while WWTPs in the same combined system may stabilize the waste and reduce the use of chemical reagents (Huang et al., 2017). A partial oxidation treatment may produce intermediates even more recalcitrant, but chemically-oxidized intermediates are often less recalcitrant than the parent compound. Many studies have proved that prior chemical oxidation may cause the biodegradability changes of a waste stream (Mantzavinos and Psillakis, 2004). Therefore, the main role of the chemical pre-treatment may be explained as partial oxidation of the biologically persistent part to produce biodegradable reaction intermediates which remove the pointless expense of chemicals and energy (Oller et al., 2011).

A conceptual challenge for developing a mathematical model for the AB is to find which variables in the AOP model require to be properly linked to which variables in the WWTP model. Moreover, the effect of the chemically-oxidized intermediates from the AOPs on the performance of the WWTP needs to be modeled. In this first step, these intermediates are considered to have no adverse impact (toxicity or inhibitory effect). In this regard, for the integration of the processes using the set of reported reactions, the outlet biodegradable TOC and the oxygen concentration in the AOP were introduced equally as the inlet substrate content and the dissolved oxygen in the biotreatment, respectively. The following linking conditions were associated to couple the photo-Fenton and the WWTP models as continuous stirred tanks reactor (CSTR):

- The outlet flowrate from the AOP reactor was directly entered to the WWTP;
- The biodegradable TOC_b from the AOP was fed as the inlet substrate to the WWTP;
- The oxygen flow from the AOP was connected to dissolved oxygen in the bioreactor;
- The non-biodegradable compounds were assumed to be inert through the WWTP

Figure 2 illustrates the configuration AB.

Figure 2. AB scheme presenting the photo-Fenton process (A) followed by the bio-treatment(B)

3.2. Combined modeling: configuration BA

The alternative post-treatment of AOPs are often suggested for WW containing the recalcitrant organic pollutants with low toxicity concentrations. The transformation products generated during biodegradation would be recalcitrant and even hazardous (Zimbron and Reardon, 2011; Sánchez Pérez et al., 2014). In this study, the combined model represents the biological treatment followed by the photo-Fenton reactor as CSTR using first-order kinetics and mass balances. The same conceptual integration process was applied correspondingly through linking the outlet substrate and the dissolved oxygen in WWTP to inlet biodegradable TOC and the oxygen content in the AOP model as presented in Figure 3.

Figure 3. BA schematic presenting the bio-treatment(B) followed by the photo-Fenton process(A)

4. Simulation results

The preliminary simulations of the outlet organic matter concentration (TOC and/or substrate) in the single-reactor design (A or B) as well as the combined system for both AB and BA configurations were performed according to the data of the kinetic constants provided by Cabrera Reina et al. (2012) and Vlad et al. (2011). The simulation of the hybrid processes indicated promising results compared to each individual process. The integrated model was able to predict and track the biodegradability evolution, which is crucial for the WWTPs. Figure 4 shows the results obtained for the three case studies (non-biodegradable wastewater, W1; partially biodegradable wastewater, W2; and biodegradable wastewater, W3) and the four arrangements (A, B, AB, and BA). In general, the simulations produced the expected profiles as for the higher biodegradability, the lower outlet organic matter concentration was predicted. The outcomes of the integrated models produced similar trends and all of them confirm decreasing outlet organic matter concentrations as the inlet biodegradability increases ($W1 < W2 < W3$). This is not the case for a single AOP (Figure 4a), for which all profiles overlap according to the non-selective oxidizing capacity of the hydroxyl radicals. Figure 4a also shows a conversion limit given by an insufficient supply of hydrogen peroxide. Conversely, the single WWTP (Figure 4b) presents the most disparate outcomes: the total organic matter removal for a complete biodegradable input (W3) and no change at all for a totally non-biodegradable feed (W1).

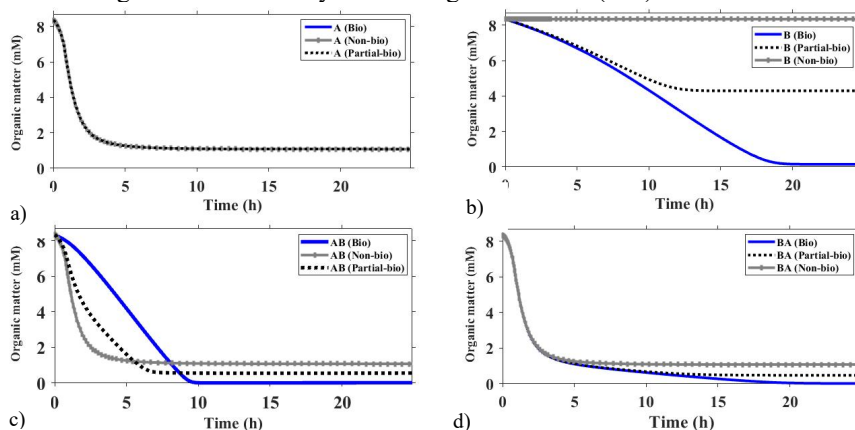

Figure 4. Simulated profiles of the single and integrated models for a) A, b) B, c) AB, and d) BA.

On the other hand, the combined processes AB (Figure 4c) and BA (Figure 4d) resulted in different behavior in the transition period but, they showed the expected higher steady-state performance compared to the single processes A and B. Again, a total conversion for is not attained, this time only for the partially and non-biodegradable cases (W2 and W1) due to the lack of reagents (hydrogen peroxide), which hints at the need to adjust this variable. The different kinetics produce different transient periods in the combined models but show the same long term behavior given by the biodegradability ratio.

These preliminary simulations of the combined model meet the expectations, but reveal the limitations and next steps, mainly the incorporation of new features allowing to discriminate the behavior of processes as a function of the biodegradability and the chemical nature of the contaminants, so that toxicity and inhibitory effects of recalcitrant species in the bio-treatment can be considered and the true system trade-offs could be addressed for decision-making support.

5. Conclusions

This contribution proposes a combined model coupling the photo-Fenton process and WWTP for the removal of recalcitrant contaminants in wastewaters. The lumped parameter TOC in the photo-Fenton process is considered equivalent to the substrate content in WWTP for the model integration of the processes. Additionally, dissolved oxygen is directly linked to the oxygen content in the photo-Fenton process. The simulations were consistent through all case studies designed including biodegradable, partial biodegradable, and non-biodegradable influent. The simulation results from different configurations led to the variation curves of the outlet organic matter in the effluent that may be useful to design and control the integrated wastewater treatment systems. The analysis of the model arose some limitations to be addressed, such as the need, to include the inhibitory effect of recalcitrant species in the bio-treatment. Further research needs to be carried out through the proposed model to validate and improve the understanding of the potential key parameters as well as their inclusion in the model.

Abstract

This paper deals with the modelling and simulation of the dissolution of phosphate ore particles in a dilute phosphoric acid solution in a batch stirred tank reactor. A shrinking core model with elimination of the products is used to describe the reaction and mass transfer phenomena involved in the three phases considered, i.e., liquid bulk, liquid film surrounding the particles and solid phase. The model is based on mass balance equations in the three phases and consist of algebraic equations in the liquid bulk, an ODE in the solid phase, and PDEs in the liquid film. An estimability analysis method based on global sensitivities is used to determine the most estimable unknown parameters involved in the model equations from the available experimental data. The values of the least estimable parameters are fixed from the literature, while gProms environment is used to implement and solve the equations and to identify the most estimable parameters. The results obtained exhibit a good agreement between the model predictions and the measurements with coherent values of the identified parameters. Furthermore, the model is tested on the measurements carried out by van der Sluis et al. (1987) and showed that the dissolution process is mainly controlled by the diffusion step.

Keywords: Phosphate ore, Phosphoric acid, dissolution mechanism, shrinking core model, parameter identification.

1. Introduction

Phosphoric acid is the key element in the phosphate industry, particularly in the fertilizer industry, and even in the pharmaceutical and food industries (Becker, 1983). It is mainly produced by the wet process which consists of reacting the phosphate ore with concentrated sulfuric acid solutions in a digestion tank. Two main phenomena therefore take place in the tank, i.e., the dissolution of the ore and the crystallization of the gypsum. In this work, only phosphoric acid is used in the attack of the phosphate ore in order to decouple the two phenomena and deal only with the dissolution. The latter is

one of the most complex phenomena involved in the wet process of industrial manufacture of phosphoric acid. Its understanding is one of the key issues for the optimal design and operation of the phosphoric acid processes.

The objective of the present paper is to investigate the mechanism of the attack of the phosphate ore by a phosphoric acid solution in the digestion tank. More specifically, the shrinking core model (SCM) with elimination of the products will be used to describe the chemical reactions and mass transfer phenomena that take place in the tank. The resulting model will inevitably involve several unknown parameters that are often deduced from experimental measurements by means of a parameter optimization method. However, it is recognized that the available experimental measurements do not always contain the necessary information to accurately identify all the unknown parameters. A global estimability analysis will therefore be carried out to determine which parameters are estimable from the available measurements. The most estimable parameters will then be identified, and the values of the least estimable parameters will be fixed from the literature or from previous studies. gProms environment will be used to implement and solve the model equations and for parameter identification as well.

2. Model formulation

Tri-calcium phosphate (TCP) is one of the most interesting elements to be recovered from the phosphate ore. The objective of the digestion is to dissolve the TCP in a dilute phosphoric acid solution before its attack with a concentrated sulfuric acid solution to produce concentrated phosphoric acid and gypsum. Two main reactions take place in the digestion tank during the dissolution process (Elmore and Farr, 1940), but in this work we will focus on the most important one which transforms TCP into mono-calcium phosphate (MCP) as:

The conversion rate of this reaction depends on different operating parameters, including temperature, phosphoric acid concentration, porosity and size distribution of phosphate ore particles, residence time, solid rate, and hydrodynamics.

2.1. Dissolution mechanism

The attack of the phosphate ore particles by a phosphoric acid solution is a non-catalytic liquid/solid reaction with a complex kinetic mechanism. We assume that three phases are involved in the mechanism, i.e., liquid bulk, liquid film surrounding the particles, and solid phase (Figure 1).

Figure 1: Schematic illustration of the SCM in the dissolution mechanism

The dissolution mechanism considered assumes that the phosphoric acid diffuses through the film towards the solid, adsorbs to the phosphate ore particles, and finally reacts with the TCP reagent at the solid surface. The MCP product takes the opposite path where it first desorbs from the solid surface, then diffuses through the liquid film towards the liquid bulk. It is noteworthy that the chemical reaction and all the mass transport phenomena take place simultaneously in the digestion tank.

3. Phosphate ore dissolution modelling

The dissolution model developed is based on the following assumptions: (i) the particles are well dispersed in the liquid phase, are spherical with the same diameter, and shrink uniformly during the dissolution process, (ii) the digestion tank is perfectly mixed, (iii) the reaction is irreversible and only takes place at the surface of the particles, (iv) the adsorption and desorption steps are assumed to be very fast and are not considered.

Moreover, the shrinking core model (SCM) with elimination of the products used is adapted from the model developed by Salmi et al. (2017) with two main major differences. The first one assumes that the solid reagent is not soluble in the liquid, which is the case of the Moroccan phosphate ore, and the second one considers that the surface of the particles is not saturated with the solid reagent. The model equations are based on the transient mass balances in the solid phase, in the liquid film, and in the liquid bulk. They are presented below.

- In the solid phase, the mass balance can be written as:

$$\frac{x_{TCP}}{M_{TCP}} \frac{dm_s}{dt} = -4\pi R^2 k_{MCP} (C_{MCP}|_{r=R} - C'_{MCP}) \quad (2)$$

where m_s is the mass of the solid (i.e., phosphate ore particles) and R its radius.

x_{TCP} is the mass composition of TCP in the particles, M_{TCP} is the molecular weight of TCP, and $C_{MCP}|_{r=R}$ and C'_{MCP} are the concentrations of MCP at the solid surface and

in the liquid bulk, respectively. k_{MCP} is the liquid/solid mass transfer coefficient of MCP, it is expressed by D_{MCP}/δ using the film theory, where δ is the thickness of the liquid film surrounding the particles and D_{MCP} the diffusion coefficient of MCP. Eq. (2) can be developed in terms of TCP conversion rate X and particle radius R as:

$$\frac{dX}{dt} = \frac{3M_{TCP}D_{MCP}}{x_{TCP}\rho_s R_0\delta} (1-X)^{\frac{2}{3}} (C_{MCP}|_{r=R} - C'_{MCP}) \quad (3)$$

where ρ_s and R_0 are the density and the initial radius of the particles respectively, and

$$X = 1 - \left(\frac{R}{R_0}\right)^3$$

- In the liquid film, the mass balance is expressed by the second law of Fick as:

$$\frac{\partial C_i}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left(D_i r^2 \frac{\partial C_i}{\partial r} \right); \quad i = H_3PO_4, MCP \quad (4)$$

with the following boundary conditions:

$$-D_i \frac{\partial C_i}{\partial r} \Big|_{r=R} = \mathfrak{R}_i \quad (5)$$

• at the solid interface:

where the kinetic rate equation is assumed to be of first order with respect to phosphoric acid at the particle surface, and is defined as: $\mathfrak{R}_i = v_i k_r C_{H_3PO_4}|_{r=R}$. k_r is the rate constant, D_i is the diffusion coefficient of component i and v_i is the stoichiometric coefficient of component i in the reaction (1).

$$\bullet \text{ at the liquid film/liquid bulk interface: } C_i|_{r=R+\delta} = C'_i; \quad i = H_3PO_4, MCP \quad (6)$$

- The mass balance in the liquid bulk provides the MCP and acid concentrations as:

$$C'_{MCP} = \frac{3n_{TCP}^0 X}{V_L} \quad \text{and} \quad C'_{H_3PO_4} = C_{H_3PO_4}^0 - \frac{4n_{TCP}^0 X}{V_L} \quad (7)$$

where n_{TCP}^0 is the initial number of moles of TCP in the solid and V_L is the liquid volume in the tank. The initial conditions used are : $n_{TCP}^0 = 0.0322$ mole, $C_{H_3PO_4}^0 = 4760$ mol/m³, $C'_{MCP,0} = 0$, $C_{MCP,0} = C_{H_3PO_4,0} = 0$, and $X = 0$. The liquid film thickness is calculated using the mass transfer correlation of Rakoczy and Masiuk (2011) as:

$$\delta = R \left[1 + \alpha \left(\frac{R}{R_0} \right)^{8/9} D_{MCP}^{-1/3} \right]^{-1} \quad \text{where} \quad (8)$$

$$\alpha = 0.46 \left(\frac{\varepsilon^{2/3} R_0^{8/3}}{2\nu_L} \right)^{1/3}$$

α is a parameter which considers the hydrodynamics through the energy dissipation per unit mass (ε) of reaction mixture in the tank. ν_L is the kinematic viscosity of the mixture.

The dynamic model is described by a set of partial differential equations (PDEs) in the liquid film and an ordinary differential equation (ODE) in the solid phase and algebraic equations in the liquid bulk. The model equations are implemented and solved within gProms software which provides an environment for modeling, simulation, and parameter identification of dynamic systems (Process Systems Enterprise, 1997-2020).

4. Simulation and parameter identification

As can be noticed, the model involves several unknown parameters, i.e., k_r , $D_{H_3PO_4}$ and D_{MCP} , that should be identified from the available experimental measurements by means of a parameter optimization method. To test the model, we used the measurements of the conversion rate of TCP over time and for different temperatures in a stirred batch reactor where the digestion of the phosphate ore particles by a phosphoric acid solution takes place (van der Sluis et al, 1987). In their study, the authors assumed that the dissolution process is controlled by the diffusion of MCP and determined the corresponding values of the mass transfer coefficient of TCP. In this work, the developed model is adapted to fulfill the same conditions assuming that the diffusion of acid is not the rate-limiting step. The influence of the diffusion coefficient $D_{H_3PO_4}$ on the model is therefore neglected. However, the reaction at the solid surface as well as the diffusion of MCP in the film are considered. The competition between these steps will be analyzed by means of Damköhler number $Da_{MCP} = k_r R / D_{MCP}$. However, the question is to know whether these experiments contain the necessary information to identify all the unknown parameters of the model. To answer this question, we used our recently developed estimability analysis method based on global sensitivities (Bouchkira et al, 2021) to rank the unknown parameters from the most to the least estimable.

Table 1 presents the data used in the simulations. The measured values of the kinematic viscosity at different temperatures can be found in (van der Sluis et al., 1987).

Table 1: Model parameter values

Parameter	ρ_s	ε	x_{TCP}	M_{MCP}	R_0	m_s^0	V_L
Value	7.2×10^3	5.0×10^3	51	3.1×10^{-1}	5.45×10^{-4}	2×10^{-2}	4×10^{-4}
Unit	kg.m^{-3}	W.kg^{-1}	% wt	kg.mol^{-1}	m	kg	m^3

5. Results and discussion

The estimability analysis method showed that k_r is the only estimable parameter. It is then identified using a gradient-based optimization method, while D_{MCP} is deduced from the measurements of van der Sluis et al. (1987) by means of the mass transfer correlation of Rakoczy and Masiuk (2011). Table 2 presents the computed results which consist of the values of the hydrodynamic parameter α , the diffusion coefficient D_{MCP} , and the constant rate k_r along with its corresponding 95% confidence intervals, for three different values of temperature. The tight confidence intervals show that k_r is accurately determined. Moreover, the use of an Arrhenius-type of equation allows us to determine the pre-exponential factor (1.18×10^{-4} m/s) and the activation energy (8641 J/mol). The low value of the activation energy confirms that the diffusion of the MCP product is indeed the limiting step in the dissolution of the particles.

Figure 2: Comparison of simulated and measured values of MCP concentrations

Figure 3: Profiles of Damköhler number for three different values of temperature

Figure 2 exhibits a very good agreement between the model predictions of the MCP concentrations and the measurements carried out at three values of temperature, thus highlighting the quality of the model.

On the other hand, as the dissolution proceeds, the radius of the particles as well as the thickness of the film decrease over time. The resulting Damköhler number also decreases over time and with increasing temperature (Figure 3).

Table 2: Computed values of α , D_{MCP} and k_r at different values of temperature

T(K)	α	D_{MCP} (m ² /s)	k_r (m/s)
333	0.27	3.1×10^{-11}	$5.24 \times 10^{-6} \pm 3.40 \times 10^{-7}$
348	0.29	4.7×10^{-11}	$5.86 \times 10^{-6} \pm 4.29 \times 10^{-7}$
363	0.31	6.3×10^{-11}	$6.78 \times 10^{-6} \pm 3.89 \times 10^{-7}$

In the beginning of the digestion, the dissolution is controlled by the diffusion of MCP in the liquid film for the three values of temperature. This control is reduced over time in favor of the reaction of TCP at the surface of the particles which takes over at the end of the dissolution. The control is actually shared by diffusion and reaction throughout the process. The diffusion prevails at the beginning and the reaction at the very end of dissolution. This phenomenon is very likely to occur in such transient processes.

6. Conclusions

It is interesting to notice that the model developed in this work leads to the same conclusions as in van der Sluis et al. (1987) on the phenomenon that controls the dissolution using the same set of experimental measurements and assuming that the diffusion of the acid in the liquid film is not limiting. Furthermore, the model developed here is more accurate since it is based on more realistic assumptions and predicts a diffusion control which decreases with time. Indeed, we did not assume that the concentration of MCP at the surface of the solid is given by its saturation concentration, it is determined by solving the second Fourier law in transient regime in the liquid film. We also considered the thickness of the liquid film which decreases over time as the radius of the particles. However, the model can be further improved by investigating the phenomena taking place at the surface of the particles and by carrying out additional experiments to better calibrate and validate the model prior to its use in subsequent optimization of the reactor performances.

Abstract

Accurate process models which are the key to a reliable model-based process design usually need to be identified on the basis of expensive laboratory experiments. In this work, we present an integrated methodology which enables to focus these experiments on the most relevant model parameters by combining a global sensitivity analysis and optimal design of experiments. We apply the methodology to the homogeneous catalyzed hydroformylation of 1-dodecene as an example process. The comparison to an ordinary optimal experimental design and a factorial design show that by this approach the experimental effort could be reduced. Furthermore, we compare the use of a local and a global sensitivity analysis; the global sensitivity analysis can indeed enhance the process design.

Keywords: early phase process design, global sensitivity analysis, optimal design of experiments.

1. Introduction

In the early design phase of new chemical processes, the most cost influencing decisions are taken, so this is the key phase of process development. As nowadays product cycles in the chemical industry become shorter, the pressure to reduce the development time is increasing. Sequential steps of laboratory experiments, identification of model parameters and physical properties and process simulation and optimization lead to long development cycles, thus a new methodology that integrates these steps and helps to focus the work is required. Optimal design of experiments (ODoE) is used to reduce the effort of experimental work. An overview of ODoE can be found in Franceschini & Macchietto (2008). Chen & Grossmann (2017) describe the recent developments in optimization-based process synthesis, including the handling of uncertainty in the process parameters. Asprión et al. (2019) developed an interface that enables to integrate optimal experimental design in a flowsheet simulator. The framework can be used for focused model improvement and parameter estimation but does not include a method for process design. Recker et al. (2013) integrated process optimization and optimal design of experiments. In order to focus the experiments on the relevant parameters, they weight the Fischer information matrix in the optimal experimental design. However, in their approach uncertainties in the process optimization are neglected which can lead to suboptimal processes. Commonly, local sensitivity analysis is used for the identification of the cost driving parameters, but this has the drawback

that it is only valid at one point and not for the complete operating range. This issue can be overcome by replacing the local sensitivity analysis with a global sensitivity analysis. In this work, we present a methodology that integrates superstructure optimization under uncertainties, a global sensitivity analysis and optimal design of experiments. For the best design identified by the superstructure optimization the sensitivities of the cost function with respect to the uncertain parameters are computed and used as weights in the optimal design of experiments. The proposed method is applied to a case study of the homogeneously catalyzed hydroformylation of 1-dodecene. The results are compared with the non-weighted optimal experimental design and a factorial design in order to see the effect of applying the weighting on the number of experiments that is required to get a sufficiently good process model.

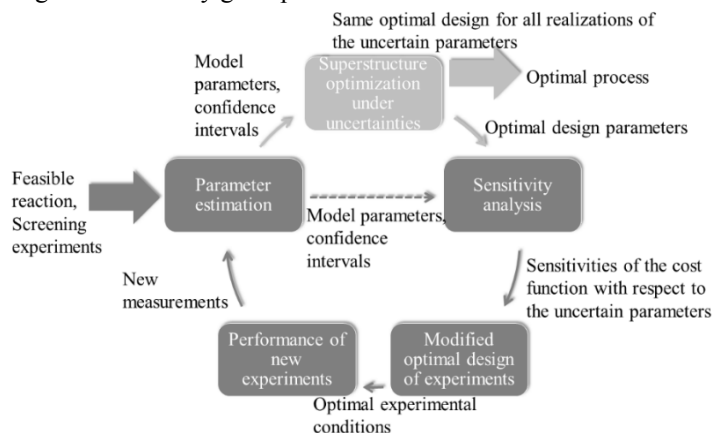

Figure 1: Schematic representation of the proposed methodology for integrated process.

2. Methodology

It is proposed here to use model-based tools already in the early design phase although only little knowledge is available during this phase. It is assumed that first experiments have been performed and the key elements of the process, in particular the chemical reaction system have been identified. The general procedure of the proposed methodology has been described in Kaiser & Engell (2020) and it is depicted in Figure 1. Based on the first screening experiments, kinetic and thermodynamic models with still significant parametric uncertainties are assumed to be available and are used in a subsequent step for superstructure optimization under uncertainties as introduced by Steimel & Engell (2015). For the best design, a sensitivity analysis - either local or global - is performed followed by a subsequent optimal design of experiments (ODoE) which is weighted with the computed sensitivities. The focus of this paper is on the weighted optimal design of experiments using the previously computed sensitivities.

2.1. Sensitivity analysis

Sensitivity analysis is performed in order to obtain information about the influence of each uncertain parameter on the cost function. The local sensitivities are computationally less expensive but are valid only in a small region around the nominal values of the parameters. The global sensitivities are valid in average over the complete region of the uncertain parameters and they give information about nonlinear effects. However, the global sensitivity analysis is computationally more expensive. It is assumed that the operating conditions of a process can be adjusted depending on the realization of the uncertain parameters. Therefore, the cost function is optimized at each

sampling point in the computation of the local and the global sensitivities with respect to the operating conditions (u_{opt}) for given design parameters.

2.1.1. Local sensitivity analysis

The local sensitivities are computed as described by Kaiser & Engell (2020). The uncertain parameters are sampled using 1 % deviation from their nominal values and a linear regression is used to correlate the n uncertain parameters x_i to the regressed objective value \hat{Z}_j :

$$\hat{Z}_j = \beta_0 + \sum_{i=1}^n \beta_i x_i \quad (1)$$

The least squares method is used to determine the intercept β_0 and the regression coefficients β_i . The regression coefficients are standardized with zero mean and a standard deviation of one. For N samples the standardized regression coefficients are computed as:

$$SRC_j = \frac{\beta_j \hat{s}_i}{\hat{s}} \quad \text{with} \quad \hat{s} = \left[\sum_j \frac{(Z_j - \bar{Z})^2}{N-1} \right]^{1/2} \quad \text{and} \quad \hat{s}_i = \left[\sum_j \frac{(x_j - \bar{x})^2}{N-1} \right]^{1/2}. \quad (2-4)$$

2.1.2. Global Sensitivity Analysis

The global sensitivities are computed using the Sobol' indices (Sobol, 2001). The effect of a single parameter can be computed by

$$S_i = \frac{var(y|x_i)}{var(y)} \quad (5)$$

where $var(y|x_i)$ describes the conditional variance of the output y with respect to the parameter i and $var(y)$ describes the general variance of y . The total effect S_T also takes non-linearity and interaction effects into account. It can be computed as

$$S_{T,i} = 1 - \frac{var(y|x_{\sim i})}{var(y)} \quad (6)$$

where $var(y|x_{\sim i})$ is the conditional variance of the output y with respect to all the parameter except parameter i . Using a latin-hypercube sampling, N different scenarios of the realization of the uncertain parameters within the 95 % confidence intervals are generated.

2.2. Modified optimal design of experiments

In order to design new experiments to gain information about the parameters that were identified as cost driving, a modified ODoE is used. As in the ordinary experimental design, a metric of the Fisher information matrix (FIM) is minimized. The FIM is defined as

$$FIM = \sum_{\tau=\tau_1}^{\tau_N} Q^T(u_\tau) \text{diag}^{-1}(\sigma_1^2, \dots, \sigma_n^2) Q(u_\tau) \quad (7)$$

with $Q(u_\tau)$ containing the derivatives of the model outputs with respect to the parameters of the experiment with the input u_τ . To drive the designed experiments towards gaining information about the relevant parameters, an intuitive way is weighting the FIM with the previously computed sensitivities (Recker et al., 2013).

$$\tilde{FIM} = W^{1/2} \sum_{\tau=\tau_1}^{\tau_N} Q^T(u_\tau) \text{diag}^{-1}(\sigma_1^2, \dots, \sigma_{n_y}^2) Q(u_\tau) W^{1/2} \quad (8)$$

where the matrix W contains the sensitivities of the process costs with respect to the model parameters θ_i at the current estimated value of the parameters θ_{est} .

Figure 2: Simplified process flowsheet.

Figure 3: Reaction network of the hydroformylation.

$$W = \begin{bmatrix} \frac{\partial C_{process}}{\partial \theta_1} \Big|_{u_{opt, \theta_{est}}} & \dots & 0 & \ddots & \ddots & 0 & \dots & \frac{\partial C_{process}}{\partial \theta_p} \Big|_{u_{opt, \theta_{est}}} \end{bmatrix} \quad (9)$$

In this work we use an A-optimal DoE which aims at minimizing the trace of the FIM .

3. Case study

The proposed methodology is applied to the case study of the homogeneously catalyzed hydroformylation of 1-dodecene using a thermomorphic solvent system. The process is described in Hernandez et al. (2018). A thermomorphic solvent system consisting of the polar solvent dimethylformamide and a non-polar solvent decane that separates into two phases at low temperatures is used to recycle the expensive rhodium catalyst. The catalyst dissolves in the polar phase and can be recycled into the reactor, while the product tridecanal dissolves in the non-polar phase which can be purified in a further thermal separation step. A simplified process flowsheet is shown in Figure 2. A detailed description of the process model can be found in Hernandez et al. (2018). The kinetic model depicted in Figure 3 was developed by Hentschel et al. (2015). The pre-exponential factors and the activation energies of the hydroformylation of n-dodecene (r_1) and of the isomerization of n-dodecene (r_2) in the kinetic model are considered as uncertain parameters.

The other kinetic parameters have been observed as less influencing and are hence fixed to their pre-defined values. We use the standardized regression coefficients (eq. 2-4) as local sensitivities and the total effects (eq. 6) as global sensitivities. The planned experiments are isothermal batch experiments where the evolution of the concentration is measured over the batch time. The degrees of freedom in the ODoE are the reaction temperature, the initial concentration of n-dodecene, the initial concentration of iso-dodecene, the ratio of H2 to CO and the catalyst concentration. Furthermore, the sampling times of the concentration measurements are included as degrees of freedom. The number of measurements is fixed to 6. The measurements are generated using a simulation model with the true parameters, corrupted by white noise with a standard deviation of 5 %.

The yield of n-undecanal in the product stream with respect to the n-dodecene in the feed is used as the cost function.

3.1. Comparison of different design strategies

In this section we compare the results of different strategies for model refinement: (i) A standard ODeE without weighting the FIM. (ii) A modified ODoE weighting the FIM with local sensitivities. (iii) A modified ODoE weighing the FIM with global sensitivities.

In all cases, the same two experiments performed at two different temperatures are used as the basis for the first parameter estimation and then 25 new experiments are planned in iterative steps of parameter estimation and ODoE according to the applied method. The number of process optimizations that are used for the computation of the weighting matrix W is 10 in case of the local sensitivity analysis and 1200 in case of the global sensitivity analysis. For the standard ODoE, no process optimization is required.

The progress over the number of experiments is compared to the results of a static factorial design, in which experiments are performed at the lower and upper bounds of the five degrees of freedom, leading to 32 experiments. After the parameter estimation, the 95 % confidence intervals are computed. For different scenarios within these confidence intervals the minimal and the maximal yields are computed. As the predicted parameters and hence the predicted yields depend on the random process noise, the procedure is repeated ten times for each case and the mean values are considered. The evolution of the maximum and minimum computed process cost is shown in Figure 4.

The figure shows the change of the maximum and minimum predicted yield for all three cases as well as the true yield and the yield predicted using the factorial sampling. It can be seen that for all cases a better prediction of the yield in comparison to a factorial design can be reached after only 9 iterations for the weighting obtained from the global sensitivity analysis and after 15 iterations using the local sensitivity analysis. The absolute differences in the minimum expected yield between the two approaches is small after 6 iterations. Standard ODoE performs somewhat erratically in comparison.

Figure 4: Evolution of the predicted intervals of the yield for the different methods. The true yield is represented by the solid line and the interval of the predicted yield using a factorial design is represented by the dashed line.

Since in the ordinary ODoE equal weights are put on determining the uncertain parameters, it can occur that experiments are planned that improve one parameter that has a small influence on the process yield. By using specific weights on the parameters that have the highest impact on the cost function, more efficient experiments can be planned. The advantage of using global sensitivities can be explained by the fact that the

model is highly nonlinear with respect to the uncertain parameters. By taking these effects into account, the ODoE can further reduce the predicted interval of the cost function.

4. Conclusion and outlook

We presented an integrated methodology that can accelerate early phase process design. Optimal design of experiments can be used to efficiently design experiments to determine model parameters that are needed for a model-based process design. The most relevant parameters that should be determined more precisely by experimental work can be identified reliably by a sensitivity analysis. A modified optimal design of experiments weighted with these sensitivities enables to focus the experimental work on the most relevant model parameters and can hence be a promising tool for process design. In a case study it was shown that in case of nonlinear and interaction effect a global sensitivity analysis is superior compared to a local sensitivity analysis. It is expected that the global sensitivity analysis is even more beneficial in cases with structural uncertainties, because these cannot be quantified using local sensitivities. This will be the subject of further investigations.

This work presented here focused on the experimental design. It will be embedded into a complete process design procedure, including superstructure optimization under uncertainty and the presented modified ODoE.

Abstract

The design and operation of process systems are required to meet multiple constraints related to production schedules, product quality, safety, economic performance and environmental footprint. These constraints define the set of feasible design and/or operational parameters which is called process Design Space (DS). In most instances, process constraints are defined as functions of state variables of the system in which case the full-scale process model must be solved for their verification which can be a computationally demanding task for large-scale nonlinear models. This a challenge for online applications such as model-predictive control or real-time optimisation.

In this study we present a computationally efficient method of evaluating the feasibility of a set of model parameters using a surrogate indicator function of the DS through Gaussian Process approximation of deterministic inequality model constraints. The method allows finding a compromise between the computational effort required and the level of confidence reflecting the accuracy of DS approximation.

Keywords: design space, constraints, Gaussian process, uncertainty.

1. Introduction

Mathematical models developed for the design and control of manufacturing processes are subject to multiple constraints imposed on a wide range of process parameters (equipment sizes, mass and energy flowrates, controllability, reliability, etc.), product characteristics (quality and yield) as well as economic performance measures and other Key Performance Indicators (KPIs) of the process. Many of these models are highly nonlinear and/or large in scale which makes them computationally expensive to run. This can be problematic, especially when the model needs to be solved repeatedly either in the context of model-predictive control/real-time optimisation or simply to verify the feasibility of a state of the system.

The latter is particularly important in assuring the quality of a product in fine chemicals industries such as (bio)pharmaceuticals where deviations of product characteristics from those approved by a regulator can have drastic safety and financial repercussions. In such cases, the Design Space (DS) defined as “the multidimensional combination and interaction of input variables (e.g., material attributes) and process parameters that have

been demonstrated to provide assurance of quality” (Pharmaceutical Development Q8(R2), 2009) plays a crucial role in process design in accordance with the Quality-by-Design paradigm, control and product approval.

Considering a generalised process model $f: R^n \rightarrow R^m$ that maps an n -dimensional input space into an m -dimensional space of the outputs of interest, let us define a set of C inequality constraints delineating combinations of model inputs leading to feasible outputs (i.e., the DS) as $g(x, f(x)) \geq 0$, $g: R^{n+m} \rightarrow R^c$. In the following, we will refer to such constraints, which depend on model function $f(x)$, as ‘implicit’. Generally, the whole process model must be solved to evaluate implicit constraints and establish whether x lies in the DS. In most cases, this also precludes any possibility of finding an explicit expression or procedure for determining the feasibility of a given set of model inputs.

This fact and the computational complexity of ‘discovering’ the true DS have led to a situation when only DS descriptions in the form of hyperrectangles (i.e., Cartesian products of ranges of model inputs) can be approved by regulators while these are generally only subsets of much larger feasible subspaces. There have been relatively few attempts in the literature to systematically approach the problem of model-based non-convex DS identification (Bano et al., 2019; García-Muñoz et al., 2015; Kotidis et al., 2019; Kucherenko et al., 2020), including finding a hyperrectangle of maximum volume inscribed into the DS (Ochoa et al., 2019). While the cited approaches also considered that the model constraints depend on uncertain parameters, they stress that a high number of process model evaluations is required to obtain a reasonable description of the DS.

Emerging research in DS modelling investigates the construction of a feasibility probability map to obtain an easy-to-evaluate feasibility indicator for each constraint using regression and classification methods (Knudde et al., 2019; Kusumo et al., 2020). To address the computational inefficiencies of DS identification, we adopt the application of Gaussian Processes (GPs) exploiting their intrinsic measures of uncertainty in the feasibility estimates. Our method introduces a confidence threshold to the estimated feasibility measures to control the quality of approximation thus balancing the computational effort of training the GP with the accuracy of DS representation. The proposed framework accelerates the identification of the whole non-convex DS, rather than its orthogonal subspace, tailoring space filling designs to enable extended flexibility of process operation while preserving the feasibility of model constraints.

2. Theory

In the following for simplicity we will assume that the maximum ranges of model input variations have been mapped onto a unit hypercube denoted as $H^n = [0, 1]^n$.

The joint distribution of model inputs x is assumed to be represented by a probability density function $p(x)$. Model constraints will be denoted as $g(x)$ regardless of whether they are explicit (i.e., do not depend on model outputs $f(x)$) or implicit (i.e., dependent on $f(x)$ as in $g(x, f(x))$).

The Design Space denoted as Ω^n is a subspace of H^n such that all of its points are feasible with respect to the constraints. The DS can be defined through its indicator function as

$$\Omega^n = \{x: I(x) = 1\} \subset H^n, \text{ where } I(x) = \begin{cases} 1, & g(x) \geq 0 \\ 0, & g(x) < 0 \end{cases} \quad (1)$$

A single constraint will be considered to develop the methodology below. When multiple inequality constraints determine the feasibility of a point in the input space the indicator function, $I(x)$, can be formulated as the product of C indicators corresponding to individual constraint functions $g_i(x)$ such that $I(x) = \prod_{i=1}^C I_i(x)$.

2.1. Gaussian process interpolation of model constraints

The unit hypercube H^n containing the feasible DS Ω^n is sampled from distribution $p(x)$ and the values of model constraint $g(x)$ are computed at the sample points. A Gaussian Process interpolant is then fitted on the set of sample points, and additional samples can be generated as required by the convergence criteria.

A Gaussian Process (GP) over the constraint function g is a stochastic process comprised by an infinite collection of random variables any finite subset of which, $Y = \{g(x^{(1)}), \dots, g(x^{(N)})\}$, is normally distributed as shown in (Rasmussen, 2004)

$$p(Y) = N(m(x), K(x, x')) \quad (2)$$

where $m(x) = E[x]$ is the mean function, and $k(x, x') = E[(x' - m(x'))(x - m(x))]$ denotes a positive-definite covariance function corresponding to two points $(x, x') \in H^n$.

Bayesian inference of GPs allows using a prior distribution in Eq. 4 to derive a posterior conditional distribution based on a set of model evaluations. The latter is used as a predictive distribution over $g(\cdot)$ at any testing point $x_* \in H^n$. Considering a training set $X = \{x^{(1)}, \dots, x^{(N)}\}$ and a test sample $X_* = \{x_*^{(1)}, \dots, x_*^{(N_*)}\}$ distributed according to $p(x)$, the joint distribution of the corresponding random variables based on a GP is given by

$$p(Y, Y_*) = N\left(\begin{bmatrix} m(X) & m(X_*) \end{bmatrix}, \begin{bmatrix} K_{XX} & K_{XX_*} & K_{X_*X} & K_{X_*X_*} \end{bmatrix}\right) \quad (3)$$

where $K_{XX_*} = k(X, X_*)$. GP interpolation is based on conditioning the probability density function (Eq. 3) for non-parametric estimation of Y_* . Assuming $m(x) = 0$, it follows that

$$p(Y, X, X_*) = N(M_*, \Sigma_*) \quad (4)$$

where $M_* = K_{X_*X} K_{XX}^{-1} Y$ and $\Sigma_* = K_{X_*X_*} - K_{X_*X} K_{XX}^{-1} K_{XX_*}$.

2.2. Confidence level of indicator approximation

Conditioning the GP on a training sample X and a test point $x \in H^n$, the posterior density function of $GP(x)$ is $p(Y, X, x) = N(\mu_x, \Sigma_x)$, where μ_x, Σ_x are given by Eq. 4. Considering $g(x) \geq 0 \Leftrightarrow I(x) = 1$, the conditional posterior distribution is used to express the probability that test point x is feasible according to the approximation of the constraint by the GP:

$$P(I(x) = 1) \approx P_I(x) = P(GP(x) \geq 0) = 1 - P(GP(x) < 0) \tag{5}$$

where $P_I(x) = P(GP(x) \geq 0)$ is computed using the normal cumulative distribution function $F_{GP(x)}(0)$ of the GP-based approximation:

$$P_I(x) = 1 - F_{GP(x)}(0) = 1 - \int_{-\infty}^0 p(Y, X, x) du = \frac{1}{2} \left[1 - \left(\frac{-\mu_x}{\Sigma_x \sqrt{2}} \right) \right] \tag{6}$$

Using the measure of uncertainty around the approximation of the exact $I(x)$ in Eq. 6, a GP-based indicator $\tilde{I}_\varepsilon(x)$ is computed by introducing a threshold $\varepsilon \in (0, 1)$ in the estimated $P_I(x)$. Hence, an approximate DS is described as

$$\tilde{\Omega}^n = \{x: \tilde{I}_\varepsilon(x) = 1\} = \{x: P_I(x) \geq \varepsilon\} \tag{7}$$

The uncertainty threshold ε represents the lowest level of confidence which can be tolerated in the approximation of $I(x)$ by the GP. Therefore, ε serves as a quality metric when evaluating $\tilde{I}_\varepsilon(x)$ at the design point x and as a classifier parameter which is applied on the intrinsic uncertainty of the GP-based estimates rather than their mean values. The method can be extended for multiple inequality constraints, when C GPs must be trained for the identification of the corresponding DS such that

$$\tilde{\Omega}^n = \left\{ x: \prod_{i=1}^C \tilde{I}_\varepsilon^i(x) = 1 \right\}.$$

Convergence of the approximate indicator $\tilde{I}_\varepsilon(x)$ of $\tilde{\Omega}^n$ to the true one $I(x)$ can be assessed using the volume of the approximate DS $V_{\tilde{\Omega}_\varepsilon^n}$. The latter can be computed using a large but computationally inexpensive Monte Carlo (MC) sample of the GP of size $N_* \gg N$:

$$V_{\tilde{\Omega}^n} = \int I(x) dx \approx N_*^{-1} \sum_{i=1}^{N_*} \tilde{I}_\varepsilon(x_i) = V_{\tilde{\Omega}_\varepsilon^n} \tag{8}$$

Convergence of $V_{\tilde{\Omega}_\varepsilon^n}$ to $V_{\tilde{\Omega}^n}$ depends on the size of training sample N , size of N_* and the value of ε . With increasing N , Σ_x in Eq. 6 decreases for all $x \in H^n$ leading to convergence of $\tilde{I}_\varepsilon(\cdot)$ to $I(\cdot)$. It can be shown that for any $\varepsilon \in (0, 1)$ there exists $\Sigma_0(\varepsilon)$ corresponding to a finite number of training samples N_ε such that for each $x \in H^n$

$\Sigma_x \leq \Sigma_0(\varepsilon)$ and $\left| V_{\tilde{\Omega}_\varepsilon^n} - V_{\tilde{\Omega}^n} \right| < \delta_\varepsilon$. Thus, the convergence of $V_{\tilde{\Omega}_\varepsilon^n}$ is uniform in ε over $(0, 1)$ for training sample of size $N > N_\varepsilon$ and $\frac{d}{d\varepsilon} V_{\tilde{\Omega}_\varepsilon^n} \rightarrow 0$ for all ε except $\varepsilon = 0$ or 1 . The latter can be used as a convergence criterion for the approximation of $V_{\tilde{\Omega}^n}$.

3. Results

The proposed framework was tested with an inequality constraint based on Sobol’ product function (Eq. 9) because of its properties including nonlinearity, non-smoothness, symmetry and scalability in higher dimensions.

$$h(x_1, \dots, x_n) = 1 - \prod_{i=1}^n \frac{|4x_i - 2| + a_i}{1 + a_i} \geq 0, \quad a_i = i - 1 \quad (9)$$

Considering that inputs are uniform iid variables, sampling is performed in H^n using the space-filling Sobol’ pseudo-random sequence (Sobol et al., 2011), which accelerates convergence in higher dimensions compared to conventional random number generators.

Without implying any knowledge of $h(\cdot)$, the GP is defined by zero mean and squared exponential covariance function as commonly suggested in most applications. Based on a 95% confidence threshold for the definition of the feasible DS, and $N = 2^{11}$ training samples for the GP, Figure 1 shows the 2-dimensional boundary of Eq. 9. Herein, $h(\cdot)$ represents a non-smooth example of how DS identification based on integration of the Gaussian uncertainty around the interpolant can achieve a robust DS approximation without significant loss of feasible volume. However, in higher dimensions and for highly non-smooth constraint functions the performance of a GP-based surrogate indicator it is expected to deteriorate.

Figure 1: Exact DS boundary and its approximation based on 95% confidence

Figure 2(a) demonstrates how increasing the number of training samples, N , reduces the uncertainty in a 6-dimensional DS volume approximation, by showing that the effect of ε on $V_{\Omega_\varepsilon}^{\sim n}$ becomes less significant as sampling size grows. Based on this, $\frac{d}{d\varepsilon} V_{\Omega_\varepsilon}^{\sim n}$ is suggested as a measure of convergence of $V_{\Omega_\varepsilon}^{\sim n}$ and hence of the approximate indicator

$\tilde{I}_\varepsilon(x)$. Indeed, only if $\left| \frac{d}{d\varepsilon} V_{\Omega_\varepsilon}^{\sim n} \right| < 1$ around $\varepsilon \approx 0.5$ any discrimination between feasible and infeasible subspaces of H^n is possible. In applications where a conservative value of

ε (close to one) is required, because no violation of the constraints can be afforded, the approximated $V_{\sim n}$ is smaller, thus there is a tradeoff between the level of confidence in the approximation and feasible DS volume for any fixed training sample of size N .

The problem of approximating the DS is magnified in higher dimensions due to the curse of dimensionality. As dimensionality n increases, the volume of a subspace with a characteristic linear dimension $L < 1$ decreases exponentially. Thus, the size of the training sample N required to achieve a good approximation of Ω^n increases significantly. Figure 2(b) illustrates the effects of the curse of dimensionality when using a fixed sample size ($N = 2^{10}$) and indicates that the convergence of $V_{\sim n}$ to its true value may be slow in higher dimensions.

Figure 2: The effect of confidence threshold ε on DS volume approximation when increasing size of training sample (a) and dimensionality (b)

4. Conclusions

A computational framework for efficient approximation of the process Design Space is introduced, based on the use of Gaussian Processes as surrogate models of inequality constraint functions describing process safety, reliability and product quality. Gaussian Processes play a dual role as a flexible and inexpensive interpolation method for a wide class of constraint functions, accelerating sampling-based exploration of the process DS and measuring the uncertainty in the estimated constraints feasibility. In our approach, the quality and robustness of DS approximation can be controlled through the size of a training sample and desired confidence level. However, the method is not immune to the curse of dimensionality with a large number of training points and full model evaluations required in higher dimensions for reliable DS identification.

Employing Adaptive Just-In-Time-Learning in a Transfer Learning Frame for Soft-Sensor Design

Burak Alakent^a

burak.alakent@boun.edu.tr

Abstract

Online learning methods, such as moving window (MW) and just in time learning (JITL), have been proposed in the literature to remedy concept drift problem deteriorating soft-sensor performance. While these methods are effective against different types of drifts, a single method may not be sufficient in combating against heterogeneous concept drifts. In the current study, we propose combining MW and JITL methods within a transfer learning frame coupled with a relevant instance selection method to improve the prediction accuracy offered by either method. The proposed method involves i) forming a relevant sample of historical observations via backward elimination of the clusters composed of the extended nearest neighbors of the query point, ii) constructing a task transferred JITL model via kernel ridge regression, and iii) using a transductive MW learner. Employing the proposed method on two publicly available real benchmark datasets yields highly accurate predictions, showing convenience for industrial applications.

Keywords: Concept drift, K-means clustering, Kernel regression, Online learning, Relevant sample.

1. Introduction

Soft-sensors are predictive models used to exploit information extracted from the secondary process variable measurements for online prediction of the quality variables in chemical processes [1]. Rise of the machine learning in the last ~20 years has rendered a shift in the design methodology of soft sensors from mechanistic to data-based paradigm. While state-of-the-art learners make it possible to obtain sufficiently accurate predictions for future operations similar to those used in the training set, changes in process conditions, i.e. concept drifts, may easily deteriorate the prediction accuracy of any learner. In “virtual” concept drifts, only the distribution of the secondary variables (features) is perturbed, while the functional relation between the secondary and quality variables changes under “real” concept drifts [2]. Various online learning methods are proposed to reduce the harmful effects of concept drifts, such as moving window (MW) and just-in-time-learning (JITL) models. The former method involves using a sliding window, consisting of the most recent observations for the training set, while the latter involves choosing the most relevant observations, usually obtained by a variation of nearest neighbor (NN) criterion. It is known that MW is affective against real and gradual concept drifts while JITL is affective against abrupt recurrent virtual drifts [3]. Industrial processes, however, encounter heterogeneous concept drifts, hence it is not reasonable to

expect a single MW or JITL model to maintain its prediction accuracy during the whole operation.

Transfer learning offers a new perspective for predicting a target task, for which a small number of labeled observations exist, via utilizing information from a source domain with a larger number of labeled samples [4]. We have recently proposed transductive MW (MW_{tr}) [5], and task transferred JITL coupled MW_{tr} ($JITL_{TT}-MW_{tr}$) learners [6] for combining MW and JITL models in a transfer learning perspective, and shown that high predictive accuracy can be reached against heterogeneous concept drifts. In these studies, however, i) we did not check the relevance of the NN points with the current task, and ii) we used linear learners for the JITL model. In the current study, we improve these issues using an adaptive task transferred JITL coupled transductive MW ($AdJITL_{TT}-MW_{tr}$) learner. Application of $AdJITL_{TT}-MW_{tr}$ on three cases from two publicly available industrial real datasets shows that the proposed online learner has significantly high predictive accuracy, and is robust with respect to learning parameters.

2. Online Learning Methods

In supervised machine learning, a historical dataset of N points $\{(\mathbf{x}_n, y_n)\}_{n=1}^N$ with $\mathbf{x}_n \in \mathbb{R}^p$ and $y_n \in \mathbb{R}$ is used to predict the response (or quality) variable (\hat{y}_{N+1}) of the test (query) point \mathbf{x}_{N+1} . When the mapping function from the features to the quality variables, $f(\mathbf{x}_n)$, changes with respect to the domain of the features and/or time, online learning is more convenient in adapting the predictive function to the current task, contrary to batch learning, which offers a constant predictive function.

2.1. Moving Window (MW) and Just-in-Time-Learning (JITL)

Most of the online learning schemes in soft-sensor design for chemical processes involve choosing relevant training samples. The most recent samples are selected in MW modeling, while JITL is commonly based on the selection of the most similar samples to the test point in the feature space. The rationale behind sample selection methods lies in combating real and virtual concept drifts; the current task is assumed to be more accurately represented by the recent samples, and samples collected in the current domain of the query point. To improve the prediction performance of single MW or JITL models, novel methods using ensemble techniques [7], and combinations of MW and JITL [8] are proposed in the literature. Prediction accuracy of MW and JITL models depends on the window size (W) and the size of NN set (K). While a small W usually yields a more accurate representation of the current task, the resulting training set would only span a limited subspace of the whole domain of operation. In JITL, sample selection based on feature similarity usually leads to a larger training set, comprising samples from various time segments, and spanning a wider subspace. Since linear learners are less prone to overfitting for small multicollinear datasets, we use a linear learner (Lasso) for MW, and a nonlinear learner (Kernel Ridge Regression) for JITL in the current study.

2.2. Least Absolute Shrinkage and Selection Operator (Lasso)

Sum of squares of fitting errors is regularized using the L1 norm of coefficient estimates and parameter λ in Lasso, also yielding an embedded feature selection mechanism [9]:

$$\min_{\boldsymbol{\beta}} \left\{ \lambda \sum_{j=1}^p |\beta_j| + \sum_{n=1}^N (y_n - \mathbf{x}_n^T \boldsymbol{\beta})^2 \right\} \quad (1)$$

2.3. Kernel Ridge Regression (KRR)

In KRR, regression in feature space is regularized via L2 norm of regression coefficients:

$$\min_{\boldsymbol{\beta}} \left\{ \lambda \boldsymbol{\beta}^T \boldsymbol{\beta} + \sum_{n=1}^N (y_n - \Phi(\mathbf{x}_n)^T \boldsymbol{\beta})^2 \right\} \quad (2)$$

Here, $\Phi(\cdot)$ corresponds to the nonlinear mapping of the input variables to the feature space. Using the “kernel trick”, which makes it possible to determine the inner product in Hilbert feature space using a kernel $k(\mathbf{x}_i, \mathbf{x}_j)$ computed in the input space, the prediction for y_{N+1} can be determined as follows:

$$\hat{y}_{N+1} = \sum_{n=1}^N c_n k(\mathbf{x}_{N+1}, \mathbf{x}_n) \quad (3)$$

In the above formulation, $\mathbf{c} = (\mathbf{I}\lambda + \mathbf{G})^{-1} \mathbf{y}$, in which \mathbf{G} is the gram matrix with $G_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$, $i, j = 1, 2, \dots, N$ and $\mathbf{y} = [y_1, y_2, \dots, y_N]^T$ [10]. Simply put, using a positive semi definite kernel, representing the similarity between samples in the training set, the query point may be predicted using the similarity of the query point to the training samples. We use exponential kernel in the current study, i.e. $k(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\|\mathbf{x}_i - \mathbf{x}_j\|_2^2 / 2\sigma^2\right)$.

3. Transfer Learning

In transfer learning, information in a source domain is used in predicting the task defined in the target domain. It is assumed that either i) the source domain (D_S) and target domain (D_T) differ, or ii) the source task ($f_S(\mathbf{x})$) and target task ($f_T(\mathbf{x})$) are different. The former and the latter scenarios are named transductive and inductive transfer learning, respectively. While there are various information transfer mechanisms, we have employed instance transfer in the current study. In industrial processes under heterogeneous drifts, we assume that the tasks governing the query point and small sized MW samples are identical, but the domains from which these two sets of points are sampled may be different. To solve this issue, we have recently proposed transductive MW learner (see Section 4.3) [5]. We also assume that the query point and JITL samples belong to identical domains, but possibly are governed via different task functions. To solve this problem, we have recently proposed task transferred JITL (JITL_{TT}) learner (see Section 4.2) [6]. In JITL_{TT}, we transfer a single sample from MW to NN set in order to adapt the JITL model to the current task. It should, however, be pointed out that even this mode of information transfer may not be sufficient for realizing a feasible task transfer of the JITL model, since there already may exist samples in the NN set detrimental for query point prediction.

4. The Proposed Method

4.1. Adaptation of the NN Set to the Current Task

The novelty of the current study lies in integrating a relevant data selection method to our recently proposed transfer learning methods. The fundamental motivation here is to select a subset of samples from an extended NN observations set, that “better” represents the current operation conditions. To this aim, first an initial NN set of the query point, based on Euclidean distance similarity of the feature values, is formed; then, this set is extended via including samples in time-proximity. Finally, a subset of the extended NN set that yields the smallest validation error for the MW samples is determined via backward elimination. The algorithm is described in detail as follows:

- i. Determine the time-ordered NN samples set: Obtain $\text{NN} = \{(\mathbf{x}_{n_k}, y_{n_k})\}_{k=1}^K$ from the samples in the historical dataset excluding the MW samples, with the ranked Euclidean distances $\{d_{E(1)}, d_{E(2)}, \dots, d_{E(N)}\}$, such that $d_{E(k)} = \|\mathbf{x}_{n_k} - \mathbf{x}_{N+1}\|_2$.
- ii. Identify different time segments, possibly corresponding to different operating regions in the NN set: Determine successive samples in NN set with L time lags separated, i.e. $n_{k+1} - n_k > L$, for $k = 1, 2, \dots, N - 1$. Let total number of different time segments, from which NN samples are collected, be equal to T , e.g. if there are no two consecutive samples separated with L samples, then $T = 1$.
- iii. Extend each time segment to include the neighboring samples: For each time segment of samples, denoted by \mathbf{n}_t , $t = 1, 2, \dots, T$, all time indices between the minimum and maximum indices, after extending by $\pm L/2$, are included in \mathbf{n}_t , e.g. taking $L = 10$, for a time segment \mathbf{n}_1 initially consisting of samples with indices $\{28, 29, 34, 36, 38\}$, \mathbf{n}_1 is extended so as to include the time indices $\{23, 24, \dots, 43\}$.
- iv. Define the extended NN_E set via concatenating the sample indices from each time segment: $\text{NN}_E = \{(\mathbf{x}_{n_k}, y_{n_k})\}_{k=1}^{K^*}$, where $K^* = \sum_{t=1}^T |\mathbf{n}_t|$.
- v. Determine the principal component scores of the extended NN set: Perform principal components analysis on NN_E , and obtain the first A scores vectors (\mathbf{t}) with eigenvalues greater than the average eigenvalue value.
- vi. Divide NN_E into a predetermined number of clusters (C) using K-means on \mathbf{t} vectors.
- vii. Use backward elimination (BE) to determine the clusters with the smallest validation errors: Remove each cluster one by one, and predict the MW samples using KRR. Stop, when the validation set error starts to increase. Pool all the observations in the remaining clusters into a final ‘‘adapted’’ NN set (NN_{Ad}). Note that the elements and the size of the resulting NN_{Ad} set, which is to be used in JITL in the next section, are likely to be different from those of the initial NN set.

4.2. Adaptive Task Transferred JITL (AdJITL_{TT}) model

JITL_{TT} was proposed in a very recent study [6], in which we transferred the nearest single point from MW samples to adapt the JITL model to the current task using a Lasso estimator. We, here, make two modifications to this method to meet the demands of the current study. First, we use all of the MW samples for regularization, and second, we use a KRR estimator for obtaining a task transferred predictive function $f_{S \rightarrow T}(\cdot)$. We name this method Adaptive Task Transferred JITL learner (AdJITL_{TT}):

$$\min_{\boldsymbol{\beta}} \left\{ \lambda_1 \boldsymbol{\beta}^T \boldsymbol{\beta} + \sum_{k \in \text{NN}_{Ad}} (y_k - \Phi(\mathbf{x}_k)^T \boldsymbol{\beta})^2 + w_1^2 \sum_{m \in \text{MW}} (y_m - \Phi(\mathbf{x}_m)^T \boldsymbol{\beta})^2 \right\} \quad (4)$$

The solution to Eq. 4 can also be easily determined in kernelized formulation shown in Eq. 3 to determine the pseudo-label (y_{N+1}^*) for the $(N+1)^{\text{th}}$ query point.

4.3. Transductive MW Learner (MW_{tr})

In MW_{tr} model, deviations of the fitted value of the query point from its pseudo-label (y_{N+1}^*) is used as an additional penalty in a weighted Lasso formulation [5]:

$$\min_{\boldsymbol{\beta}} \left\{ \lambda_2 \sum_{j=1}^p |\beta_j| + \sum_{n \in \text{MW}} (y_n - \mathbf{x}_n^T \boldsymbol{\beta})^2 + w_2^2 (y_{N+1}^* - \mathbf{x}_{N+1}^T \boldsymbol{\beta})^2 \right\} \quad (5)$$

In this way, a model consistent with both MW samples and the JITL prediction is obtained, completing the formulation of the proposed AdJITL_{TT}-MW_{tr} method. The final prediction of the query point is obtained via $\hat{y}_{N+1} = \mathbf{x}_{N+1}^T \hat{\boldsymbol{\beta}}$, in which $\hat{\boldsymbol{\beta}}$ is obtained from Eq. 5.

5. Results and Discussion

5.1. Datasets Studied

The proposed method was employed on two publicly available industrial benchmark datasets, a debutanizer column (DC) and a sulfur-recovery unit (SRU) [11]. DC is located in a desulfuring and naphtha splitter plant, and a soft sensor is to be designed using seven online measured secondary process variables for predicting the butane content in the bottom product. We divided DC dataset into 1000/1382 samples for training/testing via rolling-origin-recalibration (RORC) evaluation [5,6], respectively. A SRU is used for removing polluting agents from acid gas, and a soft sensor is to be designed using five online measured secondary process variables for predicting H₂S and SO₂ content in the tail gas of Maxisulfur plant. We divided the SRU dataset into 5000/5076 samples for training/testing, respectively. We used feature vectors of lagged measurement for JITL calculations, while we used only the current variable measurements for MW predictions [5,6]. For AdjITL_{TT}-MW_{tr}, RORC evaluation was conducted over a multidimensional grid of parameter values assigned to $\lambda_1, \lambda_2, w_1, w_2$ and σ^2 at fixed values of W, K and C for the training set. The parameter values, which yield the smallest RMSE for the training set, were used for testing. Additionally, we report a posteriori best-case results for MW, JITL and MW_{tr} learners on the same test set data; hence, the current results reflect a conservative prediction performance of AdjITL_{TT}-MW_{tr} compared to other methods.

5.2. Metrics Used for Assessing Predictive Performance

Root mean squared error (RMSE) and R^2_{pred} of test samples are used to assess the prediction accuracy of the learning methods:

$$\text{RMSE} = \sqrt{\frac{1}{N_{test}} \sum_{n=1}^{N_{test}} (y_n - \hat{y}_n)^2} \quad (6)$$

$$R^2_{pred} = 1 - \frac{\sum_{n=1}^{N_{test}} (y_n - \hat{y}_n)^2}{\sum_{n=1}^{N_{test}} (y_n - \bar{y})^2} \quad (7)$$

Above, \bar{y} refers to average of the quality variable measurements.

5.3. Comparisons of Prediction Accuracy of AdjITL_{TT}-MW_{tr} with Other Methods

Table 1 shows that AdjITL_{TT}-MW_{tr} is superior in prediction accuracy compared to other methods for all three quality variables. Low RMSE values obtained from predictions of AdjITL_{TT}-MW_{tr} over a range of K (size of the initial NN) and C (number of clusters) values demonstrate the robustness of the proposed method with respect to its parameters (Fig. 1). Skipping the adaptation step (Section 4.1) is shown to increase the RMSE values significantly, indicating that adapting the NN set to the current task is indeed helpful in decreasing prediction errors. It is also seen that using four clusters yields marginally more accurate predictions compared to other cluster sizes.

6. Conclusion

The current study aims to improve the recently suggested methods on reconciling MW and JITL models in an inductive/transductive transfer learning setting via including an adaptation of nearest neighbors in a kernelized regression frame. The merit of the current method lies in coupling a small size MW learner, aiming to focus only on the most recent task function, with a JITL learner, constructed from a larger number of historical samples, that are consistent both with the current domain and the task. The proposed AdjITL_{TT}-MW_{tr} method is shown to yield significantly high predictive accuracy on benchmark

industrial datasets, and is robust with respect to its learning parameters. Overall, AdJITL_{TT}-MW_{tr} offers a promising soft-sensing methodology for chemical processes.

Table 1. Comparison of prediction accuracy of various learners on all datasets.

Dataset studied/ Online Learning Method	DC		SRU-H ₂ S		SRU-SO ₂	
	RMSE	R^2_{pred}	RMSE	R^2_{pred}	RMSE	R^2_{pred}
MW ⁽ⁱ⁾	0.0288	0.978	0.0205	0.839	0.0164	0.900
JITL	0.0537	0.923	0.0201	0.845	0.0245	0.776
MW _{tr}	0.0149	0.994	0.0153	0.910	0.0135	0.931
AdJITL_{TT}-MW_{tr}	0.0116	0.996	0.0138	0.926	0.0120	0.946

ⁱ: Test results for MW, JITL and MW_{tr} are taken from a previous study [5].

Figure 1. RMSE values for the test set obtained using AdJITL_{TT}-MW_{tr} with $K = \{10, 20, \dots, 50\}$ and $C = \{3, 4, 5\}$ for (A) DC ($W=3$), (B) H₂S in SRU ($W=2$), and (C) SO₂ in SRU ($W=2$) datasets. No adaptation refers to using the NN samples directly, i.e. skipping the adaptation step (Section 4.1), in JITL_{TT}-MW_{tr}.

Abstract

In power grid operation, optimal power flow (OPF) problems are solved several times per day to find economically optimal generator setpoints that balance given load demands. Ideally, we seek an optimal solution that is also “ $N-1$ secure”, meaning the system can absorb contingency events such as transmission line or generator failure without loss of service. Current practice is to solve the OPF problem and then check a subset of contingencies against heuristic values, resulting in, at best, suboptimal solutions. Unfortunately, online solution of the OPF problem including the full $N-1$ contingencies (i.e., two-stage stochastic programming formulation) is intractable for even modest sized electrical grids. To address this challenge, this work presents an efficient method to embed $N-1$ security constraints into the solution of the OPF by using Neural Network (NN) models to represent the security boundary. Our approach introduces a novel sampling technique, as well as a tuneable parameter to allow operators to balance the conservativeness of the security model within the OPF problem. Our results show that we are able to solve contingency formulations of larger size grids than reported in literature using non-linear programming (NLP) formulations with embedded NN models to local optimality. Solutions found with the NN constraint have marginally increased computational time but are more secure to contingency events.

Keywords: Optimization, Machine Learning, Neural Networks, Power Grid Modeling

1. Introduction

1.1 Background

Power grids are very large, complex systems that require operation that is both financially optimal and secure to unforeseen outage events. The US Federal Energy Commission estimates that effective optimization of power grids can save tens of billions of dollars annually (Cain et al. 2012). Furthermore, the need for powerful optimization tools will only increase as more renewables and non-conventional energy sources are added to the grid. This is largely done via optimal power flow (OPF) programs which balance real-time load demands with generator outputs in the most economically optimal way. Some approaches to solving OPF include rigorous formulations with non-linear and non-convex functions (AC-OPF), convex relaxations

of this problem (e.g. Second Order Cone OPF), and linear approximations (e.g. DC-OPF) that are standardly used in industrial applications. In the case of AC-OPF, further distinction can be made between local and global solution algorithms due to non-convexities. This work focuses on the optimization of the rigorous AC-OPF formulation with local solvers, since it can handle large problems without approximating underlying power flow physics and very often achieves solutions close to global optimality (O'Neill et al 2012).

As grids are operated close to their optimal points (i.e., less conservatively), security must be considered as they are more prone to system component failure that may result in serious financial and safety consequences. Operating at suboptimal set points will yield significant cost increases, whereas economically-optimal though insecure set points have potentially catastrophic consequences under a contingency event, as cascading failures can cause blackouts for millions of people. Therefore it is incumbent upon system operators to balance these interests effectively. One way to check system security is to simulate system failures and enforce the resulting security of the system as constraints. If this is done for every component in the system, it is said to be *N-1* secure. While the scalability and accuracy of AC-OPF algorithms have seen major improvements for both local and global techniques, ensuring *N-1* security remains challenging. The current practice is to solve the OPF problem without consideration of contingencies, and then check the solution for *N-1* feasibility. If the solution is not feasible, heuristics are used to add constraints to the OPF problem, and the process is repeated. This approach yields suboptimal results, and since only a subset of the contingencies is typically checked, this may also yield insecure results. While it is possible to formulate a two-stage stochastic programming problem that considers all contingencies, this large scale problem is not tractable for realistic networks. This work aims at solving security constrained (SC) AC-OPF problems with the aid of deep Neural Networks (NN) that can be trained offline to learn the input space of the original optimization problem that is *N-1* secure. The trained NN model can then be used as a single constraint to enforce *N-1* security of any resultant AC-OPF solution across the input space and contingency events.

1.2 Literature Review and Contribution

Capitanescu et al. (2011) provide a thorough review of previous research in the area of SC OPF and future methods that may address some of the challenges detailed above. Heuristic methods are frequently used in practice, but more robust relationships can be derived as algebraic constraints. However, due to the problem size and complexity, fully detailed formulations remain intractable and often reduced or simplified techniques are required. Gutierrez-Martinez et al. (2011) trained non-linear regression models and single layer NN models to find the security boundary of a given load profile for the worst case contingency. Our work builds on this by using deep NN models as a map of the secure and insecure space of all contingencies of interest, variable generation patterns, and higher dimensional representations of the security boundary. Velloso et al. 2020 replace the full SC AC-OPF with a NN model that includes physics-based constraints via a Lagrangian-dual. Venzke et al. (2020) trained a NN security classifier with ReLU activation functions and added the constraints to the AC-OPF problem as a set of linear constraints with binary variables that results in a mixed-integer non-linear program (MINLP). They linearize the power equations to convert this to a MILP. This work instead maintains the non-linearity of the NN based security-constraints and formulates the overall problem instead as a nonlinear program (NLP) that can be solved efficiently via interior-point methods. Some key advantages of our approach include: (a)

computationally challenging security simulations are performed offline, (b) security is represented by a single NN constraint without integer variables, (c) the fully detailed AC-OPF formulation is used, (d) the security constraint scales linearly with grid size, and (e) our method is implemented within the Pyomo platform that enables easy integration with Python-based algorithms for training ML models.

2. Overview of Methods

2.1. AC Optimal Power Flow Problem Formulation

Below, the AC-OPF formulation used in this work is given. Real power, reactive power, voltage magnitude and voltage angle are denoted by p , q , v and θ respectively. N and K denote the sets of all nodes and branches in the system.

$$\text{Min } C(p^g) \quad (1)$$

$$\text{s. t. } \sum_{k(n,m) \in K_n^{\text{out}}} p_{k(n,m)}^f + \sum_{k(n,m) \in K_n^{\text{in}}} p_{k(n,m)}^t - p_n^g + p_n^d = 0, \quad \forall n \in N \quad (2)$$

$$\sum_{k(n,m) \in K_n^{\text{out}}} q_{k(n,m)}^f + \sum_{k(n,m) \in K_n^{\text{in}}} q_{k(n,m)}^t - q_n^g + q_n^d = 0, \quad \forall n \in N \quad (3)$$

$$p_{k(n,m)}^f = g_k v_n^2 - v_n v_m (g_k \cos \theta_{n,m} + b_k \sin \theta_{n,m}), \quad \forall k \in K \quad (4)$$

$$p_{k(n,m)}^t = g_k v_m^2 - v_n v_m (g_k \cos \theta_{n,m} - b_k \sin \theta_{n,m}), \quad \forall k \in K \quad (5)$$

$$q_{k(n,m)}^f = - (b_k + b_k^{\text{sh}}) v_n^2 - v_n v_m (g_k \sin \theta_{n,m} - b_k \cos \theta_{n,m}), \quad \forall k \in K \quad (6)$$

$$q_{k(n,m)}^t = - (b_k + b_k^{\text{sh}}) v_m^2 + v_n v_m (g_k \sin \theta_{n,m} + b_k \cos \theta_{n,m}), \quad \forall k \in K \quad (7)$$

$$v_n^{\text{min}} \leq v_n \leq v_n^{\text{max}}, \quad \forall n \in N \quad (8)$$

$$\theta_{nm}^{\text{min}} \leq \theta_n - \theta_m \leq \theta_{nm}^{\text{max}}, \quad \forall \{n, m\} \in K \quad (10)$$

$$p_n^{\text{min}} \leq p_n \leq p_n^{\text{max}}, \quad \forall n \in N \quad (11)$$

$$q_n^{\text{min}} \leq q_n \leq q_n^{\text{max}}, \quad \forall n \in N \quad (12)$$

$$(p_k^f + q_k^f)^2 \leq (\text{Thermal Limit})^2, \quad \forall k \in K \quad (13)$$

$$(p_k^t + q_k^t)^2 \leq (\text{Thermal Limit})^2, \quad \forall k \in K \quad (14)$$

Eq 1 minimizes the cost of real power at generator buses. Eqs 2-3 represent the nodal power balance derived from Kirchoff's Law. Power flow through each branch is given in Eqs 4-7. Finally, Eqs 8-14 ensure the AC-OPF solution is secure with no contingencies ($N-0$). To check static $N-1$ security of an AC-OPF solution, (v_n, p^g) are set for all generators, (p^d, q^d) for all loads, and (v_n, θ) at the reference bus. Then under each contingency in a given set, the specific element is taken out of the system (e.g., broken line) and Eqs 2-7 are re-solved, without the objective function. If a solution is found that satisfies Eqs 8-14, the solution is secure to that contingency. If this is true for all contingencies, the system is said to be $N-1$ secure. An extensive formulation guaranteeing $N-1$ security requires a scenario for each contingency, leading to a very large non-linear two-step stochastic programming problem. In this work, we train a NN

to capture the $N-1$ security boundary and then embed this NN into the AC-OPF formulation.

2.2. Sampling and Data Set Construction

While one major advantage of this approach is to shift computational costs to offline contingency simulations, it is still necessary to have a methodology that samples data points in an intelligent manner. The input space for the problem is very large with a majority of points far from the security boundary. In order to train a NN model that effectively distinguishes these regions, many points must be generated on the security boundary itself in addition to secure/insecure points. Our sampling algorithm presented below.

Sampling Algorithm for Boundary Points

```

Load_Factors=[LFmin,...,LFmax], Load_Dirs=[LD-0, ..., LD-j]
for LF in Load_Factors:
    sol=Solve_ACOPF( $p^d * LF$ , Power Factor =  $p^d / (q + p^d)^2$ )
    ysec=check_Nmin1(sol) (check N-1 compliance of baseline sol'n)
    for j in Load_Dirs:
        while ysec=True: (continue until no longer N-1 secure)
            sol=solve_acopf( $p^d * LD^{-j} * 1.1$ )
            ysec=check_Nmin1(sol)

```

A set of load factors is constructed between maximum and minimal values that give $N-0$ security. For each of these load factors, an AC-OPF problem is solved given this load profile, and the resulting model is used to check $N-1$ contingencies via the method described in Section 2.1. If the system is $N-1$ secure, the load vector is ramped up by 10% increases until the security check fails. The points directly before and after failure are saved to enhance boundary classification. This is done for all LF's, several load ramping directions (normalized vectors generated via Latin Hypercube sampling), and variable generation patterns (i.e.. variable generator costing parameters) resulting in an increased set of boundary data points. Intermediate solutions that satisfy $N-1$ contingency are saved as secure and points that are infeasible for AC-OPF are saved as insecure to complement the boundary data. This approach provides a set of points that straddle the security boundary, producing a more balanced and targeted training set.

2.3. Neural Network Model Training

Using the constructed data-set, the next stage is to train a NN model that can predict whether a given AC-OPF solution is $N-1$ secure. An important decision is the selection of input variables. The real power setpoints at generators (p^g) are included as they are the ultimate variables in the objective function of AC-OPF, allowing for a direct mapping. Power load (p^d) at all buses are also included since they have a strong correlation with grid security and improve NN accuracy. Thus, the input space of the NN model scales linearly with the number of buses and generators. More input variables may augment NN accuracy in future cases but didn't show strong independent correlation with system security. The Sequential model from Tensorflow's Keras is used as the basis for the feed-forward NN model. It is composed of two hidden layers of 20 nodes each and hyperbolic tangent activation function plus a softmax output layer. Output variable y_{sec} was set to 1 for insecure points and 0 for secure points. ADAM

optimizer was used with a standard cross-entropy loss function. Training continued until validation error plateaued or 4000 epochs were reached.

2.4. Constrained Optimization Formulation

The trained NN can now be thought of as a large non-linear constraint that must be satisfied in order to return an AC-OPF solution that is secure under all contingencies. The NN constraint can be added to the original optimization problem (Eqs 1-14) to encode $N-1$ security.

$$y_{sec} = NN(\{p^d\}, \{p^g\}) \tag{15}$$

$$y_{sec} \leq \alpha \tag{16}$$

Using the trained weights and biases of the NN, Eqs 15-16 are embedded within the AC-OPF model from Egret using Pyomo symbolic equation construction (Knuevan et al 2019). The resulting constraint is fully differentiable and able to be solved with IPOPT. Parameter α is a scalar that controls the constraint conservativeness.

3. Results

Two case studies are used to demonstrate the method: the first (Case 30) contains 30 buses, 6 generators, 21 loads, and 41 branches. The contingency set includes branches {1, 2, 3, 6, and 10}. The next (Case 118) contains 118 buses, 54 generators, 99 loads, and 186 branches. The contingency set includes branches {55,168,169,171,172,173,175}. The contingency set is selected during the sampling process by eliminating contingency events that always make the system insecure or never pose an issue to security. The unconstrained AC-OPF returns a solution that is not $N-1$ secure for 45% of the sampled points for Case 30 and 64% for Case 118. This proves that standard AC-OPF is inadequate for considering grid security. With the NN constraint, the vast majority of insecure operating conditions can be identified and avoided. The control of conservativeness by α can be illustrated through a receiver operator curve (ROC) which shows the false positive and true positive rate of the NN classifier. Figure 1 shows the ROC results for the NN classifier with the full training set and for a model with half the training data.

Figure 1. Receiver Operator Curve (ROC) Results (Case 118)

Again, there is an expected trade-off between conservativeness and accuracy. While a high true positive rate allows us the most confidence in grid security, the accuracy trade-off would be important to tailor to the specific grid application. For an α value of 0.5, model accuracy is 89%, much better than base case AC-OPF. The results for Case 30 show nearly identical behavior on the ROC. Another important factor to consider is

computational time of the proposed approach, where it distinguishes itself from the extensive formulation. Literature values for Case 118 take ~400 sec to run SC AC-OPF (Kang et al 2015) on a single processor of Sandia's Red Mesa supercomputer. Our NNSC AC-OPF approach never exceeds **15 sec for all points, with an average of 7 sec.**

One more important thing to consider is the effect of the security constraint on the objective function. We can quantify the cost of incorporating the NNSC constraint by considering the change in objective function value compared to the base case AC-OPF. In order to distinguish meaningful cost increases (to preserve security) from an overly conservative NNSC, models are tested with points that are base case secure and insecure. Increases in the objective function are negligible for over 70% of secure test points and the majority of remaining points constitute increases of less than 5%. This shows that α of 0.5 does a good job of not being overly conservative with respect to security. For insecure inputs, the objective function increases up to 50% in order to meet the NNSC constraint. These solutions come with far greater confidence about security under contingency but also come at an economic cost. Further comparisons with the extensive formulation and cost/risk strategies would be needed to definitively set α in real-world applications.

4. Conclusions

Power grid optimization and security is a vital area of research that can help save money, avoid black-outs, and promote the integration of non-traditional energy sources onto the grid. Using detailed simulations, it is possible to optimize very accurate models of power grids using non-convex/non-linear formulations such as AC-OPF. Adding security constraints for all N-1 contingencies to this problem is computationally challenging and extensive formulations are intractable in large-scale grids. This work addresses this challenge by approximating security constraints with a NN model that can be trained offline and then embedded within a Pyomo-based model as a single non-linear constraint. Results show that this approach can accurately estimate the security boundary and provide a framework to balance optimality and security of system set points. The NLP formulation allows for computationally tractable solutions even for large grids.

The impact of CO₂ pricing in SC Resilience – An optimisation model

João Pires Ribeiro^{a,*} and Ana Barbosa-Póvoa^a

^a*Centre for Management Studies, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais 1, 1049-001 Lisboa, Portugal*
pires.ribeiro@tecnico.pt

Abstract

Environmental and resilience are currently vital concerns when managing Supply Chains (SC). Doing so in a competitive setting, with diverse stakeholders' perspectives and dealing with unforeseen disruptive events is challenging. Today, this is a reality where, with the actual COVID-19 pandemic, supply chains face reduced demand and stoppages at different levels, calling for the urgent need to invest in designing and planning resilient SC. But resilience must not leave apart other vital goals as is the environmental goal, which nowadays requires special attention. This is especially critical in the process industries where environmental concerns are often at stake. We address this challenge in the current work by representing the cost associated with CO₂ emissions, considering the EU emissions trading system (EU ETS). This system makes the cost associated with emissions a variable value attributed by the market. A Mixed Integer Linear Programming model (MILP) is here presented which allows to understand the supply chain resilience of different supply chain structures. This is done with the objective of maximising the Expected Net Present Value (ENPV) while facing disruptions, and the presence of uncertainty in demand is considered. The results show that our model can help decision-makers to create resilient SC with good environmental behaviour and without compromising financial results.

Keywords: Supply Chain Resilience, CO₂ Emissions, Modelling

1. Introduction

Supply chain (SC) Resilience comes as a recent offspring of Supply Chain Management (SCM), with most of the attention only being given in recent years. Even with a multitude of definitions, one can define such behaviour as follows: "a resilient supply chain should be able to prepare, respond and recover from disturbances and afterwards maintain a positive steady-state operation in an acceptable cost and time" (Ribeiro and Barbosa-Póvoa, 2018). It is a field of study with research gaps to explore (Kamalahmadi and Parast, 2016), thus adding knowledge and simultaneously know-how on SCM. One of these research gaps is related to the inclusion of green concerns with economic goals (Fahimnia and Jabbarzadeh, 2016).

The European Union (EU) has set an objective to reduce 80% of CO₂ emissions by 2050 (having 1990 levels as a reference value). To achieve this goal, one of the policy frameworks underway is the European Union Emissions Trading System (EU ETS).

Through this framework, also known as the "cap-and-trade" system, a maximum limit is imposed on the amount of greenhouse gases emitted. This limit is reduced over time so that total emissions are continuously decreasing. Within this set, organisations can buy emission allowances, which, as the name indicates, allow for a certain amount of CO₂ emissions. If the organisation is able to stay under the estimated emissions level, it can sell and trade these allowances or keep them for future needs. Allowances have become commodities, and auctioning is the default method for allocating them. Its value has been rising over the last year, currently reaching +153% of the reference value that existed until mid-2018, showing the utmost importance of considering CO₂ costs in the supply chain decision-making process.

It is then very relevant to explore the coexistence of environmental and resilience concerns when designing and planning a SC (Jabbarzadeh et al., 2018), even more in process supply chains where the environmental impacts are often a considerable concern (Barbosa-Póvoa et al., 2018). This study comes in a time of great pertinence to practitioners that are now making long-standing decisions in their SC, with the changes that arrive from new trends that complement the sustainability as is adaptability to new markets trends at a very fast pace. This type of decisions tends to be complex, with significant investments and implemented in the long term, adding special necessity for decision aiding tools regarding strategic and tactical decisions.

This paper addresses this need and develops a strategic optimisation model that explores the relationship between Resilience and Green goals when designing and planning SC. A relationship that has failed to reach a consensus on its merits and benefits for companies. If on the one hand, sustainability tends to reduce flexibility and redundancy, crucial for SC Resilience, on the other circular economy principles can add responsiveness to the SC. Here we aim at exploring the relationship between the two concepts and test if sustainability and resilience are compatible in SC.

A European SC case study is studied, applying the new model where resilience and environmental concerns are considered, apart from the common SC profit. The strategic decisions regarding SC's design and planning are modelled in three periods of five years, leading the model to a 15-year time-span. Useful managerial insights are obtained to help in the process of acknowledging the full impacts of disruptive events in the fitness of operations under different scenarios and consequently, how much can proactive management contribute to a competitiveness advantage.

2. Problem Characteristics and Model description

The SC to be modelled is generic and involves five different echelons: Raw Materials Suppliers, Plants, Warehouses and Markets and with the possibility to outsource the production of final products and provide direct shipment to warehouses (see Figure 2). It allows for direct flows, transshipment in plants and warehouses, direct flows between warehouses and markets, and it also includes the possibility of reverse flows. Three types of reverse flows are considered: Non-conforming products that go from the markets to warehouses to be repacked and introduced in the forward SC; End-of-life products that are collected, when the expected lifetime of the product is reached, and are refurbished to be introduced in the forward SC; The products that fail to be refurbished are sent for disposal. Two different cases are considered: Case A, with only forward flows (in grey),

and Case E a Closed-Loop SC, with forward and reverse flows (in grey and orange).

When studying resilience, there is the need to define disruptions on which to test the model, an activity that can prove itself challenging. One must define disruptions that represent a broad set of possible disruptions without falling into the error of defining disruptions that are too specific. Disruptive events are associated with some kind of unknowns in terms of risks. By choosing a type of disruptive events, it is possible to generate a representative set of disruptions that meet the objective of providing generic, but useful, results. These disruptions are then studied on each run of the model, as will be detailed below.

The environmental impacts are assessed using the Life Cycle Assessment (LCA) approach. The system boundary defined is cradle to gate and the functional units considered are one kilogram of product and one kilometre travelled. The SimaPro software was used to determine the climate change impact (in CO₂ equivalent) from: truck transportation in forward flows (per kg.km); truck transportation in reverse flows (per kg.km); final product production (per kg of product).

In combination with the cost of 1 Kg of CO₂, these parameters are used in the model to quantify the SC's environmental impact.

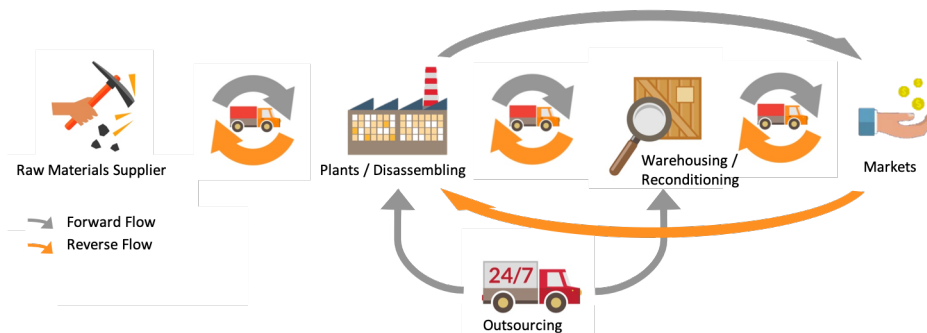

Figure 1: A schematic characterisation of the SC, with its echelons and allowed flows.

Taking as point of origin the work published by Cardoso et al. (2015), the model here presented adapts to create a new model to fulfil the research objectives, described in the introduction, while maintaining the possibility of comparing and discussing the current results with previous results. The model possesses relevant characteristics. It includes a closed-loop SC, with forward logistics and reverse logistics and entails uncertainty, relevant when considering the time span needed for tactical and strategic decisions. Uncertainty is considered in the SC demand and on disruptions. A scenario tree is constructed, combining these two sources of uncertainty. Demand variability is introduced by generating a scenario on each period from a set of three possibilities (Pessimistic, Realistic or Optimistic). The probabilistic nodes are then combined with the variability from the disruption that can only assume two options, or it occurs, or it does not occur in a specific time period to consider. With this, each scenario probability is given by the path's probabilities, with all stages, between the root node and each final leaf node. The proposed model relies on maximising Expected Net Present Value (ENPV), also considering environmental costs, under a set of disruptions and uncertainty.

$$\max \text{ENPV} = \sum pb_s \times \text{NPV}_s \quad (1)$$

Expected Net Present Value (ENPV) is calculated considering each scenario probability (pb_s), in the scenario tree, using cash flows and an interest rate. The net earnings come from the difference between the income (Sales revenue) and the costs (the refunds from non-conforming products, purchases, operational, inventory, transportation, depreciation of invested capital considering taxes, and the environmental costs defined in Equations 2 and 3. Two environmental cost equations are considered, one to account for transportation, Equation 2, and another to account for the production of final products, Equation 3. The costs of the environmental impact of transport are given by the summation of emissions (Kg.km CO₂ eq) associated with forward (*envfactorforward*) and reverse flows (*envfactorreverse*) multiplied by the quantities shipped in forward (*QPL*) and reverse flows (*QNC* for non conform products and *QEL* for end-of-life products) multiplied by the cost of emitting one kg of CO₂ (*CO₂Cost_t*) and the distance between the two locations (*FIPL_{v,w}*), that is given by Equation 2:

$$\begin{aligned} \text{TranspCO}_2 = \sum_t (\text{CO}_2\text{Cost}_t \cdot (& \sum_{s,v,w,p,t} (\text{QPL}_{v,w,p,s,t} \cdot \text{FIPL}_{v,w} \cdot \text{envfactorforward}) + \\ & \sum_{s,v,w,p,t} (\text{QNC}_{v,w,p,s,t} \cdot \text{FIPL}_{v,w} \cdot \text{envfactorreverse}) + \\ & \sum_{s,v,w,p,t} (\text{QEL}_{v,w,p,s,t} \text{FIPL}_{v,w} \cdot \text{envfactorreverse}))) \quad (2) \end{aligned}$$

The cost of production emissions is given by the summation of emissions when a specific product p is produced multiplied by the cost of emitting one kg of CO₂, which is given by Equation 3. Emissions for reverse product flows are expected to be lower than those that are produced directly from raw materials:

$$\text{CO}_2\text{prodtot} = \sum_t (\text{costCO}_2t \cdot \sum_p \text{CO}_2\text{eachp}_p) \quad (3)$$

The opinions diverge on the behaviour of the price of CO₂ emission in the long term since there are two sets of factors that are plausible to happen, and that affects the price of CO₂ in different directions. If in one hand, it is expected a continuous effort to reduce CO₂ emissions and therefore the public efforts to force companies to reduce CO₂ emissions. On the other hand, these efforts can lead to the decarbonisation of the economy that drastically reduces demand for CO₂ allowances. Considering these effects, three scenarios were generated:

Stable scenario - The CO₂ prices are kept constant at 27,1e/ton

Up and Up scenario - The CO₂ prices are expected to rise in each time period.
t1=27.1e/ton t2=40e/ton t3=50e/ton

Up and Down scenario - The CO₂ prices increase in the shorter term but go down again in the longer term. t1=27.1e/ton t2=40e/ton t3=27.1e/ton

Apart from the above objectives function the model involves a set of constraints (entity capacity constraints, transportation constraints, technology constraints) so as to correctly and thoroughly model the SC. This formulation can be explored in further detail in (Cardoso et al., 2013).

3. Case Study

The model is applied to a European SC that is interested in the improvement of its network design. The initial network relies on one plant in Hamburg with the possibility of opening new plants in Bilbao and/or in Milan. Each one of the new plants has a set of suppliers associated. There is also the possibility to open new warehouses or to upgrade the already existing ones. The activities performed by each entity are categorised as production technologies, that result in intermediate products; and assembling technologies, that combine products and result in the final products. Reverse logistics is implemented by disassembling technologies that can use final products (as defined in the Model description) to generate intermediate products.

In this work, the SC will be tested under a reference scenario, where no disruption occurs, and three types of disruptions frequently used and as defined by Rice and Caniato (2003):

Disruption 1: Supply - 100% decrease in the production capacity of the most important plant in time period 2, located in Milan.

Disruption 2: Production - The most important raw material suppliers have their supply suspended in time period 2. These suppliers are located in Birmingham, Badajoz, Marseille, Ljubljana and Lausanne.

Disruption 3: Transportation - The flows that carry the highest quantity of products are stopped in time period 2. In this case study that represents the flows from the factory in Milan to warehouses in Munich, Portsmouth and Bologna.

The disruptions are implemented in the model by not allowing flows between the identified entities, as described above.

4. Results and Discussion

The results of our model related to the ENPV are present in Table 1. Disruption 2 is the one that most affects the SC, as it has the lowest ENPV results (around 0,30E+07€) for both chain configurations as well as for the three cost evolution scenarios of CO₂. On the other hand, disruption 3 is the one that least affects the system, with results very similar to the scenario without disruption in the case of forward SC, Case A. In the closed-loop SC, Case E, there is a decrease in ENPV. However, it ends up having economic results always greater than Case A.

Table 1: Expected Net Present Value (ENPV) for all scenarios and disruptions

ENPV (€)	Case A - Forward Supply Chain			ENPV (€)	Case E - Closed-Loop Supply Chain		
	CO ₂ emissions cost scenarios				CO ₂ emissions cost scenarios		
	Stable	Up & Up	Up & Down		Stable	Up & Up	Up & Down
No disruption	1,74E+07	1,32E+07	1,42E+07	No disruption	1,86E+07	1,51E+07	1,61E+07
Disruption 1	1,49E+07	0,99E+07	1,12E+07	Disruption 1	1,74E+07	1,33E+07	1,42E+07
Disruption 2	1,40E+07	0,89E+07	1,03E+07	Disruption 2	1,72E+07	1,35E+07	1,41E+07
Disruption 3	1,74E+07	1,32E+07	1,42E+07	Disruption 3	1,77E+07	1,43E+07	1,52E+07

From Table 2, a clear conclusion is that Forward SC (Case A) have a higher CO₂ cost than SC with circularity principles (Case E). In cases where there is an increase in cost, this difference is about 1E06€ when there is no disruption and greater than 2E06€ in disruptive scenarios.

Table 2: Total CO_2 cost for all scenarios and disruptions
 Case A - Forward Supply Chain Case E - Closed-Loop Supply Chain
CO₂ emissions cost scenarios *CO₂ emissions cost scenarios*

CO_2 Prod (e)	Stable	Up & Up	Up & Down	CO_2 Prod (e)	Stable	Up & Up	Up & Down
No disruption	1,86E+06	6,15E+06	5,13E+06	No disruption	1,46E+06	5,38E+06	4,50E+06
Disruption 1	1,91E+06	8,07E+06	6,54E+06	Disruption 1	1,54E+06	5,51E+06	4,66E+06
Disruption 2	1,90E+06	8,03E+06	6,51+06	Disruption 2	1,50E+06	5,53E+06	4,86E+06
Disruption 3	1,86E+06	6,16E+06	5,13E+06	Disruption 3	1,41E+06	5,21E+06	4,26E+06

From the interpretation of our results, it can be said that the environmental concern approach compensates, even more, when the price of CO_2 is expected to continue to rise. That is seen for Case E, not only is the return greater (ENPV), but the difference with the scenario without disruption is less. Thus, the variability introduced by disruptions is also reduced.

The best result of Case E is mostly due to the fact that the environmental concern translates into a reduction in long-distance transport and a greater investment in facilities close to each other. This measure will increase resilience in the sense that it increases redundancy and flexibility, with more production facilities and more possible flows. The circular economy principles are also crucial, the production of final products from the reuse of end-of-life products leads to less dependence of factories on raw materials suppliers while reducing the total CO_2 associated with a given product.

Case E brings not only a higher return on ENPV but also a lower CO_2 cost, which provides a fantastic opportunity for companies to take advantage of environmental concerns/obligations to build a more resilient SC.

Abstract

Organic solvent nanofiltration (OSN) is one of the most anticipated separation technologies that provides wide-ranged industrial applications such as solvent recovery, solute concentration, and diluent separation. Despite of technical merits of the OSN technology, the numerous characteristics and perplexing nonlinearity on the OSN system have been a critical obstacle for understanding the governing principles, thereby prohibiting practical deployments. Recently, machine learning (ML) based approaches have been widely used for the modelling, discovery and optimization of complex design problems in chemical engineering area such as catalysis, electrochemistry and physicochemical systems. Therefore, this study aims to develop a new ML-based approach for modelling and optimizing the design scheme and operating condition of the OSN system. By collecting commercial OSN data through literatures reviews, the major descriptors for the prediction of the OSN membrane, such as MWCO, solute mole weight, solute concentration, solvent parameter, temperature, pressure, flux, were defined. We then screened noises and outliers of the collected data to ensure a high and consistent density and uniqueness. Support vector machine (SVM) was implemented as a prediction models to simulate the OSN performance and identify the optimal conditions as well as the process scheme. As a result, the optimal operation strategies (i.e., pressure, temperature and solvent and solvent types) were analyzed to meet the targeted specification of the OSN system (mass flux and rejection rate). The proposed ML-based approach can promote a real-world OSN application by reducing a number of time-consuming and expensive experiments for establishing OSN design and operation strategy.

Keywords: Organic Solvent Nanofiltration, Machine learning, Separation, Optimization

1. Introduction

Organic solvent nanofiltration (OSN) is one of promising separation technologies that provide economic and technical benefits compared to existing technologies (e.g., distillation) in petrochemical industries. To accelerate the practical deployment of the OSN technology, A number of studies have been reported in literature from a new material discovery to operation research in real industries.

To facilitate the industrial acceptance and real deployment of novel OSN membrane, precise modeling methodologies should be accompanied, such as conventional the principles of thermodynamics and transport phenomenon. However, due to a huge number of design combinations with different solvents, solutes and membrane materials, predicting performance using first principles of thermodynamics and transport phenomenon requires a number of time-consuming and expensive experiments.

Machine learning (ML) is one of artificial intelligence methods, which have widely used for modeling and predicting multi-dimensional and quite complex systems. Screening out possible metal-organic frameworks (MOF) structure and predicting lifespan of Li-ion battery are salient examples of ML technique employment. Likewise, the emergence of ML techniques on the OSN performance prediction problems has brought about advancements and has become relatively accessible by other disciplines.

In this study, a new machine learning-based approach is developed to identify the optimal design strategy and operation condition of the OSN membrane. 884 OSN membrane datasets are collected and curated to define main descriptors of OSN membrane. Support vector machine (SVM) is then employed to predict the performance of OSN membrane using key descriptors affecting the membrane permeance and rejection, which were obtained through principal component analysis (PCA).

2. Method

2.1. Overview

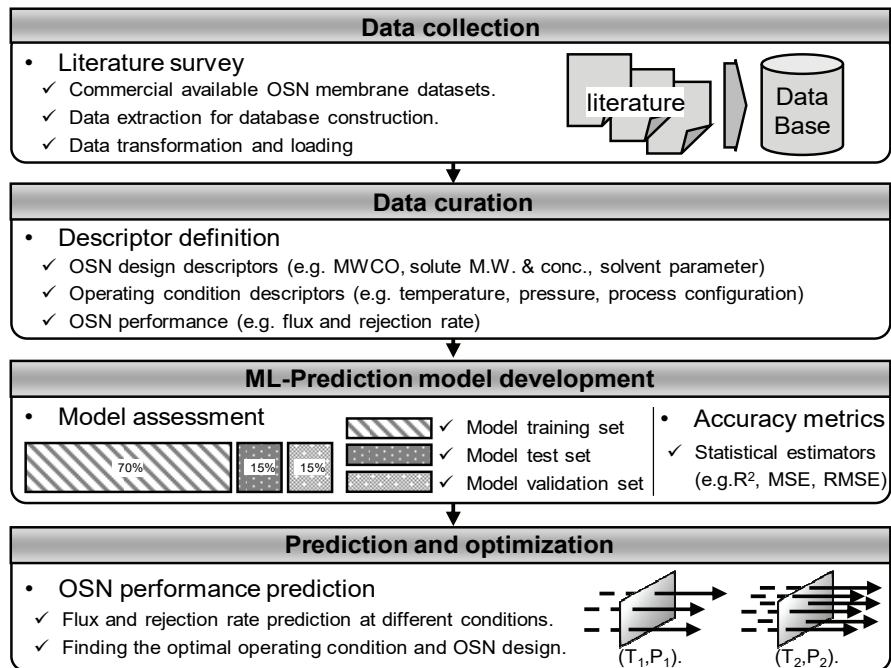

Figure 1: Overview of machine learning-based approaches on the OSN membrane performance prediction and optimization.

The main steps of this study are illustrated in Figure 1. The commercial OSN membrane data is collected from literatures. Datasets include OSN membrane characteristics such as material properties, operating condition, and OSN membrane performances. Among many OSN characteristics, critical OSN descriptors (e.g. molecular weight cut-off, solute mole weight, solute concentration, characteristic solvent parameter, temperature, pressure, process configuration, flux, and rejection) are defined from data curation step. Then, datasets are separated into training sets, validation sets, and test sets in order to verify the capability of prediction model. In this research, prediction model is developed by using the SVM. For prediction capability evaluation, three statistical estimators such as R^2 , MSE, RMSE are used. Finally, from predicting OSN performances (flux and rejection) at different conditions, the optimal operating condition and OSN design are qualitatively analysed by using the PCA.

2.2. Data description

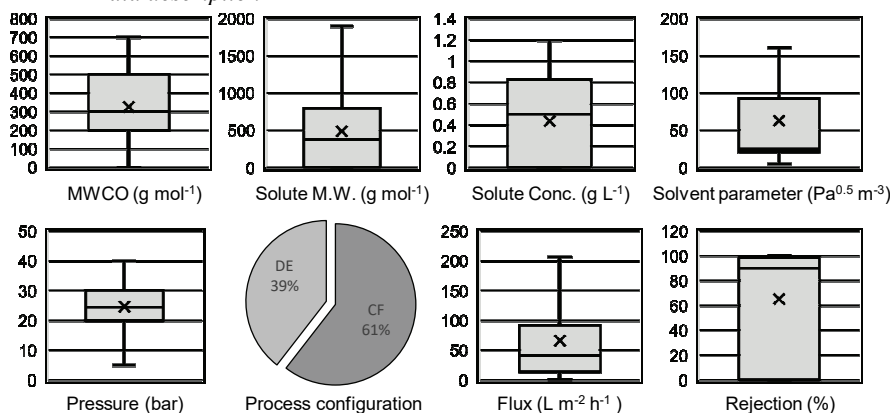

Figure 2: Distribution of OSN descriptors.

The distribution of OSN descriptors is illustrated in Figure 2. Descriptors are varied as followed: MWCO (150-1000 g mol^{-1}), solute mole weight (0-1900 g mol^{-1}), solute concentration (0-1.2 g L^{-1}), characteristic solvent parameter (5-160 $\text{Pa}^{0.5} \text{m}^{-3}$), pressure (20-60 bar), process configuration (dead-end, cross-flow), flux (1-416 $\text{L m}^{-2} \text{h}^{-1}$), rejection (0-100 %). For temperature, most test were experimented at 25°C.

2.3. Support vector machine (SVM)

The SVM is a prominent ML technique for regression and classification analysis. By representing datasets in multidimensional descriptor space, the regression hyperplane is created. The mathematical model and constraint are described in Eqns. 1 and 2, respectively.

$$\min_{\alpha, \alpha^*} \frac{1}{2} (\alpha - \alpha^*)^T Q (\alpha - \alpha^*) + \varepsilon \sum_i (\alpha_i + \alpha_i^*) + \sum_i y_i (\alpha_i + \alpha_i^*) \quad (1)$$

$$0 \leq \alpha_i, \alpha_i^* \leq C, \sum_{i=1}^l (\alpha_i - \alpha_i^*) = 0, i = 1, \dots, l \quad (2)$$

To ensure a high accuracy of the prediction model, the hyperparameter is optimized by using a grid-search algorithm. Tables 1-3 compare the accuracy of major metrics by the SVM and the HO-SVM (Hyperparameter-optimized SVM).

Table 1: Accuracy comparison between SVM and HO-SVM on training set

Training set	R ²	MSE	RMSE
SVM (Flux)	0.939	155.120	12.454
HO-SVM (Flux)	0.985	69.135	8.314
SVM (Rejection rate)	0.959	77.001	8.775
HO-SVM (Rejection rate)	0.966	58.577	4.671

Table 2: Accuracy comparison between SVM and HO-SVM on validation set

Validation set	R ²	MSE	RMSE
SVM (Flux)	0.934	388.648	19.714
HO-SVM (Flux)	0.928	310.088	17.609
SVM (Rejection rate)	0.903	176.58	13.288
HO-SVM (Rejection rate)	0.940	107.286	10.357

Table 3: Accuracy comparison between SVM and HO-SVM on test set

Test set	R ²	MSE	RMSE
SVM (Flux)	0.914	397.255	19.931
HO-SVM (Flux)	0.923	305.099	17.467
SVM (Rejection rate)	0.906	175.139	13.234
HO-SVM (Rejection rate)	0.960	66.534	8.156

2.4. Principal component analysis (PCA)

PCA is a dimension reduction technique that represents and visualizes multi-dimensional data. From simplifying multi-dimensional descriptor space, the most important information could be extracted by PCA. In this work, the predicted performances of OSN membrane is visualized and the effect of descriptors is analysed by PCA technique.

3. Result

Flux and rejection of the OSN membrane are predicted at conditions of MWCO (150-300 g mol⁻¹), solute mole weight (300 g mol⁻¹), solute concentration (0.1-1.0 g L⁻¹), characteristic solvent parameter (0-100 Pa^{0.5} m⁻³), pressure (10-40 bar), temperature (25°C), and process configuration (cross-flow). In the PCA of both flux and rejection, four dimensions that cover 96% and 87 % data variance are obtained.

Table 4: PCA variance (dimension coverage) of each principal component on flux.

Flux	PC1 (%)	PC2 (%)	PC3 (%)	PC4 (%)
PCA variance	0.3695	0.2	0.2	0.2

Table 5: PCA variance (dimension coverage) of each principal component on rejection.

Rejection rate	PC1 (%)	PC2 (%)	PC3 (%)	PC4 (%)
PCA variance	0.2723	0.2	0.2	0.2

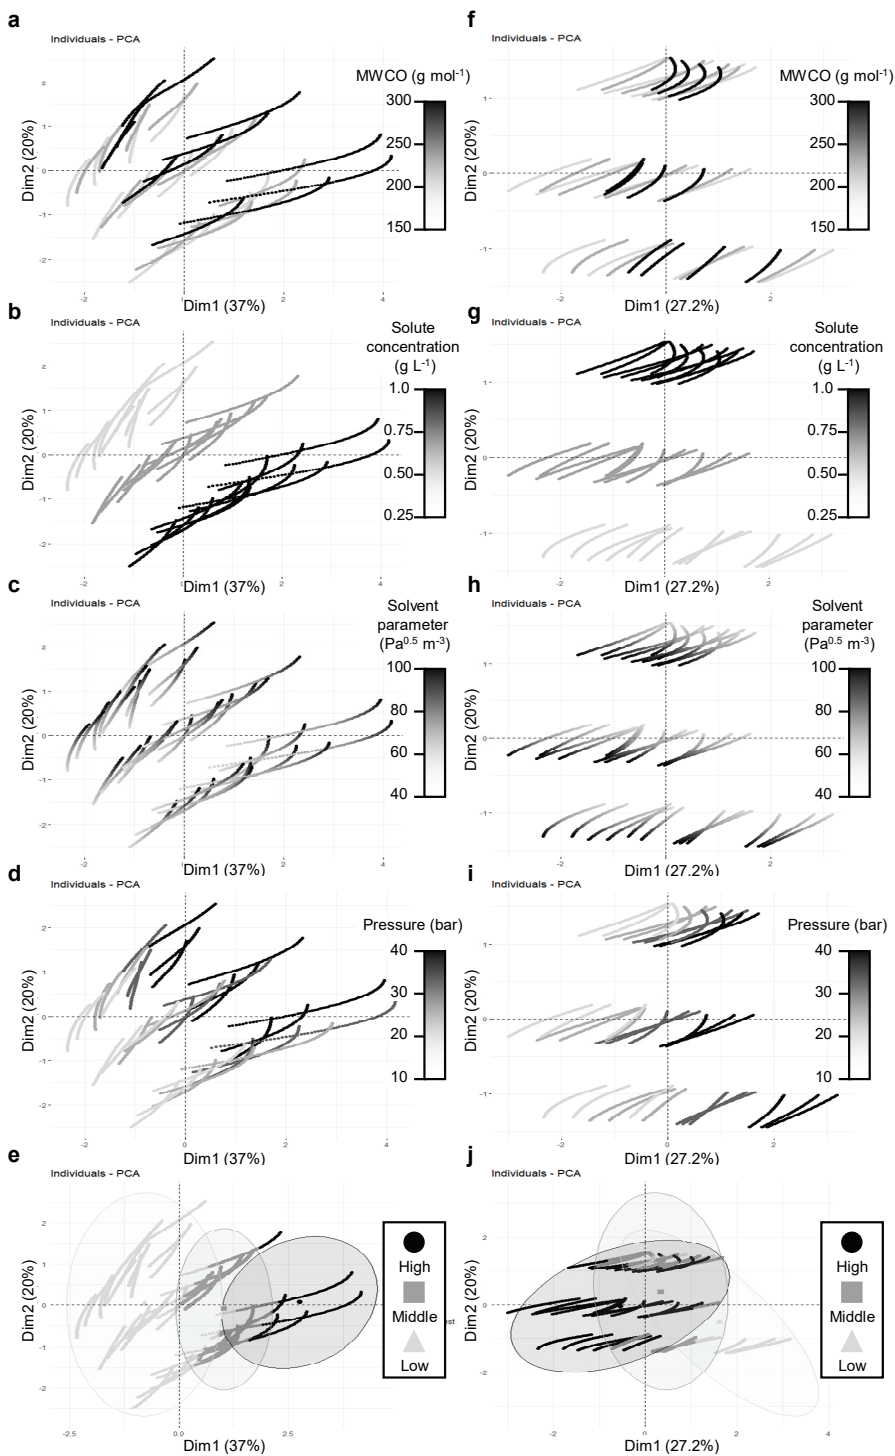

Figure 3: PCA results on OSN membrane descriptors; (a-d) and (f-i) for MWCO, solute concentration, solvent parameter, and pressure, respectively; (e) and (j) for flux and rejection, respectively. (a-d) representing (e) and (f-i) representing (j).

The effect of descriptors on OSN membrane performance is illustrated in Figure 3. In Figure 3 e and j, the flux and rejection rate are described and clustered. The level of OSN membrane descriptors is described in Figure 3 a-d and f-i, which are represented in flux and rejection rate dimension, respectively.

The flux and rejection rate are described in three different levels, which are divided by distribution of datasets. For flux, levels are high (more than $200 \text{ L m}^{-2} \text{ h}^{-1}$), middle ($100\text{--}200 \text{ L m}^{-2} \text{ h}^{-1}$), and low (less than $100 \text{ L m}^{-2} \text{ h}^{-1}$). As well as in rejection rate, levels are high (more than 90%), middle (80-90%), and low (less than 80%).

As shown in Figure 3 e, the clusters representing the flux level show that high flux datasets could be distinguishable from middle to low flux datasets. In case of the high-flux level, OSN membrane tended to have high MWCO (Figure 3 a), high solute concentration (Figure 3 b), and high pressure (Figure 3 d).

For the rejection rate in Figure 3 j, three different clusters are represented to analyse the effect of the major descriptors on the rejection rate. In particular, the high-rejection cluster was highlighted to distinguish the core OSN characteristics leading to the high rejection rate over the middle-and low-rejection rate clusters. On the other hand, it is also found that the OSN system with a low-concentration solute needs to be operated at low pressure to avoid low rejection rate.

4. Conclusions

The performances (flux and rejection rate) of the OSN membrane were predicted with the HO-SVM to investigate and understand the behaviour of the OSN system. In this study, using 9 main descriptors, including material properties and operation conditions, HO-SVM model predicted the OSN performance at different design specifications and operation conditions. As a result, it was found that i) a high-flux OSN could be accomplished by applying high MWCO, high solute concentration, and high pressure and, ii) the operation strategies to ensure high rejection rate in the OSN membrane (e.g., low-pressure operation for low-concentration solute) was analysed. Based on this study, the fundamental knowledge and understanding to design and operate the OSN membrane was preliminary discussed. As a future work, more detailed and practical ML-based guideline for the OSN membrane design and operation will be investigated by pointing out the optimal operation strategies as well as design solutions.

Development of System Dynamic Model for Sustainability driven Technology Adoption in Indian Transport Sector

Nandita Saraf^a Yogendra Shastri^{a,*}

^aDepartment of Chemical Engineering, Indian Institute of Technology, Bombay, 400076, India

yshastri@che.iitb.ac.in

Abstract

Indian transport sector is the second largest greenhouse gas (GHG) emitter after power sector. For climate change mitigation, transition to more sustainable transport options such as ethanol blended petrol (E-85) and electric vehicle (EV) is necessary. However, to understand how their adoptions evolve among privately owned vehicles, we have developed a system dynamic model. System dynamics captures the underlying causal relation among the variables of the system and hence helps in understanding its behaviour. Causal interactions, feedback loops and delays have been identified in the system. Negative feedback loops connecting fuel supply to its demand, predict their apparent prices. Fuel price adds to the ownership cost of respective vehicle, which is used in logit model to determine respective annual purchase demand. Effect of inconveniences associated with adoption of EV and fluctuation in ethanol supply have been incorporated. Model predicts the penetration of E-85 and EV up-to 32.5 % of total private vehicle stock by 2050. As a consequence, 5.2 billion tons of carbon dioxide emissions can be saved. Market dynamics seems to be insufficient in encouraging high penetration of renewable options. Stronger incentives and development of better infrastructure could improve the situation.

Keywords: System dynamics, logit model, causal-loop diagram

1. Introduction

India is world's third-largest GHG emitter and second most populous country. India's total GHG emission in 2019 were 132 million tons of CO₂e (Joshi& Chen, 2020). Indian government has pledged to reduce emission intensity by 33-35% by 2030 compared to its 2005 level according to the Paris agreement target. Transition to renewable energy sources for transport sector has been recognized as an essential move to meet this pledge. In this regard, government has set a target of achieving 20% blending of ethanol in gasoline and 30% penetration of electric vehicles in new sale by 2030. However, penetration of new transport options among existing once seems difficult owing to large size and complex nature of transport sector. In order to understand how adoption of these options will develop in future, it is necessary to explore the cause-and-effect interaction among variables, which thus defines the dynamics of the transport sector. System dynamics (SD) modelling is a promising approach to perform such studies. This

methodology has been used previously to understand transition from ICE to EV (Pasaoglu et al., 2016; Vilchez et al., 2013). Also it has been used to test the effectiveness of various energy policies on transport sector (Menon & Mahanty, 2015). This has motivated the use of SD modelling in present research work. This research aimed at understanding the adoption of renewable transport options, i.e., E-85 and EV among private vehicles. Model could be used to study the implication of penetration of these options on GHG emissions and fuel prices. Also, this study could help in designing policies in order to meet desirable sustainable development goals.

2. Model development

System dynamics helps in analysing the behaviour of complex socio-economic systems due to underlying interactions which governs the dynamics (Forrester, 1994). To develop a SD model, first step is to develop a causal loop diagram (CLD). It depicts causal relation that exist between variables of the system. This requires a good understanding of how two variables interact. The next step is to formulate mathematical equations which go as input to the model. The specific functional form of equation is decided based on either causal relation or historical trend. Equation parameters are estimated through fitting historical data to the proposed function. SD model developed in this work focuses on private transport vehicles in India. Important assumptions of the model are: -

1. Ownership cost is the only decisive factor in determining the purchase demand for various vehicle options
2. The number of vehicles and distance travelled per vehicle are always related to per capita GDP
3. Fuel price is always related to fuel supply-demand dynamics
4. Electricity price is considered as independent of electricity demand coming from transport sector

The CLD of the model is shown in Fig.1. Population and GDP per capita positively influence the demand for car and two-wheeler, which is divided among various available options. Annual demand of vehicle adds to vehicle stock, which increases the fuel demand. Dynamics of fuel demand and supply impacts the fuel price. Annual fuel expense of vehicle adds to the ownership cost of vehicle, which is used in logit model to determine the annual demand for the vehicle for next time step.

1. Model inputs

Car and two-wheelers ownership and annual distance travelled are the inputs to the model. From annual car and two-wheeler ownership, annual demand for cars and two-wheelers are calculated. Correlation of vehicle ownership and annual distance travelled with per capita income is represented by Gompertz function. S-shape of the function gives more realistic growth of these variables than other logistic functions. Parameter values were estimated by fitting historical data.

2. Gasoline and diesel prices

Gasoline and diesel prices are positively influenced by their respective demand and Brent crude oil price (Fig. 1). Differential equations are formulated to capture the impact of the annual change in fuel demand and Brent crude oil price on annual change in respective fuel prices. Annual change in fuel price for i^{th} time step is added to respective fuel price in $i-1^{\text{th}}$ time step to get the fuel price at i^{th} . The equation coefficients are estimated by minimizing the sum of square of error between actual and predicted

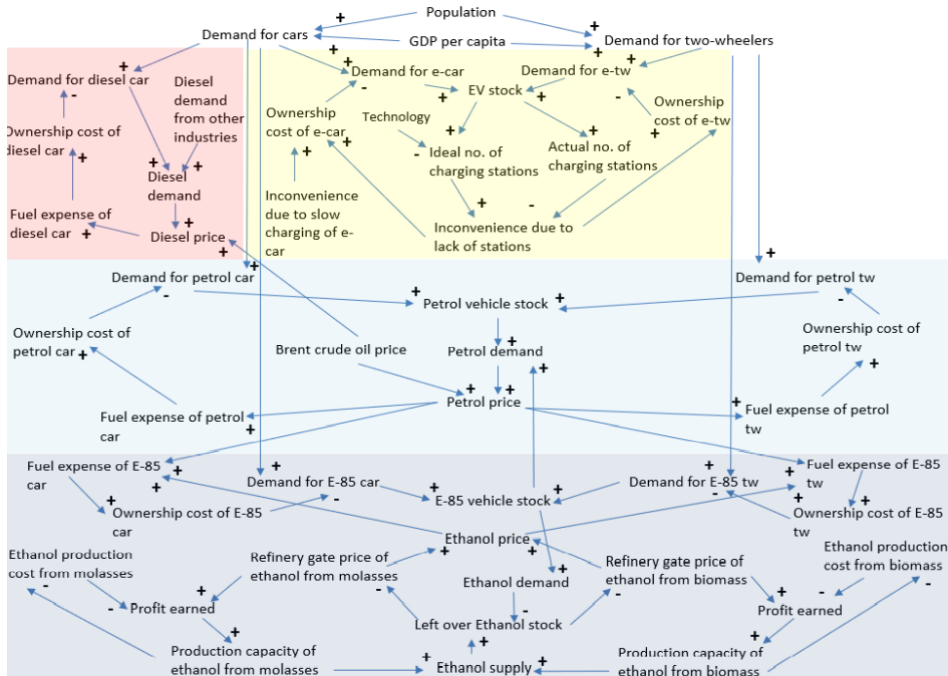

Figure. 1: Causal loop diagram

gasoline and diesel prices between 2001-2018. Calculation of fuel prices are shown in Eq. 1 and 2:

$$P^i = P^{i-1} + 0.7224 \times \frac{dD_p^i}{dt} + 1.1772 \times \frac{dC^i}{dt} \quad (1)$$

$$D^i = D^{i-1} + 0.1702 \times \frac{dD_D^i}{dt} + 0.7712 \times \frac{dC^i}{dt} \quad (2)$$

Where, P^i and D^i are gasoline and diesel prices, $\frac{dC^i}{dt}$, $\frac{dD_p^i}{dt}$ and $\frac{dD_D^i}{dt}$ are annual change in brent crude oil price, gasoline and, diesel demand respectively.

3. Ethanol supply, demand and pricing

Biorefineries producing ethanol from molasses and lignocellulosic biomass have been considered. If biorefinery generates profit, it encourages more investment in the sector, thereby resulting in greater production. Impact is inverse in case sector incur a loss. Since biorefineries require high capital investment and multiple years for erection and commissioning, the model has captured the time-lag in the impact of profit/loss on the actual increase/decrease in the ethanol production using ARX time series model. The equation parameters are estimated by fitting historical data. The ethanol production equations are given by Eq. 3 and 4:

$$EP_M^{i+2} = 0.8967 \times EP_M^i + 0.3224 \times P_M^i + 0.0307 \times P_M^{i-1} \quad (3)$$

$$EP_B^{i+3} = 1.1365 \times EP_B^i + 0.0367 \times P_B^i + 0.0338 \times P_B^{i-1} \quad (4)$$

Where, EP_M^i , EP_B^i , P_M^i and, P_B^i are ethanol production capacity in million litres and profit earned in INR by molasses and biomass based biorefineries respectively.

Literature have reported reduction in production cost of biomass-based ethanol falls within range of 15-25% as capacity doubles (van den Wall Bake et al., 2009). Based on this it is assumed that production cost will reduce by 15% for lignocellulosic ethanol. Production process of ethanol from molasses is fairly matured hence production cost is assumed constant. Ethanol demand comes from E-85 vehicle stock and mandatory blending in gasoline. Refinery gate price of ethanol is the price at which biorefineries sell their ethanol to oil manufacturing companies. If ethanol demand is higher/lower than supply then refinery gate ethanol price will have proportionate influence, as shown by negative causal relation in Fig.1.

4. Electric vehicles and associated inconveniences

Adoption of EVs is associated with many challenges from consumers' side. The model considers two basic inconveniences, i.e., insufficient charging stations and long charging time. Insufficient charging stations lead to limited options for charging. Additionally, slow charging may further affect the desirability of an EV for a consumer. Among these, inconvenience due to lack of charging stations is considered as common for both electric car and two-wheeler as shown in CLD. This is because the charging stations would be shared by both. Inconvenience due to long charging time would be a function of their battery capacity. Hence, this would be vehicle specific. The model converts these inconveniences into monetary values and adds that to the total cost of ownership of the vehicle. Higher inconvenience results in higher ownership cost thereby reducing the demand for EVs. The inconvenience due to lack of charging stations is calculated by comparing existing number of stations with the number of stations ideally required based on electric vehicle stock. Calculation of inconvenience cost due to insufficient charging stations and long charging time is shown in Eq. 5 and 6:

$$I^{CS} = \frac{(CS^i - CS^a) * C^{cs}}{EV^{stock}} \quad (5)$$

$$I^{CT} = \frac{(ST^{car} - FT^{car}) * (C^{SC} - C^{FC})}{E_{car}^{stock}} \quad (6)$$

where, I^{CS} , I^{CT} are inconvenience costs due to insufficient charging stations and long charging time, CS^i , CS^a are ideal and actual number of charging stations, C^S , C^{SC} and, C^{FC} are the setup cost of station, slow and fast charger, EV^{stock} and E_{car}^{stock} are combined EV stock and electric car stock respectively. Inconvenience due to insufficient charging stations is the additional funds required to setup charging stations to meet the ideal requirement. The inconvenience due to long charging time is the fund required to pay in order to save the additional time required to charge electric car by a slow charger.

5. Ownership cost and logit model

Ownership cost of vehicle is the sum of annualised purchase price, fuel expense and, maintenance cost of vehicle. Vehicle purchase price and maintenance cost are inputs to the model. Fuel expense is determined from feedback loops of the model. Ownership cost of vehicle is negatively related to vehicle demand. Literature have used logit model to calculate purchase probability of various vehicle models in competition (Lin & Greene, 2015). Based on this the purchase probabilities n^{th} vehicle option having OC_n as ownership cost is calculated using logit model as shown in Eq. 7.

$$P_n = \frac{e^{\frac{\mu}{OC_n}}}{\sum_{n=1}^m e^{\frac{\mu}{OC_n}}} \quad (7)$$

The parameter μ in the Eq.7 is called scale parameter. It gives the statistical dispersion of probability distribution. Estimation of coefficient μ for car and two-wheelers is performed by comparing the historical sales of petrol and diesel driven vehicles.

3. Results

Based on model formulation and assumptions we have modelled two scenarios: business-as-usual (BAU) and new technology adoption (NTA). BAU scenario assumes no penetration of any renewable transport options. Hence available options in BAU scenario are gasoline and diesel driven cars and gasoline driven two-wheelers. NTA scenario assumes penetration of E-85 and electric cars and two-wheelers. Fig. 2 shows composition of private vehicle stock which includes car and two-wheeler stocks in 2050 for both scenarios. It shows 87% of private vehicle stock will be gasoline and rest will be diesel driven in BAU scenario. There is a reduction in gasoline and diesel driven vehicles in NTA scenario, as it is taken over by E-85 and electric vehicles. As diesel cars only forms the diesel vehicle stock, the reduction is not as significant as gasoline vehicle stock. E-85 vehicles have slightly higher penetration than EV due to associated inconveniences. The overall penetration of E-85 and electric vehicles will be 32% in total private vehicle stock. Due to lower gasoline and diesel vehicle stock, there is a reduction in their respective demands in NTA compared to BAU scenario. Implication of lower demand can be seen in the fuel price plot shown in Fig.3. It can be noticed that gasoline and diesel prices for BAU scenario is higher than NTA scenario due to lower gasoline and diesel vehicle stocks in NTA. Car and two-wheeler ownership saturate towards 2050, therefore new demand for vehicles is very low during this period.

Demand for gasoline vehicles also reduces, thereby stabilizing the gasoline demand. As demand doesn't change much, gasoline price tends to saturate. Diesel demand comes from diesel driven cars, heavy vehicle and other industrial machineries. As the demand for diesel car reduces in NTA scenario, diesel demand coming from heavy vehicles and other industries continues to grow. Therefore, profile of diesel price is increasing throughout the simulation horizon. NTA scenario saves 5.2 billion tons of carbon dioxide than BAU scenario.

Figure 3: Fuel prices in \$/gallon

4. Conclusion

This work has tried to understand the adoption of renewable travel options, i.e., E-85 and EVs among privately owned vehicles by developing a system dynamics model. Penetration of these options have shown a significant reduction in fuel demand and GHG emissions. However, market dynamics is insufficient to ensure high penetration rate. Favourable scenarios of sufficient charging stations combined with carbon tax and incentives need to be investigated.

Abstract

The design of fixed-bed reactors has gained interest in the light of load-flexible operation. This is due to the expectation that some process feeds will be more volatile in the near future, for example, within the framework of the power-to-methane concept. In this regard, the application of an inert shell onto the catalyst particles has proven advantageous. In this work, a multi-period design optimization of a fixed-bed methanation reactor is performed by employing a heterogeneous reactor model, in which the catalyst particle is divided into an active core and an inert shell. Due to the model's computational demand, it is reduced by using stoichiometric relations at the reactor and catalyst particle scale. Subsequently, dynamic transition simulations between the optimized steady states coming from the multi-period design optimization as well as a reactor start-up and shut-down simulation are carried out, and the results of the full model are compared to those of the reduced model. Our results show that the model size can be reduced significantly by using the stoichiometric relations without loss of accuracy in steady state and negligible accuracy loss in transient scenarios. The optimized fixed-bed methanation reactor can be operated over a wide load range by optimally adjusting the operating variables and the dynamic simulations show smooth transitions between the steady states.

Keywords: Multi-Period Design Optimization, Heterogeneous Reactor Model, Stoichiometric Relations, Load-Flexible Reactor, Dynamic Reactor Operation

1. Introduction

Fixed-bed reactors are commonly used in the chemical industry to carry out heterogeneously catalyzed gas-phase reactions. A key design aspect in the presence of exothermic reactions is heat management to avoid temperatures that might damage catalyst and reactor material. For this reason, the fixed-bed is often located in several tubes, which are externally surrounded by a coolant. Despite intensive cooling, critical reactor conditions may arise, which lead to pronounced temperature hot-spots in the reactor, which is known as thermal runaway. The understanding and technical handling of this aspect have been intensively researched for steady-state reactor operation.

However, due to the expectation that certain process feeds will be more volatile in the near future, it must be ensured that the reactors do not only operate safe and economical in a single steady state but in multiple steady states as well as in transitions between them.

It was shown that reactor runaway conditions could be prevented by applying an inert shell on the active catalyst particles. If designed correctly, the effective reaction rate is significantly slowed down at high temperatures, where the mass transport through the inert shell becomes rate-determining. On the other hand, if the shell is sufficiently thin, it does not influence the effective reaction rate at low temperatures. In this way, a safe and economical reactor operation can be ensured, as shown by Zimmermann et al. (2020).

A possible application of such catalyst particles is within the power-to-methane concept (Rönsch et al. (2016)). In this context, hydrogen is produced via water electrolysis in the first part of the process chain. In regions that lack hydrogen infrastructure, hydrogen is subsequently converted with carbon dioxide into methane, which can be fed into the natural gas grid. It is assumed that the employed water electrolyzer operates in a flexible manner, according to the availability of surplus energy. Consequently, to avoid expensive intermediate hydrogen storage, the employed methanation reactor must also be operated flexibly (Bremer and Sundmacher (2019)).

The design of a multi-tubular fixed-bed methanation reactor, which is able to operate with a fluctuating feed by using the described core-shell catalyst particles, is the aim of this work. For this purpose, a multi-period design optimization is performed by employing a heterogeneous reactor model. Since this is a numerically challenging task, the model is reduced by introducing stoichiometric relations on the reactor and particle scale. As the use of the stoichiometric relations is strictly valid only in steady state, dynamic simulations are performed to investigate whether the reduced model can also reflect the behavior of the more complex model in transient scenarios.

2. Heterogeneous Reactor Model

A 1D-1D heterogeneous fixed-bed reactor model is used, which distinguishes mass balance equations for the components $i \in \{\text{CO}_2, \text{H}_2, \text{CH}_4, \text{H}_2\text{O}\}$ and heat balance equations for the gas phase (index G), the inert catalyst particle shell (index S) and the catalytically active catalyst particle core (index C). The balance equations on reactor scale with initial and boundary conditions read as

$$\epsilon_G \frac{\partial c_{G,i}}{\partial t} = - \frac{\partial c_{G,i} u}{\partial z} - \frac{(1-\epsilon)}{d} k_i (c_{G,i} - c_{S,i}(R_S)) \quad (1)$$

$$\epsilon_G (\rho c_p)_G \frac{\partial T_G}{\partial t} + u_{in} (\rho_{in} c_p)_G \frac{\partial T_G}{\partial z} = \frac{\partial}{\partial z} \left[\Lambda_{ax} \frac{\partial T_G}{\partial z} \right] - \frac{4U}{D} (T_G - T_{cool}) - \frac{(1-\epsilon)}{d} h (T_G - T_S(R_S)) \quad (2)$$

$$c_{G,i}(z=0) = c_{G,i,in}, \quad \Lambda_{ax} \frac{\partial T_G}{\partial z} \Big|_{z=0} = u_{in} (\rho_{in} c_p)_G (T_G - T_{in}) \quad (3)$$

$$\Lambda_{ax} \frac{\partial^2 T_G}{\partial z^2} \Big|_{z=L} = 0, \quad c_{G,i}(t=0) = c_{G,i,0}, \quad T_G(t=0) = T_{G,0} \quad (4)$$

and on the catalyst particle scale as

$$\epsilon_C \frac{\partial c_{C,i}}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left[r^2 D_{C,i} \frac{\partial c_{C,i}}{\partial r} \right] + \rho_C \nu_i \mathbf{R}, \quad \epsilon_S \frac{\partial c_{S,i}}{\partial t} = \frac{\partial}{\partial r} \left[D_{S,i} \frac{\partial c_{S,i}}{\partial r} \right] \quad (5)$$

$$(\rho c_p)_C \frac{\partial T_C}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left[r^2 \Lambda_C \frac{\partial T_C}{\partial r} \right] + \rho_C H_r \mathbf{R}, \quad (\rho c_p)_S \frac{\partial T_S}{\partial t} = \frac{\partial}{\partial r} \left[\Lambda_S \frac{\partial T_S}{\partial r} \right] \quad (6)$$

$$D_{C,i} \frac{\partial c_{C,i}}{\partial r} \Big|_{r=0} = 0, \quad D_{C,i} \frac{\partial c_{C,i}}{\partial r} \Big|_{r=R_C} = D_{S,i} \frac{\partial c_{S,i}}{\partial r} \Big|_{r=R_C} \quad (7)$$

$$\Lambda_C \frac{\partial T_C}{\partial r} \Big|_{r=0} = 0, \quad \Lambda_C \frac{\partial T_C}{\partial r} \Big|_{r=R_C} = \Lambda_S \frac{\partial T_S}{\partial r} \Big|_{r=R_C} \quad (8)$$

$$c_{C,i}(r = R_C) = c_{S,i}(r = R_C), \quad D_{S,i} \frac{\partial c_{S,i}}{\partial r} \Big|_{r=R_S} = k_i (c_{G,i} - c_{S,i}(r = R_S)) \quad (9)$$

$$T_C(r = R_C) = T_S(r = R_C), \quad \Lambda_S \frac{\partial T_S}{\partial r} \Big|_{r=R_S} = h(T_G - T_S(r = R_S)) \quad (10)$$

$$c_{C,i}(t = 0) = c_{S,i}(t = 0) = c_{i,0}, \quad T_C(t = 0) = T_S(t = 0) = T_0 \quad (11)$$

In addition to the radially averaged temperature T_G , the fixed-bed's center temperature \hat{T}_G is approximated by the correlation of Dixon (1996). The reaction kinetic model of Koschany et al. (2016), which considers no side reactions, is employed to describe the methanation reaction. Details about the remaining constitutive equations are given by Zimmermann et al. (2021).

It is known that the n_i - n_r mass balance equations in Eq. 1 can be expressed by n_r mass balance equations of key components, where n_i is the number of components and n_r is the number of linearly independent reactions. The same can be done on the catalyst pellet scale by introducing the stoichiometric relations $N_i/\nu_i = N_j/\nu_j$ as discussed in detail by Burghardt (1986) and Jackson (1977). In the case of piecewise constant diffusion coefficients or Knudsen diffusion, these equations can be integrated analytically. Thus, n_i - n_r concentration profiles can be expressed as

$$c_{G,j} u = c_{G,j,\text{in}} u_{\text{in}} - \nu_j/\nu_i X_i c_{G,i,\text{in}} u_{\text{in}} \quad \text{with} \quad X_i = \frac{c_{G,i,\text{in}} u_{\text{in}} - c_{G,i} u}{c_{G,i,\text{in}} u_{\text{in}}} \quad (12)$$

$$c_{S,j}(r = R_S) = \nu_j/\nu_i k_i/k_j (c_{S,i}(r = R_S) - c_{G,i}) + c_{G,j} \quad (13)$$

$$c_{S,j}(r) = \nu_j/\nu_i \sqrt{M_i/M_j} (c_{S,i}(r) - c_{S,i}(r = R_S)) + c_{S,j}(r = R_S) \quad (14)$$

$$c_{C,j}(r) = \nu_j/\nu_i \sqrt{M_i/M_j} (c_{C,i}(r) - c_{C,i}(r = R_C)) + c_{C,j}(r = R_C) \quad (15)$$

In the dependence of the system, the number of mass balance equations and thus the computational demand can be reduced significantly. However, it has to be kept in mind that the stoichiometric relations are valid only in steady state. Thus, n_i - n_r concentration profiles are assumed as quasi-stationary. Therefore, the degree of approximation in dynamic simulations depends on the choice of the chosen key component.

3. Multi-Period Design Optimization Problem

The discussed model is reduced via the stoichiometric relations. Carbon dioxide is taken as the key component, as it exhibits the highest molar mass of all reactants and, as a result, it exhibits the slowest dynamics at the catalyst particle scale. Consequently, the quasi-

steady-state assumption of the other components should lead to an accurate approximation of the system dynamics, at 40 % of the full model size.

A multi-period design optimization, as discussed by Grossmann and Sargent (1979), is performed by employing the reduced reactor model. Eleven periods of equal temporal length and equally spaced carbon dioxide loads from 500 kg/h to 1500 kg/h are used. As objective function, the mean methane space-time yield is maximized. The operating variables consist of the inlet pressure, velocity, and temperature as well as the coolant temperature and wall heat transfer coefficient. The inlet feed is always a stoichiometric mixture of pure carbon dioxide and hydrogen. The design variables are the reactor's tube length, diameter, and number, together with the catalyst particle diameter, shell porosity, pore diameter, and thickness. In each state, the temperature in the center of the fixed-bed must never exceed 750 K, and the conversion at the outlet of the reactor must be at least 95 %.

The given balance equations are spatially discretized via the Finite Volume Method. In total, 150 logarithmically spaced finite volumes are used at the reactor scale. On the catalyst particle scale, 15 finite volumes with equal volume size are used within the catalyst particle core and five within the catalyst particle shell. Details on the employed software for solving the optimization problem and for performing subsequent dynamic simulations are given by Zimmermann et al. (2021).

4. Results

4.1. Multi-Period Design Optimization

Figure 1: Multi-period design optimization results: The optimal profiles of the radial mean temperature T_G (—), center temperature \hat{T}_G (- - -) and carbon dioxide conversion X_{CO_2} (—) are shown on the left (darker colors correspond to higher loads). The corresponding inlet temperature T_{in} (+), pressure p_{in} (—*), and velocity u_{in} (—*) as well as the coolant temperature T_{cool} (—o) and wall heat transfer coefficient α_{out} (—o) are shown on the right.

The multi-period design optimization with the reduced model is solved within 75 iterations in 118 seconds. Solving the optimization problem of the full model on the employed desktop PC with 32 GB ram is not possible. The optimal temperature and conversion profiles, together with the respective operating variables, are shown in Fig 1. The optimal catalyst particles consist of a shell, where porosity and pore diameter are at their lower bounds of 10 % and 5 nm, respectively. As discussed in the introduction, this allows for a thin shell, which on the one hand, inhibits the effective reaction rate at high temperatures

and, on the other hand, does not significantly influence the effective reaction at low temperatures.

The optimal reactor is then designed such that the maximum heat transfer to the coolant is realized, as the tube diameter is at the lower bound of 2 cm and the coolant wall heat transfer coefficient is at the maximum of 2 kW/m²K for all loads. One hundred eighty tubes are needed to handle the maximum load of 1.5 t_{CO2}/h at the given operating conditions with inlet velocity and pressure at the upper bound. The reactor length of 3.9 m is determined by the residence time of the reactant mixture required to achieve the lower limit of the conversion of 95 % at the outlet at the highest load. To decrease the reactor load, the simultaneous variation of reactor inlet pressure and velocity is optimal, as long as none of the values is at its upper bound. Since lower reactor pressures tend to shift the hot-spot towards the reactor outlet, but lower inlet velocities shift the hot-spot towards the inlet, both effects almost cancel out. Thus, the hot-spot is almost in the same position for each load. Since the decrease of inlet velocity and pressure also decreases the heat transfer to the coolant, inlet and coolant temperature also decrease, such that the hot-spot does not exceed the limit of 750 K. As the reaction is equilibrium-limited, this also allows for outlet conversions of higher than 95 %. Overall, a mean methane space-time yield of 0.44 kg/m³s is achieved.

4.2. Dynamic Transitions

Figure 2: Dynamic simulation results: Maximum radial mean temperature (full model (—), reduced model (----)) and outlet carbon dioxide conversion (full model (—), reduced model (----)) for some load changes as well as a start-up and shut-down.

As the multi-period design optimization neglects the system dynamics, transitions between selected optimal steady states are simulated with both models. For this purpose, the reactor load is changed stepwise, and the operating variables are changed instantaneously according to the results of the multi-period design optimization. Additionally, a reactor start-up and shut-down are investigated. The initial conditions for the start-up are given as $X_{0,CO_2} = 0$ % and $T_0 = 300$ K. For the shut-down, T_{in} and T_{cool} are reduced to 300 K.

The results, shown in Fig. 2, indicate quick transitions in all periods of about one to two minutes. Despite drastic load changes, only slight oscillations in the temperature profile

can be observed during the transitions. Additionally, on positive load changes, a slight undershooting of the conversion is present. It is further evident that the reduced model is suitable to describe the dynamics of the full model. The models predict only a small difference in the outlet conversion in a period of about two seconds after a load change and a maximum hot-spot temperature difference of 0.05 K is observed in the displayed scenario. The total integration times of both models are comparable for the performed simulations (109 s for the reduced model vs. 122 s for the full model).

5. Conclusion

The presented results indicate that a fixed-bed reactor filled with catalyst particles that consist of an active core surrounded by an inert shell can be operated safely and economically within a wide load range. The simultaneous variation of reactor inlet velocity and pressure is favorable in this context, as shown by multi-period design optimization. Subsequent dynamic simulations between the optimal steady states as well as a start-up and shut-down indicate smooth transitions, even at drastic stepwise load changes. It is further concluded that applying stoichiometric relations at the catalyst particle scale gives accurate an approximation of the considered system dynamics.

Abstract

Chemical process simulations rely on the accurate representation of thermodynamic phenomena. Complex models like the Perturbed-Chain Statistical Associating Fluid Theory (PC-SAFT) provide such accurate descriptions but due to their implicit formulation, process optimization based on such models is computationally very demanding. This issue can be avoided by surrogate modeling, where a data-based model approximates the costly computation. When setting up a surrogate model, the question of which data to collect to fit the surrogate arises. In previous work, methods have been developed to combine sampling with optimization to only collect data in regions of interest for the optimization. These methods however mostly assume that the surrogate model describes the objective function. In this work, an extension to gray-box models is proposed.

Keywords: surrogate modeling, adaptive sampling, Bayesian optimization, chemical processes, gray-box modeling

1. Introduction

Surrogate and gray-box modeling rely on data. When the original relationship that the surrogate should approximate is a simulation or a computer code, the process of acquiring this data is commonly known as sampling. An intuitive sampling method is to sample the space as uniformly as possible with respect to the input variables. This is denoted as space-filling sampling, thoroughly reviewed in Garud et al. (2017). Adaptive sampling methods sample the space non-uniformly in order to cover regions of more complex behavior of the approximated function better. Cozad et al. (2014) use derivative free optimization methods to find points of high deviation of the surrogate from the original function. A similar technique is applied by Garud et al. (2016) who maximize a so-called departure function which describes the sensitivity of the surrogate prediction to samples that are part of the training set.

Kleijnen and Van Beers (2004) do not use optimization of a criterion to find new samples but instead select candidate inputs at which the jackknife variance is maximized. This approach was extended by Eason and Cremaschi (2014) by using a criterion that incorporates both the jackknife variance and a nearest-neighbor distance to address the exploration vs. exploitation trade-off. This has been further refined by Nentwich and Engell (2019) who used surrogate modeling to describe phase-equilibria. Because of the

simultaneous description of phase composition and miscibility gap, both a regression and classification surrogate were combined resulting in a modified sampling criterion.

The goal of these approaches is to obtain a surrogate model that possesses high accuracy over the whole range of input values. This does not reflect the later use of the model which often is an optimization where the surrogate model is incorporated as a submodel. The field of Bayesian optimization deals with combining surrogate modeling, sampling and optimization. Jones et al. (1998) used Kriging surrogates and their description of the prediction uncertainty to statistically describe the expected improvement.

This was extended by Gardner et al. (2014) to deal with constraints for a black-box model for the objective function and by Astudillo and Frazier (2019) to incorporate simple gray-box models with Monte Carlo simulation.

To overcome these assumptions we propose an optimization based sampling algorithm for embedded gray-box models.

2. A novel optimization based sampling approach

The novel approach is based on the upper confidence bound (UCB) acquisition function, which was developed in the field of Bayesian optimization by Cox and John (1992). The idea of UCB-sampling is to evaluate the uncertainty that results from the surrogate prediction in an optimistic manner. This approach is similar to the expected improvement (EI) acquisition function by complementing the surrogate prediction with its standard deviation. The main difference is that using EI the probability distribution is integrated analytically, while using UCB explicit confidence intervals are used. The proposed UCB acquisition function $f^{UCB-GB}(x)$ is optimized for determining a new sample that is added to the training set.

$$f^{UCB-GB}(x) = f^{GB}(x, \hat{y}(x)) + \kappa |g^T| \sqrt{\hat{\sigma}^2(x)} + \Phi(x) \quad (1)$$

Here, the modified acquisition function f^{UCB-GB} is estimated based on a gray-box model f^{GB} , which in turn depends on a surrogate model prediction \hat{y} and decision variables x . The surrogate prediction variance $\hat{\sigma}^2$ is multiplied with the gray-box model sensitivity to the deviation in the surrogate model g and a weighting factor κ . Φ is used for parallelization as described below.

To determine g , the optimization problem can be modified by including additional decision variables z , which are constrained to equal the surrogate prediction, as shown in Eq. (2) for the original (left side) and the UCB objective function (right side).

$$\begin{aligned} \min_{x,z} \quad & f^{GB}(x, z) & \min_{x,z} \quad & f^{GB}(x, z) + \kappa |g^T| \sqrt{\hat{\sigma}^2(x)} + \Phi(x) \\ \text{s. t.} \quad & \hat{y}(x) = z \quad | \lambda^{GB} & \Rightarrow \quad & \hat{y}(x) = z \quad | \lambda^{UCB-GB} \\ & h(x, z) < 0 & & h(x, z) < 0 \end{aligned} \quad (2)$$

From the theory of constrained optimization, at the optimum (denoted by $*$) the sensitivity of the objective function value with respect to surrogate prediction is given by the corresponding Lagrange multiplier $\lambda^{GB,*}$. The problem on the right hand side is dealt with iteratively, g is assumed to be constant during optimization and in the next iteration

updated to $\lambda^{GB,*}$. This is calculated from $\lambda^{UCB-GB,*}$ with a factor $k(x)$ correcting the difference in the gradients of f^{GB} and f^{UCB-GB} , shown in Eq. (3).

$$k(x^*)\lambda^{UCB-GB,*} \approx \lambda^{GB,*} \approx g$$

$$k(x) = \frac{\|\nabla_x f^{GB}(x)\|_2}{\|\nabla_x f^{UCB-GB}(x)\|_2} \quad (3)$$

Parallelization here means techniques to reduce the number of times the surrogate model has to be trained. Common approaches optimize the acquisition function that describes for example the expected improvement for several input combinations at once as in Ginsbourger et al. (2008). New sampling points are computed several times before the surrogate model is retrained. To avoid adding identical samples, $h_{penalty}$ is added to Φ for penalizing sampling near new samples so that different new sampling locations are computed. $h_{penalty}$ is given by

$$h_{penalty}(x_1, x_2, g) = \frac{\kappa |g|^T \sqrt{\hat{\sigma}(x_1)^2}}{\sqrt{2\pi}\sigma_\Phi} \exp\left(-\frac{\|\bar{x}_1 - \bar{x}_2\|_2^2}{2\sigma_\Phi^2}\right). \quad (4)$$

The parameter that determines the broadness of the penalty is σ_Φ . \bar{x} is the normalized value of x to overcome problems with different ranges of the variables. The total amount of penalty is set to the assumed added value in cost function: $\kappa |g|^T \sqrt{\hat{\sigma}(x)^2}$. The exploration vs. exploitation trade-off is addressed because in the early stage of sampling the larger estimated variance $\hat{\sigma}^2$ leads to a higher penalty and more exploration of the whole input space.

Data: Initial training input and output sets X and Y

```

while  $|X| < n_{maxsamples}$  do
    Initialize  $\Phi(x) \leftarrow 0$ ,  $X_{iter} \leftarrow \emptyset$ ,  $Y_{iter} \leftarrow \emptyset$ 
    Train surrogate model  $\hat{y}$  using inputs  $X$  and outputs  $Y$ 
    Calculate jackknife variance  $\hat{\sigma}^2$  using inputs  $X$  and outputs  $Y$ 
    while  $|X_{iter}| < n_{iter}$  do
        Initialize  $x^0$ ,  $z^0$ ,  $g$ 
        while:  $\|x^0 - x^*\|_2 > \epsilon$  do
            Solve Eq. (2), right hand side with initial guesses  $x^0$ ,  $z^0$  to  $x^*$ ,  $z^*$ ,  $\lambda^{UCB-GB,*}$ 
            Update  $x^0 \leftarrow x^*$ ,  $z^0 \leftarrow z^*$ ,  $g \leftarrow k(x^*)\lambda^{UCB-GB,*}$ 
        end
        Update Sets  $X_{iter} \leftarrow \cup(X_{iter}, x^*)$ ,  $Y_{iter} \leftarrow \cup(Y_{iter}, y(x^*))$ 
         $\Phi(x) \leftarrow \Phi(x) + h_{penalty}(x, x^*, g)$ 
    end
    Update Sets  $X \leftarrow \cup(X, X_{iter})$ ,  $Y \leftarrow \cup(Y, Y_{iter})$ 
end

```

Algorithm 1: Sampling method based on the upper confidence bound acquisition function (UCB) with parallelization

With a growing training set exploitation of already explored optima is performed. Based on these definitions Algorithm 1 is proposed, which is the main contribution of this work. $|A|$ denotes the cardinality of a set A . In Algorithm 1 three loops are iterated. The innermost loop adapts the value of g with direct substitution until the change in the optimum regarding the decision variables x is below a threshold ϵ , which leads to $g \approx k(x^*)\lambda^{UCB-GB,*}$. The second loop incorporates the parallelization by filling intermediate sets of samples X_{iter} and Y_{iter} , adjusting the penalty Φ in each step. In the outermost loop X_{iter} , Y_{iter} and Φ are reset after merging the intermediate sets X_{iter} and Y_{iter} with the training sets X and Y . The surrogate model is retrained and the prediction variance $\hat{\sigma}^2$ is calculated by using the jackknife.

3. Case study

The proposed method is applied to the model of the chemical process of the hydroformylation of 1-dodecene in a thermomorphic solvent system, taken from Nentwich et al. (2019). The considered flowsheet can be seen in Figure 1.

Figure 1: Flowsheet of hydroformylation process

This process consists of three unit operations: reactor, heat exchanger and decanter. In the reactor the catalyzed reaction of n-dodecene with synthesis gas (CO and H₂) to n-tridecanal takes place in a homogeneous liquid phase. The following two unit operations of cooling down the liquid stream coming from the reactor and using a decanter to recycle the catalyst cost efficiently are introduced because a thermomorphic solvent system is used that leads to a temperature dependent miscibility gap. This way, the catalyst can be recycled with the polar phase while the product is removed with the organic phase.

To accurately describe the liquid-liquid equilibrium in the decanter, the equation of state PC-SAFT is used, because it has been shown to provide accurate predictions for the system at hand by Schäfer et al. (2012). Surrogate modeling of the compositions of the two phases from the decanter feed composition and temperature is applied to overcome the issue of computational cost resulting from the implicit formulation. A simplified quaternary system consisting of n-decane, dimethylformamid, n-dodecene and n-tridecanal is used.

The objective function is chosen to be the theoretical cost in \$ per ton of product (CPT) assuming a production of 10,000 tons of n-tridecanal per year. The results of applying the algorithm presented in section 2 to this case study are shown in the next section.

4. Results

To evaluate the performance of Algorithm 1, denoted as UCB, it is compared to the mixed-adaptive approach as developed by Nentwich and Engell (2019). Parameters specific to the UCB-method are ϵ and σ_Φ , which are set to 10^{-5} and 0.05, respectively.

The parameters $n_{max\ samples}$, n_{iter} and the number of jackknifing groups are used in both algorithms. The values are 1000, 20 % of $|X|$ and 5. Additionally, the surrogate structure is the same for all methods.

Artificial neural networks (ANN) with two fully-connected hidden layers of 10 nodes each using the tanh-activation function are used as surrogates as even complex functional relationships can be modeled accurately by this structure.

Additionally, a set of 570 basis functions consisting of polynomial and exponential terms that were determined by using LASSO regression with regularization to minimize Akaike's information criterion (AIC) is applied as a surrogate model. It is expected that the set of considered basis functions and the regularization leads to a response surface which is more convenient for optimization.

The results of the optimization (Eq. (2), left) are shown over the iterations of the sequential sampling. For reference, also results using Latin hypercube sampling (LHS) designs with the same number of samples for each iteration are shown.

Figure 2: Predicted molar fraction of n-decane at the reactor outlet at the optimum for ANN (left hand side) and LASSO (right hand side) surrogates for different sampling methods; blue: Latin Hypercube sampling (LHS), orange: mixed adaptive sampling, black: upper confidence bound sampling as proposed

In Figure 2 the molar fraction of n-decane at the reactor outlet is shown at the optimum for different stages of sampling, evaluated from six randomly distributed initial points for five runs of each of the methods, because this quantity is sensitive to the surrogate prediction. The number of samples increases by 20 % in each iteration and ranges from initially 60 to more than 1000 samples. It can be seen from the figure that in later iterations the optimum regarding p converges to about 18 % for all considered sampling methods for the ANN surrogates. In the early stages, varying predictions of the optima occur. For LHS and mixed adaptive sampling molar fractions below the final value of convergence can be observed, while using UCB sampling an accurate description of the optimum is obtained already at low numbers of samples.

For LASSO surrogates, convergence to the optimal value is only observed for the UCB sampling. Both mixed adaptive and Latin hypercube sampling lead to an average prediction of around 14 % with a high variance even for large numbers of samples. This can be explained by a too small flexibility of the surrogate model caused by strong regularization, where sampling with the goal to decrease the overall deviation leads to a surrogate with a still mediocre accuracy. When focusing on the region around the optimum with UCB sampling, the accuracy can be increased where it is needed, neglecting deviations elsewhere.

5. Conclusion and outlook

In this work a sampling method for surrogate models is proposed with the goal to focus the improvement in model accuracy on regions that are of interest regarding the

optimization of a nested gray-box model. The main idea is to make use of the upper confidence bound acquisition function developed in the field of Bayesian optimization. Its performance is investigated for the case study of the hydroformylation of 1-dodecene in a thermomorphic solvent system. Using the proposed algorithm, convergence to the optimum is reached with significantly fewer samples compared to conventional methods. In future work, an optimal weighting of prediction and uncertainty will be investigated. Additionally, the combination of the proposed method with other parallelization methods can give further insights into the capability of this method.

Abstract

Industrial systems are complex in terms of types of material exchanged (water, electricity, vapour...), types of industries involved, and size of companies, temporality and many others. Regarding this complexity, this paper aims at developing a generic methodology able to design exchanges between companies in an eco-industrial park in terms of electricity, water and several pressures of vapour. The number of companies and their types of processes can also be various. In this sense, a generic model would be able to be adapted to a great diversity of case studies. This multi-objective optimization method can deal with the minimization of total cost, environmental impacts (through a life cycle analysis indicators) or complexity of the network designed (technical aspects linked to interconnections between companies). Four time-periods are studied and the objective functions to minimize are the total cost of the network, its complexity (related to the interdependence between companies) and the energy consumed linked to environmental impact. The procedure developed reaches to design all the pipes constituting the exchanges between companies while minimizing the cost through a multi-objective optimization approach. Additionally, the design of the network takes into account a better dependency of companies what makes the EIP more attractive for them.

Keywords: optimization, industrial ecology, networks, energies, flexibility.

1. Introduction

Regarding the economic, environmental and political challenges, the development of sustainable industrial zones becomes urgent. The competitive advantages offered by the business of industrial clusters need also to be eco-efficient to reduce the environmental impact of economic growth (Kastner et al., 2015). Eco-industrial parks (EIP) constitute a typical illustration of industrial symbiosis and cooperation between different stakeholders in the same area needs to be optimally designed (Boix et al., 2015). Industrial systems are complex in terms of types of material exchanged (water, electricity, vapour...), types of industries involved, size of companies, temporality and many others. Regarding this complexity, this paper aims at developing a generic methodology able to design exchanges between different companies in an EIP. On the other hand, Tian et al. (2014) noted that for different EIPs in China a key measure to support the sustainability of EIPs is the development of the network. Another important factor is the ability of a network to be resilient. In order to reduce the impact of disruptions, resilient network design is a branch of scientific research that aims to develop networks that have a greater propensity to support change. Most particularly, Leo and Engell (2020) took into account

uncertainties where the decisions at one point in time have an impact on the probability of the uncertainty. The general principle of resilience is to maximize the number of interconnections in order to increase the possibilities for distributing flows in the event of a disturbance (Valenzuela-Venegas et al., 2019). As a result, this approach has the bias of seeking to systematically interconnect industries and therefore create dependencies, increase the risk taken, which is a source of reluctance for manufacturers.

