In this case study, the proposed model has been implemented on a TGS producing steam and power from a CSP plant. Freshwater can also be produced onsite via desalination, using a seawater source with a salinity of 25 g/L. The desalination technologies considered in the study are: multi-stage flashing (MSF), multi-effect distillation (MED) and reverse osmosis (RO). Each technology is associated with its own set of specifications and constraints, which have been accounted for in the model. All the parameters required to estimate CSP plant performance have been obtained from Gunawan et al. (2019), whereas the parameters associated with each desalination technology have been obtained from Klaimi and Alnouri (2020). As previously mentioned, three different molten salts (solar salt, Hitec, Hitec XL) have been assessed for their heat transfer fluid abilities within the system. Each molten salt has its own set of specifications, such as operating temperatures, specific heat capacity and cost, all of which have been provided in Table 1. Since VHP steam temperature is greatly correlated with high operating molten salt temperatures, it was very important to observe this property factor while assessing the effect of those different salts onto the overall system design. Table 1 below summarizes the molten salt specifications, noting that the low operating temperature has been assumed to be 290°C in all cases. Moreover, all conducted cases assume an inlet seawater flowrate of 100,000 m³/d, with a total system recovery of 40 %.

Table 1: Molten salts specifications (Chang et al., 2015)

Molten Salt	High Operating Temperature (°C)	Specific Heat Capacity (kJ/kg K)	Cost (USD/kg)
Solar Salt	600	1.37	0.49
Hitec	535	1.56	0.93
Hitec XL	500	1.41	0.19

The MINLP optimization problem has been implemented on GAMS, using BARON as the global solver (GAMS Software). When solar salt is used, the optimal configuration of the TGS-CSP system obtained is provided in Figure 2. The results show that 11,961 m³/d of solar salt is required to generate steam and power. The optimal steam expansion technologies that have been chosen by the solver are one CTG and two CTP units. It was found that the turbo-generator produces 7.47 MW to cover the electric power required for desalination, while the rest is exported to the grid. On the other hand, the turbo-pumps produce 15.49 MW of shaft power for desalination. Both MED and RO have been selected for seawater desalination. The selection of these two technologies have been attributed to the fact that MED has a lower energy requirement than MSF, while RO is characterized with a higher water recovery than thermal-based technologies. It is important to note that 26 % of inlet seawater has been allocated to MED, while the amount of power allocated to the grid was 4.75 MW. Overall, this results in an energy production cost (EPC) that is equivalent to 28 cents/kWh.

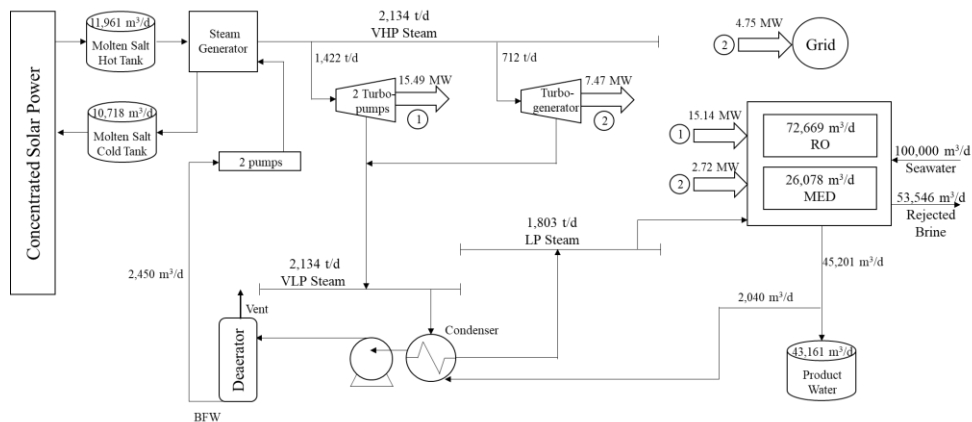

Figure 2. Optimal System Configuration for Case 1, using Solar Salt as the heat transfer medium