In addition, in previous studies, interconnections have been widely studied from the point of view of the complexity of the network but there is an absence of studies regarding resilience. The optimal design of a network by integrating the interdependence generated by the interconnections could be interesting to analyse. Indeed, a powerful obstacle to the development of eco-industrial networks is the trust that companies must have among themselves to accept losing their independence. The work presented in this study provides a new vision since it takes into account the behaviour of industries, wishing to maintain their independence while taking advantage of the advantages they have in coming together on the same site to maximize their benefits (economic, environmental, social). Thus, based on the model developed in a previous study (Mousqué et al., 2020) the methodology proposed may advise industries to integrate the EIP network or to remain autonomous.

The scientific issue here is therefore the development of approaches to design a flexible network that remains optimal in view of the design criteria in a changing operational context. To achieve this, the first objective of this study is to propose an optimal solution for designing a network of exchanges.

2. Methodology

The main novelty of the approach is its ability to consider the great majority of possible exchanges in an EIP:

- Electricity: it can be produced from renewable sources (wind turbines, solar panels) or taken from the external grid network,
- Water: water can be exchanged throughout the network
- Vapour: different levels of pressure are considered through the design of a utility system for each company of the EIP (low, medium and high pressures).

The number of companies and the types of processes can also be various. In this sense, this generic model is able to be adapted to a great diversity of case studies. The multi-objective optimization method can deal with the minimization of total cost, environmental impacts (through a life cycle analysis indicators) or complexity of the network designed (technical aspects linked to interconnections between companies). The aim is to propose simultaneously the optimal design of the Hybrid Renewable Energy System (HRES) feeding the EIP and the exchanges between and within companies while minimizing the objectives previously enounced.

The methodology consists in several steps described in Figure 1:

- Building the superstructure regarding the case study chosen and evaluating the granularity of the model to be developed. It is important to notice that even of a so-called “black box” approach is used; a detailed modelling has to be performed in order to obtain the characteristics of each box of the superstructure.

- Formulation of the problem through a MILP optimization
- Application of the procedure developed to design the network of resources exchanges and evaluation of its flexibility through a multicriteria decision making tool.

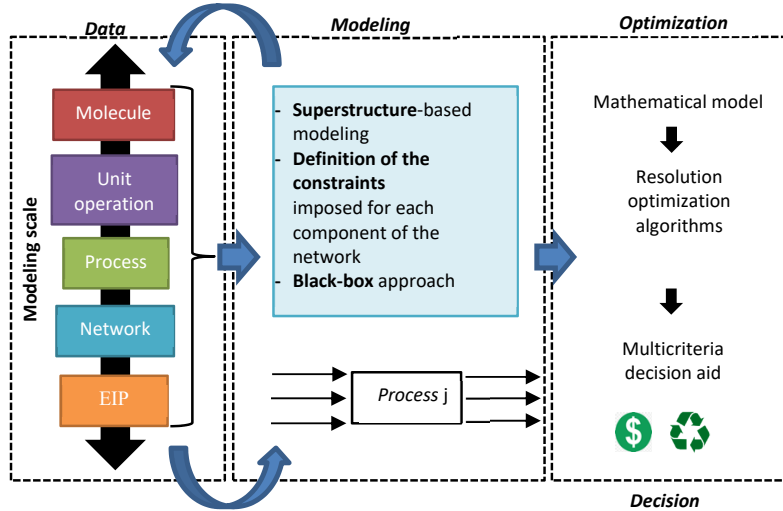

Figure 1. Generic methodology developed

3. Problem statement

Given is a set of industries represented by sinks and demands in terms of vapour, water and electricity throughout four time periods represented by a superstructure previously detailed in Mousqué et al. (2020). The aim is to design the optimal network for making a cooperative symbiosis and to evaluate its flexibility and resilience.

The variables of the optimization model are both continuous and binary: flow-rates (water, energies) exchanged, flow-rates between each box of the superstructure, production of boilers, electricity consumed, existence of each connection and of each component (boilers, turbines). The constraints are represented by all the mass balances, the conservation of materials and minimum and maximum capacity production of each boiler. The MILP model formulation is taken from Mousqué et al. (2020) and solved with ILOG CPLEX solver.

The present paper brings a specific procedure developed and implemented in order to take into account and to evaluate flexibility of the obtained solution (Figure 2). The procedure developed reaches to design all the pipes constituting the exchanges between companies while minimizing the cost through a multi-objective optimization approach. Additionally, the design of the network takes into account a better dependency of companies what makes the EIP more attractive for them.

The objective function to minimize is the total cost of the network calculated through the Net Present Cost (Turkay and Telli, 2011).

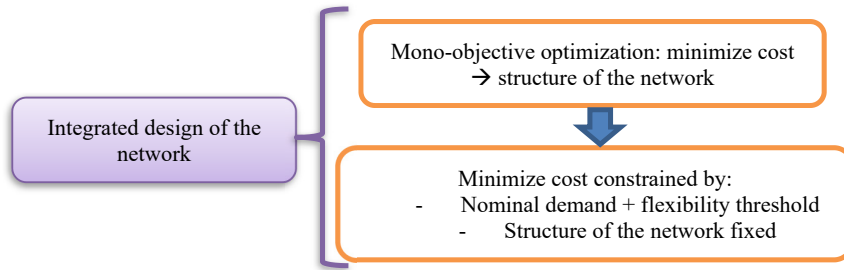

Figure 2. Optimization procedure to consider flexibility of the network

4. Case study

The case study chosen contains 15 different industries grouped in the Yeosu industrial zone in China, this park was previously introduced by Kim et al. (2010). For more details about this particular case study and the mathematical model associated, the reader can refer to Mousqué et al. (2020 b). In this utility network model coupled with a hybrid renewable energy system, steam demand is the key parameter to study the flexibility of the network. Indeed, the capacity to supply the demand of companies with steam is directly linked to the sizing of the production, conversion and transport facilities (boilers, turbines and pipes respectively). On the other hand, the electricity network is connected to the external grid which is considered as an unlimited source, its supply capacity would be unlimited. The flexibility of the connected electricity network being infinite, the study of its flexibility is therefore not relevant.

To detail this case study, nominal demand is discretized over four periods representing the 4 seasons. Each scenario (nominal and disturbances) therefore comprises four periods. In addition, the study parameter taken into account is an industry's vapor demands. This encompasses the demand for very high pressure (VHP), high pressure (HP), medium pressure (MP) and low pressure (LP) steam in an industry. There are therefore 15 input parameters studied given that there are 15 industries. The evaluated parameter therefore corresponds to the smallest maximum deviation among the demands of an industry. To achieve this, the demands of the evaluated industry are variable and the smallest variation in demands is maximized. In fact, during this assessment step, the demands of other industries and all the infrastructures are fixed.

5. Results and analysis

5.1. Flexibility of the nominal solution

The flexibility of the nominal solution has been first evaluated by taking into account the minimal flexibility of each company. Eleven companies among fifteen have a flexibility equal to zero for the nominal solution; that is to say its global flexibility is null. Figure 3 shows the repartition of flexibility for each company of the EIP over the four time periods considered. These results show us that the optimal design in terms of costs leads to a solution that has very little flexibility. This is because the minimization of the cost also entails a minimization of installations which are sized just to the capacity necessary to meet the demand under nominal conditions.

A little flexibility is nevertheless observed in a few industries. This flexibility comes from the turbines installed. In fact, during a disturbance it is possible to stop the condensing turbines, the steam then directly supplies the processes. The additional quantity of steam is then equal to the quantity which would have been lost by condensation in the turbines. More generally, certain elements make it possible to increase the flexibility of a network, such as storage elements or controllable elements that can be stopped. Note that as a function of time, it is over the first period that the model presents the least flexibility, in fact, the flexibility of industries is zero for a large number of industries, nevertheless for industry 2, 4, 12 and 13, this flexibility is respectively 8.6%, 0.7%, 9.3% and 37.7%. The first time step is the period when we observe the least flexibility, this is explained, because it is also the period when the demand is the most important for each process.

Figure 3. Flexibility of the nominal solution over time periods

5.2. Analyses of the impact of flexibility on the cost

As a reminder, the deviation is then the smallest deviation calculated of the various processes in an industry. The threshold on the flexibility of the optimal solution increases while the cost is minimized. It is important to note that improving flexibility in a whole network can be possible at the design stage by adding some equipment, what leads to additional cost (Figure 4). Regarding the trend of increasing cost versus flexibility, design solutions get results for 20% and 30% flexibility with relatively linear evolution. Indeed, when a flexibility of 30% is taken into account, 7.25% of additional cost is considered to overcome these fluctuations. It implies that, for this solution, all companies will have more than 30% of flexibility over the four time periods.

This overall approach can help to design sustainable industrial systems that can overcome fluctuations in their demands over the time by integrating some additional costs during the conception stage.

Figure 4. Flexibility of the network regarding cost evaluation

6. Conclusion

A generic procedure to design optimal networks of EIPs has been developed in order to evaluate cooperative exchange network. A generic superstructure that allows to take into account several types of exchanges in an EIP has been developed and the associated MILP model has been adapted to solve large-scale problems. The procedure was validated on a case study involving fifteen industries. Starting from a nominal solution with zero flexibility, one can increase it by adding some cost to overcome potential fluctuations in the network. In addition, in the interest of developing a generic method, this indicator does not require knowing the probabilities of the appearance of the various disturbances.

Abstract

Pan granulation is a particle formation process with widespread practical applications such as fertilizer and pharmaceutical manufacturing. The continuous operation mode is especially promising with respect to industrial demands. For process automation and intensification, a suitable dynamical process model is required. Therefore, the focus of this contribution is on identification of agglomeration kernel parameters in a population balance model based on empirical data. To this end, an objective functional, representing the error between model and measurement data, is minimized. It is shown that the steady state particle size distribution of a lab-scale process can be reproduced accurately using the population balance with the identified parameters.

Keywords: Population balance modeling, Pan granulation modeling and simulation, Agglomeration.

1. Introduction

Agglomeration is a particle formation process in which at least two primary particles are combined to form a new one. This principle is often used in many industries, e.g. pharmaceutical manufacturing, food processing and fertilizer production. The properties of the formed agglomerates, e.g. size, shape and porosity, significantly affect certain end-use properties, e.g. dissolubility, processability and storability (Bück and Tsotsas, 2016). In particular for fertilizer production and mineral processing, agglomerates are often formed in drums or pans (Ouchiyama and Tanaka, 1981; Litster and Ennis, 2004) in continuous operation which may provide constant throughput with constant product quality (in terms of specific agglomerate properties) during steady-state operation. Besides sophisticated experiments, modeling those processes in view of emerging agglomerate property distributions supports understanding of the underlying dynamic mechanisms on multiple scales and application of model-based process control and intensification. In this contribution, focus is on modelling of pan granulation, which is also known under the term dish or disc granulation.

The process scheme is shown in Fig 1: a powder is fed constantly to an inclined rotating dish and liquid binder is sprayed on the powder. The wet particles are sticking together, forming larger agglomerates. The flux from the pan represents the product particles. Feed powder as well as product particles vary with respect to individual particle properties. It has been shown that variations of process operation parameters, such as inclination angle, rotational velocity, binder spray rate and composition, significantly affect the product particle properties (Kapur et al., 1993; Kapur and Runkana, 2003; Obraniak and Gluba,

2012). Furthermore, zone formation of different sized agglomerates in the pan is commonly observed (Litster and Ennis, 2004).

It is well-known that for size-enlargement processes, like pan granulation, individual properties, like characteristic volume and porosity, differ from particle to particle. As an alternative to Monte-Carlo modeling approaches (Zhao et al., 2007; Rieck et al., 2018) population balance modeling (PBM) (Ramkrishna, 2000; Ramkrishna and Singh, 2014) represents an established framework to model such processes (Kapur and Runkana, 2003). For standard monivariate PBEs, accounting mostly for characteristic particle size or volume, efficient and accurate numerical solution algorithms have been developed, see e.g. Kumar et al. (2008); Bück et al. (2012) and the references therein.

This contribution aims at modeling of a lab-scale pan granulation setup and model adaption to experimental data in terms of minimization of the error between experimental samples of the particle-volume distribution and the corresponding model predictions in steady state, i.e. for constant feed powder flux and constant product flow.

2. Materials and Methods

2.1. Experimental and Analytical Setup

The experiment was realized in a pilot scale pan granulator shown in Fig. 1 (left). The pan has an inner diameter of 400 mm, and depth of 100 mm, schematically shown in Fig. 1 (right). The primary particles are stored in a tank and then transported into the pan using a vibratory conveyor. The binder is distributed through a nozzle, which is installed in a top-spray configuration at distance of 350 mm above the pan. An external pump and an air compressor ensure the supply of sprayed binder solution. The rotation of the pan is obtained by a motor (Model AR304, ERWEKA GmbH), which allows to adjust the rotational speed in the range of 2 rpm - 80 rpm and the inclination angle of the pan in the range of $0^\circ - 70^\circ$. The control of binder flow, primary particle flow and air flow is obtained using the main control panel (Model CE255, G.U.N.T. Gerätebau GmbH). All components of experimental setup are made of stainless steel and assembled on a metal table.

Figure 1: (Left) Experimental pan granulation setup. (Right) Schematic representation of pan granulation process

The particle material is powdered dolomite. It is a grey powder, typically used in the construction industry and as a fertilizer to increase the pH-value of soil. The binder solution contains 1 wt% sucrose and 99 wt% of water. The duration of the experiment

was 75 min with a 50 g/min feed flow rate, and 8,5 g/min binder flow rate. The initial bed mass for the experiment was 400 g. The nozzle air flow pressure was 2 bar. An overview of the process parameters is shown in Table 1. For the offline analysis, 5 particle samples of the pan and 5 samples of the product were taken every 15 minutes after the beginning of the experiment. The particle size distribution (PSD) of each sample was measured offline with a Mastersizer (Malvern Instruments, Malvern, Worcestershire, United Kingdom), which infers particle size via dynamic light scattering. The output data from the analyzer is the normalized volume distribution for each sample and thereby over the process time.

Table 1: Experimental process operation parameters

Parameter	Unit	Value
Initial powder mass	[kg]	0.4
Rotational speed	[rpm]	25
Inclination angle	[°]	35
Binder flow rate	[kg/h]	0.51
Binder composition	[wt%]	1
Primary particle feed rate	[kg/h]	0.3
Average density of initial particles	[kg/m ³]	1300

2.2. Process Modeling

Population balance modeling has proven to be an established concept to describe size enlargement processes like granulation Ramkrishna (2000). Assuming that particle volume is the sole significant particle property, the particle ensemble can be represented by its number density distribution function (NDF) $n(t, v)$ providing information of the number of particles within an infinitesimal volume range. If it is furthermore assumed that size enlargement is dominated by agglomeration, the NDF's dynamics are given by the population balance equation (PBE)

$$\frac{\partial n(t, v)}{\partial t} = \dot{n}_{\text{feed}(t, v)} - \dot{n}_{\text{prod}(t, v)} + \frac{1}{2} \int_0^v \beta(t, u, v - u) n(t, u) n(t, v - u) du - \int_0^\infty \beta(t, u, v) n(t, v) n(t, u) du \quad (1)$$

The corresponding initial NDF is $n(0, v)$. While the left-hand side of Equation 1 describes the dynamics, the first two elements of the right-hand side describe the influx of feed powder and the outflux of product particles from the pan. The feed is further resolved

$$\dot{n}_{\text{feed}}(t, v) = \dot{N}_{\text{feed}}(t) \tilde{n}_{\text{feed}}(v) \quad (2)$$

with $\dot{N}_{\text{feed}}(t) = \text{const.}$ denoting the constant feed rate and $\tilde{n}_{\text{feed}}(v)$ the normalized feed powder NDF. The outflux of product particles $\dot{n}_{\text{out}}(t, v)$ is computed from the measured product mass flow $\dot{m}_{\text{prod}}(t)$ and product volume distribution $q_{3, \text{prod}}(x)$. The last two elements of the right-hand side of Equation (2) denote generation and formation of new particles of volume v by agglomeration of two particles with volumes u and $v - u$. Here,

the agglomeration kernel $\beta(t, u, v)$ contains information about the probability of forming a new agglomerate and is often separated into a volume and time-dependent part

$$\beta(t, u, v) = \beta_0(t)\beta_v(u, v). \quad (3)$$

In general, the volume-dependent part $\beta_v(u, v)$ is a non-negative symmetric function which can be derived either from micro-scale mechanistics, heuristic assumptions or abstract data-driven approaches (see Golovin et al. (2018) and the references therein). The time-dependent coalescence efficiency $\beta_0(t)$ mirrors the effects of the process conditions and operating parameters. In this work, focus is on the steady state operation, thus we assume $d\beta_0/dt = 0$ holds.

3. Model adaption

In the following section the estimation of model parameters is presented. Parameter estimation for (multi-dimensional) population balances has been investigated in great detail in Ramachandran and Barton (2010). For further information regarding techniques and frequently occurring problems the reader is referred to this source.

The unknown kernel parameters \mathbf{p} have to be estimated from experimental data via minimization of a suitable objective function

$$J(\mathbf{p}_{est}) = \|e_u(x, \mathbf{p}_{est})\|_2, \quad (4)$$

where e_u is the error in the weighted particle size distribution (Golovin et al., 2018)

$$e_u(x, \mathbf{p}_{est}) = u_{act}(x) - u_{est}(x, \mathbf{p}_{est}), \quad u(x) = \frac{\pi}{6}x^3n(x), \quad (5)$$

and x represents the characteristic size of the particles. Using local conservation of the particle number, $u_{est}(x, \mathbf{p}_{est})$ is computed from the simulated particle volume distribution. For the simulation the PBE was discretized using the cell-average technique (Kumar et al., 2008). Note that the particles are assumed to be of spherical shape, which is a valid assumption for many particle formation processes. However, for the experiment considered here it has to be checked in future investigations. The experimental distribution $u_{est}(x)$ is computed from the normalized particle size distribution $q_{3,est}(x)$ provided by the Mastersizer measurements and the measured mass in the pan $m_{b,act}$ under the assumption of spherical particle shape and particle material density ρ . In this contribution, only the steady state distribution of the continuous process is considered in the objective function. It is represented by the measurements at $t = 75$ min.

Minimizing the objective function (Eq. 4) using local optimization techniques proved to be difficult for one of the kernel functions since different local minima were found for different initial parameter guesses. Therefore, the optimization was conducted by using a genetic algorithm which is able to provide non-local results (Goldberg, 1989). However, it has to be mentioned that there is no guarantee of finding global minima. The algorithm was implemented in Matlab R2018b using the build-in function `ga`. The parameter search space was restricted to $0 \leq a, b \leq 2$ and $-20 \leq \log_{10}(\beta_0) \leq -4$, based on the author's

experience. The initial population for the genetic algorithm was created randomly within the search space.

4. Results

At first, the proposed model adaption method is used to fit the model with volume independent coalescence kernel $\beta_v(u, v) = 1$. Therefore, only β_0 has to be estimated. The optimal steady state distribution $q_3(x)$ is obtained with $\beta_0 = 2.56 \cdot 10^{-7}$ and depicted on the left-hand side of Fig. 2. The corresponding objective function value amounts to $J = 1.56 \cdot 10^5$. It is seen, that the distribution's mode and the density of large particles are captured, yet significant errors are observed for particles up to 1.5 mm characteristic size. Since this result is unsatisfactory the two-parametric Kapur kernel (Kapur, 1972)

$$\beta_v(u, v) = \frac{(u+v)^a}{(uv)^b} \quad (6)$$

is chosen as coalescence kernel. Due to the free parameters a and b , the kernel possesses the necessary versatility to fit a wide range of agglomeration processes. The optimal steady state volume distribution with the Kapur kernel is presented on the right-hand side of Fig. 2. The objective function value $J = 3.3 \cdot 10^4$ is obtained with the optimal parameters $\beta_0 = 3.76 \cdot 10^{-8}$, $a = 0.92$ and $b = 0.6$. The supremacy of the Kapur-kernel approach, which provides an accurate reproduction of the experimental results, compared to the volume-independent kernel is obvious. In future publications the identified parameters have to be validated with further experiments and thorough analysis of identifiability has to be conducted.

Figure 2: Measured (black) and simulated (red) normalized volume density distributions for the volume-independent kernel (**left**) and the Kapur kernel (**right**).

5. Conclusion

This contribution was concerned with identifying a process model for a continuous pan granulation process. Therefore, agglomeration kernel parameters were identified by fitting a population balance model to lab-scale experimental measurements of particle size distributions by minimizing an error functional. The optimization was implemented as a genetic algorithm. It has been shown that a population balance with a Kapur coalescence

kernel is able to provide very good agreement between model and measurements with respect to the steady state volume distribution of particles. Future work will be concerned with investigating the influence of process conditions on the agglomeration process which is represented by the kernel parameters by adapting the model to additional experiments using the presented methodology (Otto et al., 2020). It is expected, that the Kapur kernel will provide accurate fits. Furthermore, research will include identification of models that also capture the process dynamics. Finally, the identified process models can be used for model-based control and process intensification.

Estimation of cutpoint temperature under uncertain feed composition and process conditions using artificial intelligence methods

Junaid Shahzad,^a Iftikhar Ahmad^{a,*}

School of Chemical and Materials Engineering (SCME), National University of Sciences and Technology (NUST) H12, Islamabad, Pakistan

Abstract

Crude distillation unit (CDU) is the most energy-consuming and energy deficient process in a refinery, hence saving energy consumption in its operation is the main target. The CDU separates crude oils into light gas streams, naphtha, kerosene, diesel, atmospheric gasoil and residue. The cutpoint temperature management dictates the quantity and quality of the products, therefore a proper model for determination of its causes and effects is fundamental. The cutpoint temperature heavily depends on the composition of crude-oil and process conditions. In this study, the effect of uncertainty in process conditions, such as temperature, pressure, flow rates, etc., and feed composition on cutpoint temperature is researched. A hybrid approach based on Taguchi method and genetic algorithm is used to derive optimum cutpoint temperature for different variants of feed composition and process conditions. Then, an artificial neural networks (ANN) model is developed to predict the optimum cutpoint temperature by eliminating the need for the hybrid approach. The method is validated with two Pakistani crudes oils from the Zamzama field, where the ANN predicted the cutpoint temperature with enough accuracy for industrial application.

Keywords: Deep learning, ANN, Cutpoint temperature optimisation, CDU.

1. Introduction

The efficient design and operation of petroleum refining processes have always been researched due to their energy-intensive nature. The most important refinery process is found in crude distillation units (CDU) that separate the petroleum in its distillates. CDU is one of the most complex process in the refinery, hence there is a huge opportunity for saving energy consumption in its operation (Brueske et al., 2015). It may count on optimisation of scheduling, reduced giveaways in properties of intermediate products, as well as real-time optimisation of the cutpoint temperature of the CDU (Luyben et al., 2013). The cutpoint temperature heavily depends on composition of crude-oils and process conditions. Several methods like categorisation approach, swing-cut modeling, fractionation index model, Taguchi method, weight transfer ratio (WTR) approach, Taguchi and genetic algorithm (GA) hybridization, and monotonic interpolation have been devised for the cutpoint temperature optimisation (Brooks et al., 2018; Trierwiler et al., 2001; Zhang et al., 2001; Li et al., 2007; Alattas et al., 2011; Ali et al., 2012; Menezes et al., 2013; Kelly et al., 2014; Durrani et al., 2018; Franzoi et al., 2020).

In Durrani et al. (2018a), an artificial neural networks (ANN) model capable of multi-outputs is developed from optimised data sets which are generated by the hybrid

framework of the Taguchi method and genetic algorithm (GA) to deal with uncertain feed composition. The current work is an extension of this previous approach, whereby the effect of uncertainty in all process conditions, i.e., temperature, pressure, flow rates, etc., are considered in addition to the uncertainty in feed composition adopted in Durrani et al. (2018b). The application domain is extended to crude-oil assays of the Pakistani oil fields known as Zamzama. Several hundred variations of the Zamzama assay are generated by incorporating artificial uncertainty in the actual crude-oil composition and process conditions. The sample components having variations in crude-oil composition with different cutpoint temperatures and process conditions are derived from the hybrid approach, i.e., Taguchi and GA. The sample components comprised of the crude-oil variants and their cutpoints are being used to train an ANN model. The ANN model has a 0.98 correlation coefficient and required lesser computational power compared to the hybrid method in the prediction of the desired cutpoint temperatures.

In this study, variations will be introduced in 10 process conditions. They are: the standard ideal liquid volumetric flow, temperature and pressure of the Zamzama crude-oil feed to the pre-flashing stage, the pressure of the diesel steam fed to the crude distillation column, the mass flow rate, temperature and pressure of the atmospheric gas oil steam fed to the crude distillation column, the mass flow rate, temperature and pressure of the main steam fed to the crude distillation column, and the operating pressure of the condensing stage in the distillation column, along with the feed compositions. The different sets of data generated by varying the process conditions and feed compositions will be fed to the hybrid model developed in ASPEN HYSYS. The data sets of these uncertain process conditions will be used to generate cutpoints at those different variants. The new sets of optimised cutpoints are used to train and develop an ANN-model.

The process description and process flow along with details of the crude distillation are shown in section 2. The methodology used for generating data from the CDU by the hybrid framework to train and developing the ANN-based model is discussed in section 3. Results for this study are presented in section 4. Section 5 shows the findings from this research.

2. Process description

A representation of the CDU and the process flow can be seen in Figure 1. The selected crude-oils are from Pakistan, from the Zamzama fields, which are sweet, light, and have a specific gravity varying from 0.75 to 0.76. The sulphur and water content are less than 0.05% by weight (for sulphur) and volume (for water). The crude-oil is fed at the temperature of 232.22°C and pressure of 517.107 kPa into the pre-flash column. The pre-flashing stage separates the gases from the liquid phase, reducing the overall duty required in the furnace to promote the separation in the CDU. The furnace pre-heats the crude-oil for the desired fractionation in the distillation tower. The gas stream, which are separated in the pre-flash stage, are mixed with the hot crude-oil stream in a mixer before reaching the a fractionation column. The column has a total of 29 theoretical trays with three strippers to the side and pre-flash condensers along the cutpoint stages and for internal reflux three pumps around installed. The feed is fed at the tray 28 of the column.

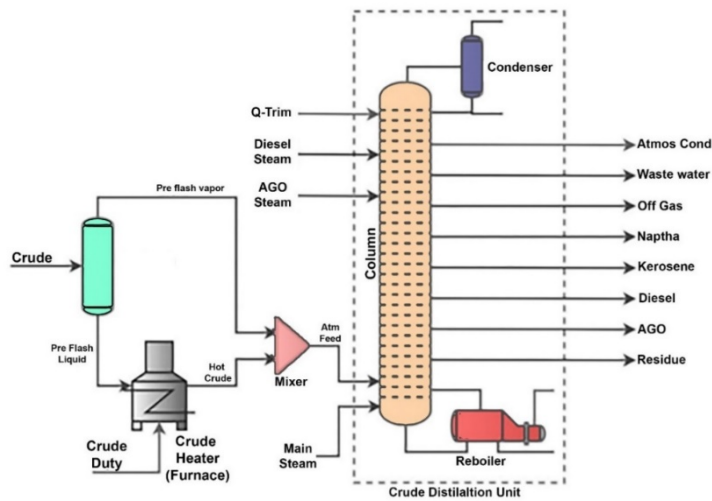

Figure 1. Crude distillation unit.

3. Methodology

The hybrid framework is developed from Taguchi and genetic algorithm in Durrani et al. (2018). The method now is extended to other process conditions of the crude feed and column streams. Variations of Zamzama assay are generated by incorporating artificial uncertainty in the actual crude-oil composition and ten process conditions. The process conditions, which are artificially varied, are listed below:

- Standard ideal liquid volumetric flow, temperature, and pressure of the Zamzama crude-oil feed at the pre-flashing stage.
- The pressure of the diesel steam.
- The mass flow rate, temperature and pressure of the atmospheric gas oil steam.
- The mass flow rate, temperature, and pressure of the main steam.
- The operating pressure of the condensing stage in the CDU.

The main steps for developing and testing are shown in Figure 2 are as follows:

Phase I: Several process data sets are generated at different feed and process conditions by inserting artificial variations which would deviate these feed and operating conditions by a factor of $\pm 1\%$, $\pm 2\%$ and $\pm 3\%$.

Phase II: Cutpoint temperatures are now calculated for these variants through the hybrid framework of Taguchi and GA.

Phase III: ANN model is developed using 75% of the data sets with their associated cutpoints.

Phase IV: The model developed has to be validated now by predicting the cutpoints of the remaining 25% of the data sets with varied feed and process conditions.

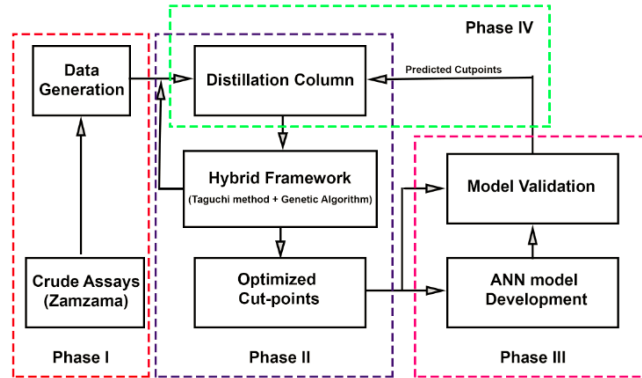

Figure 2. Schematic representation of how the hybrid framework and ANN model are integrated.

4. Result and discussions

In Table 1 is showed the ten different operational variables from 6 different datesets that are varied from their given standard values.

Table 1. Process condition data sets for distillation of Zamzama crude-oils.

Process Condition	Data set 1	Data set 2	Data set 3	Data set 4	Data set 5	Data set 6
Zamzama Mass Flow (KBPD)	97.000	95.060	94.109	95.051	96.952	99.860
Zamzama Temperature (°C)	225.234	220.729	218.522	220.707	225.121	231.875
Zamzama Pressure (kPa)	554.064	542.983	537.553	542.928	553.787	570.401
Condenser Pressure (kPa)	131.752	129.117	127.826	129.104	131.686	135.637
Steam Mass Flow (kg/h)	3299.940	3233.941	3201.602	3233.618	3298.290	3397.239
Steam Temperature (°C)	184.882	181.184	179.373	181.166	184.790	190.333
Steam pressure (kPa)	1002.980	982.920	973.091	982.822	1002.479	1032.553
AGO Steam Mass Flow (kg/h)	1099.980	1077.980	1067.201	1077.873	1099.430	1132.413
AGO steam Temperature (°C)	144.433	141.544	140.129	141.530	144.361	148.692
AGO steam Pressure (kPa)	334.359	327.672	324.395	327.639	334.192	344.218

Variations in the data set 1 are generated by addition of variation of -3%. In data set 2, a change of -2% is introduced. Similarly, for data set 3 until 6, a change of -1%, 1%, 2%, and 3% is applied, respectively. An ANN model is developed using data generated for feed compositions and 10 process conditions for the CDU. From the 198 data sets generated, 148 are used for training the ANN-based model, while 50 data sets are used to validate the model. The ANN model has three hidden layers, where neurons in hidden layers 1, 2, and 3 are 13, 17, and 16, respectively. The correlation coefficient between the target cutpoint and the predicted cutpoint is 0.98.

The reported average value for diesel production in KBPD (kilo barrels per day) in Figure 3 and the individual productions capacity of the sample components are calculated for a set of 50 sample components. The trend for straight runs model shows that production for

33 sample components are reported to be above average, among the sample components for straight runs a maximum of 36.79 KBPD and a minimum of 35.29 KBPD is achieved. For the hybrid model, a maximum of 42.77 KBPD and a minimum of 37.37 KBPD is obtained. For the ANN-based model, the diesel production for 50 sample components reaches an average of 39.38 KBPD for an average energy/volume (E/V) value of 779.67 kW/KBPD from Figure 4 for the ANN-based model. The ANN-based model shows that production for 29 sample components are above average, among the sample components for the ANN-based model a maximum of 41.06 KBPD and a minimum of 36.35 KBPD is achieved. Figure 5 shows the energy to volume ratio of diesel for different sample components. The hybrid model obviously requires a longer time to update the cut points while the ANN-based model is aimed to reduce the time required for updating cutpoints.

Figure 3: Average diesel production in E/V.

Figure 4: Average E/V values.

Figure 5: E/V ratio for diesel achieved using the three models.

5. Conclusion

In this study an ANN-based approach for cutpoint optimisation of CDU is proposed. The ANN-based model is trained on data of sets of feed compositions, process conditions, and their corresponding optimised cutpoints derived through hybrid model of Taguchi method and GA. The proposed mechanism is demonstrated via integration of MATLAB and Aspen HYSYS and is applied to a CDU model for Pakistani crude-oils. The ANN model and the hybrid framework are found more reliable and consistent for the diesel production in comparison to the straight-run model, which showed lower production rates of diesel and an overall lower total production. It is found that using the hybrid model, a decrease

of 17.69% in the energy to volume ratio for an increased diesel production of 7.98% is achieved, compared to the straight runs. On the other hand, using the ANN-based model a decrease of 19.44% in the energy to volume ratio for an increased diesel production of 8.39% is achieved compared to the straight-run model.

Application of Constrained EKF based State Estimation to a Coiled Flow Inverter Copolymerization Reactor

Robin Semrau^a, Filippo Tamagnini^a, Alexandru Tatulea-Codrean^a and Sebastian Engell^a

^a*TU Dortmund University, August-Schmidt-Straße 1, 44227 Dortmund, Germany*

Abstract

The performance of the reconstruction of the states of the controlled system is a key factor for the performance of nonlinear model-based control. In this work, the design and experimental evaluation of a Constrained Extended Kalman Filter (CEKF) for a continuous copolymerization process is presented. The experimental set-up and the model are introduced. The performance of the CEKF scheme with a systematic tuning, sampling-based constraint handling approach is tested in simulation studies, and the performance of the CEKF formulation is validated for experimental data.

Keywords: Copolymerization, State Estimation, Constrained EKF, Coiled Flow Inverter

1. Introduction

The production of polymers by free radical solution polymerization is a major branch of the process industry. In most cases, free radical polymerization is carried out in batch or semi-batch reactors. However, these modes of operation have several disadvantages, such as cleaning and transfer times, variations in product quality between different batches, and limited heat removal. Therefore, the transfer to continuous processes has been investigated intensely in recent years as presented by Goerke et al. (2016); Durand and Engell (2016).

The challenge of radical solution polymerization in continuous reactors is to handle the increasing viscosity and to avoid runaway and a resulting blockage of the reactor. This necessitates fast and precise control of the reactor, which is difficult because of the lack of measurements inside the reactor. Therefore, reliable and fast state estimation is a must.

The Extended Kalman Filter (EKF) is the most often used state estimator for nonlinear systems in the field of chemical engineering. The popularity of the EKF results from the simplicity of the implementation and the low computational effort. On the other hand, it is known that the EKF may fail for strongly nonlinear processes, especially in the vicinity validity limits, e.g. negative concentrations. Therefore, a significant amount of research regarding the handling of inequality constraints in EKF based state estimation has been done as presented by Simon (2010). Possible approaches range from simple clipping to sampling-based approaches as presented by Prakash et al. (2014).

2. Experimental Setup

A sketch of the experimental setup is shown in Figure 1. The feed streams are aqueous solutions of the monomers acrylamide (AM) and 2-acrylamido-2-methyl-propane sulfonic acid (AMPS) and the redox initiator system potassium persulfate and sodium formaldehyde sulfoxylate. The different streams are mixed and subsequently fed to a Coiled Flow Inverter reactor (CFI). The CFI provides a homogeneous radial profile due to good radial mixing and low axial mixing even at laminar flow conditions as described by Klutz et al. (2015). The throughput of the reactor ranges from 0.5 kg/h to 1.5 kg/h. The reactor has an inner diameter of $d_i=3$ mm and a total length of 8 m. The reactor is placed inside an oven, which is operated at 343 K. Within the reactor, the cold inlet stream is heated and thereby the polymerization initiated. Additionally, the exothermic polymerization reaction leads to a temperature rise.

Figure 1: Schematic of the CFI Copolymerization process including measurement set-up

The reaction temperature is monitored by tube temperature measurements. These measurements are located at axial reactor positions of 1 m, 3 m, 5 m and 7 m. The monomer concentration at the outlet is measured using an online Raman spectrometer. With increasing conversion, the viscosity of the reaction mixture increases drastically. The viscosity is inferred from pressure difference measurements. Therefore, the pressure drop over the whole reactor and at the outlet, over a measuring section, are measured.

3. Model

The copolymerization reaction is described by the method of moments and the model accounts for the initiation, propagation, oxygen inhibition, and termination with first and second-order reactions. The energy balances of the reaction fluid and the reactor material are considered including convection, reaction, and heat transfer.

The viscosity dependency on the polymer moments is modeled with a Mark-Houwink approach and the shear dependency with a power law fluid. Back-mixing in the CFI is described with the axial dispersion model. The spatial derivatives of the highly convective dominated mass transport equation and the energy transport equations are approximated using the WENO-3-5 scheme, on 18 grid points. The resulting ode model with 324 states poses a highly nonlinear and stiff problem.

4. Constrained Recursive State Estimation

The Extended Kalman Filter is used as a state estimator. In order to process the available measurement information, the recursive state estimation needs a smaller computation time than the measurement interval, which is 1 s. This cannot be realized with computationally more expensive techniques such as Moving Horizon Estimation or Particle Filtering. Therefore, the EKF is used due to the comparably low computational effort. The performance of the EKF is enhanced by several extensions, such as effective constraint handling and systematic tuning, as described in the following.

4.1. The Extended Kalman Filter

The continuous-discrete EKF employed here consists of a prediction and a correction step. In the prediction, problem (1) is solved to compute the a-priori estimates of the states $x_{k|k-1}$ and the covariance $P_{k|k-1}$.

$$\dot{x} = f(x, u) \quad (1a)$$

$$\dot{P} = \frac{\partial f}{\partial x} P + P \frac{\partial f^T}{\partial x} + Q \quad (1b)$$

In the correction step, the a-priori estimates are corrected with the measurement information y_k using the formula (2) to compute the a-posteriori estimates $x_{k|k}$, $P_{k|k}$.

$$K_k = P_{k|k-1} \frac{\partial h}{\partial x} \Big|_{x_{k|k-1}} \left(\frac{\partial h}{\partial x} \Big|_{x_{k|k-1}} P_{k|k-1} \frac{\partial h}{\partial x} \Big|_{x_{k|k-1}}^T + R_k \right)^{-1} \quad (2a)$$

$$x_{k|k} = x_{k|k-1} + K_k (y_k - h(x_{k|k-1}, u)) \quad (2b)$$

$$P_{k|k} = \left(I - K_k \frac{\partial h}{\partial x} \Big|_{x_{k|k-1}} \right) P_{k|k-1} \left(I - K_k \frac{\partial h}{\partial x} \Big|_{x_{k|k-1}} \right)^T + K_k R_k K_k^T \quad (2c)$$

4.2. Systematic tuning approach

The tuning of an Extended Kalman Filter is not trivial. Especially for large complex models an inappropriate choice of the tuning parameters leads to suboptimal performance and trial-and-error tuning is tedious. A systematic tuning approach that was introduced by Valappil and Georgakis (2000) is used here, as shown in equation (3). The parameter covariance matrix C_p results from a parameter fitting of the model to experimental data. $\frac{\partial f}{\partial p}(x, u)$ is evaluated at every time point in the covariance prediction.

$$Q(x, u) = \frac{\partial f}{\partial p} C_p \frac{\partial f^T}{\partial p} \quad (3)$$

4.3. Inequality constraint handling

In the case considered here, the state estimates are strongly dependent on the pressure drop near the constraints. Therefore, an effective constraint handling stabilizes the EKF and creates the basis a suitable filtering of the pressure drop measurements. In contrast to other approaches that correct only the estimated states, in the sampling-based approach also the state covariance is adapted. In this approach, referred to as MEKF-1 and introduced by Prakash et al. (2014), the constraints are handled in the following way. First, random sample points $\{x_{k|j,i}\}$ from a multivariate normal distribution $\mathcal{N}(x_{k|j}, P_{k|j})$ with the mean $x_{k|j}$ and covariance of $P_{k|j}$ are drawn. Then, the sample points that violate the constraints are clipped to the constraints. Based on this corrected ensemble $\{\tilde{x}_{k|j,i}\}$ the state $\tilde{x}_{k|j}$ and the covariance matrix $\tilde{P}_{k|j}$ are calculated using the equations (4). The

approach is applied after the prediction and after the correction step, accordingly $\tilde{x}_{k|j}$ is the constraint a-priori state estimate $\tilde{x}_{k|k-1}$ or the a-posteriori state estimate $\tilde{x}_{k|k}$.

$$\tilde{x}_{k|j} = \frac{1}{N} \sum_{i=1}^N \hat{x}_{k|j,i} \quad (4a)$$

$$\tilde{P}_{k|j} = \frac{1}{N-1} \sum_{i=1}^N (\hat{x}_{k|j,i} - \tilde{x}_{k|j})(\hat{x}_{k|j,i} - \tilde{x}_{k|j}) \quad (4b)$$

4.4. Computational aspects

The CEKF is implemented in the do-mpc framework, introduced by Lucia et al. (2017), which uses the CasADi 3.5.1 implementation by Andersson et al. (2018). The continuous-time state covariance update is computed using the approach by Mazzoni (2007). To enable the real-time computation, the covariance prediction is performed on a regular grid, with a time step of 0.1 s. The number of sampling points for MEKF-1 was chosen as 3240. The performance was also tested with 32400 sampling points, which did not lead to a different solution. All computations are performed on an AMD Ryzen 9 3950.

5. Results

First, the estimation is tested against a simulation of the plant without model mismatch. The estimator is initialized at the steady state for a throughput of 0.8 kg/h. The plant is initialized at a steady state for a throughput of 0.7 kg/h. At the begin of the simulation, the throughput is increased to 0.8 kg/h. The measurements, which are used in the estimation, are the tube temperatures along the reactor, the mass fraction of the residual monomers at the end of the reactor, the pressure drop over the reactor, and the pressure drop at the reactor outlet. The behavior of the plant and the EKF is shown in Figure 2. The black line displays the mean and the blue line the mean of the a-priori predicted measurements / states over 25 runs with different random measurement noise. The shaded areas indicate the 2σ confidence intervals. In the upper and mid plots, the different measurements are displayed, while in the lower plot the weight average chain length (WACL) and the acrylamide polymer mass fraction at the reactor outlet are shown. In all of the plots, the convergence of the estimator can be seen. However, while the temperature and pressure measurements are predicted accurately within 200 s, the convergence of the residual acrylamide mass fraction and the WACL and the polymer mass fraction takes 400 s. The overall convergence of the estimator takes also about 400 s. The correct prediction of the pressure drop, at the beginning is caused by the fact that the estimator corrects the first and second moment of the polymer chains such that the prediction of the pressure is correct, but the estimates of the states are differing from the true states. The convergence time of the estimator cannot be accelerated by a different tuning, it is an internal limit of the system, which is caused by the convective information transport. Before residence time (316 s) has passed, the system is not completely observable, due to the convective information transport to the pressure and concentration measurements and the limited observability from temperature information. However, while converging, the estimator is able to provide accurate predictions of the pressure drop and consequently the viscosity, which is the main indicator for product quality and safety of the plant. The estimator is fast in comparison to the plant behavior, which does not reach a steady state within 1000 s. The computational time of the estimator is 0.84 ± 0.084 s, therefore, the estimation scheme is real-time feasible.

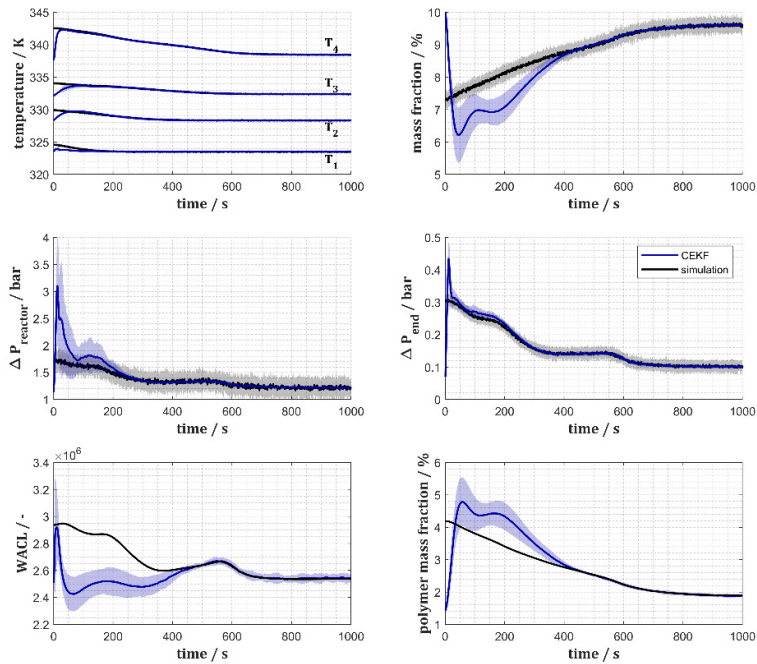

Figure 2: Simulated plant measurements and predicted measurements of the CEKF state estimation

The estimation scheme was also tested with real plant measurements as shown in Figure 3. The results show a fast convergence of the temperatures to the measured values of the tube temperature measurements within 30 s, as can be seen in the upper left plot. The pressure at the end of the reactor also shows similar performance with fast convergence

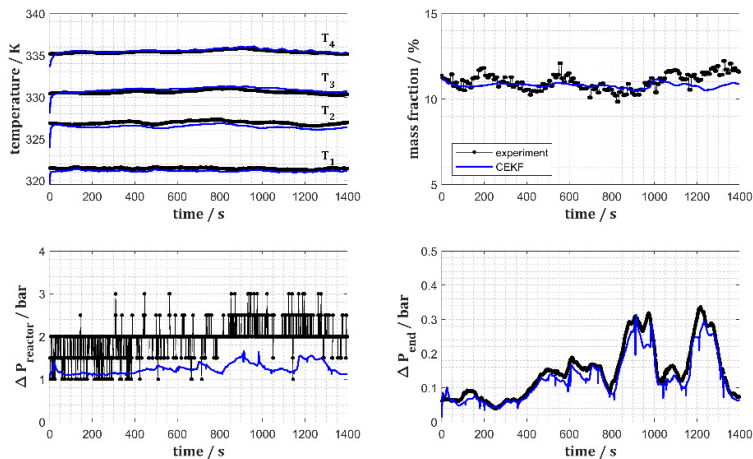

Figure 3: Plant measurements and predicted measurements of the CEKF state estimation

of the estimate. The monomer mass fraction is initialized close to the measured value and the estimates stay close to the measured value. Although there are only minor variations in the monomer mass fractions, the pressure drop shows quite large variations. The reason for this behavior is the high sensitivity of the pressure drop at the outlet to process variations. The total pressure drop over the reactor displays an offset and obviously, the measurement is not reliable. This calls for improvements in the instrumentation. In conclusion, the estimator works reliably with the plant data. In future work, it will be explored whether the performance of the estimator can be improved by a reduced plant model mismatch achievable e.g. through parameter estimation and by using computationally more demanding methods as moving horizon estimation can improve the estimator performance. Nonetheless, the convection dominated behavior of the reactor poses limits to the speed of convergence of the estimation, as also observed in Hashemi et al. (2016).

6. Conclusion

In this work, a CEKF based state estimation scheme for a tubular reactor for a polymerization that leads to a sharp rise of the viscosity was developed and tested in simulation studies and against plant data. The CEKF scheme was applied with a systematic tuning and constraint handling approach and an accurate covariance matrix prediction. Its performance was investigated in simulation studies and with real plant measurements. The speed of convergence is limited by the convection-dominated behavior of the plant. Further extensions of this work include efforts in reducing the plant model mismatch by including parameter estimation and using the estimator in output feedback model-based control of the plant.

Abstract

Process modeling requires both data (chemical reaction yields, kinetic constants, cost estimates, environmental indicators, etc.) and knowledge (operation models and formulations, alternative processes and technologies, etc.). Searching in databases and published research may provide such information, but there is a lack of systematic methods and tools guiding this procedure. The present work describes and assesses an information retrieval methodology that is part of a proposed retrieval and extraction cycle addressing this problem. Two query construction methods for sampling academic databases are proposed assessed and compared. Departing from a seed corpus of a limited number of papers, Scopus® is used as an academic database to retrieve literature containing information associated with pyrolysis processes of waste plastic. It is found that, with minimal human intervention, the methodology is able to return a ranked list of candidate documents that have a considerable (linguistic) relevance.

Keywords: Information Retrieval, Big Data, Text Mining, Academic Databases, Waste-to-Resource

1. Introduction

Due to new communication technologies the world becomes increasingly interconnected.

This enables researchers from all around the globe to publish their work and access publications from their peers. In recent years this has led to a yearly growth of about 9% in academic publications (Landhuis, 2016). The abundance of available information raises the need for strategies to handle this Big Data in order to pinpoint the truly relevant information. In this work we present a methodology to semi-automatically screen academic databases to obtain a set of promising documents related to a given research question.

In Process Systems Engineering (PSE), the modeling of technical systems is a fundamental task. Model parameters and knowledge can be obtained from publications in academic databases but with the ever increasing volume of data this becomes an increasingly difficult task. Text mining and Natural Language Processing are tools that emerged to handle and make use of Big Data. In the field of Systematic Reviews they are being applied to find and classify relevant contributions within a (sub-) field of a discipline in order to include them in a review paper (Usai et al., 2018). A related example where this concept is applied in a natural science field is shown in the work by (Kottmann et al., 2010). They present an IRE system that retrieves, classifies and extracts papers related to metagenomics marine science from the PubMed database.

This work is motivated by the waste-to-resource route assessment work presented by (Pacheco-López et al., 2020). The authors compare the potential of transformation routes of plastic waste to valuable raw materials. By applying an IRE process it is expected to populate a process database for comparison and go beyond what a manual retrieval procedure could achieve, both in terms of retrieved volume and identification of non-intuitive relations. In order to facilitate the search process in a systematic way we propose an Information Retrieval and Extraction (IRE) cycle that departs from an initial set of relevant documents. The main novelty of this contribution is the proposal and validation of a retrieval method to screen access-limited academic databases with the goal of retrieving specific parameters (in this case the ones that characterize chemical transformation processes as part of waste-to-resource routes). Here, we demonstrate our progress in the first step of the cycle, the information retrieval.

2. Problem Statement

To address this objective the problem can be stated as follows:

Given (1) a research question, (2) a set of relevant documents (seed corpus) and (3) an academic database, find an extended corpus (new relevant documents).

The extended corpus must be similarly relevant to the research question and a design objective is to postpone and so to reduce human interaction as much as possible.

3. Methodology

The proposed IRE cycle is presented in Figure 1. First, an academic database is queried using a sampling method that is conditioned to the initial set of documents (seed corpus). Second, the retrieved documents are analyzed in order of decreasing estimated relevance to find the text passages that contain the desired information. So far, all parts of the information retrieval part are implemented in Python 3.8. The database used in this study is Scopus® and is accessed via the Elsevier API. The following subsections describe the hypotheses and individual steps within the information retrieval part of the cycle.

3.1. Hypotheses

1. Linguistically similar texts contain semantically similar information.
2. A seed corpus composed of documents fitting a domain represents that domain.

3. Using relevant keywords extracted from that corpus for constructing queries to structured sets of documents, organized as databases, allows for finding documents having semantically similar information

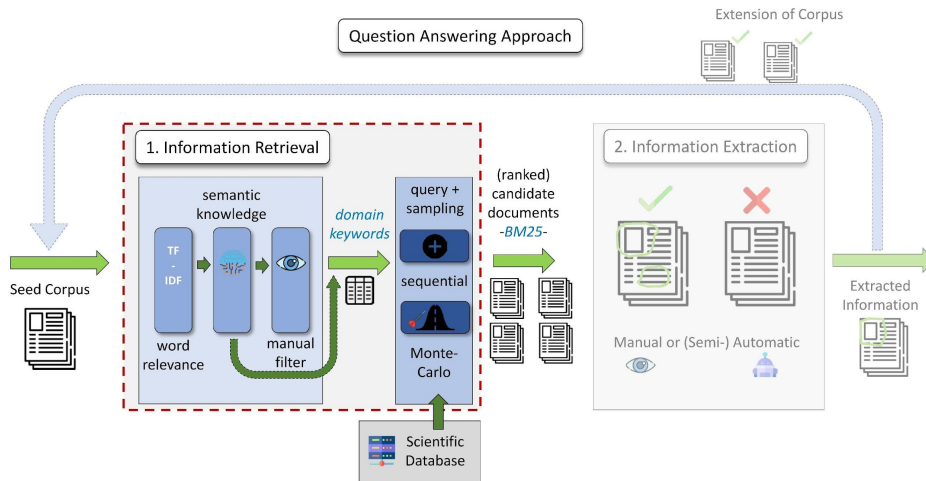

Figure 1. Proposed information retrieval and extraction cycle.

3.2. Extraction of Domain Keywords from Seed Corpus

First, a set of relevant domain keywords must be extracted from the seed corpus to characterize the domain. The Term Frequency-Inverse Document Frequency (TF-IDF) metric (Qaiser and Ali, 2018) determines the relative importance of a word in a set of documents, considering the words with high number of appearances in few documents as relevant while frequent words in all documents and non-frequent words as non-relevant.

3.3. Query Construction Methods for Sampling Academic Databases

In this work we assess and compare two methods:

- Sequential Sampling (SEQ): Add keywords to the query in decreasing relevance order until the number of search results is below a user-defined threshold.
- Monte-Carlo Sampling (MC): Build multiple queries by randomly adding keywords according to their relevance until the number of results is below a user defined threshold. An inherent ranking metric is the appearance frequency (the number of queries a given document appears in, divided by the total amount of queries).

3.4. Ranking of Retrieved Documents

The BM25 ranking function (Robertson and Zaragoza, 2009) is a popular approach in information retrieval to determine the relevance of a document to a query compared to

the other documents in the retrieved corpus. It yields a metric that can be considered as relative (linguistic) relevance.

3.5. *Validation and Limitations*

In order to validate the retrieval method, the normalized BM25 relevance of the retrieved full text documents are compared with each other and with the seed documents. The full text information is chosen because (1) a test on using the abstracts of the documents to determine the relevance of the full documents showed an unreasonable classification and (2) the desired knowledge is contained within the full text.

4. **Case Study**

The methodology is applied to a set of eight seed documents that contain quantitative information about processes for the pyrolysis of plastic waste. The information extracted from these documents was used by (Somoza-Tornos et al., 2021) to assess a process screening framework for the synthesis of process networks from a circular economy perspective. The retrieved documents departing from this seed corpus are expected to help extending the study by identifying additional candidate process conditions and pathways.

4.1. *Targeted Information*

One example of textual information is taken from a seed document (Onwudili et al., 2009) and the keywords are highlighted by general concepts that are searched:

“The compositions of the process (pyrolysis) products of pure low-density waste product (polyethylene), waste product (LDPE) and waste product (polystyrene) and their mixtures have been investigated over a condition (temperature) range from 300 to 500 condition (°C).”

5. **Results and Discussion**

Table 1 shows the top 16 keywords extracted from the seed abstracts. The sequential method was applied with a threshold of 1,000 documents leading to 376 abstracts and full text documents that could be retrieved with the available licensing options. The Monte-Carlo method was performed with 1,000 iterations using 10, 20 and 30 keywords to identify three lists of candidate documents. From the top 2,500 documents of each list a total of 553, 568 and 1,110 abstracts and corresponding full documents could be retrieved respectively. Additionally, from the 30 keywords list (63,186 entries) a randomly selected subset of 2,500 papers was chosen from which a total of 972 could be retrieved and is treated as reference set. The BM25 ranking function was applied to the complete set of retrieved full text documents, as these contain the relevant information. From Figure 2 it can be seen that the documents from the 10 and 20 keywords list have a very similar distribution and a generally higher relevance compared to the 30 keywords list and the sequential method. This trend holds true when using different amounts of keywords for relevance determination. The documents from the randomly selected subset have a considerably lower relevance proving that the methods perform as expected. The number of keywords when sampling the database is a key parameter and the results show that using more “relevant” keywords does not lead to improved

retrieval results. Moreover, it is evident that the Monte-Carlo method retrieved generally more relevant documents than the sequential method.

Table 1. Top 20 keywords and TF-IDF values extracted from the seed corpus abstracts.

Keyword	TF-IDF	Keyword	TF-IDF	Keyword	TF-IDF	Keyword	TF-IDF
pyrolysis	1.23	gas	0.85	bed	0.64	fluidise	0.55
waste	1.12	temperature	0.76	increase	0.64	time	0.50
product	1.01	plastic	0.76	feedstock	0.60	residence	0.50
oil	0.86	yield	0.73	wt	0.60	recycling	0.46
process	0.85	catalyst	0.68	polyethylene	0.58	flash	0.44

Figure 2. Cumulative distribution of normalized BM25 relevance values.

Figure 3 illustrates that the inherent ranking metric of the Monte-Carlo method correlates to some extent with the document relevance. The point clouds represent the relevance and document frequency of all retrieved documents within the 30 keywords list. It can be identified that, when only choosing documents with a normalized frequency higher than 0.1, a significant amount of irrelevant papers can be discarded (here: 80.3% of set size). Moreover, a large number of newly identified documents has an even higher relevance (22.9%) than the average relevance of the seed corpus, which is a promising starting point for the information extraction step. The sequential method, on the other hand, does not directly have an inherent ranking. Figure 3 (right) shows a derived metric that is the number of keywords contained in the downloaded papers. It appears that there is no clear correlation between the number of keywords included and the BM25 relevance.

The general impression is that the documents are indeed fitting the domain and potentially contain the desired information. A selected truly relevant document appearing in all three MC lists within the upper ranks is titled “Hydrocarbons obtained by waste plastic pyrolysis: Comparative analysis of decomposition described by different kinetic models” (Miskolczi and Nagy, 2012). A relevant passage reads as follows:

“... the parameter (yields) of volatile products were 15.0% [410 condition (°C)], 24.1% [430 condition (°C)] and 55.3% [450 condition (°C)] in case of W-2 marked sample process (pyrolysis), while ...”

Figure 3. BM25 values plotted against model inherent ranking for Monte-Carlo (left) and sequential (right) method. Shown is the data obtained from the 30 keywords list.

6. Conclusions

Lists of (linguistically) relevant documents were identified with minimal human intervention. These lists have the characteristic of being populated by highly relevant documents in the upper ranks which allows to limit the selection of documents to download for the subsequent information extraction step. The candidate documents proved to have similar or even higher relevance to the domain than the documents in the seed corpus. A first qualitative assessment of the titles and abstracts indicates that these documents are truly relevant to the posed question. Our investigations showed that the proposed information retrieval methodology performs appropriately using the selected database and seed corpus taken from a chemical engineering field. This implies the potential of establishing a systematic machine-assisted search procedure for model parameters and knowledge, effectively reducing the workload of engineers in the PSE community and going beyond what a completely manual procedure could achieve. As of now, the methodology assesses document relevance by means of the BM25 metric. This metric allows for a pre-selection of documents but the next necessary step in the development of the whole information retrieval and extraction cycle is to systematically classify the true relevance of the documents by a machine-assisted information extraction methodology. Moreover, the methodology has been tested using only one database. Further work is in progress to extend the search and improve its efficiency (speed and accuracy).

Abstract

This paper presents a Graph Neural Network (GNN) approach for the prediction of bioconcentration factors (BCF). We show that GNNs are able to exploit structural information of molecules to regress BCF values that are comparable to commonly used quantitative structure-activity relationship (QSAR) models in terms of the coefficient of determination R^2 . However, the main advantage of GNNs is that molecular descriptors do not need to be determined and pre-selected by the user. Instead, they are learned directly by the GNN using backpropagation. A database of 473 molecules was used to train and test the present model. The results obtained suggest that GNNs might be useful for the prediction of other types of sustainable indicators of molecules, which is subject of our further research.

Keywords: Bioconcentration Factor (BCF), Graph Neural Network (GNN), green chemistry, machine learning

1. Introduction

When moving towards a sustainable chemical industry, commonly used toxic solvents have to be replaced with more environmentally responsible options. For this, two main objectives have to be met: the replacements have to be comparable to certain degree in terms of their thermodynamic behavior; and their environmental, health and safety properties (EHS) have to qualify them as safe and sustainable replacements. While great effort has been set to find thermodynamically beneficial solvents, analyzing the EHS properties of the proposed molecules experimentally is quite expensive and time-consuming. To overcome this problem, quantitative structure-activity relationship (QSAR) models are commonly used as prediction methods (Benfenati et al., 2013).

One of the EHS of interest is the accumulation of chemical substances in body tissues (normally measured in fish tissue). This property is usually expressed as a bioconcentration factor (BCF), which measures the difference between the concentration of the substance in the organism's tissue to that in the environment. The QSAR models currently employed to predict BCF are based on several molecular descriptors and regression models such as multiple linear regression (MLR), support vector machines (SVM) and radial basis function neural networks (RBFNN) (Miller et al., 2019). However, all these methods require that the user pre-selects and calculates the appropriate molecular descriptors to serve as inputs to the model, which is a difficult

task given the large number of possible descriptors, e.g. Zhao et al. (2008) analyzed 1022 descriptors. This paper presents a Graph Neural Network (GNN) approach for the prediction of BCF. The advantage of the GNN compared to traditional QSAR methods is that molecular fingerprints are automatically generated. These fingerprints are later used to train a regression model (e.g. a multi-layer perceptron (MLP)). In this way, the complete set-up can be trained using backpropagation and an end-to-end model is obtained that relates the molecular structure (e.g. represented as SMILES strings) to the BCF value. The concept of GNNs is introduced next, before describing the methodology used, and the results obtained in terms of the coefficient of determination R^2 , the mean absolute error MAE and the standard deviation on the error of prediction SDEP. A comparison with traditional QSAR models is then provided.

2. Background

Graphs: A graph G can be defined as a tuple of features corresponding to nodes V and edges E , i.e., $G = (V, E)$. It is also necessary for a graph to specify the connectivity of its nodes, e.g. via an adjacency matrix. In this scheme, some nodes act as receivers and some as senders depending on the direction of connectivity. For undirected graphs, both connected nodes act as sender and receiver for each other.

Graph Neural Networks: Similarly, to artificial neural networks that operate over vectors, Graph Neural Networks (GNNs) operate on graph-structured data. This means that a GNN performs mathematical transformations on a graph as input and returns an updated graph as output (graph-to-graph). The transformations on G can be divided into three operations within a layer l :

- (i) Message passing: Given a node v with features $h_v^{(l-1)}$, for each node w connected to v , there is a differentiable function ϕ_M that sends the information of w to v .

$$m_{v,w}^{(l)} = \phi_M(h_v^{(l-1)}, h_w^{(l-1)}) \quad (1)$$

- (ii) Message aggregation: Given the messages $m_{v,w}^{(l)}$ for all nodes in the neighborhood N of v , there is a differentiable and permutation invariant function ϕ_A that aggregates all messages across all neighbors of v in an aggregated vector $a_v^{(l)}$.

$$a_v^{(l)} = \phi_A(\{m_{v,w}^{(l)} : w \in N(v)\}) \quad (2)$$

- (iii) Features updating: Given the aggregated features of all neighboring nodes $a_v^{(l)}$, there is a differentiable function ϕ_U that combines the features $h_v^{(l-1)}$ with $a_v^{(l)}$ to update the features $h_v^{(l)}$.

$$h_v^{(l)} = \phi_U(h_v^{(l-1)}, a_v^{(l)}) \quad (3)$$

This process of message passing, aggregation and updating can be repeated for many layers, similarly to the convolutional layers used for image processing. Edge features might be also included as part of the inputs of the function ϕ_M . This allows for the edge information to also be part of the message passing scheme. After multiple graph convolutions L , an updated graph is obtained whose nodes contain combined

information of their local neighborhood within an L -node radius. In this way, each node and edge in the final graph possesses information about itself in the context of the whole graph structure. Then, the final graph information can be transformed using a permutation invariant pooling layer to obtain a vectorial representation of the final graph. Finally, this vector might then be used as an input for a regression or classification model depending on the task at hand. Since all the functions involved in this scheme are differentiable, the whole model can be trained using backpropagation. GNNs have been the focus of research since the past decade (Gori et al., 2005), but their popularity has increased rapidly in recent years, especially in the context of molecular structure to property prediction (Coley et al., 2017; Gilmer et al., 2017; Sanchez-Lengeling et al., 2019; Schweidtmann et al., 2020).

3. Methodology

3.1. Database

Several publicly available datasets containing BCF values for different molecules can be found in the literature (Arnot and Gobas, 2006; EURAS, 2007). However, their values depend on many experimental factors, such as the fish species utilized during the experiments. For this reason, a reliability score is sometimes available along with the BCF values. Previous efforts have been made to carefully select high quality data which is suitable for regulatory purposes, such as the REACH legislation. The database reported by Zhao et al. (2008), which was used to construct QSAR models available in the VEGA toolbox (Benfenati et al., 2013), is one of these carefully selected collections of data. This database contains 473 compounds and covers a log-(BCF) range from -1.00 to 4.85, for molecular weights ranging from 68 to 943 g/mol. This same database was used in the present work. The molecule classes proportion in the dataset are shown in Figure 1.

Figure 1: Percentage distribution of molecular classes in the complete dataset and test set.

3.2. Molecule to graph

First, the molecular information has to be integrated into a graph. Starting from Simplified Molecular Input Line Entry System (SMILES) strings, a graph is created for each molecule in the dataset. This is performed using the open-source package for cheminformatics RDKit (<http://www.rdkit.org>) in Python 3.7. In each graph the nodes represent the atoms, and the edges represent the chemical bonds. For simplicity hydrogens were not considered as part of the graphs. Tables 1 and 2 show the type of features used for nodes and edges, respectively. Given the small size of the dataset, a generalized atom type "Other" was included. This accounts for the few instances of rarely appearing atoms in the database while conserving the other features information of the involved molecules.

Table 1: Node features used to define molecular graphs.

Node feature	Description	Dimensions
Type *	Type of atom (C, O, Cl, N, F, Br, S, Other)	8
Ring	Whether the atom is part of a ring	1
Aromaticity	Whether the atom is part of an aromatic ring	1
Hybridization *	Hybridization of the atom (sp, sp ² , sp ³ , sp ³ d, sp ³ d ²)	5
Bonds *	Number of bonds to the atom	6

* Implemented using one-hot-encoding (vector of binary values for each unique integer value).

Table 2: Edge features used to define molecular graphs.

Edge feature	Description	Dimensions
Type *	Type of bond (single, double, triple, aromatic)	4
Conjugated	Whether the bond is in a ring	1
Ring	Whether the bond is in a ring	1

* Implemented using one-hot-encoding (vector of binary values for each unique integer value).

3.3 GNN architecture

The GNN model was implemented using Pytorch Geometric (Fey and Lenssen, 2019) and follows a similar architecture to the one presented by Gilmer et al. (2017). In this structure, the message passing function is denoted by $m_{v,w}^{(l)} = h_w^{(l-1)} \cdot \text{MPL}(e_{v,w})$, where MPL stands for a multi-layer perceptron and $e_{v,w}$ for the edge features vector between the nodes v and w . For this MLP, the rectified linear unit (ReLU) activation function was used with a single hidden layer of 128 neurons. This MLP serves to combine edge information to the node. The aggregation function is just the sum over the

messages in the neighborhood v , $a_v^{(l)} = \sum_{w \in N(v)} m_{v,w}^{(l)}$. And the update function is

$h_v^{(l)} = \text{GRU}(\Theta^{(l)} h_v^{(l-1)} + a_v^{(l)})$ where $\Theta^{(l)}$ is a layer-specific trainable weight matrix.

GRU stands for Gated Recurrent Unit, which allows the sharing of parameters among layers. The use of GRU in GNNs was studied by Li et al. (2016) and was also applied by Schweidtmann et al. (2020) for the prediction of molecular properties. Regarding the method used, it is worth mentioning that, while the node features are being updated from one convolutional layer to the next one, the edge features remain the same.

A *set2set* (Vinyals et al., 2015) pooling layer was used to obtain the vectorial representation of the final graph. Gilmer et al. (2017) suggested that this type of graph embedding should produce a more expressive molecular fingerprint compared to the sum embedding. The number of processing steps was tuned between $0 \leq T \leq 10$. A final value of $T = 3$ was selected. Then, a multi-layer perceptron (MLP) was used to predict the BCF from the molecular fingerprint. This MLP uses the exponential linear unit (ELU) activation function. The model hyperparameters were extensively explored considering the following ranges: initial learning rate $\in \{0.0001, 0.001, 0.01\}$, number of convolutional layers $\in \{1, 2, 3\}$, hidden size of convolutional layers $\in \{21, 32, 59\}$, final MLP layers' size $\in \{64, 32, 16\}$. An initial learning rate of 0.001, 2 convolutional layers with size 21 and a three-layer MLP with 64, 32 and 16 neurons were finally selected based on the models' mean absolute error (MAE). The data splits used during the hyperparameter selection are discussed in the following.

3.4 Training, validation and testing

In order to compare our model with the one reported by Zhao et al. (2008), the same train/validation/test split proportions were used (80% of the whole dataset, 20% of the training set and 20% of the whole dataset respectively). Following the work by Schweidtmann et al. (2020), ensemble learning was used to improve the quality of the predictions given the small dataset in this work. A total of 10 models were trained using randomly selected splits for the validation set. The test predictions of each model were averaged to produce the final prediction. The model was trained for 300 epochs using the optimizer Adam with batches of 30 graphs. A dropout of 50% was used both for the convolutional layers and the final MLP to avoid overfitting. The training data was also normalized to have a zero mean and unit variance. The loss function was selected to be the same one used by Zhao et al. (2008), i.e., mean squared error (MSE). And the reported metrics used were the mean absolute error (MAE) and the R^2 score. A scheduler was specified to reduce the learning rate by 70% whenever the validation error reaches a plateau on 5 consecutive epochs with a threshold of 10^{-4} .

4. Results and discussion

The GNN model presented in this work was compared with the best QSAR model presented by Zhao et al. (2008) (in their original paper referred to as "Model 7" or "Hybrid model"). The results for the test and validation sets can be seen in Table 3. Compared to the QSAR model, our GNN-based model shows similar results. However, the main difference between both modeling approaches is that the GNN is able to map the structural information of the molecule to its property without the need to externally compute any molecular descriptor. As opposed to the 1022 descriptors analyzed by the Zhao et al. (2008), the GNN computes a molecular fingerprint from just 8 relatively intuitive structural parameters for molecules (see Tables 1 and 2). Despite this notable difference in descriptors, QSAR models might provide a physical insight that might be lacking when using GNNs. It is important to mention that both models were constructed using 2D information only. However, including stereochemistry information to a GNN would be relatively straightforward to do (e.g. by adding torsion angles as extra edge features). This is an important advantage given that spatial configuration plays a big role in the EHS properties of molecules. The parity plot for the test set is shown in Figure 2.

Figure 2: Parity plot for the final GNN model predictions on the test set.

Table 3: Comparison of models for predicting BCF (bold numbers indicate preferred value).

Model	Test set			Validation set			Training set		
	R^2	MAE	SDEP	R^2	MAE	SDEP	R^2	MAE	SDEP
GNN	0.82	0.49	0.34	0.83	0.44	0.32	0.82	0.44	0.35
Zhao	0.79	0.45	0.59	0.79	-	0.66	0.83	-	0.56

5. Conclusion

In this work a GNN-based model to predict BCF is presented. The main advantage of the proposed method is that molecular descriptors do not need to be chosen and calculated externally. Instead, molecular structure patterns are learned by the GNN to map them to the property of interest (e.g. BCF). First, the structure information is exploited by using graph convolutional layers. Then, a pooling method, herein *set2set*, is applied to obtain a molecular fingerprint that would play the role of the commonly used molecular descriptors. Finally, a multi-layer perceptron maps the fingerprint to the property. The investigation of the viability of GNNs with more EHS indicators is subject of future research. Also, the determination of confidence intervals on the GNNs predictions is still missing and an important aspect that needs to be investigated in the future.

Abstract

In this paper, a five-step approach coupling data science and life-cycle assessment is detailed. The main purposes of the study are to collect and analyse the process data from scientific literature, to characterize clusters, and to help the decision support in the preliminary choice of biomass or valorisation process according to the environmental indicators. The approach is tested on the comparison of rice straw and corn stover pretreatment processes for glucose production. Following the goal and scope, data architecture, life-cycle inventory, and environmental assessment steps, an impact-process matrix is analyzed in the last step using the multidimensional scaling method (MDS). The visualization of the results shows clusters that allow making a first analysis of the processes.

Keywords: Circular economy, biorefinery, machine learning, life cycle assessment, biomass pretreatments

1. Introduction

In the agriculture field, which is a major source of waste production, the circular economy has become a major study subject over recent years. In France, the waste from the agri-food industries is estimated at 2.6 million tons per year. Globally, this rate will increase with the expected increase in the population. Much of this waste is lignocellulosic byproducts that can be transformed into bioenergy, biomolecules, or biomaterials. A lot of researches are being done to transform these byproducts through sustainable processes, i.e. environmentally responsible, economically viable, and socially accepted (Sammons et al., 2009). Many transformation processes have been studied and published over the last thirty years (Davis et al., 2017). However, there is a lack of criteria to guide the choice between all these processes. The use of environmental, economic, and social assessment in a CE context is a good way to guide this choice. These assessments require a large amount of data, in particular data on processes potentially available in the scientific or technical literature or feeding by off-line simulation (Morales-Mendoza et al., 2012). The huge amount of scientific articles describing the valorization processes of agricultural byproducts constitutes a great and largely under-exploited source of data. This amount can be difficult to process. However, many tools and methods are now available for this purpose thanks to Big Data technics. Environmental evaluation tools such as Life Cycle Assessment (LCA) would benefit from these technologies to analyze process data and results from these evaluations. Some studies utilize massive data to complement LCA. J. Cooper et al. applied massive data to supplement background data (Cooper et al., 2013). The DILCA (Data-Intensive Life Cycle Assessment) method exploits knowledge

engineering (KE) and integrates technological developments that can change the LCA outcome for a given product over time (Bhinge et al., 2015). Divers studies combined Data Envelope Analysis (DEA) and LCA (Kouchaki-Penchah et al., 2017).

The main purposes of our study are (1) to collect and analyze the process data from scientific literature, (2) to characterize trend or clusters, (3) minimize experiments that are costly and energy-consuming, and (4) support the decision in the preliminary choice of biomass or a valorization process according to environmental indicators.

The approach is discussed in section 2 and section 3 deals with a study case: rice straw and corn stover pretreatment processes for glucose production.

2. General approach

The approach is based on multidisciplinary field: data management, sustainability engineering, and life cycle thinking. It supports the analysis of environmental impacts in an automatic way in grouping processes. Following the goal of their study, the researcher or the R&D engineering can compare or choose processes based on our approach's results. It is defined by five steps: (1) goal and scope, (2) data architecture, (3) life cycle inventory (LCI), (4) sustainability assessment, and (5) visualization and analysis of results.

In the first step, the *goal and scope of the study* must be clearly defined. Life cycle thinking is recommended. This thinking encourages a "cradle-to-grave" or "cradle-to-gate" approach if the logistics of a value chain are difficult to get. System boundaries and functional unit significantly influence evaluations. For example, it needs to be clarified whether the upstream biomass supply chain is considered. Once the goal and scope have been properly defined, the supply chain, technologies, and transformation processes should also be described.

The *data architecture* is directly inspired by the construction of big data architecture and consists of five sub-steps: (i) data collection and extraction, (ii) data enrichment and storage, (iii) data processing, (iv) (raw) data analysis, and (v) (raw) data visualization. This step can be automatic, semi-automatic, or manual and it uses data technics e.g. machine-learning methods for the (raw) data analysis. These substeps are detailed in (Belaud et al., 2019).

The *Life Cycle Inventory (LCI)* is completed using the process data (also called foreground data) from the previous step. The background data come from free or commercial LCI databases such as EcoInvent Database.

For the fourth step, one or more impact calculation methods must be determined in accordance with the first step that integrates the nature of the study and the system. Then, the environmental impacts are calculated using these methods. At the end of this stage, the main result is a structure [processes: biomasses: impacts] which is difficult to analyze.

The *visualization and analysis of the results* step include methods derived from artificial intelligence and more precisely from "machine learning" to help in the analysis of environmental impacts. Starting from the statistical literature, traditional dimension reduction (DR) and unsupervised clustering techniques are combined to extract information from environmental impacts. More precisely, this hybrid approach is based on the Multi-Dimensional Scaling (MDS) using the Canberra distance and k-means. The objective is to search for "hidden" structures in multi-dimensional data and to help interpret the matrix. The advantage of this approach is that data-based methods require very little knowledge of processes to perform. Figure 1 summarizes the treatment for a [processes: impacts] matrix. First, DR techniques project the raw process data into a

lower-dimensional space (2 or 3). After a projection of the data by a DR technique, the clustering approach is then applied to consider similar impacts and processes within the lower-dimensional space. Finally, the user (expert) analyzes the points grouped in clusters to link them to significant processes/impacts. The visualization of the data clusters will help the researcher or R&D engineers in the final decision following the goal of their study.

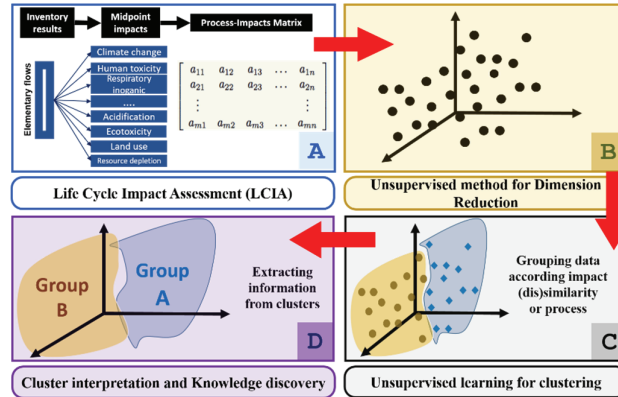

Figure 1: Schematic of data driven processing

3. Case study

In this section, the first results of our approach are presented with an intention to compare different pre-treatment processes for two biomasses: corn stover and rice straw. This study examines twenty processes extracted from twenty scientific articles. The study aims to help the researchers or R&D engineers to analyse processes for glucose production. Life cycle thinking is from “cradle to grave” i.e. the study’s boundaries are from biomass to the enzymatic hydrolysis stage. Biomass is considered as agricultural waste (destined to become a co-product): it has a zero impact - the impacts of the agricultural phase are attributed to the end product of agriculture (corn and rice). The biorefinery is considered to be relatively close to the site. Therefore the transport stage impact is minor. The main function of the system is the production of glucose. The functional unit is “production of 1 kg of glucose” and results are expressed in a functional unit.

Twenty scientific articles have been selected thanks to specific keywords in Science Direct and Web of Science. Process data from articles are extracted semi-automatically using an ontology. The ontology structures the process data and ensures an export in CSV files and supplying internal software. This software developed on Microsoft Excel carries out a first “cleaning” of the data by simulating the processes to calculate and checking the mass balance. The data from three articles are removed from our study because they contain inconsistencies or many missing data that can not be verified by our simulation. The study, therefore, analyses 17 processes of two biomasses. The (attributorial) LCA method applied is ReCiPe 2016, the background database is from EcoInvent v2.2 and the foreground data are “cleaned” process data. The environmental assessment evaluates 17 “midpoint” impacts. The Excel tool has been validated using the commercial simulator ProSim+ for process simulation and SimaPro® for the simulation of the environmental impacts. The matrix of results [impacts: processes] is then analyzed by multi-dimensional scaling using R software. Figure 2 shows the global architecture of our application.

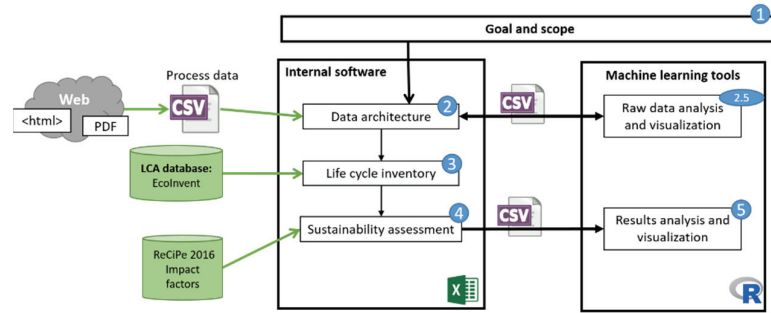

Figure 2: Architecture of the application

Classical Multidimensional Scaling (MDS) is a method for visualizing (dis)similarities between objects in a space of a reduced dimension. It is designed to help understand the structures of proximity and opposition. Starting from information about the mutual similarities of n objects, often with the similarity matrix $\Delta = \delta(i, j)_{0 \leq i \leq n; 0 \leq j \leq n}$, we look for a configuration of n points (in R^2 in general) which would be like that if the object i resembles to j more than the object l to k , we have $\delta(i, j) < \delta(l, k)$. For any distance matrix of size $n \times n$, the MDS allows us to find a set of n points marked by their coordinates whose similarity matrix is equal or very close to the distance matrix according to the data. In our approach, we use the Canberra distance (Lance & Williams, 1966), a weighted version of the Manhattan distance.

Let x_r ($r = 1, \dots, n$) be the coordinates of n points in a p dimensional Euclidean space where $x_r = (x_{r1}, x_{r2}, \dots, x_{rp})^T$ and $[B]_{rs} = b_{rs} = x_r^T x_s$. For an Euclidean distance $\Delta = \delta_{rs}$, from a matrix A of elements $[A]_{rs} = a_{rs} = -\frac{1}{2} \delta_{rs}^2$, deduced from the decomposition $x_r^T x_s$, the matrix B is obtained using the following relation :

$$\mathbf{B} = \mathbf{H}\mathbf{A}\mathbf{H} \quad (1)$$

where H is the centering matrix: $H = I - n^{-1}I \cdot I^T$ with $I = (1, 1, \dots, n)^T$. Elements of A are defined as $a_{r\bullet} = n^{-1} \sum_s a_{rs}$, $a_{\bullet s} = n^{-1} \sum_r a_{rs}$ and $a_{\bullet\bullet} = n^{-1} \sum_r \sum_s a_{rs}$.

The following steps can summarize the algorithmic procedure of multi-dimensional scaling, as illustrated in (Cox & Cox, 2001):

1. Obtain the proximity matrix $\Delta = \delta_{rs}$
2. Find the matrix $A = [-\frac{1}{2} \delta_{rs}^2]$
3. Find the matrix $B = [a_{rs} - a_{r\bullet} - a_{\bullet s} + a_{\bullet\bullet}]$
4. Find the eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_{n-1}$ and the eigenvectors v_1, v_2, \dots, v_{n-1}
if B is semi-defined positive (some eigenvalues are negative), either (i) ignore the negative values and continue, or (ii) add an appropriate constant c to the (dis)similarities
5. Choose an appropriate size number l , possibly using $\frac{\sum_1^l \lambda_i}{\sum (\text{positive eigenvalues})}$.
6. The coordinates of the n points in Euclidean dimension space l are given by $x_{ri} = v_{ir}$ ($r = 1, \dots, n; i = 1, \dots, p$).

The interpretation of an MDS result is the same as for any other dimension reduction method: objects that are closer on the scatterplot are more similar than those that are further away. That is, the projected points are arranged in such a way that the grouped points (small distance between them) reflect the original relationships in the data. However, additional information is needed to make the projection more informative. As shown in Figure 1, a clustering algorithm (k-means) was applied to the MDS projection to highlight the most similar objects (Impacts - Processes). Two-dimensional maps of aggregated impacts and processes are shown in Figure 3. For the scatter plot of the impact points (Figure 3 left), we can distinguish three groups using k-means:

- Group 1: This group includes almost all impacts related to the chemical pollution of soils and water bodies.
- Group 2: This group forms three subgroups with superimposed points (in a 2-D perspective). This suggests that these points are very similar based on the Canberra distance. Here, we find a group quite heterogeneous in terms of impact with some not present in groups 1 and 3.
- Group 3: This group mainly includes impacts related to land use and land transformation.

To clarify the discussion, the names of the impacts within groups 1, 2, and 3 are not detailed. The clustering results of projected Process items are similar to those obtained for impacts. Indeed, three distinct clusters have been identified. However, tight and highly separated clusters occur within process data, this may suggest that each cluster is a domain or subdomain which should be analyzed individually. The acronyms captioning the dots represent each type of process which will not be explained here. In group 3, for example, there are two purely mechanical pre-treatments. Going back to the impacts, we find that these two pre-treatments have a very significant impact on the depletion of fossil fuels compared to the others. For Group 1, the three pre-treatments have relatively similar impacts and fossil fuels depletion impact costs around \$10, whereas group 2 pre-treatments have an impact cost of around \$1. However, these results are partial. Indeed, only a representation of dimension 1 is used instead of dimension 2, which gives a low percentage of representativeness and therefore a loss of information. It is planned to extend this study to represent dimensions 3 and 4 and complete the analysis.

Figure 3: Scatter plot of (MDS) projection (two dimensions) and k-means clustering based on Impacts distance matrix (left) and Process distance matrix (right)

4. Conclusion and perspectives

A five steps approach coupling data science and environmental assessment is proposed and presented as an aid for researchers or R&D engineers during a preliminary study. This approach is being tested by studying the valorization of agricultural waste to promote a circular local economy. It compares different pretreatment of two lignocellulosic biomasses corn stalk and rice straw for glucose production. Following the goal and scope, data architecture, LCI, and environmental assessment steps, an impact-process matrix is analyzed in the last step using the multidimensional scaling method. The approach provides an initial insight to sort by groups and to establish a way to pre-select technologies or biomasses rigorously. The case study application reveals various limitations. Data from the scientific literature are by nature data from experiments in the laboratory and the LCA is therefore carried out for a low level of technological maturity (TRL 1/2). The approach does not incorporate the change in scale required to implement a semi-industrial pilot. Another limitation is the abundance and the quality of the data, which may not be sufficient for new technological pathways.

Different perspectives can be detailed for the approach. We can reconsider the functional unit and the global environmental assessment strategy by integrating the upstream agricultural phase and taking into account the global supply chain according to dynamic analysis, i.e. spatial or temporal. In this study, all the impacts are attributed to the final product (glucose), the policy of impacts relating to effluents can be modified by taking into account the fate of these effluents and their valorization in the circular economy context.

Abstract

In bio-based chemical processes, stable and efficient process control is challenging because the feedstock composition made by microbial fermentation is uncontrollable. Many researchers have developed data-driven models that predict the operating condition using a correlation between the process data. Since the performance of a data-driven model depends on the quality of the data, data preprocessing techniques such as noise removal and outlier detection are generally considered to enhance the model performance. Thus, research to establish an appropriate data preprocessing method and range is required to increase the performance of the model. In this study, we developed a data-based prediction model for the bio-based 2,3-butanediol distillation column. We prepared sixty train datasets by applying noise removal and outlier detection with different methods and ranges on the raw data and confirmed the correlation between the data using Pearson's correlation coefficient. We considered two kinds of feature selection depending on data preprocessing and compared the performance (R^2 and normalized RMSE (NRMSE)) and reproducibility. The case in which the features were selected by only noise removal showed a similar coefficient value to that of the raw data; therefore, it had a higher performance than the case which applied outlier detection. The best performance provided R^2 and NRMSE values of 0.962 and 0.045, respectively, and it could be enhanced by hyperparameter tuning. Based on this result, we plan to develop a robust predictive model that features adaptable real-time prediction and control throughout the entire process time and period.

Keywords: 2,3-butanediol, 2,3-BDO, data-based prediction model, data preprocessing, feature selection

1. Introduction

Based on the rapid development of computer-related technologies and industries, new technologies integrating artificial intelligence are being established in various fields. The petrochemical industry is based on large equipment and processes, where the connection between unit processes and various sensors is complicated. However, too many unintended internal and external variables hinder efficient operation. Many machine learning-based studies have been conducted to improve prediction and control. Because a machine learning-based model predicts the output based on correlations between input and output data, the performance and stability of the model strongly depend on the data quality. Therefore, it is important to appropriately preprocess the raw data and select correct variables (sometimes called features) to increase the accuracy of the model. In addition, the performance of the predictive model may be inconsistent despite using the same data because the initial weights of the predictive model are randomly determined, and under- and over-fitting can occur during model training. Thus, the reproducibility must be considered to develop a robust predictive model.

2,3-butanediol (BDO) is the only isomer of butanediol that is widely found in nature. It is produced during a bioprocess, i.e. the fermentation of microorganisms, and not by a petrochemical process. GS Caltex is currently developing and operating a demo plant of a microbial-based 2,3-BDO production process (D. Tinôco *et al.*, 2020). However, the raw 2,3-BDO product has a low purity of 10–15 % and includes dozens of minor substances that cannot be detected during the analysis. This causes unstable operating

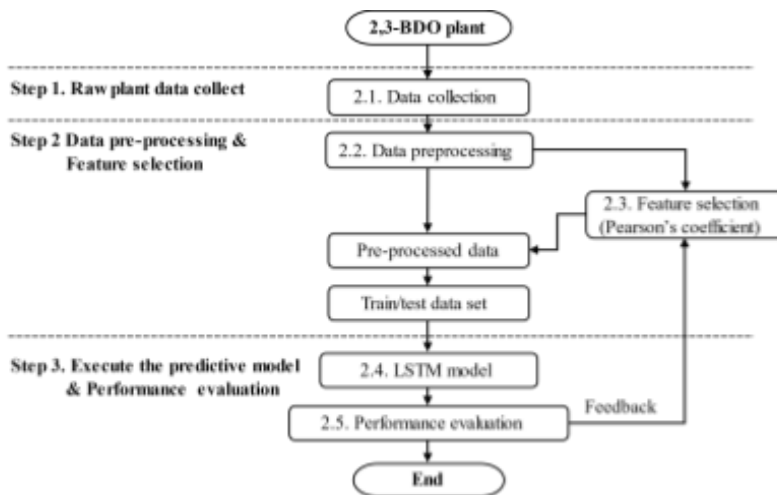

Figure SEQ Figure 1 ARABIC 1. Development strategy for a data-based predictive model

conditions, leading to noise and outliers in the raw data. To solve this problem, a prediction model that delivers a robust performance regardless of the early stopping option or initial weight factor must be established.

In this study, we developed a robust prediction model for the distillation column of bio-based 2,3-BDO by data preprocessing, such as noise removal and outlier detection, and selected features based on the correlation coefficient. The raw data were preprocessed by applying a low-pass filter (LPF) for noise removal and the interquartile range (IQR) and z-score for outlier detection. Subsequently, the features of the

predictive model were selected using the Pearson's correlation coefficient. To evaluate the performance, the coefficient of determination (R^2) and the standard deviation-based normalized root-mean-square error (NRMSE) were used. Each model run was repeated ten times to evaluate the reproducibility of the model. The overall model-development methodology in this study can be divided into three stages, as shown in Figure 1. The methods are detailed in the following section.

2. Methodology

2.1. Data collection

The bio-2,3-BDO plant data used in this study were collected by GS Caltex. The data were collected at one-minute intervals from July 10, 2020, to July 13, 2020 including the process start-up period. As shown in Figure 2, each dataset consists of 20 variables (features) including the control valves and instruments for temperature, pressure, and water-level measurements. The target variable is the temperature of the main product stream (the effluent at the bottom of the distillation column).

Figure 2. The data type and position in the distillation column

2.2. Data preprocessing

The data used in this study did not contain missing values. Therefore, only noise removal and outlier detection were performed. A first order low-pass filter was used for the noise removal. To compare the changes in correlation coefficient depending on the weight and performance of the prediction model, the weights were divided into the following categories: 0.3, 0.6, and 0.9 (labeled L1, L2, and L3, respectively).

The IQR and z-score, which are the most commonly used statistical methods, were used to remove the outliers (Ivanushkin et al., 2019). Four ranges corresponding to each outlier detection method were used: 2.5, 3.0, 3.5, and 4.0 (labeled I1, I2, I3, and I4, respectively, for IQR, and Z1, Z2, Z3, and Z4, respectively, for z-score). A total of 60 preprocessed datasets, including raw data, were obtained based on the application of individual methods and their combinations. The data were used for the model feature selection.

2.3. Feature selection

The Pearson correlation coefficient was used in this study for feature selection. In general, the coefficients between variables are considered to correlate if the absolute value of the coefficient is greater than 0.3, and this criterion was applied in this study.

2.4. Long short-term memory (LSTM) Model

The LSTM model, a recurrent neural network (RNN)-based algorithm, was used as the machine-learning algorithm (Hochreiter and Schmidhuber, 1997). The LSTM model can be used to solve the vanishing gradient problem; the weight update of the activation function converges to zero when long-term data are learned in an RNN algorithm, which is useful for data with a long learning period.

The predictive model is composed of an input layer containing selected features, a hidden LSTM layer consisting of four hidden units, and an output layer that outputs the temperature of the 2,3-BDO production stage. Seventy percent of the total data were randomly selected and used for training and validation, and 100 % of the data, including the training data, were used to determine the model performance.

The hyperparameters of the model were set based on a previous study (Kwon *et al.*, 2021). The numbers of batches, the number of epochs, the learning rate, and the activation function were set to 10, 1000, 0.01, and Elu, respectively. To prevent under- and/or over-fitting of the predictive model, the “patience” option was used as the early stopping option; it is defined as the number of epochs without an improvement after which the training will be stopped. The number of epochs was set at five for this study.

2.5. Evaluation factors for performance and reproducibility

Because the prediction performance is affected by the initial weight setting of the prediction model and the number of epochs, the reproducibility of the model was confirmed by running the model ten times using the preprocessed data. The R^2 value was used as the accuracy index because the RMSE, which generally represents the precision, significantly differs depending on the scale of the subject. Therefore, the NRMSE—RMSE divided by the standard deviation (σ)—was used in this study.

$$R^2 = \frac{\sum_i^n (y_i - \hat{y}_i)}{\sum_i^n (y_i - \bar{y}_i)} \quad (1)$$

y_i : Actual data

\hat{y}_i : Predicted data

\bar{y}_i : The mean value of actual data

$$NRMSE = \frac{\sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2}}{\sigma} \quad (2)$$

n : Number of datasets

σ : Standard deviation of actual data

3. Results and discussion

3.1. Feature selection through data preprocessing

Table 1 lists the correlation coefficients between the raw data and those after applying the preprocessing methods. The coefficient values with different ranges corresponding to each preprocessing method showed similar values; the correlation coefficient applied with an LPF of 0.6 and a z-score of 3.5 is listed in Table 1. This result shows that the correlation coefficient obtained after noise removal is similar to that of the raw data. In contrast, the correlation coefficient corresponding to the outlier detection significantly differs from that of the raw data because outlier detection removes anomalous data and retains the data that follow the theoretical law.

We established two feature-selection cases for the predictive model and compared their performances and reproducibility based on different datasets. As described in Section 2.3, features with an absolute value above 0.3 were selected. The 13 features were selected from the raw data and the data obtained after noise removal, and 11 features were selected from the data obtained after outlier detection. The feature-selection cases are called scenario R3 and O3 hereafter.

Table 1. Pearson's correlation coefficients for raw and preprocessed data

Variables (Features)	Raw data		Noise removal (Applied LPF 0.6)		Outlier detection (Applied z-score 3.5)

3.2. Prediction performance based on the feature selection

Figure 3 shows the ten datasets with the best performances according to each feature-selection case. The line and bar show the minimal, average, and maximum values for permeance and epoch. As shown in Figure 3, the scenario R3 showed a higher and more stable performance than the scenario O3. Although the best performance exhibited R^2 and NRMSE values of 0.962 and 0.045, respectively, we expect that this result can be enhanced by hyperparameter tuning and algorithm change. This study shows that the process characteristics in the feature selection step affect the performance of data-driven predictive models. It is also possible to develop a prediction model that reflects the characteristics of the actual process through appropriate data preprocessing.

Although the outlier detection method with high performance was applied in both cases, it could not predict the start-up period, which is a limitation of this study. The case using raw data and the L1-L3 dataset could predict the whole process period, including the start-up period, but it showed a low performance, with R^2 and NRMSE as 0.936 and 0.254, respectively, because of the inclusion of the outlier data. Therefore, to improve the overall model performance, it is necessary to tune the hyperparameters or to consider other preprocessing methods that efficiently process outlier data for dynamic systems.

4. Conclusions

In this study, a data-based model was developed for the bio 2,3-BDO distillation process, and an appropriate data preprocessing method and range were established considering the process characteristics. A total of 60 datasets, among which 1 comprised raw data and 59 comprised data preprocessed with noise removal and outlier detection, were prepared. To examine whether the feature selection affects the model performance and reproducibility, Pearson's correlation coefficients of the datasets were compared. Two kinds of feature selection scenarios, scenarios R3 and O3, were established as the case studies. Scenario R3 showed a higher performance than that of scenario O3 because it included the process characteristics. We concluded that feature selection based on correlation of the raw data improves the performance of the data-based predictive model. However, it has a limitation, wherein it shows low performance when using L1–L3 data because the start-up period data is recognized as an outlier. Therefore, future studies should focus on developing a data preprocessing method which can classify outlier data efficiently under dynamic conditions in the whole process.

Figure 1. Top 10 results of the R^2 and NRMSE performances based on the feature-selection for scenario R3 (left) and O3 (right).

Abstract

Process design based on physical models often faces computational problems with respect to convergence, especially if the underlying flowsheets are complex. The use of data-driven surrogate models promises to overcome these challenges. This contribution presents the development of surrogate models and their use for flowsheet simulation. A new sampling strategy consisting of a combination of adaptive and sequential sampling enables the selective placement of new sample points. It is shown, however, that this hybrid strategy does not necessarily lead to higher accuracies than a pure sequential sampling. Surrogates are built for selected key units of the steam methane reforming process, and their individual accuracies are analyzed. When the surrogates are combined to form flowsheets, the prediction errors show a tendency to damp from unit to unit. This proves the suitability of surrogate models for flowsheet simulations. The promising results of this paper pave the way for future work, such as the optimization of flowsheets or superstructure optimization.

Keywords: surrogate modeling, adaptive sampling, artificial neural networks, error propagation, hydrogen production.

1. Introduction

Surrogates replacing flowsheet models have attracted broad attention in process engineering due to their potential to accelerate rigorous simulations for purposes such as exploring the allowed operating window (Heese et al., 2019) and global optimization (Schweidtmann et al., 2019). Their training data is generated with the original simulation according to some sampling strategy. A recent review on the topic can be found in (McBride and Sundmacher, 2019). When dealing with such surrogate models, it is important to distinguish between two different applications: on the one hand, it can be sufficient for the surrogate model to map only subsets of the input space, for example in case of process optimization it is only necessary to be accurate along the trajectory to the optimal solution. Accordingly, the training data does not need to cover the entire input space. On the other hand, the purpose of the surrogate can require to map large parts of the input space. This is for example the case when it is coupled to other sub-models like a unit operation in a flowsheet, as done in this work. Hence, techniques tailored to this

situation are required. A survey on such sampling strategies for global surrogate modeling can be found in (Liu et al., 2018).

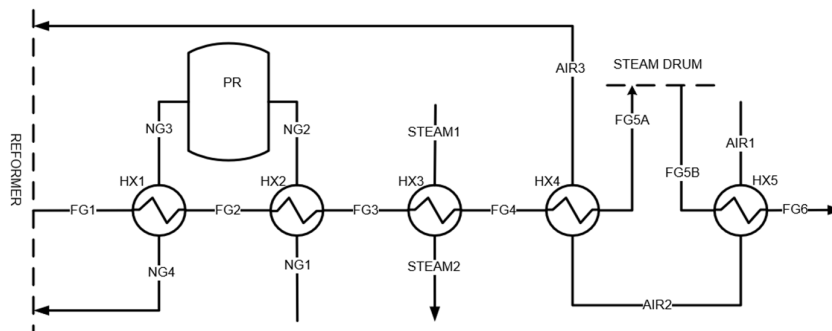

Figure 1: Schematic illustration of the pre-reformer and flue gas waste heat recovery section of an SMR process. The flowsheet is based on Genkin et al. (2010).

This paper continues Air Liquide’s recent activities in the field of surrogate modeling (Soroush et al., 2020; Schmidt et al., 2020). Using the example of the Steam Methane Reforming (SMR) process, the relevant steps for generating a process model for individual surrogate units as well as their combination to a flowsheet are presented. SMR is the state-of-the-art method of producing hydrogen, where a natural gas feedstock (NG) is mixed with steam to produce syngas, and finally hydrogen and CO₂. The focus of this contribution is on the heat recovery from the flue gas (FG) of the SMR process comprising five heat exchangers (HX1-HX5) and one pre-reformer (PR) as illustrated in Figure 1.

2. Methods

2.1. Determination of technically relevant operating conditions of process units

In order to develop a data-driven surrogate model for a specific unit operation, a feasible input region, from which points are sampled for data generation, has to be found. In this work, the definition of these input regions is based on a design simulation of the entire SMR process in Aspen Plus[®] with the following adjustable parameters: (i) The type of natural gas feedstock; (ii) the steam-to-carbon ratio (S/C) in the reformer feed; (iii) the ratio of hydrogen recycle; (iv) the temperature in the pre-reformer feed; (v) the temperature in the reformer feed. Varying these parameters directly influences the composition and/or flow rate of the natural gas and steam streams, and indirectly the properties of the flue gas and air streams in the sub-process in Figure 1. Thus, by varying the adjustable parameters and evaluating the rigorous process simulation accordingly, a set of input points can be recorded at each unit, which is used to define a feasible input region. Here, this is achieved by defining a box domain around the input values and adding a 25 % margin in each dimension to ensure that the boundary regions of the domain are well represented.

For units occurring multiple times within a flowsheet, such as the heat exchanger in the sub-process from Figure 1, there are two modeling options: either to assign an input region and train a surrogate model for each unit (‘one-for-each’), or to define an input region around the combined input domains of all units and use the same surrogate model for each of them (‘one-for-all’). The latter approach will likely result in a more complex surrogate, since a larger input space has to be covered. However, the ‘one-for-all’ model

could also be used more generally, for example in superstructure optimization problems. In this work, the two approaches will be compared with respect to their accuracy in a simulation setting.

2.2. Sampling

In a preceding contribution (Schmidt et al., 2020), the focus was on a Latin Hypercube design (a space-filling strategy) for global metamodeling of the pre-reformer reactor as a sub-model of the overall SMR process. In the current work, this sub-model is used to evaluate an adaptive sampling strategy. Adaptive sampling methods can be based on cross validation, such as the one suggested by Aute et al. (2013). This type of strategy is applicable to any type of model. However, it is prone to rather long computation times because it requires the model to be trained very often. Instead, the variance-based method by Lam and Notz (2008) is adjusted. I.e., the merit function

$$f(\varphi) = (\hat{y}(\varphi) - y^*(\varphi))^2 \frac{\Delta\varphi^2}{\Delta y^2} + d^2(\varphi) \quad (1)$$

is iteratively maximized, the resulting point φ is added to the training data and the model is retrained. Here, $\varphi \in R^{11}$ is the input vector of the pre-reformer simulation. $\hat{y}(\varphi)$ is the model prediction for the response, chosen as the temperature of the product stream, and $y^*(\varphi)$ is the corresponding response value at the training point closest to φ . $\Delta\varphi$ is the Euclidean norm of the ranges spanned by the input variables and Δy is the response range. $d(\varphi)$ is the average Euclidean distance between φ and its k nearest neighbors, where $k = 5$ is chosen. Thus, the first term in $f(\varphi)$ is responsible for local exploitation of strong variations in the response, and the second term ensures a global exploration of the input space. This adaptive sampling method is turned into a hybrid strategy by combining it with a space-filling Sobol sequence. I.e., an adaptive percentage z^* is defined, and in each iteration a random number z is drawn from a uniform distribution. Then f is maximized for $z \leq z^*$, whereas φ is taken to be the next Sobol point for $z > z^*$.

2.3. Development of surrogate unit models

The data used to train the heat exchanger surrogate is generated using the Aspen Plus[®] ‘HEX’ shortcut model, with the added consideration of heat loss. Thus, the following variables are chosen as model input: temperature T , pressure p , molar flow rate F and the composition vector \mathbf{x} for both inlet streams (denoted with c,in and h,in), UA (the exchanger area multiplied by its heat transfer coefficient) and the percentage heat loss $f_{Q,loss}$, as well as the pressure drop dp . The surrogate model predicts the temperatures of both outlet streams (denoted with c,out and h,out). The functional relationships learned from data are given by F_{sur} in Eqs. (2)-(3). Depending on the type of surrogate model used, F_{sur} will have different mathematical forms. In this work, only artificial neural networks (ANNs) are considered:

$$T_{h,out} = F_{sur}^T(\{T, p, F, \mathbf{x}\}_{h,in}, \{T, p, F, \mathbf{x}\}_{c,in}, dp_{c,in}, dp_{h,in}, UA, f_{Q,loss}), \quad (2)$$

$$T_{c,out} = F_{sur}^Z(\{T, p, F, \mathbf{x}\}_{h,in}, \{T, p, F, \mathbf{x}\}_{c,in}, dp_{c,in}, dp_{h,in}, UA, f_{Q,loss}). \quad (3)$$

As mentioned in Sec. 2.2, the model for the pre-reformer reactor is adopted from a previous contribution by Schmidt et al. (2020).

2.4. Connection of surrogate models to form a flowsheet

After the trained ANNs are embedded into the surrogate unit models, it is straightforward to construct a surrogate flowsheet for the entire sub-process in Figure 1. To this end, terminal conditions are introduced that connect the output of one unit with the input of another to represent the process streams. The resulting nonlinear system of equations can be solved either in a sequential-modular or equation-oriented manner. *Pyomo* (Hart et al., 2017) was used to implement the individual units and generate functional representations for the trained ANNs. The *pyomo.network* package allows for the definition of the flowsheet as a connection of units, and it offers sequential decomposition and solution routines. Process optimization is also possible directly in *Pyomo* and will be a future step.

3. Results

3.1. Comparison of sampling strategies

A fully connected feed-forward ANN with a single hidden layer consisting of 100 nodes is used to test the hybrid sampling strategy described in Sec. 2.2. The ANN is implemented in *PyTorch* with a learning rate of 0.002 and with 4000 training epochs. The Python package *sobol_seq* is used to draw the Sobol points, and *scipy.optimize.differential_evolution* is used to maximize the merit function from Eq. (1). The strategy is run with different adaptive percentages z^* , and the root-mean-squared error (RMSE) as well as the maximum deviation of the model predictions with respect to an independent test data set of size $N = 10^4$ (generated with Latin Hypercube) are recorded for each iteration. Since *PyTorch* initializes its net weights randomly, the results are averaged over 10 repetitions of the procedure.

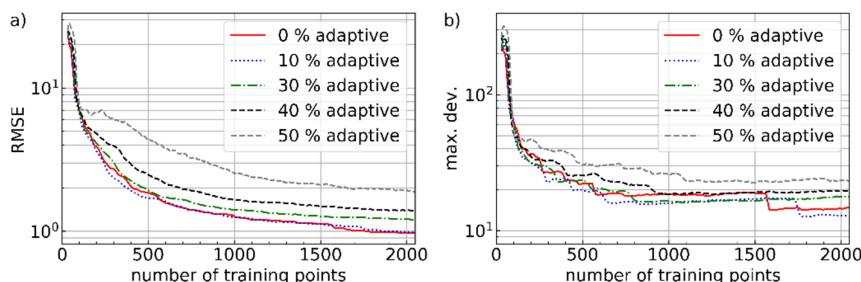

Figure 2: Quality of the ANNs for the pre-reformer reactor trained with the hybrid sampling strategy at different adaptive percentages. a) RMSE, b) maximum deviation with respect to the independent test data set. Curves are averaged over 10 repetitions and then smoothed with a moving average over 20 preceding points.

Figure 2a shows the averaged RMSE of the ANNs for the pre-reformer reactor as a function of the number of training points. The main observation is that a non-zero adaptive percentage does not improve the model accuracy compared to the 100 % Sobol design (solid red curve) for this example. Therefore, purely space-filling sampling methods are used in the subsequent sections. Figure 2b displays the corresponding maximum deviations between prediction and test data at the least accurately predicted test point. Interestingly, this quantity actually slightly increases for most added points. It

only decreases overall due to large steps which occur when a point finally corrects the worst prediction.

3.2. Accuracy of HEX surrogate models

For the ‘one-for-each’ (OFE) approach, a data set of 100,000 points is generated with Aspen Plus[®] for each of the heat exchangers in the sub-process, according to the input-output relationship established in Sec. 2.3. Alternatively, the input data of all heat exchangers are combined to train a single model in the ‘one-for-all’ (OFA) approach. In both cases, the data is then split randomly into training and test sets at a ratio of 85:15. *TensorFlow* is used to train ANNs with one hidden layer on the training set, with their performance being evaluated on the test set. The results are given in Table 1.

It is evident that an increased model complexity (i.e. higher no. of neurons) leads to a better performance for both approaches. However, the mean (‘avg’) and maximum error (‘max’) of the temperature in Kelvin for the OFA method is generally at least three times higher than for the worst performing OFE model. This was also expected, since OFA approximates the HEX model over a larger domain, and will thus be less refined locally, given the same model complexity.

Table 1: Test set accuracy metrics for ANNs of increasing size using one hidden layer. The ‘avg’ and ‘max’ operations are applied across the test set and the two outputs of the surrogate models.

unit	HX1		HX2		HX3		HX4		HX5		OFA	
abs. error (K)	avg	max	avg	max	avg	max	avg	max	avg	max	avg	max
20	0.05	1.01	0.06	0.74	0.03	0.25	0.03	0.38	0.03	0.39	0.28	2.82
50	0.02	0.32	0.02	0.24	0.01	0.08	0.01	0.15	0.01	0.11	0.09	1.22
100	0.01	0.21	0.02	0.24	0.01	0.07	0.01	0.11	0.00	0.06	0.05	1.04

3.3. Error propagation in the flowsheet

To evaluate the performance of the surrogate flowsheet, an equivalent process model in Aspen Plus[®] is used to generate a test data set of 5,000 points by space-filling sampling. The surrogate flowsheet is evaluated at the same input points and the error in the different streams is recorded. The error within the flue gas (‘FG’) stream is of particular importance since it allows the investigation of the error propagation between the surrogate units. An ‘error propagation factor’ ε is introduced, which describes the ratio of the prediction error in the flue gas stream temperature $e_{FG,out}$ to the maximum error in the input temperature for each unit e_{in} :

$$\varepsilon = \frac{|e_{FG,out}|}{|e_{in}|} \quad (4)$$

Table 2: Performance metrics of the surrogate models during evaluation of the connected surrogate flowsheet on a test set of 5,000 points.

unit	HX1		HX2		HX3		HX4		HX5	
metric	ε	max (K)	ε	max (K)	ε	max (K)	ε	max (K)	ε	max (K)

‘One for each’

no. neurons	20	0.54	0.90	1.72	0.46	0.91	0.45	0.78	0.36	-	0.10
	50	0.27	0.44	1.98	0.29	0.98	0.32	1.07	0.25	-	0.08
	100	0.25	0.43	1.51	0.28	0.89	0.31	1.14	0.24	-	0.08
<i>'One for all'</i>											
no. neurons	20	1.73	1.93	1.49	1.87	1.12	1.83	0.86	1.77	-	1.17
	50	1.34	0.62	1.37	0.69	1.06	0.66	0.71	0.57	-	0.27
	100	1.00	0.60	1.42	0.61	0.97	0.53	0.69	0.43	-	0.17

Hence, a unit amplifies the error in its input if $\varepsilon > 1$. In Table 2, the maximum absolute error and the median error propagation factor at each heat exchanger across the test set are listed for both the 'OFE' and 'OFA' approach. Again, a better performance of the OFE models compared to the more general OFA method is observed. Interestingly, the majority of the OFE models achieve propagation factors of less than one, meaning that the prediction error is actually damped along the FG stream.

4. Conclusions

In this work, the development of surrogate unit models for flowsheet simulation was presented. It was shown that an adaptive sampling strategy for the case study under consideration is not advantageous compared to a purely space-filling sampling. Consequently, space-filling designs were used in the following parts of this paper. In general, the "one-for-each" modeling approach leads to a higher accuracy than the "one-for-all" approach. Finally, it was shown that the connection of individual surrogate models to a flowsheet leads to high-quality results in terms of accuracy and error propagation, paving the way for real-time or superstructure optimization. Nevertheless, it has to be verified whether the promising results are applicable to larger processes with more process units. Future work will also focus on the minimum number of training points required to achieve a desired model accuracy as well as on investigating the distribution of the "worst" predicted points of the test set.

Input transformation for linearization, decoupling and disturbance rejection with application to steam networks

Cristina Zotică^a, Sigurd Skogestad^a

^aDepartment of Chemical Engineering, Norwegian University of Science and Technology, Sem Sælands vei 4, Trondheim 7491, Norway

Abstract

Pressure-flow networks are inherently multivariable, coupled and nonlinear systems that are not straightforward handled by conventional PID controllers. In this work, we analyze the control problem for a steam distribution network in the framework of a recent proposed method, that gives linearization and decoupling, together with a systematic design for nonlinear feedforward control for perfect disturbance rejection.

Keywords: steam networks, linearization, decentralized control, feedforward.

1. Introduction

Steam networks are used to produce and transfer steam as utility for downstream processes such as distillation columns, paper machines, reactors etc. Pressure-flow networks are inherently highly coupled systems where large and fast disturbances such as shut-downs or start-ups become large disturbances both on the generation and the demand side. In addition, the dynamics of steam generators are much slower compared to the dynamics of the steam network. Therefore, to be able to respond fast to load changes, control of the network pressure is commonly implemented in industry (Majanne, 2005).

Both decentralized and centralized control strategies for steam networks are presented in the literature. The work by Bertrand and McAvoy (1986) presents a solution based on PI-controllers that has good performance for disturbance rejection. The work by Kristoffersen et al. (2014) implements model predictive control (MPC) combined with real time optimization to increase the energy efficiency. The work by Majanne (2005) compares the performance of PI-controllers and MPC, and the latter outperforms due to its ability of handling coupled systems.

In this work, we apply the method by Zotică et al. (2020), which transforms a nonlinear system into a first-order linear decoupled system with no effect from disturbances. In addition, we extend the method by explaining how to select the new introduced tuning parameter. Similar methods have been proposed. Feedback linearization linearizes the input-state map of a nonlinear system (Isidori et al., 1981, Khalil, 1992). Input-output linearization linearizes only the input-output map of nonlinear system, while the rest of the system remains nonlinear (Henson and Seborg, 1997). Active disturbance rejection control introduces an observer to estimate unmeasured states and disturbances for

linearization and feedforward disturbance rejection (Huang and Xue, 2014). The work by Lee et al. (2016) combines an extended high-gain observer for unmeasured states and uncertainty together with dynamic inversion that inverts the model using a fast inner loop I-controller. All these methods give a chain of integrators, which brings additional limitations for control, and it is not very robust as in some cases the input might move in the opposite direction initially.

2. New method for input transformation

Figure 1 shows the block diagram for the new proposed method. The key assumptions are that we have the same number of inputs (u) and outputs (y), and that we can measure the disturbances (d). In the example, we will also allow for some measured states ($w = [T_T \ T_L]$) to be treated as measurements. We define a new input (v) from the model equations as a function of the physical input (u), disturbances (d), extra states (w) and output (y) with the objective of transforming the original nonlinear system into a linear first-order system. The resulted system is also decoupled, and therefore, we use SISO-controllers to control y by using v . We find the physical input u by solving as set of nonlinear algebraic equations that give u as a function of v, y, w, d .

Figure 1. Block diagram for transformed inputs for linearization, decoupling and perfect disturbance rejection.

Consider a general nonlinear system given by Eq. 1.

$$\frac{dy}{dt} = f(y, u, w, d) \quad (1)$$

We define the transformed input v as given in Eq. 2.

$$v = f(y, u, w, d) - Ay \quad (2)$$

where, A is a new tuning parameter, which we discuss in Section 2.1.

By introducing the new input v , the new system becomes first-order, linear, decoupled and with no effect from disturbances, as shown in Eq. 3.

$$\frac{dy}{dt} = v + Ay \quad (3)$$

2.1. New tuning parameter A

One way to select A is such that nominally the positive feedback from y to v is small. Therefore, for each output y_i , we may select A_i as the diagonal elements of the Jacobian of $f_i(y, u, w, d)$ with respect to the output y_i evaluated at the nominal operating conditions,

$$A_i = \text{diag} \left(\left. \frac{\partial f_i(y, u, w, d)}{\partial y_i} \right|_* \right)$$

We may also select a larger A to speed-up the response, or smaller to slow it down. Note that selecting $A = 0$ gives an integrating process similarly to feedback linearization for a model as given in Eq. 1.

2.2. Input calculation block

The input calculation solves Eq. 2 with respect to the inputs u given controller outputs v , extra states w , outputs y and disturbances d . If there is no explicit solution of inverting Eq. 2, we may use a numerical algebraic solver, or an I-controller in a fast inner loop. The second method can be applied to systems with singularities in the transformation.

2.3. Controller tuning

We tune the SISO-controllers based on the SIMC tuning rules in Eq. 4 (Skogestad, 2003).

$$K_c = \frac{1}{k} \frac{\tau}{\tau_c + \theta} = \frac{1}{\tau_c + \theta} \quad (4a)$$

$$\tau_I = \min(\tau, 4(\tau_c + \theta)) \quad (4b)$$

where, K_C is the proportional gain, τ_I is the integral time, k is the process gain, τ is the open-loop time constant, θ is the delay and τ_C is the desired closed-loop time constant. Note that from Eq. (3), $k = \tau = -1 / A$.

3. Case study: steam network

Figure 2 shows the system we analyze within the new proposed method. It is composed of a high-pressure header (i.e. pipelines that physically connect the steam generators and consumers), a turbine and a low-pressure header. High-pressure steam is produced at a pressure p_0 by burning fuel in a boiler. Note that we do not include the boiler in our analysis. The high-pressure steam is supplied as utility to one high pressure consumer with receiving pressure p_{HC} . The remaining steam is expanded to lower pressure steam, either through a fixed-speed back pressure turbine connected to the electric grid to produce electricity, or through a valve that bypasses the turbine (z_{TB}). Note that the fixed-speed turbine is not a degree of freedom available for operation. The low-pressure steam is supplied as utility to two consumers, with receiving pressures p_{LC1} and p_{LC2} respectively.

Figure 2. Process flowsheet of the steam network with two pressure headers (high and low) considered in this work.

The manipulated variables are $u = [z_H z_{TB}]$ (the supply of high pressure steam and the turbine bypass). The controlled variables are $y = [p_H p_L]$ (pressure in the high and low pressure headers). The main disturbances are $d = [p_0 z_{HC} z_{LC1} z_{LC2} p_{HC} p_{LC1} p_{LC2}]$ (the high pressure steam supply (p_0), and the consumers demand of high and low pressure steam, given by changes at the receivers pressure or of the valve positions (z_{HC} , z_{LC1} and z_{LC2})). The additional states are $w = [T_T T_L]$ (the temperature at the turbine outlet and in the lower pressure header.)

3.1. Nominal operating conditions

Table 1 shows the nominal operating conditions, typical for a steam network found in a chemical plant. Here, V is the volume of the two headers.

Table 1. Nominal operating conditions

Variable	p_0	p_H	p_{HC}	p_L	p_{LC1}	p_{LC2}	z_i	T_H	T_L	V_H	V_L
Value	42	40	38	7	6	5	0.5	380	200	1	5
Unit	bar	bar	bar	bar	bar	bar	-	°C	°C	m ³	m ³

3.2. Model

We assume ideal gas, constant specific heat capacity, no pressure losses and perfect mixing in both pressure headers. Assuming isothermal conditions in the high pressure header (T_H constant), the dynamic mass balance in pressure form becomes Eq. 5.

$$\frac{dp_H}{dt} = \frac{RT_H}{V_H} (q_H - q_{HC} - q_{TB} - q_T) \stackrel{def}{=} f_H \quad (5)$$

where q_i is the molar flow through a valve.

The low pressure header is not isothermal because work is extracted in the turbine, and therefore the mass and energy balance become coupled. The energy balance in temperature form is given in Eq. 6.

$$\frac{dT_L}{dt} = \frac{RT_L}{V_L p_L} (q_{TB}(T_H - T_L) + q_T(T_T - T_L)) \quad (6)$$

The mass balance in pressure form is given in Eq. 7.

$$\frac{dp_L}{dt} = \frac{R}{V_L} (q_{TB}T_H + q_T T_T - (q_{LC1} + q_{LC2})T_L) \stackrel{def}{=} f_L \quad (7)$$

We assume isentropic expansion in the turbine and that there are no constraints for the power supplied to the electric grid. Therefore, the temperature at the turbine outlet (T_T) is computed from Eq. 8.

$$T_T = T_H \left(\frac{p_L}{p_H} \right)^{\frac{\gamma-1}{\gamma}} \quad (8)$$

where γ is the heat capacity ratio of steam.

To model the molar flows through valves, we use a valve equation with a linear valve characteristic (Eq. 9).

$$q_i = C_{v,i} z_i \sqrt{|p_{in}^2 - p_{out}^2|}, \forall i \in (H, HC, TB, LC1, LC2) \quad (9)$$

where $C_{v,i}$ is the valve coefficient, z_i is the valve opening, p_{in} and p_{out} are the pressures before and after the valve respectively.

To model the molar flow through the turbine, we assume a constant mass flow coefficient (ϕ), equivalent to a choked turbine (Eq. 10).

$$q_T = \phi \frac{P_H}{\sqrt{T_H}} \quad (10)$$

3.3. Input transformation

The new input $v = [v_H \ v_L]$ is defined by applying Eq. 2 resulting in Eq. 11. We assume that the measurements for T_H , T_L and T_T are available.

$$v_i = f_i - A_i p_i, \forall i \in (H, L) \quad (11)$$

$$A_i = \text{diag} \left(\left. \frac{\partial f_i}{\partial p_i} \right|_* \right), \forall i \in (H, L)$$

where, at the nominal conditions from Table 1.

The new system in Eq. 12 is linear, decoupled and has perfect disturbance rejection.

$$\frac{dp_i}{dt} = v_i + A_i p_i, \forall i \in (H, L) \quad (12)$$

3.4. Input calculation

We find the unknown variable $u = [z_H \ z_{TB}]$ by solving the system of linear equations (Eq. 13) resulted from rewriting Eq. 11.

$$\begin{bmatrix} z_H \\ z_{TB} \end{bmatrix} = \begin{bmatrix} \alpha & -\beta \\ 0 & \beta \end{bmatrix}^{-1} \begin{bmatrix} \frac{V_H}{RT_H} (v_H + A_H p_H) + q_{HC} + q_T \\ \frac{V_L}{R} (v_L + A_L p_L) - q_T T_T + (q_{LC1} + q_{LC2}) T_L \end{bmatrix} \quad (13)$$

with $\alpha = C_{v,H} \sqrt{|p_0^2 - p_H^2|}, \beta = C_{v,TB} T_H \sqrt{|p_H^2 - p_L^2|}$

Note that from Eq. 6 and 8, T_L and T_T depend on u , therefore it is not a true disturbance. However, the use of a measured T_L and T_T in the input transformation is not a problem in

this case because the dynamics from the inputs u to the outputs y have a stable inverse (have no RHP-zeros), hence the inverse generated by the input transformation is stable.

3.5. Simulation results

Figure 3 shows the responses for disturbance rejection and setpoint changes for $y = [p_H \ p_L]$ (Figure 3a), $u = [z_H \ z_{TB}]$ (Figure 3b) and $v = [v_H \ v_L]$ (Figure 3c) to $p_0 = 42$ bar at time $t = 10$ s, $p_{HC} = 39$ bar at time $t = 20$ s, $p_{LC1} = 5.5$ bar at time $t = 30$ s, $p_{LC2} = 1$ bar at time $t = 40$ s, $p_H^s = 39$ bar at time $t = 50$ s and $p_L^s = 6$ bar at time $t = 60$ s. We tune the

PI-controllers with $\tau_{C,i} = -1 / 2A_i$, which are only used for setpoint changes. The results in Figure 3 show a decoupled process with perfect disturbance rejection.

4. Discussion

The calculation block is inherently a nonlinear feedforward controller, and therefore we do not need the feedback control in Figure 1 (typically a PI-controller) as long as we have a perfect model and measurements. Setpoint changes can be handled by directly changing the setpoint for v . However, in a real plant we will always have unmeasured disturbances and unmodelled dynamics, and we need the outer PI-controller loop.

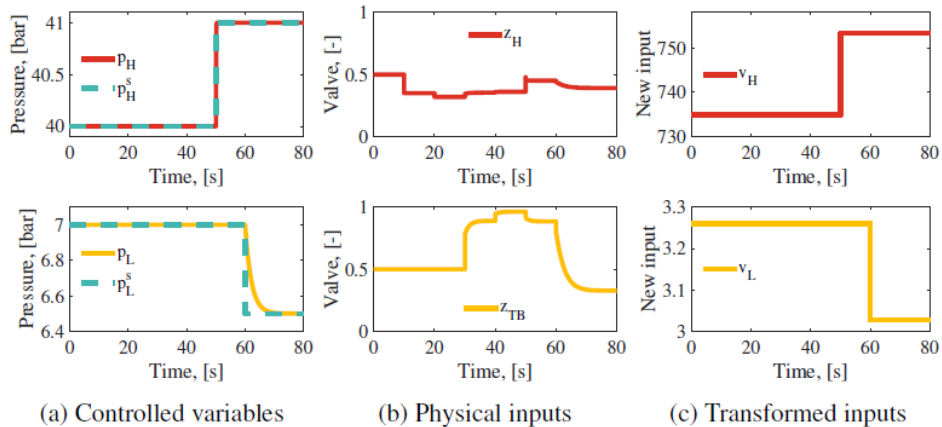

Figure 3. Simulation results for disturbance rejection and setpoint changes.

5. Conclusions

Steam networks are interactive systems, where the main task of the control system is to reject disturbances either on the steam generation or demand side. We design the control structure by using a new method for input transformation that gives linearization, decoupling and perfect disturbance rejection both dynamically and at steady-state (Eq.12), which makes it a good fit for the control structure of a steam network, as seen in Figure 3. The method also transforms a nonlinear system into a first-order linear by introducing a new tuning parameter A .

Abstract

Along with the increase in the production, distribution, and consumption of chemicals, the risk of chemical accidents is increasing, and damage by chemicals exposure accidents can be greatly expanded if initial response is inappropriate. Since early determination of chemical substances in the event of a leakage accident is essential for minimizing accidental loss, this study proposes an AI-based system that supports chemical determination by field personnel based on exposure symptoms, in addition to detection using sensors, and provides predictive information on symptoms that may be lacking for new chemicals. In order to analyze and document the symptoms expressed when contacting chemical substances, the knowledge of domestic and foreign symptoms is established as a knowledge base using a knowledge graph. Afterwards, the symptom-based chemical estimation knowledge service is completed by estimating exposed chemicals through reasoning methods such as SPARQL and providing response information that can be immediately taken on site. In order to expand the knowledge of new chemicals, machine learning is used to predict useful symptom information from molecular structure information of chemicals, so that pre-emptive risk management for new materials could be carried out using the proposed system.

Keywords: chemical accident, exposure symptom knowledge, chemical identification, machine learning, intelligent decision support

1. Introduction

Increasing the use of chemicals and improving the quality of human life are inseparable. According to international statistics, 103M chemical substances were developed as of 2015, and about 120,000 chemical substances are actually distributed (Ministry of Environment's Chemical Policy Division, 2016). In addition, about 2,000 new chemical substances are entering the market every year after safety evaluation. In Korea, the distribution volume also increased by 12.4% compared to 2014 as of 2016 (Ministry of Environment press release, 2018), and the risk of various chemical accidents is increasing as the distribution volume increases. The number of domestic chemical accidents is increasing from 233 in 2014 to 277 in 2018.

Chemicals give many benefits to people, but hazardous materials such as hazardous chemicals and chemical accidents have a dual nature that threatens people's lives. In addition, safety awareness and countermeasures for hazardous materials are not keeping up with the growth rate of the chemical industry. In order to solve these problems, various systems and studies are being conducted to respond to chemical accidents. The National

Institutes of Health (NIH) has developed the Wireless Information System for Emergency Responders (WISER) to assist in emergency rescue in case of chemical accidents. In addition, Bhavnani et al. (2007) analyzed the design of a response system to quickly identify chemicals in emergency situations (Bhavnani et al. 2007).

Figure 1. An overall framework of the proposed symptom-based knowledge reasoning.

If the initial response to a chemical exposure accident is inappropriate, there is a risk of spreading to enormous damage including personal injury and property damage. Existing chemical detection technologies are focused on the development of countermeasure technologies for leaks at known sites, analysis of candidates for leaks, and detection studies in dynamic changing environments. If a sensor is not installed at the accident site, an initial estimation can only be made based on qualitative exposure symptoms. However, the knowledge service on hazardous materials considering human bio sensing information (symptoms) is relatively insufficient in development. Therefore, in this study, we propose a real-time intelligent support system for hazardous chemical detection and diagnosis that quickly detects exposed chemicals, responds to dangerous situations early, and protects workers and exposed people from unexpected chemical accidents in the field (see Fig. 1).

2. Example SEARCH Platform: Chemical substance identification knowledge service based on symptom knowledge reasoning

When unexpected symptoms are found in industrial sites, laboratories, etc. or in multi-use facilities, the SEARCH system, which enables the detection and determination of exposed chemicals, is operated as in Fig. 2. The proposed platform supports speech recognition and output of diagnostic results, but in this paper, we will only focus on the

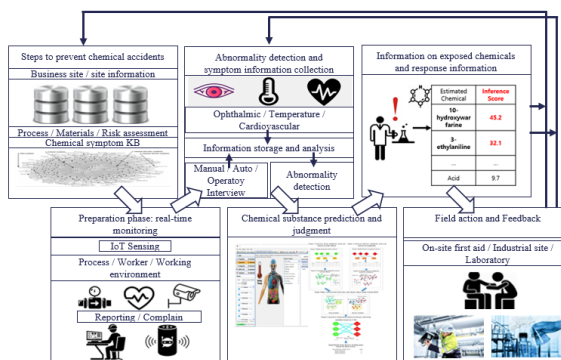

Figure 2. Flowchart of knowledge service on chemical identification and emergency response to exposed chemicals using SEARCH.

collection and storage of chemical substances and symptom information, which are key items in the operation of SEARCH, and reasoning based on the knowledge base.

3. Collection and Preprocessing of Chemical Substance and Symptom Information Data

3.1. Collection of symptom knowledge

The knowledge of symptoms of exposure to chemicals was designed based on the NIH's WISER (Hochstein, C., 2008). The WISER database contains 499 chemical substances and 79 symptom information divided into 10 categories such as temperature, nervous system, oral cavity, etc. We further expanded symptom knowledge by converting 502 data provided by PubChem.

3.2. Chemical data and information preprocessing

In order to transform the collected chemical's structure information into a molecular fingerprint, it was converted into MACCS keys and PubChem keys (see Fig. 3). MACCS keys are the most commonly used structural keys. Among the structure keys of 960 bits and 166 bits, we used a structure key of 166 bits, and a Python package RDKit was used to convert SMILES to MACCS keys. The SMILES structure of 984 chemicals was converted into MACCS keys through RDKit. PubChem keys are a molecular fingerprint used by NIH's PubChem to explore similarities, consisting of 881 bits of structural keys and encompassing a variety of substructure and features. PaDEL-Descriptor was used to convert SMILES into PubChem keys. SMILES of 984 chemical substances were converted into PubChem keys through PaDEL-Descriptor. In addition, each symptom information was transformed into a binary matrix to be applied to the classification model. The binary matrix is expressed as 1 if it has a specific symptom and 0 if it does not and was applied to 1,001 chemical substances and 79 symptoms stored in the knowledge base.

Figure 3. Transform of chemical structure to molecular fingerprints.

4. Knowledge Base Generation and Reasoning

4.1. Knowledge base generation

Since various knowledge services such as determination of exposed chemical substances require effective expression of knowledge, the knowledge base was established using a knowledge graph. Structural and physicochemical information on 449 chemicals of WISER and 502 chemicals of PubChem were extracted through Chempiper, a Python package, and 79 information extracted from WISER were used as symptom information.

Figure 4. An example of triple in knowledge base.

The extracted chemical information was saved in various input triple forms using AllegroGraph API (see Fig. 4). The chemical information stored in the knowledge base includes CAS No., symptoms, synonyms, structural information, and molecular formula etc.

4.2. Knowledge base reasoning

Using SPARQL provided by AllegroGraph, reasoning on exposed chemical substance(s) is performed by inputting a set of symptom information. As a case study, Case 1's inputs are 6 symptom information (headache, runny nose, sweating, arrhythmia, chills), and Case 2's inputs are 7 symptom information by adding throat irritation to Case 1's symptom information. Cases 1 and 2 are like "There is chemical substance B if symptom A is presented", reasoning chemical substances from existing generalized symptom information. If you do not have certain specific symptoms, in the reasoning process, you may increase the speed and accuracy of the reasoning by excluding them. Case 3 is an example: adding information on the no bloody nose to the symptom set in Case 2, in other words, the bloody nose is the excluded symptom.

As a result of the reasoning, it can be showed that 18 chemicals were printed in Case 1, 11 chemicals in Case 2, and 2 chemicals in Case 3: Cases 1 and 2 are the same as the results provided by WISER. It has been shown that if specific symptoms are clearly excluded as in Case 3, which is an unprecedented types of reasoning, less reasoning process may be required, and the speed and accuracy of reasoning for the inferred chemicals can be improved (see Fig. 5).

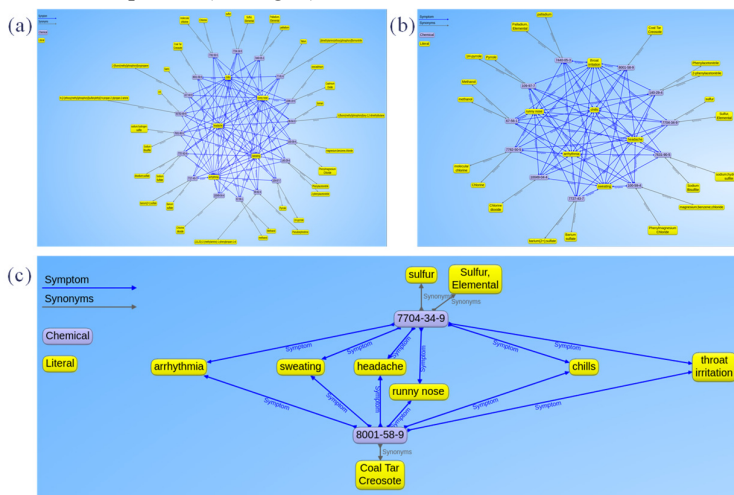

Figure 5. Reasoning results: (a) Case 1; (b) Case 2; (c) Case 3.

5. Symptom Knowledge Expansion Using Machine Learning

5.1. Problem transformation

Since the extracted chemical substances may have more than one symptom, prediction of symptom information based on chemical's structure information is a multi-label classification problem (Tsoumakas, G., 2009). To solve this problem, we apply Label Powerset (LP), Binary Relevance (BR), and Chain Classifier (CC), which are methods of solving the problem of multi-label data with a single label. LP is a method of classifying multiple labels by converting them into one class, and BR is a method of converting into a single label by determining by assigning each classifier to each label. CC is a method

that creates a learner for each classification and sequentially reflects the guess result to the next input when guessing the label (see Fig. 6).

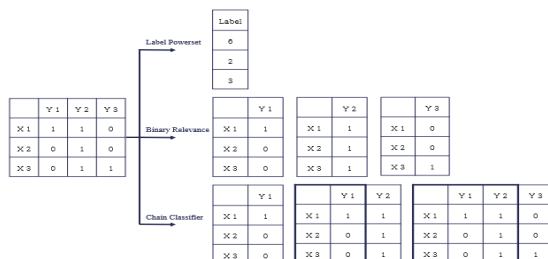

Figure 6. Multi-label classification: Problem transformation method.

5.2. Adaptation of ML algorithm

In this study, k-Nearest Neighbor (k-NN), Decision Tree (DT) and Random Forest (RF) were used as ML methods for knowledge expansion. In order to compare and analyze the effective fingerprinting method, it was divided into MACCS keys and PubChem keys. In addition, LP, BR, and CC were applied to each machine learning method in order to compare and analyze which method is more effective among solving the problem of multi-label data with a single label. In case of Case 1, MACCS keys are input as input values, and PubChem keys are input as input values in Case 2, and symptom information transformed into binary matrix form as output value is displayed.

5.3. Model training method

For accurate training of the model, training data and test data were divided into 8:2 ratio. Since there were little data in the training process, k-fold cross-validation was applied. In this study, k=5 was set.

5.4. Assessment of model performance

The performance evaluation method for a multi-label classification can be divided into example-based and label-based. Example-based is to calculate the average of the difference between the predicted label and the actual label for each case. And the label-based is to calculate the average by calculating the predicted performance individually for each label (Tsoumakias, G., 2009).

Hamming loss was used among the example-based methods because the labels of the data in this study are unbalanced. Hamming loss is the ratio of misclassified labels among all labels (Kim, S., 2017), and the Hamming loss equation is as follows:

$$\frac{1}{N \times L} \sum_{i=1}^N \sum_{j=1}^L XOR(y_{i,j}, \hat{y}_{i,j}) \quad (1)$$

where N is number of data instances, L cardinality of class space, $y_{i,j}$ actual bit of class label j in data instance i , $\hat{y}_{i,j}$ and predicted bit class label j in data instance i .

5.5. Result of model performance assessment

When looking at Cases 1 and 2, it was found that the MACCS keys showed good performance when applying the DT model, and the PubChem keys were effective when the k-NN and DT models were applied. In addition, the method of applying multi-label multiple classification is effective in the order of BR > CC > LP for k-NN and RF models, and LP > BR > CC for DT models regardless of cases. The model that shows the best

performance is the BR(RF) model, which shows the Hamming loss value of 0.2391 in Case 1 and 0.2447 in Case 2 (see Fig. 7).

Figure 7. ML model performance for each transformation method: (a) Case 1; (b) Case 2.

6. Conclusion

Based on the input of real-time symptom information, a knowledge reasoning-based chemical estimation system (SEARCH) was designed to predict exposure chemical substance(s) candidates, and its effectiveness was verified through case studies. For chemical substances with high risk at industrial or chemical incident sites, a total of 1,001 expanded symptom information was obtained by adding the existing symptoms by NIH WISER and chemical substances provided by PubChem. This was built into a KB as knowledge graph, and through reasoning knowledge graph using SPARQL, various knowledge services such as discrimination of exposed chemical substances and recommendation of field response are provided. The case study showed the same estimation results as the existing standard system, WISER, and showed that the speed and accuracy of discrimination can be improved through the reasoning method that is not available in WISER.

For the scalability of the system in the future, a function that predicts and provides symptom knowledge that can be used to detect symptoms even for new chemical substances with relatively insufficient information was prosed and implemented. Based on chemical substance information such as structure information, it was confirmed that BR(RF) is the most effective model through the development and performance comparison of a multi-label multi-class ML model that estimates symptoms of new chemical substances. Deep learning models are being developed by further expanding the data, and the developed SEARCH platform is being applied to the Gyeonggi-do Disaster and Safety Headquarters, which is responsible for the safety and accident response of the largest population in Korea.

Abstract

This work presents a case study for the application of physical systems modelling techniques on cloud computing infrastructures. The described physical system is the micronized silverskin lipids extraction using supercritical carbon dioxide on laboratory scale equipment. The experimental data of the extractions are modeled using a simplified dual phase kinetic model. The model parameters are further developed until their constituent and constant terms in order to transform the purely regressive kinetic model to a predictive one. The model parameters have been refitted through a non-linear regression using the cloud computing infrastructure purposely created for this case study. The core numerical library used to construct the cloud computing approach is the object-oriented BzzMath library for C++. Cloud computing is a very promising research field and its application to traditional solutions may provide a numerical revolution in the chemical industry as well as academic researches.

Keywords: cloud computing, supercritical fluid extraction, silverskin

1. Introduction

Cloud computing is a very promising technology that moves away from the end-user the burden of performing critical and time-consuming calculations while still retaining its results. This approach is not new and several applications have been developed throughout the years but they are mainly industrial or related to large-scale calculations. More recently, driven by the industrial focus on this topic, an increasing interest in cloud computing applications has spread also in the academy. Several academic fields can benefit from a cloud computing approach to typical problems, one of them is the chemical engineering field, especially in chemical process engineering and modelling. In this work, a cloud computing approach has been applied to the modelling of the supercritical carbon dioxide extraction of lipids from organic matrices, with a focus on coffee grounds silverskin. At first, a custom online platform accessible through a website has been created in order to accommodate the models and calculations required for this case study. This process is a viable candidate to demonstrate an online cloud solution since the mathematical model implemented is useful for the researcher who can analyse the data of different experimental campaigns with different conditions. In fact, with a versatile model for the

supercritical fluid extraction using CO₂, it is possible to interpret different operating conditions, different organic matrices, or different experimental equipment. Thus, the online tool remains the same but the solution can be applied to a plethora of different problems of the supercritical fluid extraction of lipids with carbon dioxide.

2. Cloud Process Engineering Approach

The approach adopted with this implementation makes cloud computing the core that sustains the online interface which, in turn, enables the user to upload the experimental data and perform the desired calculations in order to gain insights and relevant information on the process. The same cloud computing solution could have been deployed with dedicated software that the user should install on their machine. In this scenario, the cloud computing approach would still exist since only the user interface would not be present. However, a website interface bears several advantages with regards to a specifically installed software (Boillat and Legner, 2013; Chen et al., 2017). Some of these benefits are the ease of upgrading the core routines of calculation, the non-necessity of installing any new software other than a web browser, and the cross-compatibility between devices and operating systems.

The first step of the interaction between the user and the online platform is regulated by the upload of the experimental data through preformatted JSON files containing the experimental data of the extraction process and several other data about the system geometry or physical properties of the organic matrix. Now, the online system is able to read the uploaded files and pass all the relevant information to the binary executables which are launched on the calculating server. The executables return the results of the calculations, e.g. non-linear regression of the experimental data, in various additional JSON files structured in such a way that the system will then be able to process them and make them readable by the final user. Additionally, several graphics accompany numerical results. Finally, the resulting materials are shown on the interfacing platform where the user can download them. A schematization of the whole process is shown in Figure 1.

Every single link in this chain may be replaced and relocated elsewhere on the net since a full cloud implementation grants it (Lehrig et al., 2015). If needed, it is possible to directly act on the critical aspects of the infrastructure and fix them. Additionally, if the workload is too heavy it is still possible to serve multiple users at once by instancing several additional workers on the network. This creates an elastic system able to self adapt to computation demand (Al-Dhuraibi et al., 2018). A relevant additional advantage of a cloud implementation, which is useful especially for industrial applications, is the possibility to scale the whole system on-demand thus reducing the overall cost of unused computing power since it will be redirected in real-time to the user calculations who need it the most.

3. Materials and Methods

3.1. Materials

Micronized silverskin has been provided by an Italian roasting company. All HPLC-grade and analytical grade organic solvents were purchased. HPLC-grade water was obtained via a purification system. Carbon dioxide was purchased with a purity of 99.999 %.

Figure 1: Simplified schematization of the user-cloud interconnection.

3.2. Supercritical CO₂ extraction

The extraction equipment used for the supercritical carbon dioxide extraction consists of a pump connected to the CO₂ cylinder and the extraction vessel mounted vertically inside a thermoregulatory oven. The CO₂ is compressed up to the desired pressure and flows at a constant rate inside the column packed with approximately 40 g of micronized silverskin. Once the CO₂ reaches the extraction vessel it is heated by the oven that contains the column itself. The system is operated continuously for a certain amount of time of maximum 2 h. The coffee silverskin lipid thus extracted has been collected and weighted at several time intervals in order to assess the kinetics of the extraction. As shown in Figure 2, five different extractions have been conducted.

Figure 2: Extraction data points at different operating conditions.

4. Model

The mass transfer model applied to characterize the two-phase system was originally developed by Sovová (1994) with a kinetic simplification introduced by Patel et al. (2011). The choice of such a model is due to the existence of an analytical solution and its versatility in interpreting experimental data (Andrade et al., 2012; Martínez et al., 2003; Mezzomo et al., 2009). These features are needed in order to construct a cloud computing solution that will be able to process different experimental data fast and in a repetitive way without the need for any additional intervention to the modeling aspects. With this model, two different extraction phases are assumed which differ from each other for the mass transfer mechanism. In the first phase, the external mass transfer controls the rate of extraction while in the final phase it is controlled by the internal mass transfer. For this reason, the extraction is faster at the beginning and declines rapidly after the first stage. The two phases' existence is due to the presence of lipids on the surface of the organic matrix that are depleted during the rapid extraction of the first stage (Brunner, 1984; del Valle et al., 2000).

4.1. Simplified dual phase model

The model adopted introduces several assumptions to describe the extraction process, such as: no radial dispersion, pure solvent at extractor entrance, etc. (Patel et al., 2011). The analytical solution to the differential system comprised of the mass transfer equations for the fluid and solid phase results as:

$$e = qy_r [1 - \exp(-A)] \quad \text{for } q < q_m \quad (1)$$

$$e = x_0 - \exp[-BA(q - q_m)][x_0 - q_m y_r (1 - \exp(-A))] \quad \text{for } q \geq q_m \quad (2)$$

where several dimensionless variables are introduced, most importantly the variables e and q which are, respectively, the dimensionless extracted mass of lipid and the dimensionless time related to the amount of solvent flowed in the system. Moreover, the parameter A depends mainly on the fluid dynamics of the system since it is a function of k_f , the fluid mass transfer coefficient, a_0 which is the superficial area coefficient, the superficial velocity U and H , the column height. B is the ratio between the solid mass transfer coefficient (k_s), with the solid density (ρ_s) and the fluid mass transfer (k_f) with the fluid density (ρ_s). x_0 and y_r represent, respectively, the initial solid mass fraction of solute in the solid matrix and the solubility of lipids in the supercritical fluid. Both terms are constituent elements of the variable q_m which represents the dimensionless time of the phase inversion. For a more in-depth analysis of the variables presented, please refer to Patel et al. (2011).

4.2. Fundamental Parameters

In order to allow the model to predict the extraction curve at different operating conditions, it is needed to develop accurate correlations for all the fundamentals parameters that have a significant dependence on the operating conditions. A fine-tuning of parameter A has been performed by using a corrective correlation on the flow rate in a power-law-like form. In fact, a single additional regressive parameter has been added in order to better predict different volumetric flow rates with an empirical approach. For all the parameters that are either constant or with a negligible variation at different operating conditions and whose value is not known experimentally the value is finally evaluated with a non-linear

regression. The fundamental parameters that need an accurate correlation are the solvent density and viscosity and the fluid phase mass transfer coefficient. The density of the supercritical carbon dioxide has been described with the well-known Peng-Robinson's equation of state (Peng and Robinson, 1976) while the viscosity has been calculated with a Jossi-Stiel-Thodos correlation (Jossi et al., 1962). The fluid mass transfer coefficient has been evaluated with the Kunii and Suzuki (1967) mass transfer theory which is valid for finely packed beds characterized by very low Re and Pe numbers. This theory describes the flow of the fluid phase with a channeling effect where the solid phase tends to aggregate to form clumps that are reducing the mass transfer.

5. Results

The cloud computing approach has been successfully applied to solve the non-linear regression problem of the experimental data with the simplified dual-phase extraction model for the supercritical extraction of lipids from micronized coffee grounds silverskin. The non-linear regression has been performed by using a custom implementation of the numerical library BzzMath (Buzzi-Ferraris and Manenti, 2010, 2012) using Visual C++. The global sum of squared errors of the whole experimental set has been minimized with a modified Simplex search algorithm. The modification of the original algorithm implemented in the BzzMath library is aimed at incrementing the robustness of the minima search. The global minima found for the five experimental sets resulted in an average absolute relative deviation of 7.11 % and a standard error of the estimate of 0.00120 (both calculated on the dimensionless extracted mass parameter). These results are reasonably low values as it can be seen from Figure 3. Moreover, the model has a good predictive capability since one of the model parameters is the total solute concentration in the solid phase. This parameter is evaluated experimentally and it acts as a physical limit on the model itself since no more than the total initial concentration can be extracted. Thus, with few experimental points, it is possible to evaluate the extraction dynamic quite accurately (as shown in Figure 3) and with a physical boundary.

Figure 3: Non-linear regression results of the dual phase simplified model for the first (circles) and fourth (crosses) experimental sets.

6. Conclusions

This case study shows how typical process engineering problems may be solved using a full cloud implementation while retaining the high accuracy results of a local offline solution platform but with all the benefits of a cloud computing approach. Moreover, for the specific case study of the supercritical carbon dioxide extraction process of lipids from micronized silverskin, the implemented model has shown a good versatility in analysing and interpreting experimental data. In addition, the possibility to develop the fundamental parameters transforms the described model from a purely regressive to a predictive one. The ability to predict the behavior of the extraction process at different operating conditions is valuable for the researcher who wants to analyze the system. This numerical tool could be further developed with CAPE-OPEN and OPC protocols to enable it to manage and unify different, already established, process systems engineering tools.

Abstract

In the present paper, a multi-objective shape optimization approach based on the adjoint system method has been developed and tested on a two-dimensional fixed-bed reactor. The optimization problem considered involves two performance indices (i.e. conversion rate and dissipated energy in the reactor) and three constraints consisting of an iso-volume constraint and two manufacturing constraints. The process model, solved using OpenFOAM software, is described by the mass balance and Navier-Stokes equations in laminar flow regime. The multi-objective optimization problem is converted into a single-objective problem using weighting factors and then solved several times to determine the set of optimal solutions, i.e. Pareto front. The best optimal solution is then determined by means of the multi-attribute utility theory (MAUT) method. Finally, the resulting optimal shape which reduces the energy dissipation by 46.7% and improves the conversion rate by 2.7% is manufactured using a 3D printing technique.

Keywords: Multi-objective shape optimization, Multi-attribute utility theory (MAUT), Adjoint system method, Computational fluid dynamics (CFD), Fixed-bed reactor.

1. Introduction

In process optimization, the problems that are very often studied generally aim to determine a solution of a constrained minimization/maximization of a single objective. However, in many cases, multiple conflicting objectives are involved and need to be optimized simultaneously. In this case, the solution is no longer a single solution but a set of optimal solutions, called Pareto front. These solutions are then ranked by means of a decision-aid making method to choose the best one.

In one of our recent works (Courtais et al., 2020), a geometry optimization approach was developed to determine the optimal shape of a two-dimensional fixed-bed reactor. The objective was to maximize the conversion rate while satisfying four constraints: (i) an iso-volume constraint ensuring that the reactor operates at the same residence time, (ii) an inequality constraint which defines a maximum value for the energy dissipated by the fluid, (iii) and two manufacturing inequality constraints that impose minimum values on the pores width and the packing thickness. However, the performance index, i.e. the conversion rate, and the constraint on the dissipated energy are conflicting which means that the solution of the optimization problem is a Pareto set.

In the present paper, a constrained multi-objective optimization of the shape of a fixed-bed reactor where a single-phase liquid flows in laminar regime, is developed. The multi-objective problem is transformed into a single-objective problem using weighting factors, and solved many times to determine the Pareto front of the optimization problem. The multi-attribute utility theory (MAUT) method (Keeney et al., 1979) is then used as a decision-aid making method in order to select the “best” optimal shape of the reactor.

2. Description of the fixed-bed reactor and its modeling

The developed optimization method is used to determine the optimal packing shape of a fixed-bed reactor with a single-phase liquid flow. It is a structured packing made up of obstacles initially elliptical in shape (with half axes of 5mm and 2.5mm) uniformly distributed in the reactor.

Figure 1 : Initial configuration of the fixed-bed reactor.

The studied domain, whose initial shape is shown in Fig. Figure 1 is denoted by Ω and is delimited by its boundaries $\partial\Omega = \Gamma_{in} \cup \Gamma_{out} \cup \Gamma_{lat} \cup \Gamma$. Γ_{in} and Γ_{out} represent respectively the fluid inlet, the fluid outlet and the side wall of the reactor. Γ is the packing whose shape will be modified during the optimization process and constitutes the decision variable of the optimization problem. The model of the fluid flow in the reactor is described by means of Navier-Stokes and continuity equations (1). It is based on the following main assumptions: laminar flow regime, incompressible fluid, and steady-state conditions. The model equations are expressed as:

$$\begin{cases} -\nu \Delta \mathbf{U} + \mathbf{U} \cdot \nabla \mathbf{U} + \nabla p = 0 & \text{in } \Omega \\ \nabla \cdot \mathbf{U} = 0 & \text{in } \Omega \\ \mathbf{U} = \mathbf{U}_{in} & \text{on } \Gamma_{in} \\ \mathbf{U} = 0 & \text{on } \Gamma_{lat} \cup \Gamma \\ \sigma(\mathbf{U}, p) \mathbf{n} = 0 & \text{on } \Gamma_{out} \end{cases} \quad (1)$$

where $\sigma(\mathbf{U}, p) = 2\nu \varepsilon(\mathbf{U}) - p\mathbf{I}$ with $\varepsilon(\mathbf{U}) = \frac{1}{2}(\nabla \mathbf{U} + (\nabla \mathbf{U})^T)$. ν is the fluid kinematic viscosity, \mathbf{I} the identity matrix, p the kinematic pressure (i.e. the absolute pressure divided by the density), and $\varepsilon(\mathbf{U})$ the strain tensor.

Reagent transport is modeled by the system of PDEs (2). It is assumed that a first order reaction takes place in the bulk of the reactor and no reaction occurs on the walls.

$$\begin{cases} -D\Delta C + \mathbf{U} \cdot \nabla C + kC = 0 & \text{in } \Omega \\ C = C_{in} & \text{on } \Gamma_{in} \\ \frac{\partial C}{\partial n} = 0 & \text{on } \Gamma_{out} \cup \Gamma_{lat} \cup \Gamma \end{cases} \quad (2)$$

D denotes the diffusion coefficient of the reagent in the solvent (i.e. water), C the reagent concentration and k the kinetic constant.

3. Multi-objective optimization problem statement

The multi-objective optimization problem is defined as follows:

- Two **performance indices** are defined by the energy dissipated by the fluid in the reactor and the average reagent concentration at the outlet of the reactor. They are respectively expressed as:

$$J_1(\Omega) = 2\nu \int_{\Omega} |\varepsilon(\mathbf{U})|^2 dx \quad \text{and} \quad J_2(\Omega) = \int_{\Gamma_{\text{out}}} C d\sigma \quad (3)$$

- The **decision variable** is the shape and the position of the packing Γ .
- The **constraints** are defined by the following equality and inequality constraints:
 - The process model described in Section 2 and solved using OpenFOAM software.
 - An iso-volume constraint is considered in order to operate at the same residence time in the initial and optimal shapes of the reactor. It is expressed as follows:

$$C_v(\Omega) = v(\Omega) - v(\Omega_0) = 0 \quad (4)$$

where $v(\Omega)$ denotes the volume of Ω .

- Two inequality constraints related to the reactor manufacturing step. Indeed, the 3D printing technique used to manufacture the reactor imposes minimal values on the local width of the pores and on the local thickness of the packing (Courtais et al., 2021)

To solve the resulting multi-objective optimization problem, it is converted into a single-objective problem by aggregating the two objectives using the linear scalarization method as:

$$J(\Omega) = \tau J_1(\Omega) + (1 - \tau) K_{\text{crit}} J_2(\Omega) \quad (5)$$

K_{crit} is a constant used to ensure the same unit of measure and the same order of magnitude of both objectives J_1 and J_2 .

4. Adjoint system method for the shape gradient computation

The approach used is an iterative method which builds from the initial form a series of shapes that improve the performance of the reactor at each iteration by adapting the position of its boundaries. This approach relies on the concept of shape derivative also called derivative in the sense of Hadamard (Henrot and Pierre, 2005). The method consists in determining at each iteration the sensitivity of the Lagrangian functional (6) with respect to a small perturbation of the domain boundaries.

$$L(\Omega, \lambda_v) = \tau J_1(\Omega) + (1 - \tau) K_{\text{crit}} J_2(\Omega) + \lambda_v C_v(\Omega) \quad (6)$$

This perturbation is given by the following equation:

$$\Omega_{t+1} = (\text{Id} + tV)(\Omega_t) \quad (7)$$

where Id is the identity operator, t is the step of the iterative method, and \mathbf{V} is the vector field representing the displacement of the mesh. Thus, the product $t\mathbf{V}$ stands for the small perturbation applied to the mesh.

Hadamard's derivative is a gradient method which involves adjoint states to compute the shape gradient $G(\Omega)$. This new functional is defined on the free boundary Γ and depends on the solutions $(\mathbf{U}, p$ and $C)$ and $(\mathbf{U}_a, p_a$ and $C_a)$ of the process model equations and their associated adjoint state equations introduced by the method. Finally, the mesh displacement \mathbf{V} leading to a decrease of the Lagrangian (6) depends on the shape gradient and is computed by solving the following system of equations:

$$\begin{cases} -\Delta \mathbf{V} + \mathbf{V} = 0 & \text{in } \Omega \\ \mathbf{V} = 0 & \text{on } \Gamma_{\text{in}} \cup \Gamma_{\text{out}} \cup \Gamma_{\text{lat}} \\ \nabla \mathbf{V} \mathbf{n} = -G(\Omega) \mathbf{n} & \text{on } \Gamma \end{cases} \quad (8)$$

5. Implementation of the optimization algorithm

The algorithm used to solve the multi-objective optimization problem consists of several resolutions of the single-objective problem by modifying the parameter τ . It is implemented within OpenFOAM CFD software which solves the PDEs using the finite volume method. The solution of each single-objective problem is achieved in 6 main steps as:

1. The initial shape of the reactor is meshed using SNAPPYHEXMESH and CFMESH, two mesh generation utilities supplied by OpenFOAM.
2. The systems of PDEs allowing to determine the state variables (\mathbf{U}, p, C) and their associated adjoint states (\mathbf{U}_a, p_a, C_a) are solved. The pressure-velocity couplings in the Navier-Stokes equations and in the equations of its adjoint system are treated using the SIMPLE algorithm.
3. The shape gradient $G(\Omega)$ and the mesh displacement \mathbf{V} are then computed. Since the manufacturing constraints are dealt with during this step, the thickness of the obstacles is defined as the double of the distance between the skeleton and the obstacle. In 2D, the skeleton is defined as the set of points equidistant from the obstacle on each side, i.e. a thin version of the obstacle centered inside it. The local pore distance is computed using an OpenFOAM function named *wallDist* (Courtais et al., 2021).
4. The Lagrange multiplier λ_v is updated as:

$$\lambda_v^{i+1} = \lambda_v^i + \beta C_v(\Omega_i) \quad (9)$$

where i denotes the iteration number and $\beta > 0$ is a small parameter.

5. A test on the mesh quality is carried out by means of 3 criteria very often used in CFD simulation: the mesh aspect ratio, the mesh non-orthogonality and the face skewness (Holzinger, 2015). If the values of these criteria are respectively higher than 10, 65° and 3.8, a remeshing of the shape is performed.
6. At the end of each iteration, a test on the convergence is carried out. If the ratio of the standard deviation to the average of the last 100 values of the Lagrangian is lower than 10^{-4} , the algorithm stops.

Figure 2: Pareto front of the multi-objective shape optimization problem.

6. Numerical results and discussion

Figure 2 presents the Pareto front where each circle corresponds to the solution of a single-objective problem. As emphasized by Courtais et al. (2020), each single-objective optimization takes between 2 and 3 days to converge on a 3.7GHz Xeon Dell Computer 5810. Consequently, the determination of this estimation of the Pareto front (Fig. 2) made up of 26 single-objective solution is time consuming and has required between 1.5 and 2 months of computations.

Figure 2 shows that the smaller the parameter τ , the greater the conversion rate and the better the homogeneity of the fluid flow in the reactor. Conversely, the closer τ is to one, the more important the energy criterion. In this case, channelings and dead zones appear thus causing the reduction of the energy dissipation in the fluid and the degradation of the conversion rate in the reactor. On Fig. 2, the black triangle of coordinates $(9.56 \times 10^{-2}; 1.7 \times 10^{-11})$ has been determined by the ϵ -constraint method since the Pareto front is slightly concave near this point and consequently the linear scalarization method is unable to determine the concave parts of the front. The performances of the reactor configuration determined by Courtais et al. (2020) are also shown on the Pareto front (white triangle). They highlight the importance of carrying out a multi-objective optimization since it was possible to improve the energy dissipation criterion by 33% with an insignificant degradation of the conversion rate.

Finally, all these optimal shapes of the reactor are ranked using the MAUT method (Fonseca et al., 2020) according to the importance given to the criteria by the decision-maker. The solution at the top of the ranking is then chosen as the best optimal solution; it reduces the energy dissipation by 46.7% and improves the conversion rate by 2.7%. This configuration of the reactor is presented in Fig. 3 and has been manufactured using a 3D printing technique for experimental tests.

Figure 3: Comparison between the best optimal reactor chosen using MAUT method (a) and the corresponding reactor manufactured by a 3D printing technique (b).

7. Conclusions

A geometry optimization approach based on the adjoint system method has been developed, implemented within OpenFOAM and tested on a 2-dimensional fixed bed reactor where a homogeneous first order reactor occurs. The optimization problem has been formulated with two performance indices (energy dissipation in the fluid and conversion rate in the reactor) and the Pareto front has been determined. Finally, the configuration which offers the best compromise between the criteria has been determined using the MAUT method and manufactured by means of a 3D printing technique.

This paper emphasizes the importance of performing multi-objective optimization of the reactor since the optimal shape determined by Courtais et al. (2020) by a single-objective optimization was not the best optimal configuration of the reactor for manufacturing issues. However, the developed method has shown several limitations. The first one is the method of shape optimization used to solve the optimization problem. Indeed, some dead zones that appear when the energy dissipation criterion is high (i.e. for $\tau > 0.7$) would disappear if topology changes were allowed. Another limitation concerns the width constraints which do not allow their violation during the optimization iterations. These issues are being addressed and significant improvements are expected.

Abstract

The iron melting furnaces are the most energy-consuming equipment of the iron and steel industry. The energy efficiency of the furnace is affected by process conditions such as the inlet temperature, velocity of the charge, and its composition. Hence, optimum values of these process conditions are vital in the efficient operation of the furnace. Computational methods have been very helpful in the optimum design and operation of process equipment. In this study, a first principle (FP) model was developed for an iron-making furnace to visualize its internal dynamics. To minimize the large computational time required for the FP-based analysis, a data-based model, i.e., Artificial Neural Networks (ANN), is developed using data extracted from the FP model. The ANN model was developed using data sets comprised of the values of temperature of the charge and gasses, velocity, concentration of the oxygen, pressure, airflow directions, energy and exergy profiles, and overall exergy efficiency of the furnace along with its height. The ANN model was highly accurate in prediction and is suitable for real-time implementation in a steel manufacturing plant.

Keywords: exergy analysis, second law of thermodynamics, energy analysis, artificial intelligence, iron, and steel industry.

1. Introduction

Iron ore melting furnaces are a core part of the iron and steel manufacturing sector and are consuming a significant share of the total energy used in a plant. To realize energy-efficient design and operation of the furnaces, exergy-based studies have been getting the attention of the researcher. Compared to the conventional energy analysis methods, exergy-based analysis is more effective in the identification of the location, causes as well as the magnitude of the energy losses in a system. Application of the computational methods in the exergy analysis has been helpful. Mathematical models as well as process simulators, i.e., Aspen, ANSYS, etc., are used for performing exergy analysis of various systems. Several studies based on computer aided exergy analysis of furnaces have also been reported.

For instance, Zhang et al., (2017) performed exergy analysis of recycling oxygen in a blast furnace to determine the optimum composition of charge i.e. feed. In another study, an exergy-based analysis of a blast furnace, using natural gas as a fuel, was performed (Guo et al., 2013). They inferred that operating a blast furnace on natural gas increases productivity, reduces silicon

content in molten metal, and carbon emission but reduces its exergetic efficiency. In another work, high exergy efficiency of the blast furnace was reported through the use of pulverized coal and preheating of the charge material which also helped in saving coke (Ziębik and Stanek, 2006). Similarly, exergy analysis of a silicon furnace has revealed that volatiles and electrodes account for about 8-10 percent of exergy destruction (Børset et al., 2015). Exergy analysis of an annealing furnace helped in identifying the fact that the combustion chamber of the annealing furnace is about 12.9 percent exergy efficient while the overall exergy efficiency of the furnace was found to be 7.3 percent (Hasanuzzaman et al., 2011).

The use of artificial intelligence in exergy analysis is a new trend that is paving way for the digitalization of energy analysis systems of process industries (Akram et al., 2018). The present study is based on the use of Artificial Neural Networks (ANN) in exergy analysis of a Blast Furnace (BF) of a steelmaking plant. Initially, a first principle model of the BF is developed that calculates temperature, velocities, the concentration of oxygen, exergy, and energy efficiencies at 8712 points across the width and height of the furnace. The dataset (8712) is used then used to develop ANN models for prediction of charge temperature, gas temperature, the concentration of oxygen, and total exergy.

Section 2 describes the process followed by the proposed methodology in section 3. Section 4 elaborate the results while section 5 concludes the present work.

2. Process Description

The process of iron production includes three continuous reduction reactions of iron oxides within the BF. As preheated air enters the furnace from the bottom, it reacts with the coal introduced from the top of the furnace, producing carbon monoxide (CO). These sets of reactions have a specific heat of formations represented below along with the reactions (Sun, 1997).

This carbon mono-oxide reacts with the feed oxide and reduces it into ferrous Oxide (FeO). In the final reduction of iron, this ferrous oxide is further reduced into iron-producing carbon dioxide (CO_2) as a by-product.

3. Methodology

The modelling framework is comprised of three steps. Initially, an FP model of the blast furnace was developed using data from the literature (Dartt, 2011). The FP model was updated to calculate physical, kinetic, and potential exergies

across the furnace. In the third step, data was generated from the FP model to develop the four ANN models. The three steps are briefly discussed below:

Figure 1: Reaction zones of the furnace (Petrucci et al., 2017)

- FP model development:** For the FP model, the height and diameter of the furnace were kept at 0.605 and 0.36 meters respectively. The inlet temperature of oxides, fluxes, and the air was 298 K, while tuyere and lid diameter were kept 0.05 and 0.11meters respectively. The blast rate of oxygen was 0.224 kg/sec. The mathematical calculations involved Ergun’s pressure drop equation, steady-state equation, reaction rate constant equation, and effective heat transfer coefficient equation.
- Addition of exergy equations in the FP model:** The standard equations used in (Szargut, 2005) were added to the FP model to calculate physical, kinetic, and potential energies. The equations are summarized below:

$$E^{Ph} = RT_o \sum_{i=1}^n Cp_i^{mean} (T_i - T_o - T_o \ln \left(\frac{r_i}{r_o} \right)) \quad (5)$$

$$Cp_i^{mean} = \int_{T_1}^{T_2} Cp_i dT \quad (6)$$

$$Cp_i \left(\frac{j}{mol.K} \right) = a_i + b_i T + c_i T^2 + d_i T^3 \quad (7)$$

where, $a_i, b_i, c_i,$ and d_i are heat capacity coefficients, R is the ideal gas constant at each point of the furnace, P_i is partial pressure, and T_i is temperature.

$$E^K = m_o \frac{c_o^2}{2} \quad (8)$$

$$E^P = m_o g_E Z_o \quad (9)$$

where m_o is the mass flow rate of the bulk stream, C_o is bulk velocity, and Z_o is the altitude above the sea level.

- **ANN modeling:** Data comprised of 8906 samples of 11 process variables/parameters from across the width and height of the furnace was collected for the development of the ANN models. Four ANN models were developed to predict charge temperature, gas temperature, the concentration of oxygen, and total exergy.

4. Results and Discussion

Contours of physical and total exergies of the furnace calculated through the FP model are shown in Fig. 2 while the regression performance of the ANN models is shown in Fig. 3.

Fig. 2 (a) represents the physical exergy of the furnace calculated through the FP model. The physical exergy depends upon the temperature of the furnace. It can be observed that the furnace exergy is high at the points where the temperature profile of the furnace remains higher. In addition to the physical exergy, kinetic and potential exergies were also calculated. The kinetic exergy depends upon the product of the bulk velocity and the bulk flow rate and it was noted that kinetic exergy is much higher at the points where velocity is higher. Potential exergy is the product of height altitude, mass flow rate, and velocity. Hence, velocity is the only factor which is having a higher effect on potential exergy and it is much higher in the high-velocity zones. While at other levels, it has only the effect of height altitude and mass flow rate which is minimized by the lower velocity levels at that position. The sum of all types of exergy termed as total exergy is shown in Fig. 2 (b).

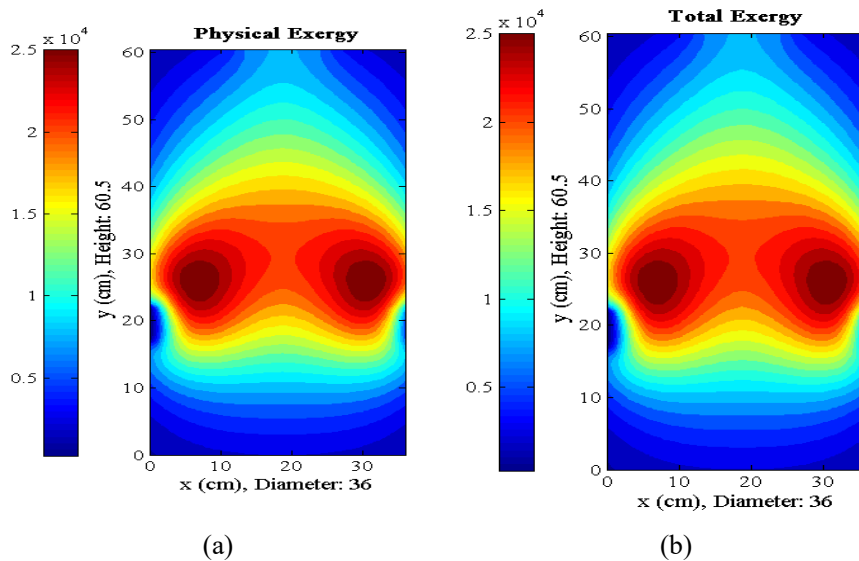

Figure 2: Contour plot (a) physical exergy (b) total exergy along the height of furnace

Fig. 3 (a) represents the prediction of the charge temperature within the furnace. The ANN model had a correlation coefficient of 0.99849 with values obtained through the FP model. Similarly, Fig. 3 (b) represents the correlation between the predicted and the FP model value for the gas temperature. In case of concentration of oxygen, the correlation coefficient was 0.99958 as shown in Fig. 3 (c). Fig. 3 (d) represents the correlation coefficient of the total exergy of the furnace calculated through the FP model and predicted through ANN. The correlation coefficient between the FP values and ANN predicted values were 0.99832.

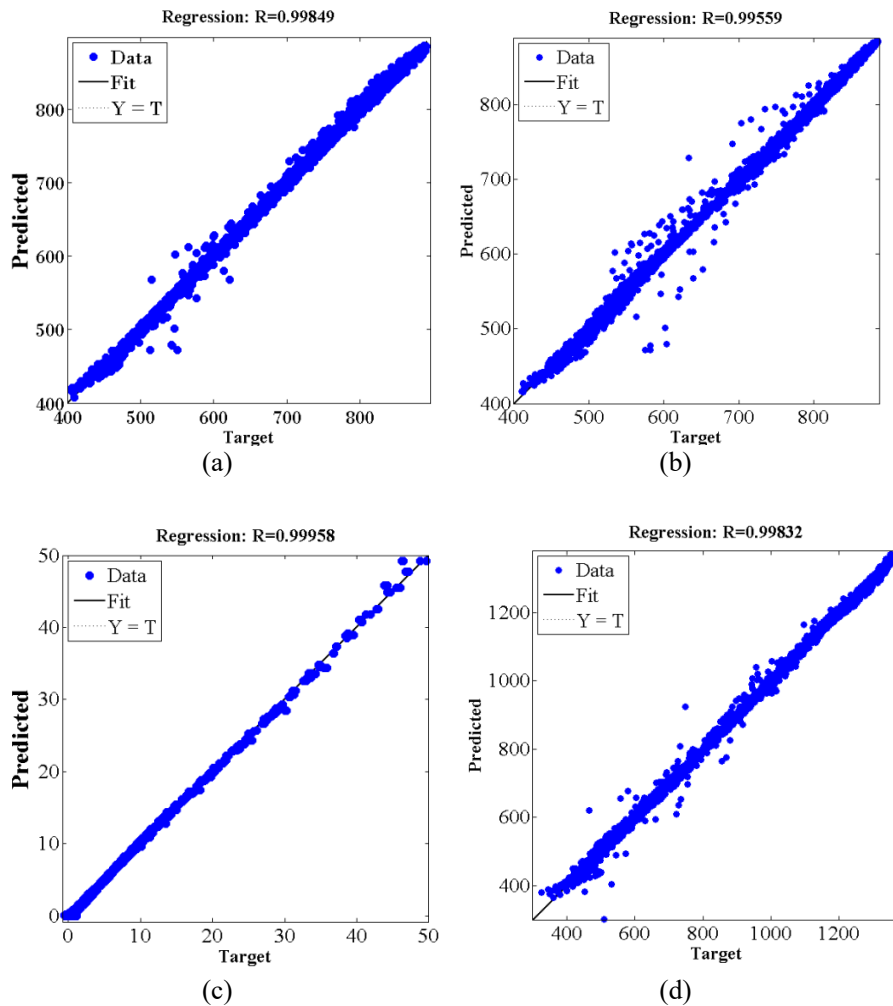

Figure 3: ANN regression plots (a) Charge temperature (b) Gas temperature (c) Concentration of Oxygen (d) Total Exergy

5. Conclusions

A First Principle (FP) was used to calculate kinetic, potential, and physical exergy exergies across the width and height of a blast furnace (BF). The furnace is found to be most exergetic at the points where the temperature of the furnace is higher. To shorten the calculation time for exergy, gas temperature, charge temperature, and concentration of oxygen, ANN models were developed using data extracted from the FP model. ANN models had a correlation coefficient of 0.996, 0.995, 0.995, and 0.993 for prediction of the concentration of oxygen, charge temperature, total exergy, and gas temperature respectively. The ANN-based prediction of process conditions specifically the exergy efficiency provides a platform for realizing a stable and efficient operation of the BF. For a more realistic representation of the internal dynamics of the BF in terms of exergy, the second generation of machine learning methods, i.e., deep learning (DL) can be applied. For training the DL models, further large databases of information may be acquired through infrared-based cameras installed for capturing the internal conditions of the furnaces.

AI System for Supporting Generation of Optimal Synthetic Pathways Based on Chemical Reaction Big Data

Nagyeong Lee, Joonsoo Jeong, Dongil Shin*

Department of Chemical Engineering, Myongji University, Yongin, Gyeonggido 17058, Korea
dongil@mju.ac.kr

Abstract

The selection and design of the appropriate reaction paths has a significant impact on the economics and productivity of the chemical process, enhanced by milder operating conditions, use of cheaper reactants and fewer reaction steps. However, exploration of reaction information is difficult even with reaction databases available, causing path explosion problem due to huge search space. In this study, we propose an AI system (ASICS), which supports synthetic path design at the basic stages of research and process design, based on the hybrid generative exploration and exploitation of reaction knowledge graphs encoding big data of patented reactions and machine learning-based retrosynthetic prediction. ASICS generates an optimal synthetic path that satisfies the given constraints (regulated compounds, etc.), based on A* search using synthetic accessibility and retrosynthetic prediction scores. The preference in searching between confirmed reaction spaces and unexplored reaction spaces through prediction can be selected by the user. The fusion of reaction knowledge base and retrosynthetic prediction model enables to generate optimal synthetic paths beyond the accumulated reaction information.

Keywords: Chemical Reaction Big Data, Synthetic Pathway Design, Knowledge Graph, Inference Reasoning, Decision Support System

1. Introduction

Choosing appropriate reaction pathways is an important part of chemical process development and laboratory research to create high-added value through chemical reactions. Before proceeding with trial-and-error experiments, related compounds and reaction information is usually searched from in-house documents, literature, databases or web. However, it is not easy to narrow down candidate reaction paths and/or to obtain the information required by the target compounds even with commercial databases.

Databases of organic synthesis, e.g., Reaxys and SciFinder, collect and provide information on compounds and reactions from various patents and literature from the past to the present. In addition to that, in order to solve the environmental and energy sustainability and economic issues, it is required to explore a wide range of reaction hyperspaces within a limited time. For example, in the network universe of organic chemistry, 80.2 distinct reactions can be applied to a non-trivial retron on average, translating into 3.5×10^{28} possible 15-step pathways (Szymkuc et al. 2016).

The methods of generating one-step reactions are divided into exploration with database, reaction rule matching and machine learning-based reaction prediction. As retrosynthesis planning methods, there is a heuristic best-first search method that

performs rule matching and exploration based on reaction networks and hand-coded reaction rules (e.g., Synthia, formerly Chematica (Szymkuc et al. 2016)). There is also a template-based, policy-guided tree search method using machine learning-based retrosynthetic prediction model (e.g., AizynthFinder (Genheden et al, 2020)). Depending on the prediction model used, it is divided into template-based or template free.

Exploring and rule matching method based on the reaction network cannot generate result beyond the accumulated information. Retrosynthetic prediction models, however, always has uncertainty and do not supply detailed reaction information such as yield and conditions. Thus, we propose a hybrid system that combines reaction networks search and retrosynthetic prediction to generate synthetic paths by exploring both dimensions. The preference in searching between confirmed reaction spaces and unexplored reaction spaces through prediction can be selected by the user. Reaction information is collected using open data, and the proposed system is intended to be provided as open source.

2. Design of Reaction Knowledge Base: Reaction database sources, essential reaction information, automatic extraction, and representation as knowledge graph

The information required to generate an optimal synthetic pathway includes information on chemical structure, chemical reaction, physical property, and commercially available compounds. We selected PubChem as the main database source for chemical structures, eMolecule for chemical structures for commercially available compounds and the USPTO patents (1976-2016) by Lowe (2014) for chemical reactions. All compounds are stored by expressing them with identifiers, e.g., SMILES (Weininger 1988).

Massive information of chemical structure and physical property was extracted from the source database through automated web crawling. USPTO patents by Lowe contain information such as year, reaction formula, reactant, product, reaction amount, yield, and synthesis procedure. By extracting reaction information and removing duplicates of the same reaction SMLIES, 1,674,945 reaction information out of ~3.3 million reactions was used as the basis for reaction knowledge. Knowledge base was constructed by expressing them as labeled property graphs using Neo4j, an open-source graph database. Knowledge graphs consisting of the knowledge base are shown in Figure 1(a) and (b).

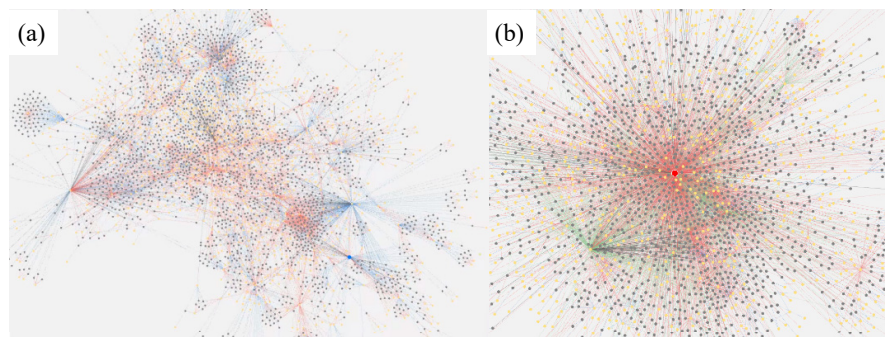

Figure 1. Reaction knowledge graph network: (a) the whole knowledge base, (b) zoomed for dichloromethane. Yellow nodes represent compounds and black nodes reactions. Edges represent relations: blue for products and reactions, red for reactants and reactions, and green catalysts or solvents and reactions.

3. One-step Retrosynthetic Prediction Using an Open-Source Model

With a retrosynthetic prediction model, we have the advantage of considering the reaction of the unreported or unexplored space beyond the definite reactions accumulated in the knowledge base. As the template-based one-step retrosynthetic prediction model, Chen et al. (2020)'s model published at GitHub was imported and used. This model uses a single-layer fully connected neural network of latent dimension 128, with ReLU as activation function. Morgan fingerprint of radius 2 with 2,048 bits is input to this model, and reaction templates are obtained as output. The reaction templates are converted to SMILES using RDKit package to obtain reactants.

4. Generation of Optimal Synthetic Pathway via Simultaneous Exploration of Knowledge Graph and Retrosynthetic Prediction

The most economical synthesis direction among similar reactions is selected based on the Synthetic Accessibility score (SAscore) scaled to be between 1 and 10 (Ertl et al. 2009). A reaction with the lowest SAscore, easier to synthesize, is favored by calculating the average SAscore of the participating reactants. It is assumed that the lower SAscore the lesser cost of reactants.

Table 1. Pseudocode of genRxn() that selects an optimal one-step reaction and returns the results of applying the reaction.

<p>Given target compound t_m and list of commercially or in-house available compounds PCL, generate list of reactants from the selected reaction RL and list containing the synthetic path up to now PL.</p> <p>genRxn(t_m, PL):</p> <p>A. Search one-step reactions in knowledge graph KG for product t_m: Search all candidate reactions and save it as list L_1. # Calculate value function scores. $V_A = [w_1 \times (SAscore(reactants\ set\ of\ x)/10) + w_2 \times (1 - prediction\ score(x)) - availabilityP(reactants\ set\ of\ x)\ for\ x\ in\ L_1]$</p> <p>B. Generate top-50 probable one-step retrosynthetic predictions for product t_m: Run Retro* and select top-50 candidate reactions to save it as list L_2. $V_B = [w_1 \times (SAscore(reactants\ set\ of\ x)/10) + w_2 \times (1 - prediction\ score(x)) - availabilityP(reactants\ set\ of\ x)\ for\ x\ in\ L_2]$</p> <p>Select the optimal reaction as r, out of L_1 and L_2, that has the lowest value of V. $RL = reactants\ set\ of\ r$ $PL.append(r)$ return RL, PL</p> <p>availabilityP(RL): """" Returns 1 only when all the reactants are commercially or in-house available. """" return numpy.prod([int(m in PCL) for m in RL])</p>

A* search proceeds in the same flow as the pseudocodes in Table 1 and 2. It explores optimal synthetic paths having minimum scores of synthetic reaction value function V , which estimates the cost, certainty and readiness of a reaction and the combined value is adjusted by weights put on the exploration of knowledge graph and exploitation by retrosynthetic prediction:

$$V = w_1 \times \frac{SAscore}{10} + w_2 \times (1 - prediction\ score) - availabilityP \quad (1)$$

where weights are decided by user's preference on exploration vs. exploitation. And the *availabilityP* predicate returns 1 only when all reactants are commercially or in-house available. The *prediction score* that represents prediction probability of reaction is 1 when reaction was searched from knowledge graph and likelihood value when predicted. The reaction consisting of commercially available reactants takes precedence in the following

cases: (1) laboratory studies that seeks to complete a target test by rapidly generating the target compound with a small number of reaction steps through active use of commercially available compounds, and (2) process development stage that prioritizes the reaction using by-products by including them in the list of available compounds.

Table 2. Pseudocode of generating the optimal synthetic path.

```

With a target compounds  $t_m$  and list of commercially or in-house available compounds  $PCL$ , generate the optimal synthetic path  $PL$ .

Set weights  $w_1, w_2$  (real numbers between 0 and 1, default = 1).

 $PL = \text{applyGenRxn}([t_m], [])$ 
print( $PL$ )

applyGenRxn( $TL, PL$ ):
    """ Returns the complete synthetic path for the list of target compounds  $TL$ . """
    for  $m$  in  $TL$ :
         $RL, PL = \text{genRxn}(m, PL)$ 
        if not  $RL$ : raise Exception("No possible path exists.")
         $RL = RL - PCL$ 
         $PL = \text{applyGenRxn}(RL, PL)$ 
    return  $PL$ 

```

5. Results and Discussion

5.1. System implementation of ASICS

The proposed system was implemented as open source in Python. Selenium and BeautifulSoup were used for web crawling; Qt Designer and PyQt5 for GUI; Pandas for data pre-processing; Neo4j Python API for knowledge base construction; RDKit for cheminformatics.

5.2. Case study 1: Generation of synthetic path for HENC

The target material 2-hydroxyethyl 5-norbornene-2-carboxylate (HENC) is mainly used as an intermediate in the pharmaceutical and electronic polymer industries. The results of the synthetic paths of SciFinder retrosynthesis, ASICS, Retro* (Chen et al 2020) and AizynthFinder are shown as shown in Figure 2. Comparison of the results of four systems is shown in Table 3.

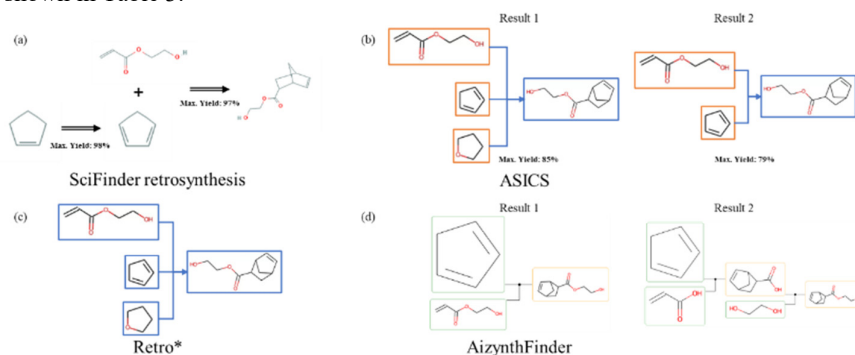

Figure 2. HENC synthetic paths results of (a) SciFinder retrosynthesis, (b) ASICS, (c) Retro* and (d) AizynthFinder.

ASICS intentionally generated two synthetic paths with different value function scores and AizynthFinder generated more number of synthetic paths. SciFinder retrosynthesis generated a two-step path. Retro* and ASICS generated one-step paths. AizynthFinder

generated one-step and two-step paths. The SciFinder retrosynthesis result had the lowest total price of starting materials at \$8.4/g using hydroxyethyl acrylate and cyclopentene, but it is a two-step path. The Retro* result and ASICS's result #1 showed the same one-step path, with hydroxyethyl acrylate, cyclopentadiene and THF being used, and the total prices were same. But the ASICS result contains more detailed additional reaction information and the cost of ASICS's result #2 is low. AizynthFinder's result #1 and ASICS's result #2 are the same, but ASICS with more detailed information. Total price of AizynthFinder's result #2 is slightly lower, but it requires two steps.

Table 3. Comparison of HENC synthetic paths results.

	Number of reaction steps	Number of starting compounds	Total price of starting compounds (\$/g)	Yield (%)	Synthesis procedure	Published year
SciFinder retrosynthesis	2	2	8.4	97	O	-
Retro*	1	3	65.8	X	X	X
AizynthFinder	1, 2	2, 3	46.8, 46	X	X	X
ASICS	1, 1	3, 2	65.8, 46.8	85, 72	O	2002, 2000

5.3. Case study 2: Generation of synthetic path for merimepodib

Results of synthetic path by ASICS and Retro* are the same in that three-step and five starting compounds are used. Both use [(3R)-oxolan-3-yl] carbonochloridate and 3-(aminomethyl)aniline as starting compounds. But in the case of Retro*, it uses a regulated compound (phosgene) and the probability of the first step of retrosynthetic path is low at 0.3336. However, there is no use of regulated compound in ASICS result, and the first step of retrosynthetic path (orange color of Figure 3(b)) is a guaranteed reaction with certainty = 1 since it originated from the knowledge graph. ASICS generated a better synthetic path by using reported reactions instead of an uncertain reaction with low probability.

5.4. Discussion

When using only retrosynthetic prediction results, e.g., Retro* and AizynthFinder, there

Figure 3. Merimepodib synthetic path results of (a) Retro* and (b) ASICS.

are disadvantages that detailed information (yield, conditions, etc.) for each reaction in synthetic paths cannot be known and the prediction results with low probability may be used. ASICS applied with hybrid generative exploration and exploitation explored

optimal synthetic paths that compensated for these shortcomings. ASICS generated optimal synthetic paths, showing less number of steps or similar to the result of SciFinder retrosynthesis based on ~112 million reaction data, ~100 times of the ASICS data.

6. Conclusion

In this study, we proposed an intelligent support system for reaction path design, generating optimal synthetic paths out of hybrid generative exploration and exploitation of reaction knowledge base and machine learning-based retrosynthetic predictions. The knowledge base, constructed from web crawling of USPTO patents (1976-2016) and related chemical data consists of relationships for 1,674,945 reactions and 923,761 compounds. ASICS generates optimal synthetic paths using lower-cost starting compounds by selecting optimal reactions with the lowest score of synthetic reaction value function. In addition, exploration and exploitation are adjusted according to the user's own preferences to enable optimal search for respective purpose.

Through case studies on HENC and merimepodib, we compared the results against SciFinder retrosynthesis, AizynthFinder and Retro*, the existing computer-aided synthesis planning systems. The ASICS results are similar or use less number of steps to the SciFinder retrosynthesis which works based on the reaction data of bigger size. Compared with the AizynthFinder and Retro* results using only prediction models, ASICS generated optimal synthetic paths consisting of reactions with higher likelihood than prediction-only results with uncertainty in reaction likelihood.

Abstract

Artificial intelligence has become an attractive science for companies as it allows effective data analysis, which helps to improve the manufacturing processes. The aim of this work is to study fluorine losses in a phosphoric acid unit by applying data science methods to process data. Conductivity was used as an indirect measure of fluorine losses in each recovery cycle. After a pre-processing of the data, a Gaussian Mixture Models (GMM) clustering algorithm was applied. Two clusters were found in the data: one with limited losses, and the other with significant losses. In addition, a ratio (R) was created from measurement data to identify the level of fluorine loss compared to fluorine gain during a time step. This ratio R is used in turn to determine whether the plant generates an acceptable amount of fluorine losses.

Keywords: Clustering, Fluorine losses, Phosphoric acid unit, Data analysis

1. Introduction

In recent years, the interest in data science has risen considerably across industries worldwide (Diez-Olivan et al., 2019; Lee and Shin, 2020). Indeed, numerous sensors record real-time data at all stages of the process. When these data are accumulated over time, they can be used as an input to data science algorithms to model complex, non-linear processes. In turn, these models help process engineers to better understand how different variables affect their plant processes.

Clustering is a data science method for analysing data that groups information into clusters with similar properties or features. Clustering is achieved by many unsupervised machine learning algorithms that can be used in various way in different industries. For example, Liu et al. (2018) applied the clustering method in order to evaluate the energy consumption in different companies. Their study allowed to position companies according to their level (high or low) of energy consumption. Sancho et al. (2020) used a clustering method to classify crude oils according to their physico-chemical properties. Zhang et al. (2017) used clustering to discriminate between operational status, i.e. the distinction between operating in a transitory regime and in a permanent regime.

The present article is an application of data science in the chemical industry on a phosphate production process. More specifically, the study will focus on the fluorine losses in a concentration unit of phosphoric acid. The goal is to qualify these losses and to understand their relationship with the process variables. In parallel, a ratio (R) is defined to quantify the losses and ease the readability and discussion of raw data. This indicator will be discussed and put in relation with the clustering results. Perspectives are a better control of the loss of a product that can be valorised and a reduction of the use of caustic soda necessary to neutralize the acidity generated by the fluorine loss.

This paper is organized as follows. In section 2, the fluorine recovery process in the considered phosphoric acid concentration plant is described. Then, in section 3, the methodology is discussed. Section 4 shows the main results that were achieved, and section 5 concludes and suggests some perspectives.

2. Background

The process of fluorine recovery (Fig.1) is divided into three main steps. First, phosphoric acid is concentrated via a vacuum evaporation, leading to a liquid product that is the concentrated phosphoric acid on one hand, and to the emission of a gaseous effluent that contains fluorine on the other hand. Second, this fluorine is recovered in liquid phase in an absorption tower. Finally, the remaining amount of fluorine from the gas phase is transformed into liquid stream rejects by another recovery system. This final recovery system is itself composed of two main units: the PraySep with a spray at its entrance is used to recover the fluocilic acid droplets contained in the gases, and a condenser is used to condense a maximum of the remaining gas. The fluorine losses are detected by a conductivity measurement in the condenser guard tank. Moreover, the amount of recovered fluorine is estimated from a density measurement in the liquid product of the absorption tower.

Figure 1: Diagram of the phosphoric acid concentration process.

3. Methods

The data used in this study contain all 2019 data, we focus on the most important variables. Initial data visualization was conducted in JMP® software (SAS Institute) (Yee *et al.*, 2000). The most important signals, which are density and conductivity, are plotted over several cycles in Figure 2. As the fluorine recovery happens in cycles of varying duration (an average of 70 min), the trends of these variables in each cycle was

of interest. During a typical cycle, density in the fluorine tank increases due to fluorine recovery, while at the process exit, conductivity in the condenser guard tank increases due to fluorine losses.

Figure 2: Evolution of the conductivity and the density in the fluorine tank as a function of time.

The figure 2 shows that the absolute values given by the conductivity sensor present a very high variability. Beyond short-term cycles, long-term variations also appear that may be due to incorrect calibration of the conductivity meter, or to other parameters which may affect the conductivity of the mixture in the condensate tank but that are not measured. For instance, the quality of the sprayed water before the PraySep, or even the water used to clean the vapour condensation could cause this long-term variation. To get rid of the long-term trend the conductivity signal has been normalised per cycle. For each conductivity point of a cycle, the value of the conductivity at the start of that cycle was subtracted. Consequently, a new standardised signal was constructed, making losses easier to analyse.

In order to study the behaviour of this conductivity in a more systematic fashion, a clustering method was applied. Gaussian Mixture Models (GMM) were used to automatically classify and label the conductivity cycles according to parameters qualifying their evolution. GMM allow to classify data coming from overlapping normal distribution. In this case, it was assumed that cycles with few losses, with medium losses and with many losses all follow a normal distribution and we want to determine these distributions. Note that, at other times, the conductivity signal is noisier or does not present a regular pattern. From these observations, we decided to fix the number of clusters to 3 in the initialisation parameters, plus a specific cluster for outliers. As the slopes of the conductivity characterise the fluorine losses well, we have used parameters derived from the slopes as inputs to this algorithm. Specifically, conductivity slopes have been calculated over 20-minute ranges at the start, the middle and at the end of each cycle, as well as the slope of the total conductivity cycle.

For the purpose of quantifying fluorine losses, a parameter was needed through which the losses could be described in a more concrete way according to their importance. The variables presenting the fluorine loss and gain were identified. The definition of a ratio R that includes these variables allows to describe the evolution of the losses during a fluorine recovery cycle. Note that this ratio cannot be used to describe losses that may be associated to longer term conductivity variations.

The way in which the density evolves during a cycle gives an idea of the productivity and the efficiency of the fluorine recovery. At the same time, the conductivity behaviour during the cycle reflects the Fluorine losses that are not recovered by the absorption

tower and the PraySep. Therefore, to accurately assess the performance of the fluorine recovery, the density gain and the conductivity loss must be considered in combination. To solve this problem an indicator that measures this recovery has been constructed. It is a ratio between the average of the normalised conductivity and the average of the density gained during a given time. Note that the density signal measures the cumulative density of the fluorine tank mixture which increases during the fluorine recovery cycle, while the conductivity gives values considered as instantaneous since the condenser guard tank is quite small, consequently the residence time of the mixture in this tank is very low. The ratio is defined as

$$R = \frac{\bar{\sigma}}{\bar{\rho}_a - \bar{\rho}_i} \quad (1)$$

Where: $\bar{\sigma}$: Average of normalized conductivity over a period Δt ; $\bar{\rho}_i$: The density of the first point of this Δt ; $\bar{\rho}_a$: Average of density over this Δt

This ratio measures how many conductivity points are generated for density points gained over a given period of time during the fluorine recovery cycle, we tried to calculate the R with different time slots (10 min, 15 min, and 20 min). Theoretically, this ratio increases as a function of time during the recovery cycle. At the beginning of the cycle, the fluorine tank is filled with fresh water. As a result, its recovery capacity is high. Subsequently, the density of the mixture in the fluorine tank increases over time. Consequently, its capacity to recover fluorine decreases, which generates more fluorine losses. As a result, the values of both the numerator and the denominator increase with time. However, the losses (numerator) increase faster than the gains (denominator), so that this ratio can be used as an indicator of when the cycle starts being inefficient in terms of fluorine recovery.

4. Results and discussion

The GMM algorithm was applied with the conductivity slopes as features. The model groups the data into 4 families, the cluster 0 contains the cycles whose probability of belonging to the 3 other groups is negligible, therefore, they can be considered as outliers. As a result of this clustering, the cluster 1 contains 53% of the cycles which corresponds to stable signals with low slopes (low fluorine losses). The cluster 2 includes disturbed signals with very high slopes and large standard deviations between the ratios, this group has over 12% of the conductivity cycles. The cluster 3 includes 33% of the cycles, it gathers signals that do not include too much noise and with high slopes compared to those of the first cluster. In the rest of this study, we will focus on the 1st and the 3rd clusters to quantify the losses of each of them, and to analyse the distributions of the production parameters. The 2nd cluster has been discarded because the signals in this group are too noisy to be interpreted.

Following this, we studied the evolution of the ratio R during the fluorine recovery cycles. To do so, each cycle has been divided into 3 parts, Then, the R value is calculated at the start, the middle, and the end of each cycle. The results by using 20min as time slot appears to be more interesting because several points of the cycle are taken, which allows a better characterization of the R. These values using periods of 20 minute

produced the R_20_Start, R_20_Middle, and R_20_End values, respectively. The figure 3 shows the distribution of these ratios for the two clusters.

Figure 3: The histogram distribution of the fluorine loss ratios for the two clusters 1 and 3.

The figure 3 illustrates that there is a progressive shift in the histograms of these ratios for the two clusters. In fact, the difference in R ratios between the two clusters starts at the beginning of the cycle, although this difference is relatively small in absolute value (0.5 on average for the first cluster and 0.94 for the third cluster). One can also observe that the standard deviation of cluster 3 is much larger than the one of cluster 1. Over time the difference becomes more and more important until the end of the cycle where the two clusters become clearly separated with a small overlapping section. At the end of the cycles, the ratio for the first cluster remains almost stable (1.08 on average), while the ratio for the third cluster considerably increases, from 0.94 at the start to 3.75 on average at the end. Also, we notice that 90% of the data of the first cluster have an R_20_End less than 3. On the other hand, for cluster 3, 50% of the data are higher than this value. So, the value R_20_End=3 can be used as a limit value which indicates high fluorine losses.

Once these observations have been made, relationships with process variables can be analysed. The important variables that can influence the fluorine recovery are weak phosphoric acid (WPA) feed rate, circulator amperage, steam flow, vacuum, and flow rate of the spray water before the PraySep. The behaviours of these variables have been studied but they do not show a very clear difference depending on whether a data point belongs to one cluster or to the other. This could be explained by the continuous nature of the slopes, by the noise on the conductivity signal and by the overlapping nature of the clusters. Therefore, this prevents a clear distinction between the two clusters in their respective process operating conditions. Nevertheless, it has been remarked that the flow rate of spray water did not change between the two clusters, whereas there is a difference for the steam flow rate. It is possible that the spray water flow rate is not adapted to the productivity of the unit.

To retrieve more information about the influence of process variables, it was decided to work on a sample that encompasses the two extreme types of conductivity cycles. Cycles with intermediate conductivity slope were manually removed from the data set in order to strengthen the differences between the two clusters. The resulting sample is composed of 253 cycles, of which 35% belong to the 1st cluster and 65% to the 3rd cluster. The distribution of R ratios for this sample is similar to the results in Figure 3. We notice that in this case all R_20_End values for the first cluster are lower than 3 and

more than 70% of the cluster 3 R_20_End values are higher than 3. This further confirms the value of R_20_End=3 as a threshold indicator of high fluorine losses.

As a second step, the process operating conditions have been studied for this sample, in the same way as it was done for the whole database. As a result, the difference between the two clusters appears more clearly when doing the study on this sample. The distribution of the WPA flow, the steam flow, the vacuum pressure, and pump amperage show that cycles belonging to the 1st cluster correspond to low values of these process variables. In contrast, cycles belonging to the 3rd cluster have higher parameter values. This confirms the important effect of the process load on the conductivity behavior during a recovery cycle. Indeed, when the flow rate of phosphoric acid to be treated is increased (WPA flow), the operating conditions are being pushed towards the process limits (for instance, more steam is required for the evaporation), but this seems to be insufficient to reach similar Fluor recovery performances. Nevertheless, all these variables present a large zone where the two clusters overlap, which confirms that the process load alone does not explain all the fluorine losses.

5. Conclusion

To conclude, this study was conducted to study fluorine recovery in a phosphoric acid concentration plant. In order to better characterize the losses during the recovery cycles, a ratio R has been defined which considers the gain (density increase in the recovery vessel) and the losses (conductivity increase in the liquid effluent waste). Since conductivity evolves in different ways, a clustering method using GMM algorithm has been used to classify the data according to low or high fluorine recovery performance. Following this methodology, it has been found that from a value of R=3 there are high fluorine losses. So, this ratio can be used as an indicator of fluorine losses.

Finally, it should be mentioned that the same procedure discussed previously was applied to another fluorine recovery unit located in the same phosphate plant. As a result, the same conclusions were reached, which means that this method can be used for any fluorine recovery plant in order to study the fluorine losses. To go beyond this study, a monitoring system that triggers an alert for high fluorine losses when the ratio R is higher than a given value (in this case when $R > 3$) will be studied. In addition, and to clearly identify the causes that influence the behaviour of fluorine losses, a detailed experiment on the flow rate and quality of the spray water injected to the PraySep unit will be carried out.

Abstract

The wide use of detailed simulations for complex systems has led to a growing interest for methods that can optimize simulation-dependent problems using data, without explicit equations or derivatives. Due to the lack of derivatives and the dependence on sampling, simulation-based optimization algorithms lack convergence guarantees and often require a significant number of samples to identify an optimal solution with consistency. Moreover, the presence of black-box constraints is an open challenge because it further complicates sampling and identification of unknown feasible spaces. Previously, we have introduced the Data-Driven Spatial Branch-and-Bound algorithm for box constrained problems, which employs data-driven convex underestimators, finds upper and lower bounds on the optimal objective value and progressively prunes suboptimal subspaces until convergence. In this work, we present recent advances of this framework for handling simulation-based and equation-based constraints. We demonstrate the performance of these features with respect to convergence and sampling requirements through benchmark constrained optimization problems.

Keywords: black-box optimization, simulation-optimization, surrogate modelling.

1. Introduction

An increasing amount of optimization applications in research and industry today require the embedding of various forms of data from simulations of various fidelity and/or scale. Such problems are challenging due to the inability to directly use efficient deterministic optimization solvers that require equation-based formulations. As a result, optimization of such problems is often referred to as “black-box” because it relies on input-output data. Many recent contributions from the engineering literature aim to apply and improve the performance of black-box optimization techniques for a wide variety of applications (Bhosekar et al., 2018). Optimization with embedded simulations can be performed with purely sampling-based algorithms, such as direct-search methods, genetic algorithms, particle swarm optimization, and many more that are reviewed in (Rios and Sahinidis, 2013, Boukouvala et al., 2016). Alternatively, a different class of methods employs approximations of data to perform optimization, and these are called model-based or surrogate-based techniques. Such techniques employ novel mechanisms for data collection, fitting of a surrogate model to represent the data, which then allows one to use equation-based optimization solvers. In order to avoid excessive sampling, most techniques in the literature use a small initial set of samples and subsequently adaptively “fit – optimize – resample” the space until their convergence criteria are met. This

adaptive scheme is always based on techniques that are designed to balance “exploration” (i.e., searching the feasible space just enough to minimize probability of missing the optimal solution), and “exploitation” (i.e., focusing sampling in promising optimal regions where surrogate models need to be accurate). Recent work focuses on the identification and comparison of different types of surrogate models and their performance for optimization (Garud et al., 2019).

Despite recent advances in the simulation-based optimization literature, several open challenges still exist. First, many of these methods suffer from the curse-of-dimensionality, since sampling requirements increase when decision-variables increase. Second, when a surrogate model is used, there are open challenges when it comes to the selection of a surrogate model that is accurate and has a tractable mathematical representation so that it can in turn be optimized (ideally globally). Specifically, some popular surrogate models result to equations with nonconvex terms, and the number of terms and variables rapidly increase with the number of dimensions, model architecture, and even with number of data points. Recent work on global optimization of Neural Networks as surrogate models are tackling this challenge (Schweidtmann and Mitsos, 2019). Third, we have previously shown (Zhai and Boukouvala, 2020) that surrogate model selection and training leads to significant variation in the optimal results, because if a different surrogate model is used, or different training data are used, many algorithms provide a different result. This inconsistency in performance is highly undesirable for any optimization algorithm. Last, earlier work in black-box optimization led to algorithms that treat the problem as a pure “black-box”, often without the ability to consider constraints. However, it is important to treat such problems as “grey-boxes”, which allows one to mix known equations that are typically constraints together with an objective and constraints that are reliant on the simulation.

In our previous work, we have proposed an approach that aims to tackle some of the open challenges mentioned above (Zhai and Boukouvala, 2020). Specifically, instead of relying on a known type of surrogate model, we develop convex quadratic underestimators of data. The data may come from high-fidelity simulations, or multiple low fidelity surrogate models. The reason for this approach is to avoid several of the disadvantages of surrogate modelling, such as: (a) variation in parameters and model type with slight changes in data; (b) computational expense of training and selection of best model out of many; and (c) intractability of complex surrogate models when it comes to their global optimization. Moreover, our approach utilizes a spatial branch-and-bound (b&b) framework to search the space and focus sampling in promising spaces, while pruning spaces that are not optimal. This strategy allows us to incorporate more rigorous convergence criteria, such as absolute or relative ε -optimality gap (as opposed to reaching a maximum sampling or CPU limit). This Data-Driven Spatial Branch-and-Bound (DD-SBB) algorithm, also provides estimates of upper and lower bounds on the optimum at any intermediate stopping point. We have found that this approach is promising and obtains optimal solutions with few sampling points, however, it requires a large amount of samples to close the optimality gap.

In this work, we propose techniques for extending the capabilities of the DD-SBB approach in terms of constraints handling. We consider two different forms of constraints: (1) simulation-based constraints (i.e., constraints that are unknown in equation format but are embedded within the simulation) and, (2) equation-based constraints (i.e., constraints that are explicitly known algebraically as a function of decision variables). The type of formulations we aim to solve in this work is shown in Problem 1 (P1), where the objective

function f and constraints g_s are embedded within a simulation and thus we do not have explicit equations for them. Constraints g_k are available in equation format. We only consider continuous variables that are bounded.

$$\begin{aligned}
 & \text{(P1) } f(x) \\
 \text{s. t. } & g_s(x) \leq 0, \quad s = 1, \dots, S \\
 & g_k(x) \leq 0, \quad k = 1, \dots, K \\
 & x^{lo} \leq x \leq x^{up}, \quad x \in R^N
 \end{aligned}$$

We implement and test different branching and bounds tightening techniques and test this extended capability of the algorithm through a set of benchmark problems. Our approach does not add computational cost to the algorithm because it does not require the fitting of surrogate models for the simulation-based constraints. Concepts from decision-tree techniques are explored for branching the search space cleverly into “feasible” and “infeasible” nodes and the performance of different branching rules are compared with respect to efficiency and convergence.

2. Methods

2.1. Data-Driven Spatial Branch-and-Bound Framework

The DD-SBB framework starts with initial sampling of the entire box-constrained space using Latin Hypercube sampling. Based on these high-fidelity samples from the simulation, a low-fidelity surrogate model can be fit, but this model is only used for ranking the importance of variables and for generation of large amounts of low-fidelity data, to be used to generate the convex underestimators. Convex underestimators are found by solving P2, where M is the total number of samples, and a, b, c are the parameters of the convex quadratic function that underestimates all of the obtained data. In previous work we have reported results on the validity of these bounds as more data is included from high- and low- fidelity samples (Zhai and Boukouvala, 2020).

$$\begin{aligned}
 & \text{(P2) } \sum_i^M (f(x_i) - f_{lb}(x_i)) \\
 \text{s. t. } & f(x_i) - f_{lb}(x_i) \geq 0 \quad \forall i = 1 \text{ to } M \\
 & f_{lb}(x_i) = ax_i^2 + bx_i + c \quad \forall i = 1 \text{ to } M \\
 & a \geq 0
 \end{aligned}$$

For each space or node of the b&b tree, a lower bound (LB) is found through minimization of the convex underestimator and an upper bound (UB) is the best high-fidelity sample collected. The algorithm then proceeds with branching the space with a selected branching rule, resampling within subspaces and updating the LB and UB of the problem. The branching heuristics originally implemented are equal bisection with respect to branch location. When deciding on which variable to branch on first, the algorithm has options prioritizing the longest side or prioritizing the most important variable with respect to the objective. The presence of constraints requires several modifications to this framework, including novel branching and pruning rules, which will be presented in the next section.

2.2. Branching rules in the presence of constraints

Branch rules are essential to a branch-and-bound algorithm. Besides equal bisection on the longest edge and equal bisection with customized variable selection (Zhai and Boukouvala, 2018, 2020), we implemented two other branch rules targeted to handle

constraints. In the presence of constraints, samples are labelled as 0 (infeasible) and 1 (feasible). The proposed branch rules are designed to separate feasible from infeasible regions, with the hypothesis that this will help with faster pruning of infeasible regions. One strategy is to use a weighted Gini impurity score commonly used in classification and regression trees (Kotsiantis, 2013). The Gini impurity score (Eq. (1)) is a measure of the tendency that a randomly chosen sample would be misclassified in a node.

$$G = \sum_{i=0}^1 p(\text{label} = i) * (1 - p(\text{label} = i)) \forall i = 0, 1 \tag{1}$$

where $p(\text{label} = i)$ represents the probability of a randomly chosen sample with label i in the node to be chosen. To select the best location to cut, we minimize the weighted Gini impurity score (Eq. (2)), which minimizes the possibility of misclassification if a cut is generated at x_k on edge d .

$$k, d = (p(x_d \leq x_{k,d}) * G_{x_d \leq x_{k,d}} + p(x_d \geq x_{k,d}) * G_{x_d \geq x_{k,d}}) \tag{2}$$

where k denotes k^{th} equidistant location on edge d and $p(x_d \leq x_{k,d})$ is the possibility of a randomly chosen point lies in the potential subspace.

The second strategy is a customized purity score (Eq. (3)) that measures the difference in the fraction of infeasible samples and fraction of feasible samples in each subspace.

$$\text{Purity}_{k,d} = \left| \frac{N_{\text{infeasible}_{x \leq x_{k,d}}}}{N_{\text{infeasible}}} - \frac{N_{\text{feasible}_{x \leq x_{k,d}}}}{N_{\text{feasible}}} \right| \tag{3}$$

If one subspace contains samples with only one label, the purity score will be 1. Otherwise, the purity score is between 0 and 1. To select the best location, we maximize the purity score (Eq. (4)) to separate purely feasible and infeasible spaces.

$$k, d = \text{argmax}_{k,d} \left(\left| \frac{N_{\text{infeasible}_{x \leq x_{k,d}}}}{N_{\text{infeasible}}} - \frac{N_{\text{feasible}_{x \leq x_{k,d}}}}{N_{\text{feasible}}} \right| \right) \tag{4}$$

where k denotes k^{th} equidistant location on edge d . Note that if one node contains only samples with one label, equal bisection on longest edge will be used.

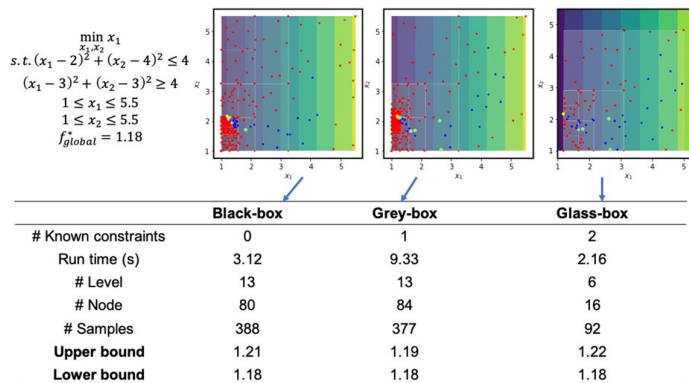

Figure . Motivating example formulation, algorithm performance and results. Red points are infeasible, blue points are feasible.

1.1. Pruning in the presence of constraints

Pruning a search node when the node appears to be less promising to find the global optimum helps the algorithm converge faster. Generally, a node is pruned when the local lower bound is higher than the global upper bound. In the presence of constraints, we implemented additional rules to prune nodes that are infeasible. When the constraints are known, we perform feasibility-based bound tightening at the root node and at each active node. Specifically, we solve a constraint-violation minimization problem to check the feasibility of each node, and if a subspace is found to be infeasible, it is pruned. When the constraints are unknown, node pruning is less straightforward because decisions are made depending on the feasibility labels on the samples instead of explicit mathematical constraints. To reduce the chance of pruning feasible regions, backtracking techniques are incorporated. When the algorithm encounters a node that contains only infeasible samples, it backtracks the parent and grandparent nodes. Only if both the parent and grandparent nodes contain purely infeasible samples, will the node be pruned. By doing so, we avoid pruning nodes prematurely and allow collection of extra samples in that node, to increase the confidence of pruning the node.

2. Results

2.1. Motivating Example

Here we present results on a simple 2-d example with unknown objective function that enables us to highlight the algorithm performance. In Figure 1, we show the formulation of the problem, as well as the performance of the algorithm when the formulation is purely black-box (all constraints are simulation-based), grey-box (first constraint is known, second is unknown), to glass-box (all constraints are known). As expected, as more constraints become known, the algorithm converges to the global optimum with less samples. In addition, we observe that the additional cost of feasibility tightening does not significantly increase the cost of the algorithm. On the contrary, due to faster convergence, the algorithm converges faster with respect to run-time when constraints are present. In this motivating example, we keep the pruning and branching rule fixed to equal bisection with branching on most important variable. A comparison of different heuristics is performed in the next section.

2.2. Algorithm benchmarking

In order to test the performance of different branching rules, we test the algorithm on a larger set of benchmark problems. These are 42 problems from the MINLPlib, with 2-5 dimensions and no limit on the number of constraints. The algorithm terminates if any of the following criteria are met: 1) the absolute gap between the lower and the upper bound is smaller than 0.05, 2) the relative gap is smaller than 0.001, 3) the longest edge in a search area is smaller than 0.05, 4) the number of samples reaches 200,000 and 5) CPU reaches 5 hr. Results are reported for the two extreme cases, namely the black-box case where no constraints are known and the glass-box case where all constraints are known (Figure 2). Results show that the algorithm can locate the global optimum for 80% of the problems in the black-box case, and more than 85% of the problems in the glass-box case. Moreover, the algorithm converges with less samples when constraints are explicitly known. Results show that the novel branching rules, namely purity score and Gini impurity score, proposed in this work expedite convergence (i.e., more problems are solved with less number of samples). However, overall, the equal-bisection branching

rule solves more problems if more samples can be collected. This implies that these decision-tree rules can expedite pruning, however, they are less conservative and thus increase the chance of removing good optimal solutions.

Figure SEQ Figure \^* ARABIC 3. Performance of algorithm and different branching rules for set of 42 benchmarks, (EB_LS: Equal-bisection on longest side, EB_VS: Equal-bisection with variable selection)

3. Conclusions

In this work we presented an extension of our algorithm for data-driven branch-and-bound for constraints handling. We propose and test several branching and pruning rules in the presence of simulation-based constraints that are based on concepts proposed in the literature of decision-trees. In order to treat equation-based constraints, we employ feasibility-based bounds tightening techniques. Results show that it is important to use any known constraints directly, because this expedites algorithm convergence and overall solves more problems without adding computational cost due to reduced sampling requirements. Moreover, branching when using decision-tree heuristics expedites convergence of the algorithm, however, in certain cases prunes valuable solution spaces. As a result, when sampling is not a significant burden, the equal-bisection approach is a more conservative and reliable heuristic.

Abstract

During the last decade, the hydrate-based CO₂ capture (HBCC) process has been approved as a promising alternative. The HBCC offers several attractive advantages such as the mild operating pressure and temperature, the ease of regeneration of CO₂, and its low energy consumption. The HBCC is at its infancy stage where the numerical methods play a key role in its research and development. This is to support the experimental research in terms of the model-based experiment design and process analysis/optimisation. In this view, HBCC modelling and simulation have been focused by researchers worldwide. Most of the published models are restricted to the processes at the particle scale that are enormously beneficial for a fundamental understanding of the process science. Nevertheless, a challenging shortfall currently exists for reactor scale models given the process scale research, and development objectives require models at the relevant scale. Accordingly, the reactor level models that may be used in a comprehensive process are required. Ideally, a multi-scale model allows studying both science and technology. This paper presents an HBCC process model at the reactor level for batch and semi-batch operations. The scaled-up model is capable of simulating the CO₂ dissolution, and growth phases. The model evaluates the hydrate layer boundary and estimates the total gas uptake in batch semi-batch reactors. A modified version of the model made it possible to account. The present study establishes a groundwork for the large-scale application of the HBCC.

Keywords: Gas hydrates, CO₂ capture, reactor scale modelling, kinetic model

1. Introduction

During the last decade, there has been growing interest in deploying hydrate-based CO₂ capture (HBCC) due to its moderate operating temperature and pressure, low energy consumption and easy regeneration of the aqueous solution (Dashti and Lou, 2018, Dashti et al., 2015). For full commercialisation, the process computation tools are crucial. To model the HBCC at reactor level, it is essential to achieve fundamental insights at micro and mesoscales. This is vital for computing the kinetics of crystallisation, mass/heat transfer rates. Nucleation and growth are the two interlinked stages involved in the hydrate formation process, making the model development at particle level challenging. Despite a vast amount of research conducted, there is the hydrate kinetics and routes yet to be well understood, revealing the importance of

micro-scale studies. The commercialisation challenges, however, need reactor scale studies and analysis tools.

In a recent study, the modelling of CO₂ hydration growth and nucleation was conducted through the utilisation of the shrinking core method (SCM) (Dashti et al., 2019; Dashti et al., 2019). The models presented in the mentioned works were capable of capturing the conversion trajectory and nucleation phase behaviour over the process time. The boundary condition used in these works was assumed based on the reactor conditions averaged. This may affect the model results due to the non-homogeneity that normally exists in a reactor. This is, in particular, crucial to local temperature and concentration are used as boundary conditions of single particles. Ideally, a CFD model should be employed to capture the spatiotemporal data in a mixed reactor while the particle model is simultaneously deployed. This will be computationally time-consuming due to the giant particle number and the tremendous data exchange between the scales. For a hydrate reactor with no agitator, an applied model does not necessarily need such complexity and computation load. Traditionally, HBCC processes utilised stirred tank reactors as it thought that the mixing provides improved mass transfer kinetics; however, the reactor faces problems of agglomeration of hydrate crystals and the reduced coefficients of mass transfer. It is unfavourable for significant scale-up due to the high stirrer-driving power consumption (Mori, Y. H, 2015). These lead to the application of unstirred reactors with gas hydrate promoters (Dashti et al., 2015, Veluswamy et al., 2018). The packed beds of sand, silica or pulverised coal have been used in some studies (Linga and Clarke, 2017). This paper presents a computationally, fast and fundamentally efficient model for hydrator. This is of interest to couple the particle scale and the reactor scale models. This paper establishes a model to describe the HBCC process during batch and semi-batch operations at the reactor level. Initially, three models, including transient mass transfer, transient heat transfer and CO₂ hydrate formation (Improved model) models for the batch operation, have been developed further, the models adopted for the semi-batch operation. Finally, a scale-up reactor model which is capable of simulating the CO₂ dissolution, nucleation, and growth phases has been developed.

2. Methodology

2.1. Basic and improved model

Gas hydrate formation consists of two main steps: gas dissolution and gas hydrate formation. First, a basic model for CO₂ dissociation has been developed and then this model serves as a reference to the improved model. The basic model for the batch reactor considers transfer rates of CO₂ diffusion in water by first establishing the rate-determining mechanism between the transport phenomena, mass transfer and heat transfer of CO₂ in the stationary water medium. The controlling mechanism will then be utilised as the core of the model to describe the dissolution of CO₂ (A) through the reactor. The concentration and the temperatures are time (t) and location (x) dependent. Only mass diffusion (D) and conductive heat transfer (kVT) are considered in the stationary water. This is a justifiable assumption due to the low temperature and no-agitating system. Table 1 presents the governing equations for basic and improved models. The models' parameters are presented in Table 2.

 Figure 1: Reactor schematic for CO₂ hydrate operation

Table 1. Model equations and initial and boundary conditions (BC and IC)

Model	Equations	BC and IC
Basic Model	$\frac{\partial C_A}{\partial t} = D \frac{\partial^2 C_A}{\partial x^2}$	$C_A(0, x) = 0; C_A(t, 0) = C_{A0}; dC_A(t, L) = 0$
	$\frac{\partial C_A}{\partial t} = D \frac{\partial^2 C_A}{\partial x^2}$	
	$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2}, \alpha = \frac{k}{\rho c_p}$	$T(0, x) = T_0; T(t, 0) = T_0; dT(t, L) = 0$
Improved model	$\frac{\partial C_A}{\partial t} = D \frac{\partial^2 C_A}{\partial x^2} - k_0 e^{\left(\frac{-E_a}{RT}\right)} \cdot C_A \cdot \frac{S}{V}$	$C_A(0, x) = 0; C_A(t, 0) = C_{A0}; dC_A(t, L) = 0$ $T(0, x) = T_0; T(t, 0) = T_0; dT(t, L) = 0$
	$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2} + k_0 e^{\left(\frac{-E_a}{RT}\right)} \cdot C_A \cdot \frac{S}{V} \cdot \frac{\Delta H}{\rho c_p}$	

 Table 2. Parameters used for the semi-batch process of CO₂ hydrate formation

Parameters	Value
D (m ² /h)	6.912×10 ⁻⁶ (Cussler, E. L., 1997)
α (m ² /h)	5.24×10 ⁻⁴
C _A (J/mol.K)	4181
ρ (kg/m ³)	997
k ₀ (m/h)	2.05×10 ⁶⁹ (Bergeron and Servio, 2008)
E _a (J/mol)	387645.5 (Bergeron and Servio, 2008)
R (J/mol.K)	8.314 (Jensen, 2003)
ΔH (J/mol)	66800 (Claudia, 2013)

2.2. Batch and semi-batch operations

A reactor with a constant volume of water, V, and water surface area, S, that is initially maintained at 25 °C is assumed (Figure 1). In semi-batch operation, a pure CO₂ (1 bar and 5°C) is continuously supplied to apply constant CO₂ pressure at the gas-water interface. Therefore CO₂ concentration estimated based ideal gas law, has been used as a boundary condition. For the batch operation, As CO₂ diffuses through the water to be consumed in hydration over time, its concentration in gas bulk decreases. A time-dependent concentration must be considered at the top boundary. A mathematical expression Eq. (1) was derived from (Raizi, 1997) and (Zarghami, 2017) to calculate the local dynamic concentration, C(t,x). This reactor model uses a stationary non-agitated water volume; therefore, the mathematical expression is suitable for this model. The equation was simplified for the concentration of gas at the top boundary only, i.e., C(0,t).

$$C(0, t) = \frac{P}{H} \exp\left(\frac{t}{\eta^2 D}\right) \operatorname{erfc}\left(\frac{\sqrt{t}}{\eta \sqrt{D}}\right), \quad \eta = \frac{VH}{\sqrt{DART}}, \quad C(0, 0) = \frac{P}{H} \quad (1)$$

in which P is pressure, H is Henry's law constant and R is the molar gas constant.

2.3. Reactor scale-up

With a fully functional batch operation version of the improved model, the reactor scale-up can be attempted to evaluate the profiles and the gas uptake in the hydrate layer of the reactor. In the scaled-up reactor, the reactor length is scaled up from 0.12m to 1m. The theoretical volume of the reactor is 1000m³ and Area is 1000m². The term for Molecular Mass, M of CO₂ is introduced to equations for temperature profile in the CO₂ hydrate formation model and Eq. (2), to indicate the change from molar concentration to mass concentration:

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 C_A}{\partial x^2} + k_0 e^{\left(\frac{-E_a}{RT}\right)} \cdot C_A \cdot \frac{S}{V} \cdot \frac{\Delta H}{\rho C_p M}, \eta = \frac{VHM}{\sqrt{DART}} \quad (2)$$

3. Results and Discussions

The models have been solved using MATLAB ‘pdepe’ solver. The basis model PDEs were numerically solved individually. The improved model PDEs were solved simultaneously to account for the coupled dependence of both concentration and temperature. The reactor length scale and timescale were used; $0 \leq x \leq 0.12\text{m}$ and $0 \leq t \leq 80\text{hr}$. The dynamic concentration and temperature profiles in the reactor are presented in Figure 2a and 2b. Note that independent mass and heat transfers are assumed.

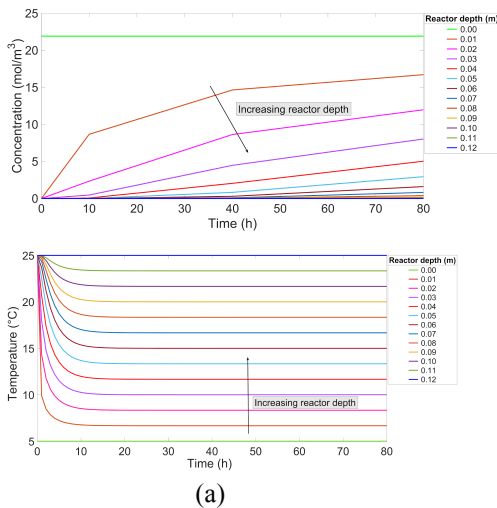

Figure 2. Results of the concentration and temperature changes in the reactor versus time for mass transfer only (2a) and heat transfer only (2b) models

The temperature graph (2b) indicates a faster rate of change over time from 0 to approximately 7 hrs for each length and reaches a steady-state ($dy/dt = 0$) at an earlier time than the concentration in figure 2a. For example, at 0.1m, the concentration has yet to reach a steady-state (indicated by a straight line parallel to the x-axis) but only begins to approach steady-state at around 30-40 hrs. However, at the same point, the temperature has already reached a steady state at a temperature of about 6.7 °C. As a result, this shows that the transient mass transfer process is much slower than the transient heat transfer process and therefore, this mechanism can be considered the rate-controlling mechanism for the CO₂ dissolution process into the water. This is due to higher mass transfer resistances involved with the transport process of CO₂ in the water body over the transport of heat. In a further analysis in this study, the basic model

which uses the only the transient mass transfer compared with the improved model that combines the effects of transient mass transfer, transient heat transfer and the hydrate formation thermodynamics/kinetics (Figure 3a). The basic model is denoted as “M” data line, and the improved model is denoted as the “MHR” data line. The results of this analysis in conjunction with the temperature profile (Figure 3b) in the improved model (MHR) can be used to predict the metastable and stable region for where the hydrate phase can occur within the reactor profile.

It can be seen from Figure 3b that between the top boundary at 0m and 0.03m, the temperature maintains a constant profile of 5-10 °C. Therefore, 0.03m is the maximum length under these parameters for hydrate nucleation and growth to occur. That is 25% of the reactor length. Also, at the maximum length, the concentration is at 3.126 mol/m³, and with the top boundary being 21.917mol/m³, this means that about 86% of the CO₂ diffused into the water remains in the stable region for hydrate growth for the improved “MHR” model. Compared to the basic model “M”, at 0.03m, the concentration is at 8.043 mol/m³. This indicates about 63% of the CO₂ diffused remained in the hydrate stable region.

Further, beyond the maximum of 0.03m for the stable region, the “M” data line continues to maintain a steady linear correlation to approximately 0.04-0.045m. This shows that even after passing through the stable region, there is no change in the concentration gradient between 0 and 0.4m (meaning a constant driving force for incremental changes in x). There is no interference for the transport of CO₂ in the basic model other than the bulk of water itself. In contrast, for the improved “MHR” model after 0.03m, there is a sharp change in the curve. This can be explained as the remaining 14% of CO₂ that diffused beyond the region for hydrate growth has less interference/resistance in the body of the water. This shows that between 0-0.03m, there was an increased constant transfer resistance caused by hydrate growth formation.

Figure 3 show that the improved model is indeed superior to the basic model for the prediction hydrate even with the appropriate temperature considerations. Furthermore, it is possible to use this type of analysis to predict the stable phase for growth and the proportion of CO₂ within the phase.

(a) (b)
 Figure 3- A comparison between the basic model (M) and improved model (MHR) in terms of concentration (3a) and temperature profile in the improved model (MHR) (3b)

The results of the scale-up reactor model for temperature and the concentration changes are presented in Figure 4. As can be seen in Figure 4a, the temperature profile does not reach steady-state after 80hr. This is due to the change in the length from 0.12 to 1m, so the temperature profile has yet to stabilise. Increasing the time for the process will ultimately push the temperature towards a steady-state profile. Also, because of the transience of the temperature profile in this time range, it means that at 10°C, the stable region for hydrate growth will continue to increase over time until a steady state is reached for that temperature. For example, at 10hr, the stable region barrier for 10°C is at 0.0325m. At 40hr, the barrier is at 0.065m, and at 80hr, the barrier is at 0.095m.

As can be seen in Figure 4b, the reactor model can be used to estimate the amount of CO₂ gas uptake in the hydrate layer. The maximum concentration uptake in the hydrate layer is approximately 380 mol/m³. The volume of the reactor has been stated as 1000m³. Therefore, about 380 kmol (or 16.7 tonnes) of CO₂ are consumed in the hydrate layer after 80hr. 16.7 tonnes per 80hr is much lower than what industry wants for CO₂ capture (typically in the 100's of tons per day). Therefore, in order to increase the rate and capacity of CO₂, considerations about increasing the pressure of the system and the total volume of the reactor to accommodate for higher gas uptake in the hydrate layer. However, researchers seek to find ways to reduce the operating pressure as it entails high costs. This reactor model can be presented as a resource or guideline for anticipating the maximum capacity of gas uptake for set parameters.

(a) (b)
 Figure 4- Temperature profile in the scale-up reactor model (4a) Concentration uptake in the hydrate layer in the scale-up reactor model at depth of 1m (4b)

4. Conclusions

Two models were developed for the HBCC process at the reactors scale. First, a basic model was derived, ignoring the reaction rate to estimate mass and heat transfer roles in the dissolution phase. It was then improved, taking both dissolution and hydrate formation into account. The results indicated that mass transfer was the rate-controlling mechanism as reactor temperature reach a steady value in a shorter time. The comparison between the two models revealed that the consumption/reaction term has a significant influence on the reactor profiles. It was shown that the improved model is more capable in predicting realistic HBCC reactor. The model was applied for batch operation by using a time-dependant boundary condition for the bulk gas. Finally, the model was scaled-up utilising all the improvements and knowledge from the previous case analysis. With the set parameters such as volume, time and length, this model can be utilised to evaluate the position of the hydrate layer boundary and estimate the total gas uptake in the system.

Abstract

This paper presents SMITH, the working prototype of a new code which significantly improves the accuracy of thermodynamic diagrams thanks to the highly performant numerical technologies including differential homotopy and automatic differentiation.

Keywords: distillation diagrams, univolatility curves, differential homotopy, automatic differentiation

1. Introduction

Extraction of singular compounds from multi-component mixtures through the separation process is the most commonly used technology in chemical, pharmaceutical and food-processing industries (Petlyuk, 2004). Analysis of the thermodynamic diagrams describing the fundamental physical properties of complex mixtures is a crucial step in the conceptual design of industrial process involving separation technologies. In very many cases the topology of these diagrams is non-trivial even for ternary mixtures. In particular, this concerns the computation of certain characteristic curves like univolatility curves, distillation profiles, the phase separation curves, the pinch-point curves, etc. Different types of diagrams are accessible via professional packages, but often they are incomplete or lack in precision, as in the example shown in Fig. 1 about univolatility curves used when designing extractive distillation process.

The insufficiency of the professional softwares creates serious obstacles for the technological transfer from academic research to industrial implementation, so the search of new algorithmic solutions to improve computational efficiency are important for the process engineering community.

The major part of existing algorithms to compute characteristic curves of thermodynamic diagrams use the Newton-Raphson like procedures over the composition space. This implies an important computational effort to access the acceptable precision and requires an a-priori knowledge of the topology of the diagram in order to provide a good initial approximation. On the other hand, algorithms based on the differential homotopy principle provide a very promising alternative to the Newton-Raphson method for path

Figure 1: Hexane (1) - Benzene (2) - Hexafluorobenzene (3) at 1.2 atm (generalized NRTL). Univolatility curves computed by ASPEN Plus v.8[®], ResidueCurve[®], and Mathematica 9[®]. Here α_{ij} are the univolatility curves of i and j compounds, Az_{ij} are binary azeotropes. Both professional codes fail to identify the pair of binary azeotropes Az_{23} , ASPEN Plus[®] ignores the azeotrope-free branch of the curve α_{23} . ResidueCurve[®] lacks in precision.

following computations (Allgower and Georg, 2003; Caillau et al., 2012). In process engineering, this approach was proposed by several authors to compute distillation profiles, pinch point curves, univolatility curves (Poellmann and Blass, 1994; Feldbab, 2012; Skiborowski et al., 2016) and phase separation boundaries (Deiters, 2016). Although these codes showed excellent results in comparison with the Newton-Raphson based analogs, still they form a marginal branch in the process engineering computing. The main reason of this poor success is the access to the derivatives of the thermodynamic models required by these methods. Indeed, using analytical expressions of the model and its derivatives significantly increase precision and numerical stability of computations, but their implementation is technically difficult and may form an additional source of error.

In this paper we present SMITH (Separation of Mixtures In Thermodynamics by Homotopy) (SMITH, 2020), a working prototype of a new code allowing highly precise and efficient computation of different types of curves of ternary diagrams. In contrast with codes cited above SMITH realizes the differential homotopy algorithm in coupling with automatic differentiation of the thermodynamic models. Such a coupling allows to easily implement a large class of thermodynamic models, and access the high numerical performance with less computational effort. The current version of SMITH is limited to compute the univolatility curves of ternary mixtures, without an a-priori knowledge of the topological structure of the underlying VLE diagram and independently of the presence of azeotropes. The same computational approach can be developed for many other types of thermodynamic diagrams.

In Section 2 we briefly recall the geometric model of the univolatility curves introduced in Shcherbakova et al. (2017). Section 3 describes the main features of the SMITH code. The paper is concluded with a series of illustration examples.

2. Geometrical model of univolatility curves

Univolatility curves α_{ij} are the sets of points on the ternary residue curve map (RCM) where the pair of compounds i and j have the same relative volatility. They are used as the feasibility indicators in the distillation process design. In extractive distillation, the placement and the terminal points of the univolatility curve on the composition tri-

angle edges determine the order of the withdrawn products as well as the proper column configuration (Gerbaud and Rodriguez-Donis, 2014).

A ternary RCM may contain up to three families of univolatility curves according by their respective index, even in zeotropic case. The topology of univolatility curves is intrinsically related to the topology of the underlying RCM (Kiva et al., 2003; Shcherbakova et al., 2017). Indeed, three univolatility curves of different index intersect at ternary azeotropic points, and each binary azeotrope gives rise to a univolatility curve. Multiple binary and ternary azeotropy can occur. Note that the presence of azeotropes is sufficient but non necessary for the existence of the univolatility curves. A RCM may contain azeotrope-free curves and multiple curves of the same index may coexist. If the topological structure of the RCM is known, the computation of univolatility curves starting at azeotropes is straightforward, while the detection of univolatility curves not associated with azeotropes is a more complicated and time-consuming process, especially in the case of zeotropic mixture.

Consider an open evaporation of a ternary mixture kept at thermodynamic equilibrium at constant pressure. Denote $x_i, y_i, i = 1, 2, 3$ the mole fractions in the liquid and in the vapor phases, and T the temperature of the system. In the absence of chemical reactions a two-phase ternary mixture has three independent state variables. By choosing x_1, x_2 and T , the complete state space of the system is $M = \{(\bar{x}, T) : T \in [T_{min}, T_{max}], \bar{x}_i \in \Omega, i = 1, 2\}$, where T_{min} and T_{max} are the minimum and maximum boiling temperatures of the mixture and $\Omega = \{\bar{x} = (x_1, x_2) : x_i \in [0, 1] \text{ with } x_1 + x_2 \leq 1, i = 1, 2\}$ is the composition space parameterized by the mole fractions of the first two compounds, while $x_3 = 1 - x_1 - x_2$. The distribution coefficients $K_i : M \rightarrow \mathbb{R}$ are the functions over M that describe the vapor-liquid equilibrium (VLE) in terms of molar fractions in the vapor and liquid phases: $y_i = K_i(\bar{x}, T)x_i$ for $i = 1, 2, 3$. Since $\sum_{i=1}^3 y_i = 1$, the following equilibrium condition holds:

$$\Phi(\bar{x}, T) = \sum_{i=1}^3 K_i(\bar{x}, T)x_i - 1 = 0. \quad (1)$$

In 3D state space M , Eq.(1) defines a smooth hyper-surface referred as the boiling temperature surface, namely W -surface. Along with W -surface, M contains three univolatility hypersurfaces defined by equations

$$\Psi_{ij}(\bar{x}, T) = K_i(\bar{x}, T) - K_j(\bar{x}, T) = 0. \quad (2)$$

Possible intersections of the W -surface with univolatility hypersurfaces are smooth curves $\Gamma_{ij} \in M$ called the generalized univolatility curves (Shcherbakova et al., 2017). Univolatility curves $\alpha_{ij} \in \Omega$ are the orthogonal projections of the curves $\Gamma_{ij} \in M$ to the composition space Ω . Since $\nabla\Phi$ and $\nabla\Psi_{ij}$ define the normal vector fields to the 2D surfaces defined by Eqs.(1, 2), the vector field $U^{ij} = \nabla\Phi \times \nabla\Psi_{ij}$ is tangent to the generalized univolatility curve Γ_{ij} . In other words, the curve Γ_{ij} is a solution to the following system of ordinary differential equations in M :

$$\dot{x}_1 = U_1^{ij}(x_1, x_2, T), \quad \dot{x}_2 = U_2^{ij}(x_1, x_2, T), \quad \dot{T} = U_3^{ij}(x_1, x_2, T). \quad (3)$$

In order to compute generalized univolatility curves it is enough to detect their end-points over the border of the composition triangle and use them as the initial points for the numerical integration of Eq.(3). This can be done solving Eqs.(1, 2) on the boundary of

the composition triangle $\partial\Omega$ in the reduced 2D space. For the sake of completeness we remark, that in some cases α_{im} curve starts from the binary edge i, j of the triangle where m compound is missing (see for instance the α_{12} curve in Fig. 1). In this case, as it was proposed in (Kiva et al., 2003), the distribution coefficient K_m must be replaced by the distribution coefficient at infinite dilution, which can be obtained from the ternary distribution coefficient by setting $x_m = 0$. This generalization enables to compute complete univolatility diagrams independently of the presence of azeotropes.

3. SMITH algorithm

3.1. Differential homotopy method

The core of SMITH code uses the differential homotopy method with arc-length parameterization to solve the systems of algebraic equations. This approach is based on the following mathematical result (see in Allgower and Georg (2003) for more details).

Let $F : \mathbb{R}^{N+1} \rightarrow \mathbb{R}^N$, $F(q, \lambda)$, denote the homotopic function where λ denotes the homotopy parameter. Under certain regularity assumptions, the solution to the equation $F(q, \lambda) = 0$ forms a one-dimensional manifold. Indeed, if F is a continuously differentiable function such that

$$F(q_0, \lambda_0) = 0, \quad \text{rank} \frac{\partial F}{\partial \lambda}(q_0, \lambda_0) = N$$

for some q_0 and λ_0 , and if zero is a regular value of F , then a continuously differentiable curve starting from (q_0, λ_0) exists and it is either diffeomorphic to a circle or to the real line. The different branches of $F^{-1}(\{0\})$ form disjoint smooth curves.

As we showed in Section 2, the generalized univolatility curve Γ_{ij} is a "path of zeros" of the function $F_{ij} = (\Phi(q, \lambda), \Psi_{ij}(q, \lambda))$ with $q = (x_1, T)$ and $\lambda = x_2$. SMITH uses a predictor-corrector algorithm via the `nutopy` package with a high order step-size control Runge-Kutta scheme for the prediction, and with a classical simplified Newton method for the correction. The key point of success is the efficient computation of the Jacobian matrix of the homotopic function F_{ij} , which reduces to the computation of the derivatives of the distribution coefficients K_i , $i = 1, 2, 3$. In SMITH code these derivatives are computed via the automatic differentiation tool `tapeenade` (Hasco and Pascual, 2012), which drastically simplifies numerical implementation of the homotopic method.

3.2. Initial points computation

To start the homotopy, the path-following method needs to be initialized at points (q_0, λ_0) verifying $F(q_0, \lambda_0) = 0$. Such points can be chosen on the border of the composition triangle Ω . In fact, according to the index i, j of the couple of compounds, each edge of $\partial\Omega$ may contain up to three types of extremity points verifying univolatility condition, moreover, several points of the same index may co-exist. Such points may be found by applying a standard Newton-Raphson procedure over the border of the composition triangle. SMITH realizes a much more efficient method, based on the following observation. Any edge I of the triangle $\partial\Omega$ can be parameterized by the mole fraction of one of the compounds $x_i = a \in [0, 1]$, $i \in 1, 2$. Denote $\phi(a, T) = \Phi(\bar{x}, T)|_{\bar{x} \in I}$, $\psi_{ij}(a, T) = \Psi_{ij}(\bar{x}, T)|_{\bar{x} \in I}$. Then initial points for the curve α_{ij} are zeros of the function $E_{ij} : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ defined by

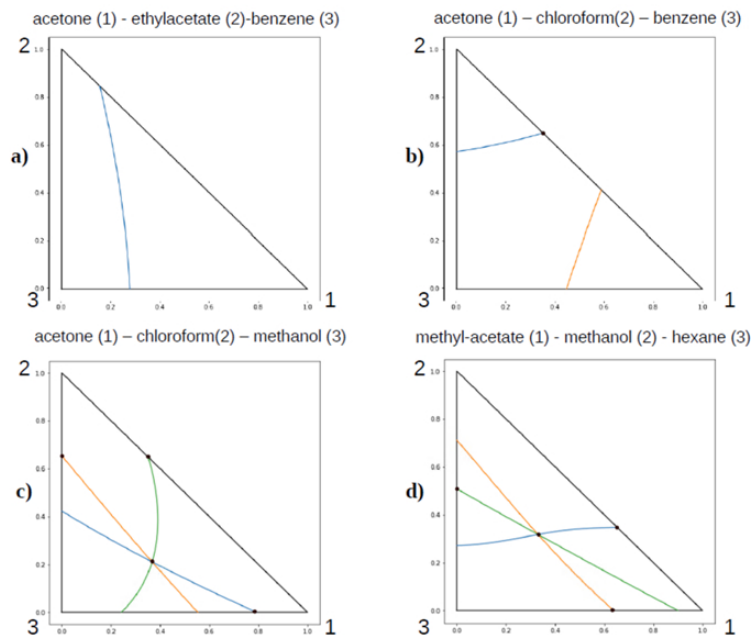

Figure 2: Univolatility diagrams of different Serafimov's VLE topological classes computed by SMITH: a) 0.0-1; b) 1.0-2; c) 3.1-4; d) 3.1-2.

$E_{ij}(a, T) = (\phi(a, T), \psi_{ij}(a, T))$. Due to the uniqueness of the boiling temperature T of a homogeneous mixture, equation $\phi(a, T) = 0$ defines a smooth graph in the 2D plan with coordinates a and T . According to the Implicit Function Theorem, it can be solved in order to express $T = T(a)$. Then the zeros of the function E_{ij} can be detected by finding zeros of the scalar function $\psi_{ij}(a, T(a))$.

SMITH implements the above idea as follows. In order to capture multiple solutions, each edge of $\partial\Omega$ is divided into K sub-intervals $[a_k, a_{k+1}]$, $k = 0, \dots, K - 1$ with $a_0 = 0$ and $a_K = 1$. $T(0)$ is computed by Brent's method in the interval $[T_{min}, T_{max}]$, and going further around the edge, $T(a_k)$ is computed via a standard Newton method using $T(a_{k-1})$ as the initial guess. The sign of $\psi_{ij}(a_k, T(a_k))$ is checked at each k . The change of the sign of ψ_{ij} at k -th step means the existence of a zero of this function in the interval $[a_{k-1}, a_k]$, which can be then found by a standard Newton-Raphson procedure. Realizing such a scheme along every edge of the triangle for all three families of equations (including the equations associated to the compound at infinite dilution) allows to build the complete set of initial points. Observe, that binary azeotropes can be detected a-posteriori by checking the condition $K_i = K_j = 1$ over the computed set of points. The binary bi-azeotropy can be easily detected.

3.3. Examples

The actual version of SMITH code allows computations using NRTL and UNIQUAC models for activity coefficients, and Antoine's and DPPR equations for vapor pressure

computations at various value of process pressure. Fig. 2 shows four examples of ternary univolatility diagrams of different topological classes (see in Kiva et al. (2003) for Serafimov's ternary VLE classes). They were computed at standard atmospheric pressure using NRTL model for activity coefficients and Antoine's equation for vapor pressure calculation. The black points indicate the position of azeotropes. Diagram a) provides an example of a purely zeotropic mixture (Serafimov class 0.0-1) which has one univolatility curve. Diagram b) contains two univolatility curves of different indexes, one of them is azeotrope-free. These two azeotrope-free univolatility curves cannot be detected by ASPEN Plus v.8[®]. Cases c) and d) provide examples of diagrams of three curves of different index, the essential difference is the type of ternary azeotrope: a saddle in c) and an unstable node in d) cases. The intersection points of the uni-volatility curves were used to find the ternary azeotropes.

4. Further perspectives

The current version of SMITH (SMITH, 2020) works on Unix systems. We are no working on the Windows version. Although the current version implements only the standard NRTL model, other thermodynamical models are under development. Soon they will be available, as well as a more efficient method of initial points localization using homotopy. In a long term perspective, we plan to develop new applications to compute phase separation boundaries, pinch point curves, etc. The described mathematical and numerical approach can be easily adapted to these types of computation.

Abstract

Global warming and climate change produced by CO₂ emissions is an important issue today. Carbon capture represents a promising option of reducing CO₂ emissions and allows the continuation of fossil fuels usage for at least a short to medium period of time. This work aims to bring to light an innovative CO₂ capture system that relies on a process intensification technique. The system proposed is a three-phase fluidized absorber, in which the low density inert packing is fluidized by the flow of gas (rich in CO₂) which is flowing in counter current with the liquid phase. A detailed dynamic mathematical model is developed in order to evaluate the post-combustion CO₂ capture process using alkanolamine-based solvents in a gas-solid-liquid capture system. The phenomena which take place in the fluidization column is described by both mass and energy balance equations and includes mass transfer models, effective mass transfer area correlations and hydrodynamic process modeling. The simulation results show the intensification of gas-liquid transfer through the fluidization process, the effective mass transfer area being 8 - 10 times larger than in the case of packed beds. In addition to this the CO₂ molar flow transferred through the gas-liquid interface is up to 8 - 12 times higher than conventional packed bed column.

Keywords: CO₂ capture, three phase fluidized bed, mathematical modelling.

1. Introduction

Carbon capture represents a promising option of reducing CO₂ emissions and allows the continuation of fossil fuels usage for at least a short to medium period of time. The gas-liquid absorption can be considered one of the most attractive, commercially mature and efficient methods for carbon dioxide capture in an attempt to reduce global climate change. Mono-ethanol-amine (MEA) is the most widely used solvent for CO₂ absorption (Rochelle, 2009), and CO₂ capture by MEA in packed bed absorption columns is one of the most common CO₂ capture technologies. Post-combustion CO₂ capture using solvents based on the conventional technology requires very large packed columns. An innovative three phase fluidized design (gas-solid-liquid) would be an interesting and potential promising option to treat high amount of flue gas usually coming from power plants (Dragan 2016). This fluidized system has many advantages, from mass transfer point of view: low pressure drops in the column, very high interfacial contact area per unit volume of the column and capacity to process a large volume of gases. Also, the solid packing is easily handled and can be removed from the column with pneumatic transport, it does not need special expertise and it can easily be made from chemical resistant plastics with low capital cost of equipment.

Figure 1. Mass transfer model for the gas-solid-liquid absorption system

The solid phase has no chemical effect on the process, but the intensive mixing of the solid packing in the column determines high turbulence and therefore enhances the mass transfer and increases it significantly comparative to conventional fixed packed beds. The continuous movement of inert solid particles leads to the perpetual renewal of the liquid film that forms on the solid particles and gives an important increase in the effective mass transfer area (Figure 1).

2. Mathematical model

In this work, a dynamic mathematical model is developed in order to evaluate the CO₂ capture process into three phase fluidized bed column. The developed model constitutes in equations that describe the complex nature of the process, referring not only to the mass transfer between the gas and the liquid phase, but also to the hydrodynamics and kinetics of absorption of CO₂.

In terms of the kinetic model for the chemical reaction between MEA and CO₂, the model uses the equations and data revised by Versteed et al (1996). The reaction between carbon dioxide and primary amines, according to the zwitterion mechanism, has an overall order of two, with a value of one with respect to both CO₂ and the amine. Hence, for the process described in this work, the reaction rate can be written as:

$$r = k \cdot C_{MEA} \cdot C_{CO_2} \quad (1)$$

$$k = 4.4 \cdot 10^8 \cdot e^{\frac{-5400}{T}} \quad (2)$$

The mass transfer between the gas phase and the liquid phase can be described using the two-film theory. The resistance to the transfer, concentrated in the thin films of gas and liquid respectively, at the interface, is quantified by the partial mass transfer coefficients described by Billet and Schultes, 1993:

$$k_l = C_l \cdot \left(\frac{g}{\vartheta_l}\right)^{\frac{1}{6}} \cdot \left(\frac{D_{CO_2}^l}{s}\right)^{\frac{1}{2}} \cdot w_{le}^{\frac{1}{2}} \quad (3)$$

$$k_g = C_g * \left(\frac{1}{\varepsilon - h_l}\right)^{\frac{1}{2}} \cdot \left(\frac{a}{s}\right)^{\frac{1}{2}} \cdot D_{CO_2}^g \cdot \left(\frac{w_{ge}}{a \cdot \mu_g}\right)^m \cdot \left(\frac{\vartheta_g}{D_{CO_2}^g}\right)^n \quad (4)$$

An important parameter in the mass transfer model is the effective mass transfer area, which is highly different from both the wetted area and the geometric area of the packing. A literature review shows that there are several correlations available that calculate its value for regular packed bed absorption columns. However, in order to be able to determine the effective mass transfer area obtained in fluidized bed absorption columns, these correlations were adapted based on experimental results (Ilea et al., 2020):

$$a_e = a \cdot e^{-3.8767} \cdot Re_{g,l}^{0.8790} \cdot We_l^{0.2198} \quad (5)$$

Moreover, the mass transfer can be quantified in terms of transferred CO₂ molar flow:

$$N_{CO_2} = a_e \cdot E \cdot k_l \cdot (C_{CO_2}^g - C_{CO_2}^l) \quad (6)$$

Due to the fluidization phenomenon, the mass transfer between the gas and the liquid phase takes place in the fluidized bed height, which is different from the entire height of the column. The model includes also equations that are used to determine the value of the fluidized bed height (Eq 7). Hence, the hydrodynamics of this process are a determining factor when it comes to the efficiency of the absorption.

$$H_{sf} = \frac{H_s^0 \cdot \pi \cdot \frac{d_p^2}{4}}{h_s \cdot s} \quad (7)$$

where $h_s = 1 - h_l - h_g$ (Letzel 1999, Billet&Schultes 1993).

The overall phenomena that take place in the process presented in this work can be described using mass and energy balance equations:

$$F_j^e = F_j^0 \pm v_j \cdot \frac{N_{CO_2} \cdot M_{CO_2}}{\rho_j} \quad (8)$$

$$\frac{dC_{CO_2}^j}{dt} = \frac{F_j^0}{v_j} \cdot C_{CO_2}^{0j} - \frac{F_j^e}{v_j} \cdot C_{CO_2}^j \pm N_{CO_2} - r \quad (9)$$

$$\frac{dC_{MEA}^j}{dt} = \frac{F_j^0}{v_j} \cdot C_{MEA}^{0j} - \frac{F_j^e}{v_j} \cdot C_{MEA}^j \mp N_{MEA} - r \quad (10)$$

$$\frac{dT_j}{dt} = \frac{F_j^0}{v_j} \cdot T_j^0 - \frac{F_j^e}{v_j} \cdot T_j^0 - \frac{\Delta H_r \cdot r}{\rho_j \cdot c_{p_j}} \mp \frac{h \cdot a_e \cdot (T_l - T_g)}{(\rho_j \cdot c_{p_j} \cdot v_j)} \pm \frac{N_{MEA} \cdot \Delta H_{MEA}^v}{\rho_j \cdot c_{p_j}} \quad (11)$$

where j represents the gas/liquid phase, the reaction and vaporization terms are included only in the equations describing the liquid phase.

The operating parameters for fluidized/packed bed system are presented in Table 1.

Table 1. The operating parameters

Model	Liquid flow [m ³ /s]	Gas flow [m ³ /s]	MEA conc. [M]	Column		CO ₂ conc [M]
				Diameter [m]	Height [m]	
Fluidized bed	2.78*10 ⁻⁵	3.25*10 ⁻²	5	0.14	1.1	0.0014
Packed bed					4.36	

3. Results and discussions

In order to be able to analyse the performance of the proposed system, the mathematical model was implemented in Matlab/Simulink and several simulations were conducted to best determine its behaviour. The developed model had been previously validated in terms of hydrodynamics (liquid holdup of fluidized bed absorption column without chemical reaction) and carbon dioxide capture efficiency in fluidized bed system and in packed bed system (for CO₂ capture in MEA aqueous solution), a good correlation ($R^2 > 0.95$) was observed (Gaspar and Cormos, 2011, Ilea et al., 2020).

Figure 2. Influence of gas velocity on CO₂ capture rate and expanded bed height

Figure 3. Influence of liquid flow on liquid and solid holdups

The hydrodynamics of the process are highly relevant when trying to achieve better performance. Thus, as seen in Figure 2, the carbon dioxide capture rate increases with the increase of the gas velocity. This dynamic behaviour takes place due to the fact that the increase of the gas velocity favours the fluidization regime and movements of inert solid particles which leads to the renewal of the liquid film and increase in the effective mass transfer area. Moreover, at constant gas velocity, the increase of liquid flow determines an increase in liquid holdup as well as a decrease in solid holdup (Figure 3).

The CO₂ cyclic capacity (quantity of CO₂ absorbed per quantity of solvent) is used to quantify the performance of different capture systems. A comparison between the values of CO₂ cyclic capacity obtained in a pilot scale fluidized bed system and an industrial scale for packed bed absorption column is presented in Figure 4. A 15-20 % increase in the CO₂ absorption cyclic capacity of the system is observed.

Figure 4. Influence of MEA concentration on CO₂ cyclic capacity

Figure 5. Influence of liquid temperature on CO₂ transferred molar flow

The simulation results show that the three-phase fluidized bed system gives highly improved CO₂ capture capacities compared to regular packed bed columns. The increase of CO₂ absorption efficiency is due to an important increase in the effective mass transfer area, 8 to 12 times higher than packed bed and mass transfer coefficients, k_l and k_g , (3 to 4 times higher). These increased parameters intensify the mass transfer between the gas and the liquid phase, such that the CO₂ molar flow transferred through gas-liquid interface is one order higher in the fluidized bed column's case (Figure 5 and Table 2).

Table 2. Comparison between fluidized bed and packed bed columns

Column	Effective mass transfer area [m ² /m ³]	Transferred flow [kmol/s]
Fluidized bed	1990.70	7.9*10 ⁻³
Packed bed (Mellapak 250Y)	123.26	4.2*10 ⁻⁴

4. Conclusions

A detailed dynamic mathematical model was developed for a three-phase fluidized bed in order to assess the CO₂ capture capacity. The phenomenon which takes place in the fluidization bed was described by mass and energy balance equations and includes mass transfer models, effective mass transfer area correlations and hydrodynamic behaviour modeling. The developed model had been previously validated based on experimental data from a pilot plant.

The simulation results show that the intensification of gas-liquid mass transfer through fluidization process leads to an important increase in the effective mass transfer area (8 - 10 times larger than in the case of packed beds). A three phase fluidized bed absorption not only increases with 8 to 12 times the CO₂ transferred flow between the gas and the liquid, but it also helps achieve a 15-20 % increase in the CO₂ absorption cyclic capacity of the system. This brings essential operational advantages such as larger capacities for CO₂ capture plants.

Abstract

Through electrolysis and methanation coupling, Power to Methane systems have raised as an attractive alternative for power generation while harnessing renewable sources' potential and reducing carbon dioxide (CO₂) emissions. However, there is a research scarcity in their coupling within a Power to Methane context. This study simulates and analyzes an alkaline electrolysis cell coupled to a methanation process in a Power to Methane context to produce electricity by an open Brayton cycle in both steady and dynamic state. Simulation software is used to analyze the operating conditions and specifications' effects, the effect of the electrolysis power input in a steady-state simulation, and the behavior of a dynamic-simulation with fluctuating renewable energy input for the electrolysis process in two different plant arrangements. Results provide a preliminary glance at the Power to Methane system's behavior finding its contribution to the continuity issues that renewable energy sources have. However, the importance of continuing the research is highlighted to deeply understand the coupling of these processes in order to improve the profitability and performance of a PtM system.

Keywords: *Power to methane, electrolysis, alkaline electrolysis, simulation, Aspen*

1. Introduction

Given the constant changes in a globalized world affected by climate change, energy from fossil sources and polluting gas emissions take on an almost antagonistic role. Hence it is imperative to find solutions to meet the energy demand while contributing to CO₂ emissions reduction through carbon capture technologies and renewable energy sources. A promising alternative that fits these new challenges is the Power to Methane (PtM) technology, in which electrolysis and methanation are coupled for methane production (Boudellal, 2018). This technology aims to harness renewable sources' potential while reducing CO₂ emissions since electrolysis uses renewable energy sources, and methanation contributes as carbon capture sequestration technology. In recent years, electrolysis has shown relevant results in numerous case studies and applications, having considerable investments in projects worldwide (Boudellal, 2018) using technologies such as proton exchange membranes, solid oxide cells, or alkaline solutions (Wang et al., 2020). Thus, it is necessary to study the coupling of these technologies looking to improve the profitability and performance of a PtM system, considering the absence of research in this area. Therefore, this study aims to simulate and analyze an alkaline electrolysis cell (AEC) coupled to a methanation process in a PtM context in both steady and dynamic state to produce electricity by an open Brayton cycle, using two different reactor types for methanation.

2. Model formulation

2.1. Electrolysis model

Alkaline electrolysis (AEC) is the most mature and commercially available technology for this type of process (Boudellal, 2018). It is characterized by commonly using a 25-35% KOH solution and operating at temperatures between 70 and 140°C and pressures up to 30 bar (Sánchez et al., 2018). For its simulation, an algebraic semi-empirical model studied by Sánchez et al. (2018, 2020) was employed. They included the polarization curve, Faraday efficiency, and gas purity in their model, taking current density and operating pressure and temperature as variables. Nevertheless, for this simulation purposes, where higher temperatures will be considered, reversible voltage (V_{rev}) is included as a temperature function shown in Eq.(1), according to Khater et al. (2011).

$$V_{rev} = 1.518 - 1.542 \times 10^{-3}T + 9.523 \times 10^{-5}T \ln(T) + 9.84 \times 10^{-8}T^2 \quad (1)$$

2.2. Methanation reaction and kinetics

A rigorous methanation reactor was modeled considering the Langmuir-Hinshelwood-Hougen-Watson (LHHW) kinetics proposed by Koschany et al. (2016). Simulation parameters were obtained from those implemented by Ortiz et al. (2020) in their analysis within a PtM context.

3. Computational and simulation aspects

AspenTech software was employed to simulate a PtM plant coupling electrolysis and methanation. The electrolysis was modeled in Aspen Custom Modeler® and exported to Aspen Plus®, where additional unit operations (including the methanation reactor) were used. First, a steady-state analysis was performed to find operating conditions and specifications for the unit operations involved in the system. The PtM plant was then exported to Aspen Plus® Dynamics for a dynamic state simulation. However, two different plant arrangements were simulated: ideal and rigorous. The ideal arrangement simulates the methanation process in a Gibbs reactor type, which uses Gibbs free energy minimization to calculate equilibrium and possible reaction products without specifying the reaction stoichiometry or temperature changes (Figure 1). An ideal CO₂ feed is used in this arrangement since other inlet compounds would affect the methanation products. The rigorous arrangement, shown in Figure 2, simulates methanation in a Plug-Flow-Reactor (PFR) type using the catalytic kinetic model mentioned in section 2.2. This arrangement is simulated with a co-current thermal fluid taken from one of the water recirculation streams and a CO₂ feed composition reported by Arenas et al. (2014). Peng-Robinson thermodynamic model was used since its appropriate for methanation (Ortiz et al., 2020) and combustion (Alderetes, 2018).

Figure 1. Ideal PtM arrangement.

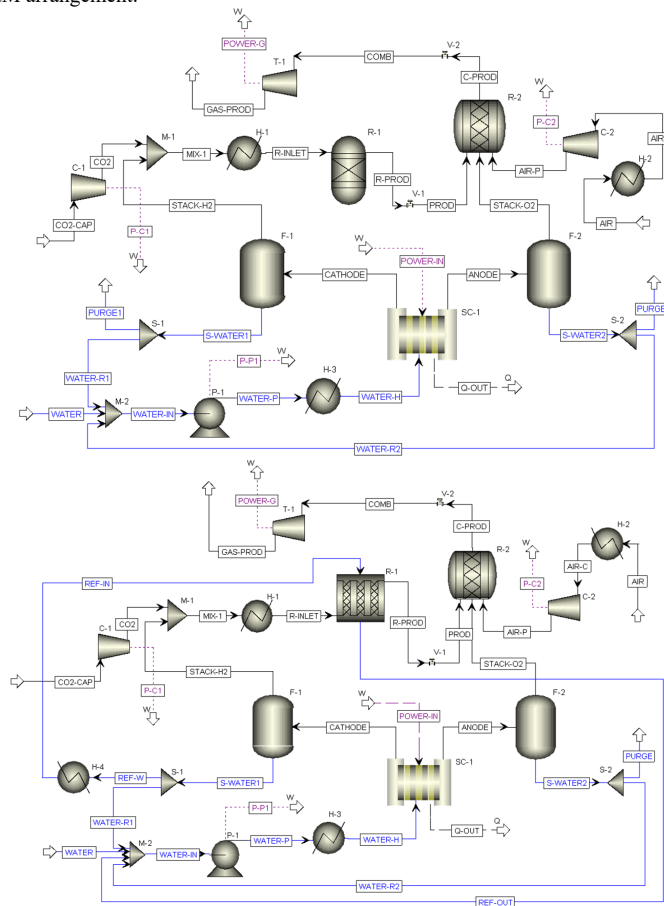

Figure 2. Rigorous PtM arrangement.

4. Results and discussion

4.1. Operating conditions and specifications

4.1.1. Electrolysis

The electrolysis model was analyzed in Aspen Plus to establish the most suitable operating conditions and specifications for the whole PtM plant. Temperature, pressure, power input, number of cells, and cell's area were taken as variables to observe the hydrogen molar flow from cathode output and Faraday's efficiency behavior.

Figure 3 shows the (a) hydrogen molar flow, (b) hydrogen to oxygen fraction (HTO), and (c) Faraday efficiency for different numbers of cells (N) and cell areas at specific operating conditions (100 °C, 7 bar, 10 kW) taken from Sanchez et al. (2020) simulation. Hydrogen molar flow increases as the cell area does, reaching a steady-state value between 0.096 and 0.098 kmol/h for any number of cells between 10 and 20. However, Faraday's efficiency decreases as cell area and cell number increase, the latter having a more significant impact on this variable. Therefore, a considerable hydrogen flow of 0.097 kmol/h, a low HTO fraction (0.018), and an appreciable efficiency of 91% can be obtained using 15 cells with an area of 0.16 m², being this specification appropriate for the cell stack.

Keeping the mentioned cell stack specifications constant, Figure 4 shows the effect of pressure and temperature on the (a) hydrogen molar flow, (b) HTO, and (c) Faraday's efficiency. This analysis shows a lower incidence of pressure (affecting the system when it exceeds 15 bar) and a higher incidence of temperature on these variables: direct for hydrogen flow and proportionally inverse to Faraday's efficiency. Consequently, it is preferable to operate at low pressures to reduce the pump's (P-1) energy requirement and the energy extraction necessary in the phase separators in later stages. Adverse effects and changes in the HTO and efficiency are noted when the temperature exceeds 100 °C, with little increase in the hydrogen flow. Hence, it is preferable to operate at temperatures below 100 °C.

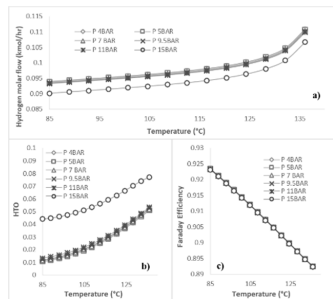

Figure 4. Hydrogen molar flow (a), HTO fraction (b) and Faraday's efficiency (c) at different temperatures and pressure (P).

4.1.2. Methanation and combustion operating conditions

Figure 6. Hydrogen conversion at different temperatures and pressure (P)

For the methanation reactor, hydrogen conversion at different temperatures and pressures is outlined in Figure 6a, showing a decreasing behavior as temperature increases, whereas pressure effects are not sizable at temperatures below 550 °C. Therefore, it is preferred low operating pressures to reduce the compression energy requirement both hydrogen and CO₂ feeds. Hence, reactor operating

temperature and pressure are set to be 226.8 °C and 5 bar, with an H₂/CO₂ ratio of 4, as recommended by Ortiz et al. (2020). A catalytic (*hexaaluminate*) combustion reactor was supposed to reach complete methane conversion since it is suitable for gas turbines and operates at high temperatures (He et al., 2020). Hence, combustion is simulated in a stoichiometric reactor with 100% methane conversion at standard operating conditions of 1230 °C and 15.8 bar (Alderetes, 2018). A 20 % air excess is specified as Eckerlin (2016) suggested for proper methane combustion performance. Table 1 shows the operating conditions for all the units involved in the PtM arrangements simulated.

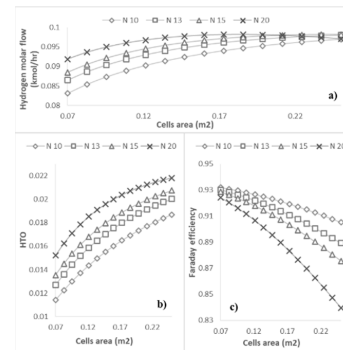

Figure 3. Hydrogen molar flow (a), HTO fraction (b) and Faraday's efficiency (c) at different number of cells (N) and cell area.

Finally, the effect of power input at different temperatures on hydrogen flow (a), HTO (b), and Faraday's efficiency (c) is shown in Figure 5. Hydrogen flow seems to increase significantly as power input does, without strongly affecting HTO fraction nor Faraday's efficiency. However, since power input is intended to be provided by renewable energy sources (e.g., solar panels), necessary arrangements and capacities to maintain more than 10 kW of power in operating times of around 6 hours a day can be costly compared to the hydrogen production that can be achieved in the stack model.

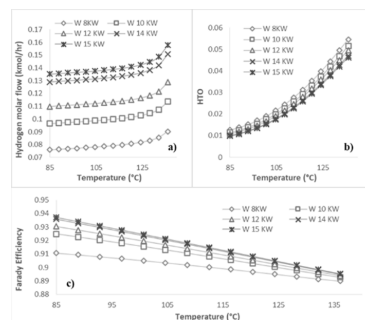

Figure 5. Hydrogen molar flow (a), HTO fraction (b) and Faraday's efficiency (c) at different temperatures and power input (W).

4.2. Steady-state simulation results

Each stream's temperature, pressure, mass flow, and composition is shown in Table 2 and 3 for ideal and rigorous PtM plants respectively. The results are very similar even for the methane flow produced at the R-1 reactor's outlet, yet the compositions change since oxygen and nitrogen are present from carbon capture. A difference is found in the outlet temperatures since RGibbs keeps it constant while the rigorous reactor considers an increase because of the Sabatier's reaction exothermic nature and a reduction by the heat exchange with the recirculating water stream. For those reasons, a few streams are added to the rigorous arrangement, where the flow of some streams changes (e.g., air, CO₂, and water feed).

Tables 2 and 3 include the power streams as well. It is shown that the turbine's generation is greater than the total power requirement for all compressors and pumps involved, having 0.92 and 1.34 kW of available power for ideal and rigorous plant, respectively. The rigorous plant has more available power because it needs a lower airflow hence a lower power input at C-2, considering that some of the oxygen requirement enters the system from CO₂ capture. The available power is lower compared to the electrolysis power supply; however, PtM systems will serve as an essential contribution to the continuity issues that renewable energy sources (intended to feed the system) have. These fluctuating renewable power sources and their effects on the system cannot be observed in a steady-state simulation (where a value of 10 kW is set), requiring a dynamic-state simulation.

4.3. Dynamic-state simulation results

For renewable energy source supply simulation, POWER-IN is adjusted with sinusoidal ramp tasks to 8 and 10 kW in a time frame of 1 hour, keeping the operating conditions set in section 4.1. The design specifications for the electrolysis water inlet, H₂/CO₂ ratio, excess air, and thermal fluid (the last one only for rigorous simulation) are manipulated using PID controllers.

Figure 9. Main products flows and CH₄ molar fraction in ideal (a) and rigorous (b) PtM arrangements

Figure 8. Design specifications' control for ideal (a) and rigorous (b) PtM arrangements

Figure 7 shows the behavior for the renewable power input (POWER-IN), the compressors required power (P-C1 and P-C2), and the power generated by the turbine (POWER-G, which is reported negative since it is leaving the system) for ideal (a) and rigorous (b) PtM arrangement. The incidence of POWER-IN on the rest of the power streams is direct: when the power input increases, the hydrogen flow leaving the cell stack does as well, and CO₂ and air feeds increases because of the ratio controllers. The feeds flow increasing requires more power to maintain the compressors' discharge pressure for the streams to enter the system. For this same reason, these feed ratios are also affected by the input power fluctuations as the system exerts control over them as design specifications. Thus, Figure 8, a) and b) show the design specifications variations with deviations less significant than 6% from the set point for both ideal and rigorous arrangements. Finally, in Figure 9, it is shown that the flows of the main reaction products (hydrogen and methane) obey the direct incidence of power input described previously. However, there is a difference in the methane fraction at the R-1 reactor's outlet from one arrangement to the other since the ideal runs with a pure CO₂ feed, and the rigorous CO₂ feed has the presence of oxygen and nitrogen.

Table 1. Units operating conditions for PtM system simulation

Unit		T (°C)	P(bar)
Heat Exchangers	H-1	226.8	5
	H-2	13.8	1

	V-2		0.3

5. Conclusions

This research compares the simulation results of an AEC coupled to a methanation process (ideal and rigorous) in a PtM context in both steady and dynamic state using two different plant arrangements. This simulation approach contributes to studying and understanding the coupling of electrolysis and methanation technologies for electricity generation by analyzing and setting the operating conditions that favor the PtM system performance. Steady-state simulations' results showed the temperature, pressure, power input, and stack specifications effects in the electrolysis process and how it affects when it is part of a PtM system for power generation. Dynamic-state simulations, considering a fluctuating renewable energy source, showed the direct effects of electrolysis power input on the main reaction products' flows and how it changes the system's power requirement. Steady and dynamic state simulations showed that despite the available power is lower than the electrolysis power supply, PtM systems serve as an essential contribution to the continuity issues that renewable energy sources have and as an attractive carbon capture technology. However, it is essential to enhance the grasp of the coupling of these processes. Different electrolysis technologies might be considered with more rigorous models, improvements in the accuracy of design specifications' control, and Brayton cycle performance.

cheiak@nus.edu.sg

Abstract

This work revises and improves our meta-learning based surrogate selection framework, LEAPS2. We perform several modifications to revise LEAPS2 (LEAPS2v2): incorporate noise in response to mimic reality, avoid recommending surrogates that fit noise, add stronger attributes that capture nonlinearities better, propose a novel performance metric that balances surrogate accuracy and complexity, and include larger pool of data sets and surrogate models. Evaluating the recommendation performance of LEAPS2v2 revealed that it successfully recommended at least one of three true best surrogates for more than 94% non-noisy and 89% noisy data sets. It showed large correlation between chances of a surrogate being recommended by LEAPS2v2 and being true best. No specific surrogate accomplished superior performance than others over all data sets. LEAPS2v2 made successful recommendations on a case study involving an industrial compressor.

Keywords: meta-learning, surrogate model, predictive accuracy, surrogate complexity.

1. Introduction

The desire and ability to accurately model complex, nonlinear processes using digital twins has been on the rise. While high-fidelity virtual models offer significant advantages in process analyses and decision-making, they suffer from two main drawbacks. Firstly, it requires rich domain knowledge, expertise, and substantial time to develop robust digital twins. Secondly, it is often computationally prohibitive to use them frequently for real-time analyses. Hence, computationally cheaper surrogate models offer an attractive alternative. They are easy to build by learning the relationships between key inputs and appropriate outputs, using process data. The literature (Queipo et al., 2005) has discussed various surrogate modeling techniques such as Artificial Neural Network (ANN), Support Vector Regression (SVR), Radial Basis Function (RBF), Multivariate Adaptive Regression Spline (MARS), among many others in detail. Identifying an appropriate surrogate is crucial for precise approximation of the system behaviour. One approach for model selection is to employ meta-learning (Rice, 1976), where surrogate selection is guided by accumulating experience of surrogates' performances for diverse data sets. A meta-learning framework is trained by correlating certain features of data or attributes to surrogates' performances, using a learning algorithm. This framework is used for identifying and recommending best surrogates for any data set, based on its learnt knowledge. A recent meta-learning framework, LEAPS2 (Learning based Evolutionary Assistive Paradigm for Surrogate Selection) was developed by Garud et al., (2018). Although LEAPS2 showed good performance in identifying accurate surrogates for a data set, it had some limitations. In this work, we aim to address the limitations of LEAPS2, in addition to upgrading and widening its scope and functionality significantly.

2. LEAPS2 and its Limitations

Garud et al., (2018) developed LEAPS2 (call it LEAPS2v1) for recommending few accurate surrogates, for modeling any data set. It was trained on 264 data sets, generated from 66 test functions, obtained from a virtual library. It extracted 14 attributes and evaluated performances based on prediction error for 25 surrogates. It used regression tree ensembles to learn attributes-performance correlations for each surrogate. Then, it used its stored knowledge for recommending P^* number of surrogates for any given data set. P^* was determined by finding a trade-off between computational burden and success while recommending few surrogates.

LEAPS2v1 had some limitations. First, it was trained completely on non-noisy, synthetic data. Second, attributes such as mean, variance, difference between extreme responses, laid more emphasis in describing and summarizing the response, rather than disclosing the underlying trend and patterns in response which would guide surrogate selection. Third, the performance metric used for evaluating a surrogate's performance was a purely error-based metric. In other words, the complexity of a model was not considered during evaluation. Finally, LEAPS2v1 often recommended as many as $P^* = 5$ or 6 surrogates, which may burden the user and defeat the basic purpose of a recommendation framework.

3. LEAPS2 Version 2 (LEAPS2v2)

Let \mathbf{x} denote N -dimensional inputs x_n ($n = 1, 2, \dots, N$), and $y = f(\mathbf{x})$ denote the response, for any data set. From a pool of M surrogate models, an m^{th} surrogate ($\hat{f}_m(\mathbf{x}), m = 1, 2, \dots, M$) is trained on a set of K sample points $[(\mathbf{x}^{(k)}, y^{(k)}), k = 1, 2, \dots, K]$ to approximate $f(\mathbf{x})$. We revise and upgrade LEAPS2v1, and call our revised framework as LEAPS2v2. LEAPS2v2 has been modified in several ways. First, we consider noise in response and widen the pool of data sets. Second, we remove ineffective attributes and add powerful attributes. Third, we develop and use a novel performance metric that considers both model accuracy and complexity. Fourth, we include many more surrogates as compared to LEAPS2v1. Finally, we revise the recommendation strategy.

3.1. Data Sets

To gather many data sets, we generated synthetic data from different analytical functions having varied characteristic shapes (Multi-modal, Valley, Plate, Bowl and Ridges-shaped). Sobol sampling was used to generate four data sets for each of the following four sample sizes, $K = 50N, 100N, 150N, 200N$. We also added 20 simulation-based data sets pertaining to LNG flash calculations (Coimbatore Meenakshi Sundaram and Karimi, 2021). This gave us 1508 ($93 \times 4 \times 4 + 20$) non-noisy data sets. For noisy data sets, we added gaussian noise with 5% standard deviation, to each non-noisy data set. Moreover, we also included 80 data sets from an industrial compressor and 3 from a machine learning repository (Dua and Graff, 2019), to accumulate 1591 noisy data sets. LEAPS2v2 was trained on data sets with up to 20 input dimensions.

3.2. Attributes

LEAPS2v2 consists of powerful attributes that capture response nonlinearities efficiently. Redundant attributes of LEAPS2v1 that solely summarize the response (such as mean, standard deviations, fluctuations) were removed. LEAPS2v2 has the following attributes:

- Dimensionality (N) of input data.
- Average Absolute Error, Root Mean Squared Error, and Maximum Absolute Error in predictions by 1st order and 2nd order PRSM models, which are simplest models. These attributes indicate the extent of inherent complexity and nonlinearity in the response.

- Degree of Local Nonlinearity (λ): λ gives an idea of local nonlinearity in the neighbourhood of any sample point. To compute λ , we compute the slope angle estimates at sample point k along dimension n , by considering the nearest sample point to k $[NN1(k)]$ and its next nearest neighbour $[NN2(k)]$. Then, we compute degree of nonlinearity ($\lambda_n^{(k)}$) at sample point k along dimension n , as:

$$\lambda_n^{(k)} = \frac{1}{2\pi} \left| \tan^{-1} \left(\frac{y^{(k)} - y^{[NN1(k)]}}{x_n^{(k)} - x_n^{[NN1(k)]}} \right) - \tan^{-1} \left(\frac{y^{(k)} - y^{[NN2(k)]}}{x_n^{(k)} - x_n^{[NN2(k)]}} \right) \right| \quad (1)$$

We calculate the average and standard deviations in $\lambda_n^{(k)}$ over all sample points, in each dimension, to extract $2N$ attributes. We also compute overall local nonlinearity as average of averaged nonlinearities, over all dimensions, as an additional attribute.

- Regional and Inter-Regional Directional Slopes: The directional slope ($m^{(i,j)} = m^{(j,i)}$) between two sample points $\mathbf{x}^{(i)}$ and $\mathbf{x}^{(j)}$ can be estimated as follows:

$$m^{(i,j)} = m^{(j,i)} = \frac{2}{\pi} \tan^{-1} \left[\frac{|y^{(j)} - y^{(i)}|}{\|\mathbf{x}^{(j)} - \mathbf{x}^{(i)}\|} \right] \quad (2)$$

We create local regions in the input space using k -means clustering technique, where $k = \text{ceil}(K/10)$. For each local region having at least two sample points, regional directional slope is estimated as the average directional slope between all pairs of points within the region. Average and standard deviation of regional directional slopes over all regions constitute two attributes. Inter-regional directional slopes are estimated by computing directional slopes between nearest local regions. Each local region is characterized by its centroid. The response at centroid is approximated by the weighted response of all points within the region. Average and standard deviations in inter-regional directional slopes over the entire input space are two more attributes.

We arranged the aforementioned $(2N + 12)$ attributes in a specific order to ensure proper correlation of attributes with surrogates' performances for any N -dimensional data set. The attributes were ordered as: N , errors after fitting simplest PRSMs, average and standard deviation in regional directional slopes, average and standard deviation in inter-regional directional slopes, overall local nonlinearity, N average local nonlinearities, $(100 - N)$ zeros, N standard deviations in local nonlinearities, and $(100 - N)$ zeros.

3.3. Surrogate Models

LEAPS2v2 has 36 surrogate models, derived from well-known modeling techniques such as Polynomial Response Surface Model (PRSM), Kriging (K), RBF, SVR, ANN, MARS, and Gaussian Kernel Regression (GKR). Each technique provides various mathematical forms such as basis functions, activation functions, kernels, etc. to build a unique surrogate. LEAPS2v2 also consists of additive power law (APL) and multiplicative power law (MPL) models, formed by linear sum and product of power law terms $x_n^{\beta_n}$, $n = 1, \dots, N$, respectively.

3.4. Surrogate Performance Metric

In a quest to evaluate a surrogate's performance based on predictive accuracy as well as complexity, we developed a novel composite performance metric called Surrogate Quality Score (SQS). SQS balances accuracy via a surrogate's coefficient of determination or R^2 -value, and complexity via its degrees of freedom (dof) or the number of independent model parameters. We define and compute SQS_m for $\hat{f}_m(\mathbf{x})$ as:

$$SQS_m = (1 - R_m^2) \times \left\{ \frac{\ln(1 + dof_m)}{\ln(1 + K)} \right\}^{0.5} \quad (3)$$

where, $(1 - R_m^2)$ measures $\hat{f}_m(\mathbf{x})$'s accuracy, while $[\ln(1 + \text{dof}_m)/\ln(1 + K)]^{0.5}$ represents its complexity. Table 1 shows dof_m for the surrogates used in LEAPS2v2.

Table 1: Degrees of freedom for surrogate models used in LEAPS2v2

Surrogate	dof	Surrogate	dof
PRSM	$(O + N)!/(O! \times N!)$ *	GKR, APL	$2N + 1$
Kriging, RBF	K	MPL	$N + 1$
SVR, MARS	$\leq K^{**}$	ANN	$Nn_{HL1} + \dots + n_{HLh}n_0 + n_{HL1} + \dots + n_{HLh}$

* O : Polynomial order; ** dof_m cannot be pre-determined explicitly; *** n_{HLp} : number of nodes in p^{th} hidden layer, h : total number of hidden layers, n_o : number of nodes in output layer

For non-noisy data sets, R_m^2 was evaluated on K sample points of the trained data set, combined with K additional points. However, for noisy data sets, we evaluated R_m^2 on K sample points of training data set alone. This is because real-world data is often limited and does not readily allow additional data sampling. In order to reject surrogates that may fit noise, LEAPS2v2 uses a user-specified limit on maximum allowable R^2 (R_{max}^2) for a surrogate. $R_m^2 > R_{max}^2$ indicates $\hat{f}_m(\mathbf{x})$ overfits, and hence should not be recommended.

3.5. LEAPS2v2 Recommendation Strategy

In order to recommend appropriate surrogates, LEAPS2v2 first requires to learn surrogates' performances (here SQS) over various data sets. Then, for any given data set, it uses its stored knowledge to predict SQS_m for all surrogates, to make recommendations. We used 36 regression tree ensembles (RTEs) to learn the correlations between data attributes and R_m^2 for the 36 surrogates. Since the aim of LEAPS2v2 is to recommend surrogates based on SQS_m , it uses its predicted R_m^2 , and corresponding dof_m (Table 1) to yield predicted SQS_m (Eq.3). However, for surrogates such as MARS and SVR, dof_m cannot be pre-estimated. Hence, predicting SQS_m for such surrogates is not possible unless the respective dof_m is known explicitly. Therefore, we use 5 additional RTEs to learn attributes- dof_m correlations for the 5 SVR and MARS models. This allows LEAPS2v2 to use its predicted R_m^2 and predicted dof_m , to compute its predicted SQS_m , for SVR and MARS as well. Finally, LEAPS2v2 identifies and recommends three surrogates with least predicted SQS_m . For noisy data sets, LEAPS2v2 performs an additional check on its predicted R_m^2 , to reject overfitting surrogates with $R_m^2 > R_{max}^2$.

4. LEAPS2v2 Performance

4.1. Performance Evaluation on Trained and Untrained Data Sets

For any data set, LEAPS2v2's recommendation was flagged as a success, if at least one of its three recommended surrogates were the 1st, 2nd, or 3rd true best surrogates. We define a metric, Degree of Success (DoS) as percentage of data sets for which LEAPS2v2 made successful recommendations. On training LEAPS2v2 on 1130 (75% of 1508) randomly selected non-noisy data sets, it achieved a DoS of 94.7% on trained data sets, and 81.8% on untrained data sets. After training LEAPS2v2 on all 1508 data sets, it showed DoS of 94.2%. For noisy data sets, we used five $R_{max}^2 = \{0.98, 0.96, 0.94, 0.92, 0.90\}$. On training LEAPS2v2 on 1192 (75% of 1591) randomly selected noisy data sets, it achieved $DoS = \{96.6\%, 96.4\%, 96.4\%, 94.6\%, 93.0\%\}$ on trained data sets, and $DoS = \{92.2\%, 90.5\%, 85.0\%, 84.5\%, 84.0\%\}$ on the untrained data sets, for the five R_{max}^2 respectively. Finally, after re-training LEAPS2v2 on all 1591 noisy data sets, it achieved $DoS = \{97.0\%, 94.9\%, 93.8\%, 91.8\%, 89.8\%\}$ for the five R_{max}^2 respectively. DoS deteriorated as R_{max}^2 decreased, as for lower R_{max}^2 , LEAPS2v2 had to reject overfitting models and recommend

true best surrogates. Most data sets for which LEAPS2v2 was unable to make successful recommendations were simple, low dimensional, as such data sets have many surrogates with similar, superior performances. Thus, identifying and recommending one of the top three true best surrogates, while duly rejecting overfitting ones becomes challenging.

We also looked at an alternative way to gauge LEAPS2v2's learning and recommendation capability. We focused on observing, to what extent a surrogate's chance of being recommended correlated with its chance of being one of the 1st, 2nd, or 3rd true best surrogate. In other words, an intelligent framework should recommend true best surrogates more often, and seldom recommend poor ones. Thus, for each surrogate, we observed the number of data sets for which it was one of the top-3 true best surrogates, and number of data sets for which it was recommended. We used Pearson correlation coefficient (*PCC*) to measure the extent of correlation between these two frequencies. LEAPS2v2 showed *PCC* of 91.7% for non-noisy data sets, and *PCC* of {96.8%, 96.3%, 97.0%, 97.3%, 96.2%} for five R_{max}^2 constraints for noisy data sets. High correlations reiterate that LEAPS2v2 can learn and recommend appropriate surrogates efficiently.

4.2. LEAPS2v2 versus LEAPS2v1

A straightforward comparison between LEAPS2v1 and LEAPS2v2 is not fair as the latter has undergone substantial modifications with respect to quality and quantity of data sets, surrogates, attributes, performance metric, and recommendation strategies. However, ignoring these differences, solely looking at respective *DoS* of the two frameworks, LEAPS2v1 achieved a *DoS* of 93% recommending 4 / 25 surrogates, while LEAPS2v2 achieved a *DoS* of 94.2% on more data sets, while recommending 3 / 36 surrogates.

4.3. True Best Surrogates for Non-Noisy and Noisy Data Sets

Observing the true performance of surrogates over various noisy and non-noisy data sets revealed that the true best surrogates for noisy data were very different to those for non-noisy data. This is because in case of noisy data, certain surrogates are prone to overfitting. Fig. 1a depicts the percentage of non-noisy data sets, for which a surrogate is one of the top-3 true best surrogates, while Fig. 1b shows the same for the noisy SDSs. It is evident that ANNs with 2N nodes, K, RBF, and 2nd order PRSMs were preferred for many non-noisy data sets, owing to their combined factors of high accuracies and simplicities. On the other hand, K and RBF were never preferred for noisy data sets as they fit noise at the trained sample points. Rather, MARS, PRSMs, SVRs with polynomial and gaussian kernels, and ANNs were more favoured choices for noisy data sets.

Fig. 1a: Percent of non-noisy data sets for which a surrogate is one of top-3 true best surrogates

Fig. 1b: Percent of noisy data sets for which a surrogate is one of top-3 true best surrogates

Moreover, no single surrogate stood out as the dominant model for modeling all data sets.

4.4. Performance Evaluation on a Case Study

To further validate the performance of LEAPS2v2, we applied it for modeling volumetric flow across a three stage reciprocating compressor in an LNG (Liquefied Natural Gas) regasification terminal. The flow was modeled for each stage, using suction temperature, suction pressure, discharge pressure, and flow setting capacity as inputs. We considered R_{max}^2 of 0.96 and 0.94. For both R_{max}^2 , LEAPS2v2 recommended one of the top three true best surrogates for stage 1 and stage 3, while two of the top three true best surrogates for stage 2. In other words, LEAPS2v2 achieved 100% *DoS* for all three stages.

5. Conclusions

This work significantly upgrades the scope and utility of our learning-based recommendation paradigm (LEAPS2) through numerous modifications. We incorporate noise in response, update attributes, propose and use a novel composite performance metric that balances surrogate's accuracy and complexity, widen the pool of data sets and surrogates, and revise the recommendation logic. Evaluation of LEAPS2v2 revealed remarkable success in recommending true best surrogates for most noisy and non-noisy data sets. The choice of best surrogates for noisy and non-noisy data sets were very different. We also illustrated LEAPS2v2's successful performance on a case study, involving an industrial reciprocating compressor. LEAPS2v2 clearly proves itself as a smarter, more robust and much refined paradigm for surrogate selection than LEAPS2v1.

Abstract

Chemical processes are usually subject to varying operating conditions. Consequently, the evaluation of the flexibility of a process with respect to variations in inlet conditions is vital to identify bottlenecks in current process flowsheets or new flowsheet design proposals. The flexibility index is a well-established concept to perform flexibility analysis of chemical processes. In this paper, we propose a novel approach to incorporate knowledge regarding dependencies between input parameters when calculating the flexibility index. The aim is to achieve a more accurate indication of a process's flexibility when dependencies between input parameters are present.

Keywords: Flexibility Index, Correlation, Parameter Dependence, Chemical Process Design

1. Introduction

Flexibility analysis of chemical processes has been investigated by the research community since the early 1980s when the Flexibility Index (FI) was introduced by Swaney and Grossmann (1985). The FI indicates the maximum disturbance range within which input parameters may vary while at the same time achieving feasible operation. To be able to solve the FI problem computationally, an active set approach was developed by Grossmann and Floudas (1987) which later was extended to a global solution algorithm by Floudas et al. (2001). Since the active set approach may result in problem formulations which are hard to solve even with state-of-the-art algorithms, alternative strategies to solve the FI problem have been reported in the literature. Li et al. (2015) suggested a framework to calculate the FI by means of an alternating direction matrix embedded in a Simulated Annealing algorithm. Additionally, Kachacha et al. (2018) proposed to conduct Monte Carlo network simulations in the entire expected disturbance range while manipulating degrees of freedom. If sufficiently many operating points are tested, the shape of the feasible uncertainty space is identified. Furthermore, Zhao and Chen (2018) proposed to explicitly calculate the shape of the feasible uncertainty space via cylindrical algebraic decomposition and quantifier elimination. In addition to different strategies to solve the FI problem, Ochoa and Grossmann (2020) extended the traditional FI problem to account also for uncertain input parameters which cannot be measured and therefore recursive actions cannot be taken to respond to variations.

Despite numerous publications on flexibility analysis and on the FI in particular, very little attention has been paid to the influence of dependencies, e.g. correlations, between uncertain input parameters on the flexibility of chemical processes. The reason for this shortcoming is that it is commonly assumed that the correlation between two (or more) input parameters can be expressed via a single algebraic equation, obtained via e.g. linear regression (compare Grossmann and Floudas (1987); Grossmann et al. (2014)). However, single equation (regression) models are only exact if the strongest possible agreement exists between the correlated input parameters (i.e. if the Pearson correlation coefficient is ± 1). Commonly, correlated input parameters in chemical processes agree only to some extent (correlation coefficient $< |\pm 1|$) which means that single equation (regression) models are only able to capture the trend between these input parameters while operating points which deviate from this trend are neglected (i.e. operating points which are caused by “other” sources of variation). However, these outlying operating points (which cannot be captured via single equation regression models) can be vital for actual plant operation. In this paper, we therefore propose a strategy to account for correlations between input parameters when calculating the FI by means of the active set approach (compare Grossmann and Floudas (1987)) which goes beyond single equation regression models.

2. Flexibility Index

As mentioned in the introduction, the FI indicates the maximum disturbance range in which inlet conditions may vary while at the same time achieving feasible operation. The feasible region of a chemical process can be described by the following set of constraints:

$$\begin{aligned} h_i(d, x, z, \theta) &= 0, i \in I \\ g_j(d, x, z, \theta) &\leq 0, j \in J \end{aligned}$$

where d is the vector of design variables, x corresponds to the state variables, z is used for the control variables or degrees of freedom and the varying inlet conditions or uncertain parameters are depicted by θ . In this context, feasibility is achieved when all constraints $i \in I$ and $j \in J$ are satisfied at the point of operation. In the case of independent input parameters, variations in these parameters can be interpreted as a hyperrectangle in the space of the input parameters. The FI is then defined as the ratio between the largest scaled hyperrectangle within the feasible region and the hyperrectangle corresponding to the expected variations. Therefore, feasibility over the expected uncertainty space is guaranteed if the FI is larger than or equal to 1. A visualization of the FI for an example is discussed in Section 3 and is shown in Figure 2.

2.1. Flexibility Index for dependent input parameters

The largest scaled hyperrectangle within the feasible region can be described by the following set of equations:

$$T(\delta) = \{\theta_{i,N} - \delta\Delta\theta_i^- \leq \theta_i \leq \theta_{i,N} + \delta\Delta\theta_i^+\} \forall \theta_i \in \theta \quad (1)$$

For the case where only some input parameters vary independently while other input parameters show dependencies such as correlating trends to the independent input parameters, the total set of input parameters θ must be divided into independent input parameters θ_{ind} and dependent input parameters θ_{dep} . To express the shape in which the input parameters vary (compare hyperrectangle in independent case), it is necessary to formulate mathematical models for the dependent input parameters, i.e. perform the transformation $\theta \rightarrow \theta_{ind}$. In the following, it is assumed that the dependent input parameters can be expressed by a set of functions M of the independent input parameters. Consequently, the space in which the input parameters vary can be described as follows:

$$T(\delta) = \{ \{ \theta_{i,N} - \delta \Delta \theta_i^- \leq \theta_i \leq \theta_{i,N} + \delta \Delta \theta_i^+ \} \forall \theta_i \in \theta_{ind} \{ f_m(\theta_{ind}) \forall m \in M \} \forall \theta_j \in \theta_{dep} \} \quad (2)$$

In general, different mathematical models are available to express the dependency between dependent and independent parameters. In the following section, it is illustrated how the choice of the mathematical model can influence the FI by comparing the results obtained with a single equation and a dual equation model.

3. Example

Let us consider three different cases for a process with two input parameters, θ_1 and θ_2 , operating at the nominal point $(\theta_{1,N}, \theta_{2,N}) = (10, 35)$. In the first case, θ_1 and θ_2 vary completely independently in the range $(\pm 5, \pm 20)$, while in the second and the third case, a significant correlation (positive and negative) between θ_1 and θ_2 is assumed. Figure 1 shows the distributions of θ_1 and θ_2 for each case. It should be noted that for the correlation cases, the variation range is similar to the independent case: $(\Delta\theta_{1,max}, \Delta\theta_{2,max}) = (\pm 5, \pm 20)$. Furthermore, assuming different cases with different distributions is highly theoretical since in reality a dependency between input parameters either occurs or does not occur.

Let us further consider that θ_1 and θ_2 are the input to a process whose feasible region can be described by a set of given constraints (compare Eq. 3a to 3f) where x_1 denotes an additional state variable. For the independent case, the FI can be calculated directly and is equal to 0.36. The graphical interpretation of the FI for the independent case is shown in Figure 2. Since all six constraints are linear, the feasible region is convex and the FI is determined by one (or several) corner points of the largest scaled rectangle inscribed in the feasible region (i.e. one or several corner points of the scaled rectangle intercept with the boundaries of the feasible region). The proportions (length-to-width ratio) of this scaled rectangle are given by the rectangle describing the expected variations. As mentioned in Section 2, the FI can be interpreted as the ratio of the size of the largest scaled rectangle compared to the size of the rectangle describing the expected variations.

As explained in Section 2.1, correlations between input parameters can be expressed using mathematical models. Two approaches have been investigated and are presented in the following two subsections.

Figure SEQ Figure * ARABIC 1: Distribution of operating points for three different cases (top) independent variation (middle) positive correlated variation (bottom)

$$\begin{aligned} \theta_1 - 2x_1 &= 0 & (3a) \\ 2x_1 - \left(40 - \frac{2}{3} * \theta_2\right) &\leq 0 & (3b) \\ 10 - 0.25\theta_2 - \theta_1 &\leq 0 & (3c) \\ \theta_1 - (0.5\theta_2 + 5) &\leq 0 & (3d) \\ 2.5 + 0.05\theta_2 - 2x_1 &\leq 0 & (3e) \\ \theta_1 - (17.5 - 0.05\theta_2) &\leq 0 & (3f) \end{aligned}$$

3.1. Linear regression model

In the first approach, the positive and negative correlations were expressed using single equation models obtained by linear regression. The linear equation models are shown in Figure 3 together with the feasible region of the problem. Compared to the independent case, the shape which describes the range of the variations (feasible and expected) is no longer a hyperrectangle but a line. The calculated values of the FI are 0.385 (positive correlation) and 0.71 (negative correlation). When using a linear function as model function, the FI is determined by the smallest possible variation for θ_2 at which the model function $f_m(\theta_2)$ intercepts with the boundary of the feasible region. The corresponding points are marked with a star in Figure 3.

From Figure 3 it can be inferred that the used linear models are able to capture the trend between θ_1 and θ_2 while neglecting operating points which deviate from this trend. However, as mentioned in Section 1, these operating points can be vital for actual process operation. To be able to include these operating points, a second approach was studied.

Figure SEQ Figure * ARABIC 2: Visualization of the flexibility index assuming input parameters and to be independent

Figure 3: Visualization of the flexibility index when using a linear equation to model (left) positive correlated variations and (right) negative correlated variations.

3.2. Correlation Corridors

Instead of modelling the correlation between the two input parameters θ_1 and θ_2 via a single linear function obtained by regression, an upper boundary function $f_u(\theta_2)$ and a lower boundary function $f_l(\theta_2)$ were defined for each case, yielding a correlation corridor. Practically, this means that θ_1 can take any value between $f_u(\theta_2)$ and $f_l(\theta_2)$ which infers additional uncertainty compared to a single equation model. Different approaches can be followed when defining $f_u(\theta_2)$ and $f_l(\theta_2)$ and a straightforward way is to parallel shift the linear function obtained by regression. This parallel shifting is demonstrated in Figure 4 for the illustrative example and was performed so that 95% of the operating points are in the region between $f_u(\theta_2)$ and $f_l(\theta_2)$. The corresponding values of the FI are 0.27 (positive

correlation) and 0.496 (negative correlation). When using a correlation corridor to model the dependencies between θ_1 and θ_2 , the FI is determined by the smallest possible variation of θ_2 at which either $f_u(\theta_2)$ or $f_l(\theta_2)$ intercepts with the boundary of the feasible region. The corresponding points are marked with a star in Figure 4.

Figure 4: Visualization of the flexibility index when using a correlation corridor to model (left) positive correlated variations and (right) negative correlated variations.

4. Results and Discussion

The results obtained for the FI are summarized in Table 1. It can be seen that the FI obtained with correlation corridors is smaller compared to the FI obtained when using a single equation to model the correlation. This is because the correlation corridor approach leads to a geometric shape describing the range of variations (feasible and expected) that is larger compared to the single equation approach (for the illustrative example: parallelogram vs. line). Figure 3 and Figure 4 show that the geometric shape of expected variations of correlated input parameters (measured operating points) can be emulated more exactly using correlation corridors compared to single equation models. Consequently, it can be implied that the results obtained using correlation corridors give a more accurate indication of a process's flexibility.

Table 1: Flexibility index for different approaches to model correlations between the two input parameters of the illustrative example.

Flexibility index [-]	Linear function	Correlation corridor
Positive correlation	0.385	0.27
Negative correlation	0.71	0.496

Furthermore, the obtained FI can differ substantially depending on the sign of the correlation coefficient. For the presented example, higher values for the FI were achieved when assuming a negative correlation between θ_1 and θ_2 . It should be noted that this observation is highly dependent on the nature of the feasible region. For illustrative purposes, the feasible region was modified by changing the intercept of Eq. 3b from 40 to 50 and the intercept of Eq. 3d from 5 to -2.1. The modified feasible region and the corresponding FI for independent variations of θ_1 and θ_2 are shown in Figure 5. The feasible region was altered in such a way that the FI for the independent case remains 0.36. However, when comparing Figure 5 and Figure 2, it is obvious that in the modified case, a positive correlation would lead to higher FI values. Consequently, no general conclusion can be drawn regarding the influence of the sign of the correlation coefficient on the FI. Generally, it should be noted that in reality a dependency between input parameters of a process either occurs or does not occur. Consequently, assuming different cases and comparing obtained values for the FI is highly theoretical since only one

solution for the FI represents reality (which must include the existence or non-existence of dependencies between input parameters).

In contrast to the presented illustrative example, the dimensionality of the uncertainty space (i.e. number of varying input parameters) of processes in industrial applications is often (much) higher than two. In such situations, it is probable that the dimensionality of dependencies also increases which leads to difficulties when identifying the correlation corridors graphically. A solution approach could be to identify correlation corridors using two-dimensional projections of the multi-dimensional correlation(s). However, this approach may become cumbersome and, thus, further work is necessary to develop automatization strategies for analyzing multi-dimensional dependencies. Furthermore, future work should address the possibility of non-linear dependencies between uncertain parameters and investigate possible impacts on the presented methodology to perform flexibility analysis.

Figure SEQ Figure * ARABIC 5: Visualization of a modified feasible region and the corresponding flexibility (independent case).

However, this approach may become cumbersome and, thus, further work is necessary to develop automatization strategies for analyzing multi-dimensional dependencies. Furthermore, future work should address the possibility of non-linear dependencies between uncertain parameters and investigate possible impacts on the presented methodology to perform flexibility analysis.

5. Conclusion

In this paper, we presented an example to illustrate that if a dependency between (some of) the input parameters is ignored, the obtained FI can be severely wrong, leading to an over- or underestimation of the process's flexibility. In the case of correlations between input parameters, it is necessary to formulate mathematical models in order to include the parameter dependencies in the FI problem formulation. Two approaches were studied, and it was demonstrated that increased accuracy can be achieved by using correlation corridors instead of single equation models if the correlation coefficient is $< |\pm 1|$.

Abstract

Nitrogen porosimetry is a characterization technique used to obtain qualitative and quantitative information about the textural properties of porous materials. The physical phenomena exploited in the technique is related to thermodynamic equilibrium and conditioned by pore blocking. The latter phenomenon becomes relevant in highly disordered solids with a wide pore size distribution and a multilevel organization. The aforementioned technique encloses topological information associated with the trend of sorption isotherm. In this work, it is shown how a pore network model can be used to simulate nitrogen sorption process by using an efficient algorithm that combines equilibrium conditions and invasion percolation considerations. Such simulation tool will be the basis for a more comprehensive treatment of experimental characteristic curves and characterization of porous material properties.

Keywords: Digital characterization, Porosimetry, Pore Network Model, Catalyst support, Percolation algorithm, Simulation.

1. Methodology for the Simulation of the Characterization Techniques

The objective of the model is to simulate the evolution of the measured variables during the nitrogen porosimetry characterization experiment. Such an experiment measures, at various nitrogen pressures, the quantity of nitrogen that is present within the porous medium, either adsorbed on the pore walls or filling the pore volume as a liquid phase. An adsorption branch is obtained by increasing the pressure from zero to saturation pressure, and a desorption branch by decreasing the pressure from saturation pressure to zero. If during adsorption, pressure is decreased before reaching saturation pressure, a so-called scanning curve is obtained.

Since the system is equilibrated at every pressure step, a thermodynamic equilibrium model (see 1.1) has to be used to relate the pore size to the volume measured during the sorption process. After generating a geometrical model of the porous medium, it is scanned using an algorithm that determines the desorption sequence of the nitrogen contained in the network pores (see 1.2). The nitrogen sorption simulations can now be performed, both for adsorption and desorption, solving the thermodynamic model equations (see *Algorithm 1*).

Algorithm 1. Pseudo-code for the sorption algorithm

The main characteristics of the pore network generation algorithm used in this work were described by Ferreira (Ferreira et al., 2017; Ferreira, 2018). The hypotheses for the sorption simulations are:

- All pores are cylindrical and rigid.
- The adsorption mechanism starts with the adsorption of the nitrogen on the walls followed by sudden condensation.
- The phase change pressure is governed by capillary forces and pore blocking phenomena.
- The meniscus shape is cylindrical for adsorption and hemispherical for desorption.
- The condensed nitrogen needs to be in contact with the vapor phase to evaporate.
- The pore-blocking phenomenon is only dependent on the topology of the system.
- The pore size distribution is within the mesopore range and over 5 nm.
- The system is in equilibrium.
- No other cooperative effects are considered.

1.1. Thermodynamic Model

To model the vapor-liquid equilibrium in a confined medium, the Kelvin-Cohan equation is used, (Equation 1) (Zhang et al., 2006).

$$\frac{p}{p_0} = \exp\left(\frac{-\sigma_{lg} \cdot V_{lm}}{RT} \cdot \left(\frac{1}{r_1(t)} + \frac{1}{r_2(t)}\right)\right)$$

Equation 1. Kelvin-Cohan equation as a function of the two curvature radii of the liquid-gas interface.

In order to calculate the thickness of adsorbed nitrogen, t , we have chosen the Harkins-Jura statistical thickness equation, (Equation 2) (Šolcová et al., 2006).

$$t[\text{Å}] = \left(\frac{13.99}{0.034 - \log_{10}\left(\frac{p}{p_0}\right)}\right)^{\frac{1}{2}}$$

Equation 2. Harkins-Jura statistical thickness equation.