When Hitec salt has been used in place of solar salt, the lower operating temperature of this salt results in a higher required flowrate of 13,162 m³/d, when comparing the respective optimal solutions. The same desalination technologies as those reported in Case 1 have been selected, but a higher fraction of seawater has been allocated to MED. Therefore, it was found that an additional amount of LP steam is required. This resulted in the selection of a throttling valve for LP steam production, since it is a less expensive option than turbo-generators. As expected, the optimal solution resulted in a higher total

cost of the system, and a lower operating temperature of Hitec salt. A higher EPC estimated at 45 cents/kWh was obtained. When Hitec XL salt is used, the optimal configuration of the TGS-CSP system shows an increase in the total amount of seawater allocated to MED, which necessitates higher LP steam production. Therefore, besides CTG and CTP units, an additional BPTG unit has been selected in place of the throttling valve, due to its capability of generating electric power. This was found an attractive option economically, as a result of the extra revenue generated. Although the required flowrate of Hitec XL (estimated by 17,894 m³/d) is higher than that required for solar salt, the total cost of Hitec XL salt was lower. EPC was found to be 47 cents/kWh, which is even higher than the energy cost when using Hitec salt. A summary is provided in Table 2 below.

Table 2: Summary of main aspects in optimal results

Molten Salt	Energy	Water	EPC (cents/kWh)
Solar Salt	CTG, CTP	MED, RO	28
Hitec	CTG, CTP, TV	MED, RO	45
Hitec XL	BPTG, CTG, CTP	MED, RO	47

5. Conclusions

In this study, a mathematical model that assesses three different molten salts as heat transfer fluids in a tri-generation system producing steam, power and freshwater, has been presented. Solar salt was found to be the best option to be used in the TGS-CSP system, amongst all options, having resulted in a configuration with the lowest EPC.

Abstract

Greenhouse gas emission reduction from energy-intensive industrial applications (e.g., power generation) is of paramount importance today. The fossil-based power plants have to be operated in a load following (cycling) scenario to balance the time intermittent renewable sources (e.g., solar and wind). This paper is assessing the techno-economic implications of load following (dynamic) operation of decarbonized super-critical power plants to improve the main performance indicators. Reactive gas-liquid absorption method is evaluated as decarbonization technology. As evaluated super-critical power plants, one coal-based concept with 1,000 MW net output was considered as illustrative example. The overall carbon capture rate is set to min. 90 %. The proposed design was simulated in both base-load and dynamic-load conditions. The load following (dynamic) operation was considered for one-week duration considering the common pattern in European power generation sector. Relevant key design elements were assessed in details in term of main techno-economic implications (e.g., dynamic operation of carbon capture unit considering lean and rich solvent storage, integration of power block and carbon capture unit, power plant cycling etc.). The results show that the flexible decarbonized power generation has significant advantages in optimizing techno-economic performance and reducing the overall environmental impact.

Keywords: Flexible operation of decarbonized power plants, Reactive gas-liquid decarbonization system, Techno-economic and environmental assessment.

1. Introduction

Reducing CO₂ emissions from energy intensive sectors is a very important element in the fight against global warming and climate change. Several methods can be used to reduce the overall carbon footprint e.g., boosting renewable energy sources (e.g., solar, wind, biomass), improving energy conversion and utilization efficiencies, developing Carbon Capture, Utilisation and Storage (CCUS) technologies (European Commission, 2019). Currently, the share of renewable energy is significantly increasing in power generation sector but the time-variability of solar and wind technologies is putting an additional pressure on existing fossil base-load capacities which have to be operated in load following (dynamic) conditions. Since the fossil fuels are predicted to remain an

important element in the overall energy sector at least for short and medium term, suitable and flexible decarbonized power generation technologies are needed (Papadis and Tsatsaronis, 2020). This paper is assessing the techno-economic implications of load following (dynamic) operation of decarbonized coal-based super-critical power plants to improve the main performance indicators for better integration into future highly time-dependent energy systems. The key innovative element of this paper towards the current state of the art in the field is the quantification of techno-economic and environmental performance indicators for a decarbonized power plant operated in dynamic (load-following) conditions using solvent storage.

2. Design of decarbonized super-critical power plant, main model assumptions and thermal integration analysis

The decarbonization of super-critical power plant was assessed using the post-combustion chemical scrubbing by alkanolamines. Methyl-Di-Ethanol-Amine (MDEA) was considered as illustrative case. The chemical reaction for post-combustion CO₂ capture is the following:

The corresponded non-decarbonized super-critical power plant was also considered as benchmark case (noted as Case 1). The conceptual design of decarbonized super-critical power plant (noted as Case 2) is presented in Figure 1.