1.2. Pore Blocking Phenomena: Triggering diameter assignment.

Nitrogen adsorption is not supposed to be constrained by the topology of the structure, but nitrogen desorption can be delayed creating a metastable state. Even if the desorption pressure in a given pore is reached, the liquid phase needs to be in contact with the gaseous phase to be able to vaporize. This condition can generate a pore-blocking phenomenon. Indeed, during the desorption step, nitrogen condensed in small

pores can constrain the nitrogen in bigger pores to evaporate at a lower pressure than the one dictated by its vapor-liquid equilibrium condition. Algorithmically, the pore-blocking phenomenon is approached from the external boundary of the pore network as a simultaneous advancing or receding problem. We will define as external pores to those located at this external boundary harboring the liquid-vapor interphase. The pore-blocking is modeled as a sequence of events, each of which corresponds to a given pore. Once the equilibrium constraints are set with Equation 1, the sequence of the events will depend on the pore size and its position within the network. A pore's triggering diameter represents the pressure at which the change of state (vaporization) will happen within the pore. Since the value of the pore's triggering diameter is not necessarily equal to the actual pore diameter, two diameters have to be assigned to each pore: its actual diameter and a triggering diameter for desorption. The actual diameter is used to calculate the quantity of nitrogen subject to the change of state that occurs at the pressure corresponding to the triggering diameter during the desorption process.

To assign a triggering diameter for desorption to each pore, a dedicated assignation algorithm was developed. There are six main rules on which our algorithm is based:

- The triggering diameter (for desorption) is assigned only once to every pore. There is no overwriting of the triggering diameter.
- A pore can be added to the search list only once.
- A node can be visited only once.
- The pore picked up from the search list must always be the pore with the biggest diameter on the list (priority rule).
- The triggering diameters of the external pores correspond to their actual pore diameters.
- The input of the search list must contain all the external pores (boundary conditions).

For the triggering diameter assignation algorithm, we employ four different lists: *visited nodes*, *visited pores*, *searchlist* and *connectivity matrix*. The first two are indexed lists. The third one is a dynamic list handled through binary heaps. The last one is a matrix that contains the information of the pore network.

First, the external pores and the external nodes of the network are identified and listed in *searchlist* and *visited nodes* respectively. *Searchlist* contains the list of pores to be analyzed. The binary heap (max heap) used to handle *searchlist* allows to rapidly find the pore with the biggest diameter, faster than using any kind of sorting algorithm (Masson and Pride, 2014). The pore with the biggest diameter is the first to be taken for analysis and will be called "guide pore". There are two nodes connected to the guide pore: one of them has already been identified and saved in *visited nodes*, so the "new" one (not visited yet) can easily be recognized. The connectivity of the unvisited node is explored to identify the pores connected to the guide pore using the *connectivity matrix*. The newly identified pores will be added to *searchlist*, but first, two actions are needed: a test and the triggering diameter assignation. First, it is verified that the newly identified pores have not been analyzed before by comparing their index to the *visited pores* list. For those that have not been analyzed before, their triggering diameter is obtained using the two following assignation rules:

- If the diameter of the pore is smaller than the triggering diameter of the guide pore, the pore conserves its original diameter as triggering diameter.
- If the diameter of the pore is bigger than the triggering diameter of the guide pore, the pore adopts the guide pore's triggering diameter as its own triggering diameter.

Once the triggering diameter is assigned, the pore is added to *searchlist* and to *visited_pores*. On the other hand, the node is saved in the *visited_nodes* list. Finally, the guide pore is removed from *searchlist*. The loop starts again with a new guide pore selected from *searchlist*. The process is repeated until *searchlist* has been emptied, which means that all the non-isolated pores (pores with a pathway to the surface) have been assigned a triggering diameter. The binary heap created in *searchlist* uses a function for creating the heap, one for *adding* new elements to the heap and one for *eliminating* the guide pore from the heap once it has been treated.

2. Simulation of Nitrogen Porosimetry Curves

The simulation starts from a relative pressure equal to zero. As the adsorption process evolves in two steps, it is necessary to establish a condensation criterion for the cumulated volume of condensed nitrogen. If the diameter of the pore (D_p) is higher than the Kelvin-Cohan equilibrium diameter (D_{eq_n-2t}) for a given relative pressure, then the adsorbed volume in the pore will be equal to:

$$V_{@p_i} = \pi \cdot (D_p - t) \cdot t \cdot l$$

Equation 3. Total adsorbed volume as a function of the adsorbed layer thickness.

Otherwise, it is considered that core volume has already been filled with liquid nitrogen and the condensed volume in the pore is simply equal to:

$$V_{@p_i} = \frac{\pi}{4} \cdot D_p^2 \cdot l$$

Equation 4. Total liquid volume within the pore

For the desorption, as the pore blocking phenomenon exist, the procedure is the same but using the triggering diameter (D_T) of the pore instead of its actual diameter (D_p) for the comparison against the Kelvin-Cohan equilibrium diameter (D_{eq_n-2t}) for the given pressure step.

2.1. Scanning Curves

It is also possible to generate scanning curves accounting for the pore blocking phenomenon by adapting the full Nitrogen Adsorption algorithm. An easy way to do this is by changing the input provided to the invasion percolation algorithm. The initial pressure of the desorption scanning branch is fixed and the corresponding critical pore diameter is calculated. For the pores with a diameter over the calculated critical diameter, they are temporarily assigned a very large diameter.

3. Case Study

3.1. Network Parameters

Networks with zero volume spherical nodes are considered for the case study. A 3D regular cubic lattice of 50x50x50 nodes was employed along with a Pore Existence Probability (PEP) equal to 0.75. The length of the pores is considered constant and equal to 21 nm. A pore size distribution generated by a Gaussian distribution centered at 10 nm and a standard deviation of 2 nm was employed. The consistency between the input and output cumulative distribution functions for the networks with zero volume spherical nodes was verified. An average connectivity equal to 4.2 and a void fraction of 0.38 were obtained.

3.2. Characteristic Curves

The simulated sorption isotherm is shown in Figure 1a. It corresponds qualitatively to typically observed experimental curves for mesoporous alumina. The isotherm

qualitatively corresponds to a type V isotherm (according to IUPAC classification) with a hysteresis loop closing at about 0.42 (Rouquerol et al., 2014). The hysteresis loop is a consequence of the pore blocking phenomenon and the meniscus curvature difference considered between condensation and vaporization in the Kelvin-Cohan equation. The starting and closing volume naturally coincide for both branches.

Figure 1b shows the back-calculated pore size distribution by applying the BJH method (Barrett et al., 1951) to the simulated isotherm. A good agreement was found between the pore size distribution generated from the adsorption branch and the original distribution used for the pore network generation.

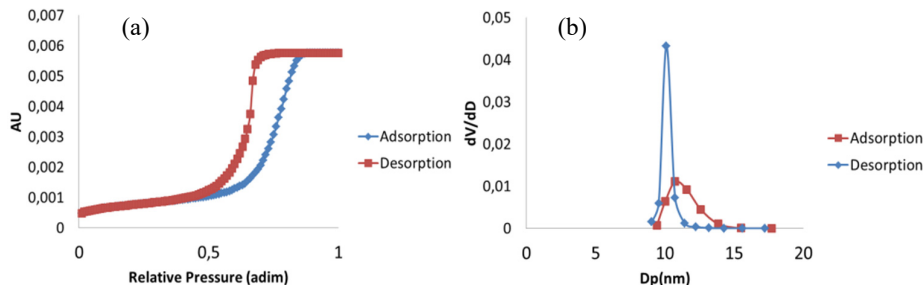

Figure 1: (a) Numerical Nitrogen Isotherm (b) Calculated BJH Pore Size Distribution (Adsorption and desorption branches)

Figure 2: Digital Scanning Curves

Finally, Figure 2 provides an example of the adsorption-desorption scanning curves obtained for this sample. The hysteresis loop is of the H2 type with the scanning curves converging to the closure point of the hysteresis loop.

3.3. Algorithm's Execution Time

In order to test how the execution time of the simulations scales with the size of the network, six cubic lattice networks of different sizes were generated. The pore existence probability (PEP) was set to 1. All the other input parameters have been maintained as described in section 3.1. The results are shown in Figure 3. The execution time is plotted as a function of the total number of pores connected to the surface. As the size of the network increases, the time required for the execution increases as well. The algorithm execution time proceeds with an $O(M\log(N))$ time.

Figure 3: Effect of the number of pores on execution time of the nitrogen porosimetry algorithm.

4. Conclusions

A fast algorithm for the simulation of nitrogen porosimetry within a digital pore network was developed. The thermodynamic equilibrium conditions within the porous solid during nitrogen porosimetry and the associated pore blocking phenomena were considered. The algorithm was sped up by using a Max-Heap. A time execution test for the nitrogen porosimetry algorithm and an octahedral lattice of about 2 million pores only required 6.7 seconds for a single simulation using the binary heap in comparison to 19 hours using conventional sorting algorithms. This shows the advantage of using the binary heap for handling the search list as suggested by Masson (Masson and Pride, 2014). The size of the network is the main parameter that affects the execution time and exhibits an $O(M\log(N))$ behavior.

Valuable information about the topology of the pore network is implicit in the desorption branch of the isotherm and can be exploited by using this type of simulation. Adding an optimizer to this algorithm in order to adjust the digital characteristic curves to those of an actual porous alumina sample will allow obtaining a digital structure that not only exhibits the same macroscopic properties but that could also represent statistically the topology of the material. This algorithm has also been adapted to other porosimetry characterization techniques, such as mercury porosimetry, cryo-porometry, and thermo-porometry.

Abstract

This paper presents an algorithm to optimize process flowsheets using Gaussian processes regression and trust regions. We exploit the modular structure of the flowsheet by training separate Gaussian processes (GPs) for each module based on data generated by a process simulator. These GPs are embedded into an optimization model, whose outcome is used to adapt the position and size of the trust region at each iteration. A complication that arises because of the multiple trust regions is that the optimization problem may become infeasible, in which case a feasibility (restoration) problem is invoked. An inherent advantage of this approach is that it removes the need for simulating the complete flowsheet at any point. We demonstrate these ideas on the case-study of an extractive distillation system in order to minimize its total annualized cost (TAC). The performance shows a robust strategy to address flowsheet optimization problems without recycles.

Keywords: Flowsheet optimization, Gaussian processes, trust regions, machine learning

1. Introduction

Process flowsheet optimization carried out using gradient-based methods requires that the gradient information for all the process models is available (i.e., equation oriented modeling). However, the convergence of the equation-oriented method is limited when comparing it to the sequential modular approach. This extra benefit in the convergence comes at the expense of the flowsheet's gradient information, preventing gradient-based optimizers to be applied. In these cases, derivative-free techniques are often paired to the simulation models for optimization. But a flowsheet simulation itself may be computationally demanding, which calls for robust and sampling-efficient methods to

drive the optimization. Existing approaches can be broadly classified into two categories. *Global approaches* proceed by constructing a surrogate model based on a flowsheet simulation before optimizing it, often within an iteration where the surrogate is progressively refined. A number of successful implementations rely on Gaussian processes (Caballero and Grossmann, 2008; Keßler et al., 2019) or artificial neural networks (Schweidtmann et al., 2019). By contrast, *local approaches* maintain an accurate representation of the flowsheet (or separate modules thereof) within a trust region, whose position and size are adapted iteratively. This procedure entails reconstructing the surrogate model as the trust region moves towards the local optimum. Applications of this approach to flowsheet optimization include the work by Eason and Biegler (2018) and Bajaj et al. (2018).

This paper leverages ideas from the real-time optimization field to optimize modular process flowsheets, by training separate Gaussian processes for each module with data generated by the process simulation in a trust region. Background material is reviewed next, before describing the new approach and illustrating it on an extractive distillation system.

2. Background

Gaussian process (GP) regression: Initially developed as an interpolation technique, GP regression can be used to describe an unknown function f using noisy observations. GPs consider a distribution over functions and can be seen as a generalization of multivariate Gaussian distributions, $f(\cdot) \sim GP(m(\bullet), k(\cdot, \cdot))$. The mean function $m(\bullet)$ can express prior knowledge about f . The covariance function $k(\cdot, \cdot)$ accounts for correlations between the function values at different points and has a great impact on the GP's prediction accuracy. The so-called hyperparameters in the covariance functions need to be estimated in order to represent the observations as accurately as possible, e.g., by maximizing a log likelihood function. The predicted distribution of $f(x)$ at an arbitrary input point x , given the input-output data (X, y) , follows a Gaussian distribution, $f(x)|X, y \sim N(\mu_f(x), \sigma_f^2(x))$.

GPs and trust regions in flowsheet optimization: The approach developed by Palmer and Realff (2002) builds GPs around the whole flowsheet, which requires converged flowsheet simulation runs over a large input domain in order to be successful. Caballero and Grossmann (2008) proposed to construct GPs around individual process modules instead, thereby removing the need to simulate the entire flowsheet. But difficulties with this approach arise due to the presence of additional equality constraints (connecting streams) in the optimization problem. del Rio-Chanona et al. (2019, 2020) recently brought trust region concepts into a modifier-adaptation scheme for real-time optimization. The main idea is to use GPs to correct the cost and constraint functions of the optimization problem locally in the trust region. The present work builds upon these ideas to enable separate Gaussian processes in multiple trust regions corresponding to the flowsheet modules.

3. Multiple trust regions and Gaussian processes for optimization

The modular flowsheet optimization problem can be stated as:

$$\sum_{i=1}^m g_{i,0}(x_i, y_i) \tag{1}$$

$$s.t. \quad g_{i,j}(x_i, y_i) \leq 0, \quad j = 1 \dots n_{g_i}, \quad i = 1 \dots m \tag{2}$$

$$c_j(x_1, y_1, \dots, x_m, y_m) = 0, \quad j = 1 \dots n_c \tag{3}$$

$$y_i = \varphi_i(x_i, \theta_i), \quad (x_1 \dots x_m) \in X, \quad (y_1 \dots y_m) \in Y, \quad i = 1 \dots m \tag{4}$$

Each module $i = 1 \dots m$ (m denoting the last connected module) has inputs x_i , process parameters θ_i , outputs y_i , cost contribution $g_{i,0}$, and design/operating constraints $g_{i,j}$. The equality constraints c_j describe the connections between modules. Notice that these connecting constraints are nonlinear in general—think for instance about the input stream to a module being obtained by mixing the output streams from two modules. And the φ_i is the input-output mapping for module i .

The proposed approach entails the use of GP regression to predict the performance of each module separately, $\varphi_i(x_i, \theta_i) \sim N(\mu_{\varphi_i}(x_i, \theta_i), \sigma_{\varphi_i}^2(x_i, \theta_i))$. The trust-region subproblems that are solved at a given iteration k in order to determine the next inputs $x_i^k + d_i^{k+1}$ are given by

$$\sum_{i=1}^m g_{i,0}(x_i^k + d_i^k, \hat{y}_i^k) \tag{5}$$

$$s.t. \quad g_{i,j}(x_i^k + d_i^k, \hat{y}_i^k) \leq 0, \quad j = 1 \dots n_{g_i}, \quad i = 1 \dots m \tag{6}$$

$$c_j(x_1^k + d_1^k, \hat{y}_1^k, \dots, x_m^k + d_m^k, \hat{y}_m^k) = 0, \quad j = 1 \dots n_c \tag{7}$$

$$\hat{y}_i = \mu_{\varphi_i}(x_i^k + d_i^k, \theta_i), \quad (\hat{y}_1 \dots \hat{y}_m) \in Y, \quad i = 1 \dots m \tag{8}$$

$$\|d_i\| \leq \Delta_i^k, \quad (x_1^k + d_1^k, \dots, x_m^k + d_m^k) \in X \tag{9}$$

where $\Delta_i^k \geq 0$ denotes the radius of the input trust region for module i . At iteration k , the GPs for module i are trained with the input-output dataset (X_i^k, Y_i^k) . This dataset is generated using a Sobol sequence sampling within the space delimited by the double of each trust region radius (i.e. $2\Delta_i^k$). Sampling beyond the trust region radius allows for the complete trust region space to be well-approximated (i.e., without large mismatch errors near the trust region boundary).

The decisions about moving the trust region center (current operating point x^k) or changing its radius are based upon:

(i) the ratio of actual cost reduction to predicted cost reduction:

$$\rho^{k+1} := \frac{\sum_{i=1}^m g_{i,0}(x_i^k, \varphi_i(x_i^k, \theta_i)) - g_{i,0}(x_i^k + d_i^{k+1}, \varphi_i(x_i^k + d_i^{k+1}, \theta_i))}{\sum_{i=1}^m g_{i,0}(x_i^k, \mu_{\varphi_i}(x_i^k, \theta_i)) - g_{i,0}(x_i^k + d_i^{k+1}, \mu_{\varphi_i}(x_i^k + d_i^{k+1}, \theta_i))} \tag{10}$$

(ii) the violation of any inequality constraint $j = 1 \dots n_{g_i}$:

$$g_{i,j}(x_i^k + d_i^{k+1}, \varphi_i(x_i^k + d_i^{k+1}, \theta_i)) > 0 \quad (11)$$

A complete statement of the scheme is provided in Algorithm 1. Whenever the optimization model (5)-(9) turns out to be infeasible, the following restoration phase is invoked, that minimizes the violation of the design/operating constraints:

$$\sum_{i=1}^m \sum_{j=1}^{n_{g_i}} g_{i,j}(x_i^k + d_i, \hat{y}_i) \quad (12)$$

$$\text{s. t. } c_j(x_i^k + d_i, \hat{y}_i) = 0, \quad i = 1 \dots m, \quad j = 1 \dots n_c \quad (13)$$

$$\hat{y}_i = \mu_{\varphi_i}(x_i^k + d_i, \theta_i), \quad (\hat{y}_1 \dots \hat{y}_m) \in Y, \quad i = 1 \dots m \quad (14)$$

$$\|d_i\| \leq \Delta_i^k, \quad (x_1^k + d_1, \dots, x_m^k + d_m) \in X \quad (15)$$

Whenever the solution of the optimization subproblem (5)-(9) is feasible, the trust regions are updated according to the value of the search performance factor shown in Eq. 10. The step is accepted whenever this accuracy ratio is large enough. The radii for each trust region are expanded whenever the largest feasible step is taken (i.e., $\|d_i\| = \Delta_i^k$) and a good enough prediction is achieved. If, on the other hand, the accuracy ratio is too small, only the radius of the last connected module (i.e., $i = m$) is reduced. This prevents a possible mismatch among trust regions while still allowing for radius shrinkage as the algorithm converges. For this reason, it is worth mentioning that the proposed algorithm is limited to acyclic process flowsheets only. If a recycle would be present the identification of the last connected module (see line 12 in Algorithm 1) would be problematic. In this case, the optimization subproblem (5)-(9) might become infeasible due to a violation of a connectivity constraint (Eq. 7). For this same reason, the violations considered within the restoration problem (12)-(15) are only coming from the design/operation inequality constraints (Eq. 6) (see line 4 in Algorithm 1).

Algorithm 1: Multiple trust regions and Gaussian process regression for optimization

Input: Input-output mappings φ_i ; process parameters θ_i ; initial trust region centers

x_i^0 ; initial and maximal trust region radii $0 < \Delta_i^k < \bar{\Delta}_i$; trust region parameters $0 < \eta_1 \leq \eta_2 \leq \eta_3 < 1$; shrinkage and expansion parameters $0 < \xi_1 < 1 < \xi_2$; bounds X and Y

Repeat for $k = 0, 1, \dots$

- 1 Retrieve input-output dataset (X_i^k, Y_i^k) using Sobol sequence sampling;
- 2 Train GP for each module i ;
- 3 Solve trust region optimization subproblem (Eqs. 5-9);
- 4 **if** Infeasible due to Eq. 11 **then**
- 5 Solve feasibility (restoration) subproblem (Eqs. 12-15);

```

6    $\Delta_i^{k+1} := \Delta_i^k$ 
7    $x_i^{k+1} := x_i^k + d_i^k$ 
8   else
9     Retrieve output values  $y_i$  for  $\varphi_i(x_i^k + d_i^{k+1}, \theta_i)$ ;
10    Compute  $\rho^{k+1}$  according to Eq. 10;
11    Update trust regions radii:
12      if  $\rho^{k+1} < \eta_2$  and  $i = m$  then  $\Delta_i^{k+1} := \Delta_i^k \xi_1$  ;
13      else if  $\rho^{k+1} < \eta_3$  and  $\|d_i^k\| = \Delta_i^k$  then  $\Delta_i^{k+1} := \min\{\bar{\Delta}_i, \Delta_i^k \xi_2\}$ ;
14      else  $\Delta_i^{k+1} := \Delta_i^k$ ;
15    Update operating point:
16      if  $\rho^{k+1} < \eta_1$  then  $x_i^{k+1} := x_i^k$ 
17      else  $x_i^{k+1} := x_i^k + d_i^{k+1}$ 

```

4. Computational case-study

4.1. Extractive distillation system

The proposed methodology is applied to the minimization of the total annualized cost (TAC) of an extractive distillation system. An isomolar mixture of n-heptane and toluene is separated using phenol as the extractive medium. The input-output mappings are two separate Aspen HYSYS V9 simulations, corresponding to the two distillation columns in the process. These two columns are connected in a serial arrangement. Figure 1 shows a schematic representation of each individual column containing important information for their simulation. Purity constraints of at least 97% mole were imposed to the n-heptane and toluene at the top of the columns.

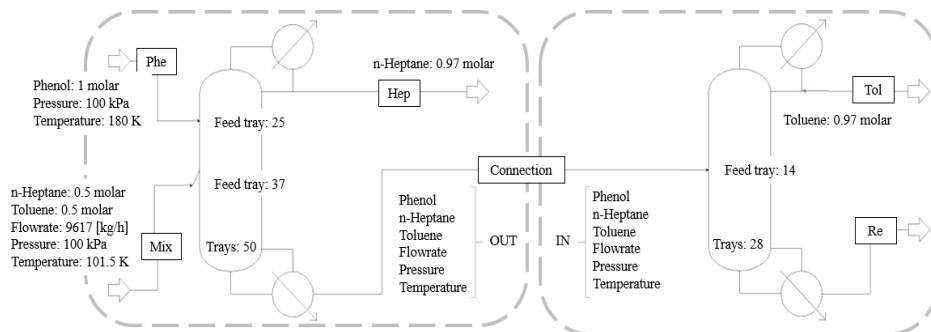

Figure 1: Extractive distillation diagram with some important information. Dashed lines represent the two individual flowsheets used in the proposed methodology.

The decision variables of this problem are the reflux and boilup ratios for both columns and the molar flowrate of phenol at the inlet of the first column. However, the process variables related to the connecting stream (IN and OUT in Fig. 1) are also part of the optimization subproblem that is solved at each iteration. The proposed algorithm requires that the initial trust regions fulfill the equality (connectivity) constraints. Then, at each iteration, a GP is trained around each column using a Sobol sequence sampling on the vicinity of the current trust region. To construct the GPs, the mean function is set to zero and the Matern 3/2 covariance function is used. For this case study, the trust region parameters were set to: $\eta_1 = \eta_2 = 0.1$; $\eta_3 = 0.9$, $\xi_1 = 0.5$ and $\xi_2 = 2$.

We implemented Algorithm 1 in Python 3.7. The optimization subproblems were solved using IPOPT (Wächter and Biegler, 2006) using CasADi (Andersson et al., 2019) for automatic differentiation. At each iteration, we used 10 and 25 samples to construct the GPs for the first and second columns, respectively. We also normalized the input values to be between 0 and 1 and used an initial trust region radius of $\Delta_1^0 = 0.02$ and $\Delta_2^0 = 0.025$. In general, the number of samples and the initial trust regions radii have to be chosen such that a relatively accurate approximation of the original function is obtained, and fast computations can be achieved. Therefore, these two are important problem-dependent hyperparameters. The optimum was reached after 50 iterations. The starting point violates the purity constraints. Therefore, the restoration phase is called

from the beginning as shown by the dashed line in Figure 2. Once the operating point reaches the feasible area, the TAC is continuously minimized at each iteration (solid line). And after the minimum is reached, the trust region radius of the second column starts to shrink to achieve a better approximation of the true problem (dotted-dashed line).

Figure 2: Optimization trajectory for the extractive distillation system. Black solid line: Total Annualized Cost [MM\$/year]. Red dashed line: Purity constraints violation. Blue dotted-dashed line: Trust region radius around second column.

5. Conclusion

In this work an algorithm to optimize process flowsheets was presented. The main advantage of the proposed method is that a complete flowsheet does not need to be simulated at any point. The modular flowsheet structure is exploited so that multiple GPs are trained independently for each individual module. These surrogates are built on separate trust regions and connected within an optimization subproblem using equality constraints corresponding to the connecting streams in the flowsheet. The location and

size of the trust regions are updated according to the search performance at each iteration. A restoration problem is invoked whenever infeasibility is encountered due to an inequality constraint violation. However, the algorithm is unable to account for a mismatch between trust regions. Therefore, its application to process flowsheets with recycles remain an open question and it is subject of future improvement and investigation. The algorithm demonstrated to reach the optimum effectively in the presented case-study.

Abstract

The current concerns regarding plastic waste accumulation and resource scarcity are leading to a waste and resource management paradigm shift, and consequently the number of alternatives for treating and upcycling waste keeps increasing. Here, we develop a new approach to determine the most promising processes or process routes to valorize waste by seeking the best environmental and economic performance. Due to the large number of alternatives, we designed this method to select a certain number of choices prior to further assessment and optimization. As a case study, we chose the treatment of mixed plastic waste. Using the methodology, we are able to select a few alternatives among a large number of different alternatives as the most promising towards closing material loops. The use of graph theory and branch and bound algorithms allows building an efficient framework for this purpose.

Keywords: waste-to-resource, chemical recycling, circular economy, short-path algorithms, material upcycling.

1. Introduction

Plastics are widely spread materials due to their versatility, good performance in a wide range of applications, lightweight and low production cost. This fact has led along the last decades to the rapid increase of plastic items production, especially in segments showing low costs and short useful life, leading to increasingly high amounts of plastic waste generation across the globe, mainly in rapidly growing economies. Thus, waste accumulation and resources depletion concerns are set to grow in the following years due to the lack of effective and efficient resource and waste management policies in most countries worldwide. In addition, there are many barriers that prevent the development of suitable long-term solutions to this problem, such as social, technological and financial, among others.

In an effort to address this challenge, there has been an increasing interest in developing waste-to-resources processes to obtain valuable products from plastic wastes. Among them, chemical recycling stands out as one of the most promising alternatives, including a significant number of different implementations, which keeps growing up. This opens up a wide range of options for the upcycling of materials. Within these resource recovery

technologies, the ones drawing more attention are thermolysis processes such as pyrolysis, hydrocracking and gasification, which are being studied under a wide range of conditions (Zhang et al., 2020).

There have been efforts towards model development in order to find optimum solutions for the treatment of available plastic waste, such as mixed plastic waste (MPW), as the one proposed by Somoza-Tornos et al., 2021. Nevertheless, based on the increasing number of choices present, there is a surging need for a methodology to systematically generate and assess new potential pathways as a means to obtain the most promising and profitable alternatives as a previous step to their detailed analysis and optimization.

To address such a problem, the methodology developed in this work extends the framework proposed in previous contributions (Pacheco-López et al., 2020). This framework aims to identify and assess the most suitable routes towards closing materials loops and resources upcycling. For the knowledge modelling of process, waste and resources information in the domain of Process Systems Engineering (PSE), we based our approach on the use of ontologies. The resulting knowledge corpus is queried in order to implicitly generate all possible routes connecting available wastes with tradable raw components. Bounds for partial and complete routes are assessed according to economic and environmental aspects for the identification of the most promising alternatives. However, due to the large number of alternatives available, we propose a pre-selection of the most promising ones, as a previous step to a more thorough assessment.

2. Problem Statement

The problem can be formally posed as follows:

- Given:
 - A large database of processes available for the domain of PSE, including information about processes, such as costs, environmental impacts and yields. Some of them can be potentially used for the treatment of plastic waste and its transformation into eventual intermediate or valuable products.
 - A list of available plastic waste sources, including information about its composition, cost and environmental footprint.
 - A list of potential products demand, including information about their marketable price, quality requirements and technical specifications.
- Find:
 - A set of the most promising routes and alternatives in order to connect waste with tradable products.

3. Methodology

This work focuses on the generation of routes using branch and bound algorithms (B&B). Before applying such algorithms, all the possible processes are obtained from the ontology with the aim of connecting waste sources with tradable products thanks to an input-output matching method, linking each material stream with each one of their tentative processes. Then a tree-like graph with all the possible paths is built using a state-task network approach (Kondili et al., 1993), where operations and processes are considered as “tasks” and feedstock, intermediate and final products as “states”, both included as explicit or implicit network interconnected nodes. Using this kind of algorithm, we are able to find a set of tentative routes avoiding the need of evaluating every single possibility. Consequently, a certain number of paths is generated whose are

fit for further assessment. The methodology can be structured into four sections: knowledge management, database querying, graph building and graph evaluation.

3.1. Knowledge management

As introduced in section 1, we are using ontologies as a knowledge management tool, providing consensual knowledge representation for a specific application domain. For the domain of Chemical Aided Chemical Engineering (CAPE), we are using an open-source, recognized ontology within the domain as it is OntoCAPE (Marquardt et al., 2010). The ontology has been analyzed and adapted to the framework in development; likewise, some concepts have been modified or added to specify aspects that were not previously defined in the ontology, such as the environmental impact indicators among others.

All the processes, plastic wastes, intermediate products and tentative final products have been asserted in the ontology with all the corresponding property relations and values such as costs, prices, yields and environmental indicators.

3.2. Database querying

For the integration of the ontology and the algorithm, an ontology-oriented interface is needed. We are using an object-oriented programming tool for accessing entities from OWL ontologies, namely an Open-Source software called Owlready developed in Python (Lamy, 2017). This tool enables, not only an easy access to all information available in the ontology, such as entities and relations between them, but also adding new information in a systematic way and running a reasoner for the inference of new missing relations or discovery of possible conceptual inconsistencies.

3.3. Graph building

With the information for each entity available in the ontology, an input-output matching method is developed to connect wastes, processes and products, thus building the corresponding graph with the STN approach mentioned above. This representation can be classified as a bipartite graph, which has two kinds of nodes, one for processes (considered in the ontology as “steps”) and another for materials (considered as “states”), which are connected through edges. At this level, the graph stores information about economic, environmental or behavioral aspects in its nodes, but no routing or path finding is performed yet.

3.4. Network evaluation

Once the graph is implicitly built, a branch and bound algorithm is implemented so as to analyze the branches rooting from the initial node, which corresponds with the waste to treat. The algorithm starts building branches and choosing only those with better performance to continue advancing towards the final products or choosing an intermediate point that could be more profitable. The algorithm is adapted to allow the completion of a limited number of paths for an easier further assessment.

With the purpose of calculating the bounds for each branch, economic and environmental aspects are added up, specifically prices with monetized impacts for materials on one side, and costs with monetized impacts for processes on the other. Then, for each process considered, a total profit is obtained and added to the respective branch as shown in equations 1 to 4.

$$EE_price_j = Price_j + Product_EI_j \quad (1)$$

$$EE_cost_i = Cost_i + Process_EI_i \quad (2)$$

$$EE_profit_i = \sum_{j \in outputs} EE_price_j - \sum_{j \in inputs} EE_price_j - EE_cost_i \quad (3)$$

$$Total_profit = \sum_{i \in route} EE_profit_i \quad (4)$$

4. Case Study

In order to test the methodology, we chose a case study for the recycling of Mixed Plastic Waste (MPW). All possible paths for the treatment of MPW are built, including those partial paths that may yield intermediate products and be used for other purposes, such as fuel for energy recovery or the transportation sector.

For this case study, the ontology has been filled with information from processes available in the literature related to this domain, including end-of-pipe processes traditionally used to get rid of this kind of wastes, such as landfilling and incineration for energy recovery, as well as other emerging processes like pyrolysis at a wide range of temperatures with and without previous mechanical sorting, leading to promising circular economy solutions. The information related to those processes which specifications not available in the literature, not reliable or contradictory has been estimated thanks to commercial simulators and standard procedures for the assessment of economic and environmental indicators.

Departing from a total of 140 tentative steps asserted in the ontology which are directly or indirectly related to this specific case study, approximately 300 potential paths are obtained, from which nearly 100 complete paths have been deployed and 200 partial routes have been also analyzed. From this high number of possibilities, we select only 20 paths for illustrative purposes, the partial process tree resulting from these 20 alternatives is schematized in Figure 1. The aggregated amounts for environmental and economic aspects, as well as the yields of each process are shown in the scheme. It is important to note that the values are unitary, i.e. per ton, and they have to be multiplied by the yield to obtain the absolute values.

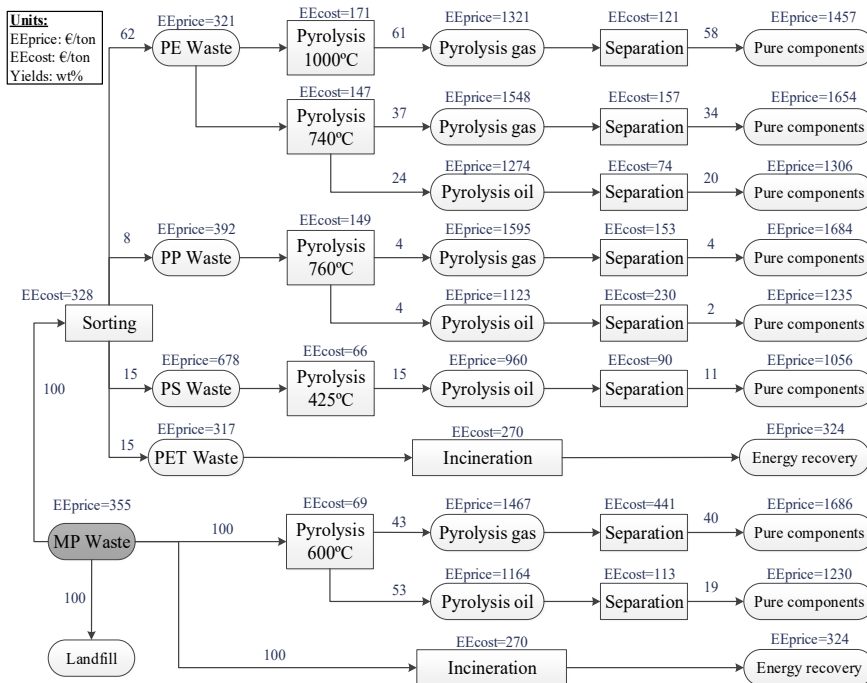

Figure 1. Possible alternatives for MPW treatment

5. Results and Discussion

Among all the possible alternatives, only the selected 20 are shown in Table 1. The algorithm builds the paths with an input-output matching as explained in section 3.3, afterwards it evaluates the branches, node by node, and keeps the alternatives that show better performance, discarding those with lower economic and environmental results.

For this case study, the upper bound corresponds to that where a sorting is applied and a pyrolysis is performed on the polyethylene waste at 1000°C and a mixture of gases is obtained apart from polypropylene, polyethylene terephthalate and polystyrene sorted wastes. As we can appreciate in Table 1 the next upper bound comes when the mixture of gases is separated into its pure components, the third one is the pyrolysis at 740°C of the polyethylene waste, obtaining a mixture of pyrolysis oil and gas, apart from the sorted wastes as mentioned before. The rest of the bounds can be consulted in Table 1.

Table 1. Deployed process paths, outputs and bounds for the illustrative 20 alternatives.

	Processes	Outputs	OF
1	Sorting + Pyro. PE 1000°C	PE 1000°C Pyrolysis gas + PP, PET, PS wastes	1457
2	Sorting + Pyrolysis PE 1000°C + Separation	Butadiene, benzene, ethylene, methane and propene + PP, PET, PS wastes	1084
3	Sorting + Pyro. PE 740°C	PE 740°C Pyro. oil and gas + PP, PET, PS wastes	1048
4	Sorting + Pyro. PS 425°C	PS 425°C Pyrolysis oil + PP, PET, PE wastes	985
5	Sorting + Pyrolysis PE 740°C + Separation(Gas)	PE 740°C Pyrolysis oil, ethylene, ethane, methane and propene + PP, PET, PS wastes	769
6	Pyrolysis MPW 600°C + Separation(Gas)	MPW Pyrolysis oil, butane, ethylene, 1-butene, propene, propane, hydrogen, methane and ethane	619
7	Sorting + Pyro. PE 740°C + Separation(Oil)	PE 740°C Pyrolysis gas, pyrene, indane, benzene and toluene + PP, PET, PS wastes	423
8	Pyrolysis MPW 600°C	MPW Pyrolysis oil and gas	356
9	Pyrolysis MPW 600°C + Separation(Both)	Butane, ethylene, propane, hydrogen, methane, ethane, ethylbenzene, styrene, benzene, toluene...	288
10	Sorting	Sorted plastic waste (PE, PP, PET, PS)	236
11	Sorting + Pyrolysis PS 425°C + Separation	Ethylbenzene, cumene and toluene + PP, PET, PE wastes	185
12	Sorting + Pyrolysis PE 740°C + Separation(Both)	Ethylene, ethane, methane, propene, pyrene, indane, benzene and toluene + PP, PET, PS wastes	144
13	Sorting + Pyrolysis PP 760°C + Separation(Gas)	PP 760°C Pyrolysis oil, ethane, methane, propene, and ethylene + PE, PET, PS wastes	123
14	Sorting + Pyro. PP 760°C	PP 760°C Pyro. gas and oil + PE, PET, PS wastes	115
15	Sorting + Pyrolysis PP 760°C + Separation(Both)	Ethane, methane, propene, ethylene, benzene, toluene and naphthalene + PE, PET, PS wastes	94
16	Pyrolysis MPW 600°C + Separation(Oil)	MPW Pyrolysis gas, ethylbenzene, styrene, benzene and toluene	25
17	Sorting + Pyrolysis PP 760°C + Separation(Oil)	PP 760°C Pyrolysis gas, benzene, toluene and naphthalene + PE, PET, PS wastes	86
18	Direct Downcycling MPW	MPW	0
19	Incineration	Energy Recovery	-17
20	Landfill	None	-238

Among the most promising possibilities for the upcycling of MPW, we find pyrolysis at different temperatures, with or without previous sorting. The number of alternatives grows exponentially with the number of available processes. Therefore, it is not efficient to assess all these alternatives individually, in addition to being more time consuming and computing resources demanding. Hence, this previous selection guarantees that the subsequent assessment and in-depth analysis is performed only on the most promising alternatives, and not all possible alternatives.

Results show that this methodology is useful to identify all the possible routes for closing the materials loops and select only those that are most promising, prior to more detailed route assessment. This contribution represents an important previous step and extension of the previously developed scheme (Pacheco-López et al., 2020), with the purpose of narrowing down the number of available alternatives.

6. Conclusions

This approach enables the systematic identification of the available opportunities for the treatment of waste and therefore closing the material loops, reducing resources exploitation and depletion, as well as the disposal of waste and reducing the environmental impact this entails. The methodology allows the pre-selection of paths according to their performance, reduces the amount of choices to those that are more promising and facilitates next steps. Moreover, the method allows the pre-selection of the most relevant paths and removes those that are economically and environmentally less profitable.

Calibration of an EPANET model by using monitoring points in the bulk distribution of Sedibeng Water, for predicting disinfectant decay

Charl van der Walt,^a Prof Evans Chirwa,^a Danie Traut,^b

^a*University of Pretoria, 2 Lynnwood Road, Pretoria, 0002, South Africa*

^b*Sedibeng Water, Protea Street Balkfontein Bothaville 9660, South Africa*

Abstract

By using the EPANET software, the distribution system of Sedibeng Water in the Republic of South Africa was modelled and populated with actual free chlorine data. It was found from the model that the maximum age of the water from leaving the plant up to a point 70 kilometres away from the plant was 160 hours. With a calculated summer chlorine decay rate of 0.052 h^{-1} for summer conditions and 0.027 h^{-1} for winter conditions, it was demonstrated that interim booster chlorination can be discontinued during the winter months, while these booster stations should be operational during the warmer periods to ensure adequate disinfection in the overall 300 kilometre pipe supply system.

In addition to optimising the current disinfectant conditions, it was also demonstrated that a switch to ClO_2 for final disinfection in the network is possible, with the benefit that interim chlorination can be discontinued. This option will require an additional USD 27,000 to be spend per annum, with provision made for a once-off capital expense of USD 65,000.

Keywords: Chlorine, Chlorine dioxide, EPANET, decay, disinfectant.

1. Introduction and Context

Sedibeng Water is a Water Board in South Africa and purifies approximately 210 MI/d raw water from the Vaal River to potable standards. This raw water is characterized by seasonal elevated levels of algae which leads to unpleasant taste and odours in the water. Sedibeng Water employs standard clarification and filtration technologies at their two water treatment plants (WTP's) namely the Balkfontein WTP and the Virginia WTP. Use is made of chlorine as disinfectant while they also make use of interim chlorination at three areas in their network due to the vast distances being covered by their supply system which uses over 300 kilometres of piping. Chlorine depletion occurs in the network and a need was established to predict this occurrence using suitable software.

EPANET is a public domain software application which can be used to track amongst others the flow of water, the pressure at nodes, chemical concentrations and the decay thereof, and the age of the water in the network.

Another aspect of this research included the evaluation of chlorine dioxide (ClO_2) as an alternative to using chlorine as final disinfectant in the network. Due to the superior ability of ClO_2 in controlling iron, manganese, and taste and odour causing compounds, the option to replace chlorine with ClO_2 becomes an attractive possibility, and once the

EPANET model was calibrated, a “what-if” scenario was modelled where the efficacy of ClO₂ to provide for sufficient residuals was investigated.

2. Disinfectant Decay

Disinfection is regarded to be the most important process in water treatment, and with known dangers associated with this action around the formation of disinfectant by-products, the formation of these compounds need to be minimised (Monteiro et al, 2014). At the same time, it is recognised that water without disinfection, will result in far greater dangers around health, and cost implications of cleaning out overgrown reticulation systems. It is also difficult to predict chlorine decay in extensive and complex distribution systems, due to all the variables such as pH, organic content, hydraulic conditions and temperature to name but a few.

Since these large number of variables limit extensive applications of universal chlorine decay models, each distribution system should be considered individually, depending on its different environmental conditions (Pasha & Lansey, 2010). The decay of disinfectants have been reported on by numerous authors and it is generally accepted that the decay of any disinfectant is affected by two main items namely the bulk reaction in the water mass and the surface reactions (wall decay) in the pipe network (Fisher, et al., 2011). The bulk reaction is influenced by chemical properties of the water such as temperature, organic content and pH, while the surface reactions are more complex and influenced by biofilm growth, sediments in the pipe, type of pipe as well as its condition and age.

Laboratory studies can be conducted on-site to determine the bulk decay rate of chlorine in treated water, while the determination of the wall decay rates can best be obtained by analysing actual data in the network. By obtaining these values, and applying a suitable mathematical model to it, it is possible to populate the EPANET model with these decay rates and calculate theoretical free chlorine values at selected points in the network. EPANET is the most well-known process based model to be used for chlorine decay as it makes provision for separate measurement and programming for bulk decay and wall reactions (Rossman, 2000)

Comparing theoretical values to actual values subsequently remains to be done in delivering a calibrated model of EPANET whereby the decay of disinfectants can be modelled and used in “what-if” scenarios for planning purposes

3. 3. Model Calibration

3.1. On-site Experimental Decay Work

The on-site decay tests were done by taking a sample of the treated chlorinated water from the sampling point at the pumping station, placing it in amber, dark glass bottles in a controlled temperature environment (13 °C and 23 °C) and testing for free chlorine readings on hourly intervals for a period of 14 hours. Free chlorine analysis was done by the laboratory using the same method employed for the weekly monitoring points in the network. These tests were done for the final chlorinated water at the Balkfontein WTP and at the Virginia WTP. [Figure 1](#) indicates the results for these tests.

Figure 1: Experimental decay rates for Balkfontein and Virginia final water

Decay rates for chlorine were calculated using the following equation:

$$C_t = C_o e^{-kt}$$

Where :

- C(t) = Calculated disinfectant concentration after time t (mg/l)
- C_o = Initial disinfectant concentration (mg/l)
- k = Decay rate (1/h)
- t = time (h)

In general it is seen that the 10 °C difference in temperature leads to an approximate doubling in decay rates, which is not nearly as drastic as the suggested 5 °C increase as per Fisher, et al., 2011, and also lower than the 16–17 °C temperature rise as per the (Sathasivan, et al., 2009) findings for doubling of decay rates.

3.2. Calibration with Network Data

Weekly monitoring of water quality is done at selected sites in the Sedibeng Water network and measured amongst others for free chlorine, pH and turbidity. This data were analysed to obtain site specific bulk- and wall decay coefficients. The method followed for every EPANET pipework section is set out below:

- Obvious errors regarding the measured values were discarded. These were mostly where an increase in free chlorine value was found following a period of decay. In discussions with Sedibeng Water it was indicated that this is acceptable and dealt with instances where interim emergency adding of chlorine was made;
- A first order equation was fit on the data to determine bulk decay coefficients and wall decay coefficients. Where data points only constitutes a pipe section, a

combined bulk and wall decay coefficient was established and where only a reservoir was monitored for inlet and outlet sections, a bulk decay coefficient was established;

- The wall decay coefficients and bulk decay coefficients were plotted on a graph as a function of time of year to determine any obvious correlations with temperature;
- Statistical evaluations were done on the data to determine a median for the data, a standard deviation of the data as well as a coefficient of variation (CV). A CV larger than one (1) was considered to be statistically less usable in the calculation of a decay coefficient, and was hence discarded.
- Finally, the coefficients for the various sections were introduced into the EPANET model and an average residual chlorine concentration was calculated for the various monitored nodes in the system and compared to an average value of chlorine residual actually monitored at the node over a period of a year (See [Table 1](#))

Two clear results stood out from the data in that:

- the decay rate during the winter months dropped to 50-60% of the decay rate experienced during the summer months. This is in line with the on-site test results and it was therefore necessary to make provision for a winter model and a summer model; and
- the bulk decay rates in the system for both winter and summer conditions approximated the value of the combined decay coefficient. This is in line with findings from (Fisher, et al., 2017) where it was found that bulk decay is predominant when pipe diameters exceeds 500 mm, which is the case in most of this network.

[Figure 2](#) below shows a typical distribution of calculated decay coefficients as a function of the time of year experienced at two of the monitoring points in the network. With South Africa being in the Southern hemisphere, the colder months are typically from April to July, and it is seen that the decay coefficient decreases in the colder months

Figure 2: Calculated decay coefficients for two monitoring points in the network

Table 1 below shows the average actual measured free chlorine values per node in the supply system, compared with the calculated EPANET free chlorine values.

Table 1: Calculated EPANET model values compared with actual measured values

Item	Summer data			Winter data		
	Actual	EPA-NET	Absolute variance (%)	Actual	EPA-NET	Absolute variance (%)
Balkfontein Old Reservoir	2.38			2.68		
Balkfontein New Reservoir	2.11			2.70

AVERAGE VARIANCE			16.4 %			10.0 %

4. Discussion

The above sections demonstrated that EPANET can be used successfully to simulate actual conditions in the bulk distribution network regarding hydraulic behaviour and chlorine decay. After calibration of the model, an 84-90 % correlation with actual measured values could be reported. To use this model in practice, a number of “what-if” scenarios have been identified to assist Sedibeng Water in planning purposes for:

- the possible change to an alternative disinfectant like chlorine dioxide and the financial implications thereof;
- the determination of minimum levels of chlorine measured at the two WTP’s to not warrant any additional chlorination in the network; and
- the determination of minimum levels of chlorination at the WTP’s and the booster chlorination stations to ensure adequate free disinfectant levels in the system.

5. Conclusions

The aim of this research was to develop a mathematical model for chlorine decay based on actual conditions prevalent in the bulk distribution system of Sedibeng Water. This model can then be used for operational and planning purposes. The following conclusions were reached following the investigation:

- a) Although the effect of wall decay rates was expected to have a similar impact of bulk decay rates, it was found that the bulk decay coefficient approached the total decay rate coefficient. This can be attributed to the large number of reservoirs in the system, mostly laminar flow conditions being experienced in the pipes and the fact that the majority of bulk pipelines has a diameter larger than 500 mm.
- b) A definite effect of temperature could be seen on the calculated decay rates with the so-called winter decay rate being 50-60% of the so-called summer decay rate.
- c) Using the monitoring values in the reservoirs, a reasonably accurate simulation of hydraulic and disinfectant decay conditions of the Sedibeng Water bulk distribution network could be done by means of the EPANET software. This model has an 84-90% correlation with actual conditions in the network;
- d) It was found that Sedibeng Water already to a large extent has optimised their booster dosing conditions. There is a possibility to further reduce average chlorine consumption at the Balkfontein WTP by 25% and save about USD 65,000 per annum in the process;
- e) It will not be possible to do away with interim chlorination during summer periods due to the impact which high levels of chlorine will have on nearby communities and due to the relatively fast decay rate of chlorine in the network; and
- f) The implementation of chlorine dioxide as secondary disinfectant at the Balkfontein WTP is an option, while the use of interim chlorine booster stations can be discontinued. This option will require an additional USD 27,000 to be spend per annum, with provision made for a once-off capital expense of USD 65,000

Compartmental Modelling of Shell Side Fouling in a Shell and Tube Heat Exchanger

Renat Targalinov^a, Federico Lozano Santamaria^a and Sandro Macchietto^{a*}

^a*Imperial College London, South Kensington Campus, London SW7 2AZ, UK*

s.macchietto@imperial.ac.uk

Abstract

Accurate and fast models are required to optimise the design, control and operations of shell and tube heat exchangers (STHE) subject to fouling. To date, research effort has mainly focused on tube side fouling. Techniques proposed for the shell side fouling are limited to i) mechanistic thermo-hydraulic models with simple Flow Stream Analysis (FSA) and ii) Computational Fluid Dynamics (CFD) models. The former ignore flow dynamics on the shell side. The latter cannot quantitatively predict fouling, are computationally very heavy and cannot be utilised for optimisation and control.

In the paper, we combine the benefits of FSA and CFD methods by creating a hybrid Compartmental Model (CM). For an actual exchanger subject to crude oil fouling we analyse its outcomes and compare them to CFD and FSA methods. A preliminary CFD study yields detailed shell side velocity field information, based on which an appropriate compartments network is created. A simulation is performed using a two dimension (2D) distributed dynamic STHE model which utilises a FSA for the shell side. A dynamic model for the compartments with a shell side threshold fouling model is developed, utilising selected results from the CFD (velocity data) and 2D-FSA (heat duty) studies. Results from the CM model and comparison with the CFD and 2D-FSA models, for the same operation, provide valuable insights regarding the role of shell side velocities in predicting overall exchanger performance.

Computationally, for this case study, the CM model is solved 5.5 times faster than the distributed dynamic model and 36 times faster than the CFD model, indicating the approach has good potential for use in design and operations optimisation.

Keywords: Compartmental multi-zonal hybrid model, CFD model, Heat exchanger shell side, crude oil fouling, Flow Stream Analysis.

1. INTRODUCTION

Accurate and robust models of STHEs under fouling are required for design, control and operations support purposes, with large economic and safety implications (Diaz-Bejarano et al., 2018). A choice must be made between model detail and usability. Mechanistic thermo-hydraulic models can simulate mass and heat transfer together with complex reaction kinetics and separations in relatively simple geometries and over long periods in reasonable computer times and are therefore useful for control and operational studies. Computational Fluid Dynamics (CFD) models, on the other hand, can describe complex fluid dynamics in far greater detail in complex geometries, however only over short periods and at the expense of long computation times. Compartmental Models (CM) aim to achieve a compromise between the two. There is a

rich literature on their use (Jourdan et al., 2019), however, not for shell and tube heat exchangers (STHE) subject to fouling. Here, a CM model, specifically capable of dealing with fouling on the shell side, is presented. A direct comparison of three approaches (CFD, a 2D distributed thermo-hydraulic and CM) is also presented.

1.1. Shell and tube heat exchanger models

To date, research effort has mainly focused on fouling on the tube side. Shell side fouling is very common but has not been adequately studied. Various mechanistic thermo-hydraulic heat exchanger models can deal with fouling (see Diaz-Bejarano et al. 2017 for a review). Lumped parameter type models do not consider spatial variations in the heat exchanger. Distributed parameter models account for spatial changes axially along the tubes and radially inside a tube (e.g. Coletti and Macchietto, 2011, Diaz-Bejarano et al., 2016) resulting in much better predictions.

Estimating the thermal and hydraulic performance on the shell side is challenging due to the complex flow distribution induced by the equipment geometry (e.g. segmental baffles, bundle supports, flow bypasses) (Figure 1). The Bell-Delaware and Flow Stream Analysis (FSA) (Hewitt, 2008) approaches, extensively used in industry for the shell side in a clean state, do not account for fouling. All the thermo-hydraulic lumped models and most of the distributed ones discussed above neglect shell side fouling. A notable exception is Diaz-Bejarano et al. (2018), who couple a shell side Flow Stream Analysis with a typical reaction fouling model, to calculate the progressive occlusion of flow bypasses. This model, implemented in Hexxcell Studio (2018) is used later. By its nature, this approach does not reflect the spatial distribution of velocities and all related quantities (e.g. Reynolds no., deposition, heat transfer) on the shell side.

CFD models calculate detailed fluid dynamics and heat transfer taking into account irregular flow distribution patterns (e.g. vorticity, recirculation joints, etc.), wall effect and boundary layer conditions. For particulate fouling in crude oil, Emani et al. (2017), calculated the particles transportation, adhesion and removal trajectories. This gives only a qualitative assessment of mass, thickness and locations of fouling. For chemical reaction fouling CFD still lacks the ability to predict accurately reaction kinetics and fouling rates. Chambon et al. (2019) calculated a-posteriori steady state fouling rates based on velocity and temperature profiles. For dynamics, CFD fouling simulations is normally restricted to seconds or minutes. Many simplifications are used, such as decoupling shell and tube sides (Wang et al., 2012, Yang et al, 2015, Emani et al., 2019; Gounder & Emani, 2018). Altogether, this presently prevents the use of CFD models for control and operations optimisation.

Compartmental Models (CM) achieve a compromise between the above approaches. CFD views an object as a very large number of small cells, CM as a small number of large, approximately homogeneous, compartments (macro cells), mapped to a finer CFD grid (Figure 2 left). Equations in a compartment detail the processes within it (e.g. heat exchange, fouling), while convective and turbulent fluxes between them define their interaction (Figure 2 right) (Bezzo *et al.*, 2000; Haag *et al.*, 2018).

1.2. Case study, CFD model, Compartment model and 2D distributed model

A case study is drawn from a well-documented CFD paper (Chambon et al., 2019), from which exchanger data (single pass, 4 baffles), properties of both fluids (residue in the shell side and crude oil in the tube side) and inlet operating conditions (Table 1), were obtained (additional details in Taurgalinov, 2020). A CFD model of the exchanger

was developed in COMSOL Multiphysics 5.4 (COMSOL Inc., 2019). A simulation without fouling gives the velocity fields on tube and shell sides (Figure 3). As expected, the shell side velocity field is greatly affected by the baffles, with low velocity wakes and recirculation joints. All central and outlet baffle spacing have a low and a high velocity zones. This CFD simulation took 72 minutes. Additional cylinders (around the tube bundle and avoiding the bypass clearance) of various lengths allowed calculating average shell side velocities in the corresponding domains (Figure 4, top left).

Figure 1 Shell-Side Flow Distribution (left, Mukherjee, 1998) and Flow Streams (right, Diaz-Bejarano et al., 2018)

Figure 2 Compartment Formation through Aggregation or Division (left) and Exchange Fluxes between Compartments (right) (Haag et al., 2018)

Based on these flow distributions, the shell side was divided into 9 cylindrical compartments (1 for the residue inlet section, 2 for each baffle section and 2 for the exit section), mapped onto the exchanger and linked between them as shown in Figure 4 (bottom). Each compartment model is structured as detailed in Figure 4 (top right). A single tube is considered to represent all tubes in the bundle, with a fouling layer deposited on the outside (shell side) according to the prevailing conditions in that compartment (for ease of assessment, no fouling is assumed to occur on the tube side). Due to space limitations selected equations only are given in Table 2. Deposition on the outside of the tube is assumed to follow the Ebert and Panchal model (Panchal et al., 1997), with conductive heat transfer through the tube wall and the fouling layer in series in the radial direction. Velocities of shell-side flows in each compartment are based initially (clean bundle) on averages from the CFD simulation, and then adjusted for fouling according to the gap reduction between the tubes (Eq. 5 in Table 2). Shell side heat transfer is modelled as forced convection across cylinders (Hilpert, 1933). The CM model was implemented in gPROMS (2018). The same exchanger was simulated using the 2D-FSA dynamic model in Hexxcell Studio (labelled HS). The CFD model does not include fouling, HS does, using FSA on the shell side. Comparison runs assumed no fouling on either side, and fouling only on the shell side with the same fouling parameters. Full details are reported in Taurgalinov (2020).

Table 1 Properties of Materials and Inlet Conditions

	Units	Residue	Crude	Carbon Steel
Density	kg/m ³	730	675	7800
Dynamic viscosity	Pa s	$7.23 \cdot 10^{-4}$	$3.75 \cdot 10^{-4}$	
Thermal conductivity	W/m/K	$8.94 \cdot 10^{-2}$	$9.18 \cdot 10^{-2}$	45
Specific heat capacity	J/kg/K	2925	2980	470
Inlet velocity	m/s	0.7	0.5	
Inlet temperature	°C	314.3	293.9	

2. Results and conclusions

The dynamic CM model runs well and calculates all variables. Without fouling, CM predicts an overall heat duty (5.949 KW) within 17.9% of the CFD result (5.045 KW), while the HS duty (7.451 KW) is 25.2% and 47.7% higher than with CM and CFD. Notably, the FSA model in HS gives a shell side velocity of 0.52 m/s, much larger than the CFD velocities for the flow through the tube bundle (0.24-0.34 m/s), also used in CM. The difference in velocities leads to differences in velocity-dependent quantities (e.g. Reynolds No., fouling deposition, deposit depth, exit temperatures). As the current CM model does not include the faster bypass flows in the gap between bundle and shell,

a by-pass flow split factor (f_b in eq. 5, Table 2) was adjusted so as to match the clean HS shell velocity, achieved with $f_b = 1.74$. This factor, assumed constant, was used in the dynamic simulation with shell side fouling. Figure 5, left shows the bulk temperature of the shell fluid along the exchanger at Days 0 and 40. The HS profile is linear, while the CM profile is “discretised” in the 9 different compartments. There are visible differences in the two compartments corresponding to parallel flows within two baffles. Differences are reduced as fouling progresses. Figure 5, right shows the predicted shell-side Fouling Thickness and Velocity for CM and HS. As before, differences in predicted velocities result in different deposit thickness.

Table 2 Selected equations in Compartment model (superscripts are omitted for clarity)

Nº	Equations	Notes and assumptions
Tube wall +Shell-side Deposit Domain		
1	$\frac{dR_f}{dt} = \alpha Re^{\beta} Pr^{\gamma} e^{-\frac{E}{RT_f}} - \gamma \tau$	Ebert and Panchal threshold fouling model (Panchal et al., 1997), with α , β , γ , and E given. R is the gas constant.
2	$\delta = R_f k_f$	k_f is assumed uniform, constant and known.
3	$Q = \frac{2\pi L(T_w^s - T_w^t)}{\ln\left(\frac{D_o}{D_i}\right)/k_w + f_c \ln\left(\frac{D_o + 2\delta}{D_o}\right)/k_f}$	Conductive radial heat transfer through the tube wall and fouling deposit layer (i.e. conduction in series). Adjustment factor (f_c) is applied to control the effect of fouling on heat conduction. k_f , k_w and all geometric parameters are assumed known.
Shell Side Domain		
5	$u = \frac{u_{in} f_u f_b}{\left(1 - \frac{2\delta}{x}\right)}$	Shell side local flow velocity u depends on: i. initial velocity relative to inlet velocity u_{in} ii. clearance between tubes due to fouling deposit of depth δ iii. compartment split factor (f_u), from CFD iv. bypass flow split factor (f_b).
13	$\frac{h_o(D_o + 2\delta)}{k} = C Re^m Pr^{1/3}$	Forced convection across cylinders (Hilpert, 1933). Constants C and m based on shell side Reynolds no. (range 4000 – 40000).

Compared to models based on FSAs, CM enables calculating the shell side fouling rates along the exchanger as a function of the local (average) conditions in each compartment. The initial results in this work suggest that some refinements may be useful in respect of selection of compartments (e.g. adding compartments for the parallel flow portions or the radial gap between bundle and shell) and velocity split factors. While the FSA methods mainly aim at getting the overall thermal behaviour right, the method proposed aims mainly at incorporating the shell side hydraulics behaviour, with an input from CFD calculations. A way of adjusting the compartment split and bypass flow split factors to improve model predictions matching (if desired), beyond their initial setting may be useful. Independent experimental verification of shell side velocities would be useful to improve both CM and fully distributed models.

Computationally, the case study presented was solved with the CM model 5.5 times and 36 times faster than with the 2D distributed and CFD models, respectively, indicating the approach has good potential for use in design and operations optimisation.

Figure 5 Simulation results with CM (bypass split factor $f_b = 1.74$) and HS: Bulk Temperature along STHE at Days 0 and 40 (left); Fouling Thickness and Shell Velocity (right)

Abstract

This work demonstrates a systematic development of a digital twin of a commercial active pharmaceutical ingredient (API) - Compound A - crystallization processes to be used for in-silico design of experiments (DoE) and process optimization. Eleven highly correlated kinetic parameters were estimated by exploiting an optimization approach with an evolutionary algorithm, to fit to concentration profile, mean size and the shape distribution of the product. Two more experiments were then performed to validate the model showing that the developed model could predict the product size and shape properties. The digital twin of the process was used to perform in silico design of experiments to understand the attainable operating space of the system and provide a framework for rapid quality-by-design (QbD). Subsequently the model was used in a dynamic optimization framework for the digital design of the API crystallization process to achieve the critical quality attributes (CQAs) without extensive experimentation.

Keywords: Digital twin, crystallization, process optimization, digital design

1. Introduction

Prediction and control of the product properties in crystallization processes represent significant challenges in the pharmaceutical industry. To meet the critical quality attributes (CQAs) with the least variation among batches, effective crystallization process design and operation techniques are needed. Hence, monitoring, modelling, and control of CSD has become the focal point of the QbD driven crystallization process design (Nagy and Braatz, 2012). The paradigm shifts in pharmaceutical crystallization from Quality-by-Testing (QbT) to QbD promoted the extensive usage of process analytical technology (PAT) tools for the direct measurement of CQAs. PAT tools not only enabled more profound process understanding but also opened the way for the application of PAT-based process control strategies and model development and have become standard instruments in crystallization process design (Saleemi, Onyemelukwe and Nagy, 2013).

From an experimental perspective, DoEs are simple, legacy tools for design space identification. The number of necessary experiments depends on the number of factors, and the levels associated to each factor. As the number of design variables increase, for

example, temperature cycles are included or combined anti-solvent and cooling crystallization process is considered, the number of experiments will increase substantially. Being labour and material intensive, this is undesired in the pharmaceutical industry. Moreover, material availability can become a bottleneck in the case of APIs under early phase clinical trials for designing such complex crystallization processes, in which case the application of mathematical modelling tools for *in silico* experimental design can be advantageous (Rosenbaum *et al.*, 2019).

The objective of this work is a process model development for the batch cooling crystallization of Compound A that is suitable for quick process simulations (for *in-silico* DoE) and process optimizations. The Compound A has high nucleation tendency and forms slow-growing high aspect ratio crystals, which requires the implementation of temperature cycles for internal fines removal and for aspect ratio improvement. Secondary nucleation, growth and dissolution of crystals is considered in the one-dimensional (1D) PBM, which is solved numerically with a high-resolution finite volume method.

2. Experimental Methods, Model Development, Parameter Estimation, and Process Optimization

Six batch cooling experiments were performed with varying operating parameters such as temperature cycle number, seed loading, seeding temperature and cooling rate to be used in model training. Two more experiments with same parameters varied were conducted after parameter estimation to validate the model in the same batch system. The experimental space is given in table 1 summarizing these changing operation conditions for these experiments.

Table 1. Experimental space for the parameter estimation calculations.

Name	C.R. (°C/min)	# Cycles	Seed load (%)*	T_{sat} (°C)	T_{seed} (°C)	T_{min} (°C)	T_{max} (°C)
Cal #1	0.1	1	1	70	65	40	60
Cal #2	0.1	2	1	75	68	45	65
Cal #3	0.1	4	1	70	65	50	70

Val #2	0.2	2	2	75	68	20	70

*% of expected product mass, **parabolic cooling was applied between the given rates to understand better the crystallization behaviour.

In each experiment, PAT tools were utilized for data acquisition and monitoring. UV/Vis spectrophotometer, focused beam reflectance measurement (FBRM), and Particle Vision Measurement (PVM) were used to measure concentration, particle count, morphology and size. In addition, Malvern Mastersizer 3000 and Nikon SMZ1500 microscope were used for offline characterization of size distribution and crystal morphology. A supervisory control software, CryMOCO, was used to implement temperature cycles with

different cooling/heating rates (Simone, Zhang and Nagy, 2015). Population balance model (PBM) was used to describe the crystallization of Compound A considering nucleation, size dependent growth (SDG) and dissolution (SDD) mechanisms based on the experimental data as shown below. The monovariate population density function is introduced and noted by $n(L, t)n(L)$, which gives the number of particles in time t within the size domain $L, L + dL$.

$$\frac{\partial n(L)}{\partial t} + \frac{\partial [Gn(L)]}{\partial L} = B_s \delta(L - L_n) \tag{1}$$

$$\frac{\partial n(L)}{\partial t} - \frac{\partial [Dn(L)]}{\partial L} = 0$$

$$\frac{dc}{dt} = \begin{cases} \{-k_v \rho_c \left(3 \int_0^\infty GL^2 n(L) dL + B_s L_n^3 \right), & \text{if } \sigma \\ > 0 \ 3k_v \rho_c \int_0^\infty DL^2 n(L) dL, & \text{else} \end{cases} \tag{2}$$

$$B_s = k_s \sigma^s V_c, G = k_g \sigma^g \exp\left(-\frac{E_A}{RT}\right) G = k_{g,0} \frac{1}{2} (\tanh \tanh(k(L_c - L)) + 1) (1 + \alpha L^Y) \sigma^g \exp\left(-\frac{E_a}{RT_K}\right), \beta(\lambda, L) = D = k_d (-\sigma)^d D = k_d(L) \sigma \tag{3}$$

$$D = (1 + \alpha_d L)^{-Y_d} \sigma$$

Finding the values of parameters was carried out by solving an optimization problem as shown:

$$O(P) = \frac{1}{I_c J_c} \sum_{i=1}^{I_c} \sum_{j=1}^{J_c} (c_{e,ij} - c_{s,ij})^2$$

$$+ \frac{w_L}{I_L J_L} \sum_{i=1}^{I_L} \sum_{j=1}^{J_L} \int_0^{L_{max}} [v_{e,ij}(L) - v_{s,ij}(L)]^2 dL \tag{4}$$

$$+ \frac{w_N}{I_N J_N} \sum_{i=1}^{I_N} \frac{1}{\mu_{0,i}^2} \sum_{j=1}^{J_N} R_{ij}^2$$

where the first term minimizes the differences between the measured ($c_{e,ij}$) and simulated ($c_{s,ij}$) concentrations in all experiments having concentration data (I_c), in all concentration sampling instance (J_c). The second term minimizes the difference between the measured ($v_{e,ij}(L)$) and simulated ($v_{s,ij}(L)$) cumulative CSDs in all experiments (I_L) in all CSD sampling instance (J_L). The last term is another novelty introduced in this work. It introduces the maximization of correlation between the FBRM count and the simulated number density function, in all experiments (I_N) and in all FBRM sampling instance (J_N). The parameters w_L and w_N are weight factors. In the last term of the objective function, $\mu_{0,i}$ denotes the mean simulated crystal number density in the i^{th} experiment, and R_{ij} is defined as:

$$R_{ij} = \mu_{0,ij} - F_{ij} \tag{5}$$

where F_{ij} is the number density calculated by the best fitting first order polynomial on the points in the FBRM count-simulated number density diagram. Therefore, R_{ij} is the

j^{th} residual of the corresponding first order polynomial fit in the i^{th} experiment. The parameters P were determined solving the multivariable minimization problem:

$$O(P) \quad (6)$$

where R_+^0 denotes the set of non-negative real numbers.

In this work, a novel SDG formulation was used combining the different behaviours of commonly used SDG rate equations as shown with G in equation 3 (Mydlarz and Jones, 1990). The reason to develop a new SDG formula was that the experimentally observed broadening in the CSD and obtaining product size distributions was not reachable with the seed CSD used in the experiments. Given the experimental observations that the small particles can get confined in the eddies and deplete the local supersaturation, one might hypothesize that strong size dependent character can be expected for the crystal size range comparable to the Kolmogorov length scale of turbulence, and there is a critical crystal size under which the particles are virtually not growing. Therefore, we looked for an equation that provides significant size dependency in the small crystal size range. The different behaviours of all the SDG formulas were examined and these were tested in the model. The behaviours of these models are shown in Figure 1 and these models are named as: Quasi power-law (QPL), exponential, hyperbolic tangent dependency (HT), and extended hyperbolic tangent formula (E-HT) (Equation 3 in this paper).

Figure 1. Comparison of the SDG functions considered in this work: the hyperbolic tangent decouples the size dependency in the small and large size domains. a) linear and b) logarithmic size scale.

3. Results and Discussion

Four SDG models are applied: QPL and exponential, as well as HT and E-HT. HT was also considered as it has the same number of parameters as model QPL and exponential. Two parameter estimations were carried out for all model structures: with and without using the FBRM count data. Although the objective function values differ depending on the usage of FBRM data, the general conclusions remain unchanged. Namely, amongst the three parameter SDG models the QPL one gave the worst calibration performance. Exponential model gave an order of magnitude lower objective function value, whereas another order of magnitude decrease was achieved by the hyperbolic tangent model. For these models, the difference in achievable performance is explained with the shape of relative growth rate curves (see Figure 1). Extending the tangent hyperbolic model HT to E-HT, improved the CSD shape fit, but less prominent objective function value decrease

is achieved. The same trends exist in the case of validation experiments, which is a good indication that there is no overfitting. These results underline the applicability of hyperbolic tangent function family as SDG model. Table 2 lists the kinetic parameters estimated using the FBRM count data in the proposed way. The first observation is that the width of confidence intervals (CI) became better i.e. less narrow for the QPL and exponential models and significantly narrower for the proposed SDG formula (E-HT). It is hypothesized that in the case of using E-HT formula, the FBRM count term contributed to de-coupling of nucleation and growth kinetics, which reduced greatly the inter-correlation of parameters between these mechanisms.

Table 2. Parameter estimation results for the considered model structures with the 95 % CI limits for the parameter estimation using the FBRM data.

Parameter	(units)	Nominal parameters (\pm confidence interval limits)			
		QPL	Exponential	HT	E-HT

γ_d	(-)	$0.5 \pm 2.5 \cdot 10^{-8}$	$1 \pm 5.9 \cdot 10^{-3}$	$0.34 \pm 8.8 \cdot 10^{-2}$	1 ± 237.6

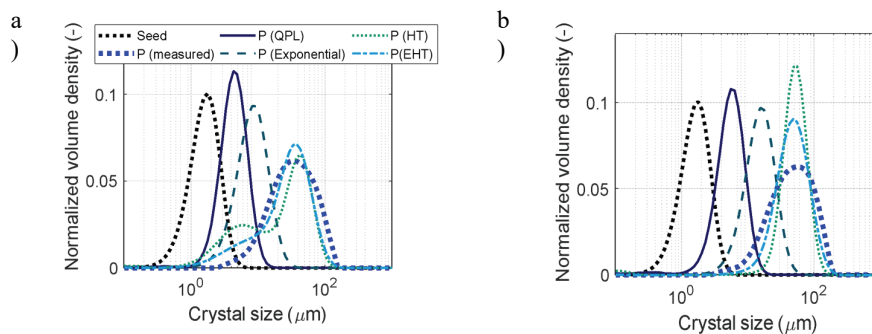

Figure 2. Model performance to predict the product CSD denoted as P (model) in the validation simulations (not used in the kinetic parameter estimations). a) Validation expt. #1 b) Validation expt. #1 (see table 1 for details).

Figure 2 presents the model performance for the two validation experiments for product CSD prediction. According to both validation simulations the QPL model showed minimal size increase throughout the process, whereas the exponential model predicted slightly larger product sizes, but still much below the measured values. Both hyperbolic tangent models captured the mean product size reasonably. The width of the distribution

given by the E-HT is broader than the HT, but still narrower than the measured product CSD, while the shape could be captured better. In addition to the model simplifications, the Mastersizer's tendency to overestimate the width of the CSD should also be mentioned as a contributing factor to this mismatch (Rønneest *et al.*, 2012).

4. Conclusions

The paper demonstrated a workflow for the crystallization process model development and calibration of a commercial API, Compound A. This model was needed for executing numerical experimentations and simulation-based DoE that permits to analyse and design the Compound A crystallization process with less experimental burden. The model developed in this work introduced two novelties: 1) new SDG formulation and 2) integration of crystal count in the objective function for parameter estimation shrinking the confidence hyper ellipsoid during parameter estimation and enhancing the search process, while making FBRM a mainstream PAT tool for modelling purposes.

The traditionally applied growth rate models are compared with a newly proposed hyperbolic tangent based equation, that is well-known in the field of crystal breakage and shown superior ability to capture the experimentally measured CSD dynamics in this case. Additionally, a graphical user interface (GUI) is developed that enables quick and coding-free (standalone application) process simulation for the batch cooling crystallization processes. This is not only suitable to simulate the crystallization of Compound A, but by changing the appropriate kinetic and thermodynamic parameters it can be used as a generic, simple to use cooling batch crystallization simulator.

Abstract

Sustainable and green industrial chemical processes enhance the profitability, production of merchandises, inherent safety, and minimize the generation of waste. Among them, profitability, and especially inherent safety, can be characterized indirectly through the controllability and flexibility of the processes. Although several indices have been proposed to measure these parameters, the flexibility index and the controllability measured by the condition number stand out. However, these two indicators are usually quantified individually, losing information inherent to the synergies by the link between profitability and process safety. The present work aims to find a quantitative parameter, similar to the condition number, to simultaneously measure the flexibility and controllability of the processes with the purpose of generating a simple measurement of the inherent safety of the processes. This indicator can be applied for designing processes enhancing their profitable, green and sustainable dimensions. To show the advantages of the use of the metric proposed, the results binary and multicomponent reactive distillation are evaluated, showing that the condition number measuring controllability at low frequencies can be related to flexibility. This results in a double indicator which can measure both controllability and flexibility simultaneously.

Keywords: Controllability, Condition Number, Flexibility, Green Chemistry.

1. Introduction

Nowadays sustainable and efficient processes are needed in the chemical industry to address the great challenges of resource depletion, energy consumption and environmental impact. Therefore, the identification, design, and development of appropriate processes are important. For the industry to remain competitive (Wang, et al., 2019), the development of sustainable and efficient processes, along with inherent safety is a primary objective. In order to achieve this, safe and reliable systems are required (Cheng & Zhao, 2019). Indirect measures of safety are the controllability and the flexibility. Therefore, the evaluation of the controllability of the system, together with the evaluation of the process flexibility can indicate the safety level of the process. An integrated indicator including these aspects, would facilitate the optimization of the

process at the design stage. Achieving that the indirect indicator provides values of inherent safety would favor the objective of having a more effective risk management, since actions can be taken to avoid accidents instead of mitigating their consequences (Medina-Herrera et al., 2019).

Inherent safety has gained popularity thanks to its ability to assess the level of safety of the plant at an early stage of design by presenting four main objectives: intensification, substitution, attenuation and limitation. Considerations of these principles allow the designer to give safety aspects the same importance than economic and environmental parameters, thus safety is considered as a key variable design, rather than a late occurrence (Vázquez et al., 2019). Having an indicator that can assess both the controllability of the system and its flexibility at the same time also contributes to the fact that the indicator can indirectly measure objectives of the metrics of green chemistry and the circular economy, such as inherent safety.

Processes designed from a control perspective to respond fast to disturbances, being less disturbed from approach of flexibility, influence the process safety. Control and flexibility are parameters with a great impact on the design of processes. Although they seem similar aspects, control and flexibility correspond to different technical concepts. On one hand, the condition number, is a method commonly used to measure control, it has to do with the stability and quality of the process in dynamic state. On the other hand, flexibility is related to the fact that the operation of the process is viable in different operating conditions in state stationary. The condition number and the minimum singular value provide important information in the theoretical control for a given frequency in a transfer function matrix in a multivariate system, it is the relationship between the maximum and minimum singular value, and represents the sensitivity of the system to the uncertainty that is presented in the input. Therefore, it is possible to have the condition number as a reference to measure the flexibility of a process (Cabrera et al., 2017).

This work proposes an indicator that relates flexibility with controllability. Having a single indicator, it would be simpler to implement in optimization processes, and obtain cheaper processes as a result, and at the same time ensure compliance with environmental and safety indicators.

2. Methodology

The study of the condition number as a quantitative measure of the flexibility of the processes, was carried out in five different processes. The three of these processes are the production of solar grade silicon (0.99999 mole fraction) following the (a) Siemens, (b) Union Carbide, and (c) Hybrid processes, as reported by Ramírez-Márquez et al. (2019). To meet the performance of 2000 t/y, the processes are fed with the components and quantities with 532.32 kg/h of SiO₂ and 369.84 kg/h of Carbon. These processes, shown Figure 1, were studied due to their complexity. In addition, two separation processes by means of distillation columns are studied, a binary distillation column that separates pentane and hexane (0.98 mole fraction), Figure 1 (d), and the intensified Petlyuk scheme to separate propane-butane-pentane (0.99 mole fraction in dome and bottom, 0.98 mole fraction in side stream), Figure 1 (e).

In Figure 2 (a) we can see the methodology for calculating the flexibility index. Equations [1] and [2] correspond to inscribing the largest proposed polytope within the feasible region, then the flexibility index is equal to the distance between the vertex (V) and the nominal operating point [0] (Di Pretoro et al., 2019). Furthermore, in Figure 2 (b) we can see the methodology for calculating the condition number (Cabrera et al.,

2017). Once both the flexibility index and the condition number have been calculated, it will be possible to see the trend of both and solve if there is a guideline that both in complex processes and in simple processes the condition number can be used as a qualitative measure of the process flexibility.

Fig. 1 a) Flowsheet of the Siemens Facility, b) Flowsheet of the Union Carbide Facility, c) Flowsheet of the Hybrid Facility, d) Flowsheet of the binary distillation column, e) Flowsheet of the Petlyuk distillation column.

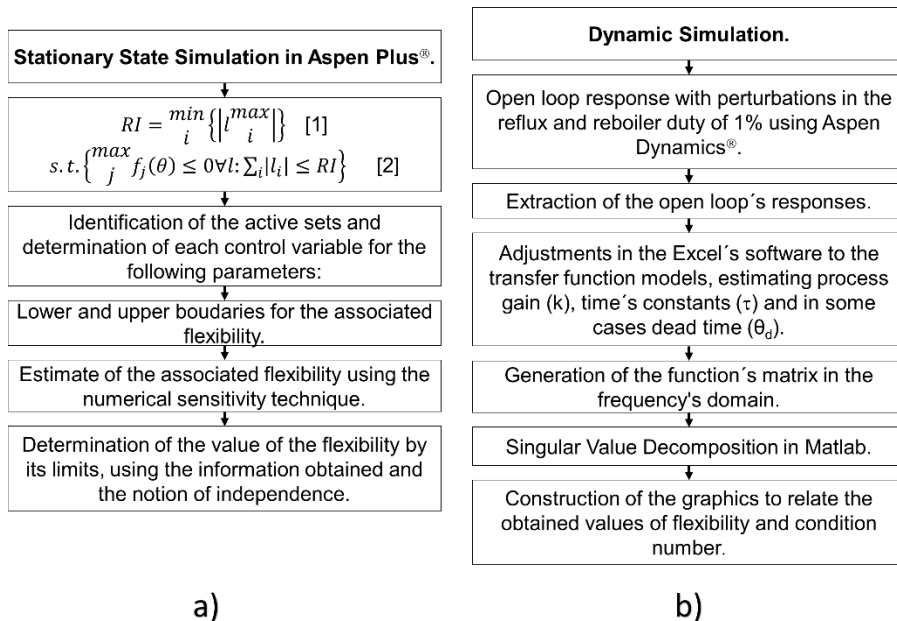

Fig. 2. a) Methodology to calculate the flexibility index. b) Methodology to calculate condition number.

3. Results

The results are shown in Figure 3. It can be observed that, in each one of the processes studied at low frequencies ($w \leq 1$), there is a very similar behavior trend between the condition number and the flexibility index. It is evident that with increasing frequency this trend changes, to the extent that at very large frequencies ($w \geq 1000$), the condition number is not useful as a quantitative measure of the flexibility of a process.

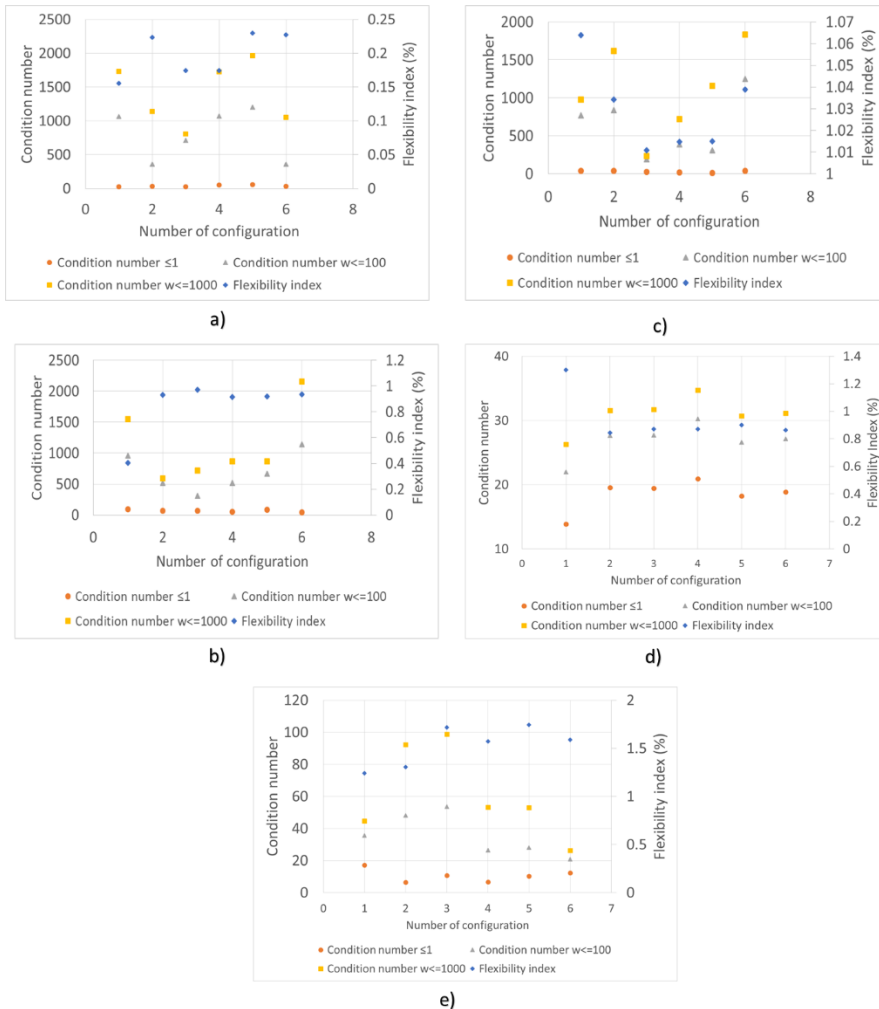

Fig. 3 a) Results of the Siemens Facility, b) Results of the Union Carbide Facility, c) Results of the Hybrid Facility, d) Results of the binary distillation column, e) Results of the Petlyuk distillation column.

The results of the processes for obtaining silicon are shown in Figure 3 (a-c). We can observe that at low and medium frequencies ($w \leq 1000$) the condition numbers have a behavior antagonistic to the flexibility index, and it is precisely the trend that we wanted to observe. That is, at low condition numbers (which represent systems with better control properties), the value of flexibility is greater (that is, processes that support a

variety of changes in steady state). The similar trend is observed in Figure 3 (d) and (e), where for the binary distillation columns and Petlyuk distillation column, at low frequencies ($w \leq 1$), the condition number can be considered as a quantitative measure of the flexibility of each of the processes. Therefore, we can observe that the flexibility has to do with the issue of ensuring a viable steady state operation under a variety of operating conditions, while controllability has to do with the quality and stability of the dynamic response of the process. This provides a suitable index for the processes control and the flexibility could be the condition number.

Table 1 shows the design parameters for the separation within the Siemens Process, such as the values of the condition number and the flexibility index. A strong relationship in the design parameters of the most relevant equipment in the processes it can be observed. In other words, the larger the height of a column or its diameter, the better control properties the process has, and subsequently, also better performance in the flexibility of the process. With parameters such as reboiler duty and reflux ratio, a similar behavior is displayed if the value is higher, a disturbance could represent such a small percentage that it would not alter the process. The performance of each configuration studied was maintained.

Table 1. Results of flexibility index, condition number (different frequencies), and other parameters for the Siemens Process.

Point	Flexibility index	Condition number	Condition number $w \leq 1000$	Stages	Reflux	Reboiler duty [kW]	Diameter [m]
1	0.155	26.97	1729.96	40	29.9	1219.94	0.89
2	0.223	31.42	1141.48	99	29.9	1220.89	0.89
3	0.174	24.58	805.37	22	71.2	2951.68	4.75
4	0.174	55.22	1727.97	39	30.0	1223.33	3.59
5	0.229	62.09	1967.96	50	39.4	1615.49	2.55
6	0.227	34.24	1051.27	54	93.5	3884.55	2.45

The results show that in each scenario it is necessary to ensure that the process is controllable in an adequate minimum time, even when the conditions of the process may change. Since the one that takes a long time to stabilize represents more operational costs, as well as not reaching the desired product in the oscillation period, stoichiometry problems would arise, more waste would be generated, resulting in a low safety profile. It would differentiate it from an unstable and unsafe process by not incorporating green metrics is an economical process from a green perspective. Therefore, not well controlled processes produce a lot of waste, consume more materials and energy per unit of finished product, and in some cases lead to a reduction in performance and life cycle. The process must also operate in the most flexible way possible in order to adapt to consumer demands, in this context the use of appropriate operational strategies for the process and control will increase production and increase the performance of high-end products value, in addition to minimizing energy consumption, pollution and, as a direct consequence, environmental impact.

According to the study, the condition number, for these processes, near the steady state has an effect directly proportional to the flexibility behavior. Therefore, it indicates that there is a direct correlation between the condition number and flexibility, and revealing the option that the condition number that can be used as a control objective function. The limitations to highlight of these results, is that for the correlation to be used, it is necessary to work with low frequencies ($w \leq 1$), because with high frequencies ($w \geq 1000$) the behavior changes, however, working with low frequencies does not represent a drawback, since Cabrera, et al. (2017) mention that a real process behaves at such frequencies ($w \leq 1$). Having relatively large diameters in the design, and a high number of stages, becomes a necessary condition, and this can associate controllability with flexibility simultaneously.

4. Conclusions

In this work, a quantitative measure is presented to evaluate simultaneously both the controllability of a process and its flexibility through the condition number. The results show that the condition number serves as a quantitative index of the controllability of the processes, and that in turn, this correlates with flexibility. However, this correlation presents problems when working with relatively high frequencies ($w \geq 1000$), but at low frequencies ($w \leq 1$) it could be a reliable index to measure both items. With the above, this index could be provided that would ensure in future optimizations to have economic, affordable, green and controllable processes, respecting and also enhancing an objective that is currently as important within sustainable processes as safety is. Considering the results obtained, the fusion of the flexibility and controllability indicators in a single indicator for the first time, such as the condition number, seems to be an important advance in the area of green and sustainable process design.

Abstract

This work presents a framework for the optimal control of several sterilization units operating in parallel to satisfy the thermal processing needs of a process motivated by a food industrial facility producing canned fish (Georgiadis et al., 2020). The objective is to consider all relevant control challenges that arise during the operation of the sterilizers such as the required microbial lethality set-point while minimizing the overall processing time. Furthermore, energy consumption minimization is also considered. To this end, a Nonlinear Model Predictive Control (NMPC) framework is developed and applied in multiple sterilization units operating in parallel and sharing the same steam network. A novel reduced order process model is derived and validated. Simulation experiments reveal significant benefits by using the NMPC framework with respect to the availability of shared resources without any loss of performance.

Keywords: optimum control, shared resource efficiency, time-varying operation, nonlinear dynamic optimization

1. Introduction

Today food industries are facing critical challenges in response to consumers' needs, which, in addition to health and safety awareness, demand products with high quality standards. Food process industries that deliver canned products are trying to satisfy the needs of new markets and population sectors, relying on more efficient processes in order to gain an increased market share (Simpson et al., 2019). Thermal processing of canned food is one of the most critical steps in the overall production chain. The duration of the sterilization process is usually dictated by the microbial lethality evolution, which is a product dependent parameter (Alonso et al., 2013). The sterilization process in the food industries must guarantee a uniform processing temperature throughout the cans and achieve the respective lethality levels. In order to systematically improve and optimize the efficiency of the sterilization processes, advanced process control can significantly enhance the efficient operation of the sterilization units by optimizing the utilization of shared resources such as the steam network.

2. Process description and modeling

The process under consideration has been inspired by a large-scale, real-life food industrial facility producing canned fish (Vilas and Alonso, 2018). Sterilization units use steam from a common plant network and their operation is constrained by the availability of this resource (Fig. 1). The cans, which are thermally sterilized, are heated at a specified temperature for a prescribed duration in a retort. The sterilizing duration is defined by a safety index, the microbial lethality evolution.

Figure 1 Overview of the sterilizer unit

Figure 2 Model response vs. experimental data

The operation cycle begins by the insertion of preheated water (~ 60°C) into the sterilizer and recycled to the Plate Heat Exchanger (PHE). The water temperature in the retort increases until it reaches the operation point ($T_{retort} = 110 - 130^{\circ}\text{C}$). Subsequently the temperature is kept constant for a given amount of time and the steam valve in the PHE is closed. After the lethality specifications are met, cold water is introduced to cool down the cans. The duration of the 2-stage cooling is usually 13mins. Initially the inlet water temperature is set at 65°C while the retort temperature is above 75°C and then the inlet water temperature is set at 20°C for the remaining cooling time.

2.1. Modeling of the sterilization process

A reduced order process model is derived and validated against a detailed model using measurements from an industrial plant. The model consists of three parts and was used by the control framework. The aim is to capture the dynamic behavior of the involved subsystems and to derive a model, suitable for control purposes. The governing equations for the can temperature (T_{can}) evolution profiles are:

$$\frac{dT_{can}}{dt} = Bi_2(T_{w,R} - (c_0 + c_1 + c_2)(1 + q/2)) - Bi_1(c_0(1 + q/2) - T_{w,R}) + 2MBi_R(T_{w,R} - (1 + q)(c_0 + c_1/2 + c_2/3)) \tag{1}$$

$$q = \frac{Bi_R(T_{w,R} / (c_0 + c_1/2 + c_2/3) - 1)}{2 + Bi_R} \tag{2}$$

$$Bi_R = \frac{h_R R}{k}, Bi_1 = \frac{h_{Z1} L}{k}, Bi_2 = \frac{h_{Z2} L}{k}, M = \frac{L^2}{R^2} \tag{3}$$

where $T_{w,R}$ is the retort water temperature, k is the thermal conductivity, L and R are the length and the radius, $h_{(R,Z1,Z2)}$ is the convective heat transfer coefficient right, top and

bottom of the can. In each time step c_o , c_1 and c_2 have to be found from the solution of the following 3x3 system of nonlinear algebraic equations:

$$T_{can} = (c_o + c_1 / 2 + c_2 / 3)(1 + q / 2) \quad (4a)$$

$$c_1(1 + q / 2) = Bi_1(c_o(1 + q / 2) - T_A) \quad (4b)$$

$$(c_1 + 2c_2)(1 + q / 2) = Bi_2(T_A - (c_o + c_1 + c_2)(1 + q / 2)) \quad (4c)$$

The integration of a single ordinary differential equation with a system of three algebraic equations describes the evolution of a two-dimensional temperature profile in the can.

2.1.1. Parallel Plate Heat Exchanger Model (PPHE)

Let us assume a parallel plate heat exchanger (PPHE) with mass flow rate of water M_w and mass flow rate of steam M_s . A steady state problem for the countercurrent parallel heat exchanger is considered. The equations can be integrated in closed form and scaled back to the whole heat exchanger to give:

$$Q = M_s c_{ps} (T_{s,in} - T_{s,out}) \quad (5)$$

$$Q = M_w c_{pw} (T_{w,out} - T_{w,in}) \quad (6)$$

$$Q = UA(T_{w,out} - T_{s,in} - (T_{w,in} - T_{s,out})) / \ln((T_{w,out} - T_{s,in}) / (T_{w,in} - T_{s,out})) \quad (7)$$

where Q is the rate of heat transferred in the PPHE. The heat transfer coefficient and the (one side) surface area of the plate is U and A respectively. Q can be eliminated between the above equations to leave with a system of two equations with two unknowns (the outlet temperatures). The system of Eq.(4) - (6) is highly non-linear and can be replaced by the linear system:

$$T_{w,out} = \frac{T_{w,in} + p2 \left((1 - p1) T_{s,in} - T_{w,in} \right)}{1 - p1p2} \quad (8)$$

$$T_{s,out} = T_{w,in} + p1 \left(T_{s,in} - T_{w,out} \right) \quad (9)$$

$$p1 = \exp \left(UA \left(\frac{1}{M_w c_{pw}} - \frac{1}{M_s c_{ps}} \right) \right) \quad (10)$$

$$p2 = \frac{M_s c_{ps}}{M_w c_{pw}} \quad (11)$$

For given inlet temperatures to PHE the outlet temperatures are computed by Eq. (8) and (9) and then Q by Eq. (5).

2.1.2. Sterilizer Model

The heat balance in the sterilizer is the leading equation of the model. The water temperature $T_{w,R}$ is dominated by the equation:

$$M_{wR} c_{pw} \frac{dT_{w,R}}{dt} = Q_{PHE} - Q_{can} - Q_{env} \quad (12)$$

$$Q_{PHE} = M_s c_{ps} (T_{s,in} - T_{s,out}) \quad (12a)$$

$$Q_{can} = n_{can} M_{can} c_{p,can} \frac{dT_{can}}{dt} \quad (12b)$$

$$Q_{env} = h_c A_c (T_{env} - T_{wR}) \quad (11c)$$

where M_{wR} is the water mass in sterilizer, Q_{can} is the heat adsorbed by the cans and Q_{env} is a simple loss term where h_c , A_c are the corresponding heat transfer coefficient and the metal cover area of the retort respectively and T_{env} is the environment temperature. The total model consists of the main Eq. (12) which must be solved simultaneously to the can heating submodel (one ODE and three algebraic equations) and to the PPHE model (two algebraic equations). Everything else is post processing (e.g. lethality, color) or control actions (e.g. steam valve) of the core model. Model predictions are in excellent agreement with experimental results (Vilas and Alonso, 2018) as illustrated in Fig. 2.

3. Control framework

To optimize the operation of the sterilization processes, advanced control can provide significant benefits by satisfying all operating constraints and managing the availability of shared resources such as the steam network. Thus, a number of time-varying parameters must be taken into account along with dynamic changes, which occur as multiple sterilizers operate in parallel. The control objective is to address, in a centralized manner, several challenging control issues that arise during the parallel operation of the sterilizers and to monitor and evaluate their performance at real time. More specifically, the operational objectives are to achieve the required microbial lethality set-point for each batch of cans while minimizing the overall processing time to avoid quality deterioration of the canned food. Furthermore, it is crucial to minimize energy consumption during the heat-up stage of the sterilization process. To achieve these objectives a Nonlinear Model Predictive Control (NMPC) framework is proposed and demonstrated in this problem involving 16 units operating in parallel.

NMPC computes online a finite-time constrained optimization problem over a prediction horizon (T_p), using the current state of the process as the initial state. The optimization yields an optimal control sequence ($u_k \dots u_{k+N_c}$) over a control horizon (T_c), which is partitioned into N_c intervals and only the first control action (u_k) for the current time is applied to the system. We consider the following formulation of the NMPC problem:

$$\min J = \sum_{j=1}^{N_p} (\hat{y}_{k+j} - y_{sp,k+j})^T QR (\hat{y}_{k+j} - y_{sp,k+j}) + \sum_{l=0}^{N_c-1} \Delta u_{k+l}^T RI \Delta u_{k+l} \quad (13)$$

$$\text{s.t.: } \dot{x} = f_d(x, u), \quad y = g(x, u) \quad (14a)$$

$$e_k = (y_{pred} - y_{meas})_k \quad (14b)$$

$$\hat{y}_{k+j} = y_{pred,k+j} + e_k \quad (14c)$$

$$u^L \leq u(t)_{k+j} \leq u^U, y^L \leq y(t)_{k+j} \leq y^U \quad (14d)$$

where u, y, x are the manipulated, the controlled and the state variables, $y_{pred}, y_{meas}, y_{sp}$ are the predicted, the measured variables and the desired set-points and QR, RI are the output tracking and the input move weighing matrices. The minimization of functional J (eq. 13) is also subject to constraints of u, x and y . The controlled variables are the retort temperature ($T_{w,R}$) and the lethality (F_0) while the manipulated variable is the steam

flow. A centralized approach is applied for the control of the sterilization process that uses the nonlinear model described by Eq. (1)-(12).

4. Operation analysis and discussion of results

A set of scenarios where multiple sterilizers operate concurrently is explored. The sole purpose of this study is to evaluate the flexibility of the NMPC framework under various conditions and different operation requirements. We assume that each sterilizer processes the same amount and type of cans. A nonlinear programming problem (NLP) is solved at each iteration while the NMPC parameters are $T_c=1$, $T_p=2$, $t_s=60$ sec. The framework is developed at the Mathworks MATLAB environment. The optimization problem is solved using a Sequential Quadratic Programming (SQP) method with constraint tolerance $1e-6$ and step tolerance $1e-8$. In order to explore the response of the NMPC architecture a scenario where three sterilizers start to operate concurrently is presented.

Fig. 3 presents the retort temperature profile while Fig. 4 illustrates the duration of batches at each sterilizer. The steam flow rate is adjusted according to the number of sterilizers that are concurrently employed during the heat-up stage. It is clearly illustrated that the heat-up time is affected accordingly when multiple sterilizers are activated. For example, the slope of the 2nd (yellow) sterilizer changes when the 1st sterilizer reaches the heat maintenance stage and when the 3rd sterilizer enters the heat-up stage.

Figure 3 Operation of three sterilizers that start to heat-up concurrently

Figure 4 Batch timing for the three sterilizers

Finally, Fig 5 shows the distribution of steam between the 3 sterilizers. Initially the 1st sterilizer operates. The 2nd sterilizer starts to heat-up at $t=8\text{min}$ and the steam is shared equally between the 2 sterilizers. Finally, the 3rd sterilizer is activated at $t=30\text{min}$ and the shared steam is further reduced between the 3 sterilizers. At $t=50\text{min}$ the 1st sterilizer reaches the temperature target and the steam requirement is reduced. After an hour only the 3rd sterilizer is still operating at the heat-up stage and is allowed to use the maximum steam flow rate from the network. Overall, it can be seen that the steam is adjusted according to the operating stage of the sterilizers.

Figure 5 Steam flow rate distribution among the three sterilizers

The sterilization time of the processing units is dynamically adjusted over time according to the availability of steam. The operation follows the optimal temperature profiles, thus ensuring that the required degree of sterilization is met, and the cost is minimized.

5. Conclusions

An NMPC framework that relies on a reduced order model is developed and validated against realistic conditions for the sterilization units of a canned food process. The predictive power of the model is clearly illustrated to capture the dynamic behaviour of the parallel plate heat exchangers, the retort temperature, the canned food product temperature evolution and the effect of food temperature on safety and quality. A case study used to illustrate the applicability and efficiency of the proposed NMPC approach. The Results illustrate that the optimal operation of the sterilizers is achieved under tight operating constraints and taking into account the availability of steam.

Design and control of triple-column pressure swing distillation process for acetone-methanol-hexane separation

Tan Akinciturk , Devrim B. Kaymak*

Department of Chemical Engineering, Istanbul Technical University, 34469 Maslak, Istanbul

Abstract

The mixture of acetone-methanol-hexane is used in the industry as a solvent, an extraction agent and for cleaning purposes. This mixture belongs to the topological class of 3.1-2 in Serafimov's classification with three binary and one ternary minimum boiling homogeneous azeotropes (Shen et al., 2016). To our knowledge, steady-state design studies for this class of azeotropes are very rare, and there is no dynamic control study in the literature. In this study, a triple-column pressure swing distillation (PSD) process is designed for separation of three components with a 99.9 mole % purity. The process is optimized based on total annual cost (TAC), and a plant-wide control structure is designed for the optimal steady-state case. The control structure including inferential temperature controllers shows an effective base-level regulatory control with acceptable offsets in compositions. This work hereby demonstrates that a ternary mixture which forms three binary and one ternary azeotropes can be separated using a triple-column PSD process, and this process system can be controlled robustly using a decentralized control structure.

Keywords: Ternary azeotropes, Pressure-swing distillation, Process design, Dynamic control.

1. Introduction

Distillation is the most attractive method of separation that is based on vapor-liquid equilibrium (VLE), and studied widely in the literature. In recent years, the interest has shifted to more complex, multicomponent distillation systems with non-ideal vapor-liquid equilibrium. Especially, distillation boundaries that are imposed by azeotropic mixtures are challenging, and require complex distillation strategies.

Pressure swing distillation (PSD) is a method that makes use of the pressure sensitivity of azeotropic mixtures for separation. Thus, by designing more than one column operating at significantly different pressures, the distillation boundaries are shifted so that the separation can be achieved. There is an extensive library on the separation of binary azeotropic mixtures using PSD processes in the literature (Luyben and Chien, 2010). Nowadays, the interest of academia is on the separation of ternary mixtures including more than one binary azeotropes and/or ternary azeotropes. Although the non-ideal thermodynamics and distillation concepts for multicomponent azeotropic mixtures have been discussed since the nineties (Doherty and Malone, 2001; Stichlmair and Fair, 1998), the papers on rigorous design and control of triple-column PSD processes are started to be published after the second half of 2010's, and there are still a very small number of papers in the literature.

Separation of acetonitrile-methanol-benzene mixture which has three binary azeotropes has been investigated by three papers (Zhu et al., 2017; Luyben, 2017; Zhang et al., 2019). Among these studies, Luyben (2017) focused on the process control aspects, while other studies dealt only with steady-state design. On the other hand, Wang et al. (2019a, 2019b) studied the separation of tetrahydrofuran-ethanol-water mixture. They compared alternative PSD sequences for the ternary mixture having three binary azeotropes.

In none of the aforementioned papers, the studied mixtures form ternary azeotropes. Nevertheless, to our knowledge, there are only two papers studied the separation of mixtures with ternary azeotropes (Cui et al., 2019; Guang et al., 2019). In the first study, benzene-isopropanol-water mixture has been investigated, while the second study focused on diisopropyl ether-isopropanol-water mixture. Both mixtures form a heterogeneous ternary azeotrope besides two homogeneous and one heterogeneous binary azeotropes. Although these papers discussed the steady-state design of triple-column PSD processes, they did not investigate the controllability of the proposed configurations.

On the other hand, Gmehling and Böltz (1996) presented in their experimental work that acetone, methanol and hexane form a ternary azeotrope besides three binary azeotropes. This mixture is used in laboratories for several purposes such as a solvent for chromatography, an extraction agent and for cleaning purposes. Although there is a patent by Forman (1952) where four columns are used for lab scale separation of this mixture, there is no integrated design and control study of this mixture in the open literature. In this study, as an alternative to the above-mentioned patent, a novel triple-column PSD process is proposed based on ternary diagram analysis. Furthermore, a robust plant-wide control structure is developed and tested for the optimum design of the proposed flowsheet.

2. Process Studied and Methods

The feed flowrate of the process is 100 kmol/h with mole fractions of 47 % methanol, 43 % acetone and 10 % hexane. The desired product specifications are 99.9 mole % for each component. First, ternary diagrams at different operating pressures are used to develop a triple-column PSD process flowsheet. Several thermodynamic model results are investigated and compared with the experimental data in the literature. Since the results of UNIFAC model are in coherence with the experimental work of Gmehling and Böltz (1996), this thermodynamic model is used in this study. Then, the steady-state simulations are conducted by Aspen Plus. The product purities are achieved using the “Design Spec/Vary” feature of the simulator. The flowsheet is optimized based on total annual cost (TAC). A sequential iterative procedure is used for the cost evaluation of the triple-column PSD process. Minimal TAC is determined by sequentially changing the values of variables such as recycle flowrate, recycle feed location for the first distillation column, and number of trays and feed tray locations for each column. The values of these variables when all the local minima are combined are presented as the best case. Equations used for capital cost calculations are taken from Douglas (1988) and Dimian (2003). Data for operating costs are found from Luyben (2013) and Patrascu et al. (2016). Next, plant-wide control structures are designed for the optimized steady-state design. Level and pressure controllers are used for inventory control purposes. Feed flowrate acting as the production rate handle is manipulated by a flow controller. PI controllers are used for temperature and/or composition control. A dead time of one minute for temperature, and three minutes for composition loops is included

into these loops. Steepest slope method is used to decide the tray location in case of temperature control. These loops are tuned by Auto Tune Variation (ATV) test following Skogestad's sequential loop method (Hovd and Skogestad, 1994). Controller parameters are calculated using Tyreus-Luyben parameter settings. All control valves are designed half-open at the nominal conditions. Finally, the robustness of the proposed control structure is tested against disturbances in feed flowrate and composition.

3. Results and Discussion

3.1. Steady-State Design

In Figure 3.1, ternary diagrams of acetone-methanol-hexane mixture are examined at two different pressures. The dashed curve represents the distillation boundary at 1 bar, while the solid curve represents the distillation boundary at 5 bar. It is seen that the distillation boundaries differ considerably as pressure changes. The F point is the composition of fresh feed stream. It is combined with the distillate of the third distillation column, which is recycled back to the first column, using a straight line on the figure. It means that the composition of the total feed into the first distillation column is anywhere on this line, shown with F^1 .

Figure 3.1: Ternary diagram for acetone-methanol-hexane

As dictated by Lever Rule, the feed, bottoms and distillate compositions of a distillation column should lie on a straight line, and this line should stay within the distillation boundary. Based on this idea, for each distillation column, a straight line starting from 99.9% pure component is connected to the point representing the column feed, and then elongated up to the composition of distillate staying within the corresponding distillation boundary.

As the result, a triple-column PSD flowsheet is developed with operating pressure of 5 bar, 1 bar and 5 bar, respectively. In this sequence; acetone, methanol and hexane are drawn from the bottoms of distillation columns, respectively. Table 3.1 shows the economic optimization results for this process configuration.

Table 3.1 : Summary of variables and costs of optimal case			
	C1	C2	C3
Number of Trays	52	52	8
Recycle Location	30	-	-
Feed Location	4	4	4
Reflux Ratio	3.02	0.03	0.23
Diameter (m)	2.84	1.42	2.00
Recycle (kmol/h)	450	-	-
Fixed Column Cost (10^3 \$)		1,778.5	
Fixed Heat Exchanger Cost (10^3 \$)		1,776.1	
Operating Cost (10^3 \$/yr)		5,765.8	
Total Annual Cost (10^3 \$/yr)		6,947.3	

3.2. Plant-wide Control Design

Several control structures are evaluated for this process, and the results of the one with the best performance are given in this study. Figure 3.2 shows the proposed control structure including inferential temperature controllers with reflux to feed (R/F) ratio. The location of the trays to control the temperature is decided via steepest slope analysis as controlling the temperature on these stages would end up with a more robust composition control. As the result of the analysis, the temperature on stage 44 is selected to be controlled for first and second distillation columns, while the temperature on stage 5 is chosen for the third distillation column.

Figure 3.2: Proposed Control Structure

Dynamic simulations are run in Aspen Dynamics, and the performance of control structures are tested by applying two types of disturbances. Response of the control structure for $\pm 20\%$ throughput change is illustrated in Figure 3.3. The solid line represents positive change and the dashed line represents the negative change. It is seen that temperatures settle down into their set-points easily. Additionally, the overshoots of temperatures are very small for all columns. Since inferential temperature controllers are used, an offset in compositions is expected. However, as seen from the figure, the composition of hexane recovers back to the steady-state, while there are only very small offset in compositions of acetone and methanol.

An improvement is done by adding composition controllers in the control structure. As the result, the temperature-composition cascade controllers eliminate the offset in compositions. However, it is observed that the settle time is approximately twice of the time spent with temperature only controllers. Additionally composition control requires analyzers, which are expensive equipment with hefty maintenance processes. Since the offset obtained with the inferential temperature controllers is tolerable, it is selected as the proposed control structure in this study.

Figure 3.3: Response of control structure for feed flowrate changes

Second disturbance given to the system is in feed composition. The magnitude of composition changes in the feed stream is selected based on the distillation boundaries of ternary diagrams. The fractions are first changed to 0.42, 0.43 and 0.15 for acetone, methanol and hexane, respectively. Then, the feed composition is changed to 0.45, 0.5 and 0.05 for acetone, methanol and hexane, respectively.

The dynamic response for the feed composition changes is illustrated in Figure 3.4. The solid line represents the first composition set, while the dashed line represents the second disturbance. Similar to the throughput change results, the temperatures settle down into their set-points easily. In addition, hexane composition does not show any offset, while there are small offsets in the compositions of acetone and methanol. Compared to the responses of throughput disturbance, the response here is more sluggish. However, offsets of the product purities are smaller. These results illustrate that the proposed control structure is capable of handling both disturbances, and provides an effective base-level regulatory control.

Figure 3.4: Response of control structure for feed composition changes

4. Conclusions

This work covers the steady-state design, cost optimization and process control of a triple-column PSD process for the separation of acetone-methanol-hexane mixture. Ternary diagrams reveal that there is significant change in distillation boundaries with the change in operating pressure for the studied process. A triple-column PSD process is designed based on ternary diagrams, where the columns operate at 5-1-5 bar,

respectively. Total annual cost of the steady-state process with 99.9% product purity is optimized using Aspen Plus. The optimal TAC of this process configuration is calculated to be 6,947,319 \$. Different control structures are designed for the optimal process design. As the result of their responses against disturbances in feed flowrate and composition, it is concluded that the control structure including the inferential temperature controllers with reflux to feed ratio provides the best performance. In the future, additional studies will be carried out in which optimal TAC of this process configuration is further reduced by applying heat integration. Furthermore, the process control of the heat integrated PSD configuration will be studied. Moreover, alternative triple-column PSD process configurations are going to be obtained based on the further analysis of ternary diagrams at different pressures, and their results will be compared in terms of total annual cost and process control aspects.

Design and control of a Biobutanol Purification Process through IBE Fermentation: Basic Design Configuration

Ilayda N. Oksal,^a Devrim B. Kaymak^a

^a*Department of Chemical Engineering, Istanbul Technical University, Istanbul 34469, Turkey*

Abstract

The decrease in energy sources, the increase in energy demand and the environmental concerns have caused to be in search of renewable and cleaner sources compared to fossil fuels. Biobutanol stands out as an alternative which has superior fuel properties compared to other alcohol-based biofuels. In this study, a novel flowsheet configuration providing high-purity alcohol products is developed for isopropanol-butanol-ethanol (IBE) purification process. First, the flowsheet is optimized by minimizing the total annual cost (TAC). Then, a plantwide control structure is designed for the optimized process configuration. The proposed control structure is evaluated by exposing it to disturbances. The results show that the developed control structure provides a robust control for this process configuration.

Keywords: biobutanol purification, plantwide control, IBE fermentation, azeotropic mixture.

1. Introduction

In recent years, renewable energy sources have started to draw attention of industry and academia because of the increasing energy demands and environmental concerns. To meet these demands and concerns, several studies have been conducted on alternative energy sources including biofuels. Among several biofuels, biobutanol comes forward with its advantages such as high energy content, less solubility in water and the ability of blending with gasoline in any percentage without any engine modification. The production of biobutanol by Clostridia microorganisms is called either acetone-butanol-ethanol (ABE) or isopropanol-butanol-ethanol (IBE) fermentation depending on the formation of acetone or isopropanol, respectively. There are several studies in the literature on biobutanol production based on ABE fermentation (Kreamer, et al. 2010, Bildea, et al. 2016, Patraşcu, et al. 2017, Kaymak, 2019). However, biobutanol production by IBE fermentation has some other advantages compared to ABE fermentation. First of all, isopropanol produced by IBE is a more requested by-product compared to acetone, because its energy density is higher than acetone. In addition, acetone has some unwanted corrosive effects on engine parts. On the other hand, downstream processing of IBE is more complex because it includes two homogeneous azeotropes between isopropanol-water and ethanol-water in addition to a heterogeneous azeotrope between butanol-water. Besides, isopropanol and ethanol form a closed-boiling mixture.

As far as we know, there are only a few studies on the downstream processing of IBE fermentation in the literature. In their pioneering study, Pyrgakis et al. developed a process flowsheet including a seven column distillation sequence to purify isopropanol,

butanol and ethanol from IBE fermentation broth (2016). Results of this study show that this process flowsheet has a very large energy consumption. In another study, a separation system including two distillation columns has been proposed for IBE dehydration, but this process flowsheet does not include any distillation sequence to purify isopropanol, butanol and ethanol (Grisales Diaz and Olivar Tost, 2017). Recently, Zhang et al. proposed a six column distillation sequence to obtain high purity biobutanol with lower energy consumption (2020). However, this process does not purify other components of IBE, and obtain them as an isopropanol-ethanol mixture. Furthermore, none of the above mentioned papers studied the controllability of the proposed process flowsheets.

The aim of this study is to develop a novel process configuration to purify all three components of IBE fermentation broth with a lower energy consumption compared to the pioneering study mentioned above. The study proposes also a plantwide control structure for this process configuration, which provides a regulatory level control.

2. Process Studied

As mentioned above, the process flowsheet reported by Pyrgakis and co-workers includes seven distillation columns in total, where they proposed a distillation column operating at 0.05 atm to separate ethanol from isopropanol-water mixture, while the azeotropic mixture of isopropanol-water is separated using a pressure swing distillation system (2016). Since the azeotropic composition of isopropanol-water mixture shifts slightly with the change of operating pressure, the use of pressure swing distillation significantly increases the energy consumption of the process. In addition, the ethanol purification column operating at 0.05 atm requires frozen brine to condense the top stream, which significantly increases the operating cost. On the other hand, the six-column configuration suggested by Zhang and co-workers focuses on obtaining high purity biobutanol, but it does not deal with the purification of isopropanol-ethanol mixture (2020). Since isopropanol and ethanol form a closed-boiling mixture, if they were aiming to separate this mixture, they had to use two more distillation column.

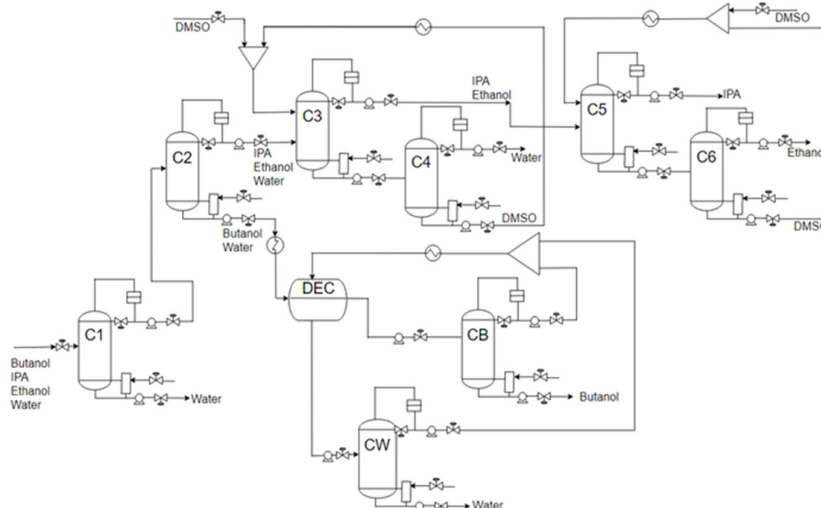

Figure 1. Steady-state design flowsheet

Thus, the configuration proposed here includes eight distillation columns as given in Figure 1 with an aim of purifying all three components of IBE mixture. The flowsheet

consists of a preconcentration column, C1, to take away the excess amount of water, a conventional distillation column, C2, to separate homogeneous and heterogeneous azeotropic mixtures from each other, a decanter-distillation hybrid system, DEC+CB+CW, to separate butanol-water heterogeneous azeotrope, and two extractive distillation systems in series, C3+C4 and C5+C6 to purify water, isopropanol and ethanol, respectively. DMSO is used as the entrainer in extractive distillation part of the process. Version 10.0 of Aspen Plus is used for the simulation of steady-state configuration. The feed properties of the downstream process are obtained from the study of Pyrgakis et al. (2016). The feed flowrate is 31282 kg/h with mass fractions of 0.024, 0.045, 0.003 and 0.928 for isopropanol, butanol, ethanol and water, respectively. NRTL is selected as the suitable thermodynamic model after comparing its results with experimental data. The basic configuration of the IBE purification process discussed in this study is economically optimized using total annual cost (TAC) as the objective function. TAC consists of operating cost and capital cost with a payback period of 3 years. Capital cost includes the cost of column shells, trays, heat exchangers and decanter, while operating cost includes the cost of steam and cooling water. The minimum value of TAC is searched using a sequential iterative optimization method. In this method, design variables such as number of trays and feed tray locations are changed until to find their optimum values minimizing TAC. For each run, “Design Spec/Vary” function of Aspen Plus is used to keep the product purities at their desired values by varying manipulated variables such as reflux ratio and product flowrates. Figure 2 gives the sequential iterative optimization procedure for the extractive distillation part of process.

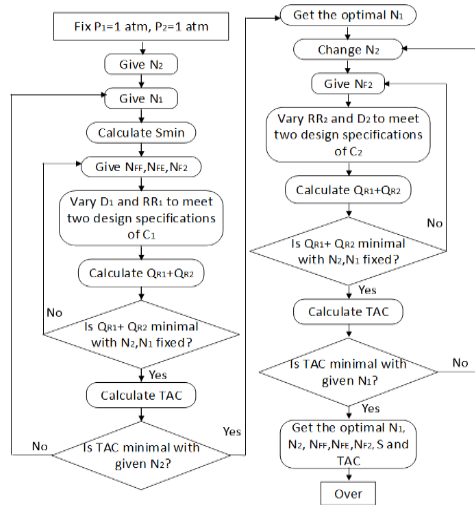

Figure 2. Sequential iterative optimization procedure for extractive distillation

In addition to economic evaluation, CO₂, SO₂ and NO_x emissions are investigated as an environmental sustainable metric, where standard coal is used as the fuel to generate steam. Gas emissions are calculated based on the following formula, where A is the standard coal conversion factor for different gases (2.493, 0.075 and 0.0375), T is the operating time (8000 hr/year), Q_{std} is the calorific value of the standard coal (29307.6 kJ/kg) and Q_R is the reboiler heat duty (Zhang et al. 2020):

$$G_E = A * M_{coal} \tag{1}$$

$$M_{coal} = Q_R * T / Q_{std} \quad (2)$$

3. Results and Discussion

3.1. Steady-State Simulation Results

The design parameters of the optimal case are given in Table 1. N_T , is the total number of trays, while N_F , and $N_{F,S}$ are the feed trays for mixture and entrainer, respectively. P, RR and D_C represent operating pressure, reflux ratio and column diameter. Heat duty of condensers and reboilers are given by Q_C and Q_R , respectively. Results indicate that the total reboiler heat duty of this configuration is 6309 kW. On the other hand, the total reboiler heat duty of seven column configuration of Pyrgakis et al. is 17370 kW, which is reduced to 10990 kW by applying heat integration (2016). Based on these results, it is seen that the basic process configuration proposed here reduces the energy consumption by 42.5%, even compared with the heat-integrated flowsheet of the benchmark study. The total annual cost of this configuration is 1881.7×10^3 \$/yr. In addition, the annual CO_2 , SO_2 , and NO_x emissions of the configuration are calculated as 15455.93, 464.98 and 232.49 t/yr, respectively.

Table 1. Design parameters for basic configuration

	C1	C2	C3	C4	C5	C6	CB	CW	DEC
N_T	27	34	55	24	50	20	19	16	-
N_F	4	6	49	15	35	8	2	2	-
$N_{F,S}$	-	-	5	-	4	-	-	-	-
P (atm)	1	2	1	1	1	1	1	1	1
RR	0.49	3.00	1.11	2.36	2.00	5.00	0.043	0.15	-
D_C (m)	1.01	0.59	0.36	0.47	0.56	0.31	0.61	0.27	1.06
Q_C (kW)	2189	1048	341	368	416	-129	577	153	-
Q_R (kW)	2617	1260	348	398	752	134	606	194	-
TAC (10^3 \$/yr)	706.1	364.6	136.7	96.9	242.8	63.7	191.1	68.5	11.3

3.2. Design of Plantwide Control Structure

Aspen Dynamics is used to run the pressure-driven dynamic simulations. Figure 3 illustrates the plantwide control structure designed for the basic process configuration. A decentralized multi-loop control system employing several single-input and single-output (SISO) feedback controllers are used in this control structure. Feed flowrate acting as the production rate handle is controlled by a flow controller. All reflux drum levels are controlled by manipulating distillate flowrates, while the column base levels are controlled by manipulating bottoms flowrates except C4 and C6. Since these are entrainer recovery columns, their base levels are controlled by arranging make-up streams. Bottoms flowrates of C4 and C6 are manipulated to control the entrainer flowrates to C3 and C5, respectively. For all columns, a feed/reflux ratio controller is used. The operating pressures are controlled by manipulating the heat removal of condensers. The organic and aqueous phase levels in the decanter are controlled by manipulating the corresponding effluent stream flowrates, respectively. The temperatures of the entrainer feed streams are held by manipulating heat duties of HX1 and HX4, respectively. Similarly, the temperatures of decanter feed streams are controlled by arranging the heat duties of HX2 and HX3. Inferential temperature controllers are used to keep the product purities at their

desired values. Tray locations for temperature control are selected based on steepest slope criteria.

All level controllers are P-only with a gain of 2. PI controllers are used for flow, pressure and temperature controls. Temperature controllers with 60 s lag implemented are tuned using ATV test, and controller parameters are calculated using Tyreus-Luyben tuning

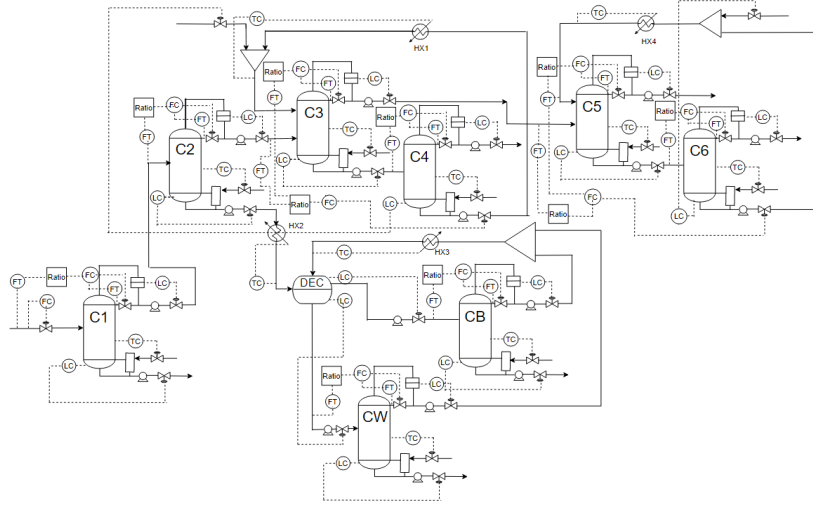

Figure 3. Plantwide control structure

relations. All valves are half opened at the nominal conditions, and the robustness of the control structure is checked against disturbances in feed flowrate and composition.

3.3. Dynamic Simulation Results

Figure 4a illustrates the dynamic response of product purities, controlled tray temperatures and manipulated reboiler heat duties against $\pm 10\%$ changes in production

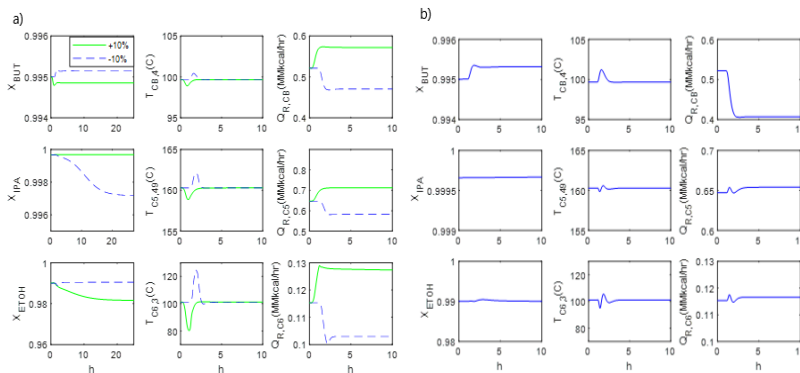

Figure 4: Dynamic response of control structure against disturbances in a) feed flowrate, b) feed composition

rate handle. It is seen that it takes approximately 4 hours for temperatures to recovery back to their set points with proper changes in their manipulated variables. However, it is not the same for product purities. Although the compositions of butanol and isopropanol settle down into close vicinity of their set point, a larger deviation in the ethanol

composition is observed in case of +10% disturbances. It is seen that there are small transient deviations in temperature controllers of butanol and isopropanol purification columns, while transient deviation of temperature controller related to ethanol purification is large. A direct composition control at the top of C6 instead of an inferential temperature control could improve dynamic behaviour ethanol composition.

The response of control structure against a change in feed composition is given in Figure 4b. It is seen that the controlled temperatures recovery back to their set points in less than 5 hours without any big transient deviation. Similarly, the product compositions settle down into their steady-state values with very small deviations in a short transient time.

4. Conclusions

In this study, a new downstream process configuration for isopropanol, butanol and ethanol purification is investigated in terms of design and control. The complex system includes two homogeneous and one heterogeneous binary azeotropes is purified using extractive distillation and decanter-distillation hybrid parts. Optimized process flowsheet reduces the energy consumption significantly compared the benchmark configuration given in the literature. A decentralized plantwide control structure designed for the optimal flowsheet configuration provides an effective base-level regulatory control against disturbance in feed flowrate and composition.

Fault Diagnosis of Electrical Power Systems with Hybrid Quantum-Classical Deep Learning

Akshay Ajagekar, Fengqi You

Cornell University, Ithaca, NY 14853, USA

asa273@cornell.edu

Abstract

In this work we develop hybrid QC-based deep learning models for fault diagnosis of electrical power systems that effectively extract suitable features from time-series data using Conditional restricted Boltzmann machine (CRBM) based network. Generatively training the CRBM network using classical learning techniques can be computationally intensive. Therefore, we train the CRBM network with a learning algorithm assisted by a quantum computer that yields better quality of optimal model parameters of the CRBM network. To demonstrate the applicability of the proposed hybrid QC-based deep learning model, we use a standard case study based on IEEE 14-bus that is commonly used to test concepts and methodologies in power systems. The obtained fault diagnosis results show that the proposed hybrid QC-CRBM fault diagnosis model clearly outperforms state-of-the-art classical fault diagnosis models with low missed detection rates and false alarm rates.

Keywords: Quantum computing, deep learning, power systems, hybrid approach

1. Introduction

Critical problems like blackouts and unwanted variations in voltages and currents can be avoided by taking timely protective actions, which require fast and accurate fault diagnosis approaches (Gao et al., 2015). This need motivates the research and development of new fault detection and diagnosis methods capable of detecting and identifying potential abnormalities in electrical power systems to minimize performance degradation (Shang and You, 2019). Pattern recognition techniques have been widely used in fault detection and diagnosis of power systems owing to their ability of extracting useful features from process signals. The ability of an artificial neural network (ANN) to learn new nonlinear relationships and generalize previously unseen data can be applied to solve complex problems in power systems (Haque and Kashtiban, 2000). Support vector machines (SVMs) due to their ability to use multiple classes and mapping to higher dimensions have also been used in fault diagnosis of power systems (Salat and Osowski, 2004).

Quantum computing (QC) which has attracted widespread attention from the scientific community in recent years, is a field that applies quantum mechanical theories to solve complex problems in a multitude of areas. There are various QC applications in process systems optimization (Ajagekar et al., 2020) and energy systems (Ajagekar and You,

2019). Quantum machine learning has also been gaining traction with technological advancements in quantum hardware (Biamonte et al., 2017) and quantum deep learning algorithms (Wiebe et al., 2014). Fast and accurate fault diagnosis can be achieved by quantum advantages offered by QC in terms of both speed and methods of operations (Ajagekar and You, 2020). Harnessing the complementary strengths of both quantum and classical computers to develop hybrid pattern recognition algorithms and overcome QC's limitations is a promising strategy for fault analysis and diagnosis. The objective of this paper is to develop hybrid QC-based deep learning models for fault diagnosis of electrical power systems that effectively extract suitable features from time-series data using conditional restricted Boltzmann machines (CRBM) based network. The superior feature extraction capabilities of the CRBM are combined with discriminative learning to identify the unknown state of measured data samples with high fidelity. To demonstrate the applicability of the proposed hybrid QC-based deep learning model, we use a standard case study based on IEEE 14-bus system.

2. Background

Restricted Boltzmann machines (RBMs) are generative neural networks used to model the unknown data distributions. CRBM is a nonlinear generative model typically used for time-series data. It uses an undirected RBM model with visible neurons and hidden neurons that represent the observable data and dependencies between the latent variables, respectively (Taylor and Hinton, 2009). In a CRBM, the visible variables \mathbf{v} and binary latent variables \mathbf{h} receive directed connections from neurons in the conditioning layer \mathbf{u} that account for the visible data at the last N timesteps. Model parameters of the CRBM network are the weight and bias vectors associated with its visible, conditioning, and hidden layers. Like the RBM, an undirected weight W_{ij} is assigned to the edge between the i^{th} visible unit and the j^{th} hidden unit of the CRBM network. Similarly, weights A_{ki} and B_{kj} are directed from the k^{th} conditioning unit to the i^{th} visible unit and the j^{th} hidden unit, respectively. The static bias terms b_i and c_j are associated with the visible and hidden units, respectively. A CRBM models the

distribution $p(\mathbf{v}|\mathbf{u})$ by using an RBM network to model \mathbf{v} and using the conditioning vector \mathbf{u} to dynamically calculate the biases of that RBM. The energy function of the CRBM for a joint configuration of visible, hidden, and conditioning units is denoted by $E(\mathbf{v}, \mathbf{h}, \mathbf{u})$ as given in Eq. (1). A joint probability distribution over \mathbf{v} and \mathbf{h} and conditional on \mathbf{u} is assigned by the CRBM model through its energy function and is analogous to the Gibbs or Boltzmann distribution.

$$E(\mathbf{v}, \mathbf{h}, \mathbf{u}) = -\sum_{i \in \text{vis}} b_i v_i - \sum_{j \in \text{hid}} c_j h_j - \sum_{i \in \text{vis}, j \in \text{hid}} w_{ij} v_i h_j - \sum_{k \in \text{cond}, i \in \text{vis}} A_{ki} u_k v_i - \sum_{k \in \text{cond}, j \in \text{hid}} B_{kj} u_k h_j \quad (1)$$

$$\frac{\partial \mathcal{L}}{\partial w_{ij}} = \langle v_i h_j \rangle_{\text{data}} - \langle v_i h_j \rangle_{\text{model}} \quad \left| \quad \frac{\partial \mathcal{L}}{\partial A_{ki}} = \langle u_k v_i \rangle_{\text{data}} - \langle u_k v_i \rangle_{\text{model}} \quad (2)$$

Learning in CRBMs generally involves performing gradient ascent to maximize the log conditional likelihood of the observed or visible data. Computing the exact model expectations could be very computationally expensive. These model expectations can be approximately estimated through the contrastive divergence (CD) learning algorithm performed on a classical computer that is extensively used to train RBM and other energy-based models (Hinton, 2002).

3. Hybrid Quantum-Classical Fault Diagnosis Model

Fault diagnosis tasks largely depend on feature extraction from the measured signals. Energy based models like RBM and CRBM are capable of learning hierarchical representations of measured data and could be used for such feature extraction tasks. CRBMs can effectively model short-term temporal structures and are suitable choices to model multivariate time-series data (Taylor and Hinton, 2009). Implementation and use of the proposed fault diagnosis model involve two sequential phases, offline training, and online fault classification. Primary components of the offline training phase in building the hybrid QC-based fault diagnosis model are quantum generative training followed by discriminative training. Quantum generative training is an automatic unsupervised learning technique that uses unlabeled measured data. The trained fault diagnosis model can then be used to classify the states of the measured data. The amount of training data required to achieve maximum performance depends on the model complexity and can be determined using statistical heuristics.

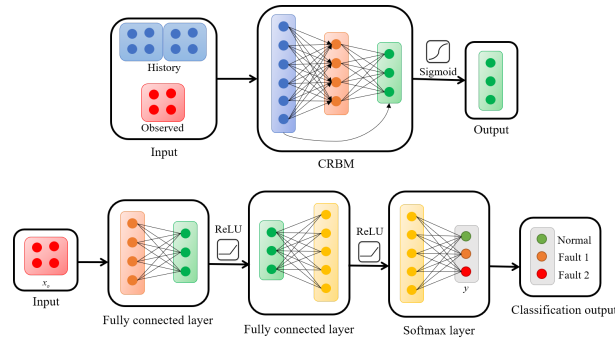

Figure 1. Model architecture of the hybrid quantum-classical fault diagnosis model in generative training and discriminative training phases

As seen in Figure 1, the model architecture consists of several components that include the input, the CRBM network, and the classification network. Input data to the CRBM network consists of two sets of inputs, the observed data samples x_o and the historical data samples x_h . History data sample x_h captures N observed data samples immediately prior to the current observed data sample. CRBMs can effectively capture higher order regularities in the input feature space. For d dimensional observed data samples and their corresponding Nd dimensional conditional data samples, a CRBM network can be constructed with associated weights and dynamic biases as the model parameters.

Weights $A_g \in \mathbb{R}^{Nd \times d}$ and $B_g \in \mathbb{R}^{Nd \times m}$ denote the directed weights between units in the conditional layer and the visible units, and between conditional units and hidden units, respectively, where m latent units are present in the hidden layer. $W_g \in \mathbb{R}^{d \times m}$ represent the weight matrix associated with the connections between the visible and the hidden layer. Additionally, the visible and hidden bias vectors $b_g \in \mathbb{R}^d$ and $c_g \in \mathbb{R}^m$ together with the weights form the CRBM model parameters. The local conditional output probabilities can be easily computed using standard sigmoid function as shown in Eqs. (3) and (4), where $\sigma(x) = 1/(1 + e^{-x})$. With all defined sets of inputs,

outputs, and model parameters, the CRBM network in the hybrid QC-based fault diagnosis model is trained in an unsupervised generative manner. Discriminative training is performed on the classification network and is achieved by attaching classification layers on top of a subgraph of the CRBM network to form the classification network.

$$P(\mathbf{h}=1|\mathbf{v},\mathbf{u})=\sigma(\mathbf{v}\cdot\mathbf{W}_g+\mathbf{u}\cdot\mathbf{B}_g+c_g) \quad (3)$$

$$P(\mathbf{v}=1|\mathbf{h},\mathbf{u})=\sigma(\mathbf{h}\cdot\mathbf{W}_g^T+\mathbf{u}\cdot\mathbf{A}_g+b_g) \quad (4)$$

Energy based models like the CRBM are often trained with the CD algorithm and its variants. However, CD is a biased algorithm that could result in poor estimates of the log conditional likelihood gradients (Carreira-Perpinan and Hinton, 2005). In some cases, CD may not even converge and fail to yield maximum likelihood estimates of the model parameters. To overcome such limitations of the CD algorithm, we train the CRBM network in the hybrid QC-based fault diagnosis model with a new quantum generative training technique proposed in this work. Quantum sampling can be carried out on an adiabatic quantum computing (AQC) device. The use of AQC devices as a sampling engine has been inspired by some of the previous works in pattern recognition (Adachi and Henderson, 2015). Problem formulation step for programming the QPU involves translating the nodes and edges of the objective or energy function to qubits and coupler strengths in the Chimera lattice of the QPU. The energy function is required to take the form of a quadratic unconstrained binary optimization problem. Model expectations required to estimate the log conditional likelihood gradients are calculated through the quantum sampling technique described above. Evidence from experiments conducted with AQC devices has confirmed that AQC devices approximately sample from a Boltzmann distribution under certain conditions (Perdomo-Ortiz et al., 2016). A subgraph of the CRBM network is an RBM network with an energy function given in Eq. (5). Sampling the RBM energy function from an AQC device requires embedding of E_{RBM} on the Chimera lattice of the QPU. As the RBM energy function takes the form of a quadratic unconstrained binary optimization problem, the visible and hidden variables can be mapped as physical qubits on the QPU. Final states of the qubits can be effectively described by a Boltzmann distribution (Benedetti et al., 2016), which allows us to approximately model the joint probability distribution of visible and hidden units. Assuming that N_q samples are drawn from the QPU for the corresponding energy function, the model parameters of the CRBM network are updated based on learning rule in Eq. (10). At every step of the quantum generative training process, the model parameters are updated for every mini-batch of training data to introduce stochasticity in gradient ascent.

$$E_{RBM}(\mathbf{v},\mathbf{h})=-\sum_{i\in vis}b_g^i v_i-\sum_{j\in hid}c_g^j h_j-\sum_{i\in vis,j\in hid}W_g^{ij}v_i h_j \quad (5)$$

$$W_g^{ij}\leftarrow\alpha W_g^{ij}+\varepsilon\left(\left\langle v_i h_j \right\rangle_{data}-\frac{1}{N_q} \sum_{QC} v_i h_j\right) \quad (6)$$

The architecture of the classification network of the hybrid QC-based fault diagnosis model used to detect the state of the measured data is shown in Figure 1. Only observed measurement data and their labels are considered for discriminatively training the

classification network. The bipartite subgraph of the CRBM network with model parameters $W_g \in \mathbb{R}^{d \times m}$ and $c_g \in \mathbb{R}^m$ forms the first fully connected layer of the classification network. An additional fully connected layer is connected to the first layer, where each input neuron is connected to every hidden unit, in order to learn nonlinear combinations of the extracted features. Model parameters of the classification network are fine-tuned and optimized by updating them sequentially, utilizing the gradients of the loss function computed at each step with the backpropagation technique. In supervised learning, categorical cross entropy between the predicted and true labels is minimized. Discriminatively training the classifier network in the hybrid QC-based network yields the model parameters that minimize the total categorical cross entropy loss. The trained model can then be used to predict the unknown state of measured data samples by identifying one of the previously defined faults.

Table 1. Computational results of the IEEE 14-bus case study

Fault Type	Support vector machine		Hybrid QC-based fault diagnosis model	
	MDR (%)	FAR (%)	MDR (%)	FAR (%)
1) ABC / ABCG	0	0	5.3	0
2) AG	5.1	13.78	3.6	1.02
3) BG	0.7	16.4	3.1	3.86
4) CG	12.7	8.89	2.2	6.02
5) AB	0	18.6	8.4	0.91
6) AC	0	22.7	3.5	2.95
7) BC	9.6	7.11	3.3	3.58
8) ABG	0	0	7.3	0
9) ACG	0	0	4.1	0
10) BCG	0	0	10.4	0

4. Computational Results : IEEE 14-Bus System

The performance of the proposed hybrid QC-based fault diagnosis model is evaluated with the IEEE 14-bus system. A MATLAB simulation of this case study is used to collect training and testing data for building and evaluating the hybrid QC-based fault diagnosis model. Three phase voltage data collected at each bus account for the 42 process variables in the IEEE 14-bus simulation. Ten different types of faults are simulated at bus 14 in the case study. We carry out computational experiments with the simulated IEEE 14-bus test system and the proposed hybrid QC-based fault diagnosis model, in order to illustrate the applicability. Quantum generative training of the CRBM network in the hybrid QC-based fault diagnosis model, which is initialized with the above configuration, is performed on an AQC device with a D-Wave 2000Q quantum processor. This QPU provides access to 2,048 qubits and 5,600 couplers that can be used to sample the energy function. We compare the training performance of the CRBM network with CD algorithm (Hinton, 2002). Another instance of the same CRBM network is trained by CD implemented on a classical computer. From the free-energy curves it can be seen that quantum generative training converges much faster than CD learning. This also implies that less computational effort is required by the quantum technique to achieve similar performance. After training the hybrid QC-based fault diagnosis model for the IEEE 14-bus system, we test its fault diagnosis performance by

identifying the state of measured data samples in the testing dataset. Computational results obtained with both methods are reported in Table 1. Symmetrical faults ABC and ABCG that rarely occur in practice are detected by both techniques easily with comparable performance. Severe faults like the line-to-line faults AB, AC, and BC are identified with slightly higher MDRs by using the hybrid QC-based fault diagnosis model for the cases of AB and AC. However, as evident from the computational results, their FARs are significantly low as compared to those of SVM. The MDRs achieved with the hybrid QC-based fault diagnosis model are less than 11%. With low MDRs for both symmetrical and unsymmetrical system faults paired with some of the lowest FARs, the proposed hybrid QC-based fault diagnosis model demonstrates a viable and superior alternative to SVM based fault diagnosis model for the IEEE 14-bus system.

5. Conclusions

In this paper, we proposed a hybrid QC-based fault diagnosis model for analysis and diagnosis of faults in electrical power systems. We performed unsupervised learning of the CRBM network using quantum generative training with quantum sampling facilitated by an AQC device. Discriminative training of the classifier network in the hybrid QC-based fault diagnosis model further allowed us to identify several types of faults from normal operating states. The obtained fault diagnosis results showed that the proposed hybrid QC-based fault diagnosis model clearly outperformed state-of-the-art classical fault diagnosis models.

Data-Driven Robust MPC for Controlled Environment Agriculture

Wei-Han Chen and Fengqi You

Cornell University, Ithaca, New York 14853, USA

wc593@cornell.edu

Abstract

In this work, a data-driven robust model predictive control (DDRMPC) framework for greenhouse climate control is proposed to minimize the total control cost, while minimizing the constraint violation on system states. First, the state-space model of the greenhouse is generated. Next, historical data on weather forecast errors which represent uncertain disturbances are collected. Support vector clustering with weighted generalized intersection kernel is adopted for constructing data-driven uncertainty sets of ambient temperature, solar radiation, and humidity. The historical data information can then be incorporated into robust model predictive control (RMPC). Uncertainty sets constructed in the proposed DDRMPC framework balance between reducing control cost and conservatism. A case study of controlling indoor temperature, CO₂ concentration, and humidity of a semi-closed greenhouse in New York City is presented to demonstrate the advantages of the proposed DDRMPC framework for greenhouse climate control over rule-based control, certainty-equivalent model predictive control, and RMPC strategies.

Keywords: Model predictive control, greenhouse climate control, uncertainty.

1. Introduction

The purpose of greenhouse is to protect plants from outdoor weather (Bakker et al., 1995). Temperature, CO₂ concentration, and humidity are the most important factors of the greenhouse's indoor climate that should be carefully regulated in controlled environment agriculture. Model predictive control (MPC) is an ideal framework for greenhouse control (Chen, 2018), because building dynamics are slow and the system model incorporates disturbances and constraints that can be derived from first principles models (Serale et al., 2018). However, most existing studies on MPC for greenhouse climate control do not consider robustness (Blasco et al., 2007), given that uncertain disturbances could deviate the greenhouse climate from the optimal condition (Shamshiri et al., 2018). For those studies using robust MPC (RMPC), the possibility of over-conservatism due to the oversized uncertainty set is not considered (Shang et al., 2019). Thus, to fill this knowledge gap, the objective of this work is to develop a novel RMPC framework for greenhouse climate control that can effectively hedge against uncertain disturbances, leverage the value of historical weather forecast data to reduce over-conservatism, and simultaneously control multiple system states of greenhouse climate to minimize the total cost and the constraint violation probability.

2. Greenhouse Dynamic Model Formulation

In this work, the states we consider are greenhouse air temperature, floor temperature, ceiling temperature, wall temperature, absolute humidity, and greenhouse CO₂ concentration. The control inputs are the heating and cooling power, dehumidifier, and CO₂ enrichment. The disturbances are solar radiation, ambient temperature, ground temperature, ambient humidity, and ambient CO₂ concentration. Forecast errors are only from solar radiation, ambient temperature, and absolute humidity. The structure of the proposed dynamic model for greenhouse climate control is shown in Figure 1.

Figure 1. Semi-closed greenhouse structure model that shows control actuators, disturbances, and greenhouse climate system states.

To control greenhouse CO₂ concentration, a model to calculate net uptake rate of CO₂ by crops per unit greenhouse area is required, and it can be estimated by an empirical model of net photosynthesis as follows (Klärning et al., 2007).

$$P_{net} = a_0 (f_I(I) \cdot f_C(C) \cdot f_{TP}(T) + f_{TR}(T)) f_L(LAI)$$

where P_{net} is the net photosynthesis, I is the photosynthetically active radiation (PAR), C is the CO₂ concentration in the air, T is the air temperature, LAI is the leaf area index of the crop, and a_0 are coefficients that can be obtained from the literature (Klärning et al., 2007). The functions f_I , f_C , and f_{TP} show the effects of solar radiation, CO₂ concentration and temperature on photosynthesis, respectively. f_{TR} is for the temperature effect on respiration, and f_L describes the effect of the leaf index on both photosynthesis and respiration.

For greenhouse humidity control, humidity is strongly affected by temperature. Since the temperature would be controlled within a small range in the greenhouse that is most beneficial for the crop's growth, absolute humidity could be taken into account in the MPC to avoid the complexity of dependency between temperature and relative humidity.

$$\frac{dQ_{gr}}{dt} = \frac{1}{l}(Q_{tran} - Q_{cond} + Q_{amb})$$

where Q_{gr} is the greenhouse absolute humidity, Q_{tran} is the plant transpiration, Q_{cond} is the condensation, Q_{amb} is the flux of ambient absolute humidity, and l is the greenhouse height.

The dynamic greenhouse climate model in this work combines the greenhouse temperature model generated by Building Resistance-Capacitance Modeling (BRCM) toolbox, CO₂ concentration model, and absolute humidity model, given in Eq. (1)-(2). When the length of prediction horizon H is given, a compact form of the dynamic greenhouse climate model is given by

$$\mathbf{x} = \mathbf{A}\mathbf{x}_0 + \mathbf{B}_u\mathbf{u} + \mathbf{B}_v\mathbf{v} + \mathbf{B}_w\mathbf{w}$$

where \mathbf{x} includes greenhouse air temperature, ceiling temperature, floor temperature, wall temperature, greenhouse CO₂ concentration, and absolute humidity. \mathbf{u} consists of heating/cooling power, CO₂ enrichment, and dehumidifying rate. \mathbf{v} contains forecast of ambient temperature, ground temperature, solar radiation, and ambient humidity. \mathbf{w} has forecast error for ambient temperature, solar radiation, and ambient humidity.

The constraints on control inputs and system states in the prediction horizon H can be stacked together. The compact forms are shown as

$$\mathbf{F}_x\mathbf{x} \leq \mathbf{f}_x, \quad \mathbf{F}_u\mathbf{u} \leq \mathbf{f}_u$$

where \mathbf{F}_x and \mathbf{f}_x are vectors that define the state constraints. \mathbf{F}_u and \mathbf{f}_u are vectors that define the control input constraints.

3. Control Strategies

3.1. Data-Driven Uncertainty Set for RMPC

In this work, we adopt support vector clustering (SVC) with weighted generalized intersection kernel (WGIK) approach to form uncertainty sets of temperature, solar radiation, and humidity due to its capability of handling asymmetry and correlation in the uncertainty distribution, as well as tackling outliers (Shang and You, 2019). The SVC approach tries to find the minimal sphere radius that can capture data (Shang et al., 2017); WGIK is implemented when solving the dual form of SVC optimization problem, and it is well suited for robust optimization due to its piecewise linearity (Shang et al., 2020). To construct the uncertainty set for ambient temperature, training data have to be first obtained. By adopting SVC with WGIK approach, the uncertainty set for temperature is formed as follows,

$$w_{temp} \in D_{temp} = \left\{ w_{temp} \mid \sum_{i \in SV} \alpha_i \left\| \mathbf{Q}_{temp} (w_{temp} - w_{temp}^{(i)}) \right\|_1 \leq \theta \right\}$$

where D_{temp} is the data-driven uncertainty set for temperature forecast error, \mathbf{Q}_{temp} is a weighting matrix that can be obtained from the covariance matrix of temperature forecast error w_{temp} , model parameters α_i and uncertainty set parameters θ are determined after solving the dual form of SVC using WGIK. Since Eq. (5) is a polytope, solving the

resulting robust optimization problem could be accomplished without difficulties. The uncertainty sets for solar radiation and absolute humidity are constructed in a similar way. Other types of data-driven uncertainty sets (Ning and You, 2019), such as those based on principle component analysis (Ning and You, 2018), could be used as well.

3.2. *Soft-Constrained Data-Driven Robust Model Predictive Control*

DDRMPC strategy in this work adopts SVC with WGIC to construct uncertainty sets that could tackle outliers of weather forecast errors. Furthermore, the performance guarantee is ensured after tuning uncertainty sets by the calibration data set. The approach to solving the optimization problem in DDRMPC also uses affine disturbance feedback (ADF) policy to obtain the approximate solution given that the original problem is intractable (Goulart et al., 2006).

Although ADF policy could transform the original optimization problem into a tractable problem, it is impossible to guarantee that it is always feasible at each time step due to the presence of system state constraints, control input constraints, and disturbances. A common approach to guarantee the recursive feasibility of MPC is to soften constraints that might be violated. The corresponding soft-constrained MPC is formulated as,

$$\begin{aligned} & \min_{\mathbf{M}, \mathbf{h}, \boldsymbol{\varepsilon}} \mathbf{c}^T \mathbf{h} + \boldsymbol{\varepsilon}^T \mathbf{S} \\ \text{s.t. } & \mathbf{F}_x [\mathbf{A}x_0 + \mathbf{B}_u \mathbf{h} + \mathbf{B}_v \mathbf{v} + (\mathbf{B}_u \mathbf{M} + \mathbf{B}_w) \mathbf{w}] \leq \mathbf{f}_x + \boldsymbol{\varepsilon}, \forall \mathbf{w} \in D \\ & \mathbf{F}_u [\mathbf{M} \mathbf{w} + \mathbf{h}] \leq \mathbf{f}_u, \forall \mathbf{w} \in D \\ & \boldsymbol{\varepsilon} \geq \mathbf{0} \end{aligned}$$

where \mathbf{S} is constraint violation penalty weight matrix, and $\boldsymbol{\varepsilon}$ is slack vector for system state constraints. Since this is a minimization problem and the penalty weights in \mathbf{S} are all positive, slack variables would be zero when hard-constrained DDRMPC is feasible.

4. **Case Study**

4.1. *Problem Description*

In this work, a semi-closed greenhouse located in Brooklyn, New York, USA for year-round tomato production is simulated for closed-loop temperature, humidity, and CO₂ concentration level control under four different control strategies: rule-based control, certainty equivalence MPC (CEMPC), RMPC, and DDRMPC. The dimension of this greenhouse is 40 m × 13 m × 4 m. The main material for roof and walls is 10 mm twin-wall polycarbonate which provides good insulation against heat. The floor is made of concrete. Historical temperature forecast data, historical temperature measurement data, and historical solar radiation data from May 2018 to June 2018 are collected from (Meteogram Generator, 2018). Historical solar radiation forecast data is hard to access, so we adopt the following model from literature (Kasten and Czeplak, 1980) to estimate solar radiation from cloud coverage, since historical cloud coverage forecast data is easier to obtain, compared to historical solar radiation forecast data.

4.2. *Results and Discussion*

Figure 2 presents the temperature control profile of May under all four control strategies. The trajectory of DDRMPC leaves some margin from the temperature constraints, so as to avoid constraint violation when the weather forecast errors are large. Therefore, due to the margin saved for prediction error, temperature constraint

would not be violated, or there is at most only very minor violation when extreme cases strike. Similar to DDRMPC, RMPC also leaves some margin for the temperature constraints. However, the margin left by RMPC is usually larger than DDRMPC's, especially from 10pm to 5am. The comparison clearly demonstrates the ability of DDRMPC to reduce conservatism. On the other hand, both CEMPC and rule-based control violate the constraints more severely. The reason for the violation is that CEMPC does not consider prediction error when the MPC optimization problem is being solved at each step, and rule-based control does not take the weather forecast into account. When the actual ambient temperature turns out to be lower than the predicted ambient temperature, greenhouse temperature could not be maintained to be above the minimum acceptable temperature, and this is when constraint violation happens. The results demonstrate the robustness of RMPC.

Figure 2. Greenhouse temperature profile in first half of May 2018 under different control strategies with upper bound constraint and lower bound constraint that change according to time of the day. Higher constraint during daytime and lower constraint during nighttime.

Table 1. Percentage of time violating temperature constraint in each month

	May	June	Average.
Rule-Based (%)	69.1	68.1	68.6
CEMPC (%)	76.5	79.14	77.82
RMPC (%)	0.13	0.28	0.21
DDRMPC (%)	0.27	0.41	0.39

Table 2. Cost of controlling temperature, CO₂ concentration, and absolute humidity under different control strategies in each month

	May	June	Total
Rule-Based (\$)	6,237	5,144	11,381
CEMPC (\$)	4,716	3,601	8,317
RMPC (\$)	5,801	4,372	10,173
DDRMPC (\$)	5,604	4,162	9,766

Overall, CEMPC shows the least conservative control profile. Although CEMPC has the lowest overall control cost, which is the sum of heating/cooling cost, CO₂ cost, and water cost, shown in Table 2, it ends up with violating system constraints the most as shown in Table 1. Neglecting the forecast errors makes CEMPC violate constraints, because of the difference between the real weather condition and the weather forecast.

Whenever the weather is colder than predicted, CEMPC would violate the constraint, because the controller neglects the weather forecast errors and usually takes the most aggressive actions. Some violations are so severe that the greenhouse indoor air temperature drops to 14°C, which is 4°C below the minimum required temperature for tomato growth. This is undesirable in a greenhouse because tomatoes are usually sensitive to temperature. Even a 2-3°C temperature drop may cause serious damages to the fruits.

5. Conclusions

In this paper, we developed a DDRMPC framework that was able to simultaneously control multiple system states for indoor climate of a semi-closed greenhouse. To prevent greenhouse climate from becoming harmful to plant and fruit due to harsh weather conditions and inherent uncertainty in weather forecast, uncertainty sets for ambient temperature, solar radiation, and absolute humidity were first constructed by adopting the SVC approach with WGIK on historical weather data. Affine disturbance feedback policy was implemented for solving the optimization problem in proposed DDRMPC. We presented a case study of simultaneously controlling the indoor temperature, CO₂ concentration, and absolute humidity of a semi-closed greenhouse located in Brooklyn, New York for tomato production. The results showed that DDRMPC reduces 14% and 4% control cost compared with rule-based control and CEMPC, respectively, while only violating temperature constraint 0.39% of time. Therefore, DDRMPC showed better control performance compared to other approaches for greenhouse climate control.

Abstract

Batch distillation is one of the most common separation processes used in the pharmaceutical, agricultural, food and biotechnology industries. The rate-based model is an accurate approach to represent the performance of distillation trays, since it involves the mass and energy transfer equations to describe the interaction between the phases. For batch distillation, such approach results in a set of nonlinear differential and algebraic equations (DAE). Because of the complexity of such systems, good initial values are required for their solution. Thus, a strategy to estimate the initial values for a trayed batch distillation column modeled with a rate-based approach is presented in this work. The column under investigation consists of four sieve trays, a pot, and a total condenser. For the initialization procedure, the model equations are solved under a steady state assumption.

Keywords: rate-based modelling, batch distillation, discretization.

1. Introduction

Distillation is the process of separating of components in the mixture based on the differences among the relative volatilities or boiling points. Distillation can be to continuous or batch, there are some guidelines that can help to decide when a batch process may be favored over a continuous one. Batch distillation the process of separation for liquid mixture that containing high value chemical, such as pharmaceutical, biochemical, food, agricultural industries. Due to their flexibility, batch column can be used for a variety of system with relatively small amounts of components, under various operating conditions and changing compositions and components. In recent years, different models have been proposed to study the performance of batch distillation columns, mainly divided into two different types: equilibrium and rate-based models. The first model requires the solution of mass and energy balances while considering the vapor-

liquid streams leaving the stage to reach thermodynamic equilibrium, but its accuracy depends on the efficiency values assumed for the trays. The rate-based model is more accurate since it involves the addition of the mass and energy transfer equations to describe the interaction between the phases. Correlations of mass and heat transport coefficients are required. The column is described by the MERSHQ equations. May-Vázquez et al. (2020) presented a rate-based model of a batch column to separate methanol and ethanol, in which a novel mass transfer model for sieve trays is incorporated to the rate-based equations. The resulting formulation comprises a set of nonlinear differential and algebraic equations (DAE), whose solution require a significant computational effort. Numerical solution techniques for solving the differential equations have been development: one step methods and multistep methods. Some methods used are Euler's, Runge-Kutta, Adams-Bashforth and Predictor-Corrector. Another classification of the integration techniques depends on whether the method is explicit or not, semi-implicit or implicit: BDF (backward difference formula) and orthogonal collocation method (Diwekar, 2014). The modeling, simulation, and optimization of batch distillation columns is of interest to improve the performance of this dynamic process, involving the solution of the set of DAEs through dynamic optimization. Safdarnejad et al. (2016) mentioned that the optimization column batch can be subdivided into optimal design problems and optimal control problems. There is a difference between the two types of optimization, the first generally deal with column configuration while the second deal with operation. The optimization of the batch column is focused on the solution of optimal control problems, the indices of performed such as maximum distillate, minimum time, and maximum profit. To solve this problem, earlier works (Logsdon and Biegler, 1989) proposed the use of orthogonal collocation over finite elements as a discretization approach to simultaneously simulate and optimize batch distillation columns. Most of the recent literature related to dynamic optimization of such columns use equilibrium models; rate-based approaches are mainly used for packed columns. In any case, to solve this complex set of DAEs using orthogonal collocation over finite elements, it is necessary to provide the initial values and limits of the variables. In this work, a strategy to estimate the initial values for a trayed batch distillation column modeled with a rate-based approach is presented; these values will be used as the initial values for future works to perform the dynamic optimization of the column.

2. Methodology

For the initialization procedure, the model equations are solved under a steady state assumption, approach that has been applied to initialize equilibrium models for batch columns (López-Saucedo et al., 2016). In this work, the use of this technique is extended for the initialization of more complex rate-based models. The methodology is divided into three stages: (i) rate-based model, (ii) initial values using Matlab R2013a, (iii) steady state simulation using GAMS.

The batch distillation column consists four sieve trays, a pot, and a total condenser. Figure 1 shows a diagram of the column. The batch system separates a methanol/ethanol, mixture, with an initial composition of 75% mol of methanol and 25% mol of ethanol. Initial charge of the mixture is 0.163 kmol. The operation is stopped at 80 minutes, with constant thermal duty of 500 W.

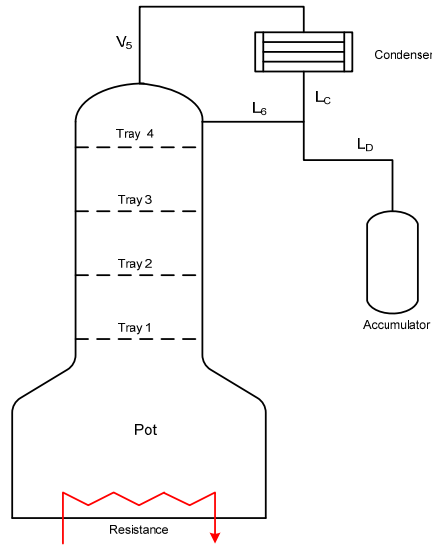

Figure 1.- Simplified representation of the batch column

The rate-based model is based on the MERSHQ equations and the following assumptions: vapor-liquid interface reaches thermodynamic equilibrium, the trays are in mechanical equilibrium, a total condenser is used, the walls of the column are perfectly insulated and the pressure along the column is constant. The mass transfer model is based on the proposal of Taylor and Krishna for sieve trays (Eq.11), with the modifications reported by May-Vazquez et al. (2020). It was also necessary to introduce correlation or methods to calculate physical and transport properties (density, viscosity, diffusivity, heat capacity and thermal conductivity).

The equations used to model the behavior of the batch column are presented below.

Accumulator:

Total material balance

$$\frac{dM_a}{dt} = L_D \quad (1)$$

Component material balance

$$\frac{dx_{i,a}}{dt} = \frac{L_D (x_{i,j} - x_{i,a})}{M_a} \quad (2)$$

Internal Trays, j=1, ...,4; i=1, 2

Total balance material for the vapor and liquid phase

$$\frac{dM_j^V}{dt} = V_{j-i} - V_j + N_{T,j} \quad (3)$$

$$\frac{dM_j^L}{dt} = L_{j+i} - L_j - N_{T,j} \quad (4)$$

Component material balances for component i in vapor and liquid phases on stage j

$$\frac{dy_{i,j}}{dt} = \frac{V_{j-1}}{M_j^V} y_{i,j-1} - \frac{V_j}{M_j^V} y_{i,j} + \frac{N_{i,j}^V}{M_j^V} \quad (5)$$

$$\frac{dx_{i,j}}{dt} = \frac{L_{j+1}}{M_j^L} x_{i,j+1} - \frac{L_j}{M_j^L} x_{i,j} - \frac{N_{i,j}^L}{M_j^L} \quad (6)$$

Energy balances on vapor and liquid phases on stage j

$$0 = V_{j-1}H_{j-1} - V_jH_j + e_j^V \quad (7)$$

$$0 = L_{j+1}h_{j+1} - L_jh_j - e_j^L \quad (8)$$

Rate of mass and energy transfer across interphase

$$e_j^V = e_j^L \quad (9)$$

$$\sum_{i=1}^c N_{i,j}^V = \sum_{i=1}^c N_{i,j}^L = N_{T,j} \quad (10)$$

$$N_i = c_i^V K_{OV} (\Omega^V)^{-1} (y_E - y_i^*) \quad (11)$$

$$N_{i,j}^V = N_{i,j}^L \quad (12)$$

Summation of mol fractions

$$\sum_{i=1}^c y_{i,j}^I = 1.0 \quad (13)$$

$$\sum_{i=1}^c x_{i,j}^I = 1.0 \quad (14)$$

Equilibrium equations

$$y_{i,j}^I = K_{i,j} x_{i,j}^I \quad (15)$$

Reboiler

Total material balance

$$\frac{dM_j}{dt} = L_{j+1} - V_j \quad (16)$$

Component material balances

$$\frac{dx_{i,j}}{dt} = \frac{L_{j+1}x_{i,j+1} - V_j y_{j,i}}{M_a} \quad (17)$$

It was necessary to have initial values for compositions and enthalpies to solve the steady state simulation. To obtain these values, the system of algebraic and differential equations of the rate-based model was written in Matlab R2013 at total reflux for 10 minutes, and the initial composition in the pot was 75% methanol and 25% ethanol. At the beginning of the simulation, the compositions and enthalpies were considered zero at the sieve trays and accumulator. The fourth order Runge-Kutta method with constant step size of 0.001

The differential equations of the rate-based model are equal to zero (Eq.1 to Eq.6 and Eq.16 to Eq.17) and the initial values obtained from MATLAB were used for the initialization of the steady state simulation. The system of algebraic system was solved at GAMS. It was also necessary to introduce upper and lower bounds to the variables.

3. Results

In this section, the obtained experimental data at total reflux is compared with the data obtained by the developed steady-state model.

The system of algebraic equations of the rate-based model at steady state of the binary batch distillation column consists of 301 equations and 28 inequality constraints. CONOPT was used to solve the nonlinear programming.

Figure 1 shows the composition profile when the column operates at steady state. The stage 1 corresponds to the pot and stage 6 to the tray 4. In this figure the composition of methanol in the liquid phase increases in each tray since it is the lightest component. The Figure shows a good agreement between the experimental results and steady state simulation, the average error is 1.63%.

Figure 2.- Composition profile

Figure 2 shows the temperature profile obtained by both, the temperature is lower in the upper stages because the amount of methanol increases. These results indicate that the steady state simulation has a good approximation with the experimental results. The deviations between the experimental data and steady state were $\pm 1.21\%$.

Figure 3.-Temperature profile

4. Conclusions

A strategy to estimate the initial values for a batch distillation column to scale pilot was proposed, the strategy shows a good approximation with the experimental results. These values will be used by the solution of the optimal control. The initial values and limits to the upper and lower bounds on variables are very important for the simulation in GAMS to converge.

Abstract

As the scale and complexity of the chemical process increase, it is important to detect anomalies in the process at an early stage and respond in real-time. Currently, however, it is difficult for process operators to identify numerous alarms in the factory and to make a consistent and immediate abnormal diagnosis because each has different safety standards. To this end, this study proposed an adversarial autoencoder(AAE) based process monitoring model. AAE uses adversarial training to impose an arbitrary prior distribution on the latent vectors. In other words, the discriminator is trained to distinguish between the samples from the data distribution and the samples from the encoder, and the encoder is trained to match the latent vectors with a prior distribution. In the AAE-based process monitoring model, normal condition samples are used for train data and prior distribution is set up to be Gaussian distribution. T^2 and SPE statistics are constructed in the feature space and residual space respectively to monitor the process. By employing AAE, the model learns a deep generative representation that maps the original data distribution. To demonstrate the performance of the proposed model, a case study using the Tennessee Eastman benchmark process is employed. False alarm rate(FAR) and false detection rate(FDR) are used as the assessment criteria to measure the monitoring performance.

Keywords: Nonlinear process monitoring, Adversarial autoencoder, Fault detection, Gaussian feature learning

1. Introduction

Timely detection of faults in chemical systems is critical to ensuring the safety product quality. However, currently, these methods are relying upon human operators who need to recognize anomalies and make timely corrective decisions. Therefore, there has been a need to develop an intelligent automated fault detection system to assist operators in handling abnormal situations. To this end, various methods have been developed over three decades(N. Olivier-Maget et al, 2008). Data-driven methods possess great potential to be applied to chemical processes since a large amount of data is collected and stored in a distributed control system. Initially, principal component analysis (PCA)(S.Joe Qin, 2003), the most popular feature extraction method, has been widely used for monitoring linear processes. However, the data characteristics of many modern industrial processes are complicated, and the relationships among different variables are highly nonlinear. To overcome this, several nonlinear methods have been proposed. One of them is kernel

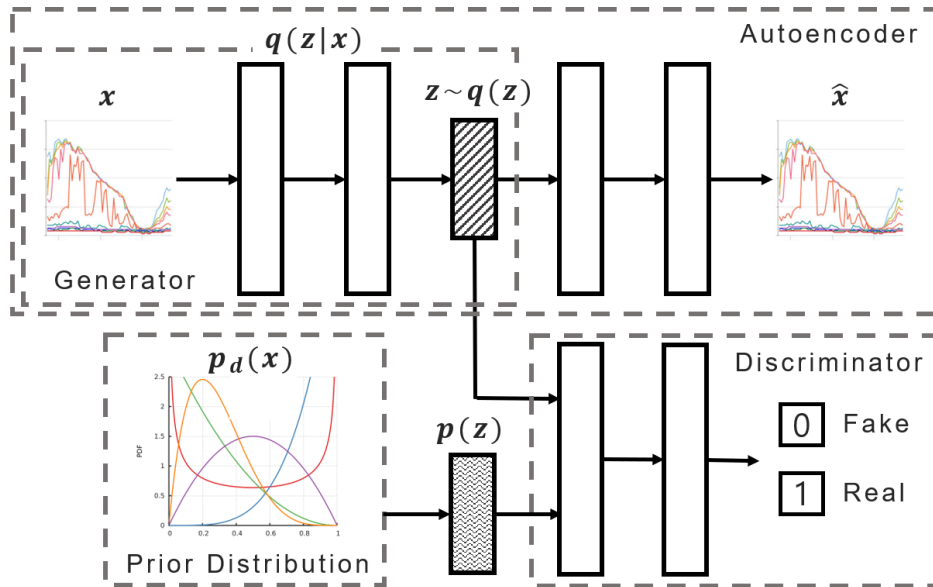

Figure SEQ Figure * ARABIC 1. Structure of AAE

PCA(KPCA)(S. W. Choi et al, 2005) which involves data transformation from the low-dimensional nonlinear observation space into the high-dimensional linear feature space. However, standard kernel functions do not always guarantee good results and the performance is also very sensitive to some hyper-parameters. Recently, deep learning (DL) has received a lot of attention in process monitoring because of its high model flexibility. Among various DL-based methods, autoencoder(AE)(Z. Zhang et al, 2018) provides good performance by achieving automated key latent variables. However, the typical autoencoder based method lacked good model interpretability(Y. Qiu and Y. Dai, 2019). To address these issues, an algorithm for process monitoring based on adversarial autoencoder (AAE) has been developed. AAE(A. Makhzani et al, 2015), which is a probabilistic autoencoder that used the generative adversarial networks, extracts the latent code vector matching the arbitrary prior distribution. Two monitoring indices are proposed and constructed based on the extracted latent code. The proposed method is applied to the Tennessee Eastman (TE) process(J. J. Downs and E. F. Vogel, 1993) to verify its monitoring performance.

2. AAE based fault detection

2.1. AAE based dimension reduction

AAE is a generative autoencoder that uses generative adversarial networks (GAN) to impose an arbitrary prior distribution on the latent code. The structure of AAE is shown in Figure 1. It contains autoencoder and discriminator of GAN. It uses adversarial training (1) to perform variational inference by matching the aggregated posterior distribution $q(z)$ with a prior distribution $p_d(x)p_d(x)$. The encoder network $q(z|x)q(z|x)$ defines

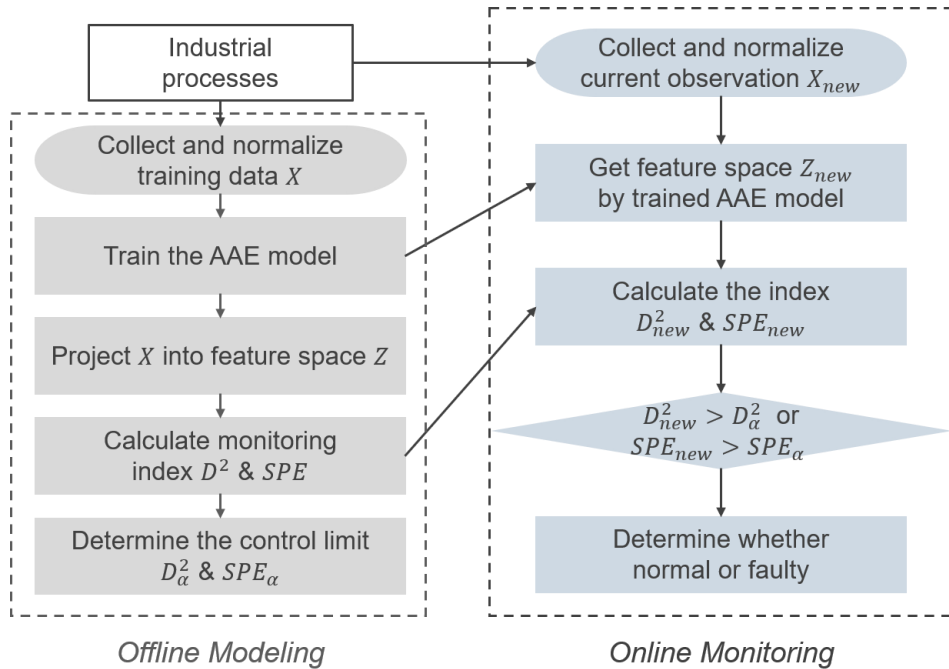

Figure SEQ Figure * ARABIC 2. Flowchart of AAE based monitoring method

an aggregated posterior distribution on the latent vector z as follows:

$$q(z) = \int_x q(z|x)p_d(x)dx$$

Meanwhile, the autoencoder attempts to minimize the reconstruction error as follows:

$$\underset{\theta, \phi}{\operatorname{argmin}} \|x - \hat{x}\|^2 \tag{2}$$

where θ and ϕ are the updating parameters of encoder and decoder respectively and \hat{x} is the reconstructed output of autoencoder. Then the adversarial network differentiates the true samples from the generated samples by updating its discriminator D . The generator G is updated to fool the discriminative network into trusting that the samples from the generator come from the prior distribution. The objective function of an adversarial network is as follows:

$$\begin{aligned} & \underset{\theta, \phi}{\operatorname{argmin}} \|x - \hat{x}\|^2 \\ & \min_{\theta} \max_{\phi} E_{x \sim p_d(x)} [\log D(x)] + E_{z \sim p(z)} [\log(1 - D(G(z)))] \\ & \min_{\theta} \max_{\phi} E_{x \sim p_d(x)} [\log D(x)] + E_{z \sim p(z)} [\log(1 - D(G(z)))] \end{aligned} \quad (3)$$

Matching the aggregated posterior to the prior samples ensures that generating ones from any part of prior space results in a meaningful latent vector. As a result, the decoder of the AAE learns a deep generative model that maps the imposed prior ones to the data distribution. The extracted latent vector has compressed and enhanced representations.

2.2. Monitoring indices

After AAE based dimension reduction model is developed, latent space and residual space are obtained by the encoder and decoder, respectively. For fault detection, the indices should be constructed to measure how far the variables are out of the normal range.

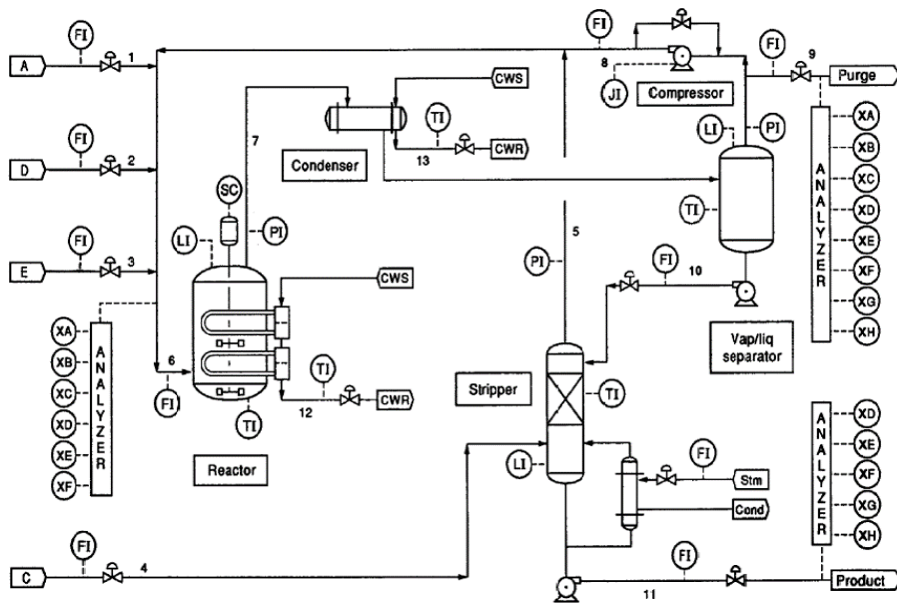

Figure SEQ Figure * ARABIC 3. Layout of Tennessee Eastman process

In the latent space, the index T^2 based on hidden representations is defined as follows:

$$\begin{aligned}
& \underset{\theta, \phi}{\operatorname{argmin}} \|x - \hat{x}\|^2 \\
& \min_G \max_D E_{x \sim p_d(x)} [\log D(x)] + E_{z \sim p(z)} [\log(1 - D(G(z)))] T^2 = z^T \Delta^{-1} z \quad (4) \\
& T^2 = z^T \Delta^{-1} z
\end{aligned}$$

where $\Delta\Delta$ is a covariance matrix of a latent vector zz . It describes the comprehensive fluctuation of the model. In the residual space, the index *SPESPE* based on reconstruction error is defined as follows:

$$\begin{aligned}
& \underset{\theta, \phi}{\operatorname{argmin}} \|x - \hat{x}\|^2 \quad \quad \quad SPE = (x - \hat{x})^T (x - \hat{x}) \\
& \min_G \max_D E_{x \sim p_d(x)} [\log D(x)] + E_{z \sim p(z)} [\log(1 - D(G(z)))] \quad (5) \\
& T^2 = z^T \Delta^{-1} z
\end{aligned}$$

It reflects the degree of deviation between the process variable and reconstructed variables from the model. In order to detect whether a new sample includes fault information, the control limits of the indices should be determined. As the distribution of real process data is unknown, it is necessary to use a density based approach. Based on

the the confidence level $\alpha\alpha$, control limit is obtained. To sum up, the flowchart with the proposed AAE based fault detection is depicted in Figure 2.

3. Case study

3.1. Process description

The Tennessee Eastman (TE) process is a well-known benchmark process in process control and monitoring. The TE process is shown in Figure 3, which is mainly composed of five operating units: a reactor, a condenser, a separator, a compressor, and a stripper. There are 22 continuously measure variables, 19 composition measurements, and 11 manipulated variables. TE process also has 21 programmed process faults like step, random variation, sticking, and unknowns. Each fault data has 960 samples with a fault introduced from sample 161. Normal data for training the proposed model contains 500 samples.

3.2. Monitoring results

In this case study, the proposed method and several comparative methods (PCA, KPCA, AE) are applied to detect the faults of the process. To demonstrate the performance of the proposed methods, fault detection rates(FDRs) for all fault types and false alarm rates(FARs) of normal data are calculated and shown in Table 1 and Table 2. For large magnitude faults 1, 2, 4, 6, 7, 8, 12, 13, 14, and 17, all four methods show similar detection results. The FDR of the proposed method outperforms that of the other three methods in

some faults (3, 5, 9, 15, 20, and 21) and the average FDR is also higher than the other three methods. Fault detection using AAE model shows strong robustness to all types of faults. In FAR, the proposed method also gives significantly better results than other methods. Extraction of robust features following Gaussian distribution improves the performance of process monitoring.

Table 1. Fault detection rates of PCA, KPCA, AE, and AAE based method

Fault type	PCA	KPCA	AE	AAE
1	1	1	0.997	1
2	0.987	0.987	0.99	0.99
3	0.258	0.135	0.258	0.348
4	0.987	0.973	0.993	0.986
5	0.511	0.336	0.497	0.55
6	1	1	1	1
7	1	1	1	1
8	0.987	0.981	0.99	0.978

20	0.731	0.697	0.692	0.786
21	0.597	0.568	0.608	0.59

Table 2. False alarm rates of PCA, KPCA, AE, and AAE based method

PCA	KPCA	AE	AAE
0.1	0.0513	0.0813	0.0313

4. Conclusion

The AAE-based process monitoring model is particularly good for nonlinear, non-Gaussian systems because AAE is specialized in extracting Gaussian features that are most desired in these systems. It automatically extracts features through the pre-trained deep neural network and calculates the monitoring statistics using the latent and residual features, so can be easily applied to large-scale data. The proposed method is applied to the benchmark process and shows superior performance in fault detection rate and false alarm rate. Extending the AAE-based model to the multimode process monitoring is an important part of future work.

Machine learning for constrained self-optimizing control

Hongxin Su,^{a,b} Chenchen Zhou,^{a,b} Yi Cao,^{a,b,*} Shuanghua Yang^{a,b,*}

Abstract

Self-optimizing control (SOC) is a method to select controlled variables (CVs) and keep them constant such that the plant operates optimally. Since the concept of SOC was proposed, some difficult problems in this field have not been solved such as active constraint changes. Previous work either handles the constrained SOC problem with complicated control structure or in the sense of local SOC, and has limitations such as structural complexity and inaccuracy of control. To address the shortcomings of the existing methods, this paper proposed a constrained variable approximation (CVA) method to solve the problem in the global sense using a simple control structure. The constrained variables which may vary between active and inactive are approximated by a nonlinear function of available measurements in the whole operational region using artificial neural network (ANN). Then the CVs are determined as the difference between the nonlinear function and the constrained variables. The system would be near optimal operation when the CVs are controlled at zero. An evaporator process is applied to illustrate the effectiveness of the proposed method.

Keywords: Self-optimizing control, Active constraint changes, Controlled variable selection.

1. Introduction

Operation optimization is difficult to achieve under various disturbances and uncertainties. Real-time optimization (RTO) offers a solution that handles the problem through repeated online optimization, however this would result in large computation burden. Besides, the RTO is an open-loop solution, which means it is not robust when the accuracy of uncertainty estimation is poor. Alternatively, self-optimizing control (SOC) (Skogestad, 2000) focuses on the selection of appropriate controlled variables (CVs), such that the plant operates almost optimally under all circumstances when these CVs are controlled at their constant setpoints through closed feedback control. Since the concept of SOC was proposed, the research associated with CV selection methods has made substantial progress (Jäschke et al., 2017). One of the most interesting problems about SOC is how to control constraints varying between inactive and active. Since there may be different number of unconstrained degrees of freedom in different disturbance regions, Manum and Skogestad (2012) designed a switching structure between different disturbance regions within each of which the active constraints remained unchanged. The extended null space method (Alstad and Skogestad, 2007) was developed to find the CVs for different regions and a special strategy is used to decide when to switch between different regions. Difficulty arises to find the switching method in the presence of measurement noise. Cao (2004) proposed a cascade control structure that the self-

optimizing CVs are in the outer loop while the variables likely to violate the constraints are in the inner loop with a saturation block to restrict the inner loop setpoint so that the variables will not go beyond the constraints. Nevertheless, this scheme requires that the number of CVs is not less than the number of the constraints likely to change between inactive and active because one constraint needs to be controlled by one CV. Hu et al. (2012) considered a simple control structure that aims to find CVs which can ensure all the variables are within their constraints and also within the whole disturbance and uncertainty region. Nonetheless, the CVs are chosen based on the exact local method through minimizing the local average loss.

Existing approaches associated with active constraint changes are either difficult to complement due to the complicated control structure or locally valid. To address this problem, this paper proposes a method to find a CV which makes the average loss acceptable once it is kept zero despite of changes of active constraint. This is achieved by constructing a nonlinear function of available measurements to track the optimal value of the constraints which may vary between active and inactive using artificial neural network (ANN). Then the CV is selected based on the difference between the nonlinear function and the constraint variable. Finally, a simple feedback control structure can achieve constrained global self-optimizing control.

The rest of the paper is organized as follows. Section 2 introduces the constrained global self-optimizing control (gSOC) problem formulation and the CV selection method, then, the proposed approach is demonstrated to be effective through an evaporator case study in Section 3. Finally, the paper is concluded in Section 4.

2. Constrained gSOC formulation and CV selection

Consider a constrained static optimization problem

$$\begin{aligned} \min_u J(u, d) \\ \text{s.t. } g(u, d) \leq 0 \end{aligned} \quad (1)$$

with available measurements

$$y_m = y + n \quad \text{and} \quad y = f(u, d) \quad (2)$$

Where J is a scalar objective (economic cost) function to be minimized, and $u \in \mathbb{R}^{n_u}$, $d \in \mathbb{R}^{n_d}$, $n \in \mathbb{R}^{n_y}$, $y_m \in \mathbb{R}^{n_y}$ and $y \in \mathbb{R}^{n_y}$ are manipulated variables, uncertain disturbances, measurement errors, measured and true output measurements, respectively. $f: \mathbb{R}^{n_u \times n_d} \rightarrow \mathbb{R}^{n_y}$ and $g: \mathbb{R}^{n_u \times n_d} \rightarrow \mathbb{R}^{n_g}$ are the input-output mapping function and operational constraints, respectively. These constraints are often related to operational safety or product qualities.

Suppose c is the self-optimizing CVs. According to the SOC principle, when c are kept as constant, the process operation is optimal or near optimal. This means the desired c at optimal condition, i.e. $c_{opt}(d)$ should be insensitive to the change of d . Therefore, the optimizing problem (1) becomes the problem of choosing appropriate c which remain almost the same under optimal conditions with respect to d . Previous work selects individual measurement y or linear combinations of available measurements Hy as c and most of them are based on the assumption that the active constraints do not change

under different disturbance scenarios. Actually, during the operation, constraints g can be divided into three types: (i) g_1 : always active; (ii) g_2 : always inactive; (iii) g_3 : vary between active and inactive. For case (i), g_1 can always be controlled by u hence consuming the same number of degrees of freedom of g_1 , and for case (ii) g_2 can be neglected because they have no effect on the optimal solution. Therefore, only g_3 deserve careful attention.

It is assumed that the optimal operation data under various disturbances are available. The aim is to select appropriate CVs which are kept at constant setpoints so that the plant is operating near optimally in spite of g_3 switching between active and inactive. Because the optimal values of g_3 are not constant in the whole operation region, they cannot be directly selected as CVs. It is proposed to find a proper function to fit the optimal constraint values of g_3 , and then CVs are selected as the difference between the function and the constraint variables. When the CVs are kept at zero, the optimality of constraint variables in g_3 is maintained by tracking the function in the whole region. Since g_3 sometimes reach the upper bounds, sometimes the lower bounds and sometimes in between, g_3 are strongly nonlinear, hence cannot be fitted well by linear functions. According to the well-known universal approximation theorem of neural network (Hidalgo et al., 2020), that is, a given feedforward neural network with enough hidden nodes, equipped with a linear output layer and activation function of the hidden layer, can approximate any function by any desired error, the ANN method is applied to obtain the nonlinear function which is used to fit the constraint variables in g_3 .

The proposed constrained variable approximation (CVA) method can be described as two parts: one is offline CV selection as shown in Figure 1, and the other is online SOC in Figure 2. As shown in Figure 1, optimal measurements y including controlled variables in g_3 are obtained by solving optimization problem (1) under different disturbances d . Then the controlled variables in g_3 are fitted by a nonlinear function of y , i.e. $Z(y)$ through ANN. Finally, the CV can be selected as $c = Z(y) - g_3$. As shown in Figure 2, the selected CV is applied to the SOC structure. The process can operate near optimally when c is kept at zero through a feedback control.

Figure 1: offline CV selection

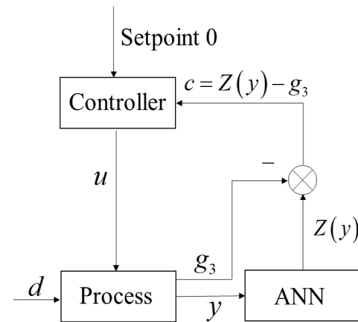

Figure 2: online SOC structure using CVA

3. Case study

A forced-circulation evaporator (Newell and Lee, 1989) is considered as shown in Figure 3. The solute concentration increases through evaporation of the solvent in the forced circulation evaporator. The detailed model equations and the nominally optimal values can both be referred to Ye et al. (2013).

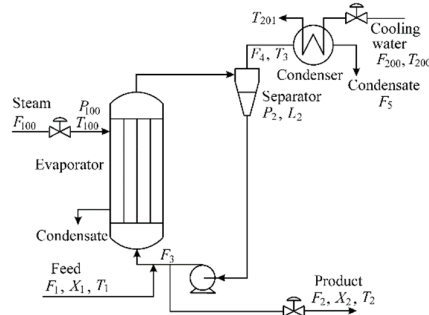

Figure 3: Evaporator system

There are three state variables L_2 , X_2 , P_2 , four manipulated variables F_2 , P_{100} , F_3 , F_{200} and four disturbances F_1 , X_1 , T_1 , T_{200} in the process. The variations of disturbance variables are $\pm 20\%$ of their nominal optimal values. The cost objective function (\$/h) of the whole process is defined as

$$J = 600F_{100} + 0.6F_{200} + 1.009(F_2 + F_3) \quad (3)$$

The process constraints are listed as follows:

$$X_2 \geq 35.5\% \quad (4)$$

$$40 \text{ kPa} \leq P_2 \leq 80 \text{ kPa} \quad (5)$$

$$P_{100} \leq 400 \text{ kPa} \quad (6)$$

$$F_{200} \leq 400 \text{ kg / min} \quad (7)$$

$$0 \text{ kg / min} \leq F_3 \leq 100 \text{ kg / min} \quad (8)$$

The constraints in (7) and (8) are always inactive, hence they can be neglected. Two constraints $P_{100} = 400 \text{ kPa}$ and $X_2 = 35.5\%$ are always active within the whole disturbance region, and the separate level L_2 which has no steady-state effect, but needs to be controlled at its nominal value, hence totally consuming three degrees of freedom (DOF). Hence, only one DOF is left for CV selection to achieve SOC.

Monte Carlo simulation is applied to generate a sequence of 1000 nonuniformly distributed samples within the predefined disturbance set and then optimal measurements are obtained by numerical optimization with respect to different disturbance. Note that P_2 in constraint (5) vary between inactive and active within the whole sampling region, so the number of activeness and inactiveness of P_2 are similar by sampling nonuniformly

to ensure the representativeness of the samples. There are 4 measurements to be considered for CVA method, which are identified as one of the best subsets (Kariwala et al., 2008):

$$y = [F_2, F_{100}, T_{201}, F_3]$$

The ANN is applied to find a nonlinear combination function of optimal y , i.e. $Z(y)$ which can fit the optimal P_2 in the whole operation region. There is one hidden layer with 12 neurons in the ANN structure and the determinant coefficient R^2 is 0.99 after training. Then the self-optimizing controlled variable can be selected as $c = Z(y) - P_2$ and kept at zero through a feedback control. In this way, $Z(y)$ is able to track the optimal setpoint of P_2 with respect to different disturbance, so P_2 can be maintained at optimum through keeping $c = 0$.

To evaluate the performance of the CV selected through the Monte Carlo experiment, 100 random samples are generated within the expected disturbance ranges without measurement noise and the results are shown in Figure 4. It is clear that the values of objective function after controlling $c = 0$ are almost similar with its optimal values at the same disturbance, and the average loss between the two is 0.0864. From Figure 5, it can be seen that P_2 after self-optimizing control is able to track the corresponding optimal P_2 well without violation of its limits. Table 1 compares the proposed constrained variable approximation (CVA) method with the necessary condition of optimality (NCO) approximation using least square method (Ye et al., 2013), which selects CVs as a linear function of the available measurements that approximates the gradient of J with respect to u . To compare fairly, the same measurement set including P_2 is chosen and the constraint equation (5) is ensured when solving the constrained gSOC problem. It is clear that the average loss and maximum loss of CVA method are about two orders of magnitude smaller than the NCO approximation method, which indicates the superiority of the proposed method.

Figure 4: Monte Carlo simulation results

Figure 5: Tracking of optimal P_2

Table 1: Comparison of previous method with this work

Method	Average loss	Maximum loss	Standard deviation
NCO approximation	2.7954	12.9476	3.1219
CVA (our approach)	0.0864	1.3779	0.2302

4. Conclusions

This work proposed a new CV selection approach to solve the constrained gSOC problems. In this approach, the constrained variable which may vary between active and inactive is tracked by a nonlinear function of available measurements using ANN. Then the CV is selected as the difference between the two which are kept zero, leading to good SOC performances. The proposed approach was applied to a forced-circulation evaporator process and was proved to be effective to achieve low loss while satisfying the constrained limits. However, as a preliminary study, only a single degree of freedom (DOF) is considered in this work and how to select CVs when more than one DOF exists will be further investigated.

Abstract

This paper presents a toolbox for driving force based integrated design and control of reactive distillation (RD) systems. The toolbox provides links to other necessary tools for the design, simulation, and analysis of RD systems. One convenient feature of the toolbox is that it guides the user through the steps of problem definition, including the selection of design-control variables and associated data-flow as well as the generation of the necessary scripts for links to simulation and analysis software. The implementation of this new toolbox is tested through binary/multielement single/double feed RD systems. For each RD system, the needed driving force calculations are done in ProCAPE. Steady state simulation and analysis are performed through ASPEN PLUS, MoT, or ProCADC. Dynamic open and closed-loop PI or MPC simulations are performed in ASPEN PLUS Dynamics, MoT, or MATLAB. The goal of the tests is to confirm the advantages of using the toolbox for studies involving RD systems in terms of fast, reliable, and efficient solution and analysis of integrated design-control problems.

Keywords: MPC, driving force, reactive distillation, ProCADC, toolbox

1. Introduction

Reactive distillation is an attractive intensified process unit because of its many advantages, e.g., the requirement of fewer process units, less heat addition, improved product removal, degradation of azeotropes, etc. (Tian et al., 2018). However, it is inherently difficult to control due to the shrinkage of the controllability region, and propagation of nonlinearity because of non-optimal design decisions (Rafiei and Ricardez-Sandoval, 2020). Hence, it is important to consider design-control issues simultaneously to eliminate potentially promising design alternatives that may be dynamically inoperable. Tian et al. (2020) have proposed a parametric optimization and control approach for simultaneous design-control of RD systems. Hamid et al. (2010) used thermodynamic insights and reverse design for decomposition based integrated design-control of nonreactive and reactive systems. Mansouri et al. (2016) have shown

that by simultaneously considering design and control issues through the driving force concept, better design-control of reactive distillation units can be achieved. Iftakher et al. (2021) extended this concept by showing that various RD systems, designed at the maximum available driving force actually lead to superior controllability under advanced controllers such as MPC. In this work, an integrated design-control toolbox especially suitable for RD systems that provides systematic process modeling, simulation, and verification options based on the extended RD design-control framework of Iftakher et al. (2021), is presented. This paper is organized as follows: first, the extended design-control framework is presented. Next, the work- and data-flow of the developed integrated RD design-control toolbox are described. Then, the calculation steps are highlighted through a case study. Finally, conclusions are stated.

2. Integrated design-control framework for RD systems

The extended integrated design-control framework has 3 main steps: data collection & problem formulation; determination of integrated design-control; and, verification.

2.1. Data collection & problem formulation

Here, an RD system is defined in terms of compounds (and catalysts), feed condition, number of reactions, and a design target. To quantify the design and control issues of the specified RD system, a multiparametric objective function is defined. Iftakher et al. (2021) proposed the use of an objective function in terms of six parameters: total energy consumption by the process, CO₂ footprint per kg feed, integral absolute error, total variation of input, relative gain array (RGA), and the Niederlinski Index. The reactive systems are expressed in terms of elements (difference between the number of compounds and the number of reactions). Therefore, a reactive system with three compounds, and one reaction is expressed in terms of binary elements, whereas a reactive system with multiple elements is represented in terms of equivalent binary elements. At the end of this step, the choice of the elements is verified through an atom-balance of the reactive system.

2.2. Determination of integrated design-control

Here, the integration of design and control is performed through operation at the maximum driving force. First, the reactive phase (vapor-liquid equilibrium) diagram and its translation to a driving force diagram are calculated based on the element reactive system, appropriate thermodynamic models, and the specified operating conditions. The location of the maximum driving force and the operational area are identified to determine the RD column design parameters. Next, the MPC controller parameters are determined (Iftakher et al. 2021).

2.3. Dynamic analysis and verification

Here, at first, the steady state analysis is performed (to verify the designed controller structure from step 2) using the linearized state space model of the process. Next, the dynamic simulation is performed (in open-loop and closed-loop with PI or MPC options). Finally, the objective function parameters are calculated to quantify the design-control performance of the designed RD system.

3. Integrated design-control toolbox for RD systems

The integrated design-control framework has been translated into a toolbox for the study of RD systems. As shown in Figure 1, the toolbox has 5 main steps, which are briefly described below.

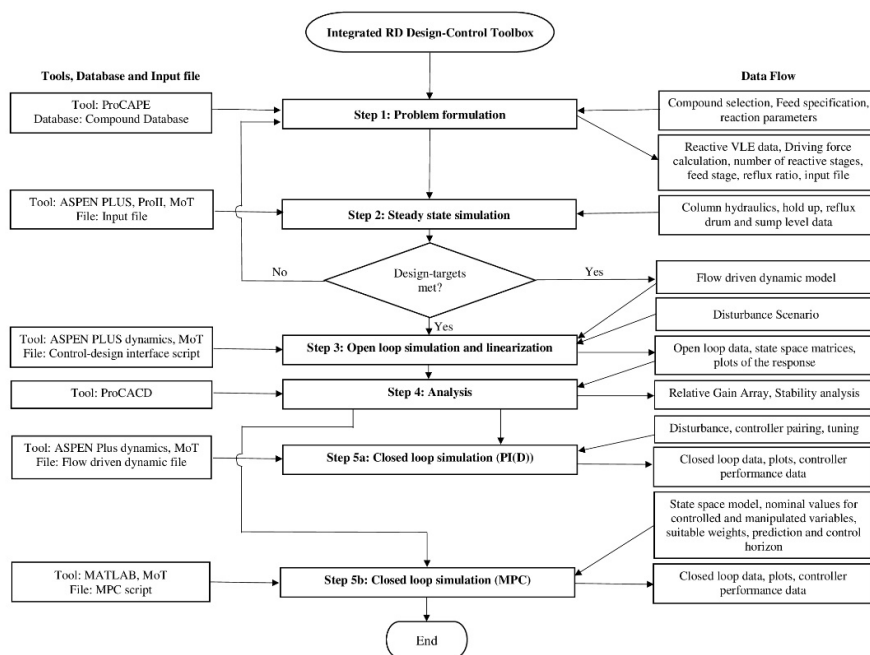

Figure 1: Work-data flow of the Integrated RD design-control Toolbox.

3.1. Step 1: Problem formulation

In this step, the user is guided to enter the following: compounds, feed specification, number of feeds, reaction definition, reaction parameters, design target, choice of elements. The RD toolbox exports these data to ProCAPE where the user selects the needed thermodynamic models to calculate the Reactive VLE data at the specified pressure. The reactive VLE data is then converted to a driving force diagram from which the necessary column design parameters (number of reactive stages, feed stage, reflux ratio) are determined. At the end of this step, a simulator input file is generated that contains all the required flowsheet and design information for steady state simulation in Step 2.

3.2. Step 2: Steady state simulation

The input file generated in Step 1 is loaded to a simulation software (ASPEN PLUS, ProII, or MoT) where all the required process and design variables are defined. Next, the steady state simulation is performed. The product compositions are inspected and if the design targets are satisfied, the required data (column hydraulics, reflux drum level, hold up, etc.) for dynamic simulation are provided for the generation of the corresponding flow driven dynamic model. Otherwise, the user is guided back to Step 1 to refine the problem formulation.

3.3. Step 3: Open-loop simulation and linearization

With the generated dynamic model file, open-loop simulation is performed in ASPEN Plus Dynamics or MoT for a selected disturbance scenario. The open-loop data are used to derive the transfer function model of the process. Also, in this step, a control-design interface script (autogenerated by the integrated RD toolbox), is applied to determine the

state space matrices of the process by linearizing the dynamic model at the nominal steady-state condition.

3.4. Step 4: Analysis

Steady state analysis is performed in ProCADC (Tula et al, 2020). The transfer function models derived from the open-loop data or the state-space matrices are used to determine the relative gain array (RGA), which indicates the degree of loop interaction. Also, the system stability is checked by determining the Niederlinski Index or directly through analysis of the transfer function model.

3.5. Step 5: Closed-loop simulation

Closed loop simulation is performed using either the regulatory controller (PI) or the supervisory controller (MPC). For both control structures, the top and bottom compositions of the product(s) of interest are controlled, by varying the reflux rate and reboiler duty, respectively. The selection of the control structure is verified by inspecting the diagonal values of RGA. For MPC closed-loop simulation, the toolbox prompts the user to provide the following inputs: nominal values of the controlled and manipulated variables, weights on the controlled and manipulated variables, prediction horizon, and control horizon. After a check of consistency of data, the integrated RD toolbox links to MATLAB or MoT where a script for MPC closed-loop simulation is autogenerated. After performing the closed-loop simulation, the controller performance is quantified by determining the Integral absolute error (IAE), and the total variation of input (TV).

4. Application example

The application of the integrated design-control toolbox is highlighted through a single feed multielement reactive system (MTBE production with inert) as a case study. Details of application examples for other reactive systems can be obtained from the corresponding authors.

The involved compounds (selected from the in-house database) are isobutene (C₄H₈); methanol (CH₄O); 1-butene (C₄H₈); and MTBE (C₅H₁₂O). The feed condition and the design targets are given in Table 1 (data obtained from Pérez Cisneros et al. 1997). Reversible and exothermic reaction (taking place in acidic catalyst) between methanol and isobutene with the presence of 1-butene (inert) yields MTBE, as follows:

The number of elements required to represent this reactive system is three. SRK equation of state and the Wilson model are used for the generation of reactive VLE data from where the driving force diagram is generated. Using the driving force diagram, the following column design parameters are obtained: total number of stages = 7 (reactive stages from 2 to 6), feed stage = 4, reflux ratio = 2.813).

Table 1: Design targets and feed specifications for MTBE system with inert.

Component	Molar composition		
	Feed	Distillate	Bottom
Isobutene (C ₄ H ₈)	0.590	0.773	0.061
Methanol (CH ₄ O)	0.343	0.0	0.012
1-butene(C ₄ H ₈)	0.067	0.196	0.024
MTBE (C ₅ H ₁₂ O)	0.0	0.031	0.907

Feed flowrate: 100 kmol/h; Feed temperature and Pressure: 320K and 11 atm.

The design-control multi-objective function is defined similarly as proposed by Iftakher et al. 2021. Next, the toolbox creates an input file containing necessary data and the flowsheet description to be loaded to ASPEN PLUS or MoT where the flowsheet is

autogenerated and the steady state simulation is performed. The design targets are satisfied, and the following objective function values (to indicate design issues) are calculated: total energy consumption, $J_1 = 958.34$ KW; total carbon-footprint, $J_6 = 0.0941$ CO₂ eq per kg feed. Next, the flow driven dynamic model is exported to ASPEN PLUS dynamics or MoT for open-loop simulation. The disturbance scenario is as follows: +16.5% step change in methanol flow rate. After linearizing the dynamic model, the following steady state metrics are obtained in ProCADC: relative gain array, $J_4 = \begin{bmatrix} 1.26 & -0.26 \\ -0.26 & 1.26 \end{bmatrix}$; Niederlinski index (N_I), $J_5 = 0.7915$. As the diagonal values are close to unity, the degree of loop interaction is predicted to be minimal. Also, the positive value of N_I along with the positive real parts of the eigenvalues of both the open loop and closed loop dynamic model verifies that the system is stable.

PI closed loop simulation is carried out in ASPEN Plus dynamics or MoT. Based on the RGA values, the MTBE top composition is controlled by varying the reflux rate, and the MTBE bottom composition is controlled by varying the reboiler duty. The controllers are tuned using the IMC rules. The reflux drum and sump level controllers (proportional type) are also included for dynamic model consistency and perfect pressure control is assumed for the RD column.

For the MPC closed-loop simulation, a linear MPC with MIMO control strategy is used. The controller design and corresponding simulation is carried out in MATLAB or MoT where a script is autogenerated by the toolbox. Note that the controller pairings are kept the same as for the PI controllers. The plant inputs are: the condenser duty - Q_c , the reflux mass flow rate - R (kg/hr), the reboiler duty - Q_R , the distillate mass flow rate - D (kg/hr), the bottoms mass flow rate - B (kg/hr), and the feed molar flow rate (kmol/hr). The plant outputs are: the column pressure (stage 1) - P (atm), the mole fraction of the distillate of interest - x^D , the mole fraction of the bottoms of interest - x^B , the reflux drum liquid level - R_{lev} (m), and the sump liquid level - S_{lev} (m). MPC controller is designed in such a way that the nominal set point for all the controlled and manipulated variables is set at 50%. The simulation is run for 25 hours with a sampling time of 30s. The weights on the controlled variables are as follows: $[10 \ 1 \ 1 \ 0.1 \ 0.1]^T$. Note that the relative weights are a measure to assign importance for keeping the controlled variables at the set point. For example, MPC controller assigns 10 times more importance to keep the distillate and bottom product compositions at their set points compared to drum level or sump level. Analogously, maintaining column pressure at the set point is given 100 times more importance than maintaining sump level, since, the column pressure must be regulated tightly for safe operation. Finally, the prediction horizon is set to 30 min which is large enough to make the controller performance insensitive to further increases of the prediction horizon. The control horizon is set to 4 min which is kept small to reduce computational effort. The resulting closed loop dynamic responses for both PI and MPC controllers are shown in Figure 2. It is clear that both PI and MPC controllers are able to reject the feed disturbance very efficiently with minimal process upset. Finally, the control performance parameters (integral absolute error, J_2 and total variation of input, J_3) are calculated for both PI and MPC controllers and listed in

Table 2. Note that the parameters are calculated both for the top and bottom control loops.

5. Conclusions

An integrated toolbox for the design and control of reactive distillation systems using the driving force approach has been presented together with an illustration of an example of application. The toolbox links to other external property prediction tools for problem

formulation and design parameter calculation. It also links to simulation and control tools for steady state simulation, dynamic simulation, and overall quantification of design and control issues. Required scripts for state space model generation and simulation are autogenerated through the integrated toolbox, thereby providing flexible and systematic work-flow through which the study of RD systems can be easily set up for modelling, simulation, and verification with respect to integrated design-control. The application results confirm that RD systems designed at the maximum driving force are able to efficiently reject disturbances under both PI and MPC controllers because the interactions are reduced by the design at the maximum driving force. Future works include the integration of design and control of Petlyuk and dividing wall columns, as well as the extension of the reported toolbox to handle distillation columns with or without reactions.

Abstract

The development of advanced process control schemes is continuing driver of research within process systems engineering. In this work, we propose a framework, which leverages existing process data to automatically learn and update a control policy. This framework is underpinned by machine learning methods, namely, apprenticeship (AL) and reinforcement learning (RL), which compose offline and online learning respectively. In offline learning, we synchronously identify a function descriptive of the control objective and a parameterisation of the existing control policy expressed in data. The parameterised control policy is then updated automatically online via data from the ongoing process and RL. Importantly, the parameterisation learned offline achieves similar performance under the identified control objective to the existing control policy. Ultimately, the framework proposed enables a reduction in the technical intensity of offline RL-based policy learning, and approximates existing controllers in a more robust fashion than by supervised learning. The performance and efficiency of the framework proposed is explored via case study. Future work should focus on increasing sample efficiency in policy learning, satisfaction of constraints and accounting for model uncertainty.

Keywords: Apprenticeship learning, Reinforcement learning, Inverse reinforcement learning, Optimal control, Machine learning

1. Introduction

Recent initiatives for efficiency improvements in industrial process operation has driven interest in the development of high performance, data-driven advanced process control (APC) schemes. Reinforcement learning (RL) has achieved impressive results on benchmark game-based control tasks (Heess et al. (2015)), providing an avenue for research in translation to APC (S. P. K. Spielberg et al. (2017)). In spite of its high and well documented potential (T. Badgwell et al. (2018)), RL has yet to produce any meaningful impact in the (bio)chemical process industry. A number of challenges exist to wider deployment of RL-based controllers. One obstacle is the technical expertise, time and computation demanded in policy training and tuning. This work presents a two-step approach to RL-based policy learning, which leverages process data to parameterise an existing control law and then improves the performance of such control further. The approach promises to increase the learning efficiency of RL-based control policies, by reducing computational and technical investment via the utilisation and synthesis of

existing process knowledge with empirical observations (data) of system response to existing control strategies.

2. Methodology

In this work, we assume that the system concerned displays elements of stochastic behaviour and that process evolution is ultimately Markovian, and adheres to the following description:

$$\begin{aligned} \mathbf{x}_{t+1} &\sim p(\mathbf{x}_{t+1} | \mathbf{x}_t, \mathbf{u}_t) \\ \mathbf{y}_{t+1} &\sim p(\mathbf{y}_{t+1} | \mathbf{x}_{t+1}) \end{aligned} \quad (1)$$

Here, we formally state the process dynamics as a conditional probability density, where the probability of observing some future state $\mathbf{x}_{t+1} \in \mathbb{R}^{n_x}$ at discrete time index $t + 1$ is not conditioned on the process history but rather the current state $\mathbf{x}_t \in \mathbb{R}^{n_x}$ and control $\mathbf{u}_t \in \mathbb{R}^{n_u}$ imparted into the system at discrete time index t . Additionally, we assume the availability of a noisy system observation $\mathbf{y}_{t+1} \in \mathbb{R}^{n_y}$. Such an observation is distributed according to some measurement process $p(\mathbf{y}_{t+1} | \mathbf{x}_{t+1})$, upon which the control policy $\pi(\mathbf{u}_t | \mathbf{y}_t)$ is conditioned. The goal of decision making within an MDP is to maximise the discounted sum of rewards accumulated during a (discrete-time) process trajectory $\boldsymbol{\tau} = (\mathbf{x}_0, \mathbf{y}_0, \mathbf{u}_0, \dots, \mathbf{x}_T, \mathbf{y}_T)$ from some initial state \mathbf{x}_0 over a finite horizon of length T . Given the underlying system adheres to some stochastic dynamics, the probability of observing a given process trajectory is denoted $p(\boldsymbol{\tau} | \pi)$. Hence, the objective of any RL method is to learn a parameterisation $\boldsymbol{\theta}$ upon which the control policy $\pi(\mathbf{u}_t | \mathbf{y}_t, \boldsymbol{\theta})$ is conditioned to maximise the following objective:

$$G(\boldsymbol{\tau}) = \sum_{t=0}^{T-1} \gamma^t R_{t+1} \quad (2)$$

$$J(\boldsymbol{\tau}) = \int p(\boldsymbol{\tau} | \pi(\cdot, \boldsymbol{\theta})) G(\boldsymbol{\tau}) d\boldsymbol{\tau} \quad (3)$$

where $\gamma \in [0, 1]$ is the discount factor and R_{t+1} is the immediate reward as allocated by a reward function $R: Y \times U \rightarrow \mathbb{R}$. The optimal policy $\pi(\cdot, \boldsymbol{\theta}^*)$ maximises Eq. 3, subject to satisfying the set of hard constraints on the available control inputs. In this work, we deploy an 'on-policy', policy optimisation RL algorithm, known as Reinforce. Due to space constraints, little discussion is provided here. For further details see the following works (Petsagkourakis et al. (2020); Sutton et al. (2000)).

Most importantly, apprenticeship learning via inverse reinforcement learning is adopted in this work to formalise an approach to learning a parameterisation of a control policy expressed in process data (Coates et al. (2009)). The general problem statement follows: **given** demonstrations $\mathbf{T} = [\tau_1^E, \dots, \tau_k^E]$ from an existing control scheme; mathematically **abstract** the control objectives guiding the existing policy via the reward function R . The foundational IRL algorithms, construct R as a linear combination of hypothesised control objectives $\boldsymbol{\varphi} = [\varphi_1, \dots, \varphi_D]$ via the following expression:

$$R = \boldsymbol{\alpha}^T \boldsymbol{\varphi} \quad (4)$$

where $\boldsymbol{\alpha} \in \mathbb{R}^D$ denotes a vector of weights and $\varphi_d: Y \times U \rightarrow \mathbb{R}$ denotes a single control hypothesis. Explicitly, each control hypothesis is a hand constructed basis function, which must provide coherent control objective temporally. Given φ_d are of fixed structure, IRL

is concerned with abstracting control objectives via learning the optimal weights α^* , which reproduce the desired characteristics of the demonstrated control response as expressed by \mathbf{T} . These characteristics are quantified by the formulation of trajectory features $\mathbf{v}^Y \in \mathbb{R}^D$, where:

$$v_d^Y = \sum_{t=0}^T \gamma^t \varphi_d(\mathbf{y}_t, \mathbf{u}_t) \quad (5)$$

Ultimately, solution α^* provides control objectives, such that the following is satisfied:

$$\mathbb{E}_{p(\tau)}[\mathbf{v}^{Y,E}] = \mathbb{E}_{p(\tau)}[\mathbf{v}^{Y,\pi}] \quad (6)$$

where $\mathbf{v}^{Y,E} \in \mathbb{R}^D$ are the characteristics of system response τ^E on the control task under the existing control scheme and $\mathbf{v}^{Y,\pi} \in \mathbb{R}^D$ are those under the response τ^π of the RL policy as learned under the weight vector α^* . Specifically, we used maximum entropy IRL (Max-Ent IRL) to learn such a weight vector α^* . From an implementation perspective, it provides explicit mechanisms for matching the condition provided by Eq. 6. More detailed explanation of this algorithm can be found in Ziebart et al. (2013). Explicitly, we propose a framework to: learn an RL-based parameterisation of an existing control scheme by leveraging existing process data and an offline learning procedure (apprenticeship learning); then, to deploy this RL-based parameterisation to the real process to continually learn and update the control policy online via the Reinforce (or other policy optimisation) algorithm. Therefore, the framework naturally mitigates the effects of plant-model mismatch and process variability. Fig. 1 expands this further.

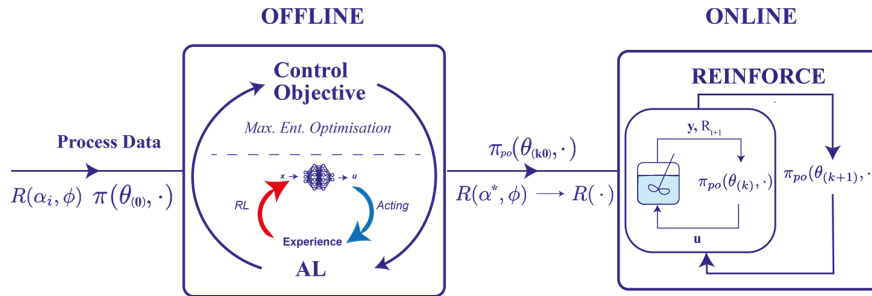

Figure 1: The framework for learning proposed. In offline learning, we leverage maximum entropy inverse RL and existing process data to synchronously abstract the objective function $R(\alpha^*, \phi)$ guiding the existing controller and a parameterisation $\pi_{po}(\theta_{k0}, \cdot)$ of the control law. We then propose to deploy the controller online to continually learn from the ongoing process under a reward function $R(\cdot)$ reflective of the true process objective.

3. Case Study

In the following section, we demonstrate the methodology presented via case study. The investigation is underpinned by a multiple-input, multiple-output (MIMO) control problem descriptive of an endothermic isomerism reaction in a continuous stirred tank reactor (CSTR) i.e. $A \xrightarrow{k_1} B$. We construct the conditional probability functions in Eq. 1 across a continuous state, control and measurement space and subsequently approximate the dynamics of the problem by the following system of stochastic differential equations:

$$\mathbf{x}_{t+1}^* = \mathbf{x}_t^* + \mathbf{h}(\mathbf{x}_t^*, \mathbf{u}_t^*)dt + \delta(\mathbf{x}_t^*)d\mathbf{W}_t \quad (7)$$

$$\mathbf{y}_{t+1}^* = \mathbf{g}(\mathbf{x}_{t+1}^*) \quad (8)$$

where $\mathbf{h}(\cdot): \mathbb{R}^{n_x \times n_u} \rightarrow \mathbb{R}^{n_x}$ represents the underlying process dynamics as derived from first principles; $\delta(\cdot): \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_x}$ is process disturbance; \mathbf{W}_t is the Wiener process; and, $\mathbf{g}(\cdot): \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_y}$ is the mechanism of noisy state observation. Explicitly, control is concerned with tracking the set points of the reactor temperature T and concentration of A , C_A in the outlet. The controls available to the scheme are the temperature of a heated jacket TE and the concentration of A in the inlet C_{A0} , respectively. Further details of the process and implementation are provided by Fig. 2. In this work, we constructed a proportional-integral-derivative (PID) control scheme of subjectively near optimal performance. The control scheme consists of two PID controllers, one for each variable control loop. The PID controllers were constructed and tuned via the MATLAB Simulink package. Existing process data \mathbf{T} was generated for the control scheme, by performing Monte Carlo realizations on the approximate process model. Implementation utilised Python 3.7.3. The data generated was then characterised by Eq. 5 in the scope of trajectory feature matching, which underpins MaxEnt IRL and the offline section of the framework.

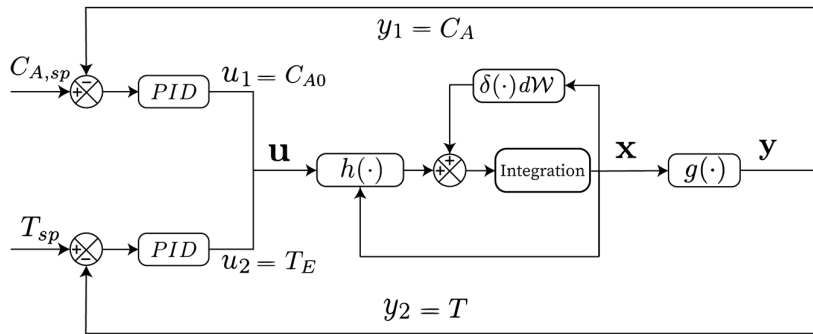

Figure 2: Flow diagram of the existing PID control scheme at implementation level. The underlying process dynamics are described by $\mathbf{h}(\cdot)$ (see Eq 7). Process stochasticity is dependent on the state \mathbf{x} and $\delta(\cdot)$, and modelled via the Wiener process \mathbf{W} . System integration was performed via the Euler-Maruyama method. The state observation is \mathbf{y} as mapped from the true state \mathbf{x} by the function $\mathbf{g}(\cdot)$; subscript sp indicates the variable set point; C_{A0} and T_E represent the control inputs to the system.

4. Results and Discussion

The purpose of this case study is to construct an RL controller which learns from demonstration provided by a near optimal control policy on a single control task and then to improve it further. As such, we demonstrate the full utility of the offline-online framework proposed. The control task itself is a set point change, such that in the concentration control loop, set point is changed by -1 kmol m^{-3} and in the temperature control loop, set point is changed by $+4 \text{ K}$. Firstly, offline learning under MaxEnt IRL is deployed to find a linear combination α^* of control hypotheses ϕ , which describes the control objectives of the existing scheme. Under this reward function a parameterisation of the control policy expressed in process data is learned in order to match the demonstrated process behavior as characterised via $\mathbb{E}_{p(\tau)}[\mathbf{v}^y]$ (see Eq. 6). The learned parameterisation is then improved under the real process objective, which in this case is pure tracking.

Here, the demonstrated control policy is that of a well-tuned PID controller and the learned policy is parameterised by a long-short term memory neural network. In this work, we use the normalized absolute error ϵ to quantify the similarity between the learned policy and that demonstrated, with respect to each v_d^y , which is formalized by Eq. 9:

$$\epsilon = \frac{\mathbb{E}_{p(\tau)}[\mathbf{v}^{y,E}] - \mathbb{E}_{p(\tau)}[\mathbf{v}^{y,\pi}]}{\mathbb{E}_{p(\tau)}[\mathbf{v}^{y,E}]} \quad (9)$$

The results of the offline learning section of the case study described are detailed by Table 1.

Table 1: The expected discounted sum of the state features of the PID ($\mathbf{v}^{y,E}$) and the policy learned through AL ($\mathbf{v}^{y,\pi}$), the normalized absolute error in approximation ϵ and the feature weight (α^*) generated in case study.

	Trajectory Features \mathbf{v}^y					
	v_1^y	v_2^y	v_3^y	v_4^y	v_5^y	v_6^y
$\mathbb{E}_{p(\tau)}[\mathbf{v}^{y,E}]$	21.63	20.68	4.08	7.93	-22.87	-22.43
$\mathbb{E}_{p(\tau)}[\mathbf{v}^{y,\pi}]$	21.41	20.76	4.31	7.03	-22.28	-22.71
ϵ	0.01	0.004	0.06	0.10	0.03	0.01
α^*	0.137	0.652	-0.067	-0.630	-0.194	-0.343

From Table 1, it is concluded that offline learning was able to abstract an RL parameterisation of the demonstrated policy (i.e. PID controller). The quality of solution is indicated by the normalized absolute error ϵ . Table 1 details that the algorithm found a solution, which achieves a maximum $\epsilon = 0.1$ and an average of $\epsilon = 0.035$. This was achieved after just four iterations of the algorithm. It is also worth noting, that the learned weight vector α^* encodes information about the process dynamics into control objectives. Although further discussion is not provided here, this implies that the weight vector itself is both specific to the set point change and the process itself. The policy was then transferred to the “real process”, which was simulated under the assumption of the same process model as in the offline setting but a reward function representative of the true process objective. Through further online learning, it is observed that the parameterisation can achieve a better control strategy compared to the existing PID controller (see Fig. 3). Specifically, RL is able to facilitate a system response, which meets set point faster with less overshoot observed than using the PID controller. For example, the updated parameterisation yields a better temperature response characterised by a fast rise time with no observable overshoot. This performance increase is derived from the ability to account for process stochasticity in a proper closed loop manner, as well as the nonlinearity of the resultant control function.

5. Conclusions

Here, we propose a framework based on apprenticeship learning (AL) to learn a control law based on process data. This approach allows us to synthesize a neural network control policy from a previous controller (e.g. PID, MPC or human controllers) more robustly than with supervised learning. Having learned a parameterisation of the control law, subsequent deployment of RL enables further policy improvement by directly interacting with the real process, thus outperforming the existing control law. Here, AL is

implemented through inverse reinforcement learning (IRL). Given the data-driven nature of AL via IRL, the RL-based policy parameterisation promises to express the action of the control scheme and process knowledge of operators. The RL controller is constructed via a policy optimisation algorithm, although other methods could be applied. Based on the case study, it is concluded that the current framework can effectively extract control information from available process data, resulting in a better optimal control policy efficiently. In future work, we will explore the performance of this framework when handling constrained chemical processes, look to account for uncertainty in the approximate process model and introduce mechanisms to account for process-model mismatch in transfer of the policy to the real process.

Figure 3: Optimal policy learned in Case study. A and B: System response in the concentration C_A control loop and in the temperature T control loop, respectively. π^A and π^E indicate the learned policy (after online update) and the PID, respectively. Shaded regions indicate the two standard deviations of system response and central line indicates the expected control response. Line properties: dashed line - π^A ; solid line - π^E . Set points are indicated. Only the first 30 control interactions are plotted, given the efficacy of system response

Systematic model-based dynamic optimization of a combined cooling and antisolvent multistage continuous crystallization process

Jiaxu Liu, Brahim Benyahia*

Department of Chemical Engineering, Loughborough University, Loughborough, LE11 3TU United Kingdom

B.Benyahia@lboro.ac.uk

Abstract

A rigorous and systematic methodology was developed to optimize multistage combined cooling and antisolvent continuous MSMPR (mixed-suspension, mixed-product removal) crystallizers. The crystallization of aspirin (acetylsalicylic acid, ASA) in ethanol (solvent) and water (antisolvent) was used as a case study. A validated mathematical model of the system was firstly used to optimize the steady state performance followed by the development of several optimizations strategies aiming at the minimization of the start-up time using optimal dynamic profiles of antisolvent addition, cooling temperature, seeding flowrate and the combination of these decision variables. The start-up scenarios were also considered in the case of initially prefilled and empty vessels. Using the proposed dynamic optimization strategies, it was predicted that the start-up time can be reduced by up to 70%, which represents a significant gain in time, cost and environmental performance.

Keywords: Continuous crystallization, start-up, antisolvent, optimal seeding, dynamic optimization.

1. Introduction

Continuous manufacturing is increasingly seen as a the most flexible and viable options for the pharmaceutical industry (Mascia et al., 2013). However, despite the strides forward, many technical challenges are still to be overcome. Continuous pharmaceutical campaigns are anticipated to have short operating windows (Benyahia et al., 2012). This makes the impact of start-up and shut-down extremely important on both cost of production and environmental footprint. To address some of these key issues, the next generation pharmaceutical plants require systematic, rigorous and robust optimization strategies for process design, operation and control of single processes and integrated plants (Benyahia et al., 2012; Lakerveld et al., 2015).

Crystallization is a key purification technology widely adopted in the pharmaceutical industry to isolate active pharmaceutical ingredients (API). The critical quality attributes of the drug product, such as solubility, safety and efficacy are commonly determined by the crystal size distribution, shape and purity, which also impact the downstream processability such as flowability, filterability and dyability. A common optimization target in crystallization is to maximise the mean crystal size, lower the coefficient of variation (CV) and improve the aspect ratio (Fysikopoulos et al., 2019;

Hatcher et al., 2020). The fundamental driving force for crystallization is supersaturation. Typically, the supersaturation is generated by cooling, solvent evaporation or addition of antisolvent. Most of crystallization literature focused on the design, optimization and control of batch processes. Various model-based and model-free technique have been extensively implemented and thoroughly discussed in the literature. However only few decision and control variables are available to optimally design and operate a batch crystallization process. The most common approach is to use the temperature or/and antisolvent ratio to optimize the crystal size distribution, CV and batch time.

Over the last decade, continuous crystallization of active pharmaceutical ingredients (API) received growing interest. To date, most literatures focused on three main continuous crystallizers: mixed suspension mixed product removal (MSMPR), plug flow crystallizers and continuous oscillatory baffled crystallizers. The most dominant type of crystallizers in the pharmaceutical industries is based on a stirred tank design which exploits well-established theory and know-how accumulated over decades of batch crystallization. Consequently, many experimental and modelling efforts have been devoted to the continuous MSMPR crystallizers. Several studies focused on the optimization of single, multistage MSMPR and integrated end-to-end continuous pharmaceutical plant with a series of MSMPR crystallizers (Lakerveld et al., 2015; Mascia et al., 2013; Benyahia, 2018; Su et al., 2015). Despite the importance of optimal start-up strategies in continuous pharmaceutical manufacturing, due its significant impact on cost and environmental footprint, only few investigations were reported in the literature which identified mainly the optimal dynamic profile of the cooling temperature and antisolvent flowrate (Yang & Nagy, 2015). However, the MSMPR vessels were assumed to be prefilled with a solution having the steady state composition. This approach is unrealistic and disregards the impact of filling the vessels during the start-up which may increase even further the start-up time. To date, only few papers showed the potential impact of different start-up scenarios, including starting from empty MSMPR vessels, on continuous pharmaceutical campaigns (Benyahia et al., 2012). The later laid the ground to the current investigation, which consists in a systematic optimization approach starting from steady state optimization, aimed at the identification of the attainable mean particle size, followed by different start-up optimization strategies including start-up from empty vessels. The start-up time will be optimized by identifying the optimal discrete piece-wise profiles of antisolvent flowrate, seed flowrate, cooling rates as well as the seed loading in the seed vessel.

2. Materials and Methods

To implement the dynamic and steady state optimization strategies, the crystallization of aspirin (acetylsalicylic acid, ASA) in ethanol (solvent) and water (antisolvent) mixture is considered as a case study. The dynamic mathematical model which represents the population balances, based on the standard method of moment, the energy balance, the total mass balance in each vessel as well as the mass balance of API, solvent and antisolvent was developed based on data available in the literature (Barik et al., 2020; Lindenberg et al., 2008; Liu & Benyahia, 2020).

Prior to the development of the optimal start-up policies, a steady-state optimization problem was solved with the aim of maximizing the mean crystal size (d) using the jacket temperature (T_J), antisolvent flowrate (F_{AS}) and residence time (R) at each

crystallization stage, as the decision variables. This approach delivered the reference attainable crystal size for a 3-stage MSMR system and the optimal design and operating steady state conditions shown in Table 1. However, the steady state optimization, does not consider the dynamic performance of the process and disregards large amounts of off-specification crystals (waste) generated during start-up. To address this issue, several dynamic optimizations strategies were developed to minimize the start-up time by identifying the discrete optimal dynamic profiles (piece-wise constant) of the antisolvent flowrates, cooling rates, seed flowrates and seed loading. In addition, the crystallizers were assumed both empty and prefilled at the beginning of the process.

Table 1 steady state control variable

	T_J (°C)	F_{AS} (g /min)	R (min)
Stage 1	32.75	9.94	5.83
Stage 2	32.10	5.88	10.15
Stage 3	25.00	2.68	14.02

2.1. Start-up optimization using dynamic antisolvent addition

The first series of start-up optimization focused on the manipulation of the antisolvent flowrate profiles at the first, the first two then all three MSMR stages. The approach was developed to investigate whether manipulating the antisolvent flowrates in multiple stages would add any value, despite the increased complexity. As a first attempt, the antisolvent flowrate profiles were divided into n_k equality spaced time intervals. The flowrates of the antisolvent at each interval are the decision variables. The first set of scenarios focussed on prefilled vessels and the second considered empty vessels. The dynamic optimization problems can be expressed using the generic mathematical formulation below:

$$\begin{aligned}
 & \text{Min}_{F_{AS,i,k}, T_{J,i,k}} t_{95} \\
 & \text{s.t.} \\
 & \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{p}, t) \quad \mathbf{x}(t=0) = \mathbf{x}_0 \\
 & 0 = \mathbf{g}(\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{p}, t) \\
 & 0 \leq F_{AS,i,k} \leq 20 \\
 & 20 \leq T_{J,i,k} \leq 40 \\
 & S_i(t) \geq 1 \\
 & i = 1, 2, 3 \\
 & k = 1, 2, \dots, n_k
 \end{aligned}$$

Where t_{95} is the time required for the crystallizer to reach controlled state of operation that has less than 5% variation. $T_{J,i,k}$ (°C) and $F_{AS,i,k}$ (g/min) are the jacket temperature

and antisolvent flow rate at the k th time interval in the i th stage. S_i is the relative supersaturation maintained above 1 in all stages to prevent dissolution of crystals.

2.2. *Start-up optimization using a dynamic seeding profile*

The addition of seeds is commonly adopted in batch systems to generate initial particles without relying on the nucleation, which is difficult to control and requires larger supersaturation levels to reach the boundary of the metastable zone. The addition of seeds in batch systems can provide an effective control strategy over the number of particles and consequently the final particle size distribution. In this work, the seeding approach was used to optimize the start-up time. Instead of one single seeding addition, the optimizer will determine the optimal seed addition profiles as well as the required initial seeding charge in the seeding vessel. The seeds are suspended in a saturated solution having the same composition as the feed solution and the size distribution of seeds was obtained from literature. The seeds were added to the first stage only, where most of the nucleation occurs. The mathematical formulation of the optimization problem is similar to the one described above, with the decision variables being the piece-wise flow rate profile of seed addition alongside the seeding bounds (0: lower bound and 20% of the API load in the feed solution).

2.3. *Start-up optimization using combined seeding, cooling and antisolvent addition*

To maximize the efficiency of the start-up optimization, the optimal seeding policies, which correspond to a piece-wise seeding profile and seed loading ($\mu_{0,seed}$), were combined with the cooling and antisolvent profiles.

3. **Results and Discussion**

The optimization problems were solved using a hybrid method which combines a genetic algorithm and a deterministic method (SQP) available in MATLAB. The start-up optimization results obtained using dynamic antisolvent and cooling (jacket temperature) profiles in the three stages are shown in Figure 1. The predicted optimal start-up time (t_{95}) was 26.1 min in the case of prefilled vessels and 22.2 min in the case empty vessels. Compared to the reference start-up time obtained by the implementation of the steady state operating conditions (69.2 min), an improvement of 62.3% and 67.0% respectively, can be achieved.

Additional start-up optimization problems based on the manipulation of the operating profiles in one stage and two stages starting from prefilled and empty vessels were also addressed. However, the predicted start-up times were larger compared to the cases discussed above. These results are not presented here for the sake of brevity. Despite the increased complexity, manipulating the antisolvent flowrates and cooling profiles in three stages enhances the flexibility and degrees of freedom and help achieve shorter start-up times and increased on-specification production.

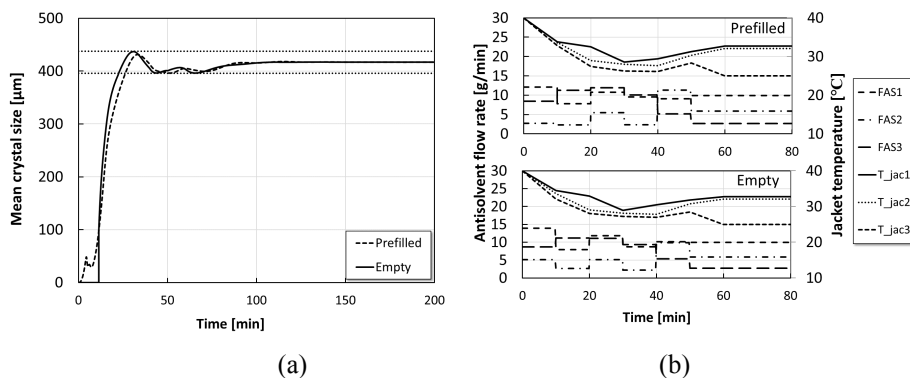

Figure 1. Optimization results obtained by manipulating jacket temperatures and antisolvent flowrates in the 3 MSMPR stages (a) Mean crystal size profiles (b) optimal cooling and antisolvent addition profiles.

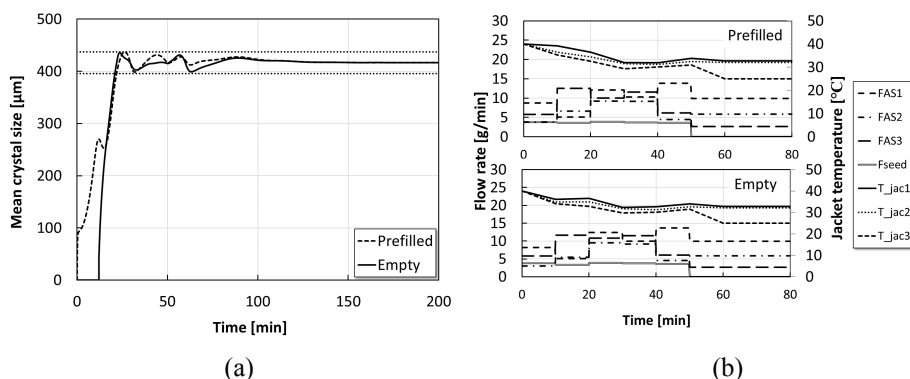

Figure 2. Optimization results obtained by manipulating the jacket temperatures and antisolvent and seeding flowrates in the 3 MSMPR stages (a) Mean crystal size profiles (b) optimal cooling, seeding and antisolvent addition profiles.

Figure 2 shows the dynamic optimization results obtained by manipulating the jacket temperatures as well as the antisolvent and seeding flowrates in the 3 MSMPR stages. With the addition of the seeding policies (seeding flow rates and initial seed load) to the set of decision variable comprising the jacket temperature and antisolvent flowrate profiles, the start-up time can be shortened to 21.8 min (in the case of prefilled vessels) and 20.9 min (in the case of initially empty vessel). This is equivalent to a 67.8% and 69.8% improvement respectively compared to the reference steady state settings. Moreover, a start-up time of 28.5 min was obtained using solely the optimal seeding policies (not presented here). It becomes clear that the combination of optimal seeding policies, cooling and antisolvent addition enhances the degrees of freedom and optimization flexibility and therefore delivers the best start-up performance.

4. Conclusion

The start-up performance of a three-stage MSMPR crystallizer was optimized based on a rigorous and systematic model-based approach. The attainable steady state particle

size and start-up time, obtained using steady state optimization, were used as references for the start-up optimization. To minimize the start-up time, several strategies were adopted including starting from empty and prefilled vessels. The dynamic optimization of the start-up was achieved using discretised piece-wise antisolvent flowrates, seed addition and the combination of both. The discretisation policy was based on equally spaced time intervals which can be refined further using optimized variable time intervals. The seed charge in the seeding vessel was also optimized in order to identify the optimal seeding policies. Overall, the start-up cases associated with the empty vessels seem to outperform the cases starting from prefilled vessels. The start from prefilled vessels may indicate that the nucleation requires longer time compared to starting from empty vessels where nucleation may happen very quickly. The number of time intervals was also increased from 5 to 10 and 20. However, these results were not presented for the sake of brevity.

It was shown that the implementation of optimal piece-wise continuous cooling and piece-wise antisolvent flowrates in the three stages can help reduce the start-up time by 67%. However, the best performance was obtained by combining the optimal cooling, antisolvent and seeding policies which predicted a reduction of the start-up time by nearly 70%. It is worth mentioning that the optimization strategies developed in this work are in essence open-loop and their implementation may require an advanced control strategy such as model predictive control to ensure effective trajectory tracking and the predicted minimization of the start-up time.

Abstract

A semi-closed greenhouse has been studied in this research. The greenhouse is designed to keep the inside temperature and relative humidity within the optimum growing range throughout the year while maximizing the utilization of solar energy for the plants. The Venlo shaped greenhouse has 4 mm tempered glass as the covering material and three air handling units which control the microclimate. Using air handling units to manage the microclimate of a greenhouse is becoming increasingly popular in arid climates. The plant yield productivity and quality depend on the accurate monitoring and control of the greenhouse microclimate. This study aims to develop a dynamic model that predicts the temperature and relative humidity to improve climate monitoring control accuracy. The data-driven model determines the temperature and relative humidity by incorporating factors affecting the microclimate, such as solar radiation, ambient temperature, relative humidity, fan speed, etc. The available greenhouse data spans from April to June (3 months). Results illustrate that the model predicted accurate values for temperature and relative humidity with an R^2 value of 0.930 and 0.911 and an RMSE value of 0.826 and 1.740, respectively. By accurately predicting the temperature and relative humidity inside the greenhouse, the crop yield can be increased, while minimizing the energy consumption by the air handling units, making greenhouses in an arid climate a more economically feasible option.

Keywords: Greenhouse, Dynamic modeling, Support vector machine, Climate control, microclimate.

1. Introduction

As the world population is expected to rise to 9.7 billion by the year 2050, achieving food security is one of the most challenging problems of the 21st century (UN, 2019). With the expected increase in the population coupled with the demand for food, it is essentially required to develop clean and sustainable food production systems. Agriculture greenhouse presents a viable solution as they minimize resource consumption while increasing the yield by 10-20% (De Gelder et al., 2012). Greenhouses offer a closed and controlled environment to the plants while maintaining optimum conditions for plant development. Maintaining these optimum growing conditions throughout the year is a significant concern as various factors affect the greenhouse microclimate. Greenhouse microclimate variables are complex and nonlinear and depend on environmental factors such as solar radiation, ambient air

temperature, outside relative humidity, etc. Therefore, developing an accurate model to predict the microclimate parameters is an essential part of greenhouse management.

Microclimate prediction models can be based on thermodynamics laws that incorporate the heat and mass exchange taking place between the different driving factors or data-driven models using data from the input-output of the process occurring inside the greenhouse. The microclimate models are highly complex, resulting in inconsistent results when physical models are used to predict the microclimate (Van Henten, 1994). On the other hand, data-driven models are increasingly being applied to the ongoing development of new computational methods. The data-driven approach provides accurate and quick results for agricultural applications such as predicting the temperature and relative humidity inside a greenhouse (Chen et al., 2016).

Neural networks have been extensively used to model nonlinear systems such as the greenhouse microclimate (Ribeiro et al., 2019). However, the application of neural networks is limited due to certain disadvantages such as overfitting and stopping at local minima (Vapnik, 1995). Support vector machines can model nonlinear systems without the mentioned disadvantages (Engel et al., 2002). Wang et al. (2009) used support vector regression (SVR) to develop a greenhouse microclimate model to predict the temperature inside the greenhouse based on external and internal factors. Results demonstrated that the SVR successfully predicted the temperature with a mean square value of 0.351. Liu et al., (2016) developed a wireless sensor network-based prediction model to predict the greenhouse microclimate. Results illustrated that SVM had a value of R^2 of 0.9865 and 0.9605 for the temperature and relative humidity inside the greenhouse, respectively. Similarly, Taki et al., (2018) developed a model to estimate the temperature of air, plant, and soil inside a greenhouse using SVM and artificial neural networks. The model included factors such as inside temperature, outside temperature, solar radiation, and wind speed. Results illustrated the SVM had an R^2 value of 0.83, 0.99, and 0.98 for the air, plant, and soil temperature, respectively.

Most of the studies existing in literature have developed models for greenhouses with natural ventilation in tropical or cold environments. Semi-closed greenhouses depend on the cooling system to maintain the optimum growing conditions inside the greenhouse. Maintaining optimum temperature is a challenging task during the summer season as the solar radiation and ambient temperature rise, increasing the cooling load of the greenhouse. In this study, a microclimate model is developed to predict the temperature and relative humidity inside a closed greenhouse with no ventilation in an arid climate to improve greenhouse management.

2. Greenhouse data

The experiments were conducted in a Venlo shaped greenhouse (800 m²) with 4 mm tempered glass as the covering material located on a greenhouse farm in Qatar. The data was collected from April 1, 2020, to June 30, 2020, using tomatoes as the plants. The temperature and relative humidity inside the greenhouse were measured using a sensor module shown in Figure 1. The data was recorded after every five minutes and saved in the data logger. The external conditions such as solar radiation, ambient temperature, and outside relative humidity were all measured and recorded by external sensors.

Figure 1: Temperature and relative humidity monitoring sensor.

3. Methodology

Support vector machines (SVM) were initially developed to recognize patterns and classify objects. A small subset from the training sample is used to define the decision boundary called support vectors. The concept of support vectors originated from the optimum separation of the hyperplane which could separate the points without error and maximize the distance between the closest point and the hyperplane. SVM is similar to perceptron in neural networks as the output is a combination of the nodes present in the middle, as illustrated in Figure 2.

Figure 2: Support vector machine structure.

Support vector machine regression (SVMR) calculates the real value function by generalizing the support vectors. Support vector machine regression (SMVR) is also called support vector regression (SVR) to differentiate it from support vector machine (SVM). SVR follows the structural risk minimization (SRM), which has been shown to give better results than empirical risk minimization (ERM) (Wang et al., 2009). SVR maps data from a vector x into an F , which is a high dimensional feature space, and the linear regression is performed as with b as the threshold value:

$$f(x) = (w \cdot \varphi(x)) + b(\varphi : R^n \rightarrow F, w \in F) \quad (1)$$

The resulting linear regression corresponds to nonlinear regression in a low dimension space. The value of w can be calculated by the following:

$$R(w) = R_{emp} + \lambda \|w\|^2 = \sum_{i=1}^l e(f(x_i) - y_i) + \lambda \|w\|^2 \quad (2)$$

Where e is the cost function, l is the number of samples, R_{emp} is the sum of empirical risk, and λ is the constant of regularization. The cost function can be represented in a linear form given as:

$$e(f(x) - y) = \max(0, |f(x) - y| - \epsilon) \quad (3)$$

Quadratic cost function:

$$e(f(x) - y) = (f(x) - y)^2 \quad (4)$$

Huber cost function:

$$e(f(x) - y) = \begin{cases} \mu |f(x) - y| - \frac{\mu^2}{2}, & \text{if } |f(x) - y| > \mu \\ \frac{1}{2} |f(x) - y|^2, & \text{other} \end{cases} \quad (5)$$

The function $R(w)$ is minimized by first determining $(\alpha - \alpha_i^*)$

$$w = \sum_{i=1}^l (\alpha_i - \alpha_i^*) \varphi(x_i) \quad (6)$$

4. Results and Discussion

The data set has outside temperature, solar radiation, fan speed, cooling temperature setpoint, and humidity deficit as the input factors, while the greenhouse temperature and relative humidity are the outputs. The dataset is split into training and testing data, with 70% dedicated for training and 30% for the testing set. The model's performance is evaluated at different time steps such as 5, 10, 15, and 20 minutes (SVM-5, SVM-10, SVM-15, SVM-20) by increasing the prediction time step. The SVM model algorithm is implemented in Python 3.7.

Table 1 shows the temperature and relative humidity predicted results using the SVR model. The results have been obtained by increasing the time step of the data from 5 up to 20 minutes.

Table 1: SVM prediction accuracy for temperature and relative humidity.

	SVM-5		SVM-10	
	Temperature	Relative Humidity	Temperature	Relative Humidity
RMSE	0.826	1.740	0.909	2.207
R²	0.930	0.911	0.917	0.857
	SVM-15		SVM-20	

	Temperature	Relative Humidity	Temperature	Relative Humidity
RMSE	0.982	2.517	0.998	2.598
R²	0.899	0.818	0.897	0.807

The temperature has an RMSE and R^2 value of 0.826 and 0.93, respectively and relative humidity has an RSME and R^2 value of 1.740 and 0.911 at time step 5. The accuracy of the model decreases by increasing the time step as the number of data points decreases and has the lowest accuracy at time step of 20 minutes, which illustrates for better prediction performance, a more extensive data set should be used. Figure 3 shows the prediction of the trained model over an unseen data set of 3 days. The graph on the left side is the actual vs. predicted temperature of the greenhouse, and the graph on the right shows the actual vs. predicted data for the relative humidity. The red shows the actual data, and the yellow lines indicate the predicted temperature and relative humidity values, respectively. The model gives accurate predictions for the temperature and relative humidity, as shown in the graphs. Also, the actual vs. predicted graph illustrates that the trained model is not overfitted as it produces accurate results for a new set of values for both the temperature and relative humidity inside the greenhouse.

Figure 3: Actual vs. Predicted for a 3-day data set; (left) Temperature (Right) Relative humidity.

To improve the prediction accuracy of the relative humidity, data regarding the irrigation history and soil moisture can be included by using the relevant sensors as the greenhouse uses a hydroponic system to provide water and nutrients to the plants.

5. Conclusion

The microclimate of a greenhouse is a dynamic system where various factors such as solar radiation, ambient temperature, relative humidity, etc., affect the temperature and relative on the inside of the greenhouse. The study shows the possibility of predicting the greenhouse temperature and relative humidity using support vector machines. Support vector machines are feasible for modeling dynamic environments where the variables are constantly changing, such as the environmental factors. The developed model has an R^2 and RMSE value of 0.930 and 0.826 for temperature and 0.911 and

1.740 for relative humidity. The accuracy of the model for temperature and relative humidity dropped by increasing the data time step as the training data points were reduced. The model had the lowest prediction accuracy at a twenty-minute interval with an R^2 value of 0.897 and 0.807 for temperature and relative humidity. By predicting the temperature and relative humidity based on the factors, the water and energy consumption can be optimized while providing optimum growing conditions to the plants. The results of this study show the potential of applying machine learning for greenhouse management.

Abstract

This paper has proposed an adjustable robust dynamic optimization (ARDO) scheme for nonlinear chemical process under time-dependent uncertainties. A novel continuous affine decision rule extended from multistage affine decision rule is developed to approximate the causal dependence of wait-and-see decision variables on the infinite dimensional uncertainty factors. Through applying the state-of-the-art first-order Taylor expansion method, the adjustable robust counterpart can be formulated. The effectiveness and applicability of the proposed ARDO scheme is demonstrated by a classic Williams-Otto semi-batch problem. Compared with traditional robust optimization for uncertain dynamic systems, the proposed framework can adjust the decision variables based on true values of the revealed uncertainties, leading to more flexible control profiles and less conservative solutions.

Keywords: adjustable robust dynamic optimization, time-dependent uncertainty, continuous affine decision rule, nonlinear semi-batch reactor

1. Introduction

Dynamic optimization has received extensive attention during the past decades to deal with batch optimal operation problems. Unfortunately, usually employing deterministic optimal control will force systems running on safety margins, potentiate constraints violation in the presence of uncertainties. Although traditional static robust optimization (SRO) methods provide effective frameworks to overcome uncertainties, in general, their inherent conservatism cannot be completely avoided, because the manipulated variables in SRO schemes, which are referred to as here-and-now decision variables, are optimized without knowledge of the true values of the uncertainties (Diehl et al, 2006). To reduce the conservativeness of the solution, lessons can be learned from the adjustable robust optimization (ARO) method for two-stage linear problems (Ben-Tal et al, 2004). By introducing wait-and-see or adjustable decision variables, part of the manipulated variables in ARO scheme can correspond to gradually revealing information about the uncertainty, thus leading to lower conservative system performance and better objective values. However, owing to the intrinsic difficulties of nonlinear problems, research on adjustable robust nonlinear optimization with only algebraic constraint or differential-algebraic constraints is scarce.

Triggered by the progresses of ARO on multistage planning and scheduling (Zhang et al, 2016), we propose an adjustable robust optimal control scheme for nonlinear chemical processes under time-dependent uncertainties on continuous time horizon. A novel continuous affine decision rule is developed to approximate the causal dependence of wait-and-see decision variables on the infinite dimensional uncertainty factors to overcome potential computational intractability. Then the classical first-order Taylor

expansion method is applied to derive the robust counterpart which is finally solved numerically by IPOPT in Pyomo. The effectiveness and applicability of the proposed ARDO scheme is demonstrated by a classic Williams-Otto semi-batch problem.

2. Model formulation

2.1. General formulation of deterministic dynamic optimization

General deterministic dynamic optimization problem defined on $t \in [0, t_f]$ can be formulated as follows:

$$\min_u \Phi(x(t_f), t_f) \quad (1)$$

$$\frac{dx}{dt} = f(x, u, t, p); \quad x(0) = x_0, \quad (2)$$

$$0 \geq G(x, u, t, p) \quad (3)$$

where $x \in \mathbb{R}^{n_x}$, $u \in \mathbb{R}^{n_u}$ and $p \in \mathbb{R}^{n_p}$ represent state, controls and model parameters respectively. Besides, $\Phi(\cdot)$ is a scalar Mayer-type cost function, $f(\cdot)$ represents differential equations with initial conditions x_0 while $G(\cdot)$ denotes inequalities.

2.2. General formulation of traditional static robust dynamic optimization

Regarding the problem under uncertainty, model parameters are divided into $p = [\zeta; \bar{p}]$ where $\zeta \in \mathbb{R}^{n_\zeta}$ and $\bar{p} \in \mathbb{R}^{n_p}$ denote uncertain and known parameters respectively. Furthermore, time-dependent uncertainties are denoted as $\zeta(\tau) \in \mathbb{R}^{n_\zeta}$. Time horizon for uncertainty realization is denoted as $\tau \in [0, t_f]$ while horizon for states and controls is $t \in [0, t_f]$. Formulation of traditional SRO defined on $\tau, t \in [0, t_f]$ is:

$$\underset{u(t)}{\text{minimize}} \quad \max_{\zeta(\tau) \in Z} \Phi(x(t_f), t_f) \quad (4)$$

$$\frac{dx}{dt} = f(x, u, t, \bar{p}, \zeta); \quad x(0) = x_0; \quad \forall \zeta(\tau) \in Z \quad (5)$$

$$0 \geq G(x, u, t, \bar{p}, \zeta); \quad \forall \zeta(\tau) \in Z \quad (6)$$

$$Z := \{\zeta(\tau) \in \mathbb{R}^{n_\zeta} \mid -\Delta\zeta_j \leq \zeta_j(\tau) - \zeta_j^{nom} \leq \Delta\zeta_j, \quad j \in I_\zeta\} \quad (7)$$

Where Z is a predefined box uncertainty set and I_ζ is the subscript set of uncertainties.

2.3. General scheme of proposed adjustable robust dynamic optimization

The proposed adjustable robust dynamic optimization is proposed by applying wait-and-see strategy to nonlinear dynamic optimization problems under time-dependent uncertainty. In the proposed ARDO scheme, the wait-and-see decision variables are determined based on a general decision policy $d_t(\cdot)$ defined as:

$$u(t) = d_t(\hat{\zeta}(t)), \quad d_t(\cdot): \prod_{\tau=t_0}^{\tau=t} Z_\tau \rightarrow \mathbb{R}^{n_u} \quad (8)$$

where $\hat{\zeta}(t)$ is the trajectory of uncertainties revealing in time interval $\tau \in [0, t]$.

Proposed ARDO scheme is defined as Eqs.(9)-(13),

$$\underset{d_t(\cdot)}{\text{minimize}} \quad \max_{\zeta(\tau) \in Z_\tau} \Phi(x(t_f), t_f) \quad (9)$$

$$\frac{dx}{dt} = f(x, u, t, \bar{p}, \zeta); \quad x(0) = x_0; \quad \forall \zeta(\tau) \in Z \quad (10)$$

$$0 \geq G(x, u, t, \bar{p}, \zeta); \quad \forall \zeta(\tau) \in Z \quad (11)$$

$$Z := \{\zeta(\tau) \in \mathbb{R}^{n_\zeta} \mid -\Delta\zeta_j \leq \zeta_j(\tau) - \zeta_j^{nom} \leq \Delta\zeta_j, j \in I_\zeta\} \quad (12)$$

$$u(t) = d_t(\hat{\zeta}(t)) \quad (13)$$

The above formulation is generally computationally intractable due to undermentioned reasons. On one hand, functional space of possible $d_t(\cdot)$ is infinite. On the other hand,

requirement of satisfying constraints over uncertainty set leads to a semi-infinite problem. Therefore, this general ARDO model will be reformulated to gain tractability in next section.

3. ARDO reformulations

3.1. Continuous affine decision rule

As a preliminary, multistage affine decision rule is defined as Eq.(14), which restricts decision-making at t_k depend on observed uncertainty till t_k , since the undesired effect of uncertainty at t_1 may not be fully compensated only by decision $u(t_1)$, which is bounded within operation limits.

$$\mathbf{u}(t_k) = \mathbf{u}^0(t_k) + \sum_{i=0}^k \mathbf{u}^1(t_k, \tau_i) \zeta(\tau_i), \quad k = 0, 1, \dots, N \quad (14)$$

Obviously, Eq.(14) cannot be directly employed for differential-algebraic systems due to its discrete nature. Therefore, a novel continuous affine decision policy is proposed to approximate $\mathcal{d}_t(\cdot)$ for dynamic optimization problem on continuous time horizon.

The slope parameter in Eq.(14) can be written as $\mathbf{u}^1(t_k, \tau_i) = w(t_k, \tau_i) \Delta \tau_i$ where the time span is defined as $\Delta \tau_i = \tau_i - \tau_{i-1}$. In such way, Eq.(14) is converted to,

$$\mathbf{u}(t_k) = \mathbf{u}^0(t_k) + \sum_{i=0}^k w(t_k, \tau_i) \zeta(\tau_i) \Delta \tau_i, \quad k = 0, 1, \dots, N \quad (15)$$

Naturally, if the number of time intervals N approaches infinity, time spans $\Delta \tau_i$ become infinitesimals, denoted as $d\tau$. Thus Eq.(15) is extended to continuous time horizon as,

$$\mathbf{u}(t_k) = \mathbf{u}^0(t_k) + \int_{\tau=0}^{\tau=t_k} w(t_k, \tau) \zeta(\tau) d\tau, \quad k = 0, 1, \dots, N \quad (16)$$

If t_k is replaced by t in Eq.(16), the continuous affine decision rule can be formulated as,

$$\mathbf{u}(t) = \mathbf{u}^0(t) + \int_0^{\tau=t} w(t, \tau) \zeta(\tau) d\tau, \quad t \in [0, t_f] \quad (17)$$

3.2. Adjustable robust counterpart formulation

The uncertain problem given by Eqs. (9)-(12) is a semi-infinite program. Therefore, the state-of-the-art first-order Taylor expansion is applied at the nominal uncertainty values to guarantee constraints be satisfied on uncertainty set. The robust counterparts of inequality constraints Eq.(11) are written as:

$$0 \geq G(x, u, t, \bar{p}, \zeta^{nom}) + \|\nabla_{\zeta} G(x, u, t, \bar{p}, \zeta) \Delta \zeta\|_1 \quad (18)$$

$$\nabla_{\zeta} G(x, u, t, \bar{p}, \zeta) = \left(\frac{\partial G}{\partial \zeta} \right) + \left(\frac{\partial G}{\partial x} \right) D(t) + \left(\frac{\partial G}{\partial u} \right) \left(\frac{\partial u}{\partial \zeta} \right) \quad (19)$$

The inner level of original objective function is approximated as:

$$\left(\max_{\zeta(\tau) \in Z_{\tau}} \Phi(x(t_f), t_f) \right) = \Phi(x(t_f), t_f) + \left\| \left(\frac{\partial \Phi}{\partial x} \right) D(t_f) \Delta \zeta \right\|_1 \quad (20)$$

To summarize, the adjustable robust counterpart of ARDO model in Eqs. (9)-(13) can be described as Eqs. (21)-(27).

$$\underset{w(t, \tau), u^0(t)}{\text{minimize}} \quad \Phi(x(t_f), t_f) + \left\| \left(\frac{\partial \Phi}{\partial x} \right) D(t_f) \Delta \zeta \right\|_1 \quad (21)$$

$$\frac{dx}{dt} = f(x, u, t, \bar{p}, \zeta^{nom}); \quad x(0) = x_0; \quad (22)$$

$$u(t) = u^0(t) + \int_0^{\tau=t} w(t, \tau) \zeta(\tau) d\tau, \quad t \in [0, t_f] \quad (23)$$

$$\frac{dD(t)}{dt} = \left(\frac{\partial f}{\partial \zeta} \right) + \left(\frac{\partial f}{\partial x} \right) D(t) + \left(\frac{\partial f}{\partial u} \right) \left(\frac{\partial u}{\partial \zeta} \right) \quad (24)$$

$$0 \geq G(x, u, t, \bar{p}, \zeta^{nom}) + \|\nabla_{\zeta} G(x, u, t, \bar{p}, \zeta) \Delta \zeta\|_1 \quad (25)$$

$$\nabla_{\zeta} G(x, u, t, \bar{p}, \zeta) = \left(\frac{\partial G}{\partial \zeta} \right) + \left(\frac{\partial G}{\partial x} \right) D(t) + \left(\frac{\partial G}{\partial u} \right) \left(\frac{\partial u}{\partial \zeta} \right) \quad (26)$$

$$D(0) = 0 \quad (27)$$

4. Case study: Williams-Otto semi-batch

We apply the adjustable robust dynamic optimization scheme to the Williams Otto process with reactions $A + B \rightarrow C$, $B + C \rightarrow P + E$ and $C + P \rightarrow G$. Reactant A is the only prefilled substance and reactant B is continuously fed in. Corresponding adjustable robust dynamic optimization formulation under uncertain inlet temperature $T_{in}(\tau)$ is:

$$\underset{F_{B,in}(t), T_j(t)}{\text{minimize}} \quad \max_{T_{in}(\tau)} \Phi(t_f) \quad (28)$$

$$\frac{dx_A}{dt} = -\frac{F_{B,in}x_A}{1000V} - k_1\eta_1x_Ax_B \quad (29)$$

$$\frac{dx_B}{dt} = -\frac{F_{B,in}(x_B - 1)}{1000V} - k_1\eta_1x_Ax_B - k_2\eta_2x_Bx_C \quad (30)$$

$$\frac{dx_C}{dt} = -\frac{F_{B,in}x_C}{1000V} + 2k_1\eta_1x_Ax_B - 2k_2\eta_2x_Bx_C - k_3\eta_3x_Cx_P \quad (31)$$

$$\frac{dx_P}{dt} = -\frac{F_{B,in}x_P}{1000V} + k_2\eta_2x_Bx_C - \frac{1}{2}k_3\eta_3x_Cx_P \quad (32)$$

$$\frac{dx_E}{dt} = -\frac{F_{B,in}x_E}{1000V} + 2k_2\eta_2x_Bx_C \quad (33)$$

$$\frac{dx_G}{dt} = -\frac{F_{B,in}x_G}{1000V} + \frac{3}{2}k_3\eta_3x_Cx_P \quad (34)$$

$$\frac{dT}{dt} = -\frac{R_1 + R_2 + R_3}{C_p} - L_1T + L_2T_j + \frac{F_{B,in}(T_{in} - T)}{1000V} \quad (35)$$

$$\frac{dV}{dt} = \frac{F_{B,in}}{1000V} \quad (36)$$

$$\frac{d\Phi}{dt} = -5554.1 \left(k_2\eta_2x_Bx_C - \frac{1}{2}k_3\eta_3x_Cx_P \right) V - 251.82k_2\eta_2x_Bx_CV \quad (37)$$

$$0 \leq V(t_f) \leq 5; \quad 60 \leq T(t) \leq 90 \quad (38)$$

$$0 \leq F_{B,in}(t) \leq 5.784; \quad 0.02 \leq T_j(t) \leq 0.1 \quad (39)$$

$$Z = \{T_{in}(\tau) \in \mathbb{R} \mid 32 \leq T_{in}(\tau) \leq 38\} \quad (40)$$

$$x(0) = [1, 0, 0, 0, 0, 0, 65, 2, 0]^T \quad (41)$$

where manipulated variables $F_{B,in}(t)$ and $T_j(t)$ are feeding flowrate and dimensionless jacket temperature limited by Eq.(38). Other necessary parameters can be found in the paper (Assassa and Marquardt, 2014). In this problem, the continuous affine decision rules for $F_{B,in}(t)$ and $T_j(t)$ are defined as:

$$F_{B,in}(t) = F_{B,in}^0(t) + \int_{\tau=0}^{\tau=t} w_1(t, \tau) T_{in}(\tau) d\tau \quad (42)$$

$$T_j(t) = T_j^0(t) + \int_{\tau=0}^{\tau=t} w_2(t, \tau) T_{in}(\tau) d\tau \quad (43)$$

4.1. Optimal continuous affine decision rule

Figure 2 depicts the optimized $w_1(t, \tau)$, $w_2(t, \tau)$, $F_{B,in}^0(t)$ and $T_j^0(t)$, respectively. Slope parameters $w_1(t, \tau)$ and $w_2(t, \tau)$ indicate the sensitivities of manipulated $F_{B,in}(t)$ and $T_j(t)$ to the realized uncertainty. The intercepts $F_{B,in}^0(t)$ and $T_j^0(t)$ represent the values of wait-and-see decisions when uncertain T_{in} equals to zero.

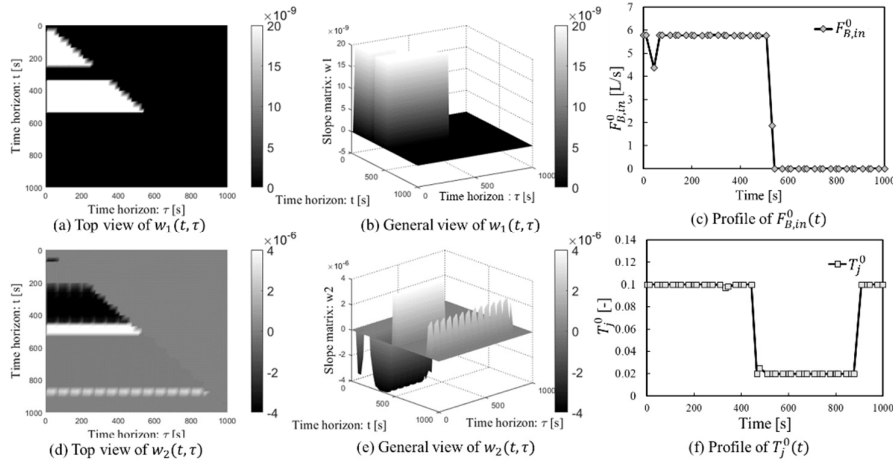

Figure 2. Optimal parameters of continuous affine decision rule

In Figure 2.(a)(b), we have $\forall t, \tau, w_1(t, \tau) \leq 2 \times 10^{-8}$, which suggests that the optimal feeding rate should take fixed actions with respect to uncertain T_{in} . Such phenomenon can be explained that the objective values monotonously decrease with the increment of volume, decided only by feeding rate $F_{B,in}(t)$, thus the reactor should always be fulfilled at terminal time regardless of uncertain feeding temperature profile.

On the other hand, the optimal $w_2(t, \tau)$ shown in Figure 2.(d)(e) can lead to a maximum adjustment at 0.02 for $T_j(t)$ applying Eq.(40). Slope parameter $w_2(t, \tau) \leq 0$ when $t \in [200, 450]$, indicating value of scaled jacket temperature should increase to meet to decrement of uncertainty in these time intervals. The choice of $w_2(t, \tau)$ is consistent with reactor temperature profiles in Figure 3.(a), where reactor temperature T is close to its lower bound in $t \in [200, 450]$. In this time period, decrement of feeding temperature may cause violation to constraint $T \geq 60$, therefore manipulated jacket temperature $T_j(t)$ should be raised to compensate the undesired effect by T_{in} falling. Moreover, the gray upper-triangular zone reflects that current manipulated action is only related to preceding uncertainty realization, while the gray areas in the lower-triangular zone indicates no adjustments are applied in these time periods.

4.2. Benefits evaluation of ARDO solution

In order to examine the benefits of ARDO solution, 200 random scenarios are generated via Eq.(44), where $r(\tau) \in [0, 1]$ is time-varying primitive uncertainty under uniform distribution.

$$T_{in}(\tau) = T_{in}^{LB} + r(\tau)(T_{in}^{UB} - T_{in}^{LB}) \quad (44)$$

The overall computational results are provided in Table 1. Conclusion can be drawn that the proposed ARDO method reaches lower average objective cost than SRO. No violation is observed in 200 random scenarios, demonstrating the robust feasibilities of proposed method.

Table 1. Benefit evaluation results of ARDO framework

Method	SRO	ARDO
Average objective value [€]	-4734.26	-4746.36
Average T_{min} [°C]	61.06	61.03
Constraint violations	0	0

Figure 3.(a) provides detailed profiles of reactor temperature and Figure 3.(b) shows the objective values of 200 uncertain scenarios, where each point stands for a single scenario. In Figure 3.(a), it is indicated that both proposed ARDO method can indeed prevent constraint violation under uncertainty as the reactor temperature profile T^{ARDO} is always between predefined lower bound T^{LB} and upper bound T^{UB} . Furthermore, in Figure 3.(b), significant improvement of objective performance by ARDO method can be seen. Objective costs Φ^{ARDO} is lower than Φ^{SRO} in every scenario, hinting the superiority of ARDO to SRO in achieving better objective performances.

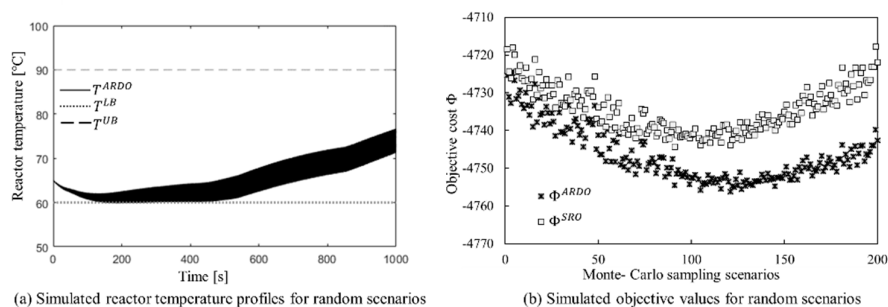

Figure 3. Robust solutions under 200 random scenarios.

5. Conclusion

The adjustable robust dynamic optimization scheme was proposed in this work. A novel continuous affine decision rule was developed to approximate the causal dependence of wait-and-see decision variables on the infinite dimensional uncertainty factors. To the best knowledge, it was the first attempt to employ adjustable robust optimization approach to addressing dynamic optimization of nonlinear chemical processes under uncertainty. Through the application to the classical nonlinear chemical process, when compared to traditional robust optimization approach, the proposed framework led to more flexible control profiles and less conservative solutions.

Abstract

This paper presents combining extreme learning machine (ELM) and recursive least square (RLS) technique in modelling and optimisation of a fed-batch fermentation process. ELM has some characteristic features of fast training together with better generalisation capability. In order to cope with batch-to-batch variations due to unknown disturbances such as unknown process condition drift, the RLS algorithm is integrated with the ELM to update the output layer weights recursively from batch to batch. The offline trained output layer weights of the ELM are used as the initial parameter estimation in RLS. After updating the ELM model, optimisation is carried out to update the feeding policy for the next batch. The proposed method is applied to a simulated baker's yeast fermentation process and the results obtained shows that the proposed method can cope with unknown disturbance and improve process operation from batch to batch.

Keywords Extreme Learning Machine, Fed-batch Process, Optimization, Recursive Least Square, Optimization Control.

1. Introduction

Mostly in biotechnology and food industries, fermentation process plays vital role in the production of baker's yeast also known as *Saccharomyces cerevisiae*, alcoholic beverages, organic solvents and antibiotics or biopolymers. The importance of these products in food industries cannot be over-emphasised which leads to their highly competitive market value demands and hence, the industrial production of baker's yeast.

Fed-batch processes operation are commonly seen in many fermentation industries. This mode of operation allows the substrate concentration and all other operating variables (such as the feed-rate, temperature, pressure, and agitation rate) to be varied and monitored during the progress of production to obtain maximum and desired biomass yield at the end of production. According to (Xiong and Zhang 2005), the significant requirement of batch process modelling lies in the accurate mathematical representation of the process.

The new trending concept of machine learning coupled with big data analytics has become a widely acceptable concept used in modelling, monitoring and optimisation of

many industrial process operations. Thus, the data-driven modelling concept utilizes statistical theories in establishing process models, monitoring the progress of pre-set conditions of operation for optimization purpose and generalization capabilities in predicting the unforeseen circumstances. In this concept, detailed knowledge of the process operation is not necessary but past historical data of the process operation is required. As much as the historical data is large and representative enough, data-driven modelling and process optimization can be established with machine learning and statistical theories conceptualization (Liu *et al.*, 2019).

In extreme learning machine (ELM), the hidden layer-weights are arbitrarily assigned and fixed without repeatedly adjustment unlike the traditional training approaches for single hidden layer feedforward networks (SLFNs). Parameters to be learnt in ELM are the connections (weights) between the hidden layer and the output layer, which are determined with a one-step regression type approach using Moore-Penrose (MP) generalized inverse operation of the hidden layer output matrices. ELM has been successfully applied to batch process modelling (Alli and Zhang, 2020).

This paper proposes integrating ELM with RLS algorithm in obtaining reliable modelling for batch-to-batch optimal control of the final biomass concentration of a baker's yeast fermentation process. An ELM model is initially developed from historical process operation data which is used to calculate the optimal control policy for the baker's yeast fermentation process. After the completion of each batch, the output layer weights of the ELM model are updated using the data from the newly completed batch through the RLS algorithm. The updated ELM model is then used to optimise the next batch and the procedure is repeated from batch to batch. By using this proposed modelling approach, the ELM model can keep track of any variations that may arise during the progress of the batch process operation.

The rest of this article is organized as follows. Batch-to-batch modelling with recursive updated ELM model is given in Section 2. Section 3 presents application to a fed-batch fermentation process and Section 4 gives the final concluding remarks.

2. Batch-to-Batch Modelling with an Updated ELM Model

2.1. Extreme Learning Machine

An ELM is a single-hidden layer feedforward networks (SLFNs) where the hidden layer weights and bias are assigned randomly (Huang *et al.*, 2006). The output layer usually uses the linear activation function, and the output is calculated as:

$$f_l(x) = \sum_{i=1}^L \beta_i h_i(x) = h(x)\beta \quad (1)$$

where $\beta = [\beta_1, \dots, \beta_L]^T$ is a vector of the output layer weights, L is the number of hidden neurons, and $h(x) = [h_1(x), \dots, h_L(x)]$ is a vector of the hidden layer outputs calculated as:

$$h_i(x) = G(a_i \cdot x_j + b_i) \quad (2)$$

where $j = 1, \dots, N$, $a_i = [a_{i1}, a_{i2}, \dots, a_{iN}]^T$ is a vector of weights connecting the i th hidden node to the inputs, b_i is the bias of the i th hidden nodes, x_j is the j th input sample, and G is the hidden layer neuron activation function typically taken as the sigmoid function.

The output layer weights, denoted by β , are obtained by solving a regression type problem as follows:

$$\|H\beta - T\|^2 \quad (3)$$

where H is the hidden layer output matrix and T is the training target matrix.

The optimal solution of Eq. (3) is given by:

$$\hat{\beta} = H^\dagger T \quad (4)$$

where H^\dagger denotes the Moore-Penrose generalised inverse of matrix H .

2.2. Batch-wise Updated ELM Model with RLS

Batch to batch variations exist due to the presence of unknown disturbances. Any variations in the batch process could make the ELM model invalid. To cope with operating condition changes, the ELM can be updated from batch to batch by using the RLS algorithm.

In RLS, the parameter estimation at the current batch is obtained by using the previous parameter estimation and data from the current batch. The correctional term applied to the output layer weights is proportional to the prediction error at the current batch. The updating output layer weights by the RLS algorithm is given as:

$$\beta(k+1) = \beta(k) + F(k).E(k+1) \quad (5)$$

$$F(k) = P(k)H_{k+1}^T [\lambda + H_{k+1}P(k)H_{k+1}^T]^{-1} \quad (6)$$

$$P(k+1) = [I - F(k).H_{k+1}] P(k) / \lambda \quad (7)$$

$$P(k) = P(0) = \sum_{i=i_1}^0 [\lambda^{k-i} H(i).H(i)^T]^{-1} \quad (8)$$

where $E(k+1) = y_{k+1} - H_{k+1}\beta(k)$ is the ELM model prediction error at the current batch, $\beta(k)$ is the current parameter estimate (the ELM output layer weights), $F(k)$ is the Kalman gain, H_{k+1} is a vector of the hidden neuron outputs at the current batch, and λ is a forgetting factor.

3. Application to a Fed-Batch Fermentation Process

3.1. Baker's Yeast Fermentation Process

Baker's yeast also known as *Saccharomyces cerevisiae* is one of the various products of culturing yeast which is being produced from glucose as substrate to grow microorganism. The main source of energy in growing this culture is the glucose in molasses for the growth reaction of the yeast cells and energy production. The chemical reaction representing this description is given by (Karakuzu et al., 2006) as:

where CH_2O , $CH_{1.83}O_{0.56}N_{0.17}$, and $CH_3O_{0.5}$ are glucose, biomass, and ethanol concentrations in (g/L) respectively, the coefficient Y_s^i represents the stoichiometric yield coefficients where $i = n, o, x, e, c, w$ and their values can be found in (Karakuzu et al., 2006). The main objective of production is to maximise the biomass production thereby limiting the formation of ethanol as a by-product in the fermentation process.

Ethanol formation can be limited either through limiting the oxygen concentration in the reaction process or overfeeding the substrate concentration to completely oxidise the yeast cells in the fermentor for maximum productivity during fermentation. To limit the amount of ethanol formation, the feed rate needs to be controlled and monitored during the progress of reaction. Detailed cell kinetics and reactor dynamic equations describing the baker's yeast fermentation process are presented in (Yüzgeç *et al.*, 2009; Baron and Zhang, 2017).

Based on the kinetics, cell dynamics and the model parameters from (Baron and Zhang, 2017), simulation algorithm codes were developed in MATLAB to generate process operational data for modelling the fed-batch fermentation process with ELM+RLS algorithms and also determine the optimal final biomass concentration of the process operation through optimal control policies.

3.2. Batch-to-Batch Modelling Using ELM and RLS

The mechanistic model-based simulation is used to produce 100 batches of historical operation data. The batch time is 16.5h and is divided into 10 equal intervals. The model inputs are the substrate feed flow rates randomly generated in the range of 0 to 2500 L/h. The ELM model is of the following form:

$$Y_i(t_f) = f(x_i) \quad (10)$$

where $Y_i(t_f)$ and $x_i = [x_1, x_2 \dots x_{10}]$ are the final biomass concentration and the substrate feed rates of the i th batch respectively. The simulated data were scaled to zero mean and unit variance before parting the data set into training and testing (70% of the data) while the remaining data were used as validation data (30% of the data).

After obtaining the ELM model with the first 20 batches, the output weight and bias obtained were used to initialize the parameter estimation of the RLS algorithm. These weights and biases are updated through the RLS algorithm based on the amount of data in the simulated training data sets.

Figure 1. Model prediction performance on training and testing data.

Figure 2. Model prediction performance on validation data

Figure 1 shows the model prediction performance on the training and testing data for both ELM and the proposed method (ELM+RLS). Figure 2 shows the model prediction performance on the validation data for both ELM and the proposed method (ELM+RLS). It can be seen from Figures 1 and 2 how the proposed method tracked the actual data accurately on both training and validation plots. Table 1 shows the mean square error (MSE) of the predictions shown in Figures 1 and 2.

Table 1. Mean Squared Error Values

Models	MSE (Training and Testing)	MSE (Validation)
ELM	0.4783	0.4234
ELM+RLS	0.0257	0.0039

3.3. Batch-to-Batch Optimization Control

The proposed adaptive optimal control of the baker's yeast fermentation is based on the ELM+RLS model prediction given by Eq. (10). The objective is to maximise the final biomass concentration by modifying the substrate feed rate subject to process constraints given below where the optimisation problem can be represented as:

$$J = -f_{ELM+RLS}(F)$$

$$\text{subject to: } \{0 \leq F_i \leq 3000, i = 1, 2, \dots, 10, V_f \leq 10000\} \quad (11)$$

where $f_{ELM+RLS}(F)$ is the ELM+RLS predicted final biomass concentration and F is the vector of substrate feeding rates. The constrained optimisation problem in Eq. (11) was solved with the "fmincon" function in the MATLAB 2019a Optimization Toolbox using interior-point method and random selection of a batch from 100 initial substrate feeding rate in modelling simulation as the starting point.

Table 2. Optimal control results on final biomass concentration

Models	Model final biomass concentration predicted (g/L)	Actual final biomass concentration (g/L)
--------	---	--

ELM	58.13	40.79
ELM+RLS	65.39	53.55

The optimisation results given in Table 2 substantiate the improvement in model accuracy and reliability of the proposed method. The optimal control policy obtained using the ELM+RLS model gives much better performance than that using the ELM model, especially when applied to the actual process (i.e., mechanistic model simulation).

4. Conclusions

An adaptive optimal control strategy of a fed-batch fermentation process is proposed in this paper through integrating ELM and RLS technique. Historical process operation data is used to establish an initial ELM model and in order to cope with the presence of unknown disturbances, the ELM model is updated after each batch using RLS. The updated ELM with RLS is used to find the optimal control policy for the next batch. The proposed batch-wise modelling and optimisation control strategy is demonstrated on a simulated fed-batch fermentation process for producing baker's yeast. It has been shown that the proposed adaptive optimal control strategy can effectively overcome the effect of unknown disturbances and achieve improved product output operation from batch to batch.

Data-based Industrial Soft-sensor Design via Optimal Subset Selection

Martin Mojto^a, Karol Lubušký^b, Miroslav Fikar^a and Radoslav Paulen^a

^a*Slovak University of Technology in Bratislava, Bratislava 81237, Slovakia*

^b*Slovnaft, a.s., Bratislava 82412, Slovakia*

Abstract

Inferential (or soft) sensors are used in industry to infer the values of imprecisely and rarely measured (or completely unmeasured) variables from variables measured online (e.g., pressures, temperatures). The main challenge, akin to classical model overfitting, in designing an effective inferential sensor is to select a correct structure represented by the number of sensor inputs. This work is focused on the design of an inferential sensor for bottom product composition of an industrial distillation column. We study effectiveness of various subset selection methods that regard different model-overfitting criteria. Our results show that the subset selection is a viable methodology to sensor design and that we are able to improve accuracy of the current refinery sensor by around 15 %.

Keywords: Inferential (Soft) Sensors, Process Monitoring, Subset Selection

1. Introduction

The accuracy and reliability of industrial measurements have a huge impact on the effectiveness of industrial process control (Khatibisepehr et al., 2013). Especially, the control performance of advanced process controllers (Qin and Badgwell, 2003) is highly related to the indication quality of controlled variables (CVs). It is often the case that the crucial CVs (e.g. distillate purity) are too expensive or impossible to measure at the frequency required for an effective feedback control. This gave rise to a use of so-called inferential (or soft) sensors (Mejdell and Skogestad, 1991; Kordon et al., 2003; Curreri et al., 2020).

The purpose of an inferential sensor is to infer the CV value (output) using the data from other measured variables (inputs). The design procedure aims at a) identifying a sensor structure and b) at estimating the sensor parameters. While the latter problem can be solved relatively easily, the former issue of structure selection can be much more challenging in practice.

The focus of the paper is on a class of subset selection (SS) methods. These methods use mixed-integer programming to determine the optimal structure of an inferential sensor using various model-overfitting criteria such as adjusted R^2 (R_{adj}^2), corrected Akaike information criterion (AIC_c), Bayesian information criterion (BIC), and cross-validation. We make a comparison of effectiveness of the SS methods investigating a

linear soft-sensor design for a depropanizer column in an industrial fluid catalytic cracking (FCC) unit.

2. Problem Description

Our goal is to identify models of inferential sensors of the following linear form:

$$y = m \left(a_1, a_2, \dots, a_{n_p} \right)^T = ma, \quad (1)$$

where y stands for the desired CV inferred by the sensor, m is the vector of available input variables, and $a \in \sim^{n_p}$ represents the vector of sensor parameters.

2.1. Industrial FCC unit

We study a depropanizer that is a part of an FCC unit of the refinery Slovnaft, a.s. in Bratislava, Slovakia. The column separates a seven-component feed to a C3-fraction-rich distillate and to a C4/C5-fraction-rich bottom product. Plant description is given in Mojto et al. (2020). The candidate input vector for inferring the bottom impurity is:

$$m = \left(F, R, Q_B, p_D, p_B, T_D, T_B, T_{10}, T_{37}, \frac{R}{F}, \frac{Q_B}{F} \right)^T, \quad (2)$$

with feed flowrate F , reflux flowrate R , reboiler heat duty Q_B , pressure at the top of the column p_D , pressure at the bottom of the column p_B , and temperatures of distillate T_D , at the 10th tray T_{10} , at the 37th tray T_{37} and at the bottom T_B . This set ($n_p = 11$) involves all variables measured directly at the column and their commonly used fractions.

Any use of a thermodynamic model to monitor top/bottom stream compositions is prohibitive here, even under some ideality assumptions. This occurs as there are too many degrees of freedom for a seven-component mixture that cannot be inferred from online data. Current inferential sensor (denoted as ref) in use in the refinery is designed according to King (2011) and uses p_B , T_{37} , and Q_B/F as inputs.

3. Soft-sensor Design by Optimal Subset Selection

This section introduces the optimal SS methods for soft-sensor design. An effective design procedure usually requires splitting the available dataset with n measurement points ($M := (m_1^T, m_2^T, \dots, m_n^T)^T, Y := (y_1, y_2, \dots, y_n)^T$) into the following subsets: dataset for sensor design that contains training data ($M(T), Y(T)$) and dataset used for the performance evaluation of designed sensors that contains testing data ($M(S), Y(S)$). Here T and S denote the corresponding row-selection operators.

3.1. Optimal Subset Selection with Model-overfitting Criteria

Subset selection denotes a class of methods that explicitly seek for the simplest possible sensor structures such that some model-overfitting criterion $J(a, z)$ is minimized (Miyashiro and Takano, 2015). Here the variable z denotes a vector with binary entries $z \in \{0, 1\}^{n_p}$ signifying selection of i^{th} input into sensor structure. Correspondingly, the sum of the vector entries $\sum_{i=1}^{n_p} z_i = 1^T z$ denotes the sensor complexity.

Optimal subset selection solves the following bi-level program (Bertsimas et al., 2016):

$$\min_{a, z \in \{0,1\}^{n_p}} J(a, z) \tag{3a}$$

$$\text{s.t. } a \in \arg \min_{\tilde{a}} \| Y(T) - M(T)\tilde{a} \|_2^2 \quad \text{s.t. } -\bar{a}z_i \leq \tilde{a}_i \leq \bar{a}z_i, \forall i \in \{1, \dots, n_p\}. \tag{3b}$$

where \bar{a} represents an upper bound on $\| a \|_\infty$ to be tuned and the optimization criterion $J(\cdot)$ might take the form (RSS := $\| Y(T) - M(T)a \|_2^2$):

$$J_{R_{\text{adj}}}^2 = \frac{\text{RSS}}{n-1^T z-1} \quad \text{or} \quad J_{\text{AICc}} = 2^T z + \log^n \frac{\text{RSS}}{n} \quad \text{or} \quad J_{\text{BIC}} = \log^{Tz}(n) + \log^n \frac{\text{RSS}}{n}. \tag{4}$$

The bi-level program (3) can be effectively solved by standard MIQP solvers using big-M reformulation as shown in Takano and Miyashiro (2020).

3.2. Optimal Subset Selection with Cross-Validation Criterion

The principle of this method is to mimic a standard cross-validation procedure within the training dataset. Let us divide the training data into K smaller subsets N_k , such that:

$$T = \bigcup_{\forall k \in \{1, \dots, K\}} N_k, \quad N_k \cap N_{k'} = \emptyset, \quad \forall k \neq k', \quad K \geq 2. \tag{5}$$

The data is distributed into training (T_k) and validation (V_k) sets as follows:

$$V_k := N_k, \quad T_k := T \setminus N_k, \quad \text{card}(T_k) \geq n_p, \quad \forall k \in \{1, \dots, K\}. \tag{6}$$

where V_k sets contain unique data, while the different T_k sets involve recurring measurements. The SS with cross-validation solves (Takano and Miyashiro, 2020):

$$\min_{a^{(k)}, \forall k \in \{1, \dots, K\}, z \in \{0,1\}^{n_p}} \sum_{k=1}^K \| Y(V_k) - M(V_k)a^{(k)} \|_2^2 \tag{7a}$$

$$\text{s.t. } \forall k \in \{1, \dots, K\}; a^{(k)} \in \arg \min_{\tilde{a}} \| Y(T_k) - M(T_k)\tilde{a} \|_2^2 \tag{7b}$$

$$\text{s.t. } -\bar{a}z_i \leq \tilde{a}_i \leq \bar{a}z_i, \forall i \in \{1, \dots, n_p\}. \tag{7c}$$

The problem (7) can be solved for several values of K — considering constraints on parameter identifiability, i.e., the cardinality condition in Eq. (6) — and for different randomly generated distributions of data into T_k and V_k sets. The structure of the resulting sensor is then given by the most frequent inputs occurring in the calculated sensors. Once the optimal sensor structure is calculated, a least-squares fitting of such model is used with the entire training dataset to determine the parameters of designed soft-sensor. Similarly to problem (3), the problem (7) can be effectively resolved by standard MIQP solvers.

4. Results

Industrial data available from the refinery represents more than two years of production. We possess 177 lab measurements of the bottom product composition.

We use MATLAB, Yalmip (Löfberg, 2004), and Gurobi (Gurobi Optimization LLC, 2020) to solve various instances of the problems (3) and (7). When determining the best sensor according to SS with cross-validation, we take a median of $1^T z$ from the results

Table 1: Comparison of the number of inputs (n_p^*) and sensor accuracy (RMSE) for the soft sensors designed using time series data.

	R_{adj}^2	AIC_c	BIC	Cross-validation	ref
n_p^*	9	4	4	4	3
RMSE	0.110	0.106	0.106	0.106	0.128

Figure 1: Comparison of the soft sensors designed using time series data.

of different runs (different $K \leq 6$ and data distribution) to obtain the $n_p^* \leq n_p$, i.e., the number of inputs of the final sensor. We then select the n_p^* most frequent inputs from the results of different runs to finalize the sensor structure.

4.1. Design of an Inferential Sensor using Time Series Data

We chronologically assign first 50 % of the data to the training set and the last 50 % of the data to the testing set. The accuracy of the designed sensors is assessed by root mean squared error (RMSE) evaluated on the testing dataset.

Table 1 shows the obtained results. The SS with R_{adj}^2 suggests to include almost all available inputs (except T_D and Q_B) and the accuracy of this sensor is slightly decreased compared to other designed soft sensors. Therefore we conclude that this criterion is not appropriate option for structure selection of an soft sensor. The performance of SS using AIC_c , BIC and cross-validation is the same. These methods suggest to include four common variables (T_B , T_{10} , T_{37} and Q_B/F) into the structure of the soft sensor. Suitable candidates for a good quality soft-sensor thus seem to be temperatures in the column (T_{10} and T_{37}) and variables measured near to the inferred variable (T_B and Q_B/F).

The inferential sensors designed via SS with AIC_c , BIC, and cross-validation show better performance compared to the reference inferential sensor. We can thus conclude that an improvement of the current inferential sensor is possible with only slight modifications, i.e., at least one extra variable in the inferential sensor is required. The accuracy

improvement achieved by the inferential sensor of SS with AIC_c , BIC and cross-validation is more than 15 % compared to the reference inferential sensor.

Table 2: Comparison of the number of inputs (n_p^*) and sensor accuracy (RMSE) for the soft sensors designed using randomly distributed data.

	R_{adj}^2	AIC_c	BIC	Cross-validation	ref
n_p^*	8	6	5	5	3
RMSE	0.107	0.107	0.109	0.111	0.127

Figure 1 shows a comparison of the measured data with the output of the sensors. We plot the predictions of the reference sensor and of the sensors designed by SS with R_{adj}^2 and SS with AIC_c (the same as the rest of SS-based sensors). The performance of the designed sensors on the training data is good as can be expected, despite we can clearly observe problems of the reference sensor in fitting the data. This already suggests its inappropriate structure. This is further documented when looking at the testing data, where the quality of the reference sensor rapidly deteriorates once leaving the training-data window. The last period of the testing data (measurements 130–177) shows a significant discrepancy between the measurements and values inferred by all the designed sensors. This might be caused by a major change in the operating conditions of the FCC unit. A possible remedy could be to design a new sensor (with different structure) or a simple bias correction, which seems to be more appropriate in this case. The bias correction strategy is actually used at the refinery to improve the reference sensor.

4.2. Design of an Inferential Sensor using Randomly Distributed Data

To further investigate the problem, we study the impact of the training/testing data distribution on the sensors performance. Therefore, we randomly assign 50 % of the available data to the training set and leave the rest of the data for testing.

Table 2 shows the results averaged over fifty different randomly generated training/testing data distributions. These results show slightly increased complexity of the inferential sensors designed by SS with R_{adj}^2 and AIC_c compared to inferential sensors designed by SS with BIC and cross-validation. Nevertheless, these SS approaches suggest five common variables (Q_B , T_B , T_{10} , T_{37} and Q_B/F) into the structure of the soft sensor.

The sensors accuracy (see Table 2) confirms better performance of the inferential sensors designed via SS compared to the current inferential sensor. However, only SS with R_{adj}^2 improved its accuracy compared to the sensors in Sec. 4.1. Therefore, the overall improvement of the designed soft sensors is comparable with Sec. 4.1 (around 15 %).

In comparison to the results shown in Fig. 1, the performance of the designed inferential sensors using random distributed data (Fig. 2) is slightly improved in the section represented by the measurements 130–177. Nevertheless, the performance of the reference inferential sensor is almost the same as in Sec. 4.1. Therefore, we can conclude that the simple structure of the reference inferential sensor provides the robustness and constant accuracy at the whole time interval. On the other hand, the designed inferential sensors with enhanced structure (more input variables) are more accurate than the reference inferential sensor, but only within a short time horizon. We thus conclude that

Figure 2: Comparison of the soft sensors designed using randomly distributed data.

a design of one efficient global sensor at the whole time interval is too complicated or impossible and one should better design a family of switching sensors or an appropriate mechanism for update of sensor parameters (beyond the simple bias correction). These are the directions for our further research.

Conclusions

We analyzed effectiveness of optimal subset selection to design a soft sensor. We used several variants of the SS method with different model-overfitting criteria and with cross-validation. According to the time series data, the use of AIC_C , BIC and cross-validation results in better performing sensors than if R_{adj}^2 is used. The designed soft sensors via SS could improve the current soft sensor by around 15 %. Further investigations revealed that any further improvements would be possible using a set of switching sensors.

Abstract

This paper presents an eMPC controller that integrates Modifier Adaptation (MA) methods in order to achieve in closed loop the real optimum in spite of the presence of model-process structural mismatch. The main difficulty associated with MA is the correct process gradient estimation that usually requires waiting for several process steady states. Then in a large settling time process, the time required for computing corrective actions with MA can be so large that the method becomes impractical. To avoid these problems, this work presents an eMPC+MA that estimates process gradients using transient data and an on-line identification algorithm (TMA). The integrated eMPC+TMA method is applied to the Williams-Otto reactor. The results show that eMPC+TMA can approach the plant's real steady state optimum despite process-model mismatch without using steady state measurements in a sensible period of time.

Keywords: Real-time Optimization, Modifier Adaptation, Uncertainty, Transient Measurements, MPC.

1. Introduction

Real-Time Optimization (RTO) is a largely used technique to increase the industry competitiveness, fulfilling quality, environmental, and security demands. RTO is formulated as an optimization problem with economic objectives that use explicit process models to calculate the optimal decision variables to be used as setpoints of low-level controllers, commonly MPC (Model Predictive Control). RTO generally optimizes an economic cost function ϕ with respect to the decision variables or inputs \mathbf{u} and constraints \mathbf{g} using a steady state model as in (1).

$$\begin{aligned} & \text{Min}_{\mathbf{u}^L \leq \mathbf{u} \leq \mathbf{u}^U} \phi(\mathbf{u}, \mathbf{y}) \\ & \text{s.t. } \mathbf{g}(\mathbf{u}, \mathbf{y}) \leq 0 \end{aligned} \quad (1)$$

In case of parametric and/or structural model-process mismatch, (1) will not provide the correct process optimum. So modifier adaptation methodology (MA) can be applied to (1) in order to match model and real plant optimum (Marchetti et al., 2009). MA adds modifiers to the cost function and constraints, resulting in problem (2).

$$\begin{aligned} \min_{\mathbf{u}^L \leq \mathbf{u} \leq \mathbf{u}^U} \phi_{MA} &= \phi(\mathbf{u}) + \boldsymbol{\lambda}_k^T (\mathbf{u} - \mathbf{u}_{k-1}^*) \\ \text{s.t. } \mathbf{g}_{MA}(\mathbf{u}) &= \mathbf{g}(\mathbf{u}) + \boldsymbol{\gamma}_{k,i}^T (\mathbf{u} - \mathbf{u}_{k-1}^*) + \boldsymbol{\varepsilon}_k \leq 0 \end{aligned} \quad (2)$$

Where ϕ_{MA} is the modified cost function and \mathbf{u}_{k-1}^* are the optimum values of the decision variables in the previous steady state. $\boldsymbol{\lambda}$, $\boldsymbol{\gamma}$, and $\boldsymbol{\varepsilon}$ are the modifiers computed as in **Error! Reference source not found.**, using the information of the plant (subscript P) and model.

$$\boldsymbol{\lambda}_k^T = \left. \frac{\partial \phi_P}{\partial \mathbf{u}} \right|_{\mathbf{u}_{k-1}^*} - \left. \frac{\partial \phi}{\partial \mathbf{u}} \right|_{\mathbf{u}_{k-1}^*}, \boldsymbol{\gamma}_k^T = \left. \frac{\partial \mathbf{g}_P}{\partial \mathbf{u}} \right|_{\mathbf{u}_{k-1}^*} - \left. \frac{\partial \mathbf{g}}{\partial \mathbf{u}} \right|_{\mathbf{u}_{k-1}^*}, \boldsymbol{\varepsilon}_k = \mathbf{g}_P(\mathbf{u}_{k-1}^*) - \mathbf{g}(\mathbf{u}_{k-1}^*) \quad (3)$$

The RTO+MA problem (2) is a static optimization that uses a different model than the model predictive controller (MPC). To avoid compatibility problems and benefit from considering dynamics, it is logical to think of an integration of these two layers where the economic problem of the RTO+MA could be used as an objective function of an economic MPC (eMPC). Another point to have in mind in this integration is the process gradient estimation. In traditional MA, process gradients in **Error! Reference source not found.** are estimated using steady state measurements, requiring quite a few steady states to the problem (2) reach the optimum. Therefore, when dealing with slow dynamics processes, as often happens in practice, the time required for computing corrective actions with RTO+MA can be so large that the method becomes impractical. Another problem is that MPC controllers usually operates in a time scale of seconds or minutes and they constantly interact with the system making a traditional MA impractical. So, an estimation of process gradients using transient measurements is required.

Recent works have presented proposals to solve the RTO+MA+MPC problem as in Vaccari and Pannocchia (2016) eMPC, Pannocchia (2018), Vaccari and Pannocchia (2018), Hernández and Engell (2019), Faulwasser and Pannocchia (2019), and Vaccari et al. (2020). Most of these papers maintain two layers inside the controller: a static economic optimization problem and a target optimization problem. Faulwasser and Pannocchia (2019) is an exception. All the authors mentioned show different frameworks to the unification eMPC+MA and some of them apply identification algorithms or other methods to estimate the processes gradients using steady or transient measurements.

To contribute to the practical applications of MA, the present paper proposes a different method, using transient measurements and an identification framework, to estimate process gradients to an eMPC+MA controller. This new architecture will be called eMPC+TMA. The paper is organized as follows. Section 2 describes the algorithm to estimate gradients with transient data. Then, the structure of the eMPC is presented and eMPC+TMA is applied to the benchmark example of William Otto reactor in Section 4. Finally, in the last section some conclusions are presented.

2. Modifier Adaptation using transient measurements (TMA)

One possible approach to estimate process gradient using transient information is to approximate the variation of the process cost function using a second order Taylor's expansion with an adaptative estimation technique (Navia et al., 2017; Rodríguez-Blanco et al., 2017). In this paper, this idea is expanded and integrated into the context of eMPC assuming that the process cost depends not only on previous decisions but also on its time dynamics. Then, a second order Taylor's expansion will lead to:

$$\begin{aligned} \Delta\phi_{P,k-1} &= \frac{\partial\phi_P}{\partial u_{k-1}}\Delta u_{k-1}^T + \frac{\partial\phi_P}{\partial u_{k-2}}\Delta u_{k-2}^T + \frac{\partial^2\phi_P}{\partial u_{k-1}^2}\frac{1}{2}\Delta u_{k-1}\Delta u_{k-1}^T \\ &+ \frac{\partial^2\phi_P}{\partial u_{k-1}u_{k-2}}\Delta u_{k-1}\Delta u_{k-2} + \frac{\partial^2\phi_P}{\partial u_{k-2}^2}\frac{1}{2}\Delta u_{k-2}\Delta u_{k-2}^T + \eta\frac{\partial J}{\partial t}\Delta t \end{aligned} \quad (4)$$

Now, if we define two vectors φ and θ as in (5), (6), then, (4) can be written as (7). Notice that (5) is a vector of the changes in the decision variables and the derivative of the cost function in the past iterations. The derivative with respect to time can be approximated using past data and Nordsieck's vector (Butcher, 2002). In the same way, (6) is a vector of unknown values that contains the gradients of the process cost function w.r.t. the decision variables in the two first positions. So (7) has the form of a typical model used in parameter identification problems.

$$\begin{aligned} \varphi_{k-1}^T &= \left[\Delta u_{k-1}^T \quad \Delta u_{k-2}^T \quad \frac{1}{2}\Delta u_{k-1}\Delta u_{k-1}^T \quad \Delta u_{k-1}\Delta u_{k-2}^T \quad \frac{1}{2}\Delta u_{k-2}\Delta u_{k-2}^T \quad \frac{\partial\phi_P}{\partial t}\Delta t \right] \end{aligned} \quad (5)$$

$$\hat{\theta}_{k-1}^T = \left[\frac{\partial\phi_P}{\partial u_{k-1}} \quad \frac{\partial\phi_P}{\partial u_{k-2}} \quad \frac{\partial^2\phi_P}{\partial u_{k-1}^2} \quad \frac{\partial^2\phi_P}{\partial u_{k-1}u_{k-2}} \quad \frac{\partial^2\phi_P}{\partial u_{k-2}^2} \quad \eta \right] \quad (6)$$

$$\Delta\hat{\phi}_{k-1} = \varphi_{k-1}^T\hat{\theta}_{k-1} \quad (7)$$

In our case, the normalized least mean square algorithm, NLMS is used to minimize the module of difference of the current estimate of \square and the real one (Isermann and Münchhof, 2011). The NLMS algorithm is easy to implement and it is computationally less expensive than other recursive methods (8).

$$\hat{\theta}_k = \hat{\theta}_{k-1} + \mu \frac{[\Delta\phi_k - \varphi_k^T\hat{\theta}_{k-1}]}{\sigma + \|\varphi_k^T\|^2}, 0 < \mu < 2 \quad (8)$$

3. eMPC+TMA formulation

The eMPC+MA is formulated in a single layer using an economic objective function composed of three terms (9). The first term, $\phi(t_{pred})$, corresponds to an economic target computed from the continuous dynamic model $F(\dot{x}, x, u, v_k)$ at the end of the prediction horizon has a typical RTO cost function. This implies that $\phi(t_{pred})$ depends on the expected dynamic of the system, control moves, and disturbances. The second term in (9) is a MA type modifier term that modifies the objective function to match the NCO of the real plant when it reaches steady state. The term is equivalent to the first order modifier in the traditional MA formulations (2). The term \square_k is computed every sampling time k using the process gradient estimated using transient measurements and model gradients as in **Error! Reference source not found.** and then filtered. Similar formulations apply to the constraints modifiers, \mathbf{y}_k and $\boldsymbol{\varepsilon}_k$. Finally, the third term of (9), with a matrix weighting factor \mathbf{Q} , penalizes changes in the manipulated variables (move suppression parameter) over the control horizon, increasing stability, and contributes to model adequacy and convexification (François and Bonvin, 2013).

An overall view of the proposed eMPC+TMA architecture is presented in Figure 1. The MHE module is a moving horizon estimator responsible for estimating states and disturbances for the controller (Rawlings et al., 2019). In each iteration k that could correspond to each sample time of the controller, the measurements \mathbf{y}_k and the value of manipulated variables \mathbf{u}_{k-1} are used to estimate the process states, $\hat{\mathbf{x}}_k$, and disturbance

\mathbf{v}_k in MHE module. These values, together with process measurements $\phi_{p,k}$, $\mathbf{g}_{p,k}$ are used to estimate the process gradients that besides model gradient are used to calculate the modifiers as in Section 2. The modifiers calculated in TMA are filtered and used in eMPC+MA module, problem (9),(10) resulting in the vector of control moves to be applied in the process.

$$\min_{\mathbf{u}_{k+i}} \phi(t_{pred}) + \mathbf{Q}_k^T(\bar{\mathbf{u}} - \mathbf{u}_{k-1}) + \sum_{i=0}^{n_u-1} \mathbf{Q}_{k+i}^T \mathbf{Q}_{k+i} \mathbf{u}_{k+i} \quad (9)$$

$$\begin{aligned} & s. t. \mathbf{g}(\mathbf{u}) + \mathbf{Y}_k^T(\bar{\mathbf{u}} - \mathbf{u}_{k-1}) + \mathbf{Q}_k \leq \mathbf{0}, \forall t \in [t_k, t_{pred}] \\ & \mathbf{u}_{k+i} = \mathbf{u}_{k+i-1} + \Delta \mathbf{u}_{k+i}, \quad i = 0, 1, \dots, n_{pred} - 1 \\ & \mathbf{u}^L \leq \mathbf{u}_{k+i} \leq \mathbf{u}^U, \quad i = 0, 1, \dots, n_{pred} \\ & \mathbf{u}(t) = \mathbf{u}_{k+i}, \quad t \in [t_{k+i}, t_{k+i+1}], \quad i = 0, 1, \dots, n_{pred} - 1 \\ & \Delta \mathbf{u}_{k+i} = \mathbf{0}, \quad i = n_u, \dots, n_{pred} - 1 \\ & \mathbf{x}(t_k) = \hat{\mathbf{x}}_k \\ & \mathbf{F}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, \mathbf{v}_k) = \mathbf{0}, \forall t \in [t_k, t_{pred}] \end{aligned} \quad (10)$$

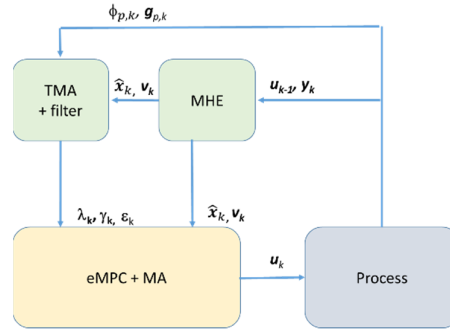

Figure 1: eMPC+TMA architecture.

4. Williams-Otto Case study

The benchmark example (Williams and Otto, 1960) is used to validate the proposed eMPC+TMA approach. The process consists of a continuous stirred tank reactor CSTR where the reactants A and B combine to generate four species C, E, G, P in three different reactions. The eMPC uses a simplified dynamic model that differs in structure and parameters from the process. Only two reactions and 5 components A, B, E, G, P are considered. The nonlinear dynamic models used to represent the real process and the controller dynamic model consist of mass balance equations for each component (Faulwasser and Pannocchia, 2019). The eMPC+TMA problem to be solved is (11). The initial states and disturbances in k are provided by the MHE module. The modifiers' values are calculated by the TMA module and then filtered with a first order filter.

The reactor simulation and the dynamic optimization problem in MHE are formulated in a continuous domain in MATLAB. The eMPC was implemented using the *nlmpc* object with the custom cost function (11). The optimization problems are solved using the NLP solver *fmincon*. The eMPC+TMA framework executes every 2 minutes. The control/prediction horizons are $n_u = 3$, $n_{pred} = 30$, MA filter $K = 0.7$ and move suppression $\beta = (0.5, 0.5)$. The NLMS parameters, $\mu = 0.1$ and σ is a small value to avoid division by zero ($\sigma = 0.0001$ for example). The first 8 minutes of data are

collected to be used in the identification algorithm. Then the controller starts at minute 10.

$$\begin{aligned}
 \max_{u=[F_B, T]} \phi &= \bar{F}_R(\bar{X}_P p_P + \bar{X}_E p_E) - F_A X_{A0} p_A - \bar{F}_B X_{B0} p_B + \lambda_{1,k} \sum_{i=0}^{n_u-1} \Delta F_{B,k+i} \\
 &+ \lambda_{2,k} \sum_{i=0}^{n_u-1} \Delta T_{k+i} + \beta_1 \sum_{i=1}^{n_u-1} (\Delta F_{B,k+i})^2 + \beta_2 \sum_{i=1}^{n_u-1} (\Delta T_{k+i})^2 \\
 \text{s.t. nonlinear dynamic model} \\
 \square F_{B,k+i} &= F_{B,k+i} - F_{B,k+i-1}, \quad i = 0 \dots n_{pred} - 1 \\
 \square T_{k+i} &= T_{k+i} - T_{k+i-1}, \quad i = 0 \dots n_{pred} - 1 \\
 F_B(t) &= F_{B_{k+n_u}}, \quad t \in [t_{k+n_u}, t_{pred}] \\
 T(t) &= T_{k+n_u}, \quad t \in [t_{k+n_u}, t_{pred}] \\
 180 \frac{l}{\text{min}} &\leq F_{B,k+i} \leq 360 \frac{l}{\text{min}}, \quad i = 0 \dots n_{pred} - 1 \\
 75^\circ\text{C} &\leq T_{k+i} \leq 100^\circ\text{C}, \quad i = 0 \dots n_{pred} - 1
 \end{aligned} \tag{11}$$

Figure 2 shows the results of the eMPC+TMA in the case of study. The closed loop system stabilizes around 50 min, which is, approximately, twice the time of the reactor open loop response (30 min). For comparison, the cost function obtained without the TMA module is shown in the right bottom. It means, if there is no MA correction in the cost function ($\lambda_1 = \lambda_2 = 0$ in (11)) as happens in traditional eMPC or RTO problems, the cost obtained could be far away from the real optimum. The small offset in the temperature results may be caused by problems in the optimizer (the cost function region next to the optimum is relatively flat), besides the process gradients are estimated using transient data and not steady-state data.