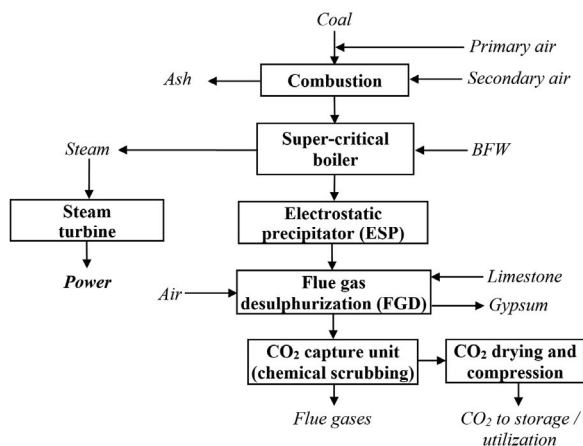

Figure 1. Design of decarbonized super-critical power plant (Case 2)

The most important model assumptions of evaluated super-critical power plants are presented in Table 1. These assumptions were used for modelling and simulation of the power plant using ChemCAD software. The model of CO₂ capture unit was then validated by comparison to experimental data (see Figure 2 left). In addition, the decarbonized design was thermally integrated using pinch method for optimization of thermal duty used in CO₂ capture unit for solvent regeneration. Figure 2 right presents the hot and cold composite curves for CO₂ capture unit.

Table 1. Design assumptions of evaluated gasification-based poly-generation systems

Power plant unit	Design assumptions
Coal composition and lower calorific value	Composition (dry): 72.30 % C, 7.45 % O, 1.69 % N, 4.11 % H, 0.56 % S, 13.89 % ash; Moisture: 8 % (as received) Lower heating value (LHV): 25.35 MJ/kg (as received)
Super-critical power block	Steam temperatures: 582 °C / 580 °C / 580 °C Steam pressures: 290 bar / 75 bar / 20 bar Steam turbine efficiencies: 88 % HP / 90 % MP / 94 % LP Final steam expansion pressure: 45 mbar Feed water pump efficiency: 85 %
Flue gas desulphurization unit	Wet desulphurization system using limestone slurry Sulphur removal efficiency: >98.5 %
CO ₂ capture unit	50 wt. % MDEA aqueous solution Absorption/desorption columns: 18 / 12 stages Carbon capture rate: 90 % Liquid to gas ratio: 3.75 Heat duty for solvent regeneration: 3 GJ/t
CO ₂ conditioning unit (drying and compression)	TEG gas-liquid absorption dehydration unit CO ₂ purity and pressure: >95 % (vol.) / 120 bar Multi-stage inter-cooling compressor with 85 % efficiency
Auxiliary units	Coal handling energy consumption: 0.5 % of thermal input Pump efficiency: 85 % Heat exchanger minimum temperature difference: 10 °C Heat exchanger pressure drops: 1 – 3 % inlet pressure

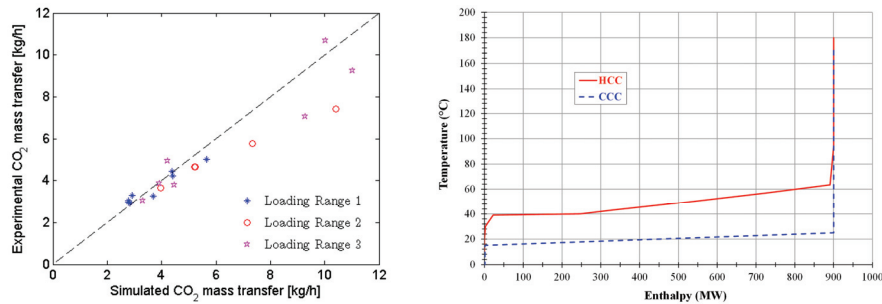

Figure 2. Validation of CO₂ capture unit (left); Thermal integration of CO₂ capture unit (right)