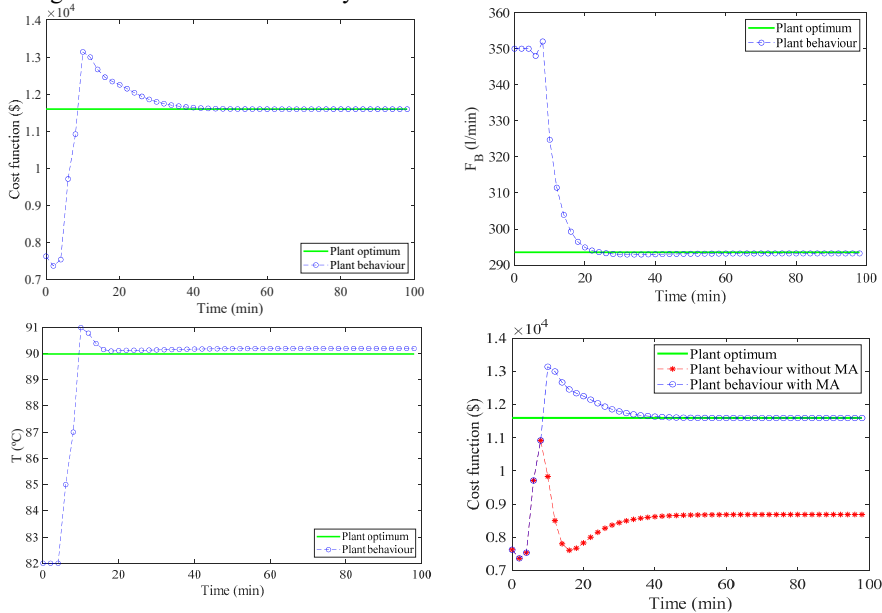

Figure 2: Cost function and manipulated variables over time.

5. Conclusions

The implementation of eMPC+TMA shows that it is possible to achieve an operating point close to the real optimum, despite the parametric and structural mismatch between model and real process using transient measurements in a shorter time than the one required in the RTO+MA+MPC traditional architecture, avoiding without waiting for multiple process steady states.

Abstract

Cyber-Physical Systems (CPS) are collections of physical and computer components that are integrated with each other to operate a process safely and efficiently. Examples of CPS include industrial control systems, water systems, robotics systems, smart grid, etc. However, the security aspect of CPS is still a concern that makes them vulnerable to cyber attacks on the control elements, network or physical systems. The work reported here is an attempt towards detecting cyber attacks and improving process monitoring in CPS; using unsupervised machine learning anomaly detection algorithms such as one-class SVM, isolation forest, elliptic envelope. These algorithms are evaluated using the dataset of a real Water Distribution Plant (WADI) built at the iTrust centre at Singapore University of Technology and Design for cyber security research. For modelling purposes, process 1 and 2 of the aforementioned plant were taken into consideration because the implemented attacks were closely related to only these sub-processes. The result of the experiment shows that one-class SVM is found to be the most effective algorithm in determining anomalies for this particular dataset.

Keywords: Cyber-Physical System, Machine Learning, Unsupervised Learning, Anomaly Detection, One-Class SVM, Isolation Forest, Elliptic Envelope, Principal Component Analysis (PCA)

1. Introduction

The automation in industries is increasing proportionally with the advancement of technology. Although, security infrastructure of Industrial Control Systems (ICS) is continuously ongoing development, yet there is an abundant possibility that artificial intelligence and domain knowledge can be merged to help us identify deviation in processes more effectively, in order to increase the safety of industries. Machine learning allows us to take into account all inputs at once and return the status of the process. Therefore, it is possible that these trained models can be installed in process industries and could potentially act as an additional layer of security and monitoring. A number of papers are available that discuss the use of various supervised learning algorithms for attack detection. Observations made by Gharibian and Ghorbani (2007) demonstrated that Decision Trees are very sensitive to the training data and don't learn quite well from imbalanced data. Furthermore, they found that Decision Trees and Random Forests (ensemble of Decision Trees) are very sensitive to the training data and their performance can vary significantly based on it. Naive Bayes Classifier implements Bayes theorem for classification problems. In comparison to MLP, Naive Bayes

classifiers can be trained within a short period of time (Fleizach and Fukushima, 1998). According to Domingos and Pazzani (1996) & Langley and Sage (1994), Naive Bayes can perform quite well when there exists a reasonable dependency in the data. It has been also observed that the performance of Naive Bayes classifier improves when redundant features are removed. The observations from Huy Anh and Deokjai (2008), where they applied a wide variety of algorithms: Bayesian approach, Decision Trees, Rule-based models, etc., states that no single algorithm is capable of detecting all kinds of attack with high detection and low false alarm rate. Muda Z, et al. (2011) performed a hybrid learning approach by combining Naive Bayes and K-means Clustering. The training dataset was divided into k-clusters based on an initial value known as the seed points into each cluster centre. The results showed that this hybrid approach performed better as compared to only Naive Bayes Classifier. Wang H. et al. (2011) made an attempt to improvise SVM by combining Principal Component Analysis (PCA) and Particle Swarm Optimization (PSO). PCA is quite effective in reducing the dimensions of data. Thereafter, PSO was used to optimize the kernel parameters. The experimental results showed that the performance of PCA and PSO combined SVM was higher than those of PSO-SVM and standard SVM. Another work is conducted by Cheng Feng et al. (2019), proposed an approach which combined several machine learning and data mining techniques to generate a significant number of invariant rules (defined as a physical condition that must be satisfied for any given state of an ICS) (S. Adepu and A. Mathur, 2016). They observed that generated invariant rules can achieve high anomaly detection performance by demonstrating on two real-world ICS case studies. Their results outperform commonly used residual error-based anomaly detection models. Another advantage of this methodology is that it can be applied to diverse ICS frameworks as it is dependent only on the general control dynamics of ICS. The approach followed in the present work is slightly different and includes the outlier detection methods using unsupervised learning.

2. Methodology

The testbed under study for the scope of this work is Water Distribution Plant (WADI), built at the iTrust centre at Singapore University of Technology and Design for cyber security research (C. M. Ahmed et al., 2017). The entire plant is divided into 3 sub-processes namely process 1 (primary supply and analysis), process 2 (domestic grid with booster pump) and process 3 (return water system) as shown in Figure 1.

Figure 1: Overview of WADI testbed

The plant was operated for 14 days and the dataset¹ is divided into two parts. The initial 12 days correspond to normal operation data, and in the last 2 days, at different time

¹ https://itrust.sutd.edu.sg/itrust-labs_datasets/dataset_info/

segments, a variety of 15 attacks were performed on the testbed. The stated attack detection task is tackled as an anomaly detection problem. Outlier and novelty detection classification algorithms, such as One-Class SVM, Isolation Forest and Elliptic Envelope were trained on cleaned and transformed normal operation data. Then, the trained models were used to predict attacks/anomalies in the remaining 2 days data, which consists of both attack and normal instances. Then, based on the prediction result for each model, their hyperparameters are manually adjusted in order to obtain the most optimum performance. Since the last 2 days data belongs to the category of imbalance dataset, using only accuracy as the performance indicator is ineffective. Therefore, the confusion matrix is used for evaluating the models' performance. The major steps involved in the present study are as follows: (I) Slicing process variables from the normal operation data (II) Data preprocessing (III) Implementing Principal Component Analysis (PCA) for dimensionality reduction. (IV) Modelling the data with all three methods followed by manual hyperparameter optimization. The above steps were executed for both process 1 and process 2 respectively.

3. Procedure and Results

3.1. Process 1 (Primary Supply and Analysis)

Process 1 data is sliced from the initial 12 days normal operation dataset. It consists of 19 process variables which include different sort of equipment, such as motorized valve, level indicator, transfer pumps, physical properties sensors (eg. turbidity, conductivity, pH, ORP, TRC). Then, this data is cleaned and preprocessed in order to prepare it for PCA implementation. After performing PCA, 19 variables were reduced to 3 principal components which explained 99.8 % variance of the original dataset. Similarly, PCA is applied to the variables of process 1 in the last 2 days data, to obtain 3 principal components. After implementing PCA, process 1 normal operation dataset is then trained for each algorithm; i.e., one-class SVM, isolation forest and elliptic envelope. After training, models were tested with last 2 days data to examine their performance. The results are shown in Table 1.

Table 1: Performance of different algorithms modelled on Process 1 data and tested on the last 2 days dataset to detect attacks.

	One-Class SVM		Isolation Forest		Elliptic Envelope	
	Attack	Normal	Attack	Normal	Attack	Normal
Precision	0.25	0.97	0.39	0.96	0.21	0.96
Recall	0.48	0.91	0.33	0.97	0.32	0.93
F-1 score	0.33	0.94	0.36	0.96	0.26	0.94

It can be observed from Table 1 that the isolation forest performed slightly better than one-class SVM in terms of F-1 score. However, considering the ability to detect maximum number of attacks, it is found that one-class SVM detected 11 attacks out of

15. Whereas, isolation forest detected 10 attacks out of 15. Figure 2 highlights the timestamps that are detected as attacks (anomalies) in the last 2 days dataset by the one-class SVM model discussed in Table 1. The model classifies inlier (normal) as 1 and outlier (anomaly) as -1. As shown in Figure 2, the duration of the last 2 days data starts at 18:00 on Day 1 and ends at 18:00 on Day 3. Similar kinds of plots were obtained for isolation forest and elliptic envelope algorithms.

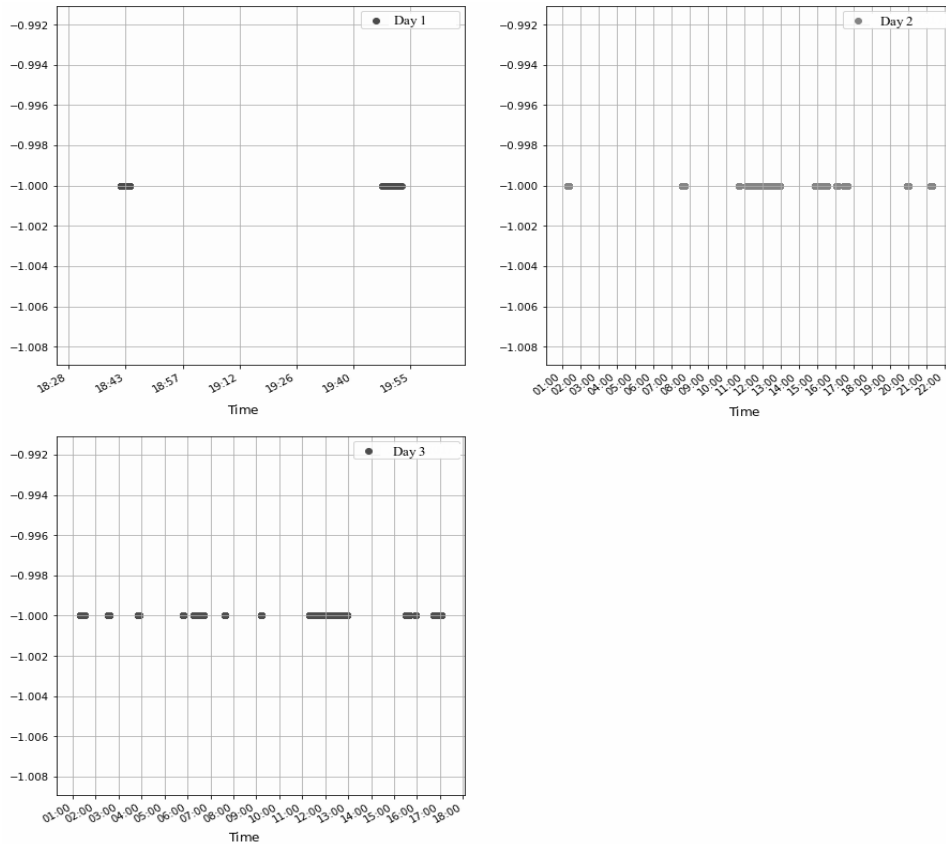

Figure 2: Predicting attacks in the last 2 days data using one-class SVM trained on process 1.

3.2. Process 2 (Domestic Grid with Booster Pump)

Process 2 is the largest among all the 3 processes. Initially, when sliced from the 12 days normal operation dataset, it consists of 86 variables. After removal of some redundant features, a total of 75 variables were extracted followed by the PCA transformation step. After performing PCA, these 75 variables were reduced to 7 principal components which explained 95 % variance of the original dataset. Similarly, PCA is applied to the variables of process 2 in the last 2 days data, to obtain 7 principal components. After implementing PCA, process 1 normal operation dataset is then trained for each algorithm; i.e., one-class SVM, isolation forest and elliptic envelope. After training, models were tested with last 2 days data to examine their performance. The results are shown in Table 2 which indicates that one-class SVM performed better

in detecting attacks as compared to isolation forest and elliptic envelope. In fact, one-class SVM detected 14 attacks out of 15 when modelled on process 2.

Table 2: Performance of different algorithms modelled on Process 2 data and tested on the last 2 days dataset to detect attacks.

	One-Class SVM		Isolation Forest		Elliptic Envelope	
	Attack	Normal	Attack	Normal	Attack	Normal
Precision	0.32	0.97	0.34	0.96	0.07	0.94
Recall	0.48	0.94	0.26	0.97	0.13	0.89
F-1 score	0.38	0.95	0.30	0.96	0.09	0.91

Figure 3 highlights the timestamps that are detected as attacks (anomalies) in the last 2 days dataset by the one-class SVM model discussed in Table 2.

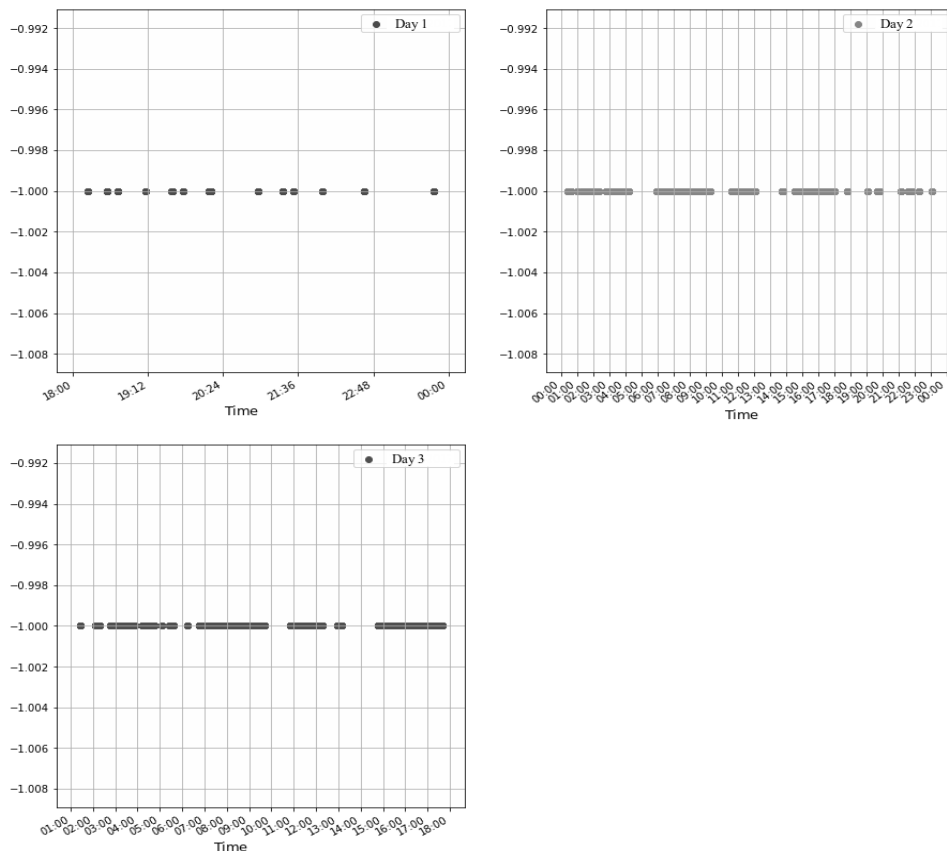

Figure 3: Predicting attacks in the last 2 days data using one-class SVM trained on process 2.

4. Conclusion

This work explored the possibility of using unsupervised machine learning anomaly detection algorithms for cyber attack detection in cyber-physical systems. The task is considered as an anomaly detection problem, where each attack instance is expected to be classified as an anomaly. Three anomaly detection techniques; i.e., one-class SVM, isolation forest and elliptic envelope were taken into consideration for the scope of this work. Modelling of all the 3 algorithms was carried out on both process 1 and process 2 of the Water Distribution Plant (WADI); i.e., a total of 6 models were trained. Based on the distribution of training data used in this work, it is found that one-class SVM performed reasonably well for detecting attacks in both the processes. However, few challenges that hold the possibility of further improvements are: (I) Reducing the number of false alarms that are generated by the models (II) Reducing the time delay in identification of attacks. It would be interesting to address these issues in the future work.

Application of Self-Optimizing Control in a Real Heat Exchanger Network

Ahmet Coşgun,^{a,*} Oğuz Uzun,^a Murathan Bağdat,^a

^a*Turkish Petroleum Refinery, 41790 Körfez, Kocaeli, Turkey*

ahmet.cosgun@tupras.com.tr

Abstract

The optimal operation of heat exchanger networks are important for increasing energy efficiency and reducing the environmental impact. In this paper control method called self-optimizing control is analysed and applied to a network with stream splits in a real refinery environment. By using only the temperature measurements, new control variables are defined. Optimization is done by manipulating the split ratios in the network. The optimal operation is defined by the economics of the process, which is maximizing the exit temperature of the exchanger network. Optimal control of the exchanger networks, whose operational purpose is to maximize the total heat transfer, are achieved by determining the amount of flow to be distributed to the individual branches at all times. Results showed that this method achieves an important increase in network exit temperature, which means a decrease in energy consumption compared to traditional strategy used in the refinery.

Keywords: optimization, self-optimizing control, heat exchanger networks

1. Introduction

Heat Exchanger Networks (HENs) are often used in refinery processes to recover as much thermal energy as possible from hot streams using thermal integration methods before sending the hot product or intermediate to the tank or to the next process (Biyanto et al., 2016).

The first main stage of oil refining is the distillation process. A pretreatment step is required for the distillation process before the crude oil stream is fed to the distillation column; preheating of crude oil to around 380 °C. For this purpose, about 60-70% of the required thermal energy is supplied by a network of heat exchangers called the crude preheat train (CPT) (Assis et al., 2013). The remainder of the thermal energy is provided by furnaces. It is important to gain as much as thermal energy from CPT units to decrease the need for energy supplied from furnaces, which uses external energy sources and increases the energy consumption of the refinery.

In CPTs, cold flow is divided into two or more branches and heated with different hot streams in different heat exchangers. The ideal operation is to maximize the total heat transfer or, in other words, to reach the highest cold flow temperature at the junction point at all times. This optimization goal is tried to be accomplished by adjusting the split ratio of the cold streams into the branches of the network. In literature, real-time optimization (RTO) approach is well studied, where the potential savings are very high but

computational needs are also very complicated. Other approach for optimization of CPTs is a practical method used in the refinery as current strategy, which is adjusting the split ratio by equalizing each cold stream's outlet temperature (Lid and Skogestad, 2001). Although this method has no computational need, it can easily diverge from optimal operation point.

Another method is called self-optimizing control (SOC), where, a cost function is continuously optimized to update the set points of the control variables to study the optimal solution. The control variable defined with its self-optimizing control concept aims to keep the process at an economically optimum level. The newly designed control variables are translated into the design of a simple control structure that keeps the process at high efficiency levels despite the changing conditions. This simplification in the control structure can result in suboptimal levels, but in most cases the benefits of a simple program outweigh the increased 'goodness' of complex models due to the high costs of implementation and maintenance. The control variables defined for CPT in self-optimizing control is called "Jäschke temperature" in the literature. For each stream, Jäschke temperature is calculated, where the objective for optimum operation is to equalize these control variables in each stream (Jäschke et al., 2017).

This study aims to optimize the heat exchanger networks of CPTs by maximizing the final CPT outlet temperature to reduce furnace fuel consumption and carbon emissions by using self-optimizing control system for flow distribution in a real refinery environment and comparing the results with current strategy used in the process.

2. Theory

The theoretical background for self-optimizing control of heat exchanger networks are well defined in the literature (Jäschke and Skogestad, 2014a). Optimization is done by assuming arithmetic mean temperature difference. This assumption causes little divergence from the real optimum but it is an acceptable loss compared to computational work needed. The objective function is defined to be the economically best scenario, which is the maximum outlet temperature in the network exit. The manipulated variable for the network optimization that maximizes the total heat transfer is the split ratio. The self-optimization control variable called Jäschke temperature is calculated for achieving this goal for each branch of the network as described in the literature (Jäschke and Skogestad, 2014b). The computation is well-defined and highly adaptable to different kinds of network configurations. For the calculations, only temperature values are used and other variables such as flow rates of the streams, heat transfer properties, or any other information regarding the process is not needed. The optimal controlled variable is also defined in the literature to be equal values of Jäschke temperatures in all branches. Jäschke temperatures can be regarded as the representation of the available potential for heat transfer. In example, a branch with zero Jäschke temperature stem from equal temperatures in cold stream outlet temperature and hot stream inlet temperature. In this case, increasing the cold stream flow rate would not result with an increase in heat transfer rate. Therefore, it can be said that all the potential in that branch is already utilized. In a network with two or more branches, for optimum operation, streams should be adjusted to increase the flow on the branch with higher Jäschke temperature. By doing that the potential of that stream would be utilized more, and corresponding Jäschke temperature will decrease. Keeping Jäschke temperature difference between branches at zero is the defined condition for optimal operation. The varying operating conditions and

disturbances, such as the change oil characteristics, fouling in heat exchangers, or the changes in stream flow rates and temperatures, are not needed to be monitored in terms of optimal operation, as the defined optimal control condition is valid in all cases (Girei et al., 2014).

3. Case Study

The study of self-optimizing control of HEX networks is performed in a vacuum distillation unit in Tüpraş İzmit refinery. The mathematical equations for the calculation of self-optimizing control variable are well defined in the literature and given in related papers (Jäschke and Skogestad, 2014a). The adaptation of the standardized calculations in the literature is carried out for the selected CPT unit by evaluating the network configuration. In Fig. 1, the network configuration of the studied CPT unit is given. The network consists of two branches with different hot stream passing through from each branch. The number and the type of the heat exchangers are different in each branch as well as the hot stream characteristics. Only temperature values are needed for the calculation of self-optimizing variables for each branch, and as shown in the Fig 1, the boxed variables are the ones used in the calculations.

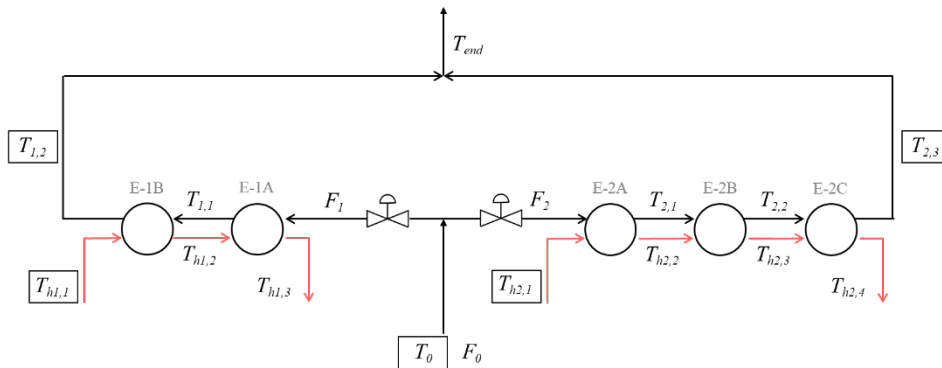

Figure 1: The heat exchanger network studied for self-optimizing control

The Jäschke temperatures for each branch is calculated. As defined in the literature equalizing these control variables in each branch results in optimum operation.

Before the implementation of this method into real operation, the historical data is collected and examined. In steady operational conditions, Jäschke temperature difference between branches must directly effects the exit temperature of the network stream as stated. To identify this behaviour, the historical data of the selected heat exchanger network is filtered by selecting a subset where the operational variables can be regarded as constant. The analysis of Jäschke temperature differences versus exit temperature of the network stream describes a negative correlation between those two as shown in Figure 2. The straight line in the figure shows the linear relationship between Jäschke difference between branches with exit temperature. Although the relationship is not a linear relationship as discussed in the literature, it is used as it is for illustration purposes, which

is a fair approximation locally. As backed up with the literature, it is also apparent in the historical data that minimizing the Jäschke temperature difference between branches positively effects the exit temperature.

Figure 2: Jäschke temperature difference between branches versus exit temperature of the network stream

4. Results

To understand the effect of self-optimizing control variables in the exit temperature of the network stream in real time, a test run is constructed. Two scenarios are tested, while the operational variables are kept constant. The duration of the scenarios were selected to be twelve hours where the starting hours are same for eliminating the effect of day and night temperature differences. Two scenarios were tested in real operation by only manipulating the control variables defined by self-optimizing control by keeping the Jäschke temperature difference between branches at 2 and 10 as shown in Figure 3. This values of Jäschke temperature difference between branches are selected to approximately compare the best use case of self-optimizing control with current strategy. The results showed that, in the region of testing, an 8 °C decrease in the differences in Jäschke temperatures, resulted in 3.6 °C increase in exit temperature of the network stream and by considering the downstream furnace operation; a 0.2 decrease in energy intensity index (EII).

Figure 3: Test run results, Jäschke difference between branches and corresponding exit temperature over time

As shown in Figure 4, the average value of the Jäschke temperature difference between branches in the heat exchanger unit in current strategy is 3.7 °C. After verification of the effect of self-optimizing control method in test run, the method is integrated into DCS screens (open loop implementation). The manipulation of the stream splits are done manually by the operators by controlling the Jäschke temperature difference between branches. By this manual operation, the average Jäschke temperature difference between branches is decreased into 1.9 °C. However, because of the need for constant action to manipulate the stream splits stemming from operational changes, an optimal operation did not sustained. For automation purposes, implementation into Automatic Performance Control (APC) system is done (closed loop implementation). As shown in Figure 4, Jäschke temperature difference between branches is decreased into 0.5 °C by automation of the self-optimizing control method.

Heat exchanger networks in operational environment is prone to the changes in the system variables. Hence, test runs are particularly important for exploring the relation between control variable and exit temperature, where all the variables are kept almost constant. After the construction of test runs, the results are linearly interpolated and, it is found that open loop implementation resulted in 0.8 °C increase in exit temperature of the network stream and 0.045 decrease in EII, and closed loop implementation resulted in 1.4 °C increase in exit temperature of the network stream and 0.08 decrease in EII.

Figure 4: Absolute Jäschke difference over time

5. Conclusions

Self-optimizing control method for heat exchanger networks is well defined in the literature. Previous works in the literature also proved the usefulness of the method by simulations. This paper focused on real use case of the method and results showed that compared to past strategy used for maximizing the exit temperature of the network, self-optimizing control resulted in more optimized solution in real refinery environment. The economic and environmental effects are investigated, although a major assumption of linear interpolation is done for estimating the effects from the test run results. Because of the simplicity of the method compared to RTO methods, the implementation and the maintenance of the self-optimizing control method is done relatively easily without any need for investment. However there are also limitations that may prevent the optimal operation stemming from the operational safety limits, minimum and maximum flows permitted for each branch and, maximum allowable level of pressure drop in the heat exchanger network.

Data-Driven Control Strategies for the Autonomous Operation of the Pharmaceutical Crystallization Process

Merve Öner,^a Gürkan Sin^a

^aProcess and Systems Engineering Center (PROSYS), Technical University of Denmark, Søtofts Plads B228A, Kgs. Lyngby 2800, Denmark

Abstract

In this contribution, we studied the deep neural network (DNN) for the control of the cooling crystallization of a model compound system. To this end, firstly the performance of the different neural network architectures in conjunction with the various combination of the time-series process data was tested for the training of the data-based model in order to assess the best fit model-training data architecture. The identified network model, which was trained with the offline process data, was utilized in a predictive control strategy. The objective of the control strategy was to optimize the supersaturation generating/decaying variable in the crystallizer to achieve a target crystal-state property profile throughout the process. The performance of the proposed control strategy was tested in the presence of the process disturbance and benchmarked against a radial basis function (RBF) based control strategy. The results showed that the DNN model was able to approximate the crystallization process input-output relation with R^2 ranging between 0.767 and 0.990 and achieve the target profile at the end of the operation with a 22.3 % offset.

Keywords: crystallization, data-based models, control, neural networks.

1. Introduction

In pharmaceutical manufacturing, crystallization is an essential unit in the downstream processing to recover and purify high-purity active pharmaceutical ingredients (API) and fine chemicals. The design, operation and control of a pharmaceutical crystallization process is a great challenge due to the highly nonlinear and multivariable nature of the crystallization process in conjunction with the strict and versatile requirements of the end-product. The current industrial practice for the crystallization process design and optimization relies on the quality-by-design framework based on the factorial design of the resource-intensive open-loop crystallization experiments (Szilagyi et al., 2020). Despite the significant progress in academia in the area of model-based (based on high fidelity population balance equations) and model-free (e.g. direct nucleation control, supersaturation control) techniques for the control of the crystallization process, establishing control over the crystallization process is still an issue in pharmaceutical manufacturing that can be reasoned due to strict dichotomy of the developed control strategies (Griffin et al., 2016). A third category, which is different from model-based and model-free techniques, can be attributed to the data-driven (based on process data) control strategies. The main advantage of the data-driven approaches is their ability to learn from the provided multidimensional process data with high accuracy. Accordingly, they became very useful and quickly applicable particularly for the optimization and

control of the complex processes that are troublesome, and have nonlinear and stochastic characteristics (Qin and Chiang, 2019; Venkatasubramanian, 2019) such as the crystallization process. A review of literature studies focusing on the data-driven control applied to the crystallization process can be found elsewhere (Öner et al., 2020a). Although the development of efficient training algorithms, availability of more powerful computers, easy-to-use software, and access to the online crystallization process data through the process analytical (PAT) tools enable overcoming of past challenges that hindered the expanding application of the data-driven strategies, the number of the studies focusing on the crystallization process is still limited. Therefore, in this contribution, we studied a data-driven control strategy based on the deep neural network (DNN) for a pharmaceutical crystallization process. The feasibility of the different neural network structures (models, training data) was explored, and the control performance was tested and benchmarked in the presence of the process disturbance.

2. Methods

2.1. Crystallization modeling

A mechanistic model incorporating population, mass, and energy balance equations for the crystallization process was developed in our previous work (Öner et al., 2020b). This model was employed firstly to generate data to be used to develop/train neural network models for the crystallization process and secondly to mimic a physical crystallization process under the data-based feedback control. As a case study, a seeded cooling crystallization (from 40 °C down to 20 °C) of paracetamol in ethanol solvent (400 mL) was demonstrated. The kinetic parameters of paracetamol crystallization were adopted from the literature. A total of 20 batches of data was generated by varying the process parameters of initial relative supersaturation (1.0 – 1.2), seed crystal size distribution (mean (90 – 250 μm) and standard deviation (5 – 10 μm) and shear rate created by the impeller in terms of secondary nucleation parameters (coefficient (50 % of the reported value) and exponent (5 % of the reported value)) based on the Latin Hypercube Sampling strategy from parameter space similar to the workflow described in our previous study (Öner et al., 2020a). The remaining process parameters were kept constant between the batches.

2.2. Deep neural network: structure, training and validation for process modeling

As one of the machine learning techniques, neural networks are structured in terms of processing units of input, hidden and output layers to resemble the human nervous system and the structure of the brain, by which they were inspired. Each layer contains nodes or units, which have connections to the other nodes and layer in adjacent layers with a weight value. Weighted summation of the inputs at each unit undergoes a transformation based on an activation function that is then fed to the respective unit in the next layer. Consequently, the outcome of the final output layer yields the solution for the problem (Shrestha and Mahmood, 2019). Various algorithms of the deep neural networks have been developed and used with varying purposes such as long short-term memory for forecasting models, convolutional neural networks in computer vision and image recognition, and recurrent neural networks for time series problems and forecasting (Hwangbo and Sin, 2020; Shrestha and Mahmood, 2019). In this study, the aim is to design a deep neural network model based on the ground of supervised learning for the crystallization process using the process data generated from the crystallization mechanistic model simulations. For this purpose, a general deep learning algorithm is adopted following the previously published framework (Hwangbo and Sin, 2020). To this end, a list of deep neural network model candidates are generated by manipulating the

hyperparameters in the structure of the deep neural network. The explored hyperparameters are the number of hidden layers and hidden neurons. A key step in the deep network architecture is to solve a regression problem embodying activation functions, connections and a loss function (Hwangbo and Sin, 2020). In this network architecture, the connections between the neurons in a hidden layer (h), weights and bias are linear as shown in Eq. (1). $W^{[h]}$ is a weight matrix and $b^{[h]}$ is a bias matrix having the shape of $(n^{[h]}, n^{[h-1]})$ and $(n^{[h]}, 1)$, respectively. The number of hidden neurons is represented by $n^{[h]}$ ($1 \leq h < H$) where $n^{[0]}$ and $n^{[H]}$ are equal to the numbers of input and target (output) variables. $A^{[h]}$ is the activation matrix (Eq. (2)) having a shape of $(n^{[h]}, 1)$, where $A^{[0]}$ represents the input matrix $[x_1, x_2, \dots]^T$ and $A^{[H]}$ contains one single value from the output layer. The activation function is indicated by $g(z)$. A commonly used function, which is the hyperbolic tangent sigmoid function, is used as the activation function in both hidden layers and the output layer (Lau and Lim, 2017; Hwangbo and Sin, 2020). As the loss function, mean squared error difference (MSE) between the target value and the estimated value from the neural network comprising all training data is used (Wang et al., 2016):

$$Z^{[h]} = W^{[h]}A^{[h-1]} + b^{[h]} \quad (1 \leq h \leq H) \quad (1)$$

$$A^{[h]} = g(Z^{[h]}) \quad (1 \leq h \leq H), \quad g(z) = \frac{2}{1 + e^{-2z}} - 1 \quad (2)$$

The machine learning toolbox in Matlab 2018b was used for the training of the DNN. The process variables such as processing time (t), bulk temperature in the crystallizer (T_b), solute concentration (C) and relative supersaturation (SS) were regarded as inputs, while the sum of square weighted crystal counts, mean crystal size and yield were used as the outputs. The choice of the parameters can be attributed to the fact that the main driving force for the crystallization process is the difference between the solute concentration and the saturation concentration (simplification of the chemical potential) that is often defined as supersaturation, and it is created by the manipulation of the temperature in a cooling crystallization process. On the other hand, crystal size distribution related measures (e.g. mean crystal size) and yield are some of the parameters that are commonly regarded as the critical product quality attributes or key process performance indicators. Therefore, a total of 165 different combinations (11 model structure, 5 input data structure, 3 output data structure) were tested (Table 1). A simple min-max data normalization was applied to both input and output data so that the data take the value between 0 and 1. To support the model selection criteria, two estimators of information criterion have been consulted. These criteria are the Akaike information criterion (AIC) and Bayesian information criterion (BIC). These information criteria are calculated from the sum of squared of errors (SSE) between the target value and the details can be found elsewhere (Hwangbo and Sin, 2020). The optimal model candidate is identified by the minimum AIC and BIC values.

2.2.1. Crystallization control

The ultimate goal of the crystallization process operation is to have a robust strategy that achieves a desired (or a reference) profile of a solid-state attribute in the presence or absence of any process disturbances. To achieve this goal, the particular control strategy

Table 1: DNN architecture candidates based on model, input and output structures.

Model	Network structure	Input	Output
1	[4 2]	[t T _b]	$\sum_{10}^{500} NL^2$ (Sum of square weighted counts)
2	[8 4]		
3	[16 4]	[T _b C]	$\frac{\sum NL}{\sum N}$ (Mean crystal size)
4	[32 4]		
5	[16 4 4]	[t T _b C]	
6	[32 8 4]		$\frac{c_o - c_f}{c_o - c_{sat(@T_f)}}$ (Yield)
7	[16 8 4 4]	[T _b SS]	
8	[32 16 4 4]		
9	[32 16 8 4]	[t T _b SS]	
10	[16 16 8 4 4]		
11	[32 16 8 4 4]		

utilizes the DNN model trained offline in a predictive control to optimize the cooling water (jacket) temperature setpoint for a specific time horizon in near future. The optimization of the temperature setpoint was realized using `fmincon` function in Matlab 2018b with respect to a cost function (minimization of the square of the normalized difference between the reference state and the DNN-predicted state) under imposed constraints (temperature and heating/cooling rate). The control strategy implemented in this study follows the same strategy published in our previous work (Öner et al., 2020a), where a radial basis network (RBF) model was used as a data-driven model trained with a very limited process data (up to 2 batches). The main difference between the DNN based strategy compared to RBF based strategy was i) the usage of a higher number of batch data and ii) training of the data-driven model offline. Considering these differences, the DNN based control was benchmarked against the RBF based control as well.

3. Results and Discussion

3.1. Deep neural network model for the crystallization process

As mentioned previously, 5 input data and 3 output data structures in conjunction with 11 neural network model structures were evaluated with respect to the best performance of the deep neural network. The datasets from 20 crystallization batches (shown in Figure 1) consisting of approximately 42000 data points were fed into all these neural network models to train and evaluate the performance. The ratio between training/validation/test data was 0.8/0.1/0.1. Levenberg-Marquardt back-propagation was used as the network training function with respect to the objective function of MSE. The maximum number of validation failure and number of epochs to train were 10 and 10,000, respectively. The training of the DNN on a computer with an Intel Core i5-6200U 2.30 GHz processor took between 30 minutes and 12 hours. The optimum combination was found considering the minimum information criteria (AIC and BIC). In the cases, in which AIC and BIC criteria showed different neural network structures, an additional criterion of the coefficient of determination (R^2) was also considered to discriminate the best fit. The obtained results can be seen in Table 2. For the outputs of the sum of the square weighted crystal counts (output 1) and mean crystal size (output 2), the same input data type [t T_b SS] yielded the best fit incorporated in the structure of the neural network Model 9 and Model 11, respectively. For the output of yield (output 3), in the discriminated structure of Model 9, the replacement of supersaturation data with the concentration data in the input showed

Figure 1: The process output data of 20 crystallization batches.

Table 2: Selected DNN structures based on the information criteria.

Output	Input	Best structure	R^2_{Training}	R^2_{Test}
Sum of sqr. wt. counts	[t T_b SS]	[32 16 8 4]	0.960-0.981	0.956-0.990
Mean crystal size	[t T_b SS]	[32 16 8 4 4]	0.675-0.853	0.653-0.864
Yield	[t T_b C]	[32 16 8 4]	0.874-0.952	0.921-0.951

the best fit. This can be rationalized with the direct relation between concentration and yield terms.

3.2. Crystallization control

The DNN based control was studied in comparison with the RBF based control in the presence of the process disturbance on the initial supersaturation. During the first 90 minutes, both data-based controls were inactivate, while a pre-defined temperature profile was applied to the system. Corresponding data was collected during this period. After this data collection period, the data-based controls were activated, and they took the control of the crystallization operation, run the system autonomously and taking decisions of heating or cooling the system to achieve the target solid-state profile. Compared to the RBF based control (final offset was 2.4 %), the DNN based control behaved more conservatively and achieved the final target profile with an offset up to 22.3 %. The manipulated variable set points predicted by the RBF based control could eliminate the disturbance-sourced offsets better in the earlier stages of the operation and consequently could follow smoothly the target profile. While these initial results showed DNN approach does not have a superior performance against RBF based data-driven approach, which employs a simpler network configuration, future work will examine the ability of DNN to extract patterns from heterogeneous sources of data including image analysis.

4. Conclusions

The results of this study demonstrated the feasibility of the data-driven models substituted for the knowledge-driven models for the crystallization process. The regarded performance metrics made evident that the DNN performs quite well with high prediction quality even though training data was still limited to 20 batches in contrast to the common applications involving the big data. However, system-dependent studies are still required

to discriminate the best network architecture for the specific input/output information and a generalization is not possible. With respect to control, the utilization of the DNN as a predictive model in a control strategy performed acceptably compared to RBF based control. As a future work, further comprehensive analyses will be performed to assess and improve the performance of the DNN based control. It can be concluded that the data driven control has a great potential due to its quick and simple implementation compared to time, effort and knowledge needed for developing a knowledge-driven model-based optimization and control for the highly nonlinear and stochastic crystallization process.

Figure 2: The performance of the DNN and RBF based predictive controls in the presence of positive disturbance on the initial supersaturation.

Dynamic optimization of a stand-alone alkaline water electrolyzer for future operation using a predicted solar forecast

Haider Niaz, J.Jay Liu*

Department of Chemical Engineering, Pukyong National University, Busan 48513, South Korea

jayliu@pknu.ac.kr

Abstract

Renewable energy is a promising candidate as a green and sustainable energy source. Nevertheless, it is also well known for its dynamic and unpredictable nature. These characteristics make it difficult to decide whether to choose it as an energy source or not. On the other hand, ample renewable energy availability creates insecurity when it comes to storing this energy. A battery can be a short-term energy storage viability. However, in the long run, hydrogen is considered a promising candidate. In this study, standalone solar powered 4.5 MW alkaline water electrolyzer (AWE) operation is optimized for one-year predicted solar data via a dynamic optimization approach. The purpose of optimization was to find (1) optimal power split fraction for the battery and electrolyzer and (2) discharge power value when subjected to a predicted solar profile. These optimal points later will be used to run the model on actual weather data to analyze the possibility of future operation and control action plan for enhanced plant performance. The optimization results show a 24.6 % increase in annual hydrogen production with a 39.14% reduction of startups compared to the base case. Conversely, the optimal values of A and P_D at 0.9784 and 111 kW, respectively, ensured 26.53% reduction in startups for the actual profile too in comparison to the base case, and with a 3.45% reduction in annual hydrogen production (kg) than the optimized case for the predicted solar profile. This study will serve as a supporting tool for future investors to analyze renewable hydrogen's operational and economic potential in any region by just inputting solar-generated power profile.

Keywords: Electrolyzer, dynamic operation, optimization, solar, hydrogen production.

Nomenclature

PV	Photovoltaic	$nH_{2_{STORED}}$	Total hydrogen (kg)
AWE	Alkaline water electrolyzer	P_A	Power to AWE
BESS	Battery energy storage system	P_C	Power to BESS

SAM	System advisor model	P_D	Power from BESS
SOC	State of charge (%)	P_X	Power for sale
nH_2^{GEN}	Hydrogen produced (kg/hr)	$P_{C_{MIN}}, P_{C_{MAX}}$	Minimum and maximum charging power
η_{Ele}	Efficiency of electrolyzer (%)	$P_{D_{MIN}}, P_{D_{MAX}}$	Minimum and maximum discharging power
P	Power to AWE	SOC_{MIN}, SOC_{MAX}	Minimum and maximum state of charge
LHV	Lower heating value of H ₂	η^+, η^-	Charging and discharging efficiencies

1. Introduction

Sooner or later, fossil fuels will run out, but their impact on our environment would take years to recover. Currently, the threshold for atmospheric CO₂ levels is at 415.26 ppm, which is the highest recorded up to date and has not been witnessed in millions of years (Moreno-Benito et al., 2016; Hannah Ritchie and Max Roser, 2020). The increase in greenhouse emissions has created an urge to implement renewable energy as an alternative to fossil fuels, but renewable energy's unpredictability is still persistent. This behavior makes renewable energy a less reliable resource when it comes to a continuous production system. However, storing renewable energy in batteries is a viable option but not the optimal one. For long-term storage, renewable hydrogen is considered the most viable means of achieving long-term energy storage at a lower cost and greater volumetric energy density than other fuels (Hirscher et al., 2020).

The principal method for converting renewable energy into hydrogen is through an electrolyzer. Among electrolyzer types, the alkaline water electrolyzer (AWE) is the most common and commercially accepted technology for hydrogen production (Brauns and Turek, 2020). However, a hydrogen production system will not be efficient if operated with an interrupted energy supply. With a proper set of controls and energy backup such as BESS, renewable energy fluctuations can be mitigated effectively (Kwon et al., 2016; Pascuzzi et al., 2016). Ulleberg presented a dynamic model of a PV-hydrogen with a battery and grid support in Germany (Ulleberg, 2003). The possibility of combining two or more renewable energy sources such as solar, wind, and hydropower to produce hydrogen has also been studied (Hoste et al., 2020). For a smooth operation, there should be a minimum interruption in power supplied to electrolyzers. To overcome that, a battery energy storage system (BESS) plays a prominent role in providing power at times with no solar-based energy or during power outages to operate the AWE at a minimum operational capacity (Eichman et al., 2014).

Therefore in this study, a 4.5 MW AWE dynamic operation for one year is optimized based on a predicted solar forecast for possible future operation based on the optimal split value of power to the AWE and BESS for hydrogen production and BESS charging, respectively. Also, an optimal discharge power value from BESS to AWE is selected for safe BESS operation. When subjected to the actual solar data-based operation, these optimized split fractions and discharge power values resulted in a continuous hydrogen production with no shutdowns, however a bit lower hydrogen production. Results suggested a substantial insight into operation planning and control for enhanced performance and optimal operation via optimizing predicted solar-based

operation for actual operation. This study will guide as a supporting tool in estimating the power distribution to the AWE and BESS based on the solar potential for any region.

2. Method

The solar irradiation data for the year 2018, both predicted, and actual weather of Incheon Korea was obtained from the System Advisor Model (SAM) (Ezeanya et al., 2018). SAM was used to simulate the power profile of a 6.5 MW PV system. The solar power production model by SAM takes the following assumptions:

- a) Solar PV modules are operated in a shadow-free environment.
- b) The PV system is standalone with no connection to the grid.

The general equations representing the dynamic operation of AWE and moles of hydrogen generated (nH_2^{GEN}) can be represented, as shown in Eq. (1).

$$nH_2^{GEN}(t) = \frac{\eta_{Ele} \times P}{LHV} \quad (1)$$

Where η_{Ele} is the efficiency of electrolyzer (68%), P the power to the electrolyzer, and LHV is lower heating value of hydrogen. The amount of hydrogen being stored ($nH_{2_{STORED}}$) can be represented, as shown in Eq. (2), where t is equal to 8760 hrs.

$$nH_{2_{STORED}}(t) = \int_0^t nH_2^{GEN}(t') dt' \quad (2)$$

To ensure a safe operation, some constraints must be considered for BESS operation and are enlisted below in Eq. (3) – (6):

$$I. \quad P_C(t) \times P_D = 0 \quad (3)$$

$$II. \quad P_{C_{MIN}} \leq P_C(t) \leq P_{C_{MAX}} \quad (4)$$

$$III. \quad P_{D_{MIN}} \leq P_D \leq P_{D_{MAX}} \quad (5)$$

$$IV. \quad SOC_{MIN} \leq SOC(t) \leq SOC_{MAX} \quad (6)$$

P_C is the power to BESS, $P_{C_{MAX}}$ is the maximum charging power for BESS, P_D is the power discharged from the BESS, $P_{D_{MIN}}$ is the minimum discharge power from the BESS to ensure hydrogen production during the night at lowest possible power. $P_{D_{MAX}}$ is

the maximum discharge power from the BESS, SOC is the state of charge of the BESS, and SOC_{MIN}, SOC_{MAX} represent the minimum and maximum SOC level respectively. In this study, SOC_{MIN}, SOC_{MAX} are 30% and 100%, respectively. Overall SOC can be represented, as shown in Eq.(7).

$$SOC(t) = SOC(t - \Delta t) + \left((\eta^+ \times P_C(t)) - (\eta^- \times P_D(t)) \right) \Delta t \quad (7)$$

Where η^+, η^- are the charging and discharging efficiencies. Charging and discharging efficiencies consider 5% loss.

Figure SEQ Figure * ARABIC 1. AWE with BESS and hydrogen storage.

The data used for modeling the electrolyzer and values of the model's parameters are taken from (Ulleberg, 2003; Mayyas and Mann, 2018). gPROMS platform was used to model the dynamic equations for the alkaline water electrolyzer. An illustration for the overall model can be seen in Figure 1. P_s represents the solar power, A/B represent the split fractions for the power to AWE ($P_A = P_s \times A$) and power to BESS ($P_B = P_s \times B$). P_x represents the surplus power when neither the AWE and neither the BESS needs power, i.e., either the BESS is fully charged, or the AWE is already operating at maximum load. P_x is used as a product and is assumed to be sold to neighboring industries. P represents the total power and is the sum of $P_A + P_D$.

Solar power (P_s) is split into two fractions (A) and (B), as shown in Figure 1. These fractions are set at different ratios. In this model, (A) is 0.7, then (B) will be 0.3, provided their sum always counts to 1.0. P_A is the power split going to the electrolyzer, and P_C is the power split going to the BESS for charging the batteries. In general, during day time (06:00 AM to 06:00 PM), power (P) is primarily the power

coming from P_A . However, during the initial morning hours, due to lesser solar energy production, the BESS supports maintaining a smooth power profile for the AWE until it is greater than the discharge power (P_D). Two data sets are considered in this study for P_s , one is based on the predicted solar data, and the second one comprises the actual weather data, both for the year 2018. Firstly the base model with predicted solar data set was run with A as 0.7, B as 0.3, and P_D as 700. Secondly, for Case 1(Optimized model), the base model was optimized to get the optimal values for A , B , and P_D . Thirdly for Case 3 (Base model with actual solar data), was run with optimal values evaluated in Case 2. The objective of the optimization was to maximize the hydrogen production, keeping the SOC within the operational constraints i.e. $SOC_{MIN} \leq SOC(t) \leq SOC_{MAX}$. The optimization formulation is shown below with the constraints mentioned in Eq. (8) – (11):

$$MAX_{A,P_D} (nH_{2_{STORED}}) \text{ s.t.}$$

$$0 \leq A \leq 1 \tag{8}$$

$$A + B = 1 \tag{9}$$

$$P_{D_{MIN}} \leq P_D \leq P_{D_{MAX}} \tag{10}$$

Figure SEQ Figure * ARABIC 2. and for base Case, Case 1 and Case 2.

$$SOC_{MIN} \leq SOC(t) \leq SOC_{MAX} \tag{11}$$

3. Results

As shown in Figure 1, the base model was run with A as 0.7, B as 0.3, and P_D as 700. The value P_D was kept higher to maximize BESS's utilization during night hours. The cumulative hydrogen produced for Base Case, Case 1, and Case 2 can be seen in Figure 2. Each graph in Figure 2 on the top right corner shows a greater resolution of

time from 70 to 100 h to better understand the main graph. Figure 2 shows that the Base case had the lowest hydrogen produced among all the discussed cases with 157,280 kg. Whereas the optimized case i.e., Case 1, had the highest production of 196,024 kg. Throughout the year, Base case faced a total of 3683 startups due to the lack of solar or not having enough power in the BESS to support the AWE operation. These startups were reduced by 39.14% for Case 1 (optimized case). Results show that an optimized operation not only produced higher production but also reduced the number of startups. Optimized decision variables from Case 1 were then given as an input for Case 2. Case 2 was powered by an actual solar profile to analyze the possibility of operation based on optimized operation for a predicted solar forecast. Hydrogen produced for Case 2 was 20.34% higher than the Base case. Furthermore, a reduction of 26.53 % in the startups throughout the year were reported. Results demonstrate that there is a possibility to pre-plan a year ahead of operations and manage any unforeseen situations to enable the plant's maximum potential based on predicted solar data and available resources. Furthermore, a year ahead of planning can help in monitoring the annual performance of the system. However, if this time is reduced from a year ahead to a week ahead of planning, the results would be different and may even result in improved control and performance. Currently, the model operates on time-invariant values. However, a huge potential lies if the model is operated with control variables that are optimized every hour based on the plant's current state and available renewable energy.

4. Conclusion

In this study, a 4.5 MW AWE dynamic operation was analysed for a year operation. The model was tested on a predicted solar profile for the upcoming year. Later the model was optimized to find optimal values for the control variables to ensure maximum production while observing model constraints. Later, those optimal values were used to run the model with the actual weather data to see if there is a possibility to plan a year before for plant operation. Results demonstrated that planning based on the predicted solar data and optimized control variables could help in better plant operation and plan for any unforeseen situation in the future operation, keeping in mind the unpredictable nature of renewable energy. Furthermore, in future work, the control variables will be optimized for piecewise control, i.e., for each interval, an optimal control variable value will be found to ensure a more robust control and reliable plan for future operation based on the predicted solar profile.

A Mixed Integer Dynamic Optimization Approach for a Hybrid-Stand Alone Solar and Wind Powered Alkaline Water Electrolyser for Renewable Hydrogen

Haider Niaz, J.Jay Liu*

Department of Chemical Engineering, Pukyong National University, Busan 48513, South Korea.

jayliu@pknu.ac.kr

Abstract

Renewable energy sources are sustainable, cost-effective, and environment-friendly alternatives for fossil fuels. However, renewable energy's intermittency and storage remain a challenge, leading researchers to study hybrid energy systems. In general, batteries can be considered as a short-time energy storage option. For sustainable and long term energy storage, hydrogen can be a suitable candidate. Among hydrogen production pathways, water electrolysis is considered a sustainable and widely accepted energy conversion route when powered by a hybrid renewable energy source (i.e., solar and wind energy). However, essential improvements are required for renewable hydrogen to be competitive enough with fossil fuels derived hydrogen energy. In this work, a mixed integer dynamic optimization (MIDO) approach is presented. The problem's objective is to minimize the Levelized cost of hydrogen (LCOH) (\$/kg) by determining the optimal size for a battery energy storage system (BESS). The hybrid system is connected with a BESS to ensure the electrolyzer's operation with no support from the grid electricity. The model is simulated over one year based on an actual solar and wind profile to include seasonal variation and its performance effect. With the inclusion of economic studies, a mixed integer dynamic optimization problem is constructed and presented a LCOH of 10.33 \$/kg and BESS capacity of 6575 kW. This study can be extended into simulation-based design tools for estimating the optimal size and approximate cost estimates for stand-alone renewable energy powered electrolyzer for hydrogen production for any given location.

1. Introduction

Fossil fuel extinction is a real threat to the upcoming generations. Their excessive use has done enough damage to our environment and will take years to recover from it. A radical step must be taken to control the ever-increasing emissions and replace fossil fuels with environment-friendly energy, providing renewable energy resources (Tokarska and Gillett, 2018). Renewable energy being dynamic creates a void at being a reliable energy source. But storing this energy in batteries can be a good remedy. Storing all energy in batteries can cost us several million dollars, but storing renewable energy in the form of hydrogen can help us overcome this huge capital investment as hydrogen has the properties to store the largest energy content among fuels (Nicita et al., 2020).

electrolyzers are recognized as green hydrogen generators when powered by a renewable energy source. The possibility of combining two or more renewable energy sources such as solar, wind, and hydropower to produce hydrogen has also been studied (Gökçek and Kale, 2018; Hoste et al., 2020). A battery energy storage system (BESS) can play an important role in ensuring a consistent energy supply to the electrolyzers. BESS can help minimize the power fluctuations by supplying the power when needed and store when there is enough renewable generation. In this context, a combination of a commercially accepted electrolyzer technology, i.e., alkaline water electrolyzer (AWE), a BESS, and solar and wind power for hydrogen generation, will be a perfect and promising candidate.

In this study, a 4.5 MW AWE is powered by a combination of 4.5 MW solar, 2.0 MW wind, and a 1.0 MW BESS. The study focuses on solving a mixed integer dynamic optimization problem to find the optimal size for a BESS, maximize the hydrogen production, and minimize the Levelized cost of hydrogen (LCOH) (\$/kg). The model is simulated over one year with one hour time interval to accommodate the solar and wind generation's seasonal variations. This study's dynamic and economic perspective can help evaluate the overall plant costs at minimum capital expenditure (CAPEX) by evaluating the optimal size for the BESS. Future work will consider minimizing the operational cost

and CAPEX based on the available hydrogen demand and required optimal size for AWE, solar, and wind capacity.

2. Method

The solar irradiation and wind data for the year 2018 was taken from Phoenix, Arizona, USA, was obtained from the System Advisor Model (SAM) (Ezeanya et al., 2018). SAM was used to simulate a 4.5 MW PV and Wind system's voltage and power profile. An overall block diagram for the solar and wind-powered AWE & BESS system with hydrogen storage can be seen in Figure 1.

Figure . Solar and Wind Powered 4.5 MW AWE with BESS and hydrogen storage.

The general equations representing the dynamic operation of AWE and moles of hydrogen generated (nH_2^{GEN}) can be represented, as shown in Eq. (1).

$$nH_2^{GEN}(t) = \frac{\eta_{Ele} \times P}{LHV} \quad (1)$$

Where η_{Ele} is the efficiency of electrolyzer (68%), P the power to the electrolyzer, and LHV is lower heating value of hydrogen. The amount of hydrogen being stored ($nH_{2_{STORED}}$) can be represented, as shown in Eq. (2), where t is equal to 8760 hrs.

$$nH_{2_{STORED}}(t) = \int_0^t nH_2^{GEN}(t') dt' \quad (2)$$

To ensure a safe operation, some constraints must be considered for BESS operation and are enlisted below in Eq. (3) – (6):

$$I. \quad P_C(t) \times P_D = 0 \quad (3)$$

$$II. \quad P_{C_{MIN}} \leq P_C(t) \leq P_{C_{MAX}} \quad (4)$$

$$III. \quad P_{D_{MIN}} \leq P_D \leq P_{D_{MAX}} \quad (5)$$

$$IV. \quad SOC_{MIN} \leq SOC(t) \leq SOC_{MAX} \quad (6)$$

P_C is the power to BESS, $P_{C_{MAX}}$ is the maximum charging power for BESS, P_D is the power discharged from the BESS, $P_{D_{MIN}}$ is the minimum discharge power from the BESS to ensure hydrogen production during the night at lowest possible power. $P_{D_{MAX}}$ is the maximum discharge power from the BESS, SOC is the state of charge of the BESS, and SOC_{MIN}, SOC_{MAX} represent the minimum and maximum SOC level respectively. In this study, SOC_{MIN}, SOC_{MAX} are 30% and 100%, respectively. Overall SOC can be represented, as shown in Eq.(7).

$$SOC(t) = SOC(t - \Delta t) + \left((\eta^+ \times P_C(t)) - (\eta^- \times P_D(t)) \right) \Delta t \quad (7)$$

Where η^+, η^- are the charging and discharging efficiencies. Charging and discharging efficiencies consider 5% loss.

The data used for modeling the electrolyzer and values of the model's parameters are taken from (Ulleberg, 2003; Mayyas and Mann, 2018). gPROMS platform was used to model the dynamic equations for the alkaline water electrolyzer. An illustration for the overall model can be seen in Figure 1. P_S represents the sum of solar and wind power, A/B represent the split fractions for the power to AWE ($P_A = P_S \times A$) and power to BESS ($P_B = P_S \times B$). P_X represents the surplus power when neither the AWE and neither the BESS needs power, i.e., either the BESS is fully charged, or the AWE is already operating at maximum load. P_X is used as a product and is assumed to be sold to neighboring industries. P represents the total power and is the sum of $P_A + P_D$.

Solar and wind power (P_S) is split into two fractions (A) and (B), as shown in Figure 1. These fractions are set at different ratios. In this model, (A) is 0.7, then (B) will be 0.3, provided their sum always counts to 1.0. P_A is the power split going to the electrolyzer, and P_C is the power split going to the BESS for charging the batteries. In general, during day time (06:00 AM to 06:00 PM), power (P) is primarily the power coming from P_A . However, at times with lesser solar and wind energy production, the BESS supports maintaining a smooth power profile for the AWE until it is greater than the discharge power (P_D).

Technoeconomic model and the method to calculate the LCOH used in this study were similar to the National Renewable Energy Laboratory (NREL) (Short et al., 1995; Dutta et al., 2011). Other raw materials (i.e., steam and KOH) consumption per kg of hydrogen produced for hydrogen production were estimated using the ones quoted in the NREL

(Ivy, 2004). The cost of the Electrolyser is taken from Gim and Yoon (Gim and Yoon, 2012). The cost of storage and compression equipment was taken from NREL and other sources. The plant life was assumed to be 30 years with an IRR of 4.5%. Our study's startup time was taken as 0.25 years with a working capital equivalent of 5% of the fixed capital investment (FCI). LCOH was calculated using NREL's equation, as shown in Eq.8 (Short et al., 1995).

$$LCOH = (TLCC - NPV_{OTHER-PRODUCTS}) / \sum_0^L (nH_2^{GEN} / (1 + D)^n) \tag{8}$$

Where $TLCC$ is the total life cycle cost of the plant, $NPV_{OTHER-PRODUCTS}$ is the net present value of the other products, i.e., P_x , D is the discount rate and n is the analysis year, and L is the analysis period in years i.e., 30.

Figure . and for a 4.5 MW AWE powered by 4.5 MW solar and 2.0 MW wind power.

The objective of the optimization was to minimize the $LCOH$ keeping the SOC within the operational constraints i.e. $SOC_{MIN} \leq SOC(t) \leq SOC_{MAX}$. $CAPEX_{BESS}$ can be represented as shown in Eq. (9).

$$CAPEX_{BESS} = CAP_{BESS} * COST_{kW} \tag{9}$$

Where $COST_{kW}$ represents the \$/kW cost for the battery. For $CAPEX_{BESS}$, SAM was used to evaluate the total cost for the BESS (Ezeanya et al., 2018). SAM incorporates the number of cells required for a specific size of a battery and can present the \$/kW for any BESS capacity. The optimization formulation is shown below with the constraints mentioned in Eq. (9) – (13), where A, B, P_D are continuous values and CAP_{BESS} is an integer value:

$$MIN_{A, P_D, CAP_{BESS}} (LCOH) \text{ s.t.}$$

$$0 \leq A \leq 1 \tag{9}$$

$$A + B = 1 \tag{10}$$

$$P_{D_{MIN}} \leq P_D \leq P_{D_{MAX}} \quad (11)$$

$$SOC_{MIN} \leq SOC(t) \leq SOC_{MAX} \quad (12)$$

$$CAP_{BESS}^{MIN} \leq CAP_{BESS} \leq CAP_{BESS}^{MAX} \quad (13)$$

gPROMS platform was used to solve the problem. Solvers used for dynamic optimization was CVP_SS (control vector parameterization), and for MINLP, OAERAP solver was employed, which uses an outer approximation (OA) algorithm for the solution of MINLP.

3. Results

Figure 2 demonstrates the power (P) to power the AWE. Followed by the hydrogen produced in a year. In Figure 2 the top right corner graph shows a greater time resolution for the main power graph. The optimization resulted in a cumulative nH_2^{GEN} of 223 tons of hydrogen a year. Keeping in mind the other objectives of the optimization was to evaluate the operational variables, i.e., A and P_D , for an optimal operation. Results demonstrated and proposed a value of 1 for A and 8 kW for P_D . It is assumed that 8 kW is the minimum possible power at which the AWE can run. Based on these values, the optimal size for the BESS was taken as 6575 kW.

Apart from operational results, the techno-economic model evaluated the LCOH, operational, and the CAPEX for the plant. Results demonstrated that for a 4.5 MW AWE powered by 4.5 solar and 2.0 MW wind turbine with a 6575 kW of BESS will have an equipment cost of \$10.81 MM. Major equipment costs include \$3.6 MM for a solar plant, \$2.83 for AWE, \$1.57 MM for BESS and \$ 2.8 MM for the wind turbine, and other costs, including compression storage and cost for inverters. The project resulted in an LCOH of \$10.33 /kg.

4. Conclusion

In this study, a mixed integer dynamic optimization was performed for a 4.5 MW AWE for a year operation using solar and wind power coupled with a BESS. The objective of the optimization was to maximize the hydrogen and minimize the LCOH and CAPEX for BESS. Results demonstrated that a dynamic operation and economic optimization could overcome and consider the seasonal fluctuations for a renewable energy powered project and provide realistic cost estimates. Furthermore, optimal sizing for the BESS can reduce the oversizing of the plant and save cost. In future work, this study will be extended into a simulation-based design tool for estimating the optimal size and approximate cost estimates for stand-alone renewable energy powered electrolyzer for hydrogen production for any given location.

Abstract

Online model-based redesign of experiments (OMBRE) methods are advanced methods to optimize input controls and sampling times to attain data with the highest information for precisely estimating the parameters of a dynamic process model. The way OMBRE methods are implemented is to first design a dynamic experiment, but only implement it over a fixed time interval, then perform parameter estimation with data collected in that interval to update the process model as the process is running and, finally, optimizing the experiment repeatedly until the experiment is concluded. In this work, we propose an adaptive version of OMBRE (A-OMBRE) where an algorithm determines when to re-optimize/update the current experiment based on parameter estimation results. The proposed method does not require any user input regarding the updating policy, instead it uses the real time parametric uncertainty to determine the updating times. The method is tested on a simulated case study of fermentation kinetics and is compared with i) a conventional offline design; ii) an OMBRE approach with user-defined redesign strategy.

Keywords: model-based redesign of experiments, adaptive design, collocation

1. Introduction

Identification of reliable mathematical models for dynamic systems is crucial as dynamic simulation mimics the behaviour of real plant and can be used to represent plant's real time operation, control and optimization. In several systems, mathematical models with a set of unobservable parameters are constructed from the physical laws governing the process and identification of those models needs precise estimation of the model parameters. Model-based design of experiments (MBDoE) methods are applied to dynamic systems with the purpose of designing a set of experiments yielding the most informative process data to be used for the estimation of the process model parameters (Franceschini and Macchietto, 2008). In conventional MBDoE methods, the experiment design phase, the actual experimental phase and the parameter estimation phase are carried out in a strictly sequential manner. This means that information is exploited only when the experiment is concluded. In contrast, in online MBDoE methods (Galvanin et al., 2009) a dynamic experiment is initially designed by optimizing input control configurations, allocation of sampling times, initial values of states and experiment duration, but the experiment is then redesigned within predefined time intervals ("updating intervals"). In each updating interval the information regarding model parameters is updated using parameter estimation techniques using past data and the updated model is used for designing the remaining part of the experiment repeatedly, until the model parameters are determined with minimal variance (Galvanin et al., 2009). Thus, in the online model-based redesign of experiments (OMBRE) method, information

content in the data is used during the experiment. The idea of online redesign was first proposed in Mehra (1974), applied to linear systems and later extended to nonlinear systems (Stigter et al., 2006). Compared to the conventional offline design, online experimental redesign methods offer great potential for the real time parameter estimation and model identification. However, a challenging aspect of the online redesign methods is the systematic choice of the number of redesigns and duration of each updating interval which are usually given as user-defined inputs. An improper choice of the above updating policy without system knowledge may lead to process data with insufficient information for parameter estimation in each updating interval. In De-Luca et al. (2016), authors proposed a method to minimize the duration of updating intervals while ensuring a sufficient reduction in parametric uncertainty in each updating interval. However, the method seems to be feasible for systems with nearly continuous measurements. More recently, a method based on auto-updating of sampling time redesign (Wang and Yue, 2019) was proposed to determine the length of updating intervals to assure identifiability for parameter estimation. To tackle the issue of properly determining the updating times, a framework for adaptive online model-based redesign of experiments for the identification of dynamic models is proposed in this work. The framework introduces a rational criterion based on the real time parametric uncertainty assessed through likelihood function of model parameters for the redesign of experiments. In the framework, orthogonal collocation method (Biegler, 2010) is used to discretize the dynamic model and the optimization is formulated as a mixed integer nonlinear programming (MINLP) problem to facilitate the optimal allocation of sampling points. The proposed redesign framework is tested on a simulated case study and compared with offline design and online redesign with user-defined redesign strategy.

2. Problem statement

The optimal design of dynamic experiments can be formulated as a dynamic optimization problem of the form of Eq. (1). The problem seeks the optimal design vector $\boldsymbol{\phi}$ that excites the dynamic system in order to optimize the function ψ towards the end of the experiment t_f . For convenience, the set of optimization variables are aggregated to form the design vector $\boldsymbol{\phi}$, which usually contains the vector of initial conditions \mathbf{y}_0 , the experiment duration t_f , the vector of input trajectories $\mathbf{u}(t)$ and the N_{sp} -dimensional set of sampling points \mathbf{t}_{sp} i.e., $\mathbf{t}_{sp} = [\mathbf{y}_0, t_f, \mathbf{u}(t), \mathbf{t}_{sp}]$. The basis for such a problem is the dynamic model \mathbf{f} that describes the evolution of the state variables with time $\mathbf{x}(t)$, starting from the initial condition $\mathbf{x}(0)$.

$$\begin{aligned}
 & \underset{\boldsymbol{\phi}}{\text{minimize}} && \psi(\mathbf{V}_{\boldsymbol{\theta}}(\boldsymbol{\phi}, \boldsymbol{\theta})) \\
 & \text{subject to} && \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \boldsymbol{\theta}, \mathbf{u}(t)), \hat{\mathbf{y}}(t) = \mathbf{g}(\mathbf{x}(t)) \quad \forall t \in [0, t_f] \\
 & && \mathbf{x}(t) \in \mathcal{X}, \mathbf{u}(t) \in \mathcal{U}, \quad \forall t \in [0, t_f] \\
 & && \mathbf{x}(0) \in \mathcal{X}_0, \boldsymbol{\theta} \in \Theta, \mathbf{t}_{sp} \in [0, t_f]
 \end{aligned} \tag{1}$$

In Eq. (1), $\mathbf{x}(\cdot) \in \mathbb{R}^{N_x}$ is the vector of differential states, $\hat{\mathbf{y}}(\cdot) \in \mathbb{R}^{N_y}$ is the vector of model predictions for the response variables $\mathbf{y}(t)$ (those state variables which are actually measured), $\mathbf{u}(\cdot) \in \mathbb{R}^{N_u}$ is the vector of input controls and $\boldsymbol{\theta} \in \mathbb{R}^{N_{\theta}}$ is the vector of model parameters. The differential states $\mathbf{x}(\cdot)$, controls $\mathbf{u}(\cdot)$ and parameters $\boldsymbol{\theta}$ are bounded within the admissible sets \mathcal{X} , \mathcal{U} and Θ respectively; $\mathbf{f}: \mathbb{R}^{N_x} \times \mathbb{R}^{N_{\theta}} \times \mathbb{R}^{N_u} \mapsto \mathbb{R}^{N_x}$ and $\mathbf{g}: \mathbb{R}^{N_x} \mapsto \mathbb{R}^{N_y}$

are differentiable functions. In Eq. (1), the predicted parameter covariance matrix $\mathbf{V}_\theta(\boldsymbol{\varphi}, \boldsymbol{\theta}, t_f)$ toward the end of the experiment is defined as

$$\mathbf{V}_\theta(\boldsymbol{\varphi}, \boldsymbol{\theta}, t_f) = \left\{ \left[\mathbf{V}_\theta^0 \right]^{-1} + \sum_{t=t_1}^{t_{N_{sp}}} \mathbf{Q}^T(t) \boldsymbol{\Sigma}_Y^{-1} \mathbf{Q}(t) \right\}^{-1} \quad (2)$$

In Eq. (2), $\boldsymbol{\Sigma}_Y$ denotes the covariance matrix of measurement errors which is assumed as a diagonal matrix with variances along the diagonal, \mathbf{V}_θ^0 denotes the prior uncertainty of the model parameters and $\mathbf{Q}(t)$ is the dynamic sensitivity matrix (Franceschini and Macchietto, 2008).

3. Methodology

In the online experimental redesign framework proposed in this work called as adaptive online model-based redesign of experiments (A-OMBRE), dynamic experiment design problem in Eq. (1) is solved using the simultaneous discretization approach using orthogonal collocation (Biegler, 2010). The method discretizes the continuous domains in the model and approximates the differential equations using algebraic equations defined at the discretization points. To incorporate the constraint on the number of measurements, we modify the optimization problem of Eq. (1) (discretized version) into a mixed integer non-linear programming (MINLP) problem in which the objective function is evaluated as

$$\mathbf{V}_\theta(\boldsymbol{\varphi}, \boldsymbol{\theta}, t_f) = \left\{ \left[\mathbf{V}_\theta^0 \right]^{-1} + \sum_{i=1}^N b_i \cdot \left(\mathbf{Q}^T(t_i) \boldsymbol{\Sigma}_Y^{-1} \mathbf{Q}(t_i) \right) \right\}^{-1} \quad (3)$$

where, $t_i \in [0, t_f]$, $b_i \in \{0, 1\}$, $\sum_{i=1}^N b_i = N_{sp}$

In Eq. (3), the binary variables b_i are used to choose the N_{sp} number of sampling points from the set of discretization points. Given the experimental budget in terms of number of samples allowed (N_{sp}) and the maximum duration of the experiment (t_f^{ub}), Eq. (1) is solved using the prior estimate $\boldsymbol{\theta}_0$ and the prior uncertainty \mathbf{V}_θ^0 to obtain the optimal experimental settings $\boldsymbol{\varphi}$ at which the dynamic experiment is started. This is shown in the first three blocks from top of the flow sheet in Figure 1 and in the first line of Algorithm 1. The first parameter estimation (PE) is carried out after sufficient data (at least as many as twice the number of model parameters; an empirical rule used in this work) is obtained, which is necessary for a proper estimation of the parameters and the variances. In cases where all parameters are not estimated well, which is most likely after the first parameter estimation, the likelihood ratio (LR) test (Quaglio et al., 2019) is used for an additional decision making which involves whether to ‘CONTINUE’ the running experiment or to ‘REDESIGN’ the experiment. At this purpose, the likelihood ratio (LR) test is carried out against a null hypothesis which states there is no significant difference between the likelihood functions at the prior $\boldsymbol{\theta}_0$ and at the new estimate $\hat{\boldsymbol{\theta}}$ obtained from the parameter estimation. The LR is evaluated by computing the statistic according to Eq. (4):

$$LR = -2 \left(\log L(\boldsymbol{\theta}_0 | \mathbf{y}(t_1, \dots, t_{n_{sp}})) - \log L(\hat{\boldsymbol{\theta}} | \mathbf{y}(t_1, \dots, t_{n_{sp}})) \right) \sim \chi^2(N_\theta, \alpha) \quad (4)$$

If the LR test appears to be statistically significant (p-value < 0.05), the current experiment which is optimized using the prior $\boldsymbol{\theta}_0$ might become sub-optimal and the remaining part of

the experiment is then redesigned using the new estimate $\hat{\theta}$ (updated prior) and modified constraints. If the LR test is not significant, there is no evidence to disprove the null hypothesis and the running experiment remains optimal and hence continues. This concept is explored to decide whether the experiment needs to be redesigned after a new sample has been collected. The above redesign strategy is shown in the second decision block of the flow sheet in Figure 1 and in lines 4 to 11 of Algorithm 1.

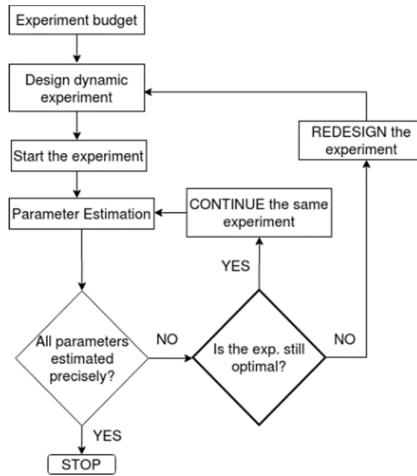

Figure 1. Flowsheet for the proposed adaptive ombre framework

Algorithm 1 Adaptive OMBRE

- 1: Input: N_{sp} , t_f^{ub} , \mathbf{V}_0^0 ; solve Eq. (1), return ϕ
- 2: Start exp; wait until $n_{sp} = 2 \cdot N_0 / N_y$
- 3: Solve PE using $y(t_1, \dots, t_{n_{sp}})$, return $\hat{\theta}$, \mathbf{V}_θ
- 4: **if** \mathbf{V}_θ is satisfactory **then** STOP
- 5: **else** compute LR statistic using Eq. (4)
- 6: **if** LR test is significant **then** modify and solve Eq. (1) and replace running exp.
- 7: **else** Continue the same experiment
- 8: **end if**
- 9: $n_{sp} = n_{sp} + 1$, solve PE and go to step 4
- 10: Continue step 9 until $n_{sp} = N_{sp}$
- 11: **end if**

4. Case study

A process for the fermentation of biomass by Baker's yeast presented in (Cooney and McDonald, 1995) is chosen as the case study to test the performance of the proposed algorithm. A Monod-type kinetic model which is described by following the set of DAEs is assumed to characterize the real system.

$$\begin{aligned}
 \frac{dx_1}{dt} &= (r - u_1 - \theta_4) x_1 \\
 \frac{dx_2}{dt} &= -\frac{r x_1}{\theta_3} + u_1 (u_2 - x_2) \\
 r &= \frac{\theta_1 x_2}{\theta_2 + x_2}
 \end{aligned} \tag{5}$$

In Eq. (5), the state variables x_1 and x_2 represent the biomass concentration [g L^{-1}] and the substrate concentration [g L^{-1}] respectively. The control variables in the model include the dilution factor [h^{-1}] and the substrate concentration in the feed [g L^{-1}], which are respectively denoted as $u_1(t)$ and $u_2(t)$. The experimental design vector ϕ contains the initial biomass concentration x_1^0 (range: 1-10 g L^{-1}), the experiment duration with an upper bound t_f^{ub} of 18 h, the dilution factor $u_1(t)$ (range: 0.05-0.20 h^{-1}), the substrate concentration in the feed $u_2(t)$ (range: 5-35 g L^{-1}) and the set of N_{sp} sampling points at which the state variables x_1 and x_2 are measured. The assumed true values for model parameters are given in Table 1 which are used to generate in-silico measurements by

adding random noise (Σ_V with 0.01 and 0.05 along the diagonal) to the simulated values. The assumed initial values of model parameters (with 90 % relative error with respect to the true values) are also provided in Table 1. The entire time horizon is divided into 18 equal control intervals or finite elements. The 18 finite element points except the starting point was allowed as potential sampling points in the MINLP design formulation. The maximum number of sampling points allowed (N_{sp}) was assumed as 12. An A-optimal criterion was used to design the experiments in all the design configurations: 1) a conventional offline method (MBDoE); 2) an online redesign method with pre-defined updating times (OMBRE); 3) the proposed method (A-OMBRE). The comparison is shown in Figure 2. In all the three cases, the experimental design involved four-point Legendre collocation, 18 finite elements and the controls have been discretized as piecewise constant profiles. The same initialisation and variable bounds discussed above were used in all the three cases.

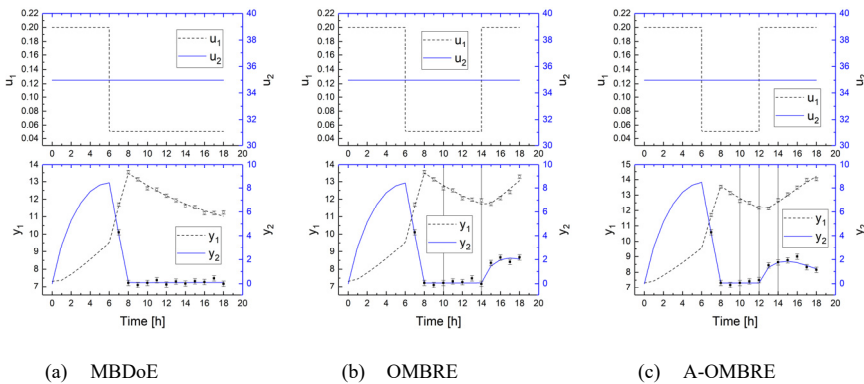

Figure 2. Experimental design results using three different design strategies (MBDoE, OMBRE, A-OMBRE). Figure shows the optimal control trajectories $\mathbf{u}(t)$ and the predicted state trajectories $\mathbf{y}(t)$. Measured states within the error bar are shown at the optimal allocation of sampling points. The vertical lines on panel b and c indicate the updating instances

In MBDoE, Eq. (1) was solved to obtain the optimal controls and sampling times shown in Figure 2(a). In OMBRE method, Eq. (1) was solved initially to obtain the design vector ϕ . Later, the running experiments were redesigned twice, each time after collecting new $2 \cdot N_\theta$ measurements or $2 \cdot N_\theta / N_y$ sampling points. The proposed A-OMBRE method followed the methodology discussed in section 3 and involved three redesigns. The optimal control settings, sampling times and the updating times in OMBRE and A-OMBRE are shown in Figure 2(b) and Figure 2(c) respectively. The comparison of parameter estimation results using the three different design strategies (Table 1) indicates that slightly more precise parameter estimation was achieved in the OMBRE method compared to the proposed adaptive OMBRE method. However, the significant advantage of the proposed method is that it allows to track the parametric uncertainty with respect to the optimal experimental design in real time with the help of a hypothesis testing (LR test) problem. The details of hypothesis testing problem (discussed in section 3) which is used to correlate the updating decision with parametric uncertainty in the proposed A-OMBRE method is illustrated in Table 2.

Table 1. Parameter estimation results including estimates and 95 % confidence intervals at the end of three different design strategies

Model parameter	True value	Initial value	Estimates from MBD _{oE}	Estimates from OMBRE	Estimates from A-OMBRE

5. Conclusion

In this work, a novel algorithm is proposed to automatically redesign a dynamic experiment in the online model-based redesign of experiments method which is used for precisely estimating the parameters of a dynamic process model. The proposed algorithm uses the updated parametric uncertainty to redesign a dynamic experiment. The effectiveness of the algorithm is tested on a simulated case study by comparing the proposed algorithm to a standard offline MBD_{oE} and an OMBRE method. The algorithm appears to be promising for online identification of dynamic models due to its ability to automate the calculation of updating times in redesign policies based on a rational criteria, an approach lacking in current state of the art algorithms.

Abstract

Hybrid Real-Time Optimization (HRTO) approaches consist of the economical steady-state optimization performed after the dynamic adaptation of the process model, usually carried out by an Extended Kalman Filter. Despite the increasing number of works concerning this technique, the literature still lacks a larger number of case studies supporting these alternatives, including cases that present nonlinear behavior at certain operating ranges and model uncertainties. This work aims to analyze the HRTO applied to a wide range of examples, exploring systems presenting different transient patterns, including slow (or fast) non-minimum (or minimum) phase behavior. Different RTO frameworks were evaluated, and nonlinear model predictive control was implemented as the advanced control layer for all architectures. As expected, under no structural uncertainties, the reached steady-state is the same for all approaches. Concerning transient operation, the area under the objective function curve was calculated by numerical integration and applied as a quantitative performance indicator, with the DRTO curve set as a reference since it outperforms its counterparts. The better performance of the HRTO for several systems with complex dynamics gives this approach more possibilities for industrial application, but care should be taken for systems with long time delays.

Keywords: Steady-state optimization, Dynamic optimization, Hybrid Real-time optimization, Kalman Filter, Van de Vusse Reactor.

1. Introduction

Real-Time Optimization (RTO) algorithms have a large participation in the industry, especially in petrochemical processes (Ruiz, 2009). Traditionally, steady-state model parameters are updated through real-time steady-state process measurements. After this step, an economic optimization is carried out with the updated steady-state model, generating the optimal setpoint for the controlled variables (Melo et al., 2009). Regarding the parameter estimation and steady-state optimization steps, the RTO is commonly referred to as a *two-step approach* (Trierweiler, 2014). One of the main challenges involving traditional RTO algorithms is the steady-state detection step, which usually uses statistics or heuristics to assess whether the system is sufficiently close to steady-state operation (Cao and Rhinehart, 1995). This matter becomes more relevant when facing real large-scale processes, with frequent transitions and long

transient dynamics (Bousbia-Salah et al., 2017).

Dynamic RTO (DRTO), unlike traditional RTO, performs the calculation of the optimal trajectory of the decision variables of the plant through a dynamic model of the process, making the steady-state detection step no longer needed. Despite this advantage, a major problem arises: the computational cost associated with the dynamic optimization. Solving a dynamic optimization problem for nonlinear systems can be a highly costly task, especially for large-scale systems. Given this fact alone, the industry in general still opts to apply the traditional RTO (Krishnamoorthy et al., 2018).

Driven by these limitations, some authors (Krishnamoorthy et al., 2018; Matias and Le Roux, 2018) have suggested an alternative hybrid approach for the real-time optimization that combines the strengths of traditional RTO and DRTO: the static optimization combined with the dynamic adaptation of the model. As this is a very recent technique, there are not many applications reported in the literature. Thus, the main goal of this work is to evaluate how hybrid RTO performs in processes presenting nonlinear and non-minimum phase behaviors and to evaluate its robustness under diverse scenarios, comparing different real-time optimization architectures.

2. Real-time optimization frameworks

Model-based real-time optimization techniques are imperative to deal with parametric plant-model mismatch (Serralunga et al., 2012). Structural divergences can make the system erroneously reach operating points that differ from the real optimum, highlighting the importance of a well-designed estimator. Thus, four RTO architectures were considered:

- **RTO-LS:** a traditional two-step RTO. First, the plant runs until its stationarity is addressed by a steady-state detection step. Once the process is at steady-state, its model is updated by a nonlinear least-squares estimator in order to perform the steady-state optimization. This optimizer returns the optimal controlled variables setpoints and the optimal manipulated variables targets that are fed into the advanced control layer with the updated model parameters. It is noteworthy that the controller only initiates when the first pair setpoint-target is calculated, i.e., when the plant is at steady-state for the first time;
- **RTO-EKF:** this framework differs from the previous RTO scheme when it comes to the model update phase. An extended Kalman filter was designed and acts as a state-parameter estimator at all sampling steps. This comes with the reasoning that, since non-measured disturbances are only estimated at steady-state, setpoint control is compromised when the process is at transient operation;
- **DRTO:** traditional dynamic real-time optimization, i.e, the optimization problem and estimation step consider the dynamic model of the process;
- **HRTO:** the original approach designed by Krishnamoorthy et al. (2018) was applied. Similarly to the mentioned RTO-EKF, the steady-state detector was removed. Thus, the dynamic model of the process is updated combined with the optimization of the steady-state model.

Concerning the mathematical formulation, more details can be found at Krishnamoorthy et al. (2018), where the optimization and estimation problems are stated for traditional

RTO (RTO-LS in the present work), DRTO, and HRTO.

3. Illustrative example: the Van de Vusse CSTR

The Van de Vusse reactor (Van de Vusse, 1962) is a continuous stirred-tank reactor containing a reaction system in which cyclopentadiene is used to synthesize cyclopentanol by electrophilic addition of water. The reaction is catalyzed by an acid solution (Diels-Alder reaction or cycloaddition), with the generation of cyclopentenediol and dicyclopentadiene as side products due to the high reactivity of reagents and products. This system is a well-known benchmark for multivariable control algorithms and nonlinear optimization. This process combines nonlinear behavior in several operational ranges with a relatively simple modelling.

Summarizing, this work considers the measurement vector $y = [C_A, C_B, T]^T$, the input vector $u = \left[\frac{F}{V}, T_k \right]^T$, $\theta = [C_{A,in}, T_{in}]^T$ as unmeasured disturbances, and C_B and T are the controlled variables. The remainder of the physico-chemical parameters are considered known.

Concerning the optimization problem for this system, the yield of B (C_B) is usually implemented as the objective function, with another common formulation being the sum of selectivity and conversion for the same component ($C_B / (C_{A,in} - C_A) + C_B / C_{A,in}$). A study of the system's steady-state profiles shows that both objective functions always raise with the increase of the jacket temperature. Thus, in order to prevent the saturation of the manipulated variables throughout RTO operation, a new objective function to be maximized that takes into account the energy cost related to higher jacket temperatures was proposed:

$$J = \frac{C_B}{C_{A,in} - C_A} + \frac{C_B}{C_{A,in}} - 6 \times 10^{-4} T_k \quad (1)$$

Regarding complex dynamics, different models were considered:

- **Base Van de Vusse:** standard model formulation with equations and parameters available in Engell and Klatt (1993);
- **Van de Vusse with dead time:** in this case, fixed time delays were inserted into the measured and input variables.

The NLP problems were implemented with CasADi v3.5.5 (Anderson, 2013) using Python v3.8.3 programming environment and solved using IPOPT v3.12.2 (Wächter and Biegler, 2006) and IDAS (Hindmarsh, 2005) was the integrator applied to develop the plant simulator with relative and absolute accuracies of 10^{-6} for both solvers. The sampling time and total simulation time were 9s and 2h for all cases and architectures. A common practice in industrial applications is to run the optimizer in a fixed frequency; in this case the optimization cycle was of 10 sampling times. For all frameworks, nonlinear model predictive control (NMPC) was considered for the advanced control layer with control and prediction horizons of 10 and 40 sampling times, respectively. The steady-state detection uses the last five plant measurements at all sampling times.

3.1. Base Van de Vusse

Figure 1 shows the results for all architectures considering step perturbations in the disturbances at different simulation times. Regarding the objective function performance and computational effort, Table 1 summarizes the average CPU time per optimization cycle for each approach.

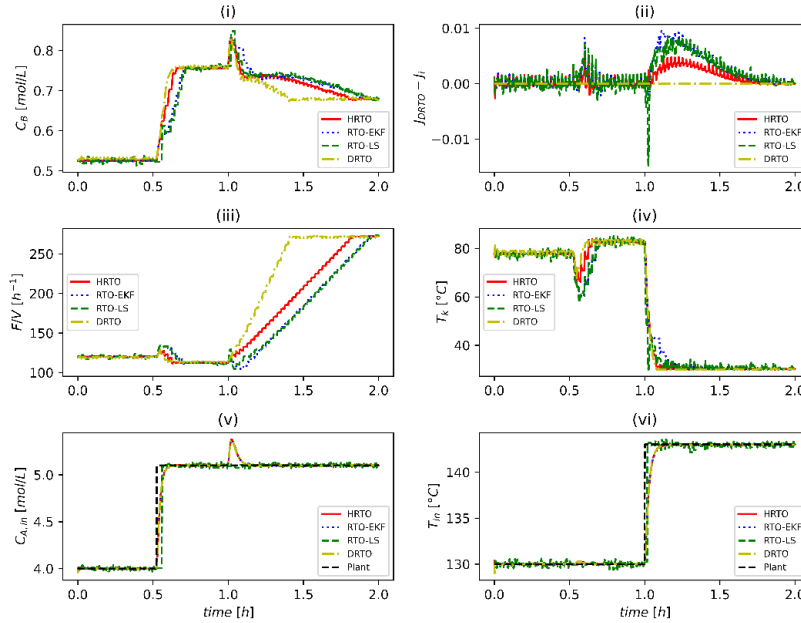

Figure 1: Performance of the RTO frameworks: (i) estimates of C_B ; (ii) difference of the objective function plant value to DRTO; (iii) input values for $\frac{F}{V}$; (iv) input values for T_k ; (v) estimates of $C_{A,in}$; and (vi) estimates of T_{in} .

Table 1: Integrated objective function and average CPU time per optimization cycle.

Approach	Integrated objective function	Avg. time per optimization cycle [s]
DRTO	518.32	2.62
HRTO	517.70	2.11
RTO-EKF	516.92	2.11
RTO-LS	517.06	2.13

It is clear that the NMPC acts faster with the DRTO, and the hybrid approach performs better when compared to its steady-state counterparts, which are held back by the steady-state detection step. The steady-state optimum is expected to be the same for all cases, and the delay in RTO-EKF and RTO-LS to reach the new optimum is evident. It is noteworthy that all optimization approaches are limited to a fixed input variation constraint of 5 units, explaining why DRTO can move faster than the other strategies since it is able to perform 3 actions during the 10 sampling times cycle. In addition, HRTO architecture behaved as fast as its steady-state counterparts while performing slightly better, as shown in Table 1 and Figure 1.

It is also important to state the robustness of the HRTO approach to disturbances of different types and magnitudes, considering that only parametric uncertainty is present and that the plant is open-loop stable. Different disturbance scenarios should only affect the estimation convergence rate since the EKF was tuned in order to converge reasonably fast for this specific perturbation scenario.

3.2. Van de Vusse with dead time

Regarding this study, the implemented delays were [10, 10] sampling times for the inputs and [15, 15, 6] for the plant measurements. Since the results for the base case study showed how HRTO overperformed in comparison to RTO-EKF and RTO-LS, this example has the purpose of evaluating its behavior in a process presenting dead time. Figure 2 illustrates performances for HRTO in four different cases: base case, delay only on the inputs, delay only on the measurements, and delay on both.

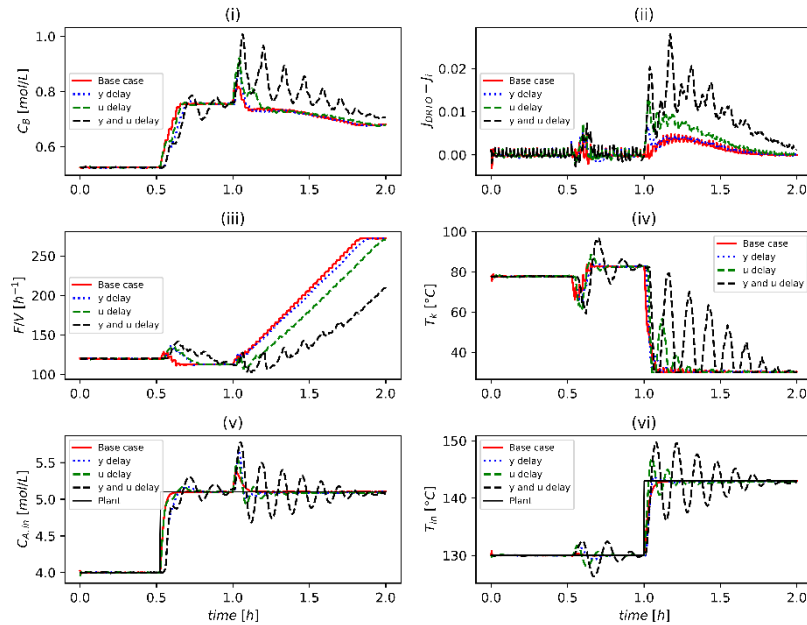

Figure 2: HRTO performance in the presence of dead-time: (i) estimates of C_B ; (ii) difference of the objective function plant value to DRTO; (iii) input values for F/V ; (iv) input values for T_k ; (v) estimates of $C_{A,in}$; and (vi) estimates of T_{in} .

Figure 2 clearly shows that the dead time's inclusion affects HRTO's performance. It is noteworthy that the estimation becomes especially compromised with the inclusion of dead times, which translates into poorer performances from the optimizer and controller. Concerning C_B and the objective function profiles, the system struggles to reach the steady-state, and the HRTO base curve stabilizes faster. As expected, the insertion of dead time in both inputs and measurements proved to be the worst-case scenario as it comes with the presence of oscillatory modes. Simulations with greater delays resulted in the system becoming unstable. It is noteworthy that the DRTO and RTO-EKF simulation with the same delays did not present oscillatory behavior, unlike HRTO and RTO-LS.

Table 2 shows the objective function performance and CPU effort for DRTO, HRTO and RTO-EKF considering dead-time in the inputs and outputs, confirming that the existence of time delays in the inputs and outputs compromises the overall performance of the real-time optimization. RTO-LS was not considered for this comparison since the LS estimator relies on steady-state operation and the system becomes highly unstable, as seen in Figure 2.

Table 2: Van de Vusse with dead-time - Integrated objective function and average CPU time per optimization cycle.

Approach	Integrated objective function	Avg. time per optimization cycle [s]
DRTO	517.84	2.58
HRTO	514.52	1.99
RTO-EKF	514.35	2.17

4. Conclusion

In this work, the hybrid RTO approach was applied to the Van de Vusse CSTR. The DRTO is still expected to outperform its counterparts. This result is showed by numerically integrating the objective function curve while in transient operation and using this value for the DRTO as reference. By comparing the objective function profile for the RTO and HRTO, a similar behavior was observed during most of the steady-state operation, with close performances. The HRTO stands out especially thanks to the absence of the steady-state detection step, which makes standard RTO have a delayed performance at some operational ranges. HRTO's behavior in the presence of dead time was also evaluated, and it was observed that it does affect its performance, especially in the estimation step. The presence of dead time arose oscillatory modes, and it is even possible to destabilize the system depending on its amplitude. However, this issue can possibly be overpassed by the use of dead-time compensators.

* raj@iitm.ac.in, babji.srinivasan@iitm.ac.in

Abstract

The significance of operator training has dramatically increased due to complex automation strategies in modern process plants. It is reported that human errors account for 70% of the accidents in process industries, with inadequate training cited as one of the most common reasons for these incidents. Our previous work has shown the potential of eye-tracking to infer the mental state of control room operators. In this work, we propose a methodology that combines multi-scale data from the process simulator, control actions performed, and eye gaze data of the operators to evaluate their training outcomes. Specifically, we use fixation transition entropy, an eye-tracking metric, which can help infer the mental models of the process abnormalities developed by the operators during repeated control room tasks. Results indicate that the fixation transition entropy decreases on account of development of correct mental models of process while it remain at higher values when operator fails to update their mental models during plant abnormalities. Thus, the proposed metric can be used to gauge the development of operator's mental models during training to understand the transition from novice to becoming experts.

Keywords: Operator Training, Eye-tracking, Transition Entropy, Mental Model, Process Safety

1. Introduction

Operator training is an important part of industrial safety, during which novice operators acquire skills and develop mental models of the process. After training, the operators are deployed to a real control room setting to monitor the automated system and intervene when the automation underperforms, especially during abnormalities. When dealing with such abnormalities, an incorrect mental model of the abnormal situation developed by the operator increases the likelihood of committing. Thus, it is crucial to have skilled operators with the correct mental models of the process. However, the complex nature of modern plants, with sophisticated and complex automation strategies, makes it challenging for the operators to develop correct mental models of the process (Kludge et al., 2014). As a result, assessment of mental models during training is important to evaluate their understanding of process dynamics.

Typically, process industries rely on Operator Training Simulators (OTS) to impart skills to the operators. Several studies have been conducted to evaluate operator performance during these training trials. Most of these studies either focus on developing comprehensive OTS that can accurately mimic plant behavior (Patle et al., 2014) or

assessing operator's ability to follow standard guidelines based on metrics derived from process and operator interactions. For instance, Manca et al. (2014) evaluated the performance based on the time taken and the sequence of actions by the operator against a standard protocol in a virtual polymerization plant. Nevertheless, these studies do not explicitly focus on the evolution of the operator's knowledge about the dynamics of the process during the training trials. In addition, there are hardly a few works that focus on understanding the cognitive behavior of operators, crucial to enhancing operators' skills and abilities (Bullemer and Nimmo, 1994).

Eye-tracking is one of the widely used approaches to analyze the cognitive behavior of human operators in several safety-critical domains such as aviation, health care, and nuclear industries (Srinivasan et al., 2019). In the past, our research group has utilized physiological data obtained from eye tracking to understand the cognitive behavior of control room operators during abnormal situations (Bhavsar et al., 2017, Srinivasan et al., 2019). Our studies indicated that eye gaze analysis could identify the orientation, diagnosis, and execution tasks performed by the operator during an experiment (Kodapully et al., 2016). Statistical studies revealed that gaze-based entropy measures could be used to understand the situational awareness of the operators while handling plant abnormalities (Bhavsar et al., 2017). With the knowledge acquired from these studies, in this work, we develop a methodology to understand the evolution of operator's mental models and expertise level during training tasks using metrics derived from process dynamics, operator actions, and eye-tracking data. The details of the proposed methodology, along with experimental studies are discussed in the following section.

2. Experimental setup and methodology

The experimental study consisted of participants interacting with the Human Machine Interface (HMI) of a simulated ethanol production plant. Participants were asked to monitor and perform necessary control actions (using sliders provided on the HMI) during plant abnormalities. There are six different scenarios that result in abnormal situations that need to be handled by the participant. If the participant fails to handle the abnormality, they can use emergency shutdown button else the plant will shut down automatically in 2 mins after the occurrence of alarms. The reader is referred to Bhavsar et al. (2017) for more details on the simulation. Ten participants were involved in the study. Each participant carried out repetitive tasks (repetition of a scenario) in different trials. Overall, these ten participants performed 81 trials for each scenario leading to a total of 486 tasks. We recorded process data, alarm information, and operator action data during all these tasks. In addition to these measurements, we also recorded eye-gaze data obtained from Tobii TX 300 eye tracker.

For assessing the effect of training (repetition of scenarios), in every trial, we analyzed the number of alarms triggered (N_t), the number of alarms cleared (N_c), and the number of slider actions (N_s). In addition to these process and action-based metrics, we also quantified operators' cognitive behavior using eye gazed fixation transition entropy (\tilde{H}_F).

To calculate \tilde{H}_F , we divided the HMI into L rectangular-shaped areas of interest (AOI) based on the location of variables tag, alarm panel, and trend panel. In this work, we have defined 19 (L) AOIs. We obtained the fixation distribution on these AOIs and generated a sequence of fixations based on the AOI they belong. Next, we computed the transition matrix (T' of size $L \times L$) which represents the frequency of fixation transitions between A_i ($i = 1, 2, \dots, L$) to A_j ($j = 1, 2, \dots, L$).

$$T' = \begin{pmatrix} A'_{11} & \cdots & A'_{1L} \\ \vdots & \ddots & \vdots \\ A'_{L1} & \cdots & A'_{LL} \end{pmatrix} \quad (1)$$

Here A'_{Lj} denotes the number of transitions from L^{th} AOI to j^{th} AOI and likewise. We then weighted T' by a weight matrix (W) to avoid the effect of unintentional fixation transitions between nearby AOI's. The weight matrix (W) is computed based on the Euclidian distance between the center of the AOIs. The coordinates of the center of i^{th} AOI (A_i) is given by (x_i, y_i) . An element of W is given by:

$$W_{ij} = \sqrt{(x_j - x_i)^2 + (y_j - y_i)^2}, i = 1, 2, \dots, L, j = 1, 2, \dots, L \quad (2)$$

where W_{ij} represents Euclidian distance between A_i and A_j . We then rescale W between 0 and 1. For the sake of simplicity, we call the rescaled weight matrix as W . The weighted transition matrix (T) is then obtained as:

$$T' = \begin{pmatrix} A'_{11}W_{11} & \cdots & A'_{1L}W_{1L} \\ \vdots & \ddots & \vdots \\ A'_{L1}W_{L1} & \cdots & A'_{LL}W_{LL} \end{pmatrix} = \begin{pmatrix} 0 & \cdots & A_{1L} \\ \vdots & \ddots & \vdots \\ A_{L1} & \cdots & 0 \end{pmatrix} \quad (3)$$

The diagonal elements in T' (self-transitions) are zero as W_{ii} (self-distance) is zero. After assigning weights to the transition matrix, we calculated \tilde{H}_F as per equation (4) and (5):

$$H_F = -\sum_{i=1}^L \sum_{j=1, j \neq i}^L P(A_{ij}|A_i) \log_2 P(A_{ij}|A_i) P(A_i) \quad (4)$$

$$\tilde{H}_F = \frac{H_F}{H_F^{max}} \quad (5)$$

where H_F is the weighted fixation transition entropy. Here $P(A_{ij}|A_i)$ denotes the probability of transition of fixation from AOI A_i to AOI A_j , and $P(A_i)$ is the probability of fixation on AOI A_i . \tilde{H}_F represents the relative weighted fixation transition entropy, while H_F^{max} is the maximum value of H_F given by $H_F^{max} = \log_2(L-1)$. The larger the \tilde{H}_F , the more disordered fixation pattern on HMI and vice-versa. It is expected that with repetition of trials, the operator's fixation pattern will move towards lower entropy values as the transition takes place only between those regions which give information of disturbance or help in removing disturbance.

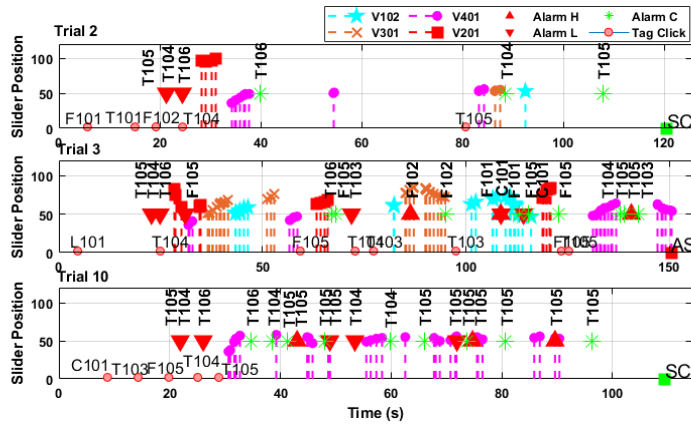

Figure 1: Operator actions with alarm and slider action details in key trials.

3. Results and Discussion

In this section, we demonstrate the potential of the proposed methodology in assessing operator's ability as well as inability in developing correct mental models of the process dynamics.

3.1. Illustrative Example 1

In this illustration, we demonstrate the potential of the proposed methodology to assess the development of a correct mental model of the process dynamics under a given abnormality with the training of novice operators. Consider an operator who performed ten trials of a scenario that involves a disturbance in the reflux ratio of the distillation column, and which can be rectified by manipulating V401. Operator actions in key trials are shown in Fig. 1. Consider trial 2 (Fig. 1), at around 22 s alarms T104 and T105 occur, followed by T106. Operator clicks on the tag of T104 to observe the trend of the process variable T104 and takes first control action at around 29 s by manipulating V201. At around 35 s, the operator manipulates V401 (correct control action). In the same trial, the operator also manipulates V301 later, depicting that the operator keeps on exploring the possible actions which can clear the disturbance in the process. In trial 2 and 3, the operator has used multiple control actions as shown by different markers of stem plot (Fig. 1). The use of multiple control actions indicates that the operator is unaware of the root cause of the disturbance. While manipulating different sliders, operator somehow manages to clear all the alarms in trial 2, but it is not necessary that the operator understands the root cause of the disturbance. Trial 3 ends in automatic shutdown because of operator's inability to deal with the disturbance. With the repetition of trials, the operator develops an understanding of the underlying principle of the process and is reflected in the trial 10 where the operator only manipulates V401.

The alarm information (N_t & N_c) and operator actions (N_s) with the trial number is shown in Fig. 2 (a) and 2 (b), respectively. We observe a decrease in N_t towards the end of the trial (Fig. 2 (a)), implying that the operator has taken the right control actions because of which few additional alarms are triggered. Also, the operator successfully cleared all the triggered alarms ($N_t - N_c = 0$). The operator action data (Fig. 2 (b)) shows a decrease in N_s from trial 8 onwards. This implies that with repetition of trials, an understanding of the scenario (less slider manipulation) is developed by the operator.

Figure 2: (a) Number of alarms triggered (N_t) and cleared (N_c) with trial number (b) Number of slider actions (N_s) with trial number (c) Weighted Fixation Transition Entropy (\tilde{H}_F) with trial number

Trials 1 and 2 need special mention as both N_t and N_s stay at lower values. In trial 1, the operator puts minimal effort ($N_s = 3$) to clear the alarms, which leads to the shutdown of the plant. During trial 2, there is a possibility that the operator manages to clear the disturbance by chance. This is supported by the fact that the next three trials (trials 3, 4 & 5) are not completed successfully. From Fig. 2 (c), it can be observed that \tilde{H}_F decreases (from 0.562 in the first trial to 0.203 in the last trial) with repetition of trials and remains at lower values towards the end of the trial. This signifies that with increasing trials, the attention is increasingly directed to the relevant AOIs. During trials 1 and 2, \tilde{H}_F remains at a higher value in contrast to N_t and N_s . This indicates that the operator is unaware of the dynamic response of the process because of which distributed attention on HMI is observed. Thus \tilde{H}_F is able to track the mental model of the operator under the given abnormality correctly and therefore has the potential to gauge the learning progress of novice operators.

3.2. Illustrative Example 2

In this illustrative example, we demonstrate the potential of \tilde{H}_F to capture the instances when operators struggle to update their mental models of the process, and as such, do not learn with repetition of trials. Consider an operator who performed seven trials of scenario 5 in which feed flow to the CSTR gets disturbed, resulting in alarms F101, F105 and C101. The number of alarms triggered and cleared (N_t & N_c), and number of slider actions (N_s) are shown in Fig. 3 (a) and 3 (b) respectively. The operator was unsuccessful in bringing the plant to the normal operating range till the last trial ($N_t - N_c > 0$), except during trials 2 and 4. The inability to learn is captured by the inability to clear all the alarms within the stipulated amount of time as shown in Fig. 3(a), and as also reflected by N_s which does not show a decreasing trend with trial number. Even though trials 2 and 4 were a success, with low values in all the process and action-based metrics, there was a very little decrease in \tilde{H}_F as depicted by Fig. 3 (c). Nevertheless, \tilde{H}_F remained more or less constant, during the other trials as well, even towards the end of the trials, indicating that the operator did not update their mental model of the given abnormality with repetitions. Failure to update the mental model is manifested in the inability to improve the fixation pattern from a disordered one to a more directed pattern of information acquisition from the HMI. Thus, the proposed eye-tracking based metric has the potential to capture whether an operator is learning or not and can complement all other process and action-based metrics by providing critical insights into the operator cognitive behaviour.

Figure 3: (a) Number of alarms triggered (N_t) and cleared (N_c) with trial number (b) Number of slider actions (N_s) with trial number (c) Weighted Fixation Transition Entropy (\tilde{H}_F) with trial number

4. Conclusions

The present work proposed a multi-scale data-driven to gauge the development of expertise level of control room operators during training. When the operators develop the correct mental models of the process, the process-based measures (N_t & N_c), operator actions (N_s), and fixation transition entropy (\tilde{H}_F) decrease and remain at a lower value. The lower values of \tilde{H}_F signifies that operators have arranged their fixation pattern on only a few regions on HMI. Further, our results demonstrate that the proposed cognitive measure \tilde{H}_F help infer the mental models of the operators even when the process and operation action based measures fail. Our future work will focus on developing robust multivariate measures using various physiological sensors (such as EEG, ECG, audio and video analytics etc.) for expertise level assessment of control room operators.

Abstract

In order to ensure the safety and stability of industrial processes, it is necessary to research more efficient and accurate fault detection technology. Methods based on multivariate statistics analysis are very suitable for complex industrial processes. Based on the pros and cons of current fault detection methods, deep principle component analysis (DePCA) was developed by Deng previously. In this work, by combining DePCA with dynamic process, the deep dynamic principle component analysis (DeDPCA) is proposed, where optimizing variables for extended time series is used to reduce computational complexity. Case study in the benchmark Tennessee Eastman process demonstrates the superior performance of the proposed DeDPCA method over the DePCA method.

Keywords: fault detection, DPCA, KPCA, deep learning

1. Introduction

With the development of modern science and technology and the intensification of market competition, the production level of the chemical process continues to improve. Traditional detection systems lack reliability, and data-driven methods are getting more and more attention^[1].

Deep learning, as one of the most currently remarkable machine learning techniques, has achieved great success in many applications such as image analysis, speech recognition and text understanding. Deng^[2] took the advantages of deep learning strategy and designed a hierarchical statistical model structure to extract multilayer data features, including both the linear and nonlinear principal components, which is called deep principle component analysis (DePCA). Although DePCA's ability to detect faults is better than kernel principle component analysis (KPCA)^[3] and serial principal component analysis (SPCA)^[4], it is not sensitive to dynamic data for most industrial processes.

When combine DePCA with dynamic process^[5], deep dynamic principle component analysis(DeDPCA) is established. Then variables for extended time series is optimized using autocorrelation analysis to reduce computational complexity. Which layer to extract dynamic feature was conducted by comparing two models with different structure, one extract dynamic feature in first linear layer and another in second nonlinear layer.

The remainder of this paper is structured as follows. In Section 2, our proposed DeDPCA method for nonlinear dynamic process monitoring is given. In Section 3, case study of TE process is used to validate the proposed method, and our conclusions are drawn in Section 4.

2. Construction of Proposed Model

2.1. Proposed DeDPCA model

The proposed DeDPCA model extracts linear and nonlinear features by integrating dynamic principle component analysis(DPCA) and KPCA into a 2-layer structure. In this deep feature extraction structure, first the training data matrix $\mathbf{X} \in \mathbb{R}^{N \times M}$ with N samples of M variables expands to an augmented matrix $\mathbf{X}(k) \in \mathbb{R}^{(N-k) \times M(k+1)}$ with a lag of k . Then the linear principal components are extracted from the augmented matrix $\mathbf{X}(k)$ to obtain the first layer feature $\mathbf{T}^{(1)} \in \mathbb{R}^{(N-k) \times \tilde{N}^{(1)}}$, where $\tilde{N}^{(1)} = M(k+1)$. Then KPCA is applied to $\mathbf{T}^{(1)}$ to extract nonlinear principal components to obtain the second layer feature $\mathbf{T}^{(2)} \in \mathbb{R}^{(N-k) \times \tilde{N}^{(2)}}$, where $\tilde{N}^{(2)}$ is the number of nonlinear non-zero features extracted in the second layer.

More specifically, in the first feature layer, the linear optimization task is designed as

$$\begin{aligned} & \max_{\mathbf{p}^{(1)}} \frac{1}{N-1} (\mathbf{p}^{(1)})^T \mathbf{X}(k)^T \mathbf{X}(k) \mathbf{p}^{(1)} \\ & \text{s. t. } (\mathbf{p}^{(1)})^T \mathbf{p}^{(1)} = 1 \end{aligned} \quad (1)$$

to obtain $M(k+1)$ projection vector $\mathbf{p}_i^{(1)} \in \mathbb{R}^{M(k+1)}$ and score vector $\mathbf{t}_i^{(1)} = \mathbf{X}(k) \mathbf{p}_i^{(1)}$, $1 \leq i \leq M(k+1)$. The score vector constitutes the first layer feature $\mathbf{T}^{(1)} = [\mathbf{t}_1^{(1)} \mathbf{t}_2^{(1)} \dots \mathbf{t}_{M(k+1)}^{(1)}]$. In the second feature layer, we perform nonlinear optimization task

$$\begin{aligned} & \max_{\mathbf{p}^{(2)}} \frac{1}{N-1} (\mathbf{p}^{(2)})^T \boldsymbol{\Phi}(\mathbf{T}^{(1)})^T \boldsymbol{\Phi}(\mathbf{T}^{(1)}) \mathbf{p}^{(2)} \\ & \text{s. t. } (\mathbf{p}^{(2)})^T \mathbf{p}^{(2)} = 1 \end{aligned} \quad (2)$$

where $\mathbf{p}^{(2)}$ is the nonlinear projection vector that can be obtained by

$$\mathbf{p}^{(2)} = \sum_{j=1}^{N-k} \boldsymbol{\Phi}^T(\bar{\mathbf{t}}_j^{(1)}) \boldsymbol{\alpha}_j^{(2)} = \boldsymbol{\Phi}^T(\mathbf{T}^{(1)}) \boldsymbol{\alpha}^{(2)} \quad (3)$$

where $\bar{\mathbf{t}}_j^{(1)} \in \mathbb{R}^{\tilde{N}^{(1)}}$ is the j th column of $(\mathbf{T}^{(1)})^T$, $\boldsymbol{\alpha}^{(2)} = [\alpha_1^{(2)} \alpha_2^{(2)} \dots \alpha_N^{(2)}]^T$. Besides, denote $\mathbf{K}^{(1)} = \boldsymbol{\Phi}(\mathbf{T}^{(1)}) \boldsymbol{\Phi}^T(\mathbf{T}^{(1)})$, The nonlinear optimization formula can be written as

$$\begin{aligned} & \max_{\boldsymbol{\alpha}^{(2)}} \frac{1}{N-k-1} (\boldsymbol{\alpha}^{(2)})^T \mathbf{K}^{(1)} \mathbf{K}^{(1)} \boldsymbol{\alpha}^{(2)} \\ & \text{s. t. } (\boldsymbol{\alpha}^{(2)})^T \mathbf{K}^{(1)} \boldsymbol{\alpha}^{(2)} = 1 \end{aligned} \quad (4)$$

resulting in the projection vector $\boldsymbol{\alpha}_i^{(2)} \in \mathbb{R}^{N-k}$ and the corresponding nonlinear score vector $\mathbf{t}_i^{(2)} = \mathbf{K}^{(1)} \boldsymbol{\alpha}_i^{(2)} \in \mathbb{R}^{N-k}$, $1 \leq i \leq \tilde{N}^2$. Therefore, the second feature layer is $\mathbf{T}^{(2)} = [\mathbf{t}_1^{(2)} \mathbf{t}_2^{(2)} \dots \mathbf{t}_{\tilde{N}^2}^{(2)}] \in \mathbb{R}^{(N-k) \times \tilde{N}^2}$.

For the testing vector $\mathbf{y}_t = [\mathbf{x}_t \mathbf{x}_{t-1} \dots \mathbf{x}_{t-k}]$, the feature vector of the first layer $\mathbf{t}_t^{(1)} = [\mathbf{t}_{t,1}^{(1)} \mathbf{t}_{t,2}^{(1)} \dots \mathbf{t}_{t,M(k+1)}^{(1)}]^T$ can be calculated as

$$\mathbf{t}_{t,i}^{(1)} = \mathbf{y}_t^T \mathbf{p}_i^{(1)}, 1 \leq i \leq M(k+1) \quad (5)$$

Second layer feature vector $\mathbf{t}_t^{(2)} = [t_{t,1}^{(2)} \ t_{t,2}^{(2)} \ \dots \ t_{t,\bar{N}^2}^{(2)}]^T$, can be expressed as

$$\mathbf{t}_{t,i}^{(2)} = \mathbf{k}_t^{(1)T} \boldsymbol{\alpha}_i^{(2)} \quad (6)$$

where the kernel vector $\mathbf{k}_t^{(1)} = \boldsymbol{\Phi}(\mathbf{T}^{(1)})\boldsymbol{\Phi}(\mathbf{t}_t^{(1)}) = [k_{t,1}^{(1)} \ k_{t,2}^{(1)} \ \dots \ k_{t,N-k}^{(1)}]^T \in \mathbb{R}^{N-k}$. As can be emphasized that, like the DePCA method, the DeDPCA method also does not require complex network optimization to achieve layer-by-layer feature extraction.

For the first layer, $T^{2(1)}$ and $Q^{(1)}$ monitoring statistics can be obtained as

$$T^{2(1)} = \mathbf{t}_t^{(1)T} \Lambda_1^{-1} \mathbf{t}_t^{(1)}$$

$$Q^{(1)} = \|\mathbf{y}_t - \hat{\mathbf{y}}_t\|^2 = (\mathbf{y}_t - \mathbf{P}_P \mathbf{t}_t^{(1)})^T (\mathbf{y}_t - \mathbf{P}_P \mathbf{t}_t^{(1)}) \quad (7)$$

where Λ_1 is $K_1 \times K_1$ -dimensional matrix. Eigenvalues $\lambda_i, 1 \leq i \leq K_1$ are their diagonal elements. $\hat{\mathbf{y}}_t = \mathbf{P}_P \mathbf{t}_t^{(1)}$ is the reconstruction of the test vector \mathbf{y}_t .

For the second layer, $T^{2(2)}$ and $Q^{(2)}$ monitoring statistics can be obtained as

$$T^{2(2)} = \mathbf{t}_t^{(2)T} \Lambda_2^{-1} \mathbf{t}_t^{(2)}$$

$$Q^{(2)} = \|\boldsymbol{\Phi}(\mathbf{y}_t) - \hat{\boldsymbol{\Phi}}(\mathbf{y}_t)\|^2 = \sum_{i=1}^{\bar{N}^2} \mathbf{t}_t^{(2)}{}^2 - \sum_{i=1}^{K_2} \mathbf{t}_t^{(2)}{}^2 \quad (8)$$

where Λ_2 is $K_2 \times K_2$ -dimensional matrix. Eigenvalues $\lambda_i, 1 \leq i \leq K_2$ are their diagonal elements. $\hat{\boldsymbol{\Phi}}(\mathbf{y}_t)$ is the reconstruction of the test vector $\boldsymbol{\Phi}(\mathbf{y}_t)$.

2.2. Improved DeDPCA

The purpose of extending the time series matrix to the original matrix is to eliminate the autocorrelation of variables. If the autocorrelation of a variable is low, not only little information can be included, but also it will increase the unnecessary calculation complexity. Therefore, the improved DeDPCA algorithm analyzes the autocorrelation α to set an appropriate lag k for each variable. We denote a strong autocorrelation standard α_{\min} . α_{\min} was set to 0.5 empirically. Taking variable x_1 for example, if $\alpha(n) > \alpha_{\min}$ when $k = n$, and $\alpha(n+1) < \alpha_{\min}$ when $k = n+1$, $[x_{1,t-1}, x_{1,t-2} \dots x_{1,t-n}]$ will be added into expansion matrix at time t , where $n \leq k_{\max}$, k_{\max} is the maximum time lag calculated above. In this way, variables with strong autocorrelation are retained and variables with weak autocorrelation are eliminated, which can effectively retain the time series characteristics of data, but also simplify the data set and reduce unnecessary calculations.

2.3. Control limit calculation

Kernel density estimation(KDE)^[6] is an effective method for estimating probably density function(PDF), especially for univariate random processes. Therefore, it is very suitable for univariate T^2 and Q index estimation.

The probability density function $\hat{p}(x)$ at point x estimated according to the kernel function $K(\cdot)$ is defined as follows

$$\hat{p}(x) = \frac{1}{Mh} \sum_{k=1}^M K\left(\frac{x - x_k}{h}\right) \quad (9)$$

Where x_k , $k=1,2,\dots,M$ is the sample of x , and h is the bandwidth.

Through the probability density function, the control limits T_{lim}^2 and Q_{lim} under a given confidence interval α can be obtained.

2.4. Fault information fusion

For DeDPCA-based online sample monitoring, each layer provides two monitoring statistics $T^{2(l)}$ and $Q^{(l)}$, where $l = 1,2$. In order to integrate the monitoring statistics of all feature layers, a fusion strategy based on Bayesian inference is proposed to conduct the overall decision.

Taking T^2 metric for example, we express the failure probability of sample \mathbf{x}_t under the fault condition C_f as $P_{T^2}^{(l)}(\mathbf{x}_t|C_f)$, under the normal condition C_n as $P_{T^2}^{(l)}(\mathbf{x}_t|C_n)$

$$P_{T^2}^{(l)}(\mathbf{x}_t|C_f) = \exp(-\gamma T_{\text{lim}}^{2(l)}/T^{2(l)}) \quad (10)$$

$$P_{T^2}^{(l)}(\mathbf{x}_t|C_n) = \exp(-\gamma T^{2(l)}/T_{\text{lim}}^{2(l)}) \quad (11)$$

where γ is a parameter and was set to 0.2 empirically.

According to Bayesian inference, monitoring statistics $T^{2(l)}$ can be transformed to posterior probability $P_{T^2}^{(l)}(C_f|\mathbf{x}_t)$ by

$$P_{T^2}^{(l)}(C_f|\mathbf{x}_t) = \frac{P_{T^2}^{(l)}(\mathbf{x}_t|C_f)P_{T^2}^{(l)}(C_f)}{P_{T^2}^{(l)}(\mathbf{x}_t)}, \quad 1 \leq l \leq 2 \quad (12)$$

where $P_{T^2}^{(l)}(C_f)$ is prior failure probability equal to significance level δ . $P_{T^2}^{(l)}(\mathbf{x}_t)$ is the occurrence probability of sample \mathbf{x}_t

$$P_{T^2}^{(l)}(\mathbf{x}_t) = P_{T^2}^{(l)}(\mathbf{x}_t|C_f)P_{T^2}^{(l)}(C_f) + P_{T^2}^{(l)}(\mathbf{x}_t|C_n)P_{T^2}^{(l)}(C_n) \quad (13)$$

where $P_{T^2}^{(l)}(C_n)$ is prior normal probability equal to confidence level $1 - \delta$.

By weighting the posterior failure probability of each layer, an overall monitoring statistic data PT^2 is constructed

$$PT^2 = \frac{\sum_{l=1}^L \omega_{T^2}^{(l)} P_{T^2}^{(l)}(C_f|\mathbf{x}_t)}{\sum_{l=1}^L \omega_{T^2}^{(l)}} = \sum_{l=1}^2 \bar{\omega}_{T^2}^{(l)} P_{T^2}^{(l)}(C_f|\mathbf{x}_t) \quad (14)$$

where $\omega_{T^2}^{(l)}$ and $\omega_Q^{(l)}$ are weighting factor, $\bar{\omega}_{T^2}^{(l)} = \omega_{T^2}^{(l)}/\sum_{l=1}^2 \omega_{T^2}^{(l)}$.

PQ can be obtained by the same way. The process is in normal condition if $PT^2 \leq PT_{\text{lim}}^2$ and $PQ \leq PQ_{\text{lim}}$, otherwise a fault is detected. PT_{lim}^2 and PQ_{lim} was set to δ .

3. Case study

The TE process^{[7],[8]}, detailed by Downs and Vogel, has been a benchmark process for evaluating the process monitoring and fault diagnosis methods. For process monitoring

modelling, we select 52 monitored variables and 21 typical faults. The corresponding simulation data can be downloaded from <http://web.mit.edu/braatzgroup/links.html>. The normal operation dataset includes 500 samples. Each fault data set involves 960 samples and the faults are introduced after the 160th sample.

For the DePCA, and DeDPCA, the Gaussian kernel function is used with a kernel width of $\sigma = 50N$ found empirically. The number of the retained linear and nonlinear PCs is determined by the average method, which keep PCs greater than the average variance. The control limits of the monitoring statistics are computed by the KDE method, and the 95% confidence limits are computed for each statistic. Bayesian inference is used to integrate the monitoring statistics of each feature layer to generate an overall decision. Three performance indices are used to evaluate the monitoring results, which are the fault detection rate (FDR), the fault detection time (FDT) and the false alarming rate (FAR).

The detection results of the DePCA and DeDPCA are demonstrated in Table I. The average FDR of DeDPCA method is higher than DePCA for about 2.35%, indicating that DeDPCA is more likely to detect faults. The average FDT of DeDPCA method is earlier than DePCA for about 7 samples, indicating that DeDPCA can discover the fault more sensitive than DePCA. The average FARs of two methods are both low. Through the comparison of the three detection performance indices, the superiority of the proposed DeDPCA method can be clearly seen.

Table I. Average FDRs(%), FDTs(sample) and FARs(%) of the 21 TE process faults obtained by DePCA and DeDPCA methods

Method	Average FDR	Average FDT	Average FAR
DePCA	81.57	17	3.21
DeDPCA	83.92	10	3.52

In order to determine which layer to extract dynamic feature could have better monitoring performance, two models with different structure have been tested. One model extracting the dynamic feature at first linear layer is called DeDPCA-1, another extracting the dynamic feature at second nonlinear layer is called DeDPCA-2. The detection results are listed in Table II. Obviously, DeDPCA-1 gets higher FDR and lower FAR, denoting that extracting the dynamic feature at first linear layer is more suitable. Extracting the dynamic feature at second layer may loss some dynamic information at the first linear feature extracting process.

Table II. Average FDRs(%), FDTs(sample) and FARs(%) of the 21 TE process faults obtained by DeDPCA-1 and DeDPCA-2 methods

Method	Average FDR	Average FDT	Average FAR
DeDPCA-1	83.92	10	3.52
DeDPCA-2	79.47	6	14.01

Although extending the time series matrix could improve the monitoring performance in TE process, it also increases the computational complexity. Thus improved DeDPCA method was proposed to reduce the computational complexity and keep effective monitoring performance at the same time. Table III shows the detection results of improved DeDPCA. Online monitoring programs of each method was runned 5 times for

average, configured with Intel Core i5-6200U CPU(2.4 GHz) and 8G RAM memory. It shows that the average time to compute one sample of improved DeDPCA reduced by 34% compared to the former. The average FDRs, FDTs and FARs are about the same.

Table III. Average FDRs(%), FDTs(sample), FARs(%) and C-time(s) of the 21 TE process faults obtained by DeDPCA and improved DeDPCA methods

Method	Average FDR	Average FDT	Average FAR	Average C-time per sample
DeDPCA	83.92	10	3.52	1.3×10^{-2}
Improved DeDPCA	81.55	7	3.25	8.6×10^{-3}

4. Conclusions

This paper takes the Tennessee-Eastman process as the test object to improve the DePCA method based on deep learning. Aiming at the problem that it does not consider the autocorrelation of process variables, a dynamic process is added to construct a DeDPCA model and is optimized. The simulation results show that DeDPCA is conducive to early detection of faults. Besides, extracting the dynamic feature at first linear layer can get best detection results. Finally, improved DeDPCA reduces the computational complexity and meanwhile keeps excellent monitoring performance.

There are still many issues worth discussing and improving. The current deep model only includes one linear layer and one non-linear layer. Whether it is necessary to extend several layers to increase the depth of potential data feature mining is a question. Besides, how to calculate the contribution of variables in the deep model to monitoring statistics requires further investigating.

Abstract

In this paper, we present digitalization, control and optimization for entire cement plants based on model predictive control (MPC) technologies. We provide an overview of the employed MPC technologies and report statistics from several industrial implementations. This demonstrates that MPC technology can simultaneously increase the production by 5-10%, reduce the fuel consumption for the cement kiln by 2-4%, reduce the power consumption by 3-8%, and significantly improve the consistency and uniformity of the final cement powder. The cement production industry contributes approximately 8% of the global CO₂ emissions. We outline oxy fuel combustion and carbon capture technologies for cement plants operated along with water electrolysis plants and other power-2-X facilities. These technologies can decarbonize the cement production completely and rely on MPC technologies for their coordinated and optimized operation.

Keywords: Model Predictive Control, Cement plants, CO₂ capture, Power-2-X

1. Introduction

World cement production has increased around 20% in the past decade and reached a high of 4100 million tonnes in 2019. The electrical energy consumed in the cement production is approximately 110 kWh/tonne. 30% of the electrical energy is used for raw material crushing and grinding while around 40% of this energy is consumed for grinding clinker to cement powder. Hence, global cement production uses 18.7 TWh which is approximately 2% of the world's primary energy consumption and 5% of the total industrial energy consumption. Furthermore, manufacturing of cement emits 3 Gton CO₂, which is 45% of industrial's CO₂ emission. (IEA, 2020). Figure 1 describes the cement manufacturing process. It consists of blending, raw meal grinding, pre-calcining, clinker burning and cement grinding. In the crusher, mixing bed, and raw mill, limestone and other materials containing calcium, silicon, aluminums, and iron oxides are crushed, blended, and milled into a raw meal of a certain chemical composition and size distribution. This raw meal is blended and heated in the pre-heating system (cyclones) to start the dissociation of calcium carbonate into calcium oxide. In the kiln, the material is heated, kept at a temperature of 1200-1450°C, and reacts to form calcium silicates and calcium aluminates. The reaction products leave the kiln as a nodular material called clinker. The clinker is cooled in the clinker coolers before being stored in the clinker silos. The clinker is ground with gypsum and other materials such as fly ash in a cement mill to form Portland cement. In this paper, we present two cement related industrial MPC applications. A cement raw-mix blending application and a cement mill grinding MPC application. In applications, we apply a linear model predictive control (LMPC) algorithm with soft constraints. The proposed LMPC in both applications is able to optimally control the system operation, reduce power consumption, and improve production.

Figure 1. Cement manufacturing process

Carbon capture, storage, and utilization (CCUS) technologies can reduce CO₂ emissions of cement plants significantly. Voldsund et al. evaluated and compared several CO₂ capture technologies, e.g., oxyfuel combustion, chilled ammonia process, membrane-assisted CO₂ liquefaction and calcium looping. Oxyfuel combustion provides the best energy performance and may significantly reduce CO₂ emissions of cement kilns (Voldsund et al. 2019). Power-2-X refers to a series of technologies which can turn electricity into hydrogen and liquid fuels. We apply Power-2-X facilities to convert captured CO₂ into added-value products by using renewable energies. The combination of CCUS and power-2-X technologies provides possibilities for reaching zero-emission cement plants and has the potential to be implemented in the cement manufacturing process of the future.

2. Cement related Industrial MPC Applications

2.1. Cement Raw-Mix Blending MPC Application

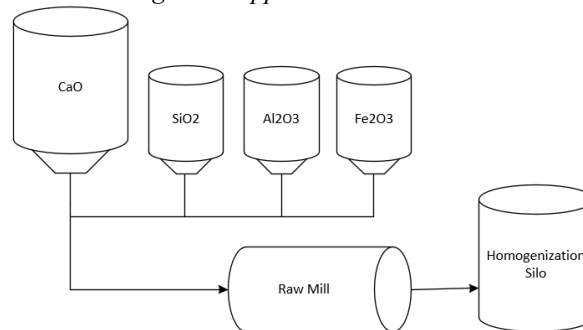

Figure 2. The cement raw-mix blending process.

Figure 2 describes the cement raw-mix blending process. The quarried materials such as limestone, clay, sand, and iron are crushed and sorted into piles in the mixing bed. The chemical compositions of sorted piles are assumed known and described in terms of the oxides CaO, SiO₂, Al₂O₃ and Fe₂O₃. These piles are transported to a raw mill by a conveyor with a certain mixture proportion. In the raw mill, the raw material mixtures are blended and ground to the raw mill with a certain size. The output raw mill then is transported and stored in the homogenization silos. The cement raw-mix blending process is important since it will affect the quality of the clinker and the quality of the final product.

Two coupled input-output models describe the blending process

$$Z_1(s) = G_1(s) \sum_{m \in M} P_m U_m(s) + H_1(s) W_1(s), \quad (1a)$$

$$Z_2(s) = G_2(s) Z_1(s) + H_2(s) W_2(s). \quad (1b)$$

Z_1 are the compositions of the mixture measured before the raw mill process and Z_2 is the compositions measured in the raw meal. $G_1(s)$, $G_2(s)$ are deterministic models and $H_1(s)$, $H_2(s)$ are stochastic models. P_m is a constant parameter indicating the compositions of pile m and U_m is the input from the pile m , W_1 and W_2 are stochastic inputs.

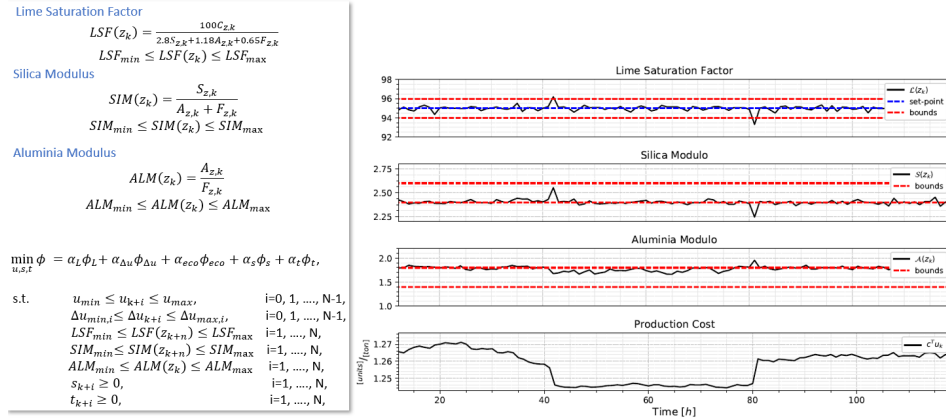

Figure 3. The objective function of the soft constrained LMPC with three compositional parameter constraints and the simulation result.

The raw meal must fulfil a set of quality requirements determined by three nonlinear compositional parameters: lime saturation parameter (LSP), silica modulus (SIM), and alumina modulus (ALM). Figure 3 shows the objective function. The objective function consists of a reference tracking objective ϕ_L , an input rate of movement objective $\phi_{\Delta u}$, an economic objective ϕ_{eco} and two penalty function terms ϕ_s , ϕ_t . For the reference tracking objective, the LSF parameter tracks the given setpoint for the optimal quality. The economic term of the LMPC objective function reduces the system input consumption. To avoid the infeasibility problem caused by hard constraints, we express the compositional parameter boundaries, LSF, ALM, and SIM as soft output constraints.

Figure 3 shows the simulation results obtained by applying the soft constrained LMPC on a cement raw-mix blending model. The soft constrained linear model predictive controller is able to control the raw meal within the compositional parameter bounds. Furthermore, the produced clinker of cement kiln is increased by 3-5% and the energy consumption of the cement raw-mix blending process is reduced by 2-4%. The product quality improvement is up to 30%.

2.2. Cement Mill Grinding MPC Application

Figure 4 describes the cement mill grinding process. Clinker, gypsum, and fly ash are fed to a ball mill by a feed conveyor with a certain proportion. The ball mill has two chambers. In the first chamber, the material is crushed roughly with large steel balls. In the second chamber, the roughly crushed material is finely ground to a fine grey powder. The grey powder then is transported by an elevator to an air separator. In the air separator, particles are suspended by the stream from the bottom and rotated with a specific speed around the

wall. Coarse particles will hit the wall and fall into the recycle pipe. Finally, classified fine particles (cement powder) will be stored in cement silos.

Figure 4. The cement mill grinding process

A MIMO continuous-time input-output model describes the cement mill grinding process

$$Z(s) = G(s)U(s) + G_d(s)(D(s) + W(s)), \quad (2a)$$

$$y(t_k) = z(t_k) + v(t_k). \quad (2b)$$

The system input is $U(s) = [\text{feed rate}; \text{separator speed}]$, $D(s) + W(s)$ are stochastic inputs. $G(s)$ is the deterministic model and $G_d(s)$ is the disturbance model. The measurement output $Y(s) = [\text{elevator load}; \text{fineness}]$ is obtained at discrete time and $v(t_k)$ is the measurement noise. In the grinding process, the unmeasurable variations in material properties will cause significant nonlinearities and uncertainties. These nonlinearities and uncertainties lead to a model mismatch problem. Furthermore, the loading material level of the ball mill can also influence the system operation. Too much loading material will cause a plugging problem and too less loading material will cause energy waste (Prasath et al, 2013).

Figure 5. The principle of MPC with soft output constraints and normal MPC (Prasath et al, 2013).

To solve the described problems, we apply a soft constrained LMPC algorithm. The soft constrained LMPC can indirectly control the loading material level of the ball mill to reach the maximum capacity. The model mismatch problem can be solved by soft output constraints. The purpose of applying soft constraints in the cement mill grinding application is to make the controlled system less sensitive to model uncertainties. Figure 5 describes the principle of normal constrained LMPC and soft constrained LMPC. A dead zone is created by the soft output constraints penalty function (red line). In this dead

zone, the penalty function is not sensitive to the change of error $e = z - r$. The value of the penalty function is extremely small and close to 0 in the dead zone and increase rapidly when the error is out of the dead zone. The range of the dead zone depends on the covariance analysis of the nominal system (Prasath et al. 2010). In this way, the controlled system is more robust to the stochastic noise and model uncertainties.

We test the soft constrained LMPC algorithm on a simulated cement mill grinding circuit. The simulation results imply that the soft constrained LMPC can control and stabilize the cement mill grinding circuit. Furthermore, it improves the quality of the final cement powder. The production is increased by 3-8% and the power consumption is reduced by 3-8%. The standard deviation of the final cement powder fineness is decreased significantly, in the range of 10-20%.

3. CCUS & Power-2-X Technologies

3.1. Oxyfuel Combustion CO₂ Capture

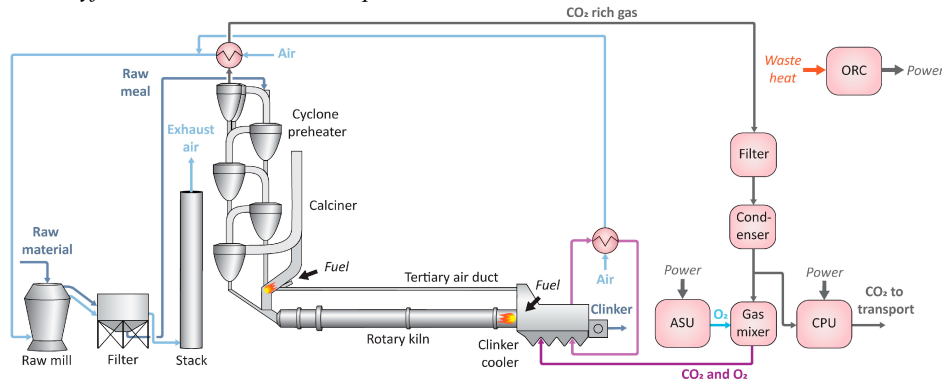

Figure 6. Reference clinker burning line with oxyfuel CO₂ capture.

Figure 6 shows a schematic illustration of a cement kiln with an oxyfuel combustion CO₂ capture system. The oxyfuel combustion process mixes recycled CO₂ and air to produce a CO₂ rich gas. Some of the CO₂ rich gas is purified by a CO₂ processing unit (CPU) and other is mixed with O₂ in a gas mixer. O₂ is produced by an air separation unit (ASU). Both ASU and CPU require power to work and some of the power requirement may be provided by an organic Rankine cycle (ORC). The mixed gas of CO₂ and O₂ is used in the rotary kiln process (Gardarsdottir et al. 2019).

We can apply MPC technology to optimal control the oxyfuel combustion CO₂ capture process. The operation of ASU and CPU requires additional electrical energy and economic MPC can help reduce system energy consumption and improve efficiency. In this way, the combination of the MPC algorithm and CO₂ capture technology can significantly reduce CO₂ emissions and power consumption.

3.2. Power-2-X Advanced Process Control

Figure 7 shows a network diagram that illustrates how Power-2-X facilities interact with CO₂-emitting industry (cement plants). Application of CCUS technologies to capture CO₂ emissions and Power-2-X facilities can convert captured CO₂ into added-value products, e.g. methanol, ammonia, fertilizer, etc. The energy consumption of these facilities is covered by renewable wind and solar energy. Furthermore, integrated electrolytic hydrogen plants can produce H₂ and SNG plants can, fuel and SNG+ by using

renewable energy. These added-value products can be used in other industries, e.g. chemical industries, farms, mobility, power and gas consumers.

Figure 7. Carbon Capture, storage, and utilization (CCUS) & Power-to-X technologies.

Coordination and optimization of such a system presented in Figure 7 require advanced process control system; and MPC technologies are in development and ideal to optimally control and coordinate the facilities in such an integrated system. In this way, we may achieve zero-emission cement plants that only rely on renewable energy.

4. Conclusion

This paper describes two cement related industrial MPC applications and outlines the oxyfuel combustion CO₂ capture process for cement kilns as well as Power-2-X technologies. A soft constrained LMPC algorithm is implemented on a cement raw-mix blending process and a cement mill grinding process. The proposed soft constrained LMPC technology can increase the production by 5-10%, reduce the energy consumption for cement kilns by 2-4%, and improve product quality significantly. For the cement mill grinding process, the production is increased by 3-8% and the power consumption is reduced by 3-8%. The standard deviation of the final cement powder fineness is decreased between 10-20%. The combination of the MPC algorithms, CCUS as well as Power-2-X technologies have the potential to achieve zero-emission cement plants.

Abstract

Pharmaceutical manufacturing plants consist of a wide range of complex unit operations, from upstream processing aimed at synthesis of Active Pharmaceutical Ingredients (APIs) to intermediate purifications and downstream processing for final product formulation. To ensure high pharma plant performance at minimised total cost and solvent waste, operators continuously assess key units, frequently with only input-output data available. First-principles modelling is desirable, yet parameterisation is often arduous and elusive. Statistical techniques, e.g. Latent Variable (LV) methods such as Principal Component Analysis (PCA) are widely used to explore industrial data and discover causality patterns. The present paper uses a PCA model to evaluate multicomponent adsorption of Volatile Organic Compound (VOC) gas emissions from salbutamol synthesis, via industrial FTIR data for mixtures of dichloromethane, chloroform, toluene, methanol and ethanol (IMS). Two industrial case studies are considered to analyse the interplay of these solvents, with strong evidence of preferential toluene adsorption on the activated carbon bed discussed.

Keywords: Principal Component Analysis (PCA), Volatile Organic Compounds (VOC).

1. Introduction

Primary (upstream) pharmaceutical manufacturing is characterized by the consumption of large solvent volumes, key in reactions and separations. Volatile Organic Compounds (VOCs) are prominent but also problematic, as their high volatility at standard conditions has catastrophic effects on human health and environment, with extensive research on mitigation (Constable et al., 2007; Balasubramanian et al., 2012; Perez-Vega et al., 2013). Adsorption is a very effective abatement method, as it exploits the strong potential of porous materials to selectively adsorb VOCs from pharma effluents (Yang et al., 2019). Widely employed to treat high waste stream volumetric flows of low VOC concentrations (Das et al., 2004), it can achieve high process efficiency at relatively low energy demand. Nevertheless, adsorbent material procurement and/or regeneration costs are a challenge.

The present paper describes the development and use of a novel *Latent Variable, LV* (specifically a *Principal Component Analysis, PCA*) model to analyse multicomponent VOC adsorption from pharma effluent mixtures onto an industrial activated carbon bed. This ongoing project has three goals. First, to develop and validate LV (PCA) models. Second, to explore causality and improve process understanding. Third, to improve VOC abatement performance by preventing undesirable (e.g. selective adsorption) phenomena.

2. Salbutamol Manufacturing Process Description

Salbutamol is a proven bronchodilation medication: reliably expanding lung airways to comfort patients with respiratory conditions, it is commonly prescribed against Chronic Obstructive Pulmonary Disease (COPD), bronchitis, emphysema and other ailments. Manufacturing this API requires 4 feedstock compounds (*diacetate*, *glycyl*, *benzyl*, *base*), each produced in the plant as part of the salbutamol batch production schedule (Fig. 1). Prior to this project, the first two (*diacetate* and *glycyl*) subsystems were conclusively identified as the two major VOC sources, thus forming the exclusive focus of our study. The root cause of VOC emissions are the distillation units needed for solvent separation. Mass balance analysis for the majority of VOC emissions has previously indicated that: (1) for *diacetate production*, VOCs come from dichloromethane (DCM) atmospheric and vacuum distillation (occurring in vessel 3/V3), and toluene distillation (in vessel 4/V4). (2) for *glycyl production*, VOCs originate from chloroform and toluene distillation (V3).

Figure 1: Diacetate (top) and glycyl (bottom) production schedules (grey denotes separation steps).

Fig. 2 describes the VOC abatement system: all solvent emissions due to salbutamol production are simultaneously fed to the same treatment (fixed activated carbon bed) unit. Gas effluents from all vessels mainly comprise four solvents: toluene, dichloromethane (DCM), trichloromethane (TCM, chloroform), and Industrial Methylated Spirit (IMS), a mixture of methanol (MeOH) and ethanol (EtOH) which is widely used in pharma plants. Incoming fumes first enter a heat exchanger, which reduces the Relative Humidity (RH) to 50%, as lower water content is known to improve VOC adsorption by the carbon bed. Once treated, the purified gas stream is subsequently discharged into the atmosphere, with the FTIR sensor collecting VOC concentration data within the exhaust stack (Fig. 2/star).

Figure 2: The VOC abatement system (a star denotes the FTIR sensor sampling point of the stack).

3. Principal Component Analysis (PCA) Methodology

Principal Component Analysis (PCA) is an established statistical methodology we use here for VOC adsorption evaluation, to extract process features and elucidate key trends (MacGregor et al., 2005; Rajalahiti & Kvalheim, 2011; Venkatasubramanian et al., 2013). Industrial (GSK) data on VOC emissions production conditions have been compiled from an effluent gas monitoring station for the salbutamol API plant (Montrose, Scotland, UK). The VOC emissions discharged from the API plant exhaust stack (Fig. 2) are continuously monitored via Fourier Transform Infrared Spectroscopy (FTIR), and the key compound concentrations, process conditions (P, T) and vessel numbers, are fed to a nearby station.

For the purpose of this project, two distinct phases and case studies have been considered, corresponding to VOC-critical production stages encompassing distillation separations. The raw FTIR data has been pre-processed and split into a training and a testing dataset. For each dataset, observations have been mean-centred and auto-scaled to reduce bias, and then pre-processed to remove obvious outliers due to sensor shutoffs. The Hotelling T^2 values have been subsequently computed in order to identify other potential outliers.

After essential pre-processing, PCA models are validated and used for two case studies. An important PCA modelling decision is the selection of the number of latent variables (Principal Components, PCs) required, for which we have considered three (3) criteria:

(1) The *first criterion* is the level of variance explained by Principal Components: we have opted for our PCA model to explain a minimum of **80% of the variance** in the data, (2) The *second criterion* is the pair of R^2 and Q^2 : the **coefficient of determination (R^2)** is the proportion of the dependent variable variance that is predictable from independent variables, Eq (1); the **predictive squared correlation coefficient (Q^2)** is the residual variation after applying it to samples held out (the portion of such a sample not explicable by the model), Eq (2). The combination of R^2 and Q^2 metrics helps selecting the number of PCs at the point where R^2 and Q^2 are about equal and as the Q^2 value begins to decline.

$$R^2 = 1 - \frac{\text{Var}(\mathbf{X} - \hat{\mathbf{X}})}{\text{Var}(\mathbf{X})} \quad (1)$$

$$Q^2 = 1 - \frac{\text{Var}(\mathbf{X} - \hat{\mathbf{X}}_{CV})}{\text{Var}(\mathbf{X})} \quad (2)$$

where Var denotes variance of the data sample (R^2) and cross-validation sample (for Q^2). Their calculation is almost identical: the only difference is that R^2 is computed from data used for PCA model training, while Q^2 is computed from held-out (cross-validation) data.

(3) The *third criterion (Root Mean Square Error of Cross-Validation, RMSECV)*, is calculated using Eq. (3). To select the number of PCs, we use the point where RMSECV values increase and then begin to decline, reflecting Q^2 trends from the second criterion.

$$RMSECV = \sqrt{\frac{1}{(IJ)} \sum_{i=1}^I \sum_{j=1}^J (X_{ij}^{(r)})^2} \quad (3)$$

where $X_{ij}^{(r)}$ is the residual of sample i (total: I) and variable j (total: J) after r components.

4. First Case Study: Results and Discussion

The first PCA model addresses the simultaneous operation of toluene distillation in V4 (during the first batch of the diacetate stage), the DCM atmospheric distillation in V3 (during the second batch of diacetate stage) and the chloroform and toluene distillation in V15 during the glycol stage. For ease of reference, this dataset is referred to as the simultaneous operation of V3 and V4, as per the colour-coded process diagram (Fig. 3). The *loadings scatter plot* (left) shows the use of Principal Components (PCs) to explain each variable: here, we note PC2 separates toluene emissions from the rest of the VOCs. The *score plot* (middle) quantifies how PCs explain each observation in a dataset, with data point colours corresponding to time periods in which vessels operate simultaneously. For example, toluene distillation (in V4) and DCM atmospheric distillation (in V3) occur together between 06:00-09:00; data point swarms clearly shift with time (orange arrows). The *biplot* (right) synthesises information from the said two plots, illustrating a combination of all PC scores and loadings which helps us draw quantitative conclusions. A key observation is that the amount of toluene recorded declines with time (data subsets).

Figure 3. Case study 1 schedule (top); loadings scatter plot, score plot and biplot (L to R, bottom).

The contribution plots are valuable in portraying variance captured vs. PCs used (Fig. 4). The first two PCs explain 55.37% but four (4) PCs can explain 80.81% of data variance. The R^2 and Q^2 plots are also key in deciding the number of PC employed: for the case of 4 PCs, we note that both R^2 and Q^2 values are similar and the Q^2 value starts to decline. The RMSECV plot confirms that 4 PCs suffice here, as it mirrors the trend of the Q^2 plot.

Figure 4. Contribution plots, R^2 and Q^2 and RMSECV plots for variable PC number - case study 1.

5. Second Study: Results and Discussion

The second PCA model addresses the simultaneous DCM vacuum distillation (in V3) and chloroform distillation (in V15), which is followed by toluene distillation therein (Fig. 5). The PCA model construction and analysis methodology is identical to the one described and followed in the first case study, but the situation and observations are quite different. The *loadings scatter plot* shows that PC1 separates toluene from other VOC emissions; the latter change considerably as time progresses, from toluene, to ethanol, to chloroform, to DCM and methanol. The biplot corroborates these indications of industrial importance.

Figure 5. Case study 2 schedule (top); loadings scatter plot, score plot and biplot (L to R, bottom).

From the contribution plots (Fig. 6), we see the first 2 PCs explain 60.57% of the data, while the first 4 PCs explain 82.76% of the data, thus being adequate for our PCA model. The R^2 and Q^2 plots, and the RMSECV plot, concur that 4 PCs suffice to explain the data.

Figure 6. Contribution plots, R^2 and Q^2 and RMSECV plots for variable PC number - case study 2.

The PCA analysis plots for both case studies clearly indicate that toluene emissions progressively decline over time, with concurrent increase of others (DCM, MeOH/IMS), despite the existence of toluene in the raw stream fed to the carbon bed at the same time. This observation suggests the *selective adsorption of toluene* onto the carbon bed, a trait that differs from what happens for other VOC compounds coexistent in the VOC mixture. *Adsorption Theory* informs us that vapour thermophysical properties can be used to probe selective absorption, the strongest indicators being high boiling point and high polarity. Toluene has a similar MW to DCM (92.1 to 84.9), but much higher b.p. (111 vs. 39.6 °C). A similar trend holds for toluene vs. TCM/chloroform (MW= 119.4, but b.p.= 61.2 °C).