3. Base-load and flexible techno-economic and environmental assessment

Firstly, the techno-economic and environmental performances of both coal-based super-critical power plants with and without decarbonization were assessed in base-load conditions. The overall description of the techno-economic assessment methodology as well as the main economic assumptions are presented in details in a separate paper of the authors (Cormos and Cormos, 2017). Table 2 presents the key performance indicators of evaluated base-load coal-based super-critical power plant concepts. As can be noticed, the introduction of carbon capture feature (a carbon capture rate of 90 % was considered) induces significant modifications of all performance indexes e.g., the net energy efficiency decreases by about 9.6 percentage points (this is the energy penalty for carbon capture), specific CO₂ emission is reduced by about 88 %, specific investment cost is increasing by about 80 %, operation and maintenance costs are increasing by about 27 %, levelized cost of electricity is increasing by about 13.5 %.

Table 2. Main techno-economic and environmental performance indicators (base-load)

Performance indicator	UM	Case 1	Case 2
Coal flow rate	t/h	327.76	420.92
Coal lower heating value (LHV)	MJ/kg	25.35	
Coal thermal energy	MW _{th}	2,308.00	2,964.00
Gross power output	MW _e	1,057.75	1,140.10
Fuel processing consumption	MW _e	11.54	14.82
CO ₂ capture and conditioning unit	MW _e	-	71.05
Power block consumption	MW _e	46.21	54.23
Ancillary power consumption	MW _e	57.75	140.10
Net power output	MW _e	1,000.00	1,000.00
Net power efficiency	%	43.32	33.73
Carbon capture rate	%	0	90.00
Specific CO ₂ emissions	kg/MWh	800.12	93.95
Capital cost	M€	1,275.00	2,288.00
Specific capital investment cost	€/kW	1,275.00	2,288.00
Operational & maintenance cost	€/MWh	28.90	36.81
Levelized cost of electricity	€/MWh	66.00	74.90
CO ₂ removal cost	€/t	-	31.50
CO ₂ avoided cost	€/t	-	37.26

After evaluation of base-load performances, a dynamic (cycling) operation scenario of decarbonized power plant was considered. In this respect, Table 3 presents the considered weekly variation of the plant capacity. This time behaviour was selected considering the daily pattern load common in Central Europe (Astolfi et al., 2019).

Table 3. Time variation of plant capacity (weekly basis)

Monday – Friday		Saturday – Sunday
6 AM to 1 PM	10 PM to 5 AM	0 AM to 12 PM (all day)
7 PM to 9 PM	2 PM to 6 PM	
100 %	50 %	50 %

Considering this time variation of decarbonized power plant capacity, the flue gases flow in a flexible operation scenario compared to the base-load operation is about 73 % for the Monday to Friday period, 50 % for the weekend and about 66.5 % for the whole week. The nominal base-load flue gases flow for decarbonized power plant concept is about 4,100 t/h with 12.35 % vol. carbon dioxide and the corresponding plant capacity is 90 %. The power plant capacity has an important influence on levelized cost of electricity (Astolfi et al., 2019). Figure 3 presents the variation of levelized cost of electricity vs. plant capacity for both super-critical concepts with and without decarbonization. As can be observed, the plant capacity starts to have an important influence on levelized cost of electricity at values below 60 %. In addition, the reduction of the power plant load affects also the energy efficiency compared to the nominal steam cycle condition. In this respect, an off-design correction factor for the overall energy efficiency has to be used to consider the influence of part-load operation (Cormos, 2020).

Figure 3. Validation of levelized cost of electricity vs. power plant capacity

For the time-flexible operation of the decarbonized super-critical power plant, when the power output is reduced, the flue gases flow is reduced with the same ratio. In order to keep the 90 % carbon capture ratio, the CO₂ capture gas-liquid absorption cycle has to be modified accordingly. In this respect, the flexible operation of decarbonized super-critical power plant is equipped with MDEA solvent storage capacities in both lean and rich CO₂ loadings. The solvent storage facility was sized considering the need for weekly operation of the power plant which implies that the absorption column follows the power plant operation and the desorption column operates at nominal load (74 % of nominal base-load) and the storage facility has enough capacity to store the both lean and rich forms of the MDEA solvent. Figure 4 presents the time variations of solvent storage and power plant loads in a weekly operation cycle. As it is shown, when power plant operates at nominal load (100 %), the rich solvent storage is gradually filling up and the lean solvent storage is discharged. When the power plant is operated at reduced loads (50 %), the process is reversed (regenerated lean solvent storage is filling up and rich solvent storage is discharged).

Figure 4. Weekly variations of lean / rich solvent storages and power plant load

The flexible operation of decarbonized power plant implies additional capital cost for solvent storage capacity. This capital cost was estimated based on its size with common cost correlations (Smith, 2016). But the capital cost of solvent storage is totally compensated by reducing the size of CO₂ capture unit, even further reduction of overall plant capital cost is achieved due to the fact the cost of liquid storage facility is lower than for a complex plant such as absorption – desorption cycle. Table 4 presents the variation of key performances in both nominal and part-load operation scenarios.

Table 4. Key performance indicators for nominal and part-load operation

Performance indicator	UM	Case 1	Case 2
Gas-liquid absorption cycle size factor	%	100.00	74.00
Specific capital investment cost	€/kW	2,288.00	2,140.00
Operational & maintenance cost	€/MWh	36.81	36.49
Levelized cost of electricity	€/MWh	74.90	72.25
CO ₂ avoided cost	€/t	37.26	33.26

It can be noticed that the flexible operation of the decarbonized power plant equipped with solvent storage facilities has better performance than nominal case e.g., reduced specific investment by about 6.5 %, reduced levelized cost of electricity by about 3.5 %.

4. Conclusions

This paper is evaluating the flexible operation of 1,000 MW super-critical power plant equipped with carbon capture feature using chemical scrubbing (90 % carbon capture rate was used). As innovative element, the load-following power plant operation considers MDEA solvent storage facility in both lean and rich forms. The evaluation shows that dynamic operation of decarbonized power plant has significant benefits e.g., reducing specific investment cost (by about 6.5 %), levelized cost of electricity (by about 3.5 %) and CO₂ capture costs (by about 10 %) compared to base-load operation.

Abstract

Jet Fuel from the gas-to-liquid (jet fuel-GTL) process is a suitable alternative to that produced from conventional oil refining because of its combustion efficiency, and compatibility to both legacy and newly designed aircrafts engines. It contributes towards the diversification and expansion of fuel supply chain in the aviation industry due to its unique properties, as it is ultraclean releasing lower levels of Sulphur Dioxide, Nitrogen Oxides and particulate emissions upon burning. The State of Qatar, with its vast quantities of natural gas resources, can lead in the widespread adoption of jet fuel-GTL. The GTL technology also can contribute positively toward CO₂ emission reduction through the integration between GTL and carbon capture and utilisation (CCU) technology, as this will enhance the total production of refined products and reduce CO₂ emissions level. The concept model of integrating of CO₂ product with GTL plant has been discussed in (Al-Yaeshi *et al.*, 2020a) and the results are demonstrated positively in terms of techno-economic-environmental aspects. In fact, fuel production in Pearl GTL has prompted Qatar Airways (QA) to become the first commercial airliner to trial jet fuel-GTL. However, mainstream utilisation is challenged due to: (a) lack of availability of jet fuel-GTL for the purpose of re-fuelling at QA's worldwide destinations. As such, the presence of GTL plants is limited globally due to the availability of natural gas and the high capital costs for GTL plant construction; (b) volatility in jet fuel-GTL prices and the uncertainty in petroleum product markets. The objective of this study is to assess the techno-economic-environmental feasibility of a novel methodological framework based on decentralised LNG-to-GTL processes (or hubs) at optimal locations of LNG terminals. The objective is to enhance the availability of jet fuel-GTL and other GTL products in global aviation and other transportation sectors.

Keywords: Liquefied Natural Gas (LNG), Gas-To-Liquid (GTL), Jet Fuel, Aviation.