6. Conclusions

Upstream pharmaceutical manufacturing inevitably relies on significant solvent volumes for many (especially reaction/separation) uses, with great environmental repercussions. Efficiently capturing VOCs from pharmaceutical effluent streams is a strategic priority for advanced manufacturing striving to embrace greener practices via limiting waste, and VOC pollutant adsorption on activated carbon beds is an established industrial practice. The power of LV (PCA) methods (MacGregor et al., 2005; Kourti, 2005) comes to aid. The present paper has validated and used a PCA model to study VOC adsorption onto an activated carbon bed which processes multicomponent effluents of salbutamol synthesis. We have confirmed that toluene clearly behaves differently from all other VOCs emitted, with strong evidence suggesting its selective adsorption; its higher boiling point vs. the other compounds is an indication of strong adsorbate-adsorbent intermolecular forces. Furthermore, Industrial Methylated Spirit (IMS) appears to play a key role in adsorption, as it appears that it has substantial interaction with the carbon bed and is potentially inhibiting the removal of more hazardous VOCs (e.g. DCM, TCM) from the raw feed. Though selective toluene adsorption has already been suspected from empirical evidence, the potentially harmful role of IMS presence is a new key finding of this research study. Ensuring inlet concentration data acquisition is essential for subsequent studies, as it is clearly important to distinguish sources and composition of streams fed to the carbon bed. Further investigation of toluene and IMS effects via data from various batches/locations can elucidate their potential for detrimental bed interactions and preferential adsorption, towards measures (e.g. effluent feed scheduling) ensuring cost-effective performance.

Abstract

Petroleum refineries are complex systems that consist of multiple integrated units. This situation makes it difficult to track down the root cause of abnormal situations that occur during production. It is noted that abnormal situations usually trigger plant-wide oscillations in a number of measured process variables. Therefore, root cause detection is often attempted to be carried out by examining these trends in process data. Observing multiple effects and underlying problems at the same time presents a challenge in determining the root cause by examining trends only. In this study, spectral envelope is used to detect oscillations by identifying the variables and categorizing them based on a statistical hypothesis test which produces Oscillation Contribution Index (OCI) in order to isolate potential root cause variables. Two distinct abnormal events in the hydrocracker unit that occur simultaneously were successfully isolated and the root causes could be assigned by using the spectral envelope analysis.

Keywords: Root-cause analysis, Multi-effects, Plant-wide oscillation, Spectral Envelope

1. Introduction

Plant-wide oscillation is a general term used to express the propagation of an oscillatory effect throughout the entire plant originating at one location in the plant. Plant-wide oscillations may cause deterioration in the quality of the product, energy losses, sudden problems/shut-downs in the plant. Poor tuning in control loops, valve problems such as valve stiction and fouling, interactions between different plants are common root-causes of oscillations.

In the literature, different techniques have been proposed for detecting similar characteristics of the variables and diagnosing root-causes. Duan et al. (2014) provided a review of these detection and diagnostic techniques (Choudhury MAAS, 2011). High-density plot is one of the off-line visualization technique to show spectral plots of related variables. Thornhill et al. (2003) have tried to detect the oscillations that have a common frequency based on the regularity of zero-crossings of the control error signal. Jiang et al. (2007) have proposed a new method called the spectral envelope to cluster

the variables, which have similar spectral behaviors. This paper shows the capability of spectral envelope method for diagnosing two different root-causes based on a real plant data from a refinery in Turkey. One of the major root cause is the temperature effect associated with a stream coming from another plant. The other root cause is related to the fouling of a control valve for a level control loop in a downstream process drum that acts to compensate for the effect of the temperature change of this stream.

2. Detection and Diagnosis with the Spectral Envelope Method

2.1. The Spectral Envelope Method

Finite number of data samples is used in a data matrix of m variables and n samples represented as $X = [x(0), x(1), \dots, x(n-1)] \in R^{m \times n}$. Here, x is a multivariate, vector-valued time series on R^m as in Eq. (1):

$$x = [x_1(t) \ x_2(t) \ \dots \ x_m(t)]^T \quad t = 0, \pm 1, \pm 2, \dots \quad (1)$$

To simplify the calculations and obtain more meaningful results, it is preferable to use the matrix created with the normalized form of each variable (Jiang et al., 2007). The periodogram of the X matrix is calculated for a large sample set based on the fast Fourier transform assumption as:

$$\hat{I}_n(\omega_k) = \frac{1}{n} \left[\sum_{t=0}^{n-1} x(t) \exp(-2\pi i t \omega_k) \right] \left[\sum_{t=0}^{n-1} x(t) \exp(-2\pi i t \omega_k) \right]^* \quad (2)$$

where $\omega_k = k/n$, for $k = 1, 2, \dots, n/2$ are the Fourier frequencies. This approach is not exactly consistent with the power spectral density (PSD). Therefore, a smoothed periodogram estimate by creating the symmetric moving average of $\hat{P}_X(\omega_k)$ can be used:

$$\hat{P}_X(\omega_k) = \sum_{j=-r}^r h_j \hat{I}_n(\omega_{k+j}) \quad (3)$$

where h_j are symmetric weights ($h_j = h_{-j}$) and $\sum_{j=-r}^r h_j = 1$. The calculated periodogram will be smoother with higher r value. In the refinery case study, h_j is assumed as: $h_j = \frac{(r-|j|+1)}{(r+1)^2}$, with $|j| = 1, 2, \dots, r$ where $r = 2$. Once the moving

average of a periodogram is calculated using Eq. (3), we have $v_n = \left(\sum_{j=-r}^r h_j^2 \right)^{1/2}$. The

eigenvalues of $\hat{P}_X(\omega)$ in the decreasing order and the corresponding eigenvectors are represented as $\{\lambda_1(\omega), \lambda_2(\omega), \dots, \lambda_m(\omega)\}$ and $\{\beta_1(\omega), \beta_2(\omega), \dots, \beta_m(\omega)\}$, respectively.

When the maximum value of the eigenvalues $\{\lambda_1(\omega), \lambda_2(\omega), \dots, \lambda_m(\omega)\}$, say $\lambda(\omega)$, is plotted against the frequency $\omega = 1, 2, \dots, n/2$ and if a peak appears at any frequency, it implies that a plant-wide oscillation may be possible at that frequency. For further detection of oscillating variables, the asymptotic covariance matrix of the optimal scaling vector $\hat{\beta}(\omega)$, $V_{\beta}(\omega)$ is estimated according to the calculated eigenvectors and eigenvalues:

$$V_{\beta}(\omega) = v_n^{-2} \lambda_1(\omega) \sum_{l=2}^m \lambda_l(\omega) [\lambda_1(\omega) - \lambda_l(\omega)]^{-2} \beta_l(\omega) \beta_l^*(\omega) \quad (4)$$

The following distribution

$$\frac{2|\hat{\beta}_{1,j}(\omega) - \beta_{1,j}(\omega)|^2}{\sigma_j(\omega)} \quad (5)$$

is a chi-square distribution with 2 degrees of freedom, where $\hat{\beta}_{1,j}(\omega)$, $j = 1, 2, \dots, m$, j^{th} element of $\hat{\beta}_1(\omega)$, and $\sigma_j(\omega)$, j^{th} diagonal element of the estimate of $V_{\beta}(\omega)$. For the null hypothesis ‘ $\beta_{1,j}(\omega) = 0$ ’, the test statistics will be $\frac{2|\hat{\beta}_{1,j}(\omega)|^2}{\sigma_j(\omega)}$ and the critical value is set to $\chi_{2,\alpha}^2$ which is the upper $\alpha\%$ of the $\chi_{2,\alpha}^2$ distribution with 2 degrees of freedom. If the test statistic exceeds the critical value, the null hypothesis is rejected and hence it is concluded that the time series has an oscillation at that frequency for the j^{th} variable (David et al., 2000).

2.2. Root Cause Diagnosis via the Spectral Envelope Method

The root-cause determination of unit-wide oscillations and the isolation of the root cause are challenging tasks. To isolate key variables after applying the chi-square test, Jiang et al. (2007) proposed a new index called as the Oscillation Contribution Index (OCI):

$$OCI_j(\omega) = \frac{\hat{\beta}_{1,j}(\omega)}{2\sigma_{\beta}(\omega)} \quad (6)$$

where $\sigma_{\beta}(\omega)$ is the standard deviation of the optimal scalings of variables which have oscillations based on the chi-square test. This index shows the contribution of variables to the oscillation at that frequency. The criterion for the most contribution to the oscillation is $OCI(\omega) > 1$ at frequency ω .

3. Refinery Case Study

3.1. Process Description

The Steam-Methane Reforming Unit, which is known as the Hydrogen Generation Unit, is a common process due to the increasing demand on producing environmentally friendly and light-end products by cracking and desulfurization in refineries and other petrochemical industries. In this paper, a process anomaly experienced in a specific part of this unit has been studied.

Since the catalyst of the reforming reactor is very sensitive to sulfur and halogens, the steam-hydrocarbon mixture undergoes a pretreating process before entering the reforming reactor. In the pretreating reactors, sulfur and halogens in the natural gas and naphtha should be converted to H_2S and HF/HCl in order not to deactivate the reforming catalyst. After the pretreatment section, a mixture of CO , CO_2 , CH_4 and H_2 , which is also known as syngas, is obtained and goes to the shift reactor for conversion of CO to CO_2 .

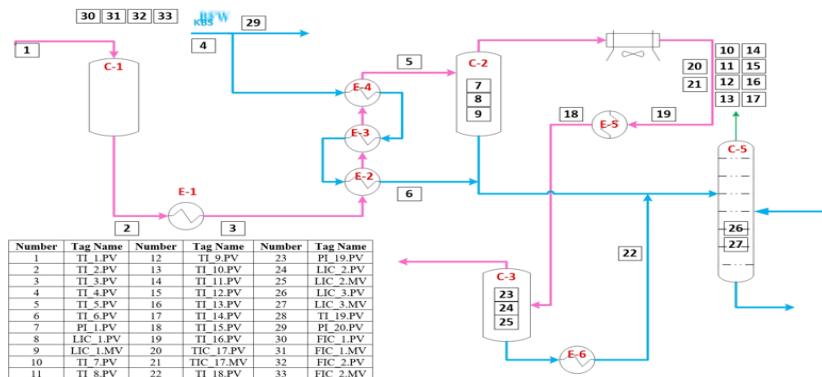

Figure 1. Process Flow Diagram of Part of the Hydrocracker Unit

In Figure 1, the process flow diagram of the section that includes the shift reactors in the unit is shown. The syngas coming out of the shift reactor (C-1 in Figure 1) is cooled first in the heat exchanger E-1 and then on the shell-side of E-2, E-3, E-4 heat exchangers with boiler feed water (BFW) on the other side. The purpose of the cooling of the stream after the reactor is the condensation of the steam and then, to remove the resulting water from the gas stream as liquid in the hot condenser drum (C-2 in Figure 1). Then, the water-gas mixture is separated into gas and water streams in C-2. The gas stream obtained from C-2 is cooled to a lower temperature in the E-5 and E-6 coolers and sent to the cold condenser drum (C-3 in Figure 1) for removing the water in the gas phase. The water stream obtained from C-2 is mixed with the output water stream of C-3 and fed into a stripper column (C-5 in Figure 1).

3.2. Case Study

As mentioned above, BFW is generally fed into the heat exchangers as a cold stream. However, BFW may sometimes be sent as a hot stream into the exchangers depending on the operations of the BFW generation unit. If the BFW stream coming from the unit

is hot, water present in the syngas cannot be condensed to the extent when BFW is charged as a cold stream. As a result, the upstream of C-2 contains much more water as steam and more steam condenses in E-5 and E-6 coolers. Condensed excess water causes an increase in the C-3 drum level and this situation is normally controlled by the valve connected to the level controller in the bottom of the drum. As time passes, however, the presence of water leads to fouling (often as scaling) inside the valve and so, in the case of a level increase, the valve stem opening cannot be effectively controlled, leading to a sticky valve situation. In this study, the simultaneous effect of temperature variation of the BFW stream and valve fouling were investigated.

3.3 Industrial Data Sets

Total of 33 tags from the hydrocracker unit in the Turkish Petroleum Refinery were studied. Four of these tags belong to the control loops and the remaining 29 tags to sensor transmitters. The points where the numbers in the general flow schema given in Figure 1. show the location of tags. The labels of both transmitter and controller information corresponding to the numbers are noted in the table in Figure 1. TI, PI, LIC, TIC and FIC represent temperature indicator, pressure indicator, level controller, temperature controller and flow controller, respectively. In this study, using historical data, the spectral envelope was estimated on a daily basis for the 64 days before the event occurred. The sampling interval was 60 s and so there were a total of 1440 data points in one day. The tags of daily data are placed in a matrix with columns as variables. The data matrix is standardized and then the spectral envelope on a daily basis is calculated using Eq. (2) to (6). Based on the estimated spectral envelope and determined oscillation frequencies, a statistical hypothesis test is performed to determine if the variables oscillate with these frequencies. Then, the OCI index is used to isolate key variables that cause (or associated with) the problem.

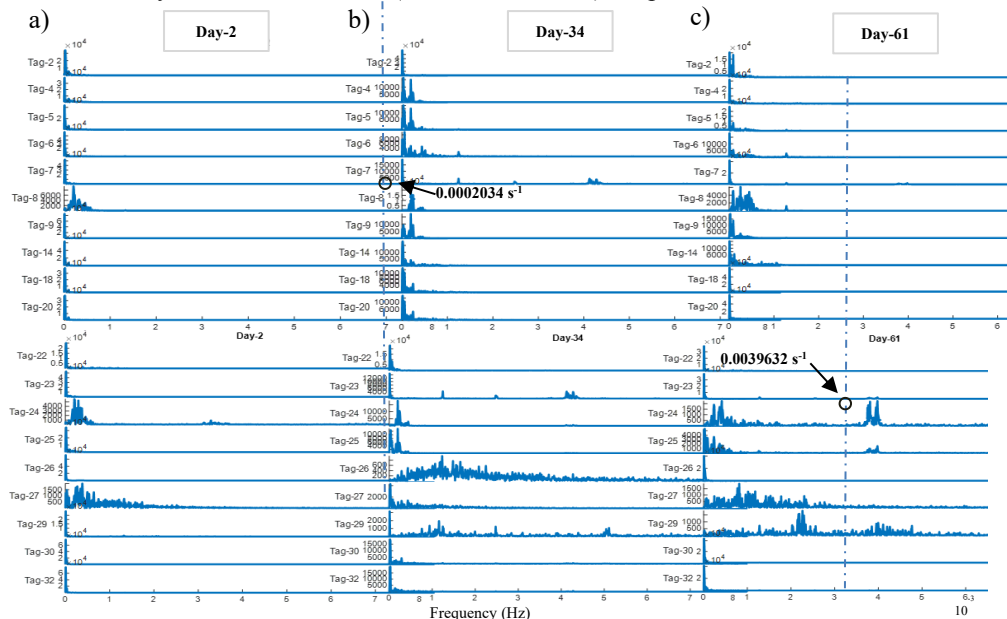

Figure 2. Power Spectrum Analysis for (a) 2nd, (b) 34th, (c) 61st days of operation

4. Results and Discussion

With the spectral envelope analysis performed for 64 days, the OCI index values show that about 20 variables could be root-cause variables contributing to the oscillation(s). Therefore, the rest of the article will examine these 20 variables known to have an effect, which are indicated on the y-axis in Figure-2. The common frequencies of the oscillations are determined by the spectral envelope and the results are verified by estimation of Power Spectra. Power spectra on the 2nd(without any problems), 34th(BFW temperature switch), 61st(with valve stiction) days are given as samples in Figure 2a, b and c, respectively.

It is expected that the effect of temperature change can be observed on days when the temperature of the BFW stream changes. If there is no temperature effect, the normal oscillation period of the level control loops will be observable. In Figure 2a, the effect of the level itself over oscillation is seen at Tag-8, Tag-24 and Tag-27. Temperature of BFW was supplied as slightly cooler to the plant on the 34th day. Therefore, the oscillations observed in all tags (Tag-4, 5, 8, 9, 14, 18, 20, 24, 25) could be attributed to the BFW temperature shift with a frequency of 0.0002034 s^{-1} as detected in Figure 2b. On the 64th day, the valve fouling reached a critical level and caused a shut-down in the unit. The fouling effect of the valve is also seen in the power spectrum of the data set from a few days before the event, i.e., 61 days, given in Figure 2c. Process and manipulated variables of the level controller (Tag-24 and Tag-25), on the C-3 drum are dominantly oscillating with a frequency of 0.0039632 s^{-1} . Power spectrum results are validated with spectral envelope as in Figure 3 and two distinct effects can be easily isolated. Variables contributing to the specified frequencies as OCI>1 were also noted on the below graph.

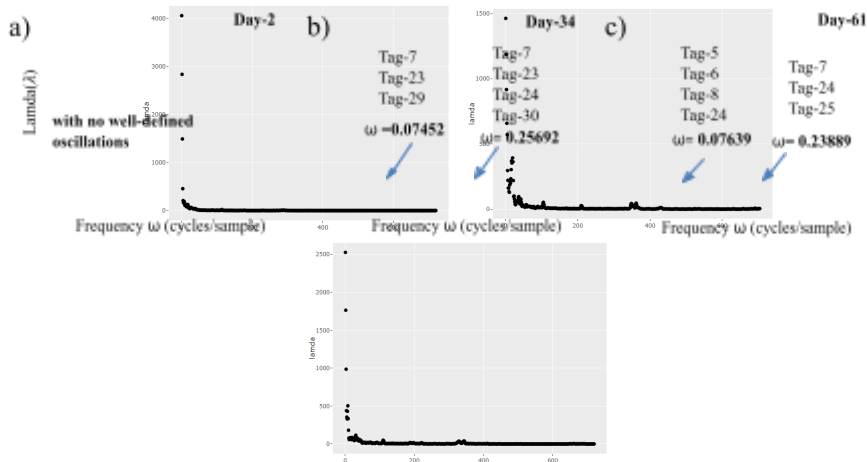

Figure 3. Spectral envelope of the 33 variables

In the early days, there was no frequency for valve contamination (as in Figure 2a). A new frequency (0.25692 s^{-1} or 0.23889 s^{-1}) with OCI>1 for both Tag-24 and Tag-25

appear over time (as in Figure 2b, 2c) and maintained its continuity close to the unit shut-down.

5. Conclusion

In this study, the simultaneous events affecting a process unit and how these effects can be isolated using a post-mortem analysis are studied. With the increasing fouling of the valve the unit has been experiencing a gradual build-up a failure mode. According to the results of spectral envelope method, the impact of the fouling can be detected up to a few days in advance without causing any serious problems in the unit, while also identifying a shift in the BFW stream temperature occurring during the same period.

Abstract

The proceeding digitalisation of industrial facilities does not only provide meeting the requirements of flexibility and just-in-time production. It comes with increasing vulnerability against cyberattacks. This already manifests in high numbers of cyberattacks against industry 4.0 facilities (KasperskyLab, 2020). In these cyber-physical-systems, cyberattacks do not only affect the informational system, they can also cause damage in the physical part that is closely coupled to the informational part. Therefore, new methods for securing industry 4.0 facilities against cyberattacks are required. The method introduced in this paper continuously checks if the measurements and setpoints fulfil the systems physical relations utilizing data reconciliation and extends it by consideration of informational properties for detecting, localizing and selectively combatting cyberattacks.

Conventional protection methods like the comparison of each measurement with a specific range of safe service cover only basic sensor failures and trivial cyberattacks. A more sophisticated protection method, which analyses the consistence of the static system state with respect to a static system model of the process was introduced in (Reibelt et al. 2020) using static data reconciliation. The new method presented here is also applicable in dynamic system states. This paper shows the adaptation of the data reconciliation based approach for dynamic system relations and demonstrates its application.

Keywords: cyber-security, data reconciliation, industry 4.0, cyber-physical systems, dynamic states

1. Introduction

Cyberattacks targeting on physical damage are usually based on false data injection. Values of measurements (or actuator setpoints) are exchanged by different values. The manipulated values pretend a system state that is different from the actual one. For causing physical damage, the manipulated system variables can pretend to require setpoint values different from the ones the actual system state requires. This can cause control actions running the system into a critical state or prevent mandatory control interventions. Manipulated actuator setpoints can directly cause critical system states. Attacks can also aim at production losses, either by disturbance of product quality or by extending down times.

Many of these manipulations can be realized in a manner they are not detected by common protection systems on comparing values to ranges of safe service. As data reconciliation uses a more detailed description of the system, taking into account the

relations between variables, it is able to detect and localize false data injection in many more cases.

The manipulation can be implemented e.g. by modifying the measurement itself, by modifying the preprocessing of values in smart sensors, by modifying the communication interface, messages, or communication connections or by manipulating the values in the process control system. This variety of possible attack vectors as well as the existence of unknown ones cannot be satisfactorily faced with attacker models. For our detection method, prior knowledge that is more general is used to improve the detection, such as exposition to networks or informational commonalities effecting the vulnerability towards cyberattacks. This also prefers anomalies caused by manipulations against sensor failures that are also detected by the anomaly detection.

This paper will give a brief summary to gross error detection based on data reconciliation and our extension for the detection of cyberattacks in section 2. In section 3, the modelling of dynamic system relations and the adaptation for data reconciliation is described. Section 4 shows the evaluation of the detection performance. Therefore, a simulated example system with manipulations is used to generate receiver operating characteristic curves (ROC-Curves).

2. Extended Data Reconciliation Gross Error Detection

For the evaluation of system variable values, the physical relations, restrictions and conservation laws are described by mathematical equations. With the vector y containing all observed system variables, the equations are converted to one common system equation

$$\mathbf{A} \cdot y = 0 \quad (1)$$

Statistical errors of the variables as well as manipulations cause deviations from this equation that manifest in equation residuals $r = \mathbf{A} \cdot y$. Data reconciliation allows for calculating optimized variables \hat{y} that are the closest values to the noisy system values y , fulfilling the system equation (1). The gross error detection methods used in this paper, are based on the evaluation of the residuals r or on the measurement deviations $(y - \hat{y})$.

- For the *measurement test* the measurement deviation of every system variable is considered. The test statistics is calculated by weighting the deviation with the corresponding variance \mathbf{V}_y : $d = \mathbf{V}_y^{-1} \cdot (y - \hat{y})$ (Tahamhane, 2010)
- The *global test* evaluates, if the sum of the residuals $r = \mathbf{A} \cdot y$ is compatible to a system without manipulations, with respect to the variance in the residual space: $\gamma = r^T \cdot \mathbf{V}_r^{-1} \cdot r$. For localizing manipulations, the variables are removed one by one and the test is repeated. (Madron, 1985)
- For the *hypotheses test*, reference residuals f for norm manipulations are calculated. They form the column vectors of a matrix \mathbf{F} . These reference residuals are compared to actual residuals f by calculating the test statistics: $T = (\mathbf{F}^T \cdot \mathbf{V}_r^{-1} \cdot \mathbf{F})^{-1} \cdot (\mathbf{F}^T \cdot \mathbf{V}_r^{-1} \cdot r)^2$. (Narasimhan et al., 1987)

In all three test methods a threshold is applied to decide whether current residuals/deviations can be explained by measurement noise or indicate a cyberattack.

In order to facilitate the detection of manipulations of combinations (subsets) X_i of variables Y with common properties P_i : $X_i = \{Y|P_i\}$ (such as common subnet or operation system of the sensors, having a common type of vulnerability towards cyberattacks) in this paper an adaption of the threshold is proposed. Therefore, the general threshold is multiplied by an adaptation factor $(1 - S_{MT/HT} \cdot I_i)$ for measurement/

There are publications using an optimization method they call dynamic data reconciliation (e.g. Bai et al. 2006), but they use a tuning factor for adapting the predicted values $x(k+1)$ to the measured values similar to the Kalman-Filter. This adaption hides manipulations that do not show fast changes, therefore it is not usable for manipulation detection.

4. Evaluation

The dynamic system example was constructed on the standard example of data reconciliation shown in Figure 1 (Narasimhan et al., 2000). Between the measurement/actuator points dampings with time constants of $T_2 = 2$ s, $T_3 = 3$ s, $T_4 = 4$ s, $T_5 = 5$ s, $T_6 = 6$ s are introduced. As varying input signal a sine function of amplitude 1 and period time of 2π s was used. The total time considered is 10 s.

Figure 1: Standard example, cooling circuit with six connected devices, matrices for continuous dynamic system model.

From these matrices describing the dynamic system in time-continuous form, the time-discrete form is calculated for sample time 1 s (zero order hold) and finally the matrix \mathcal{A} is determined.

The variables are not coupled with the same strength, so an additional normalization of the test statistics is necessary. Therefore, for a normalized manipulation of all variables and combinations, the test statistics of the variables or combinations manipulated indeed are calculated without statistical errors. For demonstration in Table 1 the test statistics for manipulations in single variables are shown for a manipulation height of 1 and 2 for measurement test and hypotheses test. For the global test all test statistics would be 0, since the manipulated variable is directly eliminated for calculating the test statistics.

Table 1: Test statistics of single variable in case of manipulation of the respective variable. Manipulation amplitudes are 1 and 2.

Var	Measurement Test		Global Test		Hypotheses Test	
	manip 1	manip 2	manip 1	manip 2	manip 1	manip 2
1	0.9792	1.9584	0	0	0.0641	0.2566
2	0.7228	1.4456	0	0	0.3028	1.2115
3	0.5025	1.0050	0	0	0.1069	0.4276
4	0.4145	0.8290	0	0	0.0567	0.2267
5	0.3205	0.6410	0	0	0.0392	0.1569
6	0.1265	0.2531	0	0	0.0156	0.0626

In the case of linear systems for hypotheses test, the test statics for manipulations with amplitude of 2 are always 4 times the value of the ones for manipulations with amplitude of 1. For measurement test they are only double the value. These relations are the same for all combinations as well. Therefore, a normalization with the test statistics value of the normalized manipulations does make sense for measurement test and hypotheses test. The relations also allow for determining the threshold adaptations S for measurement test and hypotheses test. If e.g. an unexpected manipulation should be detected at double the

amplitude of an expected one, the adapted threshold can be half the general threshold for measurement test ($\Rightarrow S_{MT} = 0.5$), a quarter of the threshold for hypotheses test ($\Rightarrow S_{HT} = 0.75$). For global test, this kind of determining the threshold adaption is not feasible, as without statistical errors, the test statistics values always become zero (test statistics for GT in Table 1). For the evaluation example the threshold was chosen to be raised by up to three quarters ($\Rightarrow S_{GT} = 0.75$).

For evaluation of the new detection method, the statistic errors are simulated with a variance of 1. More than 23,000 manipulations are simulated with amplitudes of ± 3 . The combinations of variables X_i with common properties (common type of vulnerability towards cyberattacks, i.e. expected manipulations) are listed in Table 2.

Table 2: Example for prior knowledge, used for evaluation.

Property P_i	Factor I_i	Variables $X_i = \{Y P_i\}$
e.g. online configurable	1	1
e.g. value transmitted online	1	3
e.g. non-decrypted Wifi communication	1	6
e.g. common operating system	1	1, 5
e.g. shared hardware	1	4, 6
e.g. common firmware producer	1	2, 3
e.g. common communication protocol	1	1, 2, 3
e.g. common network layer with high exposition	1	3, 4, 5
e.g. common software producer	1	2, 4, 6
...	1	3, 5, 6

For creating comprehensible results, the vulnerability factor is set to maximum ($I_i = 1$) for each property P_i . When testing for expected manipulations X_i , the adapted threshold is considered, otherwise the general threshold is used.

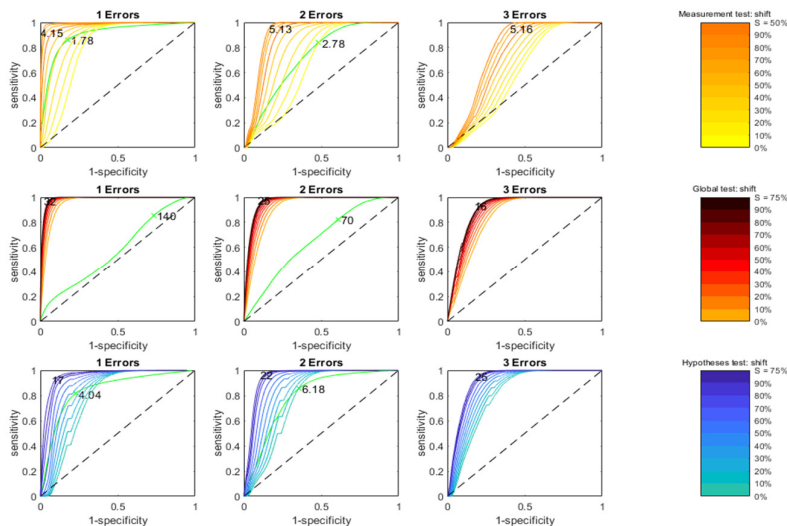

Figure 2: ROC-Curves for the three tests for different numbers of manipulated variables and different threshold adaptations.

Based on all simulated manipulations, for determining the ability of the tests and the optimal general thresholds, ROC-curves (Fawcett, 2005) are generated. ROC-curves are determined by plotting the true positive rate (sensitivity) against the false positive rate (1-

specificity) for different general thresholds (Figure 2). For optimal selectivity, the general threshold referring to the point with the highest distance to the diagonal is selected. This threshold is labelled in the plots. For all detection methods, the ROC-curves are determined for manipulations of single variables (1 Error), for conjoint manipulation of two variables (2 Errors) and for conjoint manipulation of three variables (3 Errors). To show the effect of the threshold adaption, the ROC-curves are calculated for different threshold adaptations S . The brightest coloured curve is the ROC-curve without threshold adaption ($S = 0$), and the darkest coloured curve the one for the adaption values given above. The green coloured curves refer to the test for selecting higher order combinations as candidates for the actual manipulated variables. For measurement test (yellow) and hypotheses test (blue) the threshold is used to check if single variables or certain combinations of variables are a subset of the actual manipulated variables. The area between the ROC-curves and the diagonal (random guesses) is a measure for the performance of the test. Already when using the general thresholds (adaption $S = 0$), the tests performs much better than random guesses. By introducing prior knowledge of commonalities, using adaptations $S > 0$, all three test methods show a high performance, as the majority of the area in the left upper half is below the ROC-curves.

5. Conclusion

In this paper, the adaption for dynamic systems of our new model-based detection method for cyberattacks is introduced. It is shown to come with a high performance in detection using classical data reconciliation extended by prior knowledge regarding informational properties of the system variables. The dynamic model based detection enables the application for industry 4.0 facilities during non-static system states, which are currently rarely covered by security measures. Our method is scalable, following the real system size, as most calculations can be prepared prior to its application. As the hypotheses test and the global test both evaluate resulting residuals, they can easily be adopted for any kind of system, including nonlinear systems. In case of the measurement test, an analytical reconciliation would be required. The method enables the selection of targeted countermeasures for reducing the risk of damages and losses.

Abstract

Post Combustion CO₂ Capture process (PCC) is a popular technology for regulating CO₂ emissions from Coal-based power generation plants. The process uses Mono Ethanol Amine (MEA) solvent to absorb CO₂ from Flue gas. The CO₂ rich solvent is regenerated in a stripping tower with kettle reboiler using process steam as heating media. The lean MEA solution is recirculated back to absorption column, and the recovered CO₂ is taken for further processing depending on the nature of demand.

The PCC unit control set-up has challenges in coping up with process upsets caused by variations in power demand resulting in lower operating rate for the power plant. The rapid reduction of flue gas flow rate to the absorber leads to a decreased load on the regeneration stripping tower, necessitating steep reduction of the steam flow to the reboiler. The problem is caused by the dynamic response rate of the regenerator-reboiler combine, which must match the fast-dynamics of the flue gas feed rate. The process upset in the absorber-stripper system takes time to settle down, leading to CO₂ slip from the PCC unit. The loss of CO₂ is not only an economic concern but an environmental issue as well. This study intends to observe this problem in a simulated environment and evaluate options to ensure faster stabilization of the MEA absorber-regenerator system; to minimize loss of CO₂ during changes in production rate of the power plant. The study involves developing a high-fidelity dynamic simulation model of the MEA absorber-stripper unit using 1st principles unit-op models and rigorous thermodynamics on a commercial dynamic simulator platform. Once the steady state conditions and disturbance caused in the system due to plant turn-down have been successfully replicated; the model is used to study the impact of process upsets on key operating parameters like solvent flow rate to absorber, regenerator bottom and top temperature, steam flow-rate and temperature of the reboiler, CO₂ slip from the absorber and the key parameter of overall CO₂ capture by the system. The next step is evaluation of various control schemes and operating strategies in their effectiveness of controlling the key process parameters viz. lean solvent flow rate to absorber, ratio of solvent flow to feed gas rate and regenerator bottom / reboiler temperature. In the final step the optimal control scheme and operating strategy to be followed by plant operators for the absorber-stripper system is identified. The selection is made based on the capability of the strategy to quickly react to the process upsets caused by reduction in power plant production rate, and to establish steady state operations in the least amount of time; reducing CO₂ loss during the process transients.

Keywords: Power plant, CO₂ capture, MEA solvent, Dynamic simulation, Control Strategy.

1. Introduction

Post combustion CO₂ capture unit is an important part of fossil fuel-based power plants and plays a key role in minimizing CO₂ emission. A typical challenge faced by the PCC unit is the disturbance in the flue gas feed rate to the PCC unit due to variation in demand for power production from the power plant. Timely controller action to minimize the effect of variation in feed gas rate and reestablishment of steady state conditions are required to ensure minimal impact on overall CO₂ capture quantity and environmental consequences. Several studies on control strategy of PCC unit have been done in recent times. Sharifzadeh [1], Rua [2], Mejdell [3], Chen [4] and Dutta [5] have studied several possible operating scenarios for an integrated PCC - Power plant complex and evaluated multiple control strategies for the PCC unit in detail. One specific scenario, which is quite challenging, involves rapid ramp down of power plant production rate. In this scenario, it is observed that the heating steam flowrate to the CO₂ regenerator reboiler fluctuates significantly and poses a tough challenge to quick reestablishment of steady state conditions. In our study, we have focused on this specific challenge and evaluated different configurations, controller schemes and transient state operating strategies to identify the best option to address this scenario. We have also considered an unconventional operating approach in the study, which involves rapid reduction of solvent flowrate to the CO₂ absorber; to match the reduction in incoming flue gas flow rate, while ensuring consistent CO₂ slip within acceptable operating range.

2. Process Description

A simplified process flow diagram of a typical MEA solvent based PCC unit is depicted in Figure 1. Flue gas from the power plant furnace is fed to the absorber, where CO₂ is absorbed by the circulating MEA solution. The rich MEA solvent is then regenerated in the CO₂ stripper, while the CO₂ is taken for further processing depending upon the nature of requirement. The regenerator tower is typically accompanied with a kettle type reboiler and uses process steam as heating utility. The reboiler tower is typically accompanied with a kettle type reboiler and uses process steam as heating utility.

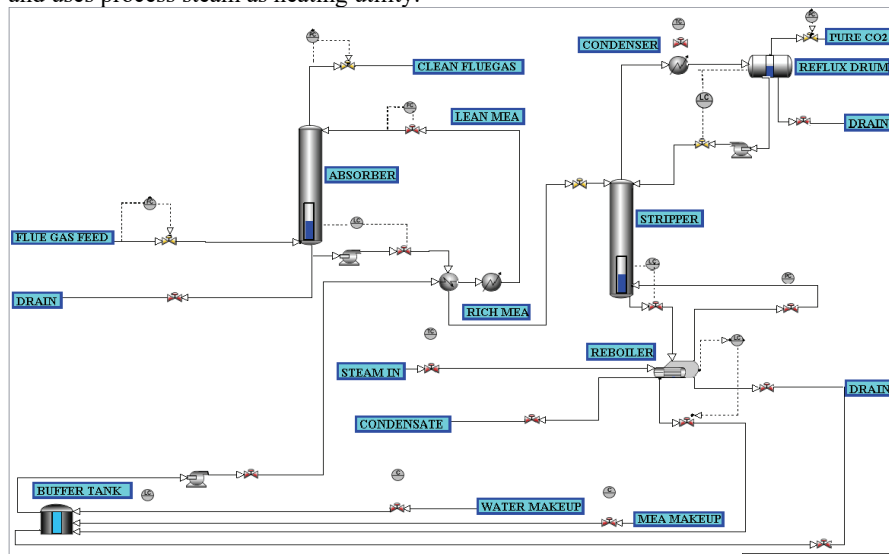

Figure 1 - Process flow diagram of a typical MEA solvent based PCC

In the process used for study, the solvent is 30 wt% aqueous Lean MEA solvent, which enters the absorber at 40 °C after being cooled by an air cooler. The solvent captures 85% of the CO₂ present in the feed. The rich solution exiting the absorber is heated by the stripper effluent stream and then fed to the stripping tower. The rich solution is regenerated in the stripping tower, and the kettle reboiler is maintained at 120 °C using steam as heating media. The CO₂ gas after condensation from stripper exit is also cooled in an air cooler, and the recovered condensate is recycled back to the stripper column as reflux. We have developed a rigorous dynamic simulation model of the above process, using a state of the art dynamic simulator, AVEVA™ Dynamic Simulation (formerly known as DYNASIM™), from AVEVA to carry out the operational study and validation of various control schemes / operating strategies.

3. Evaluation of Control Strategy

The study focusses on the operating scenario of 50% drop in power plant production, leading to a rapid drop of flue gas feed rate to the PCC unit. The details of the control strategy used for controlling the process are as per Table 1.

Table 1. Base case control strategy

Controlled Variable	Manipulated variable
Lean Amine Flow to Absorber	Inlet Valve Position
Reboiler Outlet Temperature	Steam Inlet Flow
Absorber Level	Absorber Outlet Valve Position
Stripper Level	Stripper Bottom Outlet Valve Position
Stripper Pressure	Stripper Top Outlet Valve Position
Absorber Pressure	Reflux Drum Outlet Valve Position
Reboiler Level	Reboiler Outlet Valve Position

In our study, the primary objective was to study the transient behaviour of key operating parameters, for the scenario where the feed gas flow ramps down to half of the normal value in about 30 mins and comes back to normal in about the same time. We have studied the effectivity of different control schemes in handling this process upset. The control schemes are evaluated by their capability to maintain expected operating condition in both the absorber and regenerator, i.e., avoid sharp change in gas / solvent flow rate, avoiding flooding or weeping in the towers, maintain sump levels and ultimately the CO₂ capture %.

The following three control schemes / strategies have been studied for their response to the above mention process scenario:

- a. Reboiler bottom outlet temperature control (kettle type reboiler)
- b. Stripper top outlet temperature control (kettle type reboiler)
- c. Reboiler bottom outlet temperature control (thermosyphon reboiler)

In all these scenarios, the flowrate of lean solvent to Absorber is controlled manually, i.e. the set point of the flow controller is reduced gradually by operator every 5 minutes, until the solvent flow corresponding to 50% absorber load is achieved.

4. Results and Discussion

The charts below depict all the key parameters recorded during the transient scenario, plotted against time (in minutes).

In **scenario (a)**, the reboiler outlet temperature is controlled to 120°C by varying the heating steam flow rate. Figures 2-9 show the response of the key process parameters.

Figure 2. Flue gas flow ramp down

Figure 3. Solvent flow ramp down

Figure 4 Steam Flow

Figure 5. Lean Amine Solvent Flow

Figure 6. Reboiler Outlet Temperature

Figure 7. CO₂ Capture Percentage

Figure 8. Stripper Top Outlet Temperature

Figure 9. Recovered CO₂ Temperature

In **scenario (b)**, the stripper top outlet temperature is controlled, by varying the steam flow rate to the reboiler. The main reason for considering this scenario is, in scenario (a), it is observed that the Stripper top temperature (figure 8) increases significantly during the ramp down phase. Figures 10-13 give trends of key operating parameters during the transient. The trends indicate that the steam flow, reboiler outlet temperature and stripper top temperature do not stabilize any faster than scenario (a). Further, significant oscillations are introduced into the system by this control strategy.

Figure 10. Steam flow to the Reboiler

Figure 11. Stripper Top outlet Temperature

Figure 12. Reboiler Outlet Temperature

Figure 13. CO₂ Capture percentage

In **scenario (c)**, the kettle type reboiler is replaced with an equivalent thermosyphon reboiler, and the reboiler outlet temperature is controlled with steam flow as variable. The key parameters response for this configuration is depicted in figures 14 and 15. This configuration produced oscillations in the reboiler outlet temperature, steam flow and Percent CO₂ Capture.

Figure 14. Reboiler outlet Temperature

Figure 15. Steam flow rate

5. Conclusions

A state-of-the-art dynamic simulator was utilized to perform studies and identify an optimal control strategy to minimize the impact of variation in power demand on the effectiveness of the PCC unit. The results from the study show that the reboiler temperature control plays an important role in ensuring quick stabilization of the process and should be the deciding criteria for recommending the optimal control strategy. Among the three scenarios studied, scenario (a), where the kettle type reboiler temperature is controlled, turns out to be the most optimal strategy. In this strategy the ramp down scenario was most effectively handled, and the steady state operation was achieved in a shorter period without introducing any significant oscillations.

Abstract

A mathematical model is adjusted to mimic the operational data of an industrial brewery during the fermentation process. The model is composed of a set of nonlinear ordinary differential equations. The parameters of the model were estimated using the least-squares method and the Levenberg-Marquardt algorithm. Once the model is adjusted, stochastic simulations run for different temperature profiles which are obtained using a Latin-hypercube sampling strategy. The results show the impact of the temperature uncertainty on the fermentation sub-products responsible of the final products' off-flavors.

Keywords: Mathematical modelling, Temperature uncertainty, Brewery, Off-flavor.

1. Introduction

Beer is one of the most widely consumed alcoholic beverages worldwide. Its market is estimated to be around 500 billion USD. Its competitiveness motivates breweries to encompass their production processes towards enhancing the operation to improve profitability and the ultimate success of the brewery. A key process in the industry corresponds to the fermentation stage, which not only demands high processing-times but it also guarantees key organoleptic characteristics of the beer. The industrial-scale fermentation process takes place inside a type-batch bioreactor, and the biochemical transformation of the wort or substrate into ethanol occurs through the action of yeast.

The dynamic understanding of the beer fermentation process has received considerable interest in recent years. Main reasons include the requirement of brewers to improve the process efficiency under different market conditions while complying with quality constraints. A number of mathematical models have been proposed for simulating the fermentation stage in breweries (Gee et al., 1994; Andres-Toro et al., 1998). In this context, a phenomenological-based methodology addressed the time evolution of the concentration of substrate, biomass, ethanol and off-flavors in a batch-type bioreactor (Gomez et al., 2008; Alvarez et al., 2009).

Despite these developments, the current operation in fermentation reactors can frequently be far from its desired conditions. In this sense, the incorporation and study of the uncertainty appears to be a tool of remarkable importance for model based frameworks (Salas et al., 2017, Gonzalez et al., 2020).

In this work, a mathematical model is fitted to the operational data of an industrial brewery. The model consists of a nonlinear system of ordinary differential equations, which solutions were approximated for certain conditions. The parameters of the model

were estimated using the least-squares method for nonlinear functions along with the Levenberg-Marquardt algorithm.

Once the model is adjusted, a total of 5000 stochastic simulations run for different temperature profiles, resembling common process disturbances. Finally, the results are statistically evaluated showing the effects of the temperature in the outputs of the system.

2. Mathematical Modelling

2.1. Background information

The proposed dynamic model is based in a material balance carried out on a batch-type fermenter. The model is reduced to a kinetic-type such as that proposed by (Andres-Toro et al., 1998) The state variables correspond to the concentrations of latent yeast X_{lag} ; active yeast X_{lact} ; dead yeast X_{dead} ; suspended yeast X_{sus} ; substrate C_S ; ethanol C_E ; diacetyl C_{DY} and ethyl acetate C_{EA} . Also, it is necessary a temperature profile given by a continuous function $T(t)$ with respect to time $t \geq 0$. These variables describe the two essential phases in the brewing process (see details in (Rodman et al., 2016)). During the first (lag) phase, the biomass mostly consists of latent yeast cells and, while they are activated, minimal fermentation takes place. The time interval which corresponds to this phase is $\Omega_1 = [0, t_{lag}]$, with t_{lag} the time around the lag phase ends. Once approximately half of the suspended cells are activated, the second (fermentation) phase begins. The active cell concentration is enough for inducing enzymatic effects, converting the sugar substrate into ethanol product. This phase time interval is denoted by $\Omega_2 = [t_{lag}, +\infty)$. The model considers the complete interval $\Omega = \Omega_1 \cup \Omega_2$. For defining the kinetics terms regarding the dynamics of active, dead and suspended yeast in each phase, we define the characteristic functions $\chi_i(t)$, with value of 1, if $t \in \Omega_i$, and 0 otherwise, for $i = 1, 2$. Therefore, the matrix function depending on the variables $C_S(t)$, $C_E(t)$ and $T(t)$ is defined as

$$A = \begin{pmatrix} -\mu_L & 0 & 0 & 0 \\ \mu_L(\chi_1 + \chi_2) & (\mu_X - \mu_{DT})\chi_2 & 0 & 0 \\ 0 & \mu_{DT}\chi_2 & -\mu_{SD}(\chi_1 + \chi_2) & 0 \\ 0 & \mu_X\chi_2 & \mu_{SD}(\chi_1 - \chi_2) & 0 \end{pmatrix}, \quad (1)$$

where $\mu_j = \mu_j(C_S(t), C_E(t); \theta_j)$ are given functions based on Michaelis-Menten-Arrhenius kinetics (Trelea et al., 2001) for $j \in \{E, S, X, SD\}$, and $\mu_k = \mu_k(T(t); \theta_k)$ are Arrhenius functions of T that represent specific rate for $k \in \{L, AB, DT, DY\}$. The parameters for each μ_j and μ_k are denoted as the vectors $\theta_j \in \mathbb{R}^{n_j}$ and $\theta_k \in \mathbb{R}^{n_k}$, respectively, with n_j and n_k representing their correspondent vector size. These parameters are estimated using data provided by an industrial brewery.

The model consists on determining, for all $t \in \Omega \setminus \{0\}$, the vector function, $\mathbf{X}(t) = [X_{lag}(t), X_{act}(t), X_{dead}(t), X_{sus}(t)]^T$, and the functions $C_S(t)$, $C_E(t)$, $C_{EA}(t)$ and $C_{DY}(t)$, such that,

$$\dot{\mathbf{X}}(t) = A\mathbf{X}(t), \quad (2)$$

$$\dot{C}_S(t) = -\mu_S X_{act}(t), \quad (3)$$

$$\dot{C}_E(t) = f\mu_E X_{act}(t), \quad (4)$$

$$\dot{C}_{EA}(t) = Y_{EA}\mu_X X_{act}(t), \quad (5)$$

$$\dot{C}_{DY}(t) = \mu_{DY}C_S(t)X_{act}(t) - \mu_{AB}C_{DY}(t)C_{EA}(t), \quad (6)$$

subject to initial conditions in $t = 0$. In Eq. (4), f is a function that depends on C_E (inhibition factor). In Eq. (5) the stoichiometric factor Y_{EA} is also an Arrhenius function of system temperature $T(t)$, both functions are taken from (Andres-Toro et al., 1998).

2.2. Parameter estimation

The vectors of parameters θ_j and θ_k , for $j \in \{E, S, X, SD\}$ and $k \in \{L, AB, DT, DY\}$, respectively, are estimated by minimizing in each $t_\ell \in \Omega$ the relative squared error. The operational data of the concentrations of substrate $C_{S_{exp}}(t_\ell)$ and ethanol $C_{E_{exp}}(t_\ell)$ are compared with respect to the concentrations obtained from the model depending on θ_j and θ_k , denoted by $C_S(t_\ell; \theta_j; \theta_k)$ and $C_E(t_\ell; \theta_j; \theta_k)$. Here, t_ℓ is the sampling time for $\ell = 1, \dots, N$, where $N \in \mathbb{N}^*$ is the number of fitted data points. Thereafter, the Levenberg-Marquardt algorithm estimates the parameters by solving a dynamic optimization problem (Bellavia et al., 2018) subject to the system of equations (2)-(6) and constraints. The feasible domain of variables θ_j^p , with $p = 1, \dots, n_j$, and θ_k^q , with $q = 1, \dots, n_k$, are defined by their lower and upper bounds l_j^p, l_k^q and u_j^p, u_k^q , respectively; this means $l_j^p \leq \theta_j^p \leq u_j^p$ and $l_k^q \leq \theta_k^q \leq u_k^q$.

The initial conditions of the state variables are set based on the operational data. The vectors of parameters θ_j and θ_k are constrained to guarantee the physical realizability of the parameters. The initial guests and the upper and lower bounds for the variables θ_j^p and θ_k^q are obtained from (Andres-Toro et al., 1998) and (Rodman et al., 2016).

To adjust the parameters, a set of 10 batches of a specific beer recipe were considered. A total of 19 parameters related to the kinetics of the fermentation process obtained residual norms of the difference of the experimental and simulated data between 0.002 and 0.057. The following study used the parameter's mean values for all the batches.

3. Stochastic dynamic modelling under uncertainty

To study the variability of the system dynamics when introducing temperature uncertainty, a series of stochastic simulations are carried out. In our practice a Python environment is utilized, in which the libraries NumPy, SciPy, pandas, pyDOE, matplotlib and seaborn facilitate the obtainment of meaningful results.

Initially, a total of 5000 temperature profiles are generated using the Latin-hypercube sampling method available in pyDOE. A standard deviation (σ_x) of 0.4 is considered in this case. The temperature profile changes at different pre-established time intervals. The objective of this experimental design is to represent process disturbances that affect the products of a brewery at the fermentation stage. The ODEs are solved using `solve_ivp`, available in the module `SciPy.Integrate`. The resultant state variable vectors, for each temperature profile, are stored in a data frame for further processing. This study focuses on the dynamic visualization of the process when temperature uncertainty is introduced. Thus, the library `seaborn` allows to observe its effects.

4. Results

The variation of the temperature from its recipe profile is captured in Figure 1. Notice that the bold line corresponds to the average, and the bold area the region between 25th and 75th percentiles. The temperature LHC varies as piece-wise function at the times (hour) $t = 0, 60, 72, 84, 96, 108, 120$, and 140. The blue dots correspond to the experimental values. Figure 2 illustrates the influence of the temperature uncertainty to the different yeast growth as well as the substrate (sugars) and ethanol production. It is important to notice that the active, dead, and suspended yeast show important relative variability from the input. On the other hand, active and suspended yeast only show important variability at the end of the fermentation process. The substrate plot shows the relationship between the variability and the experimental values. In this case, the model is not able to capture the variations at the beginning and at the end of the process. Although ethanol shows certain variability in the middle of the process; and after time $t = 100$, it tends to narrow the variability, showing that the result of producing ethanol is stable regarding the temperature variation.

Figure 1: Temperature including uncertainty obtained using LHS. The vertical dotted lines correspond to the times (hour) $t = 60, 72, 84, 96, 108$. The solid line corresponds to theoretical final fermentation time at $t = 120$ hours. The blue dots are the experimental values of temperature.

Regarding the off-flavors, Figure 3 illustrates the influence of the temperature uncertainty to their dynamics, which are represented by the concentrations of ethyl-acetate and the diacetyl in parts per million (ppm). The upper panel shows the concentrations of both ethyl-acetate and diacetyl. The plot inset, included at the upper east side, allows to make the comparison of the concentration of both off-flavors after the time $t = 118$ hours. The lower panel shows the σ_x of the variability of both off-flavors, providing a dynamic quantitative evaluation of the actual uncertainty introduced to the outputs. Even though they are in the magnitude of ppm, unpleasant flavors can be perceived in the taste of beer, and after certain levels they could even become toxic. The diacetyl shows an important sensitivity to the temperature uncertainty at the middle of the process. However, after fermentation time $t = 100$ hours, this uncertainty reduces significantly. Indeed, a common practice in breweries is to measure off-flavors' concentration at certain time intervals to quantify whether the fermentation should last longer or not. These results show that a strict control of the temperature seems to be critical in this stage in order to reach diacetyl concentration below 0.15 ppm (Olaniran et al., 2017).

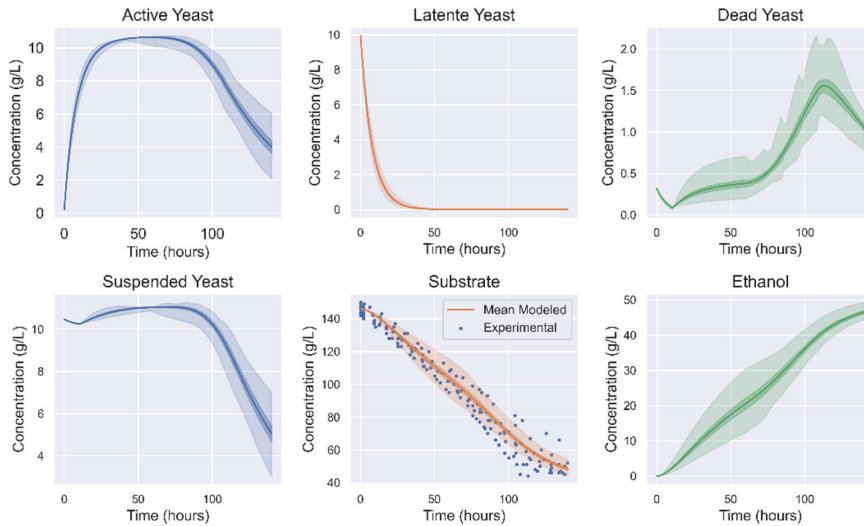

Figure 2: Concentration of active, latent, dead and suspended yeast, substrate and ethanol. The painted region corresponds to minimum and maximum values, the darker zone corresponds to the values between 25th and 75th percentiles. The blue dots in center-lower panel are the experimental values of substrate.

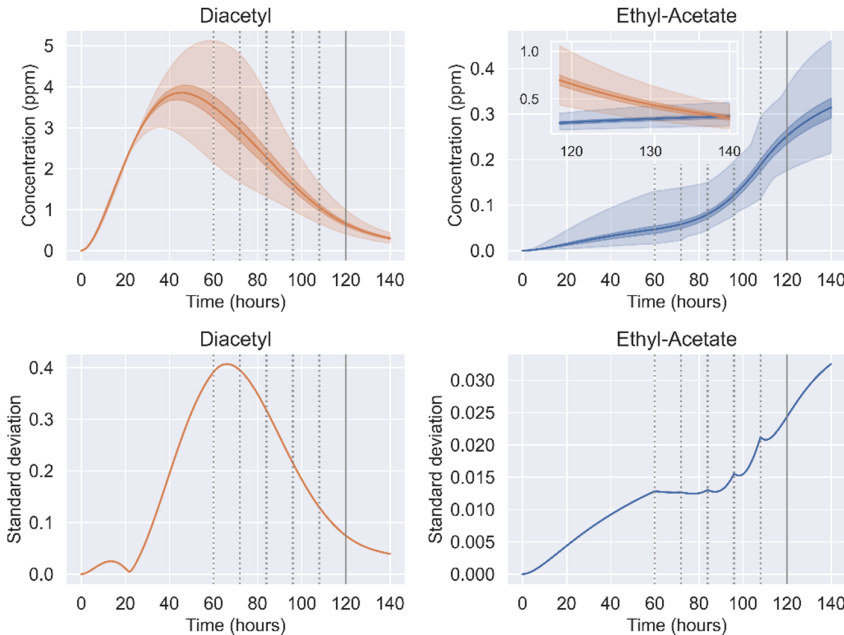

Figure 3: Ethyl-acetate and diacetyl concentration (upper panel). The painted region correspond to minimum and maximum values. The darker zone correspond to the values between 25th and 75th percentiles. Lower panel shows their respective σ_x . The vertical dotted lines correspond to the times (hour) $t = 60, 72, 84, 96, 108$. The solid line corresponds to theoretical final fermentation time at 120 hours.

5. Conclusions

In this work, the validated mathematical model of the fermentation process in an industrial brewery is studied by introducing uncertainty to the temperature. The model is adjusted using real experimental data from an industrial facility, the least-squares method, and the Levenberg-Marquardt algorithm. Stochastic simulations run for different temperature profiles which are generated using a Latin-hypercube sampling strategy setting a value of the standard deviation. The results show the impact of the temperature uncertainty to fermentation products. Among these outputs certain sub-products, responsible of the final products off-flavors, are analyzed. It is observed from the results that the off-flavors could be corrected by suitably extending the reaction and managing a well adjusted trade-off between them. Nevertheless, an extended operation could impact the economy of a brewery because it introduces an inefficient use of energy and other resources such as the tanks due to time delay in production. In this sense, these types of tools could benefit brewers for decision making as well as for adequate process scheduling.

Symbolic transfer entropy for root cause analysis of process disturbances

Ching-Mei Wen, Yuan Yao *

*Department of Chemical Engineering, National Tsing Hua University, Hsinchu, Taiwan

yyao@mx.nthu.edu.tw

Abstract

Root cause analysis is an important step in process monitoring for the disclosure of causes of process disturbances. In the past research and practice, transfer entropy has been widely adopted for its capability to handle process nonlinearity. However, the conventional transfer entropy is not robust to noise and computational inefficient, which affects its application performance. These problems can be solved by incorporating the technique of symbolization. To the best of our knowledge, symbolic transfer entropy (STE) has seldom been implemented in the field of process monitoring. In this work, the concepts of statistical process control (SPC) and STE are integrated to achieve satisfactory diagnosis results. As known, SPC charts, e.g. Shewhart charts, exponential weighted moving average charts, and cumulative sum charts, are useful tools for process monitoring, where the sample locations on the control chart indicate certain process status. Therefore, it is reasonable to symbolize process measurements according to such information. After symbolization, STE is conducted to reveal the causality among process variables which is then visualized with a signed directed graph. The case study on the Tennessee Eastman process shows that the control chart-based STE possesses a capability to understand the causes of disturbances and offers the convenience of root cause analysis.

Keywords: root cause analysis, diagnosis, symbolic transfer entropy, causality analysis, process monitoring.

1. Introduction

Disclosure of the fault root causes is a critical step in process monitoring, which is important for controlling the risks associated with process failures and preventing problem recurrence. Based on the concept of statistical process control (SPC) (Woodall and Montgomery, 1999), a large number of process monitoring methods have been developed in recent decades (Ge et al., 2013). Most of these research works focus on timely detection of process faults or disturbances, as well as accurately isolation of critical process variables, while root cause diagnosis is relatively overlooked. Conventionally, process knowledge is a necessity to achieve reasonable diagnosis results (Iri et al., 1979). In recent years, statistical causality analysis techniques have been adopted to this field so as to relieve the dependency on the prior knowledge of the investigated process (Li et al., 2016), among which transfer entropy (TE) (Schreiber, 2000) is a representative method because of its capability to handle nonlinearity. A

number of improved versions of TE have been proposed in the past years. For example, permutation entropy (Bandt and Pompe, 2002) has been proved to provide robustness to noise, which estimates transfer entropy using symbolization. The concept of symbolic transfer entropy (STE) was then extended (Staniek and Lehnertz, 2008) by using a surrogate-based testing scheme. Applications of STE demonstrated its advantages of better computational efficiency and accuracy comparing to the conventional TE.

In this work, a new scheme is proposed for root cause analysis of process disturbances, which integrates the concepts of STE and SPC. The application results illustrate the feasibility of this method.

2. Methodology

2.1. Transfer entropy

As an information theoretic measure, TE was first introduced by Schreiber (2000), the basics of which are as following. Supposing X and Y represent l^{th} and k^{th} order Markov processes, respectively, the transfer entropy from X to Y is defined as:

$$T_{X \rightarrow Y} = \sum_{y_{i+1}, y_i^{(k)}, x_i^{(l)}} p(y_{i+1}, y_i^{(k)}, x_i^{(l)}) \log_2 \frac{p(y_{i+1} | y_i^{(k)}, x_i^{(l)})}{p(y_{i+1} | y_i^{(k)})} \quad (1)$$

where $x_i^{(l)}$ and $y_i^{(k)}$ are the past l and k -step states of process, i.e. $x_i^{(l)} = x_i, \Lambda, x_{i-l+1}$ and $y_i^{(k)} = y_i, \Lambda, y_{i-k+1}$. The transfer entropy from Y to X can be defined in a similar way. As an asymmetric measure, TE allows the quantification of the directional coupling between two processes. Ideally, a TE value greater than zero and indicates the existence of causality. In Eq. (1), the complete or conditional probability density functions can be estimated by kernel methods (Silverman, 1986).

2.2. Symbolic Transfer entropy

In 2008, Staniek and Lehnertz (2008) proposed an STE as a method of calculating information transfer between time series processes with discrete states. The STE for two discrete-time random processes \tilde{X} and \tilde{Y} can be expressed as Eq. (2):

$$T_{\tilde{X} \rightarrow \tilde{Y}} = \sum_{\tilde{y}_{i+1}, \tilde{y}_i^{(k)}, \tilde{x}_i^{(l)}} p(\tilde{y}_{i+1}, \tilde{y}_i^{(k)}, \tilde{x}_i^{(l)}) \log_2 \frac{p(\tilde{y}_{i+1} | \tilde{y}_i^{(k)}, \tilde{x}_i^{(l)})}{p(\tilde{y}_{i+1} | \tilde{y}_i^{(k)})} \quad (2)$$

Here, the symbols have similar definitions to those in Eq. (1), except that the data used for estimate STE are discretized. The discretization can be achieved by partitioning the data into a finite number of bins. The size of each bin can be determined based on the user-specified upper and lower bounds or by choosing specific quantiles of the empirical distribution of the data. In detail, if the bounds of n bins are denoted as q_1, q_2, \dots, q_n , where $q_1 < q_2 < \dots < q_n$, the symbolized data can be recorded in the following

way. For $x_i \leq q_1$, $\tilde{x}_i = 1$; for $q_1 < x_i \leq q_2$, $\tilde{x}_i = 2$; and so on and so forth. In practice, the selection of bin size requires balancing information conservation and computational burden. In general, the smaller the selected bin size, the more information retained. However, the reduction of noise and computational burden becomes insignificant in such cases.

In this work, we propose to divide the bins by adopting the concept of SPC. In detail, a modified exponential weighted moving average (EWMA) chart (Hunter, 1986) is utilized. The calculation of the EWMA statistic for monitoring the time series X is as Eq. (3)

$$z_i = \lambda x_i + (1 - \lambda)z_{i-1} \quad (3)$$

Conventionally, the control limits of an EWMA chart is calculated as:

$$\text{UCL, LCL} = z_0 \pm ks_{ewma} \quad (4)$$

where

$$s_{ewma}^2 = \frac{\lambda}{2 - \lambda} [1 - (1 - \lambda)^{2i}] s^2 \quad (5)$$

z_0 and s are the process target, i.e. the mean of the historical data, and the estimated standard deviation, respectively, and k is user-specified parameter controlling the type I error rate. Therefore, totally seven bins can be set up according to the values of k . For example, for $z_i \leq z_0 - 3s_{ewma}$, $\tilde{x}_i = 1$; for $z_0 - 3s_{ewma} < z_i \leq z_0 - 2s_{ewma}$, $\tilde{x}_i = 2$; ...; for $z_0 - s_{ewma} < z_i \leq z_0 + s_{ewma}$, $\tilde{x}_i = 0$; ...; and for $z_i \geq z_0 + 3s_{ewma}$, $\tilde{x}_i = 7$. Note that the control limits approach to constant values (

$z_0 \pm k\sqrt{\frac{\lambda}{2 - \lambda}}s$) with the increased number of samples. Therefore, when the process status is out of statistical control, i.e. when it is necessary to conduct root cause diagnosis, there is a large chance that the symbolized process measurements have an unchanged value, e.g. 1 or 7, and cannot reflect the process dynamics. To solve this problem, in the proposed scheme, the estimate of standard deviation s is updated online using a moving window technique. In doing this, the EWMA control chart may have a lower alarm rate. However, note that the purpose of using the control chart here is not to detect whether the process is in statistical control. Instead, the symbolization needs to reflect the process dynamic characteristics and the information transfer between variables.

2.3. Estimation of Significance Level

No matter the conventional TE or STE is used, the estimates are seldom exactly zero even if there is no information transfer between two time series. Practically, subjective selected thresholds are usually needed for judge whether the statistical causality exists. Herein, in order to make objective judgements, it is desired to use a more statistical method. Therefore, the p-values are calculated based on bootstrap samples of the transfer entropy estimates (Behrendt et al., 2019). After conducting STE, the results are used to construct a signed directed graph (SDG), in which each vertex corresponds to a process variable, and the arrows on the edges denote the direction of information transfer, i.e. the inferred causality. In addition, a weight is assigned to each edge, whose value equals to the p-value calculated in the previous step. Only the edges with p-values smaller than 0.05 are connected.

3. Case study

3.1. Tennessee Eastman process and variable selection

Herein, the benchmark Tennessee Eastman process, developed by Downs and Vogel (1993), is used as an illustrative case. The process consists of five main units, namely reactor, product condenser, gas-liquid separation tower, product stripper, and recycle compressor. The gaseous reactants include A, C, D, and E, while the products are denoted as G and H. In addition, there is an inert component B and a by-product F. The disturbance IDV1 is used as a case study to illustrate the feasibility of the proposed method, where the composition of A in the feed stream 4 changes from 48.5 mol% to 45.5 mol% and at the same time the composition of C in the same stream changes from 51 mol% to 54 mol%. According to the previous research (Liu et al, 2014), nine process variables as listed in Table 1 were chosen as the candidates for root cause diagnosis.

Table 1. variables selection of IDV1 case study

V1	A feed (stream 1)	V20	Compressor work
V4	A and C feed (stream 4)	V31	Component C (stream 9)
V8	Reactor level	V38	Component E (stream 11)
V16	Stripper pressure	V50	Stripper steam valve
V18	Stripper temperature		

3.2. Parameter setting and symbolization

A few parameters were set before conducting symbolization. First, the average values used in the control charts were calculated based on the normal operating data. Second, the size of the moving window used for standard deviation estimation was chosen to be 5, 10, and 20, respectively, for comparison. In addition, the values of k and l used in STE were chosen to be 1 according to the literature (Yu and Yang, 2015).

Two symbolization methods were adopted for the STE calculation. In the first method, the Shewhart individual control charts are utilized, while the second method utilizes the EWMA control charts combined with the moving window strategy proposed in this paper.

3.3. Results and discussions

Three indices were used to evaluate the performance of different root cause diagnosis methods, as shown in Table 2. Sensitivity measures the correctness in identified causal correlations, specificity calculates the correctness of the identification of the non-causal relations, and edge density indicates the sparsity of the resulting SDGs. The first two indices have values between 0 to 1, where larger values are preferred. For edge density, a smaller value corresponds to a sparser graph.

Table 2. evaluation indexes of STE results

	Window size	Sensitivity	Specificity	Edge density
Shewhart	20	0.724	0.837	0.26
EWMA	5	0.86	0.58	0.43
EWMA	10	0.89	0.76	0.38
EWMA	20	0.931	0.860	0.37

As shown in Table 2, the EWMA chart-based STE methods outperformed the Shewhart chart-based method in general no matter what size of the moving window was selected. In addition, the modified EWMA chart with a moving window sized 20 performed best in this case study, because it led to the largest sensitivity and specificity values. It is noted that the edge density of the results of this model is not the lowest. However, this index is not critical to the accuracy of root cause diagnosis. In addition, the generally good performance of all three EWMA-based STE methods show that the proposed scheme is not very sensitive to the parameter setting. The SDG achieved by the EWMA chart-based STE method with the moving window sized 20 is plotted in Figure 1.

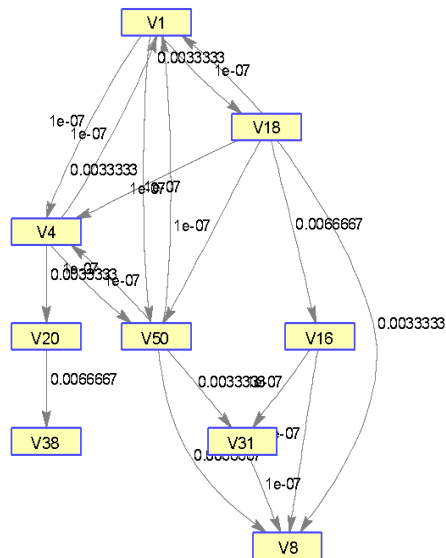

Figure 1. SDG resulted from EWMA-based STE

4. Conclusion

Symbolic transfer entropy has been used for the estimation of functional connectivity in networks. However, its applications to root cause diagnosis of process disturbances are rarely reported. In this work, STE based on a modified EWMA control chart is proposed, whose feasibility is illustrated using the benchmark Tennessee Eastman process. In the future work, the SDG obtained by using STE will be simplified to further highlight the root cause variables. As shown in Figure 1, the reciprocal causations between several variables may lead to the difficulty in identify the variable closest to the root of the disturbance. This may be partially caused by the improper selection of the time slot to be analysed, because the fault propagation may distort the information of the disturbance root cause. Therefore, how to determine the data segment for analysis is also an important topic for future research.

Abstract

In the last decade, pharmaceutical manufacturing has been undergoing a modernization trend, promoted by the US Food and Drug Administration (FDA) with the Quality-by-Design (QbD) initiative. However, in most of the cases, the product quality is still controlled in open-loop, and pharmaceutical operation is carried out in the traditional batch mode, rather than continuously. In this work, we present a framework for closed-loop quality control of a novel continuous integrated filtration-drying unit. The unit addresses the current lack of technology for continuous drug substance isolation, which is the main bottleneck in end-to-end continuous pharmaceutical manufacturing. With the proposed closed-loop control framework, the product conformity is improved, showing how a Quality-by-Control (QbC) strategy can outperform earlier QbD approaches based on open-loop control.

Keywords: Quality-by-Design, Quality-by-Control, Process control, Continuous pharmaceutical manufacturing, Continuous filtration, Fluid-solid separation

1. Introduction

The QbD initiative of the US FDA (FDA, 2004) has generated a modernization momentum in the pharmaceutical industry within the last decade. In the QbD framework, the manufacturing process is developed with a risk-based approach relying on process knowledge, to inherently build the quality into the product. The critical process parameters (CPPs), the feed properties (critical material attributes, CMAs) and the product critical quality attributes (CQAs) are first identified. Then, the design space (DS) is determined, as that region of the multivariable space of CPPs and CMAs, where the CQAs meet the target values. QbD represents a major step forward with respect to the previous Quality-by-Testing (QbT) approach, that consisted in directly testing the

quality of the end-product. In the industrial practice and in the vast majority of the academic works, the DS is used in combination with a control system at open loop with respect to the CQAs. Although active process control is used for controlling the CPPs, their set-points are moved at open-loop within the DS in response to measured changes in the CMAs. As acknowledged by regulators, practitioners and academics (Yu et al., 2014), closed-loop control of the product quality can lead to a higher level of quality assurance and can enable real time release. In a control strategy with active quality control, the CQAs are monitored in real time, and the CPPs set-points are automatically adjusted in response to registered changes in the CMAs and/or CQAs. Recent literature publications demonstrated closed-loop control implementation and its advantages for a number of pharmaceutical processes, including plant-wide applications (Lakerveld et al., 2013). These results are leading to the development of a novel QbC framework (Su et al., 2019). QbC is not an independent system with respect to QbD, but it rather is an evolution, in which active process control is the core of the control strategy.

Another recent modernization of the pharma industry brought by the QbD initiative involves the shift to a more continuous production mode, compared to the traditional batch processing (Lee et al., 2015). When feasible, continuous manufacturing (CM) is the preferred choice in the process industry for many reasons, an important one being cost saving. For pharmaceutical manufacturing, the main motivation to the transition to CM is the inherently greater product consistency that can be achieved, thanks to the greater process controllability. Generally speaking, closed-loop control for continuous processes is typically easier and has been explored more than for batch processes. Overall, a tight interconnection emerges between the two main directions of evolution of QbD: the transition to CM requires the QbC framework for systematic control system design, while QbC implementation is gaining much momentum under the increased interest in continuous processing. So far, CM and QbC publications (Su et al., 2019) mainly focused on reactive systems, on crystallization and on drug product manufacturing (e.g.: tableting lines). The intermediate steps of filtration, washing and drying of crystallization slurries, and their integration, have not been studied yet in a CM/QbC perspective. Nonetheless, they are of pivotal importance to obtain the pure drug substance for downstream drug product manufacturing.

In this study, we make a step forward towards end-to-end automated CM by developing a QbC framework for a novel continuous carousel for integrated filtration, washing and drying of drug substances. The carousel filter-dryer system, manufactured by Alconbury Weston Ltd (UK), is a breakthrough technology in the field, as it is one of the few solutions available in the market for continuous upstream filtration, washing and drying. The rest of the manuscript is organized as follows. In Section 2, the carousel technology is described, while in Section 3 the conceived QbC system is discussed and the response of the control system to a disturbance is presented. The concluding section follows.

2. The continuous carousel for integrated filtration, washing and drying

Alconbury Weston Ltd designs and manufactures different models of carousels for solid/liquid separation. In this study, we refer to a prototype installed in the Crystallization Systems Engineering laboratory at Purdue University, used for isolating active pharmaceutical ingredients (API) from crystallization slurries. The P&ID of the process is showed in Figure 1. The controllers reported in the “Level 0” box (with the exception of the pressure controllers) are all implemented in the in-built programmable

logic control (PLC) of the unit. The carousel presents a main rotating cylindrical body, with five processing stations (Figure 2a). However, in the P&ID, each processing station is sketched as an independent tank (V104-108), to better illustrate the functioning of the control system. During carousel operation, every fixed cycle duration Δt_{cycle} the unit rotates, moving the content of each station to the following one. In the P&ID, the transfer of material upon carousel rotation is symbolized through the material streams situated among tanks V104-108 (controller FC102 opens the stream valves at each cycle switch). Processing stations V104-107 present filter meshes at the bottom (F101-104), while V108 is open for discharge. Starting from the inlet of the process, the slurry from the crystallizer (V101) is transported into an intermediate storage tank (V102) with a peristaltic pump (P101). From there, every Δt_{cycle} , an amount of slurry, controlled by FC101 based on the set-point $V_{slurry,sp}$, is drawn into the charge cell V103 through the action of the vacuum pump P102. P102 is connected to V103 only during the charging phase at the beginning of every cycle, through the three-way valve. During the rest of carousel operation, the vacuum pump is connected to the filtrate receiver V110 and, hence, to the bottom of the processing stations V104-107, providing the driving force for filtration, washing and drying. After the charging phase, the slurry enters V104, and filtration starts. Meanwhile, in V105-107 the material loaded during the previous cycles is processed. In V105, cake washing occurs, to reduce the amount of impurities in the cake (V109 is the wash solvent tank), while cake deliquoring (i.e. mechanical drying) is carried out in V106. A final drying step with hot air is delivered in V107, while the product (dry API crystals cake) is discharged from V108 through the action of a piston. The fan P103 can be used for increasing the pressure drops in each station (driving force for the processing steps), or the top portion of V104-107 can be directly connected to the atmosphere (i.e., eliminating F103 from the P&ID). PC101 and PC102 are, respectively, the in-built pressure controllers of P103 and P102. The heater H101 is responsible for heating the drying air, and its jacket temperature is manipulated by TC101 to control the temperature of the air entering V107. If the jacket temperature reaches 150°C, for safety reasons it is not heated up anymore, thanks to the action of TA101 and to the low selector. Additional sensors have been installed for monitoring and control purposes. PI101 measures the pressure at the bottom of the processing stations, FI101 measures the gas flowrate entering the carousel, FI102 (a scale placed below V110) measures the flowrate of filtrate coming from the ports, and TI101-103 are, respectively, the thermocouples for the jacket temperature, for the gas temperature at the dryer inlet, and for the gas temperature at the dryer outlet. The automated filter meshes cleaning system is not reported in the P&ID for conciseness. The control systems in the “Level 1” (Section 3) box have been implemented in this study for controlling the CQAs of the process, namely the residual solvents and impurities in the discharged cake. Overall, a risk analysis (Destro et al., 2021) showed that $\Delta t_{cycle,sp}$ (set-point of Δt_{cycle}) and $V_{slurry,sp}$ are the CPPs of the process.

3. A QbC framework for the continuous carousel

We develop the control system for the carousel following a recently proposed hierarchical three-level approach for control system design (Su *et al.*, 2019), based on the ISA-95 Enterprise-Control System Integration Standard. The Level 0 of the control system consists in the built-in PLCs of the carousel and of P102-103, already described in Section 2, that allow controlling CPPs and control variables. The designed Level 1 and Level 2 are instead outlined in this Section.

The Level 1 of the control system (Figure 1) uses advanced PID loops for controlling the CQAs. Since the solvents and impurities content cannot be measured online, the CQAs are controlled by inference through AC101, directly controlling the outlet temperature profile measured by TI103. Actually, the temperature profile of the outlet drying gas is strictly correlated to the residual solvents and impurities content in the cake. At the beginning of drying, the temperature drops, due to the latent heat of vaporization. While drying progresses, the temperature starts rising, since the residual solvents and impurities, and the energy consumed by their volatilization, are always lower. A reference temperature profile $T_{drying,sp}^{out}(t)$ is obtained in normal operating conditions, and is then tracked by AC101 to control the CQAs during operation. If the cake entering the dryer

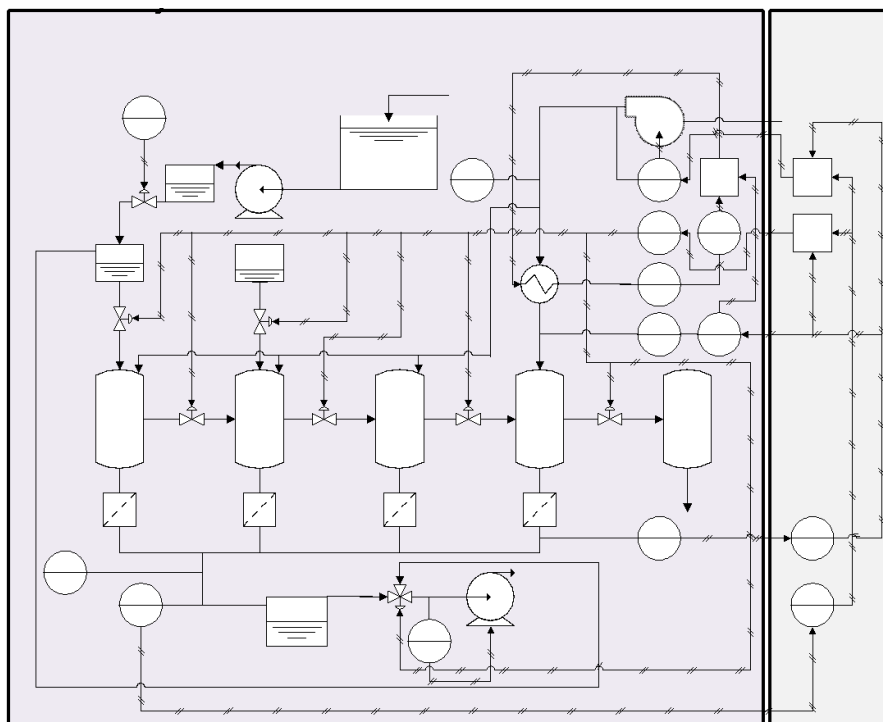

Figure 1. P&ID of the continuous carousel for integrated filtration, washing and drying.

Figure 2. (a) Carousel schematic diagram. Stations 1-4 present a filter mesh at the bottom, connected to the collector. (b) Split range controller AC101: manipulated variable (deviation form) per range of controller output (proportional to $T_{drying,sp}^{out}(t_k) - T_{drying}^{out}(t_k)$).

contains more solvents than usually, due to issues in the previous section of the process, or if drying is progressing more slowly than usually, for example due to F104 fouling, TI103 will measure an abnormally low temperature. AC101, a split range controller (Figure 2b), will react increasing the set-points of one or more of the following: the pressure drop in the processing stations ΔP_{sp} (PC101), the drying gas inlet temperature $T_{drying,sp}^{out}$ (TC101) and/or the cycle duration $\Delta t_{cycle,sp}$ (FC102). The choice of increasing $\Delta t_{cycle,sp}$ only at last (Figure 2b), after that the maximum values of ΔP_{sp} and of $T_{drying,sp}^{in}$ are reached, is meant to maximize the process throughput. Instead, if the cake entering the dryer is purer than usually, the controller will react in the opposite direction, eventually reducing $\Delta t_{cycle,sp}$ and increasing the process throughput. The flowrate controller FC103 is also designed to help controlling the CQAs. FC103 (split-range controller) controls the filtrate flowrate by increasing/decreasing ΔP_{sp} and/or of $\Delta t_{cycle,sp}$ if the filtrate flowrate is low/high. This controller compensates for the disturbances that increase the filtration duration, such as fouling of F101-104, increase of crystals concentration in V101 or increase of cake resistance. Since both AC101 and FC103 act on ΔP_{sp} and $\Delta t_{cycle,sp}$, two high selectors are needed (Figure 1).

The response of Level 0 and Level 1 control system to a same filter mesh fouling disturbance is reported in Figure 3 for the isolation of aspirin from an aqueous slurry, as simulated by means of a detailed digital twin of the carousel, described elsewhere (Destro *et al.*, 2021). With Level 0 control, the batches produced in Cycles 7-71 have to be rejected, as they do not meet the desired quality (Figure 3a), which is reached again only after the meshes are cleaned (from Cycle 72 on). Instead, Level 1 controllers react very fast to the abnormal CQAs, by increasing ΔP_{sp} and $T_{drying,sp}^{in}$. After about 15 min (~ 7 cycles) from the start of the process, ΔP_{sp} and of $T_{drying,sp}^{in}$ saturate, and Level 1 controllers start increasing $\Delta t_{cycle,sp}$ (Figure 3b). Due to the increased $\Delta t_{cycle,sp}$, with Level 1 control only 68 cycles are completed in the same amount of time in which Level 0 control completes 115 cycles (Figure 3a). However, with Level 1 control the CQAs

always respect the quality threshold. When the filter meshes are cleaned (150 min from the start of the process), a higher $\Delta t_{cycle,sp}$ is not needed anymore, and Level 1 controllers start decreasing $\Delta t_{cycle,sp}$ (Figure 3b), effectively increasing the throughput again. Level 2 improves carousel operation through model-based control, exploiting the in-house developed model of the carousel (Destro *et al.*, 2021). Due to space limitation, Level 2 is not described in detail in this manuscript, but it includes a state estimator and a real time optimization/model predictive control component (RTO/MPC).

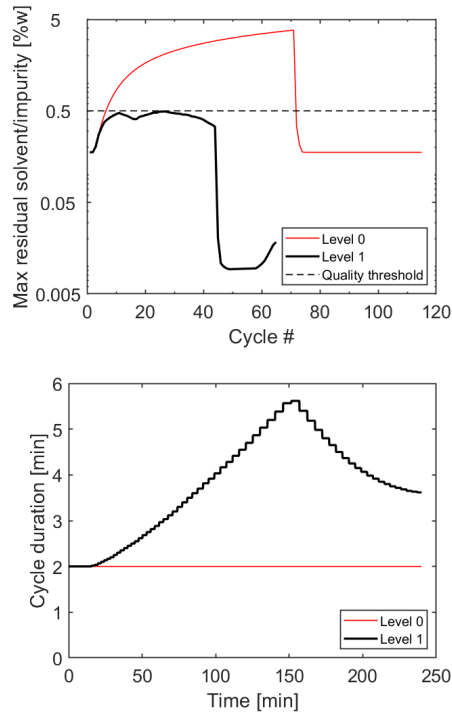

Figure 3. Control system response to a fouling disturbance: Level 0 vs Level 1. The solvent or impurity presenting the highest residual content in the discharged cake (CQAs) is reported on the left, while the profiles of $\Delta t_{cycle,sp}$ (CPP) are on the right.

The RTO/MPC updates the control vector $\mathbf{u} = [V_{slurry,sp}, \Delta t_{cycle,sp}, \Delta P_{sp}, T_{drying,sp}^{in}]$ by solving the following optimization problem:

$$W_1 \frac{V_{slurry,sp}}{\Delta t_{cycle,sp}} + (\mathbf{u} - \mathbf{u}_{ref})^T W_2 (\mathbf{u} - \mathbf{u}_{ref})$$

subject to: $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}), \mathbf{u}_{min} < \mathbf{u} < \mathbf{u}_{max}, \mathbf{x}_{min} < \mathbf{x} < \mathbf{x}_{max}$,

(1)

where \mathbf{x} is the states vector, \mathbf{W}_1 and \mathbf{W}_2 are suitable weighing matrices, f is the carousel model, \mathbf{u}_{ref} is the reference control vector and \mathbf{u}_{min} , \mathbf{u}_{max} , \mathbf{x}_{min} and \mathbf{x}_{max} are suitable bounds for \mathbf{u} and \mathbf{x} . The first term of the cost function represents the overall carousel throughput, which is maximized by the RTO/MPC respecting the quality constraints

(included in the constraints relation for \mathbf{x}). This represents a step forward with respect to Level 1, in which some sort of throughput maximization was only be achieved through split range control.

4. Conclusions

We presented a QbC three-level control system for a continuous carousel for integrated filtration, washing and drying of crystallization slurries. The control system successfully rejected a disturbance related to filter mesh fouling. This study represents a novel contribution to CM and QbC literature, as this type of process is scarcely studied. Future work will focus on Level 2 and on implementing the control system in the carousel.

Abstract

In crystallization processes, the control of particle size distribution, shape and purity are crucial to achieve the targeted critical quality attributes of the final drug product and meet the pharmaceutical regulatory requirements. This work presents novel optimal trajectory tracking control strategies for batch and continuous cooling crystallization processes using reinforcement learning (RL). The cooling crystallization of paracetamol in water was used as a case study. A model-based reinforcement learning technique is implemented to achieve large crystal size by reducing the deviation from targeted reference trajectories namely process temperature, supersaturation and particle size. This multioutput tracking control strategy was developed to address quality and performance challenges commonly encountered in batch and continuous crystallization processes. Various training strategies and reward functions were investigated to enhance the learning capabilities and robustness of the reinforcement-learning-based control. Despite the computational costs inherent to reinforcement learning, the later demonstrated robust control capabilities compared the benchmark control strategies such as model predictive control.

Keywords: Reinforcement learning; Trajectory tracking control; Batch crystallization; Continuous crystallization; Supersaturation control; Crystal size distribution.

1. Introduction and Background

The pharmaceutical industry is subject to stringent regulatory requirements. The control of quality is critical as small deviations from the quality target profiles may have a significant impact on drug safety and efficacy, which may lead to failure of the clinical trials, at early development stages, or drug recalls causing dramatic economic consequences. The development of robust, flexible and agile control strategies is the cornerstone of the current Quality-by-Design paradigms. The development and successful integration of new process analytical technologies (PAT) allowed real time measurements of the critical quality attributes which has changed dramatically the pharmaceutical manufacturing landscape and paved the way for more advanced and reliable real-time optimization and control strategies (Lakerveld et al. 2015).

The emergence of continuous manufacturing in pharma opened new opportunities for more cost-effective and flexible technologies (Benyahia 2018; Mascia et al. 2013). However, the successful development of continuous processes requires more reliable and advanced control strategies to cope with the different sources of variation and

perturbation as well the complexity associated with the large number of process outputs, interactive control loops and intrinsic process dynamics, particularly during start-up, shut-down and ramp-up.

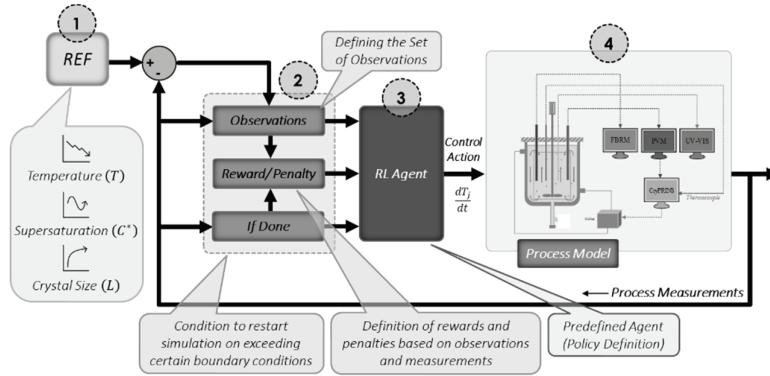

Crystallization is used extensively in the pharmaceutical industry to purify reaction intermediates and final active pharmaceutical ingredients. As such, several crystallization steps may be used at different stages of the manufacturing process (Benyahia et al., 2012). A successful crystallization requires tight control over crystal size distribution, purity, and polymorphism. These properties impact dramatically the critical quality attributes of the final pharmaceutical product, such as solubility and safety, besides the downstream processability of the crystals, such as flowability and filterability. Various control and optimization techniques have been developed and implemented over the last 2 decades ranging from model-free to model-based techniques (Lakerveld and Benyahia, 2020). Despite the significant progress in crystallization process control, there is still an increasing demand for advanced, versatile, robust, and cost-effective real-time optimization and control strategies, driven by a broader adoption of Quality-by-Design and the emergence of pharma 4. Mathematical models and digital twins are increasingly used in all aspects of process design, optimization, control, and decision making.

Over the last few years, artificial intelligence has witnessed a resurgence of interest in very broad research and industrial areas. Reinforcement Learning (RL) is particularly interesting and has the ability address dynamic problems encountered, for instance, in robotics and automotive industries (Roveda et al., 2018). These advantages have motivated recent implementation of RL as a new control strategy for bioprocesses (Petsagkourakis et al., 2020). This paper outlines the first application of RL in the field of crystallization. The approach consists in designing and training a RL agent to perform a tracking control over multiple reference trajectories, namely process temperature, supersaturation and particle size in batch and continuous crystallization processes. The performance of this model based RL control, which aims at minimizing the training costs, was compared against well-established and benchmark control strategies such as MPC.

2. Problem Formulation

The primary objective of this work is to develop a controller able to follow a set of dynamic performance trajectories effectively and reliably. This trajectory tracking control will help achieve shorter batch times as well optimal start-up, shut down and transitions between productions rates (production ramp-up). The approach will also help maintain the product critical quality attributes, such as crystal size distribution, within the acceptable and safe margins. The reference trajectories can be computed using model-based open-loop dynamic optimization for both batch and continuous crystallization processes. As a first attempt, an optimal linear cooling profile is suggested.

A model-based RL controller was developed in MATLAB Simulink. The idea is to train an agent in closed loop to achieve the best performance (highest reward) over a series of training episodes. The agent takes dynamic actions by changing the jacket temperature or cooling rate (manipulated variable) and receives rewards and penalties (negative rewards) according to its dynamic performance against the reference trajectories and process constraints. The setup of the closed loop training strategy is shown in **Figure 1**. The first block contains the reference trajectories, which are three in this case (i.e. temperature, supersaturation, and particle size). The second part receives the observations, quantifies the rewards, and decides whether the training episode should be skipped or restarted if

certain criteria are met. The third block in this sequence is the RL Agent that constitutes the policy and the training algorithm. The fourth block is the process model which is represented by a system of differential algebraic equations.

The dynamic mathematical model of the continuous crystallization of paracetamol in water was derived from the population, mass, and energy balances. The kinetic parameters of the growth and nucleation were obtained from the literature (Nagy et al., 2008). The standard method of moments is used to capture the population dynamics. The primary nucleation and size independent growth were considered whereas the secondary nucleation, agglomeration and breakage were negligible. The moment equations, mass and energy balances are described by the set of nonlinear ordinary differential equations described below.

$$\frac{d\mu_0}{dt} = \frac{F_{seed}}{V} \mu_{0,seed} - \frac{F_{out}}{V} \mu_0 + B \quad (1)$$

$$\frac{d\mu_i}{dt} = \frac{F_{seed}}{V} \mu_{i,seed} - \frac{F_{out}}{V} \mu_i + iG\mu_{i-1} \quad (2)$$

$$\frac{dC}{dt} = \frac{F_{in}}{V} C_{in} - \frac{F_{out}}{V} C - \rho_c k_v \frac{d\mu_3}{dt} \quad (3)$$

$$\frac{dT}{dt} = T_{in} \frac{F_{in}}{V} - T \frac{F_{out}}{V} - 3 \frac{\Delta H k_v \rho_c}{\rho_t C_{pt}} G \mu_2 + \frac{UA(T_j - T)}{V \rho_t C_{pt}} \quad (4)$$

where F_{in} , F_{out} and F_{seed} are the inlet, outlet and seed flowrates respectively, μ_i is the i th moment, V is the volume of the crystallizer, C is the solution concentration, ρ_c is the density of the crystals, k_v is the volumetric shape factor, T_{in} , T and T_j are the inlet, process and jacket temperatures respectively, ΔH is the enthalpy of crystallization, U is the overall heat transfer coefficient and A the jacket surface area. The nucleation and growth rates are described below.

$$B = k_b \Delta C^b \quad (5)$$

$$G = k_g \Delta C^g \quad (6)$$

$$R_t = \underbrace{(10(|T_e| \leq 1) - 1(|T_e| \geq 1))}_{\text{Reward and penalty for maintaining the error within a acceptable range}} - \underbrace{\left(0.02 \left(\int |T_e|\right)\right)}_{\text{Penalty to minimise the effect of the accumulated error}} + \underbrace{\left(25 \left(\frac{T_s}{T_f}\right)\right)}_{\text{Reward for every incremental time step of the simulation period}} - \underbrace{(100(280 \geq T \geq 315))}_{\text{Penalty if the simulation is stopped in the middle by exceeding the temperature bounds}}$$

where $\Delta C = C - C^*$ is the absolute supersaturation. The mathematical model of the batch process can be obtained by eliminating the inlet and outlet terms ($F_{in} = F_{out} = 0$).

The proposed RL strategy relies on a Recurrent Neural Network (RNN) to parameterize the policy. RNN uses both process measurements and control actions as an input to deliver a probability distribution as an output. The efficiency of the policy strongly depends on the properties of the neural network. In this work we used the Deep Deterministic Policy Gradient (DDPG) method.

The defining of an appropriate reward function is critical in RL owing its evident impact on the quality and performance of the training. The decomposing of the rewards is the best way to teach the agent with small incentives for every little positive state observed and help achieve a good compromise between exploration and exploitation. Several reward functions have been used with different levels of complexity. **Figure 2** provides an example of the reward functions used in this work. Where R_t - is the reward given to the RL agent at time 't' of the simulation; T_e - the error between the process temperature and the reference profile; T_s - the time interval during which the RL agent takes a single control action; T_f - the final simulation time.

3. Results and Discussion

The RL results were obtained using the following settings: The actor network comprises 3 hidden layers and the critic networks has 25 hidden layers for the actions and observations. Each layer comprises 100 neurons, and each training episode consists of 300 steps. In addition to this several training parameters were optimized to achieve the best training performance which will not be provided for the sake of the brevity.

The RL approach was implemented to two different case studies. The first case focused on the trajectory tracking control of a batch crystallization, aiming at minimizing the deviation from a cooling profile while achieving optimal supersaturation and mean crystal size trajectories. This RL-based control strategy can be designed to minimize the batch time while maximizing quality. The second case considers the same set of process and product quality attributes but uses different reference trajectories. The approach can be designed to minimise start-up time and achieve high quality steady state performance.

In each case, the agent was trained using several training sets based on bespoke reward functions to achieve optimal training and control performances. The trained agent was validated against the reference trajectories in both cases and compared to a standard MPC, as shown in **Figure 3**. Overall, both MPC and RL perform well in terms of trajectory tracking. The RL seems to achieve better in the case of continuous crystallization.

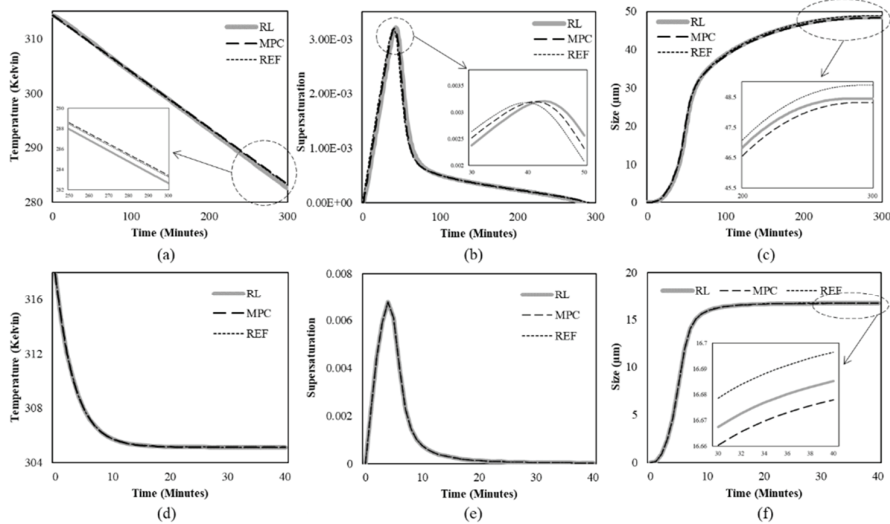

Figure SEQ Figure * ARABIC 3: Performance comparison of RL against standard MPC. (a), (b) and (c) for a batch system and (d), (e) and (f) for a continuous system.

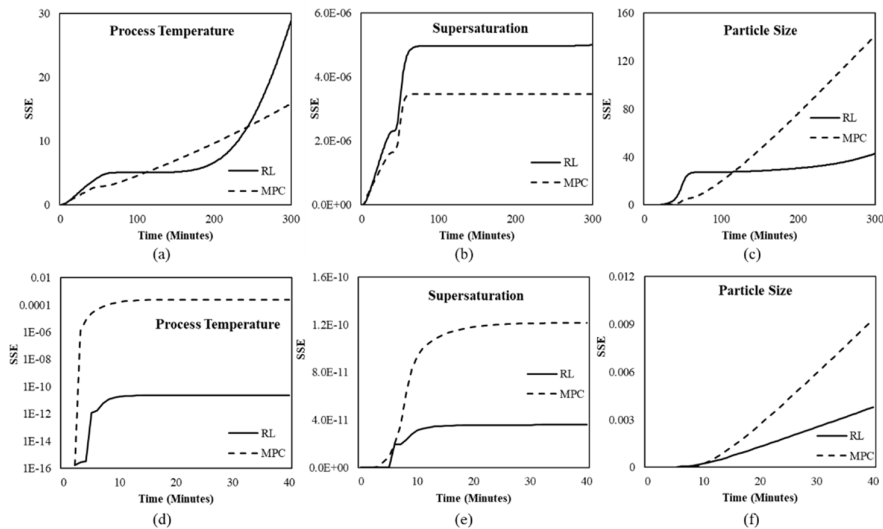

Figure SEQ Figure * ARABIC 4: Performance comparison between RL and MPC using the sum of the squared errors.

To analyze more effectively the performance of the RL-controller against the MPC, the sum of the squared errors (SSE) were computed systematically for each trajectory in both cases, batch and continuous systems, as shown in **Figure 4**. This quantitative approach makes it possible to gain more accurate insights into the control performance in each case.

4. Conclusion

A model based RL controller was designed and trained to address tracking control problems for batch and continuous crystallization processes. Three critical reference trajectories were considered namely: process temperature, supersaturation, and mean

crystal size. The jacket temperature was used as a control variable. The RL agent was trained using a range of reward functions to achieve the highest reward score, the fastest training and the best compromises between exploration and exploitation. The resulting RL-based controller was validated and compared against benchmark control strategies such as MPC. It was shown that the RL can achieve excellent performance, based on both qualitative and quantitative key performance indicators, despite the challenges inherent to the simultaneous tracking of three reference trajectories. As such, the RL can be a promising advanced process control candidate, where dynamic trajectory tracking, and constraint handling are required. Despite the computational burden, the development of model based RL, using reliable and predictable models, has a real potential to cut the high costs commonly associated with the training of the agent in real world processes. However, it is critical to assess the robustness of the agent in presence of model uncertainties, measurement noise and process upsets. This is precisely the current focus of the research group.

Process Monitoring under Uncertainty: An Opportunity for Bayesian Multilevel Modelling

Andrew J. Radcliffe,* Gintaras V. Reklaitis

*Purdue University, 480 Stadium Mall Drive, West Lafayette, IN 47907 United States
andrewjradcliffe@gmail.com*

Abstract

Bayesian modelling has recognized utility for system design, process monitoring and control strategy wherein decisions must be made under uncertainty. Applications to operation and quality assurance are particularly promising as the Bayesian paradigm enables unique multivariate probabilistic control strategies through the use of multi-level regression with post-stratification. This work demonstrates application to real-time quality control in a dropwise additive manufacturing system for pharmaceuticals. A variety of multilevel hierarchical models are developed, and rigorous model selection is performed using information criteria. Then, the probabilistic quality control strategy is presented in general form using transformations of the posterior predictive distribution, with results assessed on out-of-sample data.

Keywords: hierarchical Bayesian, multilevel modelling, machine learning, pharmaceuticals, additive manufacturing

1. Introduction

When a mechanistic model of a system cannot be fully defined, data-driven modelling provides an adaptable means of relating inputs to outputs, but often without allowing ready interpretation of the relationships obtained. The Bayesian paradigm enables the specification of known mechanistic structure, which can then be supplemented by the relationships implicit in the data, thus providing improved interpretability, while the use of probability as uncertainty measure provides a ready framework for decision analysis.

Bayesian approaches have attracted considerable interest for predictive purposes in process monitoring, control strategy, and systems design – where decisions must be made under uncertainty (Stamatis et al., 2018; Mockus et al., 2020). The ability to sensibly set up complex models with many parameters and multi-layered structure enabled by hierarchical Bayesian methods provides unique opportunities for addressing challenging problems in which a measurement model is used to predict quantities of interest from real-time sensor data. A simple example in which the data-level model is seemingly sufficient is the thermocouple, in which the measured voltage is related to temperature through its characteristic function under the assumption that the function is invariant under process conditions. In more complex sensors, the process conditions themselves may interact with the measured quantity in ways that cannot be accounted for by the measurement model. Such a scenario arises as the thermocouple ages, the thermoelectric properties change, and with them, the characteristic function. Hence the basic problem under consideration is how to utilize relevant information that arises from the process and device conditions, but which is external to the physics-based measurement model.

For inherently multi-level problems such as this, the hierarchical Bayesian approach enables creation of a model structure which reflects the relationship between phenomena, and therefore enables modelling of the parametric inter-/relations within levels, in addition to their relationship to the overarching physical variable spaces, thereby making full use of the extra information to improve predictive accuracy. As the posterior predictive distribution (PPD) is the method by which to rigorously evaluate event probabilities for new/out-of-sample data, this has direct use in control strategies based on model predictions.

In this work we demonstrate these ideas with an application to an image-based process monitoring and control strategy enacted on a dropwise additive manufacturing (DAMP) system for pharmaceutical dosage units. In previous work, a hierarchical Bayesian approach was used which involved categorical partitioning to construct hierarchical groupings across a database of 41 batches of drug products, spanning a wide range of process conditions and ink formulations (Radcliffe and Reklaitis, 2020). We expand these into multilevel models via nested hierarchical regressions on the coefficients of the image-derived explanatory variables using the numerous group-level explanatory variables which arise from the interaction of process conditions, fluid properties, and particle properties.

2. Modelling approach

The DAMP system produces dosage units through the sequential dropwise deposition of a suspension onto a substrate. The control strategy involves multiple aspects – fluid composition/rheology, temperature, substrate position; the process output – drops – is monitored in real time using an online image acquisition system. With the content of each tablet/capsule determined by the volume of material added to it, the online image data provides the means to enact quality control strategies at several levels of complexity.

2.1. Construction of the Explanatory Variables for Multi-level Regression

In our approach the historical process data is used to inform a multi-level model which takes as inputs at the data-level the features extracted from the online images, and at the upper-level the explanatory variables constructed from the process conditions. Physical reasoning plays a critical role in building the explanatory variables at both levels to achieve a hybrid model whose structure reflects the physics. Such hybrid approaches provide several advantages: enhanced interpretability, improved prediction at out-of-sample conditions, and lower requirements on volume of training data.

For use in the data-level model, each image is reduced to 8 explanatory variables: 1) primary drop volume, 2) summed satellite volume(s), 3) cylindrical approximation for partially observed satellites, 4) spherical approximation for partially observed satellites, 5) approximation for partially-observed primary drop at bottom border, 6) approximation for partially-observed primary drop at top border, 7) Euclidean distance from centroid of primary drop to image centre, and 8) mean of Euclidean distances from centroids of satellite drops to image centre. Partial observations necessitate the addition of parametric approximations for the missing volumes based on the geometry presented by each image and category of defect. The image processing, methodology and supporting logic for the image-derived explanatory variables are described in (Radcliffe and Reklaitis, 2020).

The operating conditions and suspension properties have substantial effects on drop formation. Though such variables do not belong in the data-level model, the existence of

interaction between the drops observed in the images and the underlying physics is undeniable. Including such effects requires a multi-level model in which the data-level parameters are themselves modelled using a regression on a set of upper-level explanatory variables derived from the process conditions.

In the DAMP operating with suspensions, the process conditions include ejection velocity, shear rate, nozzle radius, number of pump volume strokes, fluid properties (viscosity, density, surface tension), particle properties (size, shape, density) and particle loading. Dimensional analysis can be used to combine the numerous physical properties and process conditions, and thereby re-express them using the relevant dimensionless groups for drop formation and suspension rheology: Weber number, Ohnesorge number, suspension viscosity scaling with particle loading $f(\phi/\phi_{max})$, Stokes number and particle Reynolds number; the last two can be modified by the particle aspect ratio to produce shape-scaled variants.

2.2. Hierarchical Structure

In building a model, the extent to which data sets are similar is of fundamental importance in modelling as this determines the pooling choices and hence the model structure. Traditional methods offer two approaches: no pooling, or complete pooling; hierarchical modelling offers a third path: partial pooling, the extent of which is determined by the data. As the historical data consists of clearly portioned sets of dosage units (“a batch”) made distinct by the dosage properties themselves (e.g. target content, number of drops per unit) and their respective set of dimensionless variables, a hierarchical model can provide the necessary flexibility while avoiding overfitting.

In the context of the multi-level regression, each batch of doses (a matrix of image-derived explanatory variables) is allocated its own regression coefficient vector at the data level; the hierarchy is constructed based on the exchangeability of these vectors and is modelled through a multivariate prior. At the upper-level regression, there exists a vector of explanatory variables for each batch (dimensionless parameters), while the upper-level regression coefficients and covariance matrix are shared. This is shown in in Eq.(1)-(5).

$$y_n \sim normal\left(X_n B_{j[n]}, \sigma_{j[n]}\right) \quad n = 1, \dots, N \quad (1)$$

$$\beta_j \sim multinormal\left(U_j G, \Sigma_\beta\right) \quad j = 1, \dots, J \quad (2)$$

$$\Sigma_\beta = diag(\tau)\Omega diag(\tau); \quad \Omega \sim LKJcorr(2), \quad \tau_k \sim Cauchy(0, 2.5) \quad k = 1, \dots, K \quad (3)$$

$$G_{l,k} \sim normal(0, 5) \quad l = 1, \dots, L, \quad k = 1, \dots, K \quad (4)$$

$$\sigma_j \sim half-normal(a + bw_j, \psi) \quad j = 1, \dots, J \quad (5)$$

Support for the data-level model is based on the physics: the outcome (deposited volume, y_n) should be the sum of the contributions from the primary drop and satellite drop(s) weighted by the respective coefficients $\beta_{j,k}$. Given the high reproducibility of the process and apparent linearity of the deposited volume to image relation, a normal likelihood (Eq.(1)) is assigned to the outcome. The prior distribution on the $j=1, \dots, J$ vectors of regression coefficients is assigned a multivariate normal distribution (Eq.(2)). For each β_j there is a vector of upper-level explanatory variables, U_j ; the components of the matrix of regression coefficients, G , are assigned weakly informative priors (Eq.(4)). The covariance matrix of the multivariate normal is decomposed into a vector of scale parameters, τ , and a correlation matrix, Ω (Eq.(3)); the components of τ are assigned

weakly informative priors with the potential for heavy tails using the half-Cauchy distribution (Eq.(3)). The correlation matrix is assigned a Lewandowski-Kurowicka-Joe correlation (LKJcorr) matrix distribution with some amount of concentration toward the identity using $\eta = 2$ (Eq.(3)). The scale parameter of the data-level model is modelled parametrically (Eq.(5)) using the half-normal distribution with location parameter $a+bw_j$ and scale ψ , given the relevant explanatory variable, $w_j = 1/n_{drops}$; the slope and intercept of the regression are shared. Hyperpriors on a, b are the standard normal and $\psi \sim \text{half-normal}(0,1)$.

2.3. Model Comparison and Selection

With the form of the model established, there remain many possible choices for the data-level explanatory variables, X , and upper-level explanatory variables, U . Physical reasoning provides general guidelines, but it may not be readily apparent which to include/exclude. This problem can be approached systematically by evaluation of multiple models followed by comparison utilizing information criteria which account for the ability of a large/ more complex model to fit data better. One such fully Bayesian measure is the WAIC (widely applicable information criterion) (Vehtari et al. 2017). This measure can be used to screen hundreds of models to obtain a handful which are then examined further using graphical checks, posterior predictive performance on out-of-sample data, etc.

For the problem at hand, there are 6 possible combinations of X 's and 24 possible combinations of U 's, yielding 144 models. The possible combinations of X 's can be reasonably well-constrained by physical reasoning, e.g., $X_{1,2,3,4,5,6}$ should always be present as these are direct contributions to drop volume. However, it is not immediately clear whether the Euclidean distance measures ($X_{8,9}$) should be included; furthermore, there is the option of adding a constant intercept ($X_7 = 1$). For the upper-level explanatory variables, it is reasonable to forcibly include dimensionless groups related to drop formation – We (U_{j1}), Oh (U_{j2}) – and some measure of suspension behavior through $f(\phi/\phi_{max})$ (U_{j4}); alternately, $Oh:f(\phi/\phi_{max})$ can be used (U_{j3}). However, for other variables for which it is difficult to justify inclusion/exclusion *a priori*, terms are sequentially added to/ removed from the upper-level variable vector to construct 24 possible choices; these are denoted in the results as $U_j_l_*$, where the wildcard represents the member indices of included variables. Aspect-ratio (AR) scaling for the Stokes (U_{j5}) and particle Reynolds (U_{j6}) numbers is used for both or none. Pump volume strokes is also considered (U_{j7}).

3. Computational Methodology

Hamiltonian Monte Carlo with the No-U-Turn-Sampler, implemented in Stan (Carpenter et al., 2017), is used to draw samples from the joint posterior distribution of the model parameters given the training data. The historical dataset was partitioned into two equal halves: for each batch of doses, the odd dose indices ($i=1,3,5,\dots$) are allocated to the training data and the even indices ($i=2,4,6,\dots$) to the out-of-sample data. For each model, 4 Markov chains are simulated with warm-up period of 20,000 followed by sampling period of 20,000 iterations; this yielded 80,000 samples upon mixing. Convergence is assessed using the rank normalized \hat{R} , which must below 1.01 for a simulation to be considered for use; additionally, the effective sample size must be ≥ 400 to keep Monte Carlo error low.

Scalability of such computations can present unique challenges related to dynamic memory requirements, particularly during predictive uses, as the number of stored values

scales with proportionality $n_{\text{data points}} \times n_{\text{MCMC samples}}$. The Markov chain simulations themselves can be parallelized to fully utilize available compute resources: multi-process (1 chain per process), and multi-threaded within each process; the latter enables efficiency improvements via map-reduce, which is very helpful for log-likelihood computations.

4. Results and Discussion

4.1. Using the posterior predictive distribution

The major uses of the joint posterior distribution, $p(\theta|y,X)$, involve the PPD, $p(\tilde{y}|\tilde{X},y,X)=\int p(\tilde{y}|\tilde{X},\theta)p(\theta|y,X)d\theta$, in which θ denotes the model parameters. Predictive accuracy scoring utilizes the training data to compute scores based on the log predictive density; in this vein, WAIC is used to score predictive performance for each of the 144 models and identify superior variants, as shown in Figure 2. Detailed checks of the fit of the model to the training data, X, U, W , utilize the PPD to predict the distribution of the alternate possible realizations of the outcomes, y^{rep} ; then, test variables can be set up for this model and used to assess model performance (Radcliffe and Reklaitis, 2020).

To make predictions with regression models given out-of-sample data, $\tilde{X}, \tilde{U}, \tilde{W}$, the joint posterior draws are used to sample from the PPD of \tilde{y} . The PPD of \tilde{y} can be transformed by any function of interest, with full inference obtained on the transformed quantity since probability is conserved through transformations. Consequently, event probabilities can be evaluated in a straightforward manner on both \tilde{y} and transformed quantities; this enables probabilistic control strategies at multiple levels.

For the problem at hand, quality control can be enacted at the individual level (each dose) or for entire batches. For each new batch, there is a target value for content, T and a target tolerance, z , such that the quality specification requires each dose be within $[T(1-z), T(1+z)]$. The probability that a dose (index i) is within specification can be computed by transforming the samples from \tilde{y} using Eq.(6), then computing the expectation of the transformed variable, $E[f(\tilde{y}_i, T, z)]$. The distribution of the fraction of the batch within specification can be obtained by transforming the joint distribution of the transformed \tilde{y}_i 's using Eq.(7), in which I is the index set of doses in the batch. The samples from Eq.(7) can then be used to compute the probability that a desired fraction of the batch, denoted D , is within specification by transforming using Eq.(8) and taking the expectation of the result. In addition to event probabilities, transformations such as Eq.(7) can also be used to assess the predictive performance on new/out-of-sample data, as shown in Figure 1.

$$f(\tilde{y}_i, T, z) = \begin{cases} 1 & T(1-z) \leq \tilde{y}_i \leq T(1+z) \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

$$g(f(\tilde{y}, T, z), I) = \sum_{i \in I} f(\tilde{y}_i, T, z) / |I| \quad (7)$$

$$h(g(f(\tilde{y}, T, z), I), D) = \begin{cases} 1 & g(f(\tilde{y}, T, z), I) \geq D \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

The ability to compute event probabilities at multiple levels of abstraction provides a powerful method for multi-level control schemes. For example, suppose that $\Pr(g(f(\tilde{y}, T, z), I) \geq D)$ is low, and it is proposed that some doses from the batch be discarded in order to increase the probability. The decision of identifying the best candidates to exclude can be posed as an optimization problem in which the optimal solution is the index (sub)set which maximizes $\Pr(g(f(\tilde{y}, T, z), I) \geq D)$, subject to the constraint that the number of doses in the reduced batch be greater than some constant. Alternately, this can

be inverted: maximize the number of accepted doses, subject to the constraint that $\Pr(g(f(\tilde{y}, T, z), I) \geq D)$ must exceed some threshold.

Figure 1. Percentiles (2.5, 25, 50, 75, 97.5) of $g(f(\tilde{y}, T, z), I)$ respective to each batch at $z = 0.01, 0.025$. Actual values displayed as

Figure 2. WAI score for 144 models. Lighter color indicates better predictive accuracy.

5. Conclusions

In this work a multilevel hierarchical Bayesian model was developed for probabilistic quality control in a DAMP system. The hybrid approach utilized physical understanding in building the models, thereby increasing interpretability of the joint posterior and improved confidence in prediction at new conditions. Working in the Bayesian paradigm enabled rigorous evaluation of event probabilities through transformations of the PPD, which provides unique capabilities for optimization and quantitative decision analysis. Future work will expand on use in batch/lot optimization, in addition to considering more abstract problems wherein a sensible physical model is not available, but the data exhibits innate multi-level structure which can be leveraged.

Abstract

A pressure regulating station (PRS) is used to step down the pressure of gas distribution pipelines suitable for domestic or industrial users, irrespective of gas demand. A gas distribution network can have hundreds of PRSs. Hence, they are key assets, and have to be continuously monitored for condition deterioration and/or sudden faults. A PRS can be modelled using first principles, but it is computationally expensive. In this study, we developed a computationally cheaper machine learning based surrogate for a PRS. Subsequently, weekly cumulative flow is calculated for a PRS to monitor the filter choking and to predict the remaining useful life of the filter. Finally, a dashboard has been developed for monitoring the health of PRSs in a gas distribution network that can be integrated with online operational data for their condition monitoring and predictive maintenance. This can increase the reliability of a gas distribution network and reduce the maintenance cost.

Keywords: Gas Distribution Network, Pressure Regulating System, First Principles Modelling, Health Monitoring, Prescriptive Maintenance.

1. Introduction

Natural or town gas distribution requires a complex network of pipelines to supply gas from a supplier to the residential, commercial, and industrial end-users. Suitably placed pressure regulating stations (PRSs) are used to step down the supply pressure and maintain it within a specified range for the end-users, irrespective of the gas demand. Any issue with the PRS system should be identified and rectified before the supply of gas is adversely affected. As PRSs are critical assets of the gas distribution networks, they are carefully monitored for any health deterioration and potential faults (Leo et al., 2020).

Some vital potential health degradation and faults that may occur in a PRS are filter choking, spring decay, valve seat damage, diaphragm malfunction, and overloading of network. The health of PRS should be monitored for gradual decrease in the performance and/or sudden faults. Real-time operational data is critical for online monitoring and automated prescriptive maintenance of a PRS.

Depending upon the nature of operational data available for a PRS, both model-based and data-based techniques may be applied for its health monitoring. In this work, we applied a rigorous first principles model in for a PRS (Nabi and Dayan, 2000), which is validated using technical data provided by the vendor (RMG by Honeywell). However, a first principles based health monitoring may be computationally heavy for developing a fast

PRS health monitoring methodology for a large network. As an alternate, we have developed a computationally cheaper but equally effective machine learning (neural networks: NN) based surrogate to replace the first principles based model.

Figure 1: Overview of PRS with downstream network

Leo et al. (2019) have applied the PRS health monitoring methodology on a simulated case study. In this study, actual operational data from a gas distribution company is used. The schematic of a representative PRS is shown in Figure 1. Three potential pressure reading locations are shown in the figure. Our developed methodology for PRS health monitoring should be able to identify fault in filter, with high reliability and accuracy. In some cases, the intermediate pressure readings (P_{in}) are not available. Our methodology allows monitoring the filter chocking for both cases. For easy reference, let us call them Case 1 and Case 2. In case 1, available data set comprise all three pressure (P_0 , P_{in} , P_{out}). In Case 2, data for only two pressures (P_0 and P_{out}) are available.

Estimating Remaining Useful Life (RUL) is critical for the prescriptive maintenance of an equipment. The PRS health monitoring procedure includes prediction of RUL for its parts. Finally, a dashboard (a user-friendly GUI) has been developed for monitoring the health of all the PRSs in the gas distribution network. This dashboard can be further integrated with the real-time PRS operational data to extend health by advising on the prescriptive maintenance. In addition to supervising their gradual decline, the PRS health monitoring dashboard may also monitor swift abnormality in any PRS.

2. First Principles Model and NN Surrogate for PRS

Leo et al. (2019) have developed a first principles model for HON 280 pressure regulator. They have considered mass balance and energy balances across the flow chamber, and force balance on the assembly of valve seat and diaphragm. A pressure regulator reaches steady state almost instantaneously due to its faster dynamics compared to the downstream distribution network. Hence, solving the pressure regulator model assuming a steady state operation was found adequate.

The developed first principles model for a pressure regulator accurately predicts the flow rate using intermediate and downstream pressures (P_{in} and P_{out}). This first principles model is expected to be computationally expensive for online monitoring and fault detection of hundreds of pressure regulators in a very large network. Hence, we have developed a simpler and computationally cheaper surrogate. The neural network-based surrogate was developed using the available operational data (pressures) for a gas distribution network.

Figure 2: Development of neural network-based surrogates for 2- and 3-pressures cases

The NN-based surrogates (with 2 hidden layers) were developed using operational data (P_0 , P_{in} , and P_{out}) for the pressure regulator A (PR-A). The performance of the first principles model and surrogates were compared on the operational data of four pressure regulators (B with P_0 and P_{out} ; C, D, E with P_{in} and P_{out}). In other words, we developed surrogates for regulator A, and used them to predict the flows for other pressure regulators. Note that P_{in} (intermediate pressure in Figure 1) is not available for pressure regulator B, and $P_{in} = P_0$ (no pressure drop across the filter) is assumed for calculating flow rate using the first principles model. Figure 3 presents hourly flow rate calculated using the first principles model and NN-based surrogates. It can be seen that surrogates were able to predict the flow rate with high accuracy (~0.6 to 2.9% deviation from the first principles model). Table 1 compares the performance of the first principles model and surrogates for four pressure regulator data set. The NN-based surrogates require negligible computation time compared to the first principles model.

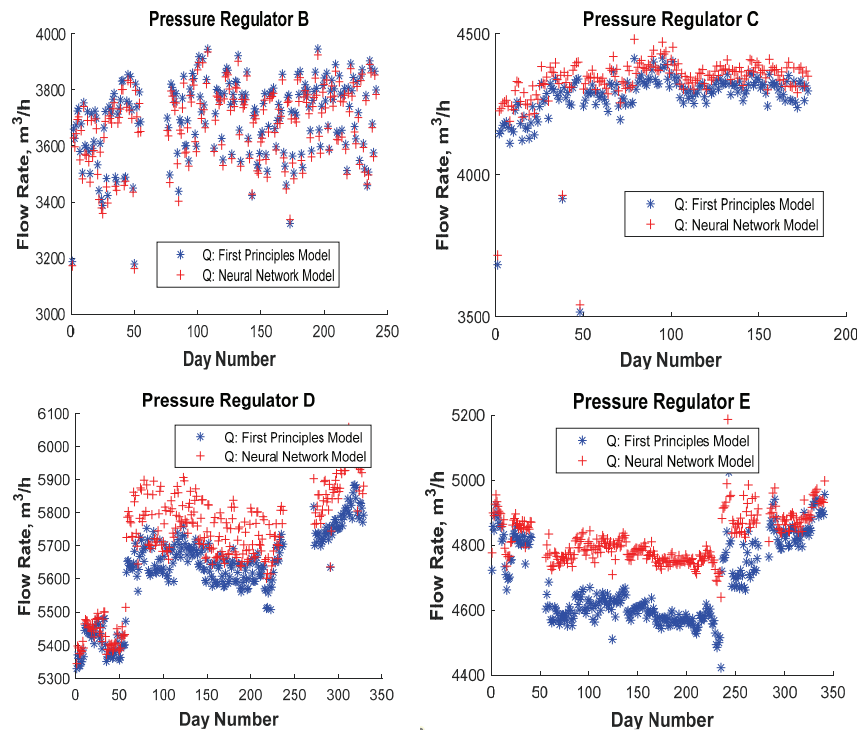

Figure 3: Hourly flow rate comparison using first principles model and neural network-based surrogates, for pressure regulators B, C, D and E

Table 1: Performance comparison between first principles (FP) model and surrogates (computer processor: i5-8265u @ 1.60 GHz & 1.80 GHz, RAM: 8 GB)

PR Name	Number of Samples	Computation Time (s)		Flow Difference b/w FP Model and Surrogates	
		FP Model	Surrogate	%	Absolute, m ³ /h
B (2P)	242691	2132	0.24	0.60	22.16
C (3P)	249753	3869	0.29	-1.28	-54.90
D (3P)	98057	859	0.20	-1.61	-91.19
E (3P)	105954	832	0.21	-2.90	-134.21

3. Monitoring Filter Choking on Gas Distribution Network Data

PRs are vital components in a gas distribution network. Hence, PR health monitoring is essential for a reliable gas supply to the customers. Leo et al. (2019) studied four PR faults on a simulated case study. Filter choking and spring decay cause an under pressure in downstream distribution network, whereas valve seat damage causes an over pressure of downstream distribution network. A PR does not work properly, if there is any damage in diaphragm. Leo et al. (2019) studied following three scenarios:

Scenario 1: P_{out} data at short intervals and cumulative flow at long intervals

Scenario 2: P_{out} and flow data at same intervals

Scenario 3: P_{in} and P_{out} data at same intervals

Mostly gas distribution companies do not measure flow rate for different pressure regulators. The gas flow is usually measured at the gas consumption sites (household, commercial or industry). Further, only inlet (P_0) and outlet (P_{out}) pressures are measured for many pressure regulators. Thus, we present a methodology for the two cases defined earlier, in the next section.

3.1. Weekly Cumulative Flow

In Case 1, monitoring of filter choking is easier as discussed by Leo et al. (2019). As stated above, both filter choking and spring decay cause under pressure downstream distribution network. Filter choking occurs much faster than the spring decay. Thus, spring constant can be assumed constant for monitoring filter choking over a relatively short time period.

An ideal pressure regulator will supply gas at P_{out} (= set point) regardless of the flow. For a real pressure regulator, if P_{in} is fixed, P_{out} will decrease with increase in flow (droop curve, Emerson, 2019). For a constant value of the inlet pressure (P_0), the intermediate pressure (P_{in}) decreases with increase in filter choking. In order to compensate for the decrease in P_{in} , P_{out} also decreases that increases cumulative flow calculated by the PR model. In this study, we have estimated weekly cumulative flow through the pressure regulators using the surrogates. The RUL of the filter can be estimated by fitting a line through the weekly cumulative flows. Maintenance should be carried out when weekly cumulative flow exceeds some threshold value. Figure 4 shows variations in the weekly cumulative flow for five pressure regulators. In order to predict the RUL, we used a

threshold value of 10^6 m^3 for weekly cumulative flow. The RUL values for different pressure regulators are also given on plots in Figure 4.

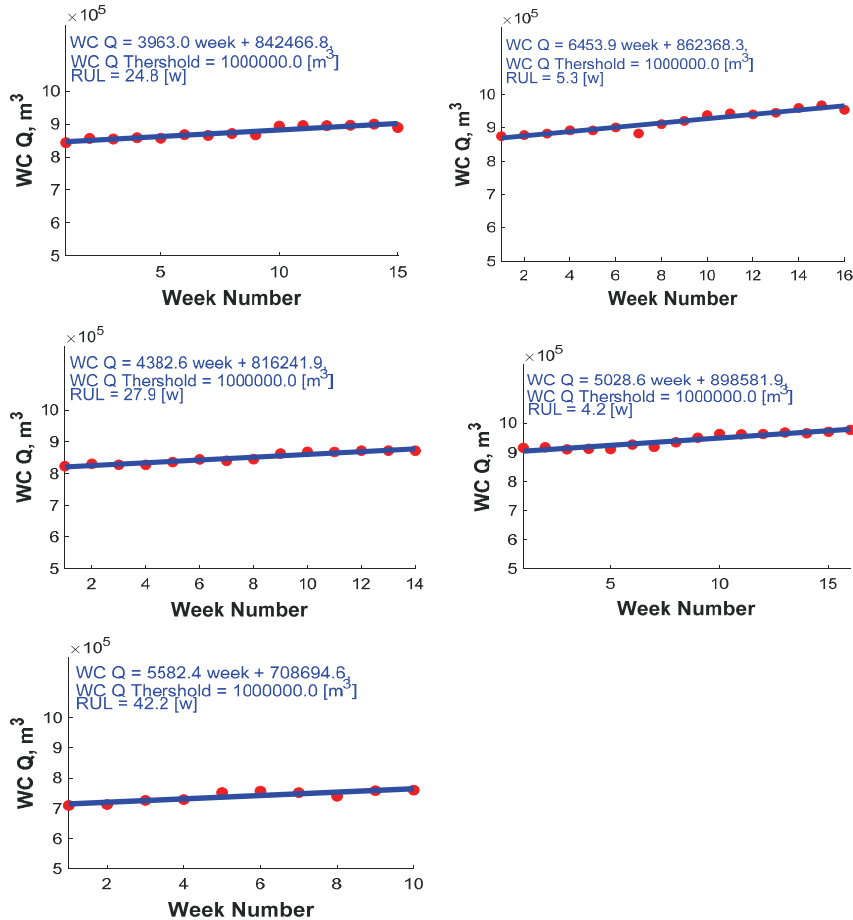

Figure 4: Weekly cumulative flow-based RUL predictions for five pressure regulators

3.2. Pressure Regulator Health Monitoring Dashboard

We have developed a dashboard for the health monitoring of the PRSs in a gas network. The pressure regulator dashboard has two parts: the ‘PR Group Analysis’ is used to analyse the performance of the pressure regulators in a group or region, and the ‘PR Performance Comparison’ is used to compare the performance of selected pressure regulators from the same or different groups or regions (see Figure 5). Some important flexible features of the dashboard are automatic update of data files, possibility of rearranging pressure regulators in different groups, selecting some or all pressure regulators for performance analysis, selecting start and end dates of analysis, and interactive display of results/plots.

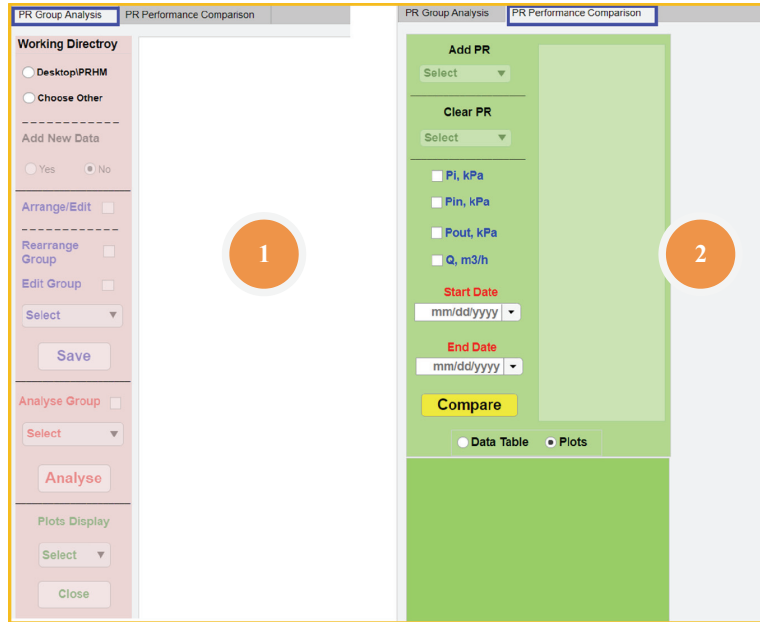

Figure 5: User interface of PRS health monitoring dashboard

4. Conclusions

The PRSs are key assets of a gas distribution network. This study compares the performance of first principles model and machine learning-based surrogate for some representative PRSs. It is demonstrated that weekly cumulative flow through the pressure regulators can be used to monitor the filter chocking and predict the RUL of the filter even if P_{in} data is not available. It is further shown that the PRS health monitoring dashboard under construction, if integrated with real time operational data of gas network, can monitor the filter health, and prescribe a predictive maintenance schedule. Other faults under investigation will be gradually included in the dashboard.

Abstract

Continuous monitoring of abnormal conditions during operation is an important requirement to increase the quality, and efficiency of chemical processes, and to optimize operating costs. In this study, fault diagnosis of abnormal conditions is considered for flocculation processes, which due to the complexity of these processes requires more attention. To this end, an unsupervised learning method is developed to diagnose the faults in chemical processes based on recurrence analysis. This method consists of two stages of pre-processing and clustering. The pre-processing stage is carried out by transferring the time series from time space to state space and converting the data into a two-dimensional recurrence plot. Quantitative parameters of recurrence analysis can be extracted from this plot. Then, in the clustering stage, the density-based spatial clustering of applications with noise (DBSCAN) method was used for clustering different operating conditions and diagnosing faults. By comparing the results with conventional methods, such as independent component analysis (ICA) and Kernel ICA (KICA) it was found that the developed method is more powerful and shows the best performance. Application of this method was illustrated throughout a laboratory scale flocculation of silica particles in water. An on-line non-invasive sampling method was used for monitoring the size distribution of particles with a dynamic image analysis sensor.

Keywords: Unsupervised learning, Recurrence plot, DBSCAN, Flocculation process, Fault diagnosis.

1. Introduction

Advances in bioprocessing equipment and instrumentation have increased the likelihood for diagnose of abnormal conditions while improving the process productivity and usability. Therefore, development of more powerful methods for monitoring the operating conditions of these processes is of particular importance. Process monitoring includes several stages of fault detection, diagnosis, and causal analysis. Fault diagnosis can be a significant help for operators and process engineers as it identifies the type of fault. Data-driven methods are widely used for this purpose since they do not need basic principles knowledge of the process (Tidriri et al., 2016). Among these methods, due to the frequent lack of information about the operating conditions, development of a method based on unsupervised learning is of greater importance. In general, any unsupervised fault

diagnosis method involves two general stages of pre-processing and clustering. In addition to the importance of clustering methods, the development and proper application of pre-processing methods is very important (Zheng and Zhao, 2020). The main research conducted in this field is based on the principal component analysis (PCA), independent component analysis (ICA) and other extensions such as Kernel PCA (KPCA), dynamic PCA (DPCA), and many more methods provided by (Liang et al., 2019, Bounoua and Bakdi, 2020). Sebzalli and Wang (2001) developed an approach based on PCA and fuzzy c-means clustering to classify the operational spaces of the RFCC reaction mechanism and grouped 303 cases in four clusters or operating zones. Also, Singhal and Seborg (2005) modified the *k*-means clustering algorithm with two similarity factors based on PCA and Mahalanobis distance to cluster time-series multivariate data from both batch and continuous chemical systems. However, despite the capability of time series analysis methods, only a few studies have been carried out in this field. Recurrence plots (Marwan et al., 2007) are among the powerful methods in the field of analysis and extraction of information from nonlinear, non-stationary and short time series (Ziaei-Halimejani et al., 2017). In this regard, Ziaei-Halimejani et al. (2021) conducted an unsupervised method using recurrence plot for fault diagnosis of Tennessee Eastman and four water tanks processes. They found that recurrence plot is a powerful method for isolating and capturing information of process time series. Accordingly, in this research recurrence plots were adopted for process monitoring of silica flocculation process. As a result, the main contributions of this research are: (i) development of a hybrid method of recurrence plot and density-based spatial clustering of applications with noise (DBSCAN) without the need for previous information about the operating conditions (unsupervised learning), and (ii) fault diagnosis of the silica flocculation process using the image processing technique

2. Experiment

Flocculation is a two-step aggregation phenomenon in which a large number of small particles form a small number of large flocs. In this study, a silica particle flocculation laboratory setup was employed to monitor the evolution of particle size distribution over time through data analysis (Nielsen et al., 2020). The particle size distribution was determined by the image segmentation algorithm developed by ParticleTech ApS (Farum, Denmark) (Nazemzadeh et al., 2020). As a result, time series of particle size distribution with particle area, minimum Feret size, maximum Feret size, mean Feret size, Feret ratio and other particle properties were obtained. The batch experiments were carried out for a range of process settings. Variation of the process settings affects particle interaction, which leads to variations in the flocculation rate. Accurate adjustment of the process settings improves the process efficiency, otherwise, abnormal conditions in the process may be encountered. The adjusted process settings are stirrer rotational speed and pH of the suspension. The stirrer rotational speed was adjusted by varying the voltage of the power supply of the stirrer and pH was varied by adding HCl (1 M) to move towards acidic conditions and NaOH (1 M) to move towards alkaline conditions. The particles used in this process were silica (acquired from Sigma-Aldrich, CAS no.: 7631-86-9) in demineralized water (0.015 wt% concentration). The suspension was then transferred to a stirring tank of 1.5 L. Also, a dynamic optical scanning device (oCelloscope by BioSense Solutions ApS, Farum, Denmark) was used to record images to monitor particle size distribution. The images were processed by ParticleTech Analyzer software, developed by ParticleTech ApS. In order to correctly diagnose different faults, six

different faults were artificially introduced into the process, which included step change, pulse and variation in the pH and stirrer rotational speed.

3. Theory

3.1. Recurrence Analysis

The Recurrence plot (RP) is a method based on the analysis of the recurrence/return behavior of time series (Eckmann, 1987). In this method, the time series is transferred from the time domain to the state space. By comparing all points of the time series trajectories in the state space and considering a radius threshold, recurrence plots can be constructed. The recurrence plot is obtained based on the following definition:

$$R_{i,j}(\varepsilon) = \Theta(\varepsilon - \|x_i^p - x_j^p\|) \quad i, j = 1, \dots, N \quad (1)$$

where N is the number of measured points x_i , ε is the radius threshold, Θ is the Heaviside function and $\|\cdot\|$ is the norm for measuring the distance between trajectories. If the difference between two trajectories is greater than ε , the Heaviside function is, $R_{i,j}(\varepsilon) = 0$. On the contrary, if the distance is less than ε , the Heaviside function becomes one, $R_{i,j}(\varepsilon) = 1$. For plotting this matrix, a black dot is shown in place of 0 and a white dot in place of 1. According to its definition, the RP is a symmetric plot and its main diagonal line is black. According to this definition, each point shows the recurrences of dynamical system states.

Complex structures in the recurrence plots include many information about the dynamic behavior of the time series. For example, diagonal lines indicate uniform and predictable behavior, and single points indicate noisy and random behavior. In addition to qualitative analysis, quantitative analysis of these patterns is required in order to accurately extract information from the time series. In this regard, the determinism (*DET*) is defined as the ratio of diagonal structures recurrence points to all recurrence points (Ziaei-Halimejani et al., 2018).

3.2. Clustering

Data clustering is a type of unsupervised classification in which a set of data is automatically placed in different clusters without any labelling. There are various methods in this field, most of which are statistical data analysis and data mining. Clustering methods are generally divided into five categories: hierarchical, partitional, distribution-based, density-based, and grid-based methods (Xu and Tian, 2015). In this study, the density-based DBSCAN method was used.

This algorithm, like other clustering methods, requires finding the proximity of data. Euclidean distance can be used to measure distance (similarity). To describe the algorithm, it is necessary to determine distance threshold (d) and minimum points of each cluster (*MinPts*). Each point in the dataset is different from other points. Any point for which the distance from a given point is less than d is considered a neighbor of that point. Also, any assumed point that has neighboring *MinPts* is a central point. In general, in the DBSCAN algorithm, a point is optionally selected that has not been visited before. The neighborhood of this point is checked with distance threshold (d). If it has the required minimum number of neighborhood points, a cluster is created; otherwise, it is labelled as a noise point. Note that after visiting all points, this point may be in the neighborhood of other points and become a part of another cluster (Saxena et al., 2017). In order to evaluate the performance of the proposed method, the adjusted rand index (*ARI*) was used, calculation of which is described by Hubert and Arabie (1985).

3.3. Method Framework

Fault diagnosis of the silica flocculation process using particle size distribution properties was carried out in the steps of the flowchart shown in Figure 1.

Figure 1. Overall workflow of the developed method for process fault diagnosis

4. Application on silica flocculation process

In order to diagnose faults associated with silica flocculation process, the particle size distribution time series was extracted from the reactor at normal operating conditions and used as input to proposed algorithm. In the pre-processing stage, after normalizing the data, the input parameters of the recurrence plot, including time delay (τ), embedding dimension (m), sub-series length (S_i) and radius threshold (ε) were determined. In this study, these values were calculated as 1, 2, 35 and 0.06, respectively. In this step, recurrence plots of time series were obtained. An example of recurrence plot for the particle size in the flocculation process during the normal operating condition is shown in Figure 2. The diagonal lines of recurrence plot correspond to the recurrence behavior of this process, at which its dynamics can be predicted by recurrence plots. In addition, the absence of the same patterns and the presence of single points in the plot indicate chaotic and nonstationary behavior. In order to extract this information in the form of quantitative index without any uncertainty, the determinism parameter was used.

Figure 2. Recurrence plot of silica particle diameters during normal operating condition

After this step, by calculating the determinism of the RP and comparing it with normal operating condition values, three variables with the highest rate of change were selected and a three-dimensional graph was obtained. Figure 3 shows the geometric location of the three variables with the highest rate of changes for various faults of the silica flocculation process. As shown in this figure, various faults are isolated by values of their determinism in different geometric locations. It can be seen that the determinism has properly isolated various faults of the process in different geometric locations. However,

in order to properly understand the extent of this quality, the DBSCAN method was used for clustering of the obtained three-dimensional graph.

Figure 3. Geometric location of various kinds of faults in silica flocculation process

Also, the results of the clustering were evaluated with the previously available methods, which were displayed in the *ARI* criterion. The results for the *ARI* criterion were given in Table 1. In order to compare the results of the developed method with other available methods, the results of the ICA and KICA method were also given in Table 1. As shown in this table, the RP-DBSCAN method is a powerful method in fault diagnosis of the silica flocculation process.

Table 1. Evaluation criteria result of different fault diagnosis scheme for silica flocculation process

Method of Diagnosis	Evaluation Criteria (<i>ARI</i>)
ICA-DBSCAN	0.68
KICA-DBSCAN	0.73
RP-DBSCAN	0.85

5. Conclusions

Fault diagnosis of abnormal condition in chemical processes is one of the main phases of on-line monitoring, which requires more attention due to the very high complexity of these processes. Therefore, in this study, flocculation of silica particles was considered for fault diagnosis. To monitor the particle size distribution of particles with an image analysis device, an on-line sampling method was used. In the proposed method, by transferring time series from time domain to state space and converting them into a two-dimensional image of a recurrence plot, the pre-processing stage was accomplished. At the end, the time series was converted into quantitative recurrence parameters. Then, the DBSCAN method was used in the clustering stage to cluster various operating conditions and diagnose faults. It was found that the quality of the developed method stood at a high level and showed the best performance by assessing and comparing the results with conventional methods.

Abstract

Biochemicals produced from lignocellulosic residues appear to be a feasible alternative to replace current chemicals derived from oil. Nevertheless, some important challenges need to be overcome in order to achieve a feasible transition towards biochemicals. These challenges are the biomass seasonality and availability, selection of suitable feedstocks, potential biorefineries allocation, as well as numerous economic environmental, social restrictions. Those challenges can be addressed through the design of a suitable supply chain. In this work a multi-period supply chain to produce furfural from agricultural wastes of Mexico is proposed, this model was written and optimized in GAMS. The demand of furfural was selected in order to replace the raw materials used to produce the terephthalic acid, which is imported to Mexico. Economic, environmental, and social criteria were chosen to evaluate the supply chain performance. Finally, the results obtained show that it is feasible the replacement of the current raw materials for producing terephthalic acid by furfural produced from agricultural wastes. The supply chain solution with the best tradeoff among the different metrics consists of a net profit of 1000 million USD/year, 19000 jobs generated and 370 million of eco-points /year.

Keywords: Furfural Production, Supply chain, Agricultural wastes, Social Impact, Biorefinery.

1. Introduction

Nowadays, the several problems associated with the climate change, pollution and the depletion of fossil resources have forced humanity to seek renewable resources and develop new technologies for using them. In this sense, the lignocellulosic residues

generated by agricultural activities are considered as promissory alternative to fossil resources due to their abundant availability, low costs and because they are not in competition with food, preventing ethical dilemmas. In the case of Mexico, it has 20 million of hectares destined for agricultural purposes, according with data provided by the Ministry of Agriculture and Fishing of Mexico (SAGARPA). This land generates about $5.86 \cdot 10^8$ metric tons of lignocellulosic residues each year, however, only the 5% of those residues are reused or leveraged. On the other hand, data from Ministry of Ecology and Climate Change (INECC) indicate that a significant amount of these agricultural wastes are burned in the harvest site generating around the 5% of the total CO₂ emissions of Mexico (INECC,2017; SAGARPA,2019).

Based on the aforementioned, the reutilization of these agricultural wastes for manufacturing new generation of bio-chemicals, bio-materials and fuels provides important and benefits since economic, environmental and social point of view. In this sense, the U.S. National Renewable Energy Laboratory (NREL) has catalogued the 30 most important chemicals produced from biomass and with the capability to compete with chemicals derived from fossil resources. In this list, the furfural stands out over other bio-chemicals because its several industrial applications for producing a wide range of commodities. Currently, the furfural is employed to produce lubricant oils, diols, solvents, furan resins and fuels (Cai et al., 2013). However, in recent years, novel furfural applications have been proposed, in this way, the manufacture of polymers and plastics to such as polyethylene terephthalate (PET), polyester or Nylon 6-6 has attracted special attention. Despite, the immense potential of bio-chemicals such as furfurals, some obstacles like biomass seasonality and availability, farmers planting decisions must be overcome in order to achieve a feasible transition towards the eco-friendly. These obstacles generate a not continuous supply of agricultural wastes and therefore an inconsistent production of bio-chemicals, as consequence several difficulties to satisfy the market demand are presented. These challenges can be overcome by an appropriate supply chain (SC) design where all those aspects are considered. A properly designed SC offers adaptability for providing feedstocks to a biorefinery and at the same time, it provides the ability to generate an optimal operational schedule and planning in order to satisfy the production required.

This work proposes the use of a supply chain model as a tool to determine the feasibility of producing furfural from agricultural wastes in Mexico at industrial scale. The demand for furfural is assumed to be the one that replaces the importation of chemicals required to produce terephthalic acid (TA). The TA is high added value chemical used in the manufacturing of polyethylene terephthalate (PET), polyester fibers, molding resins, adhesives. This study allows to determine the feasibility of replacing the current chemicals by renewable ones in the production of important current commodities. Based on sustainability criteria suggested by Garcia and You, (2015) the Economic, environmental, and social aspects were considered as the most important indicators to evaluate the supply chain solution. The economic objective is maximization of net profit, whereas the environmental impact and social objectives are the minimization of eco-indicator 99 and the maximization of the jobs generated, respectively.

2. Methodology

This work proposes the use of the four most abundant lignocellulosic residues produced each year in Mexico. The choice of raw materials was carried out according with data

provided by the Ministry of Agriculture and Fishing of Mexico (SAGARPA,2019). Based on the data provided by SAGARPA the most abundant lignocellulosic wastes produced each year in Mexico are corn stover, wheat straw, sorghum bagasse and sugarcane bagasse. In order to take into account, the biomass seasonality in each harvest site, a multiperiod inventory planning with one-year of time horizon is proposed. This horizon has been divided into the four different time periods ($t \in T$), one period for each season of the year. Figure 1 illustrates the superstructure considered for the supply chain. With the aim of providing a more realistic distribution of biomass, the Mexican territory was discretized into 59 different regions. This discretization was performed based on population data, where the zones with less population have larger lignocellulosic wastes availability, the biomass availability of each zone was fixed according with data provided by SAGARPA.

Figure 1. Supply chain superstructure.

In order to solve the problem in a simpler way some assumptions are considered. The centroid of each zone is the point where all the agricultural residues are located. This consideration could be easily relaxed only increasing the discretization zones to generate smaller sub-regions. Additionally, it is considered that the biomass is stored at the harvesting sites, which prevents the monetary losses provoked by the transportation of biomass that will not be used due to its degradation in the biorefineries. Finally, only one biorefinery per region is allowed, the biorefineries are characterized by significant use of water, this assumption avoids the excessive use of water and at the same time, it avoids the depletion of the total biomass located per region, which can be used for other purposes as cattle feed. The transportation distances and centroids locations are calculated using the Rhumb line method, which is a common method used in cartography to estimate distances. Furthermore, all the parameters required by this method can be easily obtained from Google Maps.

3. Mathematical Model

This section provides the mathematical formulation for the supply chain for furfural production and the corresponding objective functions used to evaluate the supply chain performance. The mathematical model was formulated as multiperiod Mixed Integer Lineal Programing (MILP).

The mass balances at the harvest sites can be modelled using the follow equation:

$$A_{i,j,t}^{RM} = A_{i,j,t-1}^{RM} (1 - \alpha_{j,t}) + b_{i,j,t}^{RM} - \sum_k S_{i,j,k,t}^{RM} \quad i, j \in J^{RM}, t \quad (1)$$

Where $A_{i,j,t}^{RM}$ and $A_{i,j,t-1}^{RM}$ are the inventory levels at a harvest site for a specific time and previous period, respectively. $\sigma_{i,t}$ represents the loss factor coefficient by biomass degradation, $S_{i,j,t}^{RM}$ is the shipments of biomass j from a harvest site i to a furfural plant k . Finally, $b_{i,j,t}^{RM}$ represents the lignocellulosic wastes required at a harvest site, it is calculated as follows:

$$b_{i,j,t}^{RM} \leq \varphi_{i,j,t} \quad i, j \in J^{RM}, t \tag{2}$$

Where $\varphi_{i,j,t}$ is the availability of lignocellulosic waste j at a harvest site i at a period t .

The shipments of lignocellulosic wastes from harvest to the furfural plants can be constrained as follows:

$$\sum_i b_{i,j,t}^L \cdot y_{i,j,k} \leq \sum_i S_{i,j,k,t}^{RM} \leq \sum_i y_{i,j,k} b_{i,j,t}^U \quad i, j \in J^{RM}, k \tag{3}$$

Where $b_{i,j,t}^L$ / $b_{i,j,t}^U$ represents the lower/upper bounds for the wastes required in a harvesting site, $y_{i,j,k}$ is the binary variable for selecting a specific shipment arc $i \rightarrow k$ (shipments from harvest to furfural plant).

In order to guarantee a continuous biomass supply to furfural plants, a cyclic inventory was used, which can be implemented assuming that the biomass storage in the last period ($t=T$) is equal to the storage at beginning period ($t=0$), according with the follow equation:

$$A_{i,j,t=T}^{RM} = A_{i,j,t=0}^{RM} \quad i, j \in J^{RM}, t \tag{4}$$

The mass balances for the furfural plants (biorefineries) were modeled in similarly. Additionally, three different criteria have been considered to evaluate the performance of the supply chain. These criteria are the net profit, environmental impact, which is calculated using the Eco indicator 99 and finally the jobs generated in the different activities of supply chain, the jobs generated are calculated using the Jobs and Economic Development Impact methodology (JEDI), more information about these objectives is provided by Santibanez-Aguilar et al., (2014). Mathematically, the three objectives function can be expressed as follows:

$$\min \quad Z = \{-\text{Profit}; EI99, -\text{Jobs}\} \tag{5}$$

Subject to:

$$\gamma^L \leq \sum_k S_{j,k,m,t}^P \leq \gamma^U \quad j \in J^P, m, t \tag{6}$$

The Eq.6 indicates as the shipments ($S_{j,k,m,t}$) are constrained between upper (γ^U) and lower bound (γ^L) respectively. Finally, this multi-objective optimization problem was solved using the ϵ - constrained method, in order to find a tradeoff among different objectives, more information about this method is provided by Diwekear (2008)

4. Results

The model proposed consists of 194,207 equations, 16,284 binary variables and 282,316 continuous variables. This model was solved using a computer with AMD Ryzen 5-1600 @3.2GHz, and 16GB of RAM @2400MHz. Each Pareto point was solved in an average time of 600s. The solver used was CPLEX with a relative gap of 1%. Figure 3 shows the Pareto fronts for all combinations of objectives. The form of these graphics can be easily explained based on Eq.6. Please note, that this equation restricts the solution between a lower and upper bound for the demand. The lower bound represents the demand required and the upper bound is the minimum demand plus an excess of 10%. Therefore, the extreme lines of the Pareto fronts correspond to different solutions operating between lower upper bounds. The average difference between the lower and upper bounded solutions is about 11% which is expected owing to the difference between bounds is 10%.

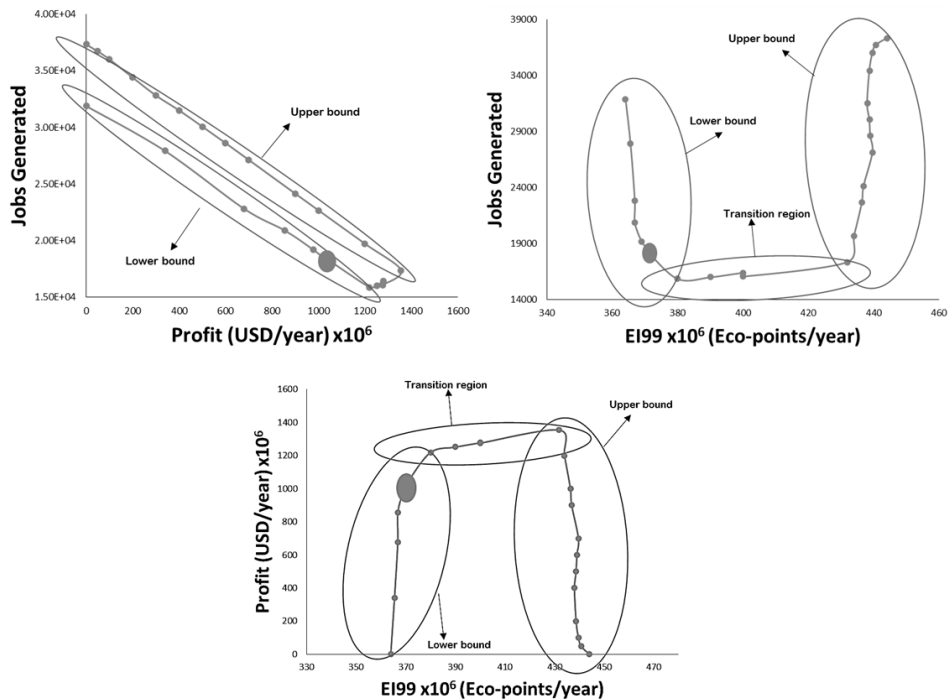

Figure 2. Pareto Fronts for furfural supply chain.

Please note, the large dots in Figure 2 correspond to the solution considered with most appropriate trade off among different metrics, thus this point was selected as the best SC solution. In this point the SC has around 75% of the maximum profitability, also the EI99 is close to its lower limit and the jobs generated are 19500 jobs, which signifies almost the 50% of the maximum possible jobs. It is important to highlight that this number of jobs is associated with different activities of the supply chain, such as recollection and distribution of raw materials and products, manufacturing in different furfural plants etc. In addition the profit was performed considering current funeral sale price of 2500USD ton. The biomass inventory in this point is given in Figure 3a. The results show that only corn stover and wheat straw are required to produce furfural due to the lower manufacturing cost than sorghum bagasse and sugarcane bagasse. Moreover, based on Figure 3a, it results evident that the production of furfural is based on corn stover principally, because the availability of wheat straw is less, especially during the period $t=1$ and $t=2$ (spring and summer). For this reason, significant amounts of corn stover must be stored in order to keep a constant furfural production.

Figure 3b illustrates the shipments of lignocellulosic wastes, during each time period. The results show a clear relation between the biomass availability and the shipments. During spring and summer ($t=1$, $t=2$), when the wheat straw availability is low the shipments are mainly based in corn stover. However, during autumn and winter seasons ($t=3$, $t=4$) the wastes shipments are based on wheat straw. These results also indicate that most furfural plants that use corn stover as raw material will be active during seasons in which corn stover is abundant, the same behavior occurs with wheat straw.