1. Introduction

The demand for energy is steadily increasing due to population growth and increased economic activity. Traditionally, crude oil has been used to satisfy various applications for energy in different forms such as gasoline, diesel, and kerosene (jet fuel). However, natural gas-based products have become increasingly competitive due to enhanced

exploration, availability and utilisation applications. Incidentally, greenhouse gas (GHG) emissions resulting from the utilisation of fossil fuels contribute towards global warming and as a result have propelled world leaders to commit to controlling the emissions generated from different sectors. A large portion of fossil fuel utilisation, especially oil derived products occurs in the transport industry which accounts for almost 66% of total global CO₂ emissions. The aviation sector forms approximately 8% from the remaining 16% of transportation sector globally (IEA, 2015). Global passengers have increased gradually from 1946-2016 reaching 3.7 billion in 2016 compared to 18 million in 1946. It is expected to continue to increase as networks and destinations increase especially to South America, China and India (Boeing, 2017). This implies that the manufacture of new planes is expected to increase as new routes are introduced and old models are replaced, where planes with a capacity of 100 seats or more are expected to increase to 42,500 from 20,500 aircrafts by 2036 (Boeing, 2017; Airbus, 2017). Since 2012, the International Civil Aviation Organisation (ICAO) has pledged to reduce GHG levels. However, the aviation sector continues to account for 4% of total global emissions, and may increase to 22 % by 2050. The IATA report stipulates that as part of efforts to remain below 2°C in a 2030 time horizon, emission levels should not exceed 39 % of levels recorded in 2005, and require a decrease by 41 % levels by 2050 compared with the reference year 2005 (Cames *et al.*, 2015).

Several options to reduce emissions from aviation exist, including the use of alternative fuels and other renewable energies. One of these fuels is the jet GTL which is derived from the Fischer-Tropsch technology to produce a synthetic lubrication oil and synthetic fuel from coal, natural gas or biomass. Introducing jet fuel-GTL as an alternative aviation fuel is especially attractive in this region due to low natural gas prices and extraction costs. However further optimisation is required to enhance the cost of extraction of natural gas and improve the cost and efficiency of GTL technology (Ramberg *et al.*, 2017). Dong *et al.* (2008) demonstrate the techno-economic analysis of GTL and LNG plants are comparable however the LNG technology is preferable attributed that the LNG is well established while the GTL is in the initial stage in the commercial market. The GTL has intending to expand widely due to the world energy demand and its clean refined products that classified as environment friendly, hence that will impact LNG markets. In terms of enhancing production of jet fuel derived from GTL, CCU can be considered a viable CO₂ reduction approach as discussed in chapter 4. Al-Yaeshi *et al.* (2020a) demonstrates the suitability of integrating CO₂ emissions into GTL plants in order to increase production rates of finished products, reduce rogue CO₂ emissions and to generate economic benefits. It is concluded that the overall process efficiency enhanced by increasing between 5-10% comparing with base reference of GTL plant. The objective of this study is to assess the techno-economic-environmental feasibility of a novel methodological framework. It considers decentralised LNG-to-GTL processes (or hubs) at optimal locations of LNG terminals promoting enhanced availability of jet fuel-GTL and other GTL products for the global aviation industry. Using Qatar which is rich in natural gas reserves as a case study, this study outlines the role of the natural gas derived fuel obtained via the gas-to-liquid (GTL) technology in the aviation sector in comparison to conventional aviation fuels obtained from crude oil.

Case Study: Qatar

The system considered comprises of an LNG supplier, Qatar Gas (QG), and various potential small-scale GTL plants worldwide that have been identified for the economic utilisation of natural gas, based on the Qatar Gas LNG customers destination zones and Qatar Airways (QA) flight destination zones. The integration model of CO₂ with GTL plant discussed in chapter 4 as a case study in Qatar and can be applied globally. The objective of the optimisation model is to develop a profitable allocation plan for proposed GTL plants and contribute towards reducing GHG emissions generated from the QA fleet and other airlines as they travel to and from Qatar generating techno-economic-environment benefits from all destinations. The State of Qatar is the world's largest exporter of Liquefied Natural Gas (LNG), driven by demands from Asia and Europe due to transitions from Crude oil and Coal to Natural gas. LNG exports from Qatar will continue to rise as new trains are developed expanding production by 40 % to 110 million tons. In terms of GTL, production from Qatar represent 70% of total global GTL production. The GTL process utilises Fischer–Tropsch technology to transform natural gas into synthetic liquid petroleum products which is a feedstock to other commercial applications and commodity markets. The national GTL output consists of an Oryx GTL plant commissioned in 2006 with capacity approximately 34,000 b/d. In addition, a second Pearl GTL plant, the largest global GTL project facility commissioned in 2011 produces approximately 140,000 bpd of refined products (Al-Yaeshi *et al.*, 2020b). Qatar Airways is one of the world's leading airlines, established on November 22, 1993, and its home, Hamad International Airport links over 150 international destinations across Africa, Central Asia, Europe, Far East, South Asia, Middle East, North America, South America and Oceania. The QA fleet consists more than 180 aircrafts and is expected to top 350 by 2022 (QA, 2016).

2. Methodology

The CCU application demonstrated in this study is discussed models developed by Al-Yaeshi *et al.* (2020a), and Al-Yaeshi *et al.* (2020b), where utilising CO₂ in GTL plant demonstrates a high potential in enhancing the GTL output products and contributes in reducing the CO₂ emissions to the atmosphere from the sources. In this study, the integral LP formulation considers optimising the GTL plant distribution based on the availability of QG LNG terminal destinations, QA route destinations, high aircraft traffic airports, high jet fuel consumption, and LNG purchase prices. The aim is to optimise the location of GTL plants upon a techno-economic-environment analysis and ensure life cycle CO₂ reductions of QA and HIA from well to wheel. In order to demonstrate significant improvement in the QA fleet performance, it is necessary for the fuel to be available in most of the destinations. As the such, the system proposed maximises the overall revenue of the Jet fuel-GTL utilisation and promotes Qatar as a hub for jet fuel-GTL.

The system described in Figure 1 consists of three main components, LNG terminal, GTL plant and distribution network. The operation starts by receiving the LNG cargo in the terminal where the unloading and regasification process begins. After which, the gas is compressed and transported by pipeline to the GTL plant where the gas is converted to the refined products such as Jet fuel, Gasoline and Diesel. The final stage is to transport the Jet fuel-GTL to the airport to refill the QA fleet and/or other aircrafts.

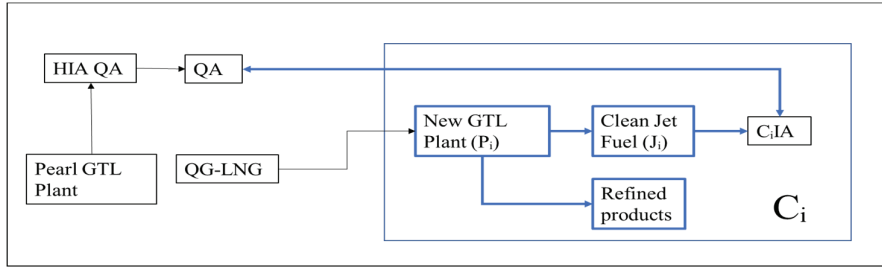

Figure 1. Model mapping the QA, LNG and GTL network.

The decision variables used in the Integer LP formulation are applied to solve the binary optimisation case study as indicated in Figure 1. The parameters model corresponds to the availability of LNG products, potential of natural gas resources, g and objects of QA connection q at the defined countries i . Each country i has an LNG price S_i and a number of QA flights F_i from Qatar to the same destination. QA consumes conventional jet fuel from country i . There is a potential to locate GTL plants P_i at country i to supply QA fleet with clean Jet fuel-GTL considering the high demand of jet fuel-GTL J_i at country i . However, this depends on the high demand of jet fuel in country i , hence the ratio R_i is defined:

$$R_i = \frac{J_s}{J_i}$$

Where J_s is the total of Jet fuel consumption at country i to the J_i Jet fuel-GTL plant produced at the same country.

The case study defines the specific GTL plant locations that will ensure a lifecycle reduction of CO₂ during return flights to Qatar using Jet fuel-GTL. The analysis is based on the 42 countries that Qatar supplies with LNG (or potentially GTL), in addition to QA routes. The LNG volume and prices are varied between (0.1 -12.2) MT/y and (\$3.5 – \$13.5) respectively (QG, 2019; Timera, 2019), while QA flights in the same countries are varied between 48–8,064 flight/y with total 51,108 flights per year (QA, 2018). The total jet fuel volume at the defined countries is 1,8750 million BBL/y while the proposed Jet fuel-GTL for each country is 4.380 million BBL/y (EIA, 2016) (The Global, 2018). A detailed nomenclature of model parameters is defined by set the formula to compute the maximum number of QA flights to determine the countries to mark the suggested GTL plant, hence access to clean Jet fuel-GTL for QA. Computation of the optimisation of QA flights is defined as;