Figure 3. Biomass inventory and shipments levels for one-year time horizon.

5. Conclusions

In this work a supply chain model for furfural production is proposed. This mathematical model is used as a tool to determine the feasibility of producing furfural at industrial scale using as raw materials agricultural residues of Mexico. Economic, environmental and social aspects, where considered as indexes to evaluate the supply chain solution and to improve the sustainability of supply chain. Based on the results, the furfural production using agricultural residues to replace chemicals derived from petroleum is feasible. The results showed important profits up to 1250 Million USD/year. The optimal SC solution consist in a profitability of 1056 million USD/year, 19300 jobs generated and 370 million of eco-points /year.

Abstract

Optimisation models for the design of distributed energy systems (DES) often exclude inherent nonlinearities and constraints associated with alternating current (AC) power flow and the underlying distribution network. This study aims to assess this gap by comparing the performance of linear and nonlinear formulations of DES design models, connected to and trading with an AC grid. The inclusion of the optimal power flow (OPF) constraints within the DES design framework is demonstrated in the methodology. A residential case study is used to test both models and compare the designs obtained from the two formulations. The results highlight that DES designs obtained are different when constraints related to the underlying distribution network are added, particularly when electricity storage is not considered. Overall, this study highlights the need for future modelling efforts to include OPF within DES optimisation frameworks to obtain practically feasible designs, rather than considering them as standalone problems.

Keywords: distributed energy system, optimal power flow, mixed-integer nonlinear programming

1. Introduction

The implementation of DES has become increasingly attractive as the power industry aims to integrate more renewable energy resources into existing networks while avoiding costly grid upgrades. DES consist of local, often privately-owned, small-scale energy resources, many of which are renewable. Optimisation models for design and operation of DES are commonly used to determine the suitability and location of the energy resources, and their performance over the system lifetime (Mavromatidis et al., 2019). However, these models often exclude inherent nonlinearities associated with AC power flow, despite most DES generating AC power and interacting with the main electricity grid. Power flow constraints, which are nonlinear and nonconvex, are included in OPF models which determine capacities of distributed generators and calculating active and reactive powers within the network, while maintaining voltage limits (Frank & Rebennack, 2016). OPF has often been treated as a standalone problem and not adequately accounted for in DES design formulations. Modellers often choose to exclude these nonlinear and nonconvex constraints in DES design models to obtain more computationally tractable models, and achieve an accuracy-complexity balance (De Mel et al., 2020). Mixed-integer linear programming (MILP) models are the most used formulations for DES design, with direct current (DC) approximations that exclude reactive power flows. However, the consequences of doing so have not been adequately analysed, with preliminary studies suggesting that either excluding or linearising certain key constraints can result in practically infeasible designs (Mashayekh et al., 2017;

Morvaj et al., 2016). This study addresses the increasing need to compare these different levels of approximation and establish which level is most suitable to achieving an accuracy-complexity balance and practically feasible designs.

2. Methodology

Four model formulations for DES design are employed in this study: 1) an MILP model with a general active power balance, based on works by Mehleri et al. (2012) for PV constraints and general power balances, and Mariaud et al. (2017) for battery representations and parameters, 2) a nonlinear programming model (labelled NLP-1) serving as a post-optimisation check with fixed binary decisions and capacities obtained from the MILP, and detailed AC power flow constraints, 3) an NLP model similar to model 2 (labelled NLP-2), however with capacities unfixed and treated as variables, and 4) a mixed-integer nonlinear programming (MINLP) model with detailed AC power flow constraints. All models minimise total annualised cost, which includes technology investment costs, operation and maintenance costs, and income from relevant tariffs. Each of the buildings comprising the DES can install one or more of the following distributed energy resources (DERs): solar photovoltaics (PVs), lithium-ion batteries, and boilers.

An OPF formulation based on the bus injection model in polar form (Frank & Rebennack, 2016) for a single-phase, balanced, low voltage network is utilised. It includes nonlinear and nonconvex constraints for net active (Eq. (1)) and reactive power (Eq. (2)), considering node $n \in \mathbf{N}$ and branch $(n, m) \in \mathbf{L}$:

$$P_{n,t} = V_{n,t} \sum_{m=1}^N V_{m,t} ((G_{nm} \cos(\theta_{n,t} - \theta_{m,t}) + (B_{nm} \sin(\theta_{n,t} - \theta_{m,t}))) \quad \forall n \in \mathbf{N} \quad (1)$$

$$Q_{n,t} = V_{n,t} \sum_{m=1}^N V_{m,t} ((G_{nm} \sin(\theta_{n,t} - \theta_{m,t}) - (B_{nm} \cos(\theta_{n,t} - \theta_{m,t}))) \quad \forall n \in \mathbf{N} \quad (2)$$

where the variables voltage magnitude and angle are denoted by $V_{n,t}$ and $\theta_{n,t}$, respectively. Note that parameters line conductance (G_{nm}) and line susceptance (B_{nm}) are obtained via bus admittance calculations (Frank & Rebennack, 2016). The OPF formulation also includes inequality constraints to ensure voltage magnitude and angles remain within specified lower and upper bounds. The layout of the network and connections are specified using a bus connectivity matrix for the set of all branches \mathbf{L} . Note that a node which injects power has positive power flow, while a node absorbing power has negative power flow. Current limitations are introduced in Eq. (3) where current magnitude in each branch, expressed as a function of voltage, cannot exceed the network-specified maximum current I^{max} (Frank & Rebennack, 2016):

$$\begin{aligned} & (V_{n,t} \cos \theta_{n,t} - V_{m,t} \cos \theta_{m,t})^2 + (V_{n,t} \sin \theta_{n,t} - V_{m,t} \sin \theta_{m,t})^2 \\ & \leq \frac{(I^{max})^2}{y_{nm}^2} \quad \forall (n, m) \in \mathbf{L} \end{aligned} \quad (3)$$

where y_{nm} refers to the magnitude of series branch admittance (which is usually calculated in complex form using the parameters series resistance (R_{nm}) and reactance (X_{nm}) for each branch). The OPF and MILP are linked by the following equality constraints for each house i connected to node n , forming the overall MINLP formulation for DES design (Frank & Rebennack, 2016):

$$P_{n,t} = P_{i,t}^{Gen} - P_{i,t}^{Load} \quad (4)$$

$$Q_{n,t} = Q_{i,t}^{Gen} - Q_{i,t}^{Load} \quad (5)$$

These determine whether the respective node is an injection or load node by calculating the net active and reactive powers, respectively. Note that the same OPF formulation is also used in the NLP models, with linear DES constraints and fixed binary decisions.

3. Results

3.1. Case study

The models are tested using the residential DES network available in Morvaj et al. (2016) in a UK context, using seasonal averaged values for electricity demand and heating demand as inputs (note that cooling is not considered in this study). Solar irradiance data obtained from Met Office (2020) are also fed as inputs to the model. Demands, available area for PV installation, and available volumes for battery installation at each location are summarised in Table 1. Note that the model considers 24 hours (one representative day) for each season, discretised into hourly timesteps. Other input parameters include DER efficiencies, capacity and area of a solar panel, and battery parameters such as maximum state of charge/discharge, volumetric energy density, etc. The DES is assumed to operate under the Feed-In-Tariff scheme (Ofgem, 2019) over 20 years, which provided prosumers with tariffs for renewable energy generation and export. Separate day and night prices are used for buying electricity from the grid to encourage battery installation.

Table 1. Average daily demands for electricity and heating per day

Building	Peak Electricity (kW)	Peak Heat (kW)	Area available (m ²)	Volume available (m ³)
A	3.8	10.0	150	5
B	18.4	47.6	700	5
C	14.1	27.1	600	5
D	3.8	6.4	150	5
E	12.0	31.3	550	5
<i>Total</i>	<i>52.2</i>	<i>122.3</i>	<i>2150</i>	<i>25</i>

The NLPs and MINLP are fed with network-related parameters, such as nominal voltage, resistance (R) and reactance (X), as presented in Figure 1. Note that the power factor (PF) for solar power is set to unity.

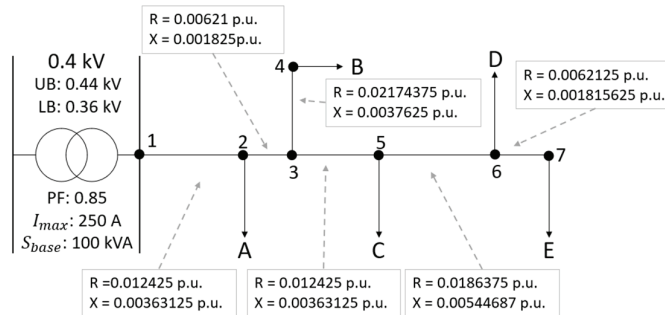

Figure 1. The distribution network and parameters, where S_{base} is the base apparent power. Two scenarios are tested 1) PVs and boilers only, and 2) PVs, batteries and boilers.

3.2. Results and discussion

The MILP, NLP and MINLP models are solved using CPLEX (IBM, 2019), CONOPT (Drud, 1985), and SBB (Bussieck and Drud, 2001), respectively, all on an Intel® Core™ i7-10510U processor. It is not possible to guarantee global optimality in the MINLP and NLP solutions, as the formulation is nonconvex and we experienced difficulties using global solvers. The statistics of the models (with all the technologies) are summarised in Table 2. The MINLP and NLPs are initialised using the MILP solution.

Table 2. Number of variables and constraints in the complete models employed in this study.

Model	Continuous variables (#)	Binary variables (#)	Constraints (#)
MILP	4,473	980	9,317
NLP	8,217	-	16,113
MINLP	8,217	980	16,133

The most notable differences in results were observed in Scenario 1 (PVs and boilers only), which are summarised in Table 3. While the MILP provides the best objective value and chooses the highest total PV capacity of 307 kWp, the post-optimisation check conducted via NLP-1 suggests that this solution is unattainable when grid constraints are considered. It is evident that curtailment of solar power is carried out in NLP-1 at nodes 1 and 2 in summer due to current violations in the network, which is also reflected by the lower income and thus an objective value approximately 6% greater than that of the MILP. This is further confirmed in Figure 2, which shows the current in branch (1, 2) (which carries the highest current out of all branches) for all four models. Both NLP-2 and MINLP opt to install lower PV capacities of 294 kWp and 287 kWp, respectively, to achieve lower objective values than NLP-1, while maintaining grid constraints. The capacities of boilers installed across all four models are the same (122 kWth), which is reflected in the boiler investment and operation costs.

Table 3. Solutions obtained from all four models for the PVs and boilers only scenario.

Breakdown	MILP	NLP-1	NLP-2	MINLP
Time taken (s)	5.29	5.57	5.84	6.86
Objective value (£)	43,793	46,380	46,158	46,102
Relative optimality gap	0	-	-	0
PV investment (£)	54231	54231	51825	50693
Boiler investment (£)	480	480	480	480
Battery investment (£)	0	0	0	0
Grid electricity (£)	37944	37944	38294	38448
PV operation (£)	5446	5382	5160	5055
Boiler operation (£)	5240	5240	5240	5240
Generation income (£)	50976	48938	47310	46498
Export income (£)	8572	7959	7532	7316

Figure 2. Current in branch (1, 2) calculated for all four models. Note that the MILP branch current was calculated via the NLP with current constraints deactivated.

Interestingly, in Scenario 2 where batteries are included in the model formulation, all four models produce the same objective value of £37,566. The total capacities for PVs (307 kWp), batteries (322 kWh), and boilers (122 kWth) across the models are the same. These results suggest that batteries allow the network to compensate for any potential violations by storing power rather than selling all excess power to the grid. Despite the capacities being equivalent, the operational strategies proposed in the models vary, particularly, the quantities of excess electricity and times it is sold as shown in Figure 3, and/or the batteries are charged. Note that the integrals of these variables across all timesteps and nodes are the same across all four models. In Figure 3, although it appears as if the excess power sold in the nonlinear models are bounded at ~100 kW, this is a result of including the current constraint (Eq. (3)) and the value varies between 102.8 kW and 103.1 kW in the models. Note that it is necessary to use an OPF formulation to determine the maximum amount of power that can be sold without violating this constraint for each case study, as it is sensitive to the design and parameters used. The MILP operational strategy is tested using a modified version of NLP-1, with fixed variables for selling electricity and charging the battery. This renders the model infeasible, confirming that the MILP strategy is unattainable without violating current constraints.

Figure 3. Total excess power sold at each time point.

Despite including nonconvex constraints, the models solved within seconds as highlighted in Table 3 (this included initialisations). However, computational expense may increase significantly if the network is enlarged to include more nodes, particularly if solved as an MINLP. In that case, using a model such as NLP-2, where an MILP is

solved first to obtain and fix binary decisions, may enable the modeller to achieve an accuracy-complexity balance without excluding network constraints.

4. Conclusions

This study focuses on consolidating two previously standalone problems, design of distributed energy systems and optimal power flow, and comparing results from linear and nonlinear model formulations for DES design. The methodology demonstrates the inclusion of nonlinear and nonconvex active and reactive power balances when formulating optimisation models for DES design, as well as other network-related constraints. Results highlight that inclusion of nonconvex constraints guarantees that the design is practically feasible and allows the inclusion of key network constraints that rely on both active and reactive power flow calculations. While the MILP model produces a better objective value for the presented case study when electricity storage is not considered, this is misleading as the inclusion of OPF constraints shows that this would not be realised in practice. Including these constraints also significantly impacts the operation of the DES, regardless of whether electricity storage is available or not, and therefore should be investigated further using DES operational models. Future work includes the extension of the nonlinear model to consider a larger, three-phase unbalanced network where voltage violations may also occur. Other network-related constraints such as line thermal limits and transformer limits will also be considered. Using sensitivity analysis to quantify the effect of uncertainties present in the system and therefore analyse the intermittence of renewable generation may further shed light on the significance of including network constraints.

Abstract

The lack of collection and processing infrastructure for waste management in developing countries is an overwhelming concern. Moreover, the growing generation of waste makes this problem even more complex. Specifically, in Mexico, the waste generation per day is approximately 0.13 MT. Landfill space is becoming increasingly constrained in some large urban centers where there are no other processing technologies, thus the use of open dump systems might be needed. The Mexican environmental protection agency (SEMARNAT) has reported that in 2012 from all the waste generated in Mexico, 72% was disposed of at sanitary landfills and regulated sites, while 23 % was disposed of at open dumps and the rest 5% was recycled. Considering these issues, we propose to optimize municipal solid waste management systems using a coordinated framework. The framework accommodates distinct stakeholders involved in the system, such as suppliers of waste, consumers of waste and derived products, and providers of transportation and processing services. The proposed optimization formulation seeks to maximize the collective profit and to balance supply and demand for waste and derived products. To achieve this, in the proposed framework, the stakeholders submit bids to a market coordinator that solves the optimization problem to find the allocations and clearing prices that guarantee that no stakeholder loses money. The framework also allows the monetization of environmental impacts, such as open dump disposal. Therefore, a taxation scheme to account for this environmental impact is evaluated. To illustrate the applicability of the presented approach, a municipal solid waste (MSW) system in Mexico was analyzed as a case study. Results show how taxation incentivizes the provision of services for all stakeholders. Furthermore, the minimum tax required to avoid diverting waste to open dump systems was identified.

Keywords: waste management, stakeholders, coordinated markets, taxation.

1. Introduction

MSW management is a complex problem that has been addressed through different approaches. Such as a taxation framework to incentivize recycling (Ko et al., 2020), a waste management cycle to guide policy regulations (Jiang et al., 2020), and mathematical models for the optimization of the MSW supply chain (See for instance:

Santibañez-Aguilar et al., 2013). Particularly in developing countries, the lack of infrastructure has led to great environmental issues including open dump disposal.

In the presented work, we propose to address the optimization of MSW management systems using a coordinated framework. We consider distinct options for the generated waste including recycling, sanitary landfills, and open dumps. Within the coordinated framework, the following stakeholders are identified: suppliers of waste, consumers of waste, consumers of products, providers of transportation, and providers of processing technologies. Specifically, in the MSW system, these stakeholders are urban centers that generate waste, sanitary landfills that consume waste, processing facilities that consume waste, urban centers that consume derived products, transportation providers that move waste or products, and transformation providers that treat different types of waste. We consider that the waste that is not allocated to consumers (sanitary landfills or processing facilities) ends up in open dumps. This problem is common in developing countries. Currently, there are not specific economic regulations associated with this practice. Therefore, to monetize this environmental impact, we include a taxation scheme. In this approach, we show how the coordinated framework allows identifying suitable tax structures and maximizing the collective profit of all stakeholders.

2. System Description

The stakeholders of the system and the proposed superstructure are presented in Figure 1. Here, we can identify the consumers, suppliers, and providers (transportation and transformation) that participate in the MSW system. Note that each of these stakeholders manages different types of waste or products at a particular geographical location (urban centers). The players are categorized by the type of waste they handle plastic, metal, organic, glass, and non-recyclables. Furthermore, subtypes are involved in some waste. For instance, for glass, we consider clear, green, and brown glass. We consider that each urban center involves a specific generation rate of waste and has available sanitary landfills, open dumps, and processing facilities. Furthermore, the transformation providers offer different types of treatment and technologies for each type of waste. The transportation providers can move waste to sanitary landfills and processing facilities. These providers can also move products to final consumers. Regarding open dump disposal, we observe that the waste that is not sent to sanitary landfills or processing facilities is sent there. It is assumed that this type of disposal does not involve any economic cost. However, the environmental cost is considered through the proposed taxation scheme. To avoid open dump disposal, we include a tax for the waste sent to such systems. Within the coordinated framework, this tax is considered as a service that the environment provides to the waste suppliers.

Into the coordination system, the suppliers, consumers, and service providers submit bids to an independent system operator (ISO). This coordinator uses the bidding information to clear the market by identifying the optimal allocations and clearing prices for all stakeholders. The next section describes these considerations.

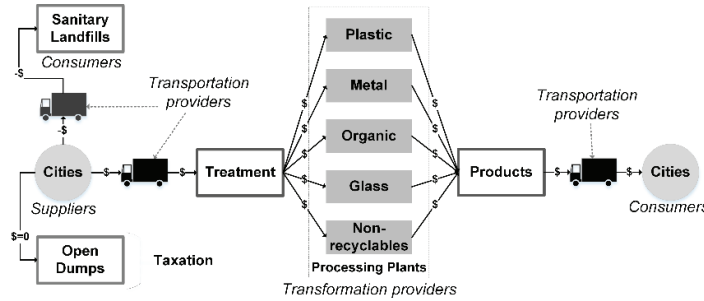

Figure 1. Superstructure for the coordinated system.

3. Coordinated Framework

The proposed framework guarantees that no cleared stakeholder loses money (payments collected are equal to payments made). This is possible because the solutions provided by the ISO satisfy a set of economic properties (Sampat et al., 2019). The solution procedure is as follows. First, the bids are submitted to the ISO (they can be positive or negative). In Figure 1, we can observe that almost all stakeholders offer positive bids (\$), however, the sanitary landfills offer negative bids (-\$). This negative bid refers to a payment that landfill suppliers are willing to give the market for taking away their waste. Furthermore, the negative bid of landfill consumers involves that the landfill will take the waste only if it is paid for this action (such as a disposal fee). Once this information is provided, the ISO solves an optimization problem to clear the market. Here, the collective profit of all stakeholders is maximized. As part of the clearing process, the allocations, prices, and profits that balance supply and demand are found. It is considered that, when a player is not cleared, no product is allocated, and this stakeholder does not participate in the market. The cleared stakeholders are paid based on their allocations and clearing prices. Specifically, transportation providers are paid considering the differences in prices at the source and destination locations. Similarly, the transformation providers are paid considering the prices of their input and output products.

4. Model Formulation

The formulation of the coordination problem involves geographical locations N , products P , consumers D , suppliers S , transportation providers K , and transformation providers M . The bidding information $(\alpha_d, \beta_s, \gamma_k, \delta_m)$ and the maximum capacities for the demand, supply, and service providers are given parameters. As shown in Eq. (1), the objective function seeks to maximize the collective profit. This profit is the difference between the demand served and the costs of supply, transportation, and transformation. The solution to the problem includes finding the optimal allocations (c_d, g_s, q_k, f_m) .

$$\max \sum_{d \in D} \alpha_d c_d - \sum_{s \in S} \beta_s g_s - \sum_{k \in K} \gamma_k q_k - \sum_{m \in M} \delta_m f_m \quad (1)$$

These allocations satisfy the physical conservation laws and capacity constraints of the following equations. The clearing prices are also part of the solution and they are estimated through the dual variables $(\pi_{n,p})$. These variables act as market clearing prices because they set values for products P at each geographical locations N . Here, $\zeta_{m,p}$ is the conversion factor for each technology and product.

$$\text{s.t } \sum_{s \in S_{n,p}} g_s - \sum_{d \in D_{n,p}} c_d + \sum_{k \in K_{n,p}^{\text{in}}} q_k - \sum_{k \in K_{n,p}^{\text{out}}} q_k + \sum_{m \in M_n} \zeta_{m,p} f_m = 0, \quad (2)$$

$$(n, p) \in N \times P, (\pi_{n,p})$$

$$0 \leq c_d \leq c_d^*, \quad d \in D \quad (3)$$

$$0 \leq g_s \leq g_s^*, \quad s \in S \quad (4)$$

$$0 \leq q_k \leq q_k^*, \quad k \in K \quad (5)$$

$$0 \leq f_m \leq f_m^*, \quad m \in M \quad (6)$$

These allocations and prices are used to charge consumers and remunerate providers. For the clearing prices of each stakeholder, we use the notation $\pi_d, \pi_s, \pi_k, \pi_m$. These prices along with the bids and the allocations are used to compute the profits of stakeholders as follows. Eq. (7) refers to the profit for consumers that is the difference between the allocated demand ($\alpha_d c_d$) and the payment made to the market ($\pi_d c_d$). For suppliers, their profit is estimated as shown in Eq. (8). Here, $\pi_s g_s$ refers to their revenue and $\beta_s g_s$ represents their operating cost. Similarly, the profits for the transportation and transformation providers are computed by Eq. (9) and Eq. (10).

$$\phi_d^D = (\alpha_d - \pi_d) c_d, \quad d \in D \quad (7)$$

$$\phi_s^S = (\pi_s - \beta_s) g_s, \quad s \in S \quad (8)$$

$$\phi_k^K = (\pi_k - \gamma_k) q_k, \quad k \in K \quad (9)$$

$$\phi_m^M = (\pi_m - \delta_m) f_m, \quad m \in M \quad (10)$$

The resulting model is linear and was solved through the GAMS modeling environment using the solver CPLEX.

5. Results and Discussion

To illustrate the applicability of the approach, we evaluate a case study of an MSW system in the central-west region of Mexico. Here, five urban centers (Morelia, Celaya, Apatzingan, Lazaro Cardenas, and Leon) are considered. These centers act as suppliers and consumers. We use the notation $l-5$ to refer to where each stakeholder is situated. Each stakeholder has a specific flow, product type, capacity, location, and bidding cost. Also, we assume that 1) the urban centers have equal technologies available for treatment, 2) the transportation bids exist to move the waste and products between locations, and 3) landfill suppliers are willing to pay for the service of taking away their waste. For the

taxation scheme, the minimum tax required to avoid open dump disposal was identified and evaluated for the case study. To compare the impact of the taxation, two scenarios were analyzed. We consider the Scenario I): a base case without taxation in which the impact of open dumps is ignored, and the Scenario II): a tax of 5.1 USD/t is applied to the waste disposed of at open dumps. We found that the collective profit of the system is 871,744 USD and 784,061 USD for Scenarios I and II, respectively. Note that when the environmental impact of open dump disposal is penalized the profit decreases. For the plastic, organic, glass, and non-recyclable waste, we found that no transformation providers participate (for both scenarios). Therefore, the suppliers (*S1-S5*), consumers (*D1-D5*), and transportation providers (*K1-K5*) refer to the waste sent to the landfill. For Scenario I, there is no waste sent to the landfills. On the other hand, for scenario II, the waste is sent to sanitary landfills and open dump disposal is avoided because of the taxation. Only for metal waste, the processing providers are cleared. Thus, part of this waste is sent to treatment. In the following, we present some of the obtained results. Figure 3 shows the profits for glass waste. The types of glass are denoted by *G1*, *G2*, and *G3*. Here, we observe that the transportation providers attain the smallest profits. On the contrary, the landfill suppliers make the highest profits. We can see that stakeholders *S1* and *K1* attain the highest benefits of the suppliers and providers, respectively. For the consumers, the stakeholder *D5* makes the highest profit. Note that all profits are positive. Regarding the types of glass, *G3* (corresponding to brown glass) represents most of the total profit. These results are similar in behavior to the solutions for plastic, organic, and non-recyclable waste since the same stakeholders are cleared. The specific profits vary due to the involved flows, bids, and prices. However, through the presented results we intend to illustrate the type of solutions that can be obtained using the coordinated framework. For metal waste, there is an important variation in the solutions since the transformation providers participate here (see Figure 4). Here, we observe the profits for involved stakeholders. As expected, the profits of the plant supply are the highest. We can see that only one plant consumer is cleared (*D1*). For the transportation providers, the profits are greater for Scenario I because no metal is sent to the landfill. For the processing providers, only the stakeholder *M1* is cleared. The profit of this stakeholder is 1,070,035 USD for both scenarios. Note that the profits for the transformation providers do not change with the taxation scenario since the tax is not involved on the recycled waste.

Figure 2. Profits for supply, demand, and transportation providers of metal for Scenarios I and II.

Figure 3. Profits for landfill supply, demand, and transportation providers by types of glass in Scenario II.

6. Conclusions

This work presented a coordinated framework for multiple stakeholders in MSW systems. We considered the waste sent to treatment, sanitary landfills, and open dumps. A taxation scheme was included to account for this environmental impact. We analyze two different scenarios (with and without taxation). The results show how the tax incentivizes stakeholders to avoid open dump disposal. Furthermore, the optimal prices and allocations for the suppliers, consumers, and services providers of all types of waste were found. The collective profit was maximized, and the individual profits were identified (all of them non-negative). We evaluated a case study to show the applicability of the formulation, however, the model can be applied to any case study.

Abstract

Turkey is one of the richest countries in terms of renewable energy resources. At the same time, the largest portion of the account deficit of Turkey is due to energy import. Optimization studies for design, integration and management of renewable energy is therefore crucial in terms of increasing overall energy efficiency. In addition, energy sources and demands in Turkey have significant uncertainty and meeting the market conditions in a profitable manner is a challenging task. Stochastic programming is an efficient approach to deal with the aforementioned challenge. It requires introducing representative and comprehensive scenarios for the optimal design and scheduling. In this study, the aim is to propose a systematic and generic scenario generation method which is compatible with historical data, dependable for forecasts, and easily tunable for the scenario likelihood. Main contributions of this work are as follows: The uncertainty in the model parameters are propagated to the forecasts to obtain prediction intervals under a desired confidence, which provides probabilities of each scenario over the whole time horizon with predetermined likelihood the generated scenario set (e.g., likely, rare or statistically very low probability). Thus, scenario reduction is not needed. We implemented our method for Yalova, a developing city in Turkey, for the scenario generation of wind speed, population, air temperature, electricity consumption and solar irradiance, with a prediction horizon of 20 years. We also developed a preliminary mixed-integer linear programming (MILP) decision making model which computes both the optimal equipment investments and the optimal sub-hourly scheduling sequences of the equipment based on these scenarios and economic considerations.

Keywords: energy systems integration, renewable energy, scenario generation, mixed-integer linear programming, stochastic programming.

1. Introduction

Optimal design and management of energy systems must take uncertainties and volatilities into account. Deterministic models represent only the most likely behavior in contrast to stochastic models where the uncertainties due to varying demands, market conditions and other variables are considered additionally. In other words, random distributions with problem specific tunable parameters are incorporated to the

optimization in order to introduce the probabilistic nature of energy systems (Zakaria et al. (2020)).

In stochastic optimization, scenario tree construction is a major approach in which a particular distribution function is discretized. In this approach, different probabilistic scenarios are generated with predetermined and limited branches in order to deal with computational load. Monte-Carlo sampling, optimal quantization and moment matching are prominent methods based on statistics for scenario tree construction (Löhndorf (2016)). In Monte-Carlo sampling, a uniform probability random sampling is done over the region (Ekblom and Blomvall (2020)). On the other hand, in optimal quantization, a distribution function is estimated by optimization whilst in moment matching method, optimization is performed by considering the higher order moments because first few moments do not represent the whole distribution (Löhndorf (2016); Høyland et al. (2003)).

In this study, empirical time series models with tunable parameters are formulated for the air temperature, solar irradiance, wind speed, population and energy demand. For the prediction intervals of associated variables, the covariance matrix of the model parameters are calculated. Those prediction intervals having a particular probability distribution function are used for the generation of scenarios based on their likelihood. The highlights of the study are summarized as: Empirical models for the instantaneous air temperature, electricity demand, solar irradiance and population prediction are obtained through training actual historical data. Using parameter uncertainty propagation, covariance matrices and prediction intervals of prediction variables are calculated. Sampling for scenario generation is performed over these predefined intervals eliminating the need for scenario reduction to avoid additional computational effort. In addition, parameter uncertainty propagation builds a wider domain for scenario generation that is expected to increase the optimal design's robustness by taking account of both the most likely representing usual operating conditions and the most unlikely cases representing extreme conditions such as sharp changes in the load demand or weather conditions. The proposed method is implemented on the optimal design of a hybrid renewable energy micro grid to be placed in Yalova, which is a developing city in Turkey. This is a pioneer and sole case study in which real historical Yalova data are used to generate scenarios based on uncertainty propagation (Yilmaz and Dincer (2017); Turkdogan (2020); Talebi et al. (2016)).

2. Theoretical Background

2.1. Formulation of Empirical Models

All wind speed, solar irradiation and ambient temperature data are obtained from real data using the Darksky API (API (2020)) and electricity consumption data were taken from UEDAS, the official electricity distributor of Yalova. The empirical parameters related to wind speed, solar irradiance, electricity demand etc, with index j , are calculated by using nonlinear optimization as the following:

$$\min_{p_j} \sum_{i=1}^N \| f_j(t_i, u_i, p_j) - y_i \| \quad (1)$$

where N is the number of measurement samples; p_j is the vector of parameters in equation j ; t_i is the time instant of measurement; u_i is the input to the equation; y_i is the measurement; f_j is the formed empirical equation for the prediction of y_i . Corresponding empirical time series models are obtained by parameter estimation using historical data. Formulated empirical models for daily and instantaneous air temperature and solar irradiance show

sinusoidal trend while wind speed model exhibits Weibull distribution. For brevity, only electricity demand and population models are given explicitly in the results part. The daily electricity demand is a function of population and time:

$$E_{daily} = p_{e,daily,1} \sin\left(\frac{2\pi}{360}(t + p_{e,daily,2})\right) + p_{e,daily,3} + p_{e,daily,4} P_t \quad (2)$$

where P_t is the population of the city at time t . The daily electricity demand demonstrates both seasonal and hourly differences by the presence of sine function. P_t is determined through:

$$P_t = P_0 + P_{p,1}t + P_{p,2}t^2 \quad (3)$$

where P_0 is the reference population. The hourly electricity demand is calculated from:

$$E_h = (p_{E,h,1}t_h^4 + p_{E,h,2}t_h^3 + p_{E,h,3}t_h^2 + p_{E,h,4}t_h)E_{daily} \quad (4)$$

2.2. Uncertainty Propagation

Parameter covariance matrix is a measure of variations from the mean parameter values. Different parameter samples which result in different prediction profiles are obtained after parameter combinations are generated with Cholesky decomposition based methods. By this way, ultimate uncertainty is calculated considering parameters' probable variations (Chakraborty (2006)). Taylor series expansion using only first order term is utilized for uncertainty propagation in this study (Tellinghuisen (2001)):

$$cov_y = Jcov_pJ^T \quad (5)$$

cov_y is the output covariance matrix; cov_p is the parameter covariance matrix; J is the Jacobian matrix evaluated at the desired prediction regime. cov_y is a measure of prediction uncertainty (Borenstein et al. (2011)) to be considered in scenario generation by participating in upper and lower bound of prediction interval as follows (Lane and Dumouchel (1994); MathWorks (2020)):

$$f_j(t_i, u_i, p_j) - \lambda\sqrt{cov_y + MSE} \ll y_i \ll f_j(t_i, u_i, p_j) + \lambda\sqrt{cov_y + MSE} \quad (6)$$

λ , which is the coefficient of standard deviation of the mean value of i^{th} output variable, depends on the confidence level and is calculated through the inverse of Student's t cumulative distribution function. MSE is the mean squared error coming from the Eqn 1.

3. Scenario Generation

Inverse transform sampling is performed (Sugiyama (2015)) over a predefined interval as shown in the Eqn 6 to create the scenarios under their desired likelihood. This sampling provides to manage the probabilities of scenarios such as the most likely or the most unlikely. For example, a likely scenario which has one standard deviation interval is sampled more closely to the mean rather than the tails of the probability distribution function. On the other hand, a mid-likely and unlikely scenario which are sampled more closely to the tails than the mean have two and three times standard deviation interval, respectively.

4. Results

Despite its small area, Yalova is an important city with a large population density and open to development due to its geographical and industrial location. It is surrounded by big industrial cities such as Istanbul, Bursa, and Kocaeli and there are ferry lines with these three cities having major industrial and financial companies. The climate of the city is very suitable for growing agricultural products with high commercial value. Because of all these reasons, Yalova is the city that has increased its share in the gross national product the most in the last ten years.

Figure 1a: Population PIs

Figure 1b: Population scenarios

Figure 2a: Electricity demand PIs

Figure 2b: Electricity demand scenarios

Figure: 1. Population prediction intervals and scenarios. 2. Electricity demand prediction intervals and scenarios.

As shown in Fig.1.a and 2.a, since the cumulative uncertainty propagates along with time, range of the prediction interval becomes wider while time horizon is extending. Fig. 1.b and 2.b show the generated scenarios over a constrained time interval because when the scenarios are drawn over the whole time period, the figures look unclear. In the figures, the scenarios sampled from the unlikely, mid-likely and most-likely prediction interval are indicated instead of the whole interval for the representation of the distribution.

5. Case Study

We developed a deterministic MILP decision making model whose objective is to maximize the profit of the design and management of an integrated renewable energy system grid for the city of Yalova, for the upcoming 20 years. This model computes the optimal equipment investment decisions together with their rated powers and capacities, and the optimal sub-hourly scheduling sequences of these equipment. Exact linearization is applied on the nonlinear unit commitment constraints. The model also takes into account spinning reserves, peak shaving, time value of money as correction factor, piecewise generation equation formulations for both solar and wind energy and strict emission limits for CO₂ (Mavromatidis et al. (2018)).

The objective function of the model is written as:

$$\max f^{\text{revenue}} - CRF f^{\text{initial}} - \sum_{k \in K} J_k^{\text{operational}} \quad (7)$$

where $f^{revenue}$ is the income from sales, CRF is capital recovery factor, $f^{initial}$ is the initial cost representing the fixed and variable costs for the investment, $f_k^{operational}$ is operational cost for year k , and K is investment period. The deterministic MILP model is formulated to supply all of the electricity demand of the city of Yalova and it is assumed that the selling price of the supplies of the system are 5 percent less than the usual price. All wind speed, solar irradiance, ambient temperature, population and electricity demand data were collected as mentioned in Section 2. Afterwards, these data are fed to the suggested scenario generation framework to obtain the required future predictions as a scenario. The decision making model is coded into the GAMS language and solved with the CPLEX solver. 32 different equipment, including both renewable and non-renewable, are characterized as candidates for the superstructure. As expected, optimal solution consists of only a subset of these equipment. Optimal equipment decisions are shown in Table 1 with the corresponding rated power values.

Table 1: Installed equipment in the optimal solution of model

Installed Units	Rated Power (kW)	Capacity (kWh)
Wind Turbine-1	200000 (upper limit)	
Wind Turbine-2	200000 (upper limit)	
Wind Turbine-3	29278.96	
Battery-1	69616.24	199019.49
Heat Pump	2006.9	
Reciprocating Internal Combustion Engine-3	9341	
Fuel Cell-1	1400	

Optimal profit is found as 13.01 billion \$ for 20 years plant life. It is observed that the wind turbines are chosen over PV units. Although they have very similar cost and capacity values, photovoltaic cells are not suggested to be installed. The reason is related to the operating power of PV units which depends on temperature and UV lights. Furthermore, the surplus electricity penetration of wind during night time brings about larger profit margins by storing the electricity in the battery. Accordingly, in daytime where the electricity prices are relatively expensive, decision making model prefers to choose the battery to supply electricity instead of buying it from the national grid. In addition to the suggested renewable energy equipment, combined heat and power generators, which produce both electricity and heat at certain ratio, are also included into the optimal configuration by the MILP model. The return on investment of such a project is around 8-9 years. On the other hand, we should mention that this study is mainly deterministic and more reliable results could be obtained using stochastic programming framework.

6. Conclusion

In conclusion, in this study, empirical mathematical models including the uncertainty of parameters are formulated and validated with historical data from Yalova, Turkey. One of the most significant feature of this study is the propagation of uncertainty with covariance matrix of parameters, which are then used to determine prediction intervals having particular distribution functions. Thus, the proposed method allows to generate scenarios with user-defined probabilities. In addition, defining predetermined intervals

removes the need for scenario reduction causing extra computational effort and time. Moreover, the model is able to provide independent scenarios for each time interval. On the other hand, there is a restriction with this method that high number of empirical models and parameters may deliver different results due to various possible future forecast behavior. Proposed method is open to adding extra system parameters such as economic conditions or unit efficiency parameters. This flexibility may generate a wider range of scenarios. Furthermore, the method may also result in broad parameter uncertainty regions to capture the wider prediction uncertainty. Handling the impact of uncertainty is a critical issue for energy system design. Finally, we also plan to integrate expert knowledge to the scenario generation method to forecast the future costs of the renewable energy systems reliably. We will employ the proposed scenario generation method for stochastic studies for Yalova and Turkey. Created scenarios with different probabilities will be fed into the stochastic version of the decision making model to assess the value and contribution of the stochastic programming to deal with uncertainty.

xiang.li@epfl.ch

Abstract

Despite numerous energy system optimization models for long-term planning on a national level, the plausibility assessment of suggested pathways is seldom involved taking into consideration: 1) the impact of existing capacity stocks on the future energy system; 2) self-corrective functionality if the pathway diverges from the projected ones *a posteriori*. In order to improve the reliability of energy planning models, a novel dynamic modeling methodology is proposed and applied to the Swiss energy systems covering power, heat, and mobility. It provides freedom for users to generate tailored pathways according to region-specific inputs and to define model horizons determined by the variable start year, end year, and time slice, taking into account dynamic minus-plus of existing stocks and new installation across 140 energy conversion technologies. Four typical emission-driven pathways representing different mitigation strategies for Switzerland are defined and analyzed. The results show that an exponential strategy of carbon mitigation seems cost-effective compared to the three other suggested pathways towards carbon neutrality.

Keywords: Energy transition pathways, dynamic optimization, carbon neutrality.

1. Introduction

In the context of transition from fossil-dominant to renewable-based society, energy system modeling plays an essential role in guiding long-term decision-making, particularly for achieving the 2°C temperature rise goal formulated by IPCC (2014). Many European countries have set net zero carbon emissions in 2050 as objective. In terms of Switzerland, the government published the Energy Strategy 2050 (SFOE, 2018) and recently declared its fulfillment to net zero emission. One of the most important decisions is to phase out nuclear power plants before 2035. How to fill the gap raised by the power production deficit, and at the same time ensuring low carbon emissions are becoming overarching in the system design. Concretely, the following questions need to be answered: 1) Is the net zero emission objective achievable? 2) Is there a risk of energy deficit in the future, especially in the period when nuclear is completely decommissioned? 3) What measures and which technologies should be prioritized for development, and how much should be deployed? What's the consequence of final energy consumption (FEC)? 4) What is the cost for achieving the energy transition?

In order to answer these questions, IPESE (Industrial Process and Energy Systems Engineering) lab and Energy center EPFL have developed Energyscope (Codina Gironès

et al., 2015), a snapshot bottom-up model based upon mixed-integer linear programming (MILP) for cost minimization subject to various constraints such as supply-demand balance, energy conversion efficiency, storage continuity, availability of resources and so on. Detailed mathematical formulations were reported in previous studies (Li et al., 2020). Energyscope assists in characterizing the theoretically optimal configuration of the energy system in a "steady" state. One of the limitations lies in the "snapshot" nature, which disables its application in depicting pathways for the energy transition. Therefore, a model capable of handling dynamic changes of the energy system is expected in practice in favor of policy-making given the *status quo* and the ultimate objectives. In this study, we propose a novel model - Energyscope Transition Pathway (ESTP) - adapted from Energyscope by applying a "glutton" algorithm for decision-making in each step. Although the results obtained from ESTP may not be strictly optimal compared to global optimization algorithms widely used over the whole time series, such as Panos et al. (2019), it is assumed to be of more realistic guidance for making plausible strategies by simulating the system's dynamic behavior in evolution. In parallel, the convergence speed of the optimization problem gets curtailed from hours to minutes depending on the granularity of time steps.

In the following sections, we firstly elucidate the modelling structure and key data (Section 2), followed by the definition and analyses of four typical scenarios representing different mitigation strategies (Section 3). Finally we summarize the key discoveries and project future research directions (Section 4).

2. Model description

2.1. Modeling structure

ESTP analyzed firstly the historical evolution of energy technologies from 1990-2018 with respect to annually newly installed capacities and energy production, leading to an estimation of the capacity deficits in future years given the lifespans of the considered technologies. Secondly, the model was applied to the reference year for calibrating energy and carbon balance. Thirdly, the optimization algorithm was executed in order to obtain the results of the current period based upon all the information already given as

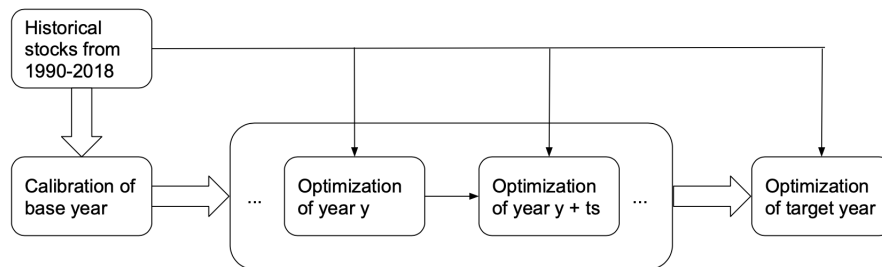

Figure 1: Model structure. Each optimization block is a MILP snapshot model. The historical stocks exert influence on all time steps from the base year to the target year. Each decision-making depends on previous optimization results.

inputs or available as the outputs from previous iterations, until the end year. Within each iteration, the total cost of the system was minimized taken into consideration the projected end energy demands (EUDs) driven by population, GDP, fuel price evolution and carbon emission objectives, as well as over 140 conversion technologies. Figure 1 shows the modeling structure. In this study, 2018 is set as the reference year with 4-year time steps towards 2050. Within each year, 12 periods represent the 12 months respectively.

The objective function for each year y within the considered horizon is expressed by Eq. 1, in which $\Phi(y' \leq y)$ represents the inventory of installations in all years y' starting from 1990 until a given year $y \in [2018, \dots, 2050]$. Different from the well-known Markov Chain where the probability of each event depends merely on the state attained in the previous event, the optimal total cost of the year y in ESTP is determined by the whole historical time series, including the previous state $y - 1$, as well as the specific parameters in the year y , e.g. the energy demands, interest rate etc. $\mathbf{F}(y)$ and $\mathbf{F}_t(y)$ represent the installed capacity and the used capacity in the month $t \in [1, \dots, 12]$ in the year y respectively.

$$\min_{\mathbf{F}(y), \mathbf{F}_t(y)} (TotalCost(y) | \Phi(y')) = (CAPEX(y) + OPEX(y) | \Phi(y')) \quad (1)$$

All the parameters used for calculating the annualized investment $CAPEX$ and operational cost $OPEX$ are year- and technology/resource-specific. Detailed mathematical formulations for one year were reported in Li et al. (2020) and the corresponding data are available in the same reference, as well as in Moret (2017) and Stadler et al. (2019).

2.2. Data: historical energy statistics

The historical data in Figure 2 on the installed capacity over 1990-2018 are based upon Swiss official reports OFEN (2020). Some missing data are calculated by historical production data and capacity factor assumptions according to Moret (2017). The calibration of the base year was conducted from two perspectives: FECs balance and EUDs balance.

Figure 2: Historical accumulated installations from 1990-2018 and expected decommissioning from 2019-2050 in the Swiss energy system. In this figure: DHN district heating

First, all the resources obtained by the model were compared with the data reported in OFEN (2020); secondly, the EUDs deduced by all the technologies in terms of electricity, industrial process heat, low temperature heat (space heating and hot water), and mobility, were calibrated with the data from JASM (2020) database. Based upon the model, the total emissions of the Swiss energy system excluding land use, land-use change, and forestry sum up to 36038 kt in 2018, with approx. 3% relative error compared with Statista (2019).

Based upon the calibrated historical data, we estimated the decommissioning time during 2019-2020 of all historical stocks before 2018. For instance, the new capacity of PV in 2015 is supposed to be decommissioned in 2040 given a typical life span of 25 years. From Figure 2, the majority of stocks phase out gradually before 2040, except hydro dam and river plants which are of long life span and encouraged by domestic policy to carry on operation for those with positive results from re-evaluation of techno-ecological feasibility after concession (Barry et al., 2015).

3. Scenarios analyses

In this study, four scenarios are defined representing four typical mitigation strategies from 2018 towards the net zero emission objective in 2050:

- (a) Linear: mitigating the emission in a constant speed;
- (b) Logarithmic: advocating a rapid decrease in the short term then slows down gradually;
- (c) Exponential: limited decarbonization in the initial stage and prompt action in the long term, in contrast to (b);
- (d) Logistic (S): allowing a quick mitigation in the mid-term whilst keeping the two ends smooth, widely applied in simulation of population growth and disease propagation.

Figure 3: Carbon mitigation pathways

Without loss of generality, we take the results of scenario (a) for analysis, as shown in Figure 4. RES represents renewable resources and WASTE_BIO and WASTE_FOS represent biogenic and fossil wastes respectively. Two typical periods could be categorized:

- Pre-2035: the transition refers substantially to the shift from oil to gas, reflected by a considerable drop of light fuel oil (LFO) and motor fuel liquids, as well as the disappearance of coal utilization in industry. Instead, the utilization of natural gas increases significantly from 33 TWh in 2018 to 50-60 TWh in the 2030s.
- Post-2035: radical revolution is witnessed from fossils to renewables, where PV, geothermal (RES_GEO), wind and biomass keep rapid increasing, reaching their corresponding potentials in 2050.

Figure 4: Evolution of resource utilization in Scenario a.

From an overall perspective, the total utilization of energy resources in the system decreases over the periods, as a result of the synergy of energy-efficient technologies, such as heat pumps, district heating, electric vehicles, and increasing reduction on the heat demand side from building and industry. Massive electrification, particularly renewable power, is witnessed in Figure 4 after 2035. Electricity import (in light blue) appears necessary in the proximity of 2035 where a drastic drop of domestic power production is foreseen due to the decommissioning of all the remaining nuclear power plants in Switzerland. Around 22 TWh net import amount is needed in that period in order to compensate the supply. Decreasing reliance on power import is expected afterwards, rendering finally an import amount of 10 TWh in 2050, approx. 1/3 of today’s value.

Associated to each mitigation scenario, Figure 5 shows the annual total system cost evolution from the first optimization year 2022 to the target year 2050. In general, cost declines in all scenarios over time predominantly due to the reduction of technology specific costs, and energy demand saving. An abnormality is observed in the scenario (d) where a steep increase is observed from 2034 to 2038. This results from a dramatic decreasing slope of the S-curve in between 2034-2038 that enforces the system to adopt more expensive choices in a short term, e.g. heat pumps, and compulsorily shutting down a part of carbon intensive gas plants that are still in operation as well to meet the climate demand. Among the four scenarios, scenario c with exponential mitigation strategy appears most cost-effective, which could be interpreted from two aspects: before

Figure 5: Evolution of energy system total cost [MCHF/year] by different mitigation strategies.

2035, less stringent emission limitation implies less investment; after 2035, emerging technologies today are supposed to become relatively mature, e.g. electrolysis, of which the specific investment is promising to be half of today's value, by consequence, the cost impact due to rapid decarbonization process could be dampened. By contrast, the most expensive pathway appears in scenario b with logarithmic mitigation strategy.

4. Conclusion

Our research is dedicated for policy-makers to define pathways and quantify their impacts towards net zero emission. The dynamic modeling approach by stepwise minus-plus representation of the energy system evolution allows flexible adjustment if the pre-defined pathway diverges from reality. The results consolidate our conclusion in previous studies that the carbon neutrality of Swiss energy system could be achieved with massive penetration of renewables (over 90 %) and wide deployment of CCUS technologies as well as sufficient infrastructure support, by showing specific pathways towards this objective taking into account the impact of decommissioning of all historical stocks and new capacities. It should be highlighted that the curvature of the carbon mitigation pathway would lead to different strategies. Therefore, exploring as exhaustively as possible the space of transitional carbon pathways, e.g. via parameterization in combination with uncertainty analysis, would be necessary in further research.

patrick.linke@qatar.tamu.edu

Abstract

The rising concerns about climate change have led to the emergence of several pathways for mitigating the increasing emissions of greenhouse gases, especially CO₂. Several technologies and actions constitute such pathways, whether through reducing the production of CO₂ streams by implementing renewable energy options for example or through processing them via CO₂ capture, utilization, and storage. For such projects to be implemented, they need to satisfy an economic favourability that serves as an incentive for the industrial stakeholders to invest. Process Integration tools have been developed recently to optimize the planning of CO₂ reduction through identifying the cheapest pathways. However, the interactions between the different stakeholders are not considered in such approaches. The existence of such interactions may lead to a non-optimal implementation of CO₂ reduction pathways under the applied policy framework. It is important for the enforced policies to guarantee the implementation of the lowest cost pathways to avoid recessive consequences associated with emissions mitigation. This work tries to identify the effect of such interactions on the feasibility of the optimal solution. CO₂ reduction policy can then be assessed based on the resulting feasible solution in comparison with the optimal solution. A conducted case study showed that a high tax on CO₂ emissions may result in deviations from the optimality. Subsidizing CO₂ capture and renewable energy would help in reducing the economic impact on the stakeholders, leading to a feasible optimal solution.

Keywords: carbon policy, process integration, minimum cost CO₂ reduction, CO₂ capture, renewable energy.

1. Introduction

The growing concern about the issue of global warming associated with the rising emissions of greenhouse gases has led to the emergence of national and international commitments to limit the pollution. CO₂ is a major greenhouse gas which is heavily produced from industrial and power plants. Different pathways exist for CO₂ reduction; however, the associated high costs prevent the required implementation (Tapia et al., 2018). Hence, it is important to identify optimal CO₂ reduction pathways to avoid unnecessary costs. In the field of process integration, various optimization methods have been developed as decision support platforms in CO₂ reduction planning (Manan et al., 2017). Such models consider different stages at which CO₂ reduction pathways can be implemented and provide detailed designs for cost-optimal implementation. Al-Mohannadi and Linke (2016) developed an optimization model to minimize the cost of implementation of CO₂ capture, utilization, and sequestration (CCUS). A multi-objective multi-period optimization was solved to determine optimal CO₂ reduction through

integration under conflicting environmental and economic objectives (Al-Mohannadi et al., 2019). Al-Mohannadi et al. (2020) considered a multiperiod optimization of CCUS and energy mix to assess CO₂ reduction planning. Since the economic motive is a major factor affecting the decisions taken, the implementation of CO₂ reducing pathways needs to achieve an economic favourability for the stakeholders to be implemented. The governments enforce different policies and regulations that act as incentives for the industries to implement pollution reduction options. As a result, symbiotic relations emerge between different interacting stakeholders that ensure the feasibility of such projects for all sides (Yazdanpanah et al., 2018). Different approaches have been developed to model such interactions. Tang et al. (2015) established an agent-based model to investigate the application of carbon emissions trading scheme on the Chinese case. Fraccascia et al. (2017) used a multi-agent model to study the effect of introducing landfill taxation and subsidy policies on the symbiotic relations within industrial parks. Aguilar et al. (2017) proposed a bi-level fuzzy optimization model to determine a proper incentive policy that results in the plants adopting proper heat and solid waste network to minimize CO₂ emissions. Such approaches implement complicated tools, and the solutions are obtained without assessing the behavior leading to optimal performance. Hence it is important to develop a simple method to determine the optimal cost for CO₂ reduction and to understand the system with the various options at a higher level. This work investigates the impact of CO₂ tax and subsidies on the implementation of CCUS and alternative energy options. The resulting feasible solution based on the interactions is determined and assessed in context of the minimum cost pathways determined from process integration perspective.

2. Methodology

The aim is to identify optimal CO₂ reduction pathways for a set of emissions sources, and to describe the interactions between the possible stakeholders in order to determine a feasible solution under the set policy framework. The CO₂ policy framework is assessed through comparing the costs of the feasible and optimal solutions. The CO₂ reduction pathways considered are CO₂ capture utilization and storage (CCUS), beside energy shifting. The system contains a set of existing emissions sources characterized by CO₂ capture and compression costs (C_{si}) and secondary emissions (γ_{si}), and a set of available sinks characterized by their profitability (CO₂ cost R_{dj}) and CO₂ reduction efficiency (η_{dj}). Power sources are characterized by their costs C_{Ek} and CO₂ intensity ε_k . Note that these techno-economic parameters are specified by the user, and their estimation is subjected to the user's assumptions.

The optimal pathways are determined through representing the possible options on a Marginal Abatement Cost (MAC) curve which shows the pathways arranged from cheapest to most expensive as represented by Lameh et al. (2020a). After that, the interactions between the stakeholders are modelled as a cooperative game where the allocation of CO₂ between a source and a sink is feasible only if both players can achieve an economic benefit from the symbiosis. The interaction can be characterised by the material and monetary flows between the different components of the system. The government plays a coordinating role through setting CO₂ tax (CT) and subsidy rates (SR) where the CO₂ emitting sources need to pay for the emissions they produce, while the government can cover a fraction of the total cost of implementation of renewable energy or CO₂ capture as an incentive to the industrial stakeholders.

The feasibility of the different options is determined by the economic favourability of the decisions. The decision of capturing and allocating a CO₂ stream from a source to a sink should have a lower cost (or higher profit) than other possible decisions. A source may emit its CO₂ to the atmosphere and pay the corresponding tax, or it can pay for the subsidized capture and allocate the emissions to the sink. The sink can afford to pay if the implemented utilization process is profitable. The stakeholders representing the sink may decide to invest in installing and operating the corresponding technology if it can reach a convincing level of profitability under the agreed-upon CO₂ price. Otherwise, the sink won't be available. Hence, under a set policy, the source (*s_i*) would have a minimum CO₂ price (*CP_{si}*) that the sink needs to pay, and the sink (*d_j*) would have a maximum price (*CP_{dj}*) which it can pay while meeting its profitability target. The CO₂ prices are determined as follows:

$$CP_{si} > C_{si} \times (1-SR) - CT \times (1-\gamma_{si}) \quad (1)$$

$$CP_{dj} < R_{dj} \quad (2)$$

Feasibility condition:

$$CP_{dj} > CP_{si} \quad (3)$$

In a system with multiple sources and sinks, the price is determined through the CO₂ market dynamics. It depends on the CO₂ availability, as well as *CP_{si}* and *CP_{dj}* for the available sources and sinks. The resulting model can be solved graphically on the CO₂ price curve (Figure 1) to determine the feasible CO₂ network scale and the participating players. The plot consists of a supply profile representing the sources by their *CP_{si}* and CO₂ availability *F_{si}*, and a demand profile representing the sinks by their *CP_{dj}* and the capacity *F_{dj}*. The sources follow the law of supply and their segments are arranged in the increasing order of *CP_{si}*. The sinks follow the law of demand, and their segments are represented in the decreasing order of *CP_{dj}*. The representation is similar to the graphical analysis presented by Lameh et al. (2020b). The CO₂ market equilibrium is defined as the point at which the profiles intersect. This point divides the graph into two sections: before the carbon market equilibrium is achieved, there is a feasible region for establishing the network where *CP_{si}* < *CP_{dj}*. Beyond that region, none of the sources or the sinks can afford to participate in the network at the set equilibrium price.

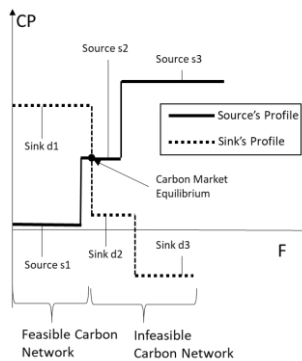

Figure 1 The graphical representation of the network with multiple sources and multiple sinks

The role of the government is played by the user through setting *CT* and *SR*. Note that the CO₂ prices for the sources can vary depending on the policy framework implemented. For example, if the tax (or the subsidy) is high, then the sources would be willing to sell

CO₂ at lower prices. Hence, the set CO₂ reduction policy can control the market equilibrium, and consequently the level of CO₂ reduction as well as the CO₂ price. For power generating sources that produce CO₂, beside the options of emitting the CO₂ streams or capturing them, they have the option of shifting to renewable energy sources. The renewable energy can be subsidized as well.

3. Case Study

Consider a system composed of different plants with different CO₂ sources. The different sources emit CO₂ streams with varying conditions which affect the total cost of CO₂ supply (capture and compression) and the resulting secondary emissions. Table 1 summarises the sources considered and the corresponding CO₂ capture cost and secondary emissions. The data used is based on case studies present in Al-Mohannadi et al. (2017a) and Lameh et al. (2020b).

Table 1 Source's data for the case study on carbon policy

Source	CO ₂ Produced (10 ⁶ tCO ₂ /y)	C _{si} (\$/tCO ₂)	γ _{si} (tCO ₂ -produced/tCO ₂ -captured)
GTL - Concentrated	4.12	2.5	0.03
Cement	1.38	32.5	0.27
GTL - Diluted	11.38	36.5	0.26
Methanol	0.64	36.5	0.26
Aluminium	3.30	36.5	0.29
Power Plant	3.8	40	0.13

The total emissions level of the considered sources is 24.62×10⁶ tCO₂/y. Amine absorption is considered as the capture process with 90% capture efficiency. The considered sinks are summarized in Table 2 (Al-Mohannadi et al., 2017b). Beside CCUS, solar energy can be used to generate up to 50% of the power plant's capacity to reduce CO₂ emissions at a marginal abatement cost of 31 \$/tCO₂-reduced. The determined cost is based on a 714 \$/kW capital cost for utility scale photovoltaic panels (IRENA, 2020), without storage and disregarding land cost, and assuming an emissions intensity of 0.54 tCO₂/MWh for the existing power plant.

Table 2 Sink's data for the case study on carbon policy

Sink (d _i)	F _{di} (10 ⁶ tCO ₂ /y)	R _{di} (\$/tCO ₂)	η _{di}
Enhanced Oil Recovery (EOR)	5	30	100%
Methanol B	2	20	99%
Storage	18	-10	100%

The MAC curve represents the optimal pathways to reduce CO₂ from the described sources, considering the CCUS and solar energy options (Figure 2). The analysis shows that the maximum profit of the CO₂ network is 113×10⁶ \$/y, achieved at 15% CO₂ reduction. The cost-neutral CO₂ reduction (X_{cost-neutral}) was found to be around 31%.

Three different scenarios for the implemented policy scheme were investigated (Table 3). A base case is considered where no policy is implemented, to examine the CO₂ reduction limit under the absence of authority interference. Two different policy scenarios were investigated to analyze the impact of CO₂ tax and subsidies on the system to achieve the 31% reduction (X_{cost-neutral}). Scenario 2 considered only the CO₂ tax as a policy, and Scenario 3 considers a mix between tax and subsidies.

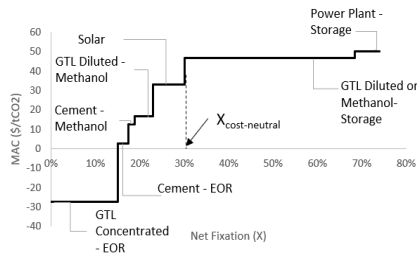

Figure 2 MAC curve for the case study on carbon policy

Table 3 CO₂ reduction policy scenarios

	CO ₂ Tax (\$/tCO ₂)	Subsidy-Capture (% of total capture cost)	Subsidy – Renewable Energy (% of the total renewable energy cost)
Scenario 1	0	0	0
Scenario 2	33	0	0
Scenario 3	5	40	85

The base case represented in the first scenario shows that there is only one feasible allocation: from the pure stream of the GTL to utilization in EOR. Such pathways would result in 15% reduction in the total CO₂ emissions, and would generate a total profit of around 113×10^6 \$/y, divided between the stakeholders of the GTL and the EOR, depending on the CO₂ price which is estimated to be within 20\$/tCO₂ to 30\$/tCO₂. This pathway abides by the optimum route for CO₂ reduction, as it is the only profitable option among the considered where a symbiotic opportunity that guarantees the economic profit for both the source and the sink exists.

After that, the CO₂ policy parameters were changed to achieve a CO₂ reduction target close to the cost-neutral CO₂ reduction suggested by the MAC curve analysis. Increasing the CO₂ tax rate would decrease the price at which the sources are willing to sell their CO₂ which pushes for more symbiotic opportunities and hence more CO₂ reduction. Since the sources would still have to pay carbon tax for the secondary emissions from the capture process, the impact of the tax differs among the sources depending on the corresponding secondary emissions factor γ_i . It was shown that the feasible CO₂ reduction pathways under the proposed carbon tax will be constituted of CCUS options between GTL-concentrated, cement, and power plant from the supply side, and from EOR and methanol on the demand side, with a CO₂ exchange flowrate of 7×10^6 tCO₂/y. Solar energy would be implemented at its maximum capacity. This showed a deviation from the MAC curve analysis where for a CO₂ reduction of 30%, power plant did not participate. Hence, the CO₂ tax resulted in a deviation from the optimal solution. The resulting feasible system from the CO₂ tax cost 5×10^6 \$/y in contrast to the zero cost of the optimal solution for the same level of CO₂ reduction.

Increasing the subsidy would have the same effect of increasing the tax in terms of providing an economic incentive that pushes down the required CO₂ price by the sources and increases the feasible CO₂ reduction limit. In the suggested policy of Scenario 3, polluting plants pay 5 \$/tCO₂, and the collected tax is used to cover 40% and 85% of the total cost of implemented CO₂ capture and solar power respectively. With the lower tax, the CO₂ price is affected by the cost of capture, and consequently, sources with lower capture cost participate in the CCUS network, beside the full implementation of solar power. This solution is coherent with the optimal pathway retrieved from the MAC curve analysis.

4. Conclusions

This work introduced a novel approach to assessing CO₂ reduction policy in context of process integration and optimization approaches. The methodology presented a simple tool that allows the identification of the symbiotic opportunities between different CO₂ sources and different CO₂ sinks based on the economics controlled by the set policy framework. A case study was then developed in which the methodology showed that different policy schemes can result in varying total costs to achieve the same CO₂ reduction limit. This approach helps in giving context to the solutions obtained from optimization models when it comes to the implementation under different stakeholder's interactions.

Back-End Design and Development of an Energy Systems Analysis Tool

Maryam Arbabzadeh,^a Sapna kumari^a, Ragini Sreenath^a, Emre Gençer^a

^aMIT Energy Initiative, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA, 02139, USA

Abstract

Low-carbon transformation of the energy system requires a combination of technology and policy options to ensure reliable, affordable, and clean energy. An assessment of plausible transition pathways can be guided with a set of tools that cover multi-sector dynamics of transitions and consider economy-wide and sectoral life-cycle analysis of numerous options. Sustainable Energy Systems Analysis Modeling Environment (SESAME) is a comprehensive system-level and pathway-level analysis model. Pathway-level analysis includes two main analysis types: life cycle assessment (LCA) and techno-economic assessment (TEA). The framework allows users to assess the sensitivity of key technological, operational, and geographical parameters associated with various energy pathways as measured by the emissions and costs. In this paper, we present the back-end design and implementation of the SESAME web application. The key contribution of web-based framework is that it supports easy integration of new LCA and/or TEA models and data sources in the backend so they can be made easily available to users for analysis via the front-end web interface. We achieve this by creating a Python-based library of classes and functions that model a higher-level code-based representation of LCA and TEA pathways. The tool is designed to capture the inherent modularity of SESAME, which makes it easier to add either new pathways or new data models and sources for existing pathways.

Keywords: energy systems modeling, computational tool, life cycle assessment, techno-economic assessment

1. Introduction

The global energy system is undergoing major transformations given the dual challenge of meeting increasing energy demand while reducing greenhouse gas (GHG) emissions. Such transformation requires a combination of technology selection and policy choices. Understanding the implications of these dynamics is challenging and requires a holistic approach to provide systems-level insights. Although there is considerable related research work emerging, there is a lack of readily available quantitative models and tools that consider a broad and robust life-cycle analysis approach for a range of plausible energy futures at regional and national levels. Such a tool is needed to help policy makers, industry, investors, and the financial sector to better understand and make decisions on energy choices and energy transitions.

One of MIT's modeling tools associated with energy choice evaluation is a comprehensive system-level and pathway-level LCA model called Sustainable Energy Systems Analysis Modeling Environment (SESAME). SESAME has a modular framework designed for supporting pathway-level and a system-level analysis (Gençer, 2020). Pathway refers to life-cycle stages of a particular product from raw material

extraction to production to its final end use. Pathway-level analysis is subdivided into main analysis types: LCA and TEA. LCA calculates GHG emissions associated with each of the various life-cycle stages whereas TEA calculates combined costs associated with the product or process through its life-cycle. Systems-level analysis models the emissions associated with large-scale energy sectors such as electric power system or a vehicle fleet. The goal is to allow users to explore variations in emissions and costs arising from different technological, operational, and geospatial parameters selected by the user. Given potential trade-offs that might arise between options, SESAME will include optimization models to guide users in selecting the optimal solution based on their preferred objectives and provide an extensive analysis. Future publications will include details of such optimization models.

The web-based framework of SESAME, developed in Python, is designed to capture the inherent modularity of the tool. The key contribution is the creation of a Python-based library of classes and functions to model a higher-level code-based representation of LCA and TEA pathways. Because LCA practitioners rely on a wide variety of models and data sources for analysing different pathways, the key aspect of our backend system design is to ensure its flexibility to incorporate new pathway models into the web framework using this library. Another contribution is defining a standard format for storage of model data for most effective ways to perform analytic calculations. A final contribution is the creation of useful HTTP end-points, abstracting away the analytic computations and programming-based back-end so that the front-end developer can easily use those endpoints to collect the required user inputs and display the results of analysis.

2. Methodology

2.1. Analysis Types

Our framework supports three main analysis types: LCA, TEA and LCA combined with TEA, with two separate metadata objects, one for LCA pathways and one for TEA pathways. Metadata object for LCA pathways is quite intricate since we don't simply design a separate model for every pathway; instead we design models for individual activities which are connected together to make up a pathway. This is because same activity may be shared across many different pathways and encoding the activity as part of a whole pathway instead of as a separate unit will lead to a lot of overhead in terms of repeated code and functions. For instance, upstream crude oil extraction activity has several different end-uses activities such as gasoline, diesel, and LPG, which make up many different energy pathways. The pathway metadata object for LCA analysis is a nested JSON data structure (Pezoa, 2016) that encapsulates all pathways available for LCA analysis in SESAME. The first layer comprises of life-cycle stages with second layer storing the activities in the stages and the third layer containing reference to the actual data source models within the activities that conduct LCA flow calculations. A new pathway for LCA analysis can easily be added to the SESAME framework by first implementing the new activity data source models and then adding all the relevant information about the implemented classes in the metadata object.

For every pathway available to LCA analysis, we build the corresponding TEA model as well, so the combined analysis is defined for all pathways. TEA metadata object is simply a one-layer JSON data structure that contains the reference to the TEA model class and the lookup table by the pathway name and id. Each TEA model class specifies the user inputs that will need to be collected for a given pathway and performs the cost calculations using both the collected user input values and data stored in various cost-specific data tables.

2.1. Pathway Representation via Python Classes

2.1.1. LCA Pathway Classes

Figure 1 shows the hierarchical relationship between the objects. Metadata is a list of stages where each stage is a list of activities. Each activity is subsequently a list of sources that contains the reference to actual activity-source class which implements the LCA flow calculations for that activity in that stage.

Figure 1 Pathway entity-relationships diagram

In implementation of these classes, we make use of the key concepts of object-oriented programming which include abstraction, encapsulation, and inheritance (D'Andrea and Gowda, 1990). Abstraction means that each object should only expose a high-level mechanism for using it, and hide the implementation details. While we describe the attributes and methods of all objects below, any user of this library only needs to know the high-level purpose of these methods and not the exact implementation detail. Inheritance means creating child classes from parent class where child classes can implement their own unique methods in addition to inheriting all the shared methods and common logic implemented by parent class. We make use of inheritance in creation of a parent Activity-Source class, which is described later.

Metadata: A Metadata object represents the set of all pathways defined in SESAME. The metadata class is initialized with an empty list of stages, and supports two main methods: register stage and get stage. The register stage method adds a new stage object, initialized with the name argument, to the stages list. The get stage method returns the stage object from the list of stages whose name matches the name passed as argument.

Stage: A Stage object represents all the activities that belong to a particular LCA stage. The stage class is initialized with attributes id, name, and an empty list of activities and supports two main methods: register activity and get activity. The register activity method adds a new activity object, initialized with the name passed as argument, to the activities list. The get activity method returns the activity object from the list of activities whose name matches the name passed as argument.

Activity: An Activity object represents a specific life-cycle activity. The Activity class is initialized with attributes id, name, stage, empty list of links and an empty list of sources, and supports three main methods: link, register source and get source. Links denote the set of activities in the next stage that this activity leads to. For instance, for transmission activity, the links would include all power production activity including NG, wind, and other electricity generation activities since transmission activity in gate to user stage implies the process activities must be power generation activities.

Source: Source objects denote the set of data source models that determine how the activity flow calculations will be performed. The Source object is initialized with attributes id, name, activity, lookup table, and class. The register source method takes as arguments a source name, the activity object, associated Activity-Source class, and lookup table and adds a new source object. The get source method returns the source object from the list of sources whose name matches the name passed as argument. The id attribute is initialized as null. The Activity-Source class is a reference to the specific class

that defines the set of user input parameters and implements the flow calculation methods. The lookup table is an optional table that may be read in the reference class and includes information for the input collection and stores associated emissions for selected pathways. When a source object is being registered to an activity object, it is also inserted as a record to a global sources database instance which stores all source records by their ids. The ids are created by concatenating the source name with activity identifier, thus ensuring their uniqueness. Sources database object is important because once the user interface collects all the user inputs for a particular source id, sources database is used to find the associated source object. The user inputs value collected are then passed to the corresponding Activity-Source class which is an attribute of this source object.

Activity-Source: Since most activity source objects share some common attributes and methods, we create a parent class called Activity-Source that implements the common methods. Creation of such a class helps avoid repeated functions and code redundancy through various activity source classes. Within an Activity-Source class, we can create child classes that can be used to implement method specific to a particular pathway. The set of relevant parameters and the exact method of calculation may vary not only between different activities but also between different source models for same activity. Hence, in our implementation, there is a separate class for every unique activity source model. For example, for NG power production activity, we have two separate source models, and thus, we have two classes which take different set of user inputs and calculate flows differently. Likewise, we have a separate class for NG transportation activity in midstream, and NG extraction activity in upstream. However, all activity source classes share the same model and they take as arguments the user inputs, an optional lookup table, and implement three methods which compute three flow types of input, output, and emission as shown in Figure 2.

Figure 2 Activity source class model

2.1. User Input Classes

User inputs are a very important part of our analysis tool. In the user interface, we let the user specify a range of technological, temporal and geographical variables for each of the analysis type. Once the user inputs are all collected on the front-end, they are routed to the back-end where they are used in performing the necessary computations. The order of input collection matters because the activities between two different stages are linked by a shared input-output flow, and which flow type is passed from one activity to another differs. Regardless of the direction in which the user inputs are collected, whether it is from upstream to end use or from end-use to upstream, we choose to perform LCA calculations in one order on the back-end i.e. from end-use to upstream.

The set of inputs required of user before they can see the analysis results can be quite large especially in case of five-stage LCA analysis. Thus, to take away some burden of specifying all inputs from the user, we put in place a mechanism for specifying defaults for all input types. Another advantage of having defaults is that not every value might be known by the user and having pre-filled data can be helpful for non-experts.

2.1.1. Input Subclass

Based on the system needs, we defined three different sub-classes of input class in the back-end which include continuous, categorical and options. Continuous inputs represent input variables that take continuous numerical values such as turbine efficiency, plant lifetime or solar power intensity. Options inputs refer to any inputs with a fixed set of options that is passed as an argument to the class. Categorical inputs denote the inputs, which the options are read from a filtered data frame based on previous user input.

2.2. Web Framework Interface

For LCA analysis module, the front-end interface fetches the LCA pathway metadata object via an HTTP endpoint, and uses the object to dynamically collect the user inputs for all pathway stages starting from end use or upstream. The storage of activity links in the metadata object guides the appropriate user input collection for each subsequent stage based on the user activity selection in previous stage. Likewise, for TEA analysis module, the front-end fetches the TEA metadata object via a separate HTTP endpoint. For LCA-TEA module, both LCA and TEA metadata are wrapped in one object to be sent to front-end for input collection. The front-end posts the pathway analysis response object to back-end, which contains the user input values for a pathway for a particular analysis type. The backend then performs the analysis on either LCA, TEA model or both by calling relevant models specified in the metadata objects for the pathway specified by user. Back-end returns the analysis results object back with either emissions data or costs data or both depending on the analysis type. The front-end uses a graphing library to display the relevant emissions/costs plot sent in the analysis results object.

3. Case Examples

3.1. Pathway classes of power production

Stage objects corresponding to the five stages (upstream, midstream, process, gate to end-use, and end-use) in a pathway are created. Next, for each, their corresponding activity objects need to be created. For example, for the process stage object, we create an activity object called XPowerProduction. X refers to energy source i.e. NG, coal, wind, or solar. For this activity object, we register a source object Data1, which is the data source we use for this calculation. Now, for this source object, we create a child class XPowerData1 (with the parent class being an ActivitySource object) and link the file with the required data as the lookup table. Lastly, under the XPowerData1 class, we define a get_emissions method that calculates emissions based on the data in the lookup table and the specific inputs provided by the user. Figure 3 displays the GHG emissions results for multiple pathways across life cycle stages. As shown in this figure, the process stage is the main contributor to emissions in case of fossil fuels. The inputs default assumptions for each pathway is provided in Figure 4, which demonstrates the user's capabilities to test the results to technological and operational varieties.

Figure 3 LCA GHG emissions of producing 1000 kWh electricity through multiple pathways

NG Power Production

Activity	Source	Generation Region	Generator Type
NGPowerProduct	GREET	US	Mix
Include Infrastructure Emissions?			
no			
Mode	Distance in miles	Loss Factor in %	
pipeline	750	0.12	
Natural Gas Type	Well Infrastructure	Leakage Parameter	
NG mix	No	EPA 2019	

Coal Power Production

Activity	Source	Coal Rank	Generation Region
CoalPowerProduct	GREETonly	Mix (50% bituminous)	US
Include Infrastructure Emissions?			
no			
Generator Type	Sub Feed	Mode	Distance in miles
Mix	mix	default mix	69991
Well Infrastructure		% Underground Mining Share	
No		31	
Loss Factor in %			
0			

Wind Power Production

Activity	Installation Type	Choose Capacity Factor or Wind Speed	Hub Height (m)
WindPowerProduct	onshore wind farm	Capacity Factor	80
Year Installed			
2014-2016			
Turbine Model		Lifetime (years)	
Typical Onshore mix		20	
Emissions in Manufacturing (gCO ₂ e/kWh)			
600			

Solar Power Production

Activity	Location of Installation	Cell Type	Installation Type
SolarPowerProduct	US NE (Boston)	multi crystal Si (mc)	utility, 1-axis tracker
Shading Losses (in %)			
2.5			
Lifetime (year)		Efficiency, STC Rated	Degradation Rate (per year)
20		20	0
Inverse Loading Ratio		Emissions in BOS Production (gCO ₂ e)	Shipping Distance from Panel Production to Installation (km)
1		660	20000

Legend: Process (green), Midstream (blue), Upstream (grey)

Figure 4 Input assumptions for 1000 kWh power production (end-use) through multiple pathways assuming 4.68% electricity loss in transmission (get-to-user). For wind and solar, the adjustment is made by computing all the flows in the process activity, but passing the computed flow values to the upstream activity for correct flow attributions.

3.2. System analysis - emissions impact of electric vehicles (EVs) charging pattern

The magnitude of the emissions reduction associated with EV deployment depends significantly on EV charging patterns as well as hourly power grid variations. In this case study, we use SESAME to estimate the emissions associated with EV deployment in 60 cases across the US using hourly grid data from 2018 and 2019 (alongside hourly charging, driving, and temperature data). The results show that the emissions impact of the charging pattern varies by region. For example, in California and New York, overnight EV charging produces ~70% more and ~20% fewer emissions than daytime charging, respectively (Miller, 2020).

Abstract

CO₂ compression and conditioning not only contributes to the overall energy penalty of Carbon Capture Utilisation and Storage (CCUS), it also influences the logistics surrounding the transportation network. The techno-economic feasibility of transporting CO₂ through pipelines or in storage vessels has been reported extensively. However, the conclusions in the existing studies are case specific, and focus on either the CO₂ source or the end-point. Whereas, in large CCUS clusters/networks, a range of sources will need to be interlinked and be able to supply conditioned CO₂ to various transportation options. With the prospect of multi-national CCUS transportation infrastructures, the link between CO₂ source and transport needs to be clearly characterised.

Herein, a process model for a CO₂ compression train is constructed in gPROMS gCCS, based off the IEAGHG base case B0 for post-combustion capture and compression. The model is capable of conditioning the CO₂ stream to the required outlet pressure, temperature and composition. The results compare various CO₂ streams from capture plants attached to a range of CO₂ sources including power generation and industry. The findings highlight the power requirement for conditioning to various end point characteristics, specifically the level of moisture control required for different pipeline options. This analysis can also be used alongside economic evaluations to enable the cost-effective deployment of CCUS transport networks, and aid in forming effective CCUS clusters.

Keywords: CCUS, CO₂ Compression, CO₂ Transport, CO₂ Sources

1. Introduction

One of the new set of challenges facing the Carbon Capture Utilisation and Storage (CCUS) industry is the formation of cluster networks, interlinking various CO₂ sources with different stream characteristics (pressure, temperature, and composition). The sources are mixed and delivered to potentially different storage options, posing technical and operational challenges for CO₂ transportation (Moe, et al., 2020). Alongside power industry focused CO₂ capture technologies (post-, pre-, and oxy-combustion), a growing interest is industrial sources such as the production of hydrogen, fertilisers, cement, iron and steel (Bui, et al., 2018).

An early study by Aspelund and Jordal (2007) investigated the interface between CO₂ capture and transportation, stating the energy requirement for CO₂ conditioning is between 90 and 120 kWh/tCO₂. However, this depends on the inlet stream characteristics (i.e. the source) and the conditioning method. Centrifugal compressors are the conventional choice in the power generation industry, but due to the low-pressure ratio (between 1.7-2:1) a multistage system is required (Martynov, et al., 2016).

Several studies have looked at optimising and comparing conditioning strategies, mainly focused on multistage compression and liquefaction processes. Witkowski & Majkut (2012) found power savings of up to 21% can be achieved through integrally geared centrifugal compressors, and over 45% using refrigerated subcritical liquefaction. IEAGHG (2011) also reported a reduced energy consumption when incorporating early liquefaction then liquid pumps, although it was only a 0.2 MW decrease, approximately 0.35% lower than conventional compression. This saving is potentially offset by an increased cooling water demand. Therefore, this study focuses on the conventional multistage compression process.

1.1. Aims and Objectives

Several parametric and techno-economic studies have analysed different CO₂ transportation options, highlighting the effects of impurities, operating phase, and system design. However, the conclusions in the existing studies are case specific, and focus on either the CO₂ source or the transportation option. The prospect of multi-national CCUS transportation infrastructures, means the link between CO₂ source and transport needs to be clearly characterised.

This study considers the impact different CO₂ sources and end point specifications have on the power demand for the compression and conditioning train. Figure 1 highlights the CO₂ capture technologies, the conditioning system, and the transportation options investigated in this study, focussing on dense phase pipelines for the transportation option (Harkin, et al., 2017). For each technology, the conventional multistage compression system will elevate the CO₂ stream pressure to 111 bar and 70°C as specified in IEAGHG (2011). Including intermediate storage and shipping in the transportation options is an unfair comparison, as the pressure requirements are much lower than for pipeline transportation. Therefore, less energy is required for conditioning. For more information on shipping transport, see MEP (2016). Three moisture control levels are used to compare different end-point composition guidelines:

- 20ppm – Beverage industry CO₂ specification as stated in EIGA (2016)
- 300ppm – Optimal pipeline moisture content (250-350ppm) from Brunsvold et al. (2016)
- 600ppm – Kinder Morgan pipeline specification stated in Jensen et al. (2014)

Figure : Study overview

2. CO₂ Sources

Table 1 shows the capture CO₂ stream characteristics used in this study. Impurities affect pipeline operation, therefore, H₂O (Brunsvold, et al., 2016) and N₂ (Peletiri, et al., 2019) are included alongside CO₂ in the composition of each stream. All other impurities are lumped as N₂.

In terms of technology readiness level (TRL) post-combustion capture using amines is TRL9 (commercial), so too is pre-combustion capture for natural gas processing using the Selexol processes (Bui, et al., 2018). In oxy-fuel combustion the purification process involves compression integrated with additional separation technologies (Pipitone & Bolland, 2009). Therefore, it is not included in this study. For post-combustion capture, the benchmark is 30wt.% MEA. Aqueous Ammonia (NH₃) was chosen as an alternative post-combustion solvent, due to the lower stripping duty 2.0-2.9 GJ/tCO₂ compared to 3.6-4.0 GJ/tCO₂ for MEA (Bui, et al., 2018). Methyl diethanolamine (MDEA) was chosen as an alternative pre-combustion capture technology to Selexol, due to the high capture rate (95%) and low stripping duty 0.99-1.34 GJ/tCO₂ (Romano, et al., 2010). Adsorption systems for post-combustion capture have advanced over past three decades, at TRL7 they are at demonstration level (Bui, et al., 2018). For smaller scale operations such as the simultaneous production of H₂ and CO₂, the Gemini PSA process can recover 94% CO₂ at 99.4% purity from steam methane reforming off-gas (Sircar & Golden, 2000). Membrane based CO₂ separation has been investigated for hydrogen production (TRL5), power generation (TRL6), and natural gas reforming (TRL7) (Bui, et al., 2018). Chung et al. (2018) highlighted the potential for using hollow-fiber Polaris™ membranes to capture high purity CO₂ from blast furnace gas in iron and steel plants.

Table 1: Captured CO₂ characteristics

Source	Temperature (°C)	Pressure (bar)	Composition (%)			Source
			CO ₂	H ₂ O	N ₂	
Post-MEA	38.00	1.6	95.88	4.11	0.01	(IEAGHG, 2011)
Post-NH3	20.00	6.00	99.00	0.40	0.00	(Yu, et al., 2011)
Pre-MDEA	30.00	1.10	96.02	3.92	0.02	(Romano, et al., 2010)
Pre-Selexol	-5.00	1.20	99.77	0.17	0.00	(IEAGHG, 2011)
	1.00	4.80	97.30	0.07	0.03	
SMR-PSA	21.00	1.00	99.40	0.00	0.00	(Sircar & Golden, 2000)
Steel-MEM	40.00	1.00	98.97	0.00	0.01	(Chung, et al., 2018)

3. Process Simulation

The base case B0 for post-combustion CO₂ compression from IEAGHG (2011) is used as the basis for the compression train model. The layout of the system is illustrated in Figure 2. The model is developed in gPROMS® gCCS 1.1.0, utilising the model library to construct a flowsheet of the compression system, including the compressor sections, inter-stage cooling, knock-out drums, surge valves and a dehydration unit.

Figure : Model topology for multistage CO₂ compression, developed in gPROMS® gCCS. Each centrifugal compressor section consists of multiple stages, modelled via polytropic efficiency, with negligible hold-up and inertia of gas. The polytropic efficiency for the 1st, 2nd, 3rd and 4th compression stages are 79.38, 86.66, 82.92 and 80.82 %, respectively, within the range (74.50-87.45 %) highlighted in IEAGHG (2011). The thermo-physical properties and phase equilibrium of the fluid is determined through gSAFT. The foreign

object CompPerformFO determines the compressor maps and number of stages for a given set of input parameters (PSE, 2016).

Specific outlet conditions for the individual water coolers are not given in IEAGHG (2011), therefore, the two inter-stage water cooling steps are lumped into one and modelled via a heat exchanger unit. The cooling water supply is a set input parameter and each of the interstage cooling heat exchangers uses water at 6 bar and 12°C. The pressure drop over the inter-stage cooling and knock-out drums is 0.2 bar each. Ensuring the inlet conditions to the compression stages are identical to IEAGHG (2011). The dehydration unit removes H₂O from the CO₂ stream to a specified moisture content, and consists of three molecular sieve beds, two used for drying and one in regeneration mode operating simultaneously. The regeneration fraction (10%) and temperature (250°C) are specified parameters, and the model calculates the heat requirement and power consumption (PSE, 2016). Table 2 shows the input parameters used to simulate the process. The inlet flow contained 95.88 vol.% CO₂, 4.11 vol.% H₂O, and 0.01 vol.% N₂. The final CO₂ product contained 50 ppm moisture at 111 bar, ready for pipeline transportation.

Table 2: Input parameters and model validation

Parameters	Value	Simulation	Deviation (%)
Inlet Flowrate (kg/s)	154.57	154.57	0.00
Inlet Temperature (°C)	38.00	38.00	0.00
Inlet Pressure (bar)	1.60	1.60	0.00
Outlet Flowrate (kg/s)	151.90	148.17	2.46
Outlet Temperature (°C)	73.00	73.00	0.00
Outlet Pressure (bar)	111.00	110.76	0.22
1 st Compressor Power (MWe)	21.70	22.63	-4.29
2 nd Compressor Power (MWe)	24.10	20.60	14.52
3 rd Compressor Power (MWe)	8.00	6.97	12.88
4 th Compressor Power (MWe)	3.70	3.44	7.03
Total Power Demand (MWe)	57.50	53.68	6.64
Energy Demand (GJ/tCO ₂)	0.39	0.36	6.64
Energy Demand (kWh/tCO ₂)	107.77	100.61	6.64

For continuity across the CCUS chain the power demand has been converted into GJ/tCO₂ and kWh/tCO₂. Based off the data for the IEAGHG (2011) base case B0 the energy demand for compression is 0.39 GJ/tCO₂ or 107.77 kWh/tCO₂, within the bounds detailed in Aspelund & Jordal (2007). The simulation results (0.36 GJ/tCO₂) are 6.71% lower than expected. The simulation calculated the dehydration unit requires 4.04 MWe, to heat the regeneration stream to 250°C. The IEAGHG report does not give the power requirements for the dehydration unit. Therefore, if this additional power is included the simulations overall power demand is only 0.31% higher.

4. Results and Discussion

The flowrate basis is 1 kg/s for all technologies, in reality large CCUS clusters will have a range of flowrates attached with some having transient production, this is another challenge highlighted in Moe et al. (2020). Figure 3 highlights the power requirement for the compressors and dehydration unit, also included is the overall energy demand. All the technologies investigated have a low enough initial H₂O content that the knock-out drums remove moisture to <600 ppm. Removing the need and the small power demand associated with the dehydration unit, subsequently decreasing the inlet flowrate and power demand for the 2nd compressor. For the post-combustion MEA case this reduces

the overall power demand by 9.35 %, when going from 20 to 600 ppm. Interestingly, the energy demand for the high moisture MEA case (162.43 kWh/tCO₂) is lower than membrane separation for blast furnace gas treatment (174 kWh/tCO₂). Whereas the low moisture MEA case is 2.82% higher, due to a higher 2nd compressor power demand and the inclusion of the dehydration unit, although this only accounts for 7.76 kWh/tCO₂. Membrane separation has no H₂O in the capture CO₂ stream and requires no dehydration unit; however, the potential savings are offset by the the initial high temperature (40°C) and low pressure (1 bar).

Starting at a higher pressure reduces the number of compressions stages and overall pressure ratio, therefore, reducing the energy demand. For NH₃ this significantly reduces the power required for the first compressor which elevates the stream to 7 bar. Resulting in NH₃ requiring 19.23% less power overall than MEA, for the 20 ppm scenario. The Selexol process produces two CO₂ streams, it is assumed a 50/50 split between them, therefore, a pre-compression stage is required to get both streams to the same pressure. Slightly offsetting the savings of a higher initial stream pressure. Overall, there is no significant conditioning difference between the pre- and post-combustion capture technologies.

Figure : Individual unit power consumption and overall conditioning energy demand

Both of the industrial sources require no dehydration unit, and produce identical energy demands of 174 kWh/tCO₂. Comparable to the 20 ppm and 300 ppm MEA cases. The results show the end moisture level does have an effect on process performance, but not as significant as the initial stream pressure.

Energy demand in terms of kWh/tCO₂ in almost all cases is higher than expected, compared to Aspelund & Jordal (2007) and the validation work. A result of the small CO₂ flowrate basis, indicating economies of scale could play a major role in determining successful cluster partnerships. For example, a small-scale H₂/CO₂ PSA system, could be connected to much larger capture streams. Whereas a small-scale pre-combustion capture plant may be economically unfavourable.

5. Conclusions

The link between CO₂ source and transport needs to be clearly quantified to aid in the design and decision making of CCUS clusters. Within this study, process simulation has shown energy requirements for compressing and conditioning CO₂ streams from various power generation and industrial sources. This is purely a technical analysis and does not consider the economic impact of altering the inlet stream properties. End point moisture level has an effect on overall power consumption; however, the greater impact comes from the initial stream pressure. Higher starting pressures result in lower overall pressure ratios, and reduced number of compressor stages. The results indicate small-scale low-pressure capture sources may suffer economies of scale during compression and conditioning. Future studies should investigate the effects of different flowrates attached in the same CCUS cluster.

Life Cycle Optimization of Hybrid Energy Systems towards Carbon Neutrality

Xueyu Tian, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

xt93@cornell.edu

Abstract

In this work, we propose a novel superstructure of the hybrid energy systems with geothermal-natural gas-hydroelectricity, biomass and earth source heating, and deep water source cooling (DWSC). Based on the superstructure, a multi-period mixed-integer nonlinear fractional programming (MINFP) model is formulated to address the optimal design of the proposed hybrid energy systems to determine the optimal energy system configuration and operational conditions corresponding to the lowest leveled cost of energy, and simultaneously assess the life cycle carbon footprint. To tackle the computational challenges stemming from the combinatorial nature and nonconvexity of the resulting MINFP problem, a tailored global optimization algorithm integrating two state-of-the-art algorithms, namely the parametric algorithm and the branch-and-refine algorithm, is employed. The applicability of the proposed optimization framework for the hybrid energy systems is illustrated through the application based on Cornell campus hybrid energy system for accommodating the seasonal demand of cooling, heating, and power across the campus.

Keywords: superstructure optimization, life cycle assessment, hybrid energy systems.

1. Introduction

Approximately 78%-80% of the commercial energy around the globe comes from fossil fuels, namely petroleum, coal, and natural gas (Güney and Kaygusuz, 2010). Considering the rapid depletion and environmental concerns with respect to fossil resource utilization, it is imperative to reduce the dependence on conventional fossil resources and shift to carbon-neutral energy (Lawan and Abidin, 2020). With increasing research interest, one promising platform to achieve such carbon-neutral energy transition is hybridization of multiple energy sources. Hybrid energy systems couples two or more energy sources, potentially including fossil fuel, biomass, geothermal energy, or nuclear power, as well as other intermittent energy supplies, such as wind turbine, photovoltaic system, and hydropower (Davis et al., 2018). Hybrid energy systems can be used for, but are not restricted to, electric power generation. Other products from hybrid energy systems include heat, cooling, and hydrogen, etc (Ning and You, 2020). On the one hand, hybrid energy systems can mitigate the problem of intermittency and over-sizing of the overall systems based on single energy source (Beckers et al., 2015). On the other hand, hybrid energy systems that couple various forms of generation together and/or with storage technology may be able to provide more elastic supply to conform with less elastic demand (Dykes et al., 2020). The

engineering reliability, environmental implications, and economic feasibility are the central aspects that must be systematically considered when designing the hybrid energy systems. In this work, we propose a novel superstructure that incorporates geothermal-natural gas-hydro electricity, biomass and earth source heating, and deep water source cooling (DWSC) (Gong and You, 2015). A mixed-integer nonlinear fractional programming (MINFP) model is formulated to minimize the levelized cost of energy and simultaneously evaluate the carbon footprint of the optimal design and operations of the proposed hybrid energy system. The model explicitly considers the seasonality of heat and cooling demand, while the electric power demand is assumed to be relatively constant. To illustrate the applicability of the proposed modelling framework, a case study of Cornell's renewable campus energy systems is considered.

2. Superstructure Generation

In this work, we propose a novel superstructure of hybrid energy systems with geothermal-natural gas-hydro electricity, biomass and earth source heating, and DWSC. The geothermal energy and DWSC are regarded as the primary heating/cooling source. Occasionally, these major energy sources cannot completely accommodate the heating and cooling demand, or their availabilities are limited due to the geographical conditions. Therefore, conventional cooling technologies and heating supplement based on renewable biomass are considered as the auxiliaries to supply the peak heating and cooling demand (Yue et al., 2014). The overall superstructure of the proposed hybrid energy system is demonstrated in Figure 1. The electric power demand is satisfied by a set of generation technologies, which substantially vary regionally and thus are not completely reflected in the general superstructure.

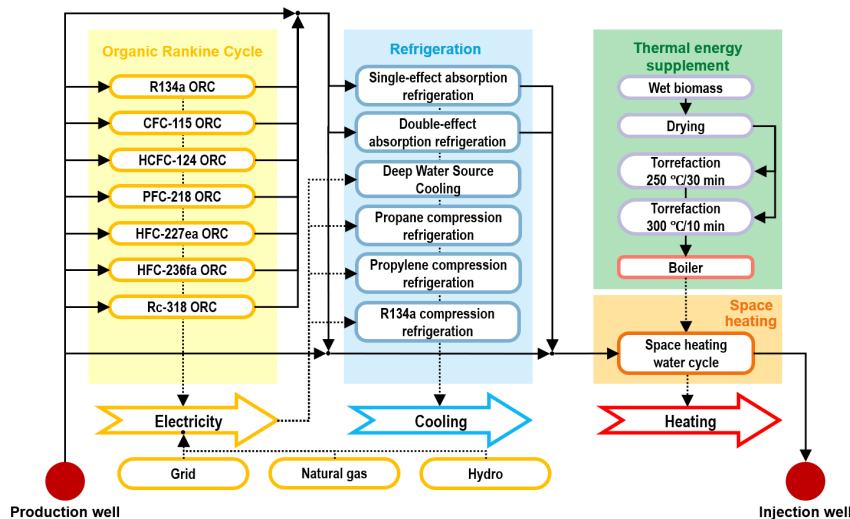

Figure 1. Overview of the proposed superstructure of hybrid energy system with geothermal-natural gas-hydro electricity, biomass and earth source heating, and DWSC.

3. Model Formulation

The general superstructure optimization model is subjected to five groups of constraints, namely, mass balance and configuration constraints, energy balance constraints,

temperature constraints, logic constraints, techno-economic evaluation constraints. The selection of technologies is represented by the integer decision variables. The number of well sets are integer decision variables. Other important decision variables such as the mass flow rates, energy flows, and technology capacities are continuous variables. The objective function, $LCOH$, includes integer variables such as the numbers of production wells and injection wells, and thus is a mixed-integer fractional term. The other nonlinear terms mainly come from the separable concave terms induced by economies of scale, as well as the bilinear terms. Therefore, the resulting problem is a MINFP problem. The general form of this MINFP problem is summarized as follows.

$$\min LCOH = \frac{\sum_{t=1}^{pl} (AIC + AOC - CREDIT)_t}{\sum_{t=1}^{pl} \frac{HEAT_t}{(1+r)^t}} \quad (1)$$

s.t. mass balance and configuration constraints; (2)

energy balance constraints; (3)

temperature constraints; (4)

logic constraints; (5)

techno-economic evaluation constraints; (6)

where $LCOH$ denotes the levelized cost of heat. AIC_t , AOC_t , and $CREDIT_t$ refer to the annualized investment costs, annual operating cost, and power and cooling credits in year t , respectively. $HEAT_t$ represents the heat produced in year t . r and pl denote the discount rate and lifetime of the plant.

14: end while
15: return  $q$ 

```

Figure 2. The pseudocode of the tailored global optimization algorithm integrating the parametric algorithm and the branch-and-refine algorithm.

LCA is also conducted based on the optimization results. The goal of the LCA study is to quantitatively assess the life cycle environmental impacts of the optimal designs. Heat is widely used for residential, commercial, and manufacturing purposes, with approximately 50% of the total heat demand coming from the residential sector (McCabe et al., 2016). Therefore, it is worth looking into the environmental performance of heat generation, which arouses special research interests in the

literature. The functional unit of this LCA is defined as 1 kWh of heat generated. The impact category to evaluate the life cycle environmental performance of the hybrid energy system is dedicated to the global warming potential (GWP) to examine the extent of carbon neutrality. GWP is calculated using the IPCC 2013 method with 100-year time frame (Stocker et al., 2013).

The resulting MINFP problem for the optimal design of the proposed hybrid energy systems is computationally challenging due to its combinatorial nature and nonconvexity. In order to tackle the computational challenge, a tailored global optimization algorithm integrating two state-of-the-art algorithms, namely the parametric algorithm (Zhong and You, 2014) and the branch-and-refine algorithm (You and Grossmann, 2011), is applied. The pseudocode of the tailored global optimization algorithm is given in Figure 2, where a dual-loop structure can be identified.

4. Application to Cornell Campus Energy System

The proposed superstructure optimization model is applied to tackle the optimal design of an envisioned hybrid energy system with lake source cooling (LSC), hybrid earth source and biomass heating, as well as geothermal binary, natural gas and hydro-based power for meeting the seasonal demand of cooling, heating and power of the facilities (Tian et al., 2019). Historical demand data for Cornell's campus in Ithaca, New York are used for developing the case study. We address the problem over 12 time periods, with each corresponding to one month. The geothermal fluid is extracted from at most five production wells and the deep lake water is pumped from the Cayuga Lake. Willow is chosen as the feedstock for torrefaction, because it is one of the main commercial woody bioenergy crops in U.S. All computational experiments are conducted on a PC with Intel (R) Core (TM) i7-6700 CPU @ 3.40GHz and 32GB RAM. The superstructure optimization model and solution procedures are coded in GAMS 33, with CPLEX 12.10 as the MILP solver and BARON (version 20.10.16), SCIP (version 7.0) being the mixed-integer nonlinear programming (MINLP) solvers. The relative optimality tolerances are all set to 10^{-6} .

The case study considers at most five production and five reinjection wells, because approximately five well sets are sufficient to meet base-load heating demand for Cornell's Ithaca campus (Beyers, 2018). The mass and energy balances for ORCs and compression refrigeration cycles are extracted from the HYSYS simulation results. The performance and cost data for the absorption refrigeration are retrieved from the literature. Mass and energy balance information for the biomass torrefaction plant is reported in existing publications. The standard levelized cost model is adopted with a constant discount rate of 5% (Lee et al., 2019). According to (Beckers et al., 2015), the geothermal gradient in Ithaca is assumed to be 25 °C/km. The well depth is assumed to be 5 km, and the average geofluid production temperature is around 125 °C (Tian et al., 2020). For the DWSC system, deep lake water (250 feet deep) at around 3.89 °C is pumped to a heat exchanger at the shore, which returns gradually to the lake at a temperature no higher than 12.8 °C (Facilities and Campus Services, 2005). The space heating supply/temperature is set to 82 °C/72 °C and 71 °C/65 °C at high and low heat demand, respectively.

For a better comprehension of the optimal design in terms of *LCOH*, the breakdown details of the *AOC* and the *AIC* are shown in Figure 3(a). *AIC* is calculated with the same project lifetime (20 years) and discount rate (5%) as the *LCOH* model. The sum of

AOC and *AIC* is the total annualized cost (*TAC*). The *TAC* for the optimal design is \$44.44 MM/yr, with *AOC* accounting for 55.5%. The major contribution from the natural gas turbine (61%) and geothermal well drilling (19%) can be easily observed in terms of capital investment. Moreover, the breakdown of the annual GWP of the optimal solutions is shown in Figure 3(b). Emissions from the gas turbine (up to 118.12 kton CO₂-eq/yr) dominates the annual GWP, while there are no direct emissions from hydro power. We note that the selection of technologies varies from month to month, as well as the operating level. We focus on three months, namely January, May, and August to represent the cold winter days, average weather conditions, and hot summer days, respectively. The DWSC is able to accommodate all the cooling demand in most months other than August, in which compression refrigeration cycle using R134a as working fluid is selected as the auxiliary cooling supplier. In January, torrefied wood is combusted to provide extra hot water for space heating.

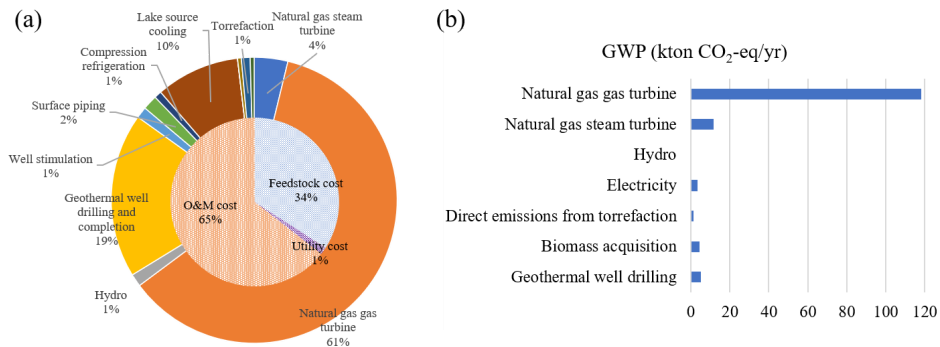

Figure 3. (a) Breakdowns of the annual operating cost (inner pie chart) and the annualized investment cost (outer donut chart); (b) Annual GWP.

Table 1. Computational performance for the case study using BARON (version 20.10.16), SCIP (version 7.0) and the tailored global optimization algorithm.

Solver	Discrete Variables	Continuous Variables	Constraints	Objective Value (\$/MMBTU)	Solution Time (CPUs)
BARON (version 20.10.16)	26,277	3,856	81,746	16.12	835.16
SCIP (version 7.0)	26,277	3,856	81,746	N/A ^a	-
Global Optimization Algorithm	26,294	3,874	81,806	16.12	24.13

^aNo upper/low bound is returned when reaching the time limit of two hours.

To demonstrate the computational performance, the proposed superstructure optimization problem is solved by general-purpose MINLP solvers BARON and SCIP, as well as the tailored global optimization algorithm. Table 1 summarizes the computational results for the case study. BARON and the tailored global optimization algorithm return the identical optimal solution. BARON returns the optimal solution within 835.16 CPU seconds, while the global optimization algorithm only requires 24.13 CPU seconds. We note that there is no upper and low bound information returned by SCIP solver before the program reaches the computation time limit of two hours. Overall, the tailored optimization algorithm is more efficient and is less dependent on initial values than general-purpose solvers. Since there is uncertainty embedded in the hybrid energy systems design problem including the seasonal utility demands in coming

years, the deterministic optimization problem proposed in this work that overlooks uncertainty may result in suboptimal or even infeasible solutions in certain uncertainty realization. It is crucial to hedge against such uncertainty using systematic approach in the future work after relevant data become available.

5. Conclusion

A novel superstructure optimization model was developed to assess the economic feasibility and environmental implications of the proposed hybrid energy systems with geothermal-natural gas-hydro electricity, biomass and earth source heating, and DWSC. The applicability of the proposed optimization framework was illustrated through a case study based on the Cornell campus energy systems. The resulting levelized cost is as low as \$16.12/MMBTU and the proposed tailored optimization algorithm showed high performance in solving the superstructure optimization model that outperformed the general-purpose solvers.

Abstract

In this work, we present a mixed integer linear programming (MILP) model to assess the economic value an aggregator-led community electrical energy storage system provides, with the inclusion of online degradation constraints. Studies have shown that community energy storage devices present additional benefits to end users, such as an increased renewable generation self-consumption, peak shaving and reduced electricity costs, when compared to individually-owned devices. Further benefits may also be realised by giving a load aggregator partial access to the device to participate in the wholesale energy market, however previous studies have mostly assessed such benefits solely from an aggregator or community point of view. Also, degradation considerations, when considered, were implemented offline via a rolling horizon approach. The proposed model in this work includes online degradation considerations over the entire planning horizon to obtain the optimal schedule of the storage device. The community consists of a number of individual participants each having local renewable energy generation and batteries installed behind-the-meter, with the ability to export energy back to the grid. The LA has partial access to the community energy storage devices to participate in the UK day-ahead energy market. The model assesses the economic value a LA can realise under different storage sharing quotas with an overall goal to maximise profits without infringing on the interests of its participants. Results show that both the community and aggregator stand to gain with certain storage device and profit sharing quotas.

Keywords: Community energy storage, Energy arbitrage, Battery degradation, Mixed integer optimisation

1. Background

Electrical energy storage (EES) technologies have been shown to improve power system reliability, flexibility and security (Ma et al., 2018). This is more important in the present day as there is a growing reliance on intermittent renewable energy sources (RES) - solar and wind energy - owing to increasing commitments to the decarbonisation and decentralisation of the electric grid. EES devices have thus been identified as the “missing piece” in the integration of such RES (Jankowiak et al., 2020) towards reduced greenhouse gas emissions.

EES devices also have the advantage of being easily deployed both in front-of-meter and behind-the-meter (BTM) applications. Once deployed, they can be controlled in a centralized – by a large energy participant e.g. a system operator, load aggregator (LA) –

or a decentralized – by small, privately owned participants – manner (Castagneto Gisse et al., 2019). Decentralized devices may also be pooled and centrally controlled in what may be referred to as community energy storage (CES) (Dong et al., 2020). Studies have shown that sharing EES devices increase RES self-consumption, participant self-sufficiency, peak demand shaving and lowers costs for individual participants (Dong et al., 2020; Roberts et al., 2019). Such CES devices may also be connected to a LA. LAs give additional advantages of access to energy markets and ancillary services markets, increasing revenue potential and system reliability for a fee (Zhou et al., 2019).

A number of authors have proposed techno-economic models for scheduling CES devices in order to determine the benefits to end-users/participants. Parra et al. (2015) proposed a simulation-based model to assess current and projected performance and benefits of Lithium ion (Li-ion) and Lead-acid (PbA) batteries, showing that a community approach reduced the projected levelised cost by as much as 37%. Schram et al. (2020) considered a multi-objective optimisation-based (MOO) approach for the community where cost and CO₂ emission objectives were explored assuming participation in the day-ahead (DA) market. Terlouw et al. (2019) also proposed a MOO approach using different EES technologies but from the perspective of a LA, exploring scenarios of energy arbitrage with/without peak shaving, with Li-ion battery technology showing the best economic and environmental performance. Cycle-induced battery degradation was considered by Pimm et al. (2019) using a rolling horizon approach in a linear optimisation model for CES devices. Degradation considerations are important as the performance of EES devices has been shown to deplete with time, rate and frequency of charging/discharging and operating temperature (Ciez and Whitacre, 2016). Hence, including such considerations presents a more accurate estimation of the benefits to end-users.

In each of the aforementioned studies, and others, benefits - cost and/or CO₂ emission reduction - were almost always solely assessed from the LA's or community's perspective. In reality, shared ownership also exists. Communities may offer partial access of their CES device to a LA with access to additional energy services in exchange for a percentage of the profit. Hence, it becomes important for considerations to be made from both the community's and aggregator's perspective in order to ascertain sharing quotas that profits both parties. To this end, an optimisation model that minimises the total cost of a CES device is proposed. The CES device serves to increase RES consumption within the community, reduce local energy consumption as well as participate in the DA market through a LA. Using different device access and profit sharing quotas, the model seeks to quantify the economic benefits to both the community members and LA. 'Online' battery degradation is also considered in a linear formulation, as opposed to post-processing such values in a rolling horizon approach.

In the rest of the paper, the optimisation problem is outlined in section 2 and the proposed model described in section 3. Results obtained from applying the model to a case study (section 4) are discussed in section 5 with final remarks given in section 6.

2. Problem description

For the system illustrated in Figure 1, the optimisation problem is described as follows.

Given a community with a known number of domestic households (i) each with its energy demand (P_{it}^l), renewable energy generation (G_{it}), partial ($x\%$) access to a CES device with capacity, \hat{C}^{max} , and power, \hat{P}^{max} , and able to purchase power from a supplier at price, C_t^p ,

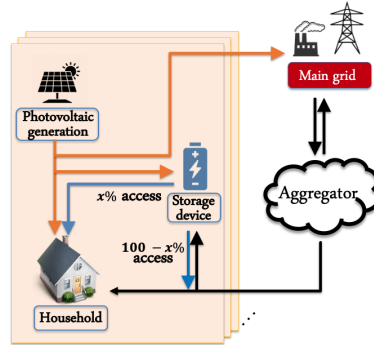

Figure 1: System description

to satisfy local demands as well as feed-in excess generation back to the grid at a price, C_t^s ; a LA (j) with partial access ($100 - x\%$) to the pooled CES device participating in the DA market;

Determine the optimal CES device schedule - charging (P_{it}^{b+}, P_{jt}^{b+}) and discharging (P_{it}^{b-}, P_{jt}^{b-}) power per time - so as to minimise the total cost of electricity purchased for the community and traded by the LA.

It is assumed that the allotted CES device quota to the community and LA are operated independently, and DA market prices (C_t^{DA}) are perfectly forecasted. The latter assumption is justified as DA prices tend to follow similar daily patterns and can be predicted with a high degree of accuracy.

3. Model description

The models for both the community and LA seek to minimise the total net cost of electricity purchased, and are described as follows. For the community, the objective function is given by eq. (1), which is the sum of the cost of power imported (P_{it}^{imp}) less the revenue generated from the amount fed into the grid (P_{it}^{exp}). The amount of power imported/exported is determined using eq. (2) with an additional restriction that the battery is solely charged using excess energy from the RES. The state of charge (SOC) of the battery (SOC_{it}) at each time period is calculated as the net power from charging and discharging the battery, where η^c and η^d are the charge and discharge efficiencies of the battery. Bounds on the battery power and SOC are enforced using eqs. (4) and (5).

$$\min \sum_{it} C_t^b \cdot P_{it}^{imp} - C_t^s \cdot P_{it}^{exp} \quad (1)$$

$$P_{it}^{imp} - P_{it}^{exp} = P_{it}^l + P_{it}^{b+} - P_{it}^{b-} - G_{it} \quad \forall i, t \quad (2)$$

$$SOC_{it} = SOC_{i,t-1} + \eta^c \cdot P_{it}^{b+} - \frac{P_{it}^{b-}}{\eta^d} \quad \forall t \quad (3)$$

$$P_{it}^{b+}, P_{it}^{b-} \leq x \hat{P}^{max} \quad \forall i, t \quad (4)$$

$$x SOC^{min} \bar{C}^{max} \leq SOC_{it} \leq x SOC^{max} \bar{C}^{max} \quad \forall i, t \quad (5)$$

The objective function for the LA is given by eq. (6) - to minimise the total cost obtained from trading in the DA market using the remaining portion ($100 - x\%$) of the CES device subject to eqs. (3) - (5) for the LA (j). It is assumed that the total quantity of electricity

traded by the LA has negligible effect on market prices, hence a 'price taker' strategy.

$$\min \sum_{jt} C_t^{DA} \cdot (P_{jt}^{b+} - P_{jt}^{b-}) \quad (6)$$

Battery degradation is modelled according to the power law relationship given by Ciez and Whitacre (2016). These expressions are given in eq. (7) for Li-ion and PbA batteries, where \hat{C}_t represents the fraction of the total capacity degraded at time t by reason of the SOC swing (SOC_t^{sw}) from battery actions in the previous time periods. The SOC swing is determined as the actual depth of discharge over the past 24 hours of battery operation, and the degradation models are implemented via a piecewise linear function.

$$\hat{C}_t = \begin{cases} \left(\frac{SOC_t^{sw}}{1307.4} \right)^{0.95}, & \text{Li_ion} \\ \left(\frac{SOC_t^{sw}}{12.838} \right)^{1.838}, & \text{PbA} \end{cases} \quad \forall t \quad (7)$$

Additional constraints are also included for members of the community and the LA to ensure that total energy discharged from the battery at each time period is always less than or equal to the net amount contributed to charging the battery. Hence, each participant may only use stored energy up to the net amount contributed in previous time periods.

4. Case study

For a case study, we consider a community with 1000 households each having a 3kWp PV cell and 1kW/2kWh Li-ion battery installed. Load profiles for groups of households for the month of January, 2019 were randomly generated using data from Elexon 10-year average load profile for domestic consumers in the United Kingdom (UK). The solar energy generated by each household is used to reduce household demands, the excess of which can either be exported to the grid at a fixed rate of 5.5p/kWh or used to charge the battery. Each of these batteries are pooled to form a CES device, a fraction ($x\%$) of which can be offered up to a LA in exchange for a percentage ($y\%$) of the profits realised from trading in the UK DA market. Households also purchase electricity to satisfy local loads using a time of day tariff. For this study, the EKO tariff (Greenenergy) is adopted.

These considerations are implemented using Pyomo 5.6.8 and solved with Gurobi 9.0 solver and an optimality gap of 1%. The piecewise linearization was implemented using Pyomo's "Piecewise function" with 11 equidistant SOC swing values ranging from 0 - 1 inclusive. In order to ascertain the value to both the community and LA, storage quotas ranging from 0 - 100%, with a step size of 20, were used to obtain results on the minimum costs to each party with/without degradation considerations.

5. Results & Discussion

Figure 2 shows the total household savings under differing CES device quotas and LA profit sharing percentages. The model was run for each scenario obtaining globally optimal solutions in less than 40s (20s for cases without degradation considerations). The total savings, with values indicated, are the sum of the average household savings and a percentage of the LA's profit. A CES device quota value of $x = 0\%$ corresponds to a case where the LA has full access, and the community members may only import power to satisfy residual load demand, or export excess solar energy at the feed-in price. This is also the base household cost value, below which the total household savings for the

community is calculated. A CES quota of 100% implies sole usage of the CES device by the community, and is the point above which additional economic benefit is realised by the community owing to LA participation.

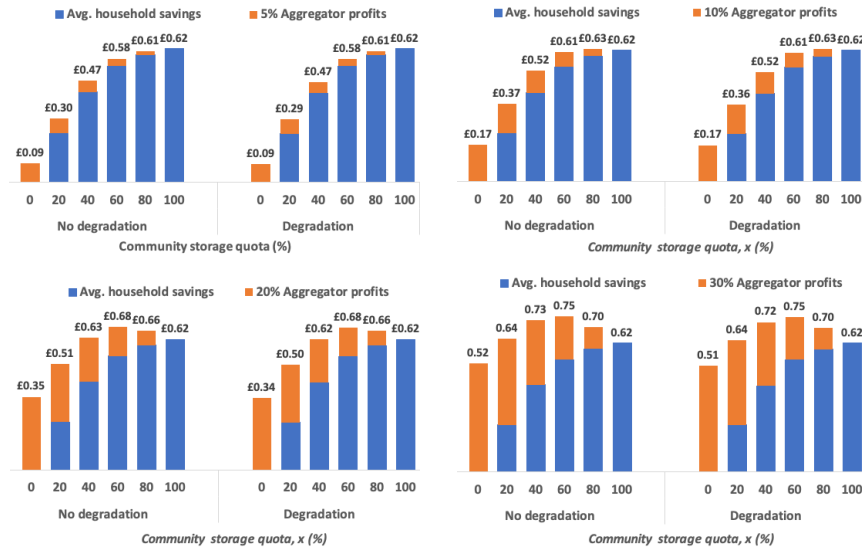

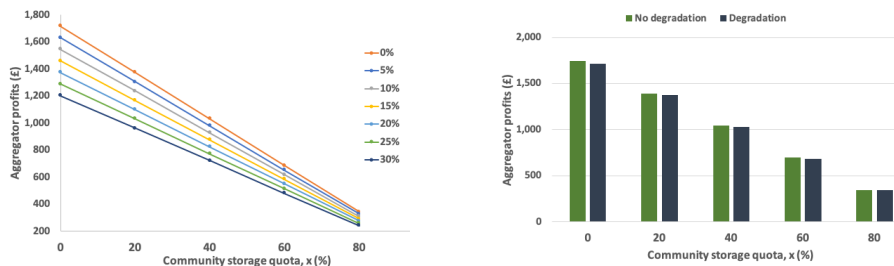

Figure 2: Total household savings

(a) Profits per revenue sharing quota (y%)

(b) Profits with/without degradation

Figure 3: Load aggregator profits

It can be first observed that for a 5% profit payment, the community stands to lose in giving the LA any form of access to the CES device. With increasing incentives payment percentages, the quota the community can let go of for a profit also increases up to 80% (community storage quota value of 20%) where 30% of the LA profits are remitted. Figure 3a also shows that the LA stands to gain from an increased profit sharing quota. This is as the community is more likely to give greater access to the CES device which leads to an increased overall profit for the aggregator.

The impact degradation has on the total household savings is barely seen as it is spread across all households for the period of consideration. Degradation considerations are better observed in the LA profits shown in Figure 3b where with higher access by the LA, and therefore greater use, the overall profits realised reduce. This is attributed to a reduction in available capacity owing to degradation over the period of consideration, and

represents a more realistic estimation of actual earnings.

6. Conclusion

In this work, the economic benefits an aggregator-led community EES device could realise were assessed from both the community's and LA's point of view. To achieve this a mixed integer linear programming (MILP) model was proposed to obtain the optimal schedule for a CES device part accessed by the community and LA. The community is assumed to consist of a set of households with energy demands, local generation and the ability to feed-in to the grid. Online degradation constraints were also included to accurately capture the final value to both parties based on use of the CES device.

Using differing CES device access quotas and LA profit sharing percentages, the economic value to the community - in terms of total household cost savings - and LA - in terms of total profits - were investigated. Results showed that both parties stand to gain at a LA profit sharing value above 5% under differing storage quota ranges. Conditions in which the community ran at a loss were also identified, and the impact of degradation, especially on the LA's profit, was highlighted.

Clean Electricity Generation from Sewage: a novel Ultra-Supercritical Water Oxidation Technology with integrated CCS

Sanjay Mukherjee,^a Solomon Brown^{a,*}

^a*Department of Chemical and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, United Kingdom*

s.f.brown@sheffield.ac.uk

Abstract

Waste management and clean electricity generation are amongst the most critical challenges and major barriers towards achieving sustainability. Ultra-Supercritical water oxidation (USWO) is an emerging technology that can possibly provide a solution for mitigating both these issues. It inherently allows the use of low-grade fuels, such as waste, for electricity generation with high efficiency. However, the true potential of USWO technology has not been extensively reported in the existing literature. This study focuses on modelling and optimisation of a novel USWO process working on the principles of Brayton cycle for electricity generation using sewage as fuel. The USWO process is integrated with carbon capture and storage (CCS) technology to reduce CO₂ emissions. The process design also incorporates water recovery facility from the sewage used as the fuel stream. An advanced system level process model is developed in Aspen Plus simulator using experimentally derived inputs together with FORTRAN programs. A sensitivity analysis is conducted to determine the impact of reactor temperature on the net electrical efficiency. The results indicate that the USWO technology can generate electricity from sewage with net electrical efficiency of 31.5%. It is also observed that integration of CCS can reduce the CO₂ emissions to zero with an efficiency penalty of 3.5% points. This efficiency penalty is comparable to the best performing CCS technologies for conventional gas- and coal-fired power plants. The sensitivity results show the electricity output is proportionate to reactor temperature and is primarily restricted by the material properties of the USWO reactor. The results also indicate nearly complete recovery of water from the sewage without any additional processing or energy requirement. Furthermore, the study also provides a systematic methodology to test other low-grade fuels (organic wastes) for the proposed USWO technology.

Keywords: Sewage Treatment, electricity generation, CO₂ capture, process modelling.

1. Introduction

With the rising world population, waste production has also soared substantially. Landfilling of waste can produce undesirable greenhouse gases, odour and leachate, which can contaminate the environment (Liu et al. 2017). Therefore, in the waste management hierarchy, landfilling is unquestionably the most unfavourable choice (Lukumon et al. 2013). Existing biochemical waste conversion processes are slow and have low conversion rates (Tyagi, 2013). Waste incineration, pyrolysis and gasification are attractive technologies that can generate waste-derived products such as electricity,

heat and synthetic fuels (Nakakubo et al. 2017, Lu et al. 2017, Gabriele and Siglinda, 2020). However, high moisture content in waste, due to its type (sewage and food waste) or lack of segregation at the source, means a considerable amount of energy intensive pre-processing required to make the waste suitable for use in the incinerator, gasifier or pyrolyser. This significantly impacts the overall efficiency of the process and can make the technology financial unviable in most cases (Syed-Hassan et al., 2017).

Supercritical water oxidation (SWO) is an emerging technology which has the potential to convert wastes with high moisture and low energy content to electricity, heat and synthetic fuels, more efficiently (Bermejo and Cocero, 2006). In a SWO technology, the oxidation of organic waste takes place in a supercritical water environment, which is an excellent non-polar solvent that dissolves the organic substance present in the sludge, thus, supporting the decomposition and reaction. Additionally, the heavy metals in the solid residues gets stabilised after the SWO (Hantoko et al., 2019). Sulphur and nitrogen in the waste gets deposited as inorganic salts in the supercritical water which means no NO_x or SO_x are released in the reactor exhaust (Guo et al., 2015). As the moisture in the waste becomes supercritical water in the reactor and helps in the conversion process, there is no requirement for waste pre-processing for moisture reduction.

Several experimentally derived reactor designs and process models for Supercritical Water Gasification or Oxidation has been extensively covered in the literature (Azadi and Farnood, 2011; Okolie et al., 2019). However, very limited studies on the USWO of waste for electricity generation is available. Moreover, almost all the published literature on SWO uses Rankine cycle for electricity generation (Bermejo and Corcero, 2006; Donatini et al., 2009, Tang et al., 2020). This work conducts a detailed performance evaluation of a novel USWO process for electricity generation using Brayton cycle, with integrated oxy-combustion CO_2 capture technology, based on electrical output, net electrical efficiency and CO_2 emissions. The work also estimates the energy penalties occurred due to carbon capture through modelling and simulation using common modelling assumptions.

2. Methodology

This section describes the assumptions and input parameters used to develop the model of the proposed USWO process.

2.1 Feedstock type

Sewage sludge contains high organic matter and therefore, can be potentially used as an energy source for electricity generation. This study uses sludge from wastewater treatment plants as feedstock in the USWO process. The characteristics of the sewage sludge used in the model are given in Table 1.

Table 1: Proximate and Ultimate analysis (wt % dry basis) of sewage (Hantoko et al., 2019).

Items	Proximate Analysis	Items	Ultimate Analysis
Fixed carbon	2.29	Carbon	18.94
Volatile matter	35.14	Hydrogen	2.21
Ash	62.57	Nitrogen	2.89
		Sulphur	0.6
Lower heating value	5.89 MJ/kg	Oxygen	12.79

2.2 Process description

A process model for the USWO of sewage sludge to produce electricity along with carbon capture is developed in Aspen Plus V10 by Aspen Technology Inc. A detailed schematic of the process is shown in Figure 1. The overall process primarily consists of five key stages, (i) Air Separation Unit (ASU), (ii) Feed Stock preparation, (iii) Reactor unit, (iv) electricity generation and (v) CO₂ capture.

Figure 1: Schematic of the USWO process of sludge with carbon capture.

In the reactor of the USWO process, the feedstock is fully oxidised by pure oxygen (O₂) in an exothermic reaction under a supercritical water environment at 300 bar and 700 °C. The O₂ required is produced in an ASU with 95% purity (by volume) at 1.0135 bar. This O₂ is then compressed to the reactor pressure in a series of intercooled compressors. The heat released from O₂ compression is used to preheat the already pressurised reactor feedstock consisting of sewage sludge mixed with make-up water. For a given flowrate of sludge, the reactor temperature can be regulated by varying the flowrate of make-up water in the sludge-water mixture. The high-pressure and hot reactor exhaust, comprising of supercritical water and products of oxidation reactions, is expanded to atmospheric pressure in an expander-generator to produce electricity. The heat in the expander exhaust is used to partially preheat the reactor feed (Sludge + water) to up to 87 °C. The expander exhaust is then sent to a water-cooled condenser unit followed by a flash separator, where most of the condensed water is extracted from the gases. The outlet gases from the flash separator consist of over 90% CO₂ (by weight). The purity of CO₂ in the stream is increased by some pre-processing, followed by CO₂ compression for transport and storage.

2.3 Aspen Plus Model

A MIXCINC stream class is selected to represent the type of components flowing through the flowsheet streams. Components such as CO₂, O₂, methane, hydrogen, H₂O and other gases are entered as ‘Conventional’ in the components list. Sewage Sludge and ash comes in a variety of compositions and therefore, are the only components entered as ‘Non-

conventional' in the list. The Peng-Robinson-Boston-Mathias (PR-BM) is used as the property method for the conventional components whereas, enthalpy models HCOALGEN and DCOALIGT are used for the non-conventional components.

Table 2: Design assumptions and input parameters used for developing the process flowsheet model in Aspen Plus.

Unit operations	Parameters
ASU and O ₂ compression	O ₂ purity: 95% (vol); Energy consumption: 250 kWh/ton of O ₂ ; Compressor efficiency: 83 %; Pressure ratio: 2.97
Air compressor	Pressure ratio: 3.12
Reactor	Pressure: 300 bar; Temperature: 700 °C; Zero pressure drop; Conversion rate: 99.9 %.
CO ₂ compression	Delivery condition: 110 bar and 30 °C; 4 stage compression; Compressor efficiency: 83 %
Expander	Isentropic efficiency: 92 %; Outlet pressure: 0.046 bar for USWO with CCS and 1 bar for USWO without CCS

The Gibbs equilibrium reactor model RGIBBS is used for modelling the reactor. The key inputs needed for RGIBBS reactor model are pressure and heat duty. A multistage MCOMPR model is used to design the compressor units with inputs such as outlet pressure, temperature and efficiency. A 'COMPR' model is used to design the expander. The pressure, isentropic efficiency and mechanical efficiency are the key input parameters to the 'COMPR' model. A 'HeatX' and 'MHeatX' type heat exchanger models are used for modelling the heat exchanger units. A 'PUMP' model is used to pressurise the make-up and cooling water in the process.

3. Results and Discussions

The performance of the USWO of sewage sludge for electricity generation with CO₂ capture is estimated through modelling using Aspen Plus V10. The key performance indicators obtained from simulations are listed in Table 3. The USWO process without CCS generates 1,871 kWh of net electricity with 31.7 % efficiency. In comparison, the USWO process with CCS generates 207 kWh less net electricity with an efficiency of 28.2 % and captures almost all the CO₂ produced in the feedstock conversion process. The lower efficiency of USWO with CCS is mainly due to the significant drop in expander energy output resulting from the reduced mass flowrate of expanding gases caused by the separation of N₂ in its ASU. The expander in USWO with CCS is modelled to partially subdue the energy losses by expanding the gases to a much lower pressure of 0.046 bars. This is only possible since the gases (mainly CO₂) left after condenser and liquid-gas separator are compressed to 110 bars for transportation and storage, instead of venting. Whereas, in USWO without CCS, the expander outlet pressure is set to slightly above atmospheric pressure to overcome any resistance occurred while venting the gases to the environment. It is worth noting that even after reducing the expander outlet pressure, its energy output still experiences a loss of 17.7 %.

Table 3. Plant performance indicators for USWO process with and without CO₂ capture.

Plant Data	Units	With Capture	Without capture
Fuel input energy, LHV (A)	kWh _{th}	5,890	5,890
Expander energy output (B)	KWh	3,126	3,798
Energy consumed in ASU (C ₁)	KWh	504	-
Energy intake in O ₂ compression (C ₂)	KWh	390	-
Energy consumed in Air compression (C ₃)	KWh	-	1,823
Energy consumed in CO ₂ compression (C ₄)	KWh	440	-
Energy consumed by pumps (C ₅)	KWh	128	104
Total auxiliary energy (C=C ₁ +.....+C ₅)	KWh	1,462	1,927
Net electrical output (D = B - C)	KWh	1,664	1,871
Net electrical efficiency (E = D/A x 100)	%	28.2	31.7
Gross electrical efficiency (F = B/A x 100)	%	53.0	64.4
CO ₂ capture efficiency	%	100	-

The design of the USWO process with CCS inherently delivers some additional energy savings achieved by compressing only pure O₂ to 300 bars instead of air, as in the case of USWO process without CCS. Although, the USWO with CCS needs auxiliary energy for the ASU and CO₂ compression unit, this additional energy requirement is much less than the energy saved by avoiding air compression to 300 bars. Table 3 indicates that the inclusion of ASU and CO₂ capture in USWO process does not impose any additional energy penalties than that already imposed by the air compressor, instead, it saves 24 % in auxiliary energy requirement. It is observed that even after one fourth reduction in auxiliary energy, the net electrical efficiency drops by 3.5 % points on adding CCS, which is mainly because of a greater loss (672 kWh) in the expander energy generation than the auxiliary energy savings (465 kWh).

Figure 2: Relation between reactor temperature and net electrical efficiency.

Figure 2 showing the outcome of sensitivity analysis conducted to observe the relation between reactor temperature and net electrical efficiency indicates that a higher reactor temperature will work in favour of the electrical output. Although conventional Brayton cycles are known to operate at temperatures above 1500 °C, the suitability of existing metals and alloys needs to be tested at ultra-supercritical pressures and high temperatures. The outcomes from this sensitivity analysis will be a useful input for suitable reactor

material development and will also help to understand the correlation between additional electricity generation at higher temperatures and associated material cost.

4. Conclusions

This study investigates performance of a novel USWO process that uses sewage as fuel to generate electricity through modelling and simulation. The findings indicate a net electrical efficiency of 28.2 % with 100 % CO₂ capture, which is comparable to some existing coal power plants. The sewage feedstock is free, which makes the technology a useful tool for waste management along with clean and affordable electricity generation.

Design of Food-Energy-Water-Waste Nexus Systems in New York State under COVID-19 Pandemic

Ning Zhao, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

nz225@cornell.edu

Abstract

This article addresses food-energy-water-waste nexus (FEWWN) optimization under the COVID-19 pandemic to alleviate the public health and environmental concerns from increasing food waste generation using waste-to-energy technologies. Food waste generation has noticeably increased during the pandemic across the globe. To alleviate the associated health and environmental concerns, food waste could be converted into electricity and heat through FEWWN systems using waste-to-energy facilities, such as anaerobic digesters and combined heat and power units in wastewater treatment plants and livestock farms. In this work, a multi-period multi-objective optimization model is proposed for the design of efficient nexus systems under various impacts of the pandemic. To illustrate the applicability of the proposed modelling framework, a case study for New York State is presented. The optimized nexus systems could potentially reduce the food waste disposal amounts by 38%. A clear trade-off between the objectives is revealed by the Pareto-optimal solutions. The minimum total cost for the FEWWN system is \$27.1 million; the optimal unit processing profit is \$11.9 per ton processed food waste. Spatial analyses illustrate a strong correlation between facility selections and their processing capacities. Sensitivity analysis revealed that electricity price and biogas yield are the most important factors for the economic objectives.

Keywords: COVID-19, waste-to-energy, nexus optimization, food waste.

1. Introduction

Coronavirus disease 2019 (COVID-19) has been detected in more than 200 countries resulting in tens of millions of confirmed cases and hundreds of thousands of deaths around the world in 2020. Under COVID-19, the food waste amount has increased substantially in the agriculture and residential sectors (Royte, 2020). If the increased amount of food waste is not managed properly, it may cause immense harm to both public health and the environment. In terms of public health, besides the risk of pathogen spread associated with food waste increases (Gerba et al., 2011), more caution and protection measures are required for the waste collectors and recyclers as suggested by the government, due to their potentially contaminating working environment (CDC, 2020). As for the environmental impacts, food waste is responsible for 6% of global greenhouse gas emissions before the COVID-19 outbreak (Poore et al., 2018). One

main cause is landfilling, a conventional method for handling food waste (Kiran et al., 2014), and it has the highest level of greenhouse gas emissions compared to other approaches (Schott et al., 2016). It is important to apply alternative processing technologies to the increased amount of food waste under the COVID-19 pandemic, to prevent the landfilling of increased food waste from further amplifying global warming.

To alleviate both the public health and the environmental concerns, the food waste can be processed through food-energy-water-waste nexus (FEWWN) systems using waste-to-energy technologies (Garcia et al., 2019), rendering it with the potential of serving as a valuable source of sustainable energy (Gong et al., 2015). For instance, anaerobic digestion (AD) has been practically used for the treatment and valorization of food waste (Chen et al., 2017). In AD, food waste is biologically degraded and converted into biogas that mainly consists of methane (60%-70%) and carbon dioxide (30%-40%) (Xu et al., 2018). The biogas produced can be subsequently used as fuel for energy production technologies (Tian et al., 2020), such as combined heat and power (CHP) (Garcia et al., 2016 and 2017) that produces thermal energy and electricity simultaneously. Considering the availability of waste-to-energy facilities represented by AD and CHP in livestock farms (Zhao et al., 2019) and wastewater treatment plants (Bora et al., 2020) across New York State, it is valuable to model and optimize the FEWWN to deal with the increased amount of food waste during the COVID-19 pandemic by including these facilities.

In this work, we address the FEWWN systems optimization on food waste valorization, while considering the impacts of the COVID-19 pandemic on the nexus systems. The impacts include the increasing food waste generation, the relatively short planning horizon, the limited availability of processing facilities, and potential transportation options using repurposed trucks. Under these impacts of the pandemic, the optimization problem focuses on addressing efficient nexus systems that convert the increased amount of food waste into electricity and heating using existing facilities, such as AD and CHP units in wastewater treatment plants and livestock farms. The nexus systems optimization is formulated as a multi-period multi-objective linear fractional program (LFP), with two objective functions of minimizing the total cost and minimizing the unit processing cost of the nexus systems. To illustrate the applicability of the proposed modeling framework, a case study on the FEWWN system for New York State under the COVID-19 pandemic is presented. The major novelties of this work include a novel FEWWN systems optimization modeling framework that considers various impacts of the COVID-19 pandemic on the nexus systems and the uses of existing waste-to-energy facilities and a unique application to a regional FEWWN system for New York State under the COVID-19 pandemic.

2. Problem Statement

The FEWWN system aims to convert the significantly increased amount of food waste due to the COVID-19 pandemic into electricity and heat, using existing waste-to-energy facilities, such as AD and CHP units on wastewater treatment plants (NYSDEC, 2019) and livestock farms (AgSTAR, 2020). In addition to facilitating energy production, such conversion could also alleviate the health and environmental concerns associated with the increasing food waste generation during the pandemic. Food waste feedstocks are collected from each collection site, and then they are transported to processing facilities. Notably, the feedstock could be transported using repurposed trucks, because the

pandemic has reduced the need for professional drivers, such as school bus workers (Guelpa, 2020). The feedstocks transported to a processing facility are converted by the available waste-to-energy technology into intermediate products (Nicoletti et al., 2019), such as biogas. Subsequently, the intermediate products are used as fuel for the energy production technologies in the facility (Ning et al., 2019). For instance, CHP could use the intermediate biogas from AD to produce heat and electricity, simultaneously. Additionally, the food waste that is not transported to waste-to-energy plants would be landfilled. We are given a planning horizon of multiple months, considering that a planning horizon of decades may not be appropriate to depict the COVID-19 pandemic. The planning horizon is partitioned into a set of time periods with identical intervals, and each time period is set to be one month in this study for the case of New York State. Considering the relatively short planning horizon due to the COVID-19 pandemic, the construction of new waste-to-energy facilities to deal with the sudden increases of food waste may not be feasible in the short timeframe, so only existing facilities are considered for food waste processing in this study. In this problem, two objective functions are considered, namely minimizing total cost and minimizing unit processing cost. The total cost depicts the overall cost to deal with the increased amount of food waste under the COVID-19 pandemic, including costs related to food waste processing using waste-to-energy facilities and costs associated with landfills. On the other hand, the unit processing cost represents the cost to acquire, transport, and convert a unit weight of food waste into electricity and heat. In terms of solution strategy, a parametric algorithm (Zhong et al., 2014) is adopted to deal with the fractional objective function, and an ε -constraint method is used to address the Pareto optimal solutions for the objective functions.

3. Results and Discussion

To investigate the potential of converting the increased food waste generation during the COVID-19 pandemic into electricity and heat, we present a case study on New York State, a state that has been influenced significantly by the pandemic. New York State has a 13% increase in monthly food waste generation compared to 2019 (DSNY, 2020). Existing AD and CHP units in wastewater treatment plants and farms in New York State are considered in this study to convert increased food waste into energy.

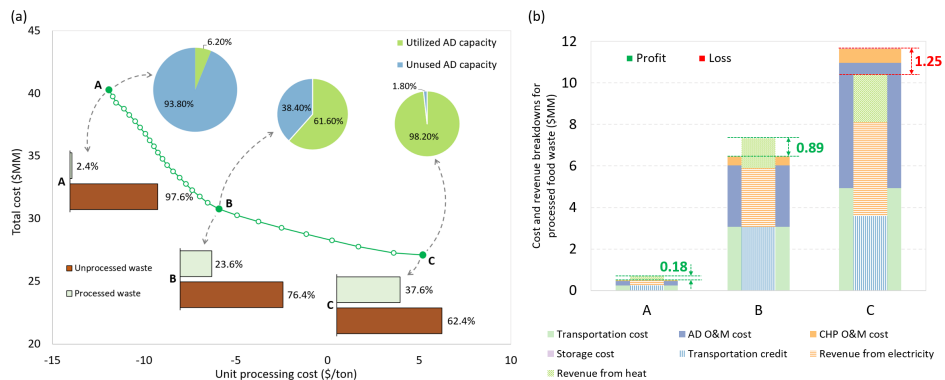

Figure 1. Optimization results for the nexus systems. (a) Pareto-optimal curve illustrating trade-offs between total cost and unit processing cost with the food waste processing level (column charts) and the extent of using existing AD capacities (pie charts). (b) Total economic breakdowns for the three representative Pareto-optimal solutions.

The Pareto-optimal solutions are shown in Figure 1(a), as well as the utilization of AD capacity and the processing levels of food waste. A clear trade-off between the total cost objective and the unit processing cost objective can be found from the Pareto-optimal curve. Notably, a negative unit processing cost indicates that the food waste processing system is profitable. Extreme point A minimizes the unit processing cost; it has the lowest unit processing cost of $-\$11.9/\text{ton}$, while extreme point C minimizes the total cost, so it has the lowest total cost of $\$27.1$ million. Point B represents a trade-off solution between the two extreme points. For the processing levels of food waste, the nexus systems have the potential of converting 37.6% of food waste produced in New York State, using 98% of the existing AD capacities in wastewater treatment plants and livestock farms. In Figure 1(b), the total economic breakdowns on cost and revenue are presented in wide columns and narrow columns, respectively, and the total profit and loss of waste processing are shown on the right-hand side of each column. Transportation costs and O&M costs for AD are the major contributors to the total processing cost for all three solutions, while O&M costs for CHP account for a small proportion of the cost. The profit increase from solution C to solution A could be $\$3.43$ million annually, due to the high transportation and production cost of solution C.

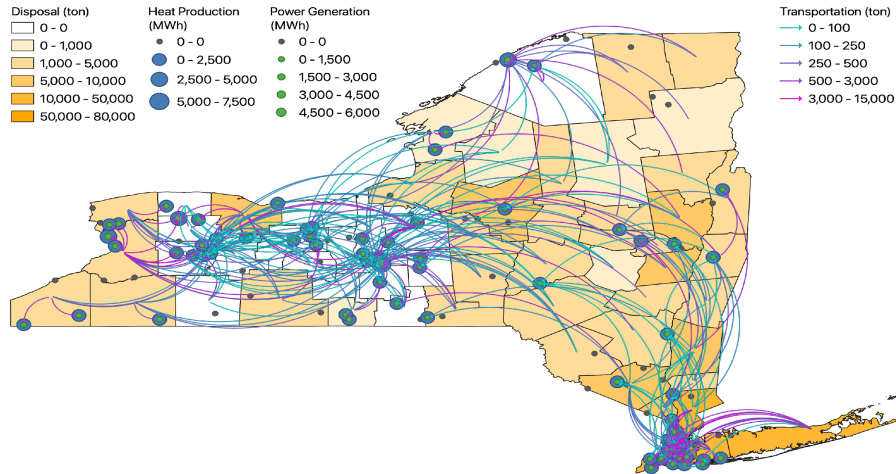

Figure 2. Facility locations, power generation, and heat production from solution C, as well as the corresponding total feedstock transportation and the county-level food waste landfill amounts within the planning horizon.

The spatial information of solution C that minimizes total cost is shown in Figure 2. In terms of facility selection, the number of active wastewater treatment facilities and farms is noticeably larger than those of solutions A and B. Notably, most plants with large capacities are active in solution C, while the small plants tend to be idle. This

trend can be further validated considering the utilization of existing AD capacities as presented in Figure 1(a). For solution C, although 98% of AD capacities are used for food waste conversion, several idle plants still exist as shown in Figure 2, indicating that these inactive plants are small ones that make less than 2% of the total state-level capacities. This is because using plants with large processing capacities could result in low unit O&M costs that can help reduce both the unit processing cost and the total cost, owing to the scaling factor of less than 1 (Ghafoori et al., 2006). In terms of transportation, feedstock collection sites near an active waste processing plant tend to transport more feedstocks to that facility. Moreover, feedstock transportations starting from collection sites with higher food waste generation levels are likely to be larger, and these trends are also observed for solutions A and B. As for landfill, most counties in New York State show considerable decreases in landfill amounts, mainly because of the vast increase of active waste-to-energy facilities for solution C. Taking advantage of these local small-scale waste processing facilities could both reduce the landfill cost and increase the energy production revenue, resulting in the minimum total cost for the nexus systems.

Sensitivity analyses are conducted in this study to quantify the impacts from the deviation of modelling parameters in a pre-optimization manner. In other words, while investigating the effects to vary one parameter, the entire nexus systems would be re-optimized under the updated value. Biogas yield, disposal cost, and electricity price are major factors affecting the total cost objective function, while the price of electricity is the most sensitive factor for the unit processing cost objective. This is presumably because the revenue from electricity generation is the largest category of revenue for the nexus systems that minimize unit processing costs as presented in Figure 1(b).

4. Conclusions

In this work, a multi-period multi-objective food-energy-water-waste nexus systems optimization model that considers various impacts of the COVID-19 pandemic on the nexus systems is proposed and applied to New York State. The model accounted for special features of the pandemic, including the increasing food waste generation, short planning horizon, limited availability of waste-to-energy facilities, and potential transportation options with repurposed trucks. Existing anaerobic digesters and combined heat and power units in wastewater treatment facilities and livestock farms were considered to process the increased amount of food waste under the pandemic and produce energy. The optimized systems showed considerable potential of reducing the disposal amounts of food waste by 38%, which could alleviate both the public health and environmental concerns. The Pareto-optimal solutions illustrated a clear trade-off between the objective functions. The minimum total cost was \$27.1 million, while the optimal unit processing profit was \$11.9 per ton processed food waste. Spatial analysis clearly revealed that facility selections were strongly correlated with their processing capacities. It also showed that the nexus systems could noticeably decrease the food waste disposal amounts in most counties in New York State. Finally, sensitivity analyses revealed that biogas yield and electricity price were the most sensitive factors for the total cost objective and the unit processing cost objective, respectively.

Abstract

Tri-Generation Systems (TGS) are designed for combined cooling, heating, and power production within a single process. In this paper, the integration of Concentrated Solar Power (CSP) together with TGS is studied. The tri-generation setup consists of a CSP facility that is integrated onto a desalination plant, producing three different levels of steam (very high pressure, low pressure and very low pressure), in addition to power and freshwater, simultaneously. Due to the complexity of the process, it was found imperative to investigate different factors that would improve the overall performance of the system, and ultimately decrease associated costs and thermal losses. Moreover, the use of molten salts offers many advantages, compared to more conventional fluid options, such as mineral and synthetic oils. Hence, a Mixed Integer Nonlinear Program (MINLP) that allows the selection of optimal heat transfer media, in TGS, has been formulated, and the performance of three different molten salts (solar salt, Hitec, and Hitec XL) has been analysed. The operating temperature of molten salts was found to have a significant effect on the steam quality generated in TGS-CSP systems. Moreover, solar salt resulted in the lowest energy production cost (at 28 cents/kWh) amongst all options. On the other hand, Hitec and Hitec XL were found to yield higher energy costs, estimated at 45 and 47 cents/kWh, respectively.

Keywords: Tri-generation systems, Concentrated solar power, Molten salts, Heat transfer, Power

1. Introduction

Concentrated solar power has been extensively proposed as an effective and economically viable renewable energy technology. CSP plants must be equipped with effective heat transfer media, and thermal energy storage systems. Molten salts have become an increasingly attractive option for high-temperature CSP applications (Fernandez et al., 2019). Several studies have investigated the performance of various molten salts from different perspectives, such as thermophysical properties, thermodynamic analysis, corrosion mitigation and system-level analysis. Such studies were found to be helpful for proposing the most convenient molten salt, to be used for commercial applications. For instance, Wang et al. (2021) conducted a system-level

analysis for $\text{MgCl}_2\text{-KCl}$ and showed that higher heat source temperatures result in slightly improved system efficiencies, due to the higher specific work associated with $\text{MgCl}_2\text{-KCl}$. Rong et al. (2021) succeeded in proving that ab-initio molecular dynamics of NaCl-CaCl_2 are effective for obtaining essential heat transfer information of molten salts, by investigating microstructures and thermophysical properties under various operating temperatures. Ibrahim et al. (2021) studied the performance of eight different molten salts, especially those that could withstand severe corrosion challenges in CSP systems. In their study, Rong et al. (2021) found that both MgNaK chloride and ZnNaK chloride possess high thermal stability, especially for temperatures above $800\text{ }^\circ\text{C}$. Additionally, low thermal energy storage costs were obtained for each. Hence, they recommended the use of molten halide salts for the next generation of CSP plants, since molten chloride salts are currently the most technologically mature. The performance of different molten salts in a tri-generation system has not been studied yet. As a result, this work develops an MINLP program that assesses the economic performance of different molten salts in TGS-CSP systems, for the production of different levels of steam, power and freshwater.

2. Methodology

The proposed model, based on the TGS-CSP system, is shown in Figure 1. First off, molten salt circulating in the CSP plant absorbs heat produced by the solar tower. The hot salt is then directed to a steam generator that produces very high pressure (VHP) steam. The temperature of VHP steam depends on the operating temperature of the studied molten salt, whereas the pressure is assumed constant at 100 bars. The generated LP steam can then be expanded into superheated steam. VLP steam may be converted to cooling water, which in turn may be used in the ejectors, and/or as a water source for VHP steam generation.

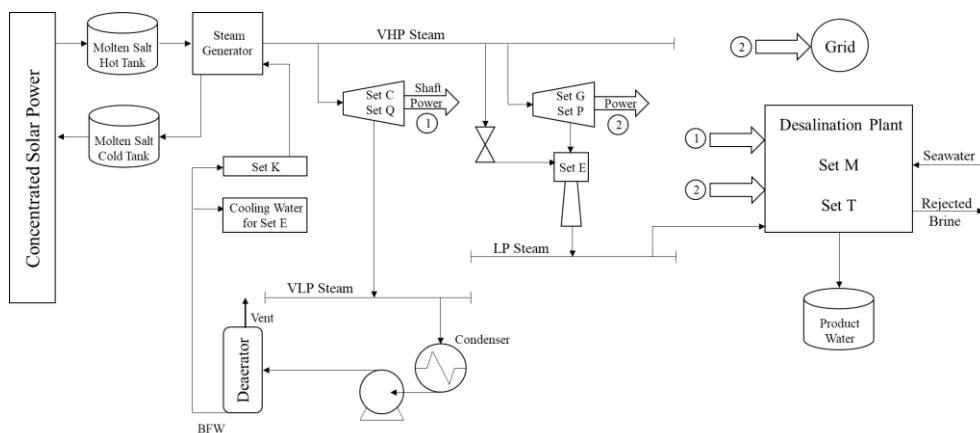

Figure 1. Tri-generation System Structure

On the other side of the system, inlet seawater can either be fed to a thermal and/or a membrane desalination option. The required energy demand for desalination may be covered either using LP steam produced from CSP, and/or shaft-electric power from

turbo-generators, and turbo-pumps. Thermal-based desalination mainly relies on LP steam for operation, since a very low electric power consumption (from turbo-generators) is required. However, membrane-based units consume shaft and electric power only, with no steam is required. Hence, any excess power produced can be sold to the grid, as a revenue stream. The molten salt used for heat transfer and energy storage in CSP is highly dependent on the required operating temperature. In fact, different salt temperatures would affect the temperature of VHP steam produced. Moreover, molten salt cost must be taken into account, especially when carrying out the assessment of different molten salt options. All of the above has been considered in the mathematical formulation of this problem.

3. Mathematical Formulation

A MINLP model, which aims to minimize the total cost of the TGS-CSP system has been developed. The objective function is shown in Eq. (1) below, where $cost^{therm}$ and $cost^{mem}$ are thermal and membrane desalination unit costs, respectively, $cost^{CSP}$ is the CSP unit cost, and rev^{elec} is the electricity revenue. All molten salt related costs are included within the capital cost of CSP plant. Based on the terminology shown in Figure 1 above, the following sets have been defined: set G as the back-pressure turbo generators, BPTG, set C as the condensing turbo-generators, CTG, set P as the back-pressure turbo-pumps, BPTP, set Q as the condensing turbo-pumps, CTP, set E as the ejectors, set K as the pumps (set K), Set T as thermal desalination units, and set M as membrane desalination units. The binary variables, Y_i , have been used to indicate the selection of technology i , whereas the decision variables of the model refer to: (1) input/output flowrates associated with each desalination technology as well as (2) mass flowrates of produced VHP steam into the different expansion units. Equality constraints have been used to ensure no violation of mass and energy balances around the different system units. For example, Eq. (2) and Eq. (3) represent the mass balance of VHP steam and molten salt, respectively, where G^{VHP} is the total mass flowrate of VHP steam produced, G_g^{in} , G_c^{in} , G_p^{in} , G_q^{in} and $G^{tv,in}$ are the inlet VHP steam flowrates to BPTG, CTG, BPTP, CTP, and throttling valve, respectively, while $G^{salt,in}$ and $G^{salt,out}$ are the inlet and outlet mass flowrates of the molten salt. Eq. (4) describes the energy balance around steam generator, where C_p^{salt} is the specific heat of salt, while T^{in} and T^{out} are the inlet and outlet temperature of molten salt to steam generator. Moreover, η_{SG} is heat transfer efficiency parameter and G^{SG} is the mass flowrate of water entering the steam generator, while $H^{out,s}$ and $H^{in,w}$ are the enthalpies for steam leaving and water, respectively.

$$Min.(cost^{therm} + cost^{mem} + cost^{CSP} - rev^{elec}) \quad (1)$$

$$G^{VHP} = \sum_{g \in G} G_g^{in} + \sum_{c \in C} G_c^{in} + \sum_{p \in P} G_p^{in} + \sum_{q \in Q} G_q^{in} + G^{tv,in} \quad (2)$$

$$G^{salt,in} = G^{salt,out} \quad (3)$$

$$G^{salt,in} C_p^{salt} (T^{in} - T^{out}) = \eta_{SG} G^{SG} (H^{out,s} - H^{in,w}) \quad (4)$$

The complete model includes similar mass and energy balance constraints on all remaining units shown in Figure 1. Moreover, performance limits on each unit have also been identified, and included as inequality constraints. For instance, the temperature of salt at the time of water boiling must ensure that no temperature cross-over is taking place in the steam generator, at any point. VHP steam inlet mass flowrate into the turbines were used to calculate the work produced by such units. Other inequality constraints ensure the minimum, (G_i^{min}, F_i^{min}) and maximum, (G_i^{max}, F_i^{max}) allowable mass flowrates of steam, G_i^{in} , and seawater, F_i , to the turbines and desalination units, respectively. In addition, the minimum water production recovery, χ_{pw} , and the minimum amount of electricity allocated to the grid, $P^{Grid,min}$, have also been accounted for. Eq. (5-6) below represent capacity constraints, whereas Eq. (7-8) refer to constraints on water production and electricity production, respectively, where PW^{total} is the product water flowrate, and P^{Grid} refers to amount of electric power allocated to the grid.

$$G_i^{min} Y_i \leq G_i^{in} \leq G_i^{max} Y_i \forall i \in G, C, P, Q \quad (5)$$

$$F_i^{min} \leq F_i \leq F_i^{max} \forall i \in T, M \quad (6)$$

$$PW^{total} \geq \chi_{pw} F^{in} \quad (7)$$

$$P^{Grid} \geq P^{Grid,min} \quad (8)$$

4. Case Study