Maximise $F(x) = \sum_{i=1}^n (F_i x_i)$, where n and F are the no. of countries and QA flights

The binary decision variables are as following;

$$(x_i) = \begin{cases} 1, & \text{if } C_i \text{ is selected} \\ 0, & \text{otherwise} \end{cases} \quad \text{where } i=1, \dots, n$$

Subject to the below conditional logics constraints;

$$\sum_{i=1}^n (S_i x_i) \leq \$25, \text{ where } S \text{ is the selling LNG price at the country } i$$

$$\sum_{i=1}^n (P_i x_i) \geq 1, \text{ where } P \text{ is the number of GTL plants at country } i$$

$$\sum_{i=1}^n (R_i x_i) \geq 10\% \text{ of } \sum_{i=1}^n J_i, \text{ where } R \text{ is the ratio of Jet production}$$

where; $S_i \geq 1, P_i \geq 1, R_i \geq 1$

3. Results

Table 1 indicates the optimum values for GTL plants locations when the total of QA flights is maximised in the defined countries based on constraints. Consequently, this reduces the annual rate of CO₂ emissions produced by the aircraft while travelling back to Qatar or during its operation in the HIA. Table 2 highlights the selected countries selected based in the integer LP formulation.

Table 1. The optimisation results.

Decision Variables	Results
Number of GTL plants	8
Number of flights/y	30960
LNG (\$)	24.11
Ratio of jet fuel (R _i)	192.4

Table 2. Country selection.

C _i	Country	C _i	Country
C ₁	Iran	C ₅	Spain
C ₂	KSA	C ₆	UAE
C ₃	Kuwait	C ₇	UK
C ₄	Oman	C ₈	USA

The modelling results illustrated in Figure 2 demonstrates that LNG prices at country *i* have the potential to make decisions in terms of the number of GTL plants. Although some countries have the highest rate for jet fuel consumption and record high QA flights however the LNG prices are the highest comparing with others in Europe and Middle east specially China, Japan and South Korea. A clear benefit is achieved in terms of increasing jet fuel utilising QA flights generating revenues in the selected countries, whilst reducing CO₂ emissions during return to Qatar. The total flights that benefit from the GTL plants exceed 60% of the total QA flights to the 42 countries resulting in emission reductions in the selected countries. The model indicates that the selected countries can establish a clean refined network consisting of LPG, and gasoline, diesel, wax to contribute effectively to CO₂ the emission reduction whilst remaining economically and environmentally attractive. It is important to note that selected countries have the potential for further optimisation based on NG accessibility.

Figure 2. Results of variables parameters at selected countries for placing GTL plants.

Countries in the Gulf cooperation country (GCC) such as Kuwait, KSA, Oman, and UAE are located in close proximity implying that a large single GTL plant is sufficient to secure the airports with the required feedstock of Jet fuel-GTL. Iran also can be part of this supply chain despite possessing a large natural gas field, therefore implying that the list of GTL plants can be short listed to four.

4. Conclusion

The growth of the global aviation sector has increased dramatically in last few decades thus inducing significant carbon reduction challenges in the light of stricter regulations. Jet fuel-GTL is an optimal alternative for currently utilised Jet fuel produced from conventional Oil Refinery. Going forward, the state of Qatar can utilise its long-term LNG contracts to begin implementing LNG-to-GTL process. The modelling and analysis presented in this paper considers the novelty of LNG-to-GTL technology to secure clean refined products especially Jet fuel-GTL at the countries that have received LNG shipments, whilst reducing CO₂ emissions at both airports and flight routes. The approach demonstrates the potential economic and environment benefit for the selected countries to locate the GTL plants whilst considering the LNG prices, number of QA flights and Jet fuel ratio of proposed GTL plant to the total Jet consumption in the selected countries. Future work will consider a techno-economics assessment to locate the plants based on the CAPEX, OPEX and economic indicators such as NPV, IRR and PIR for each selected country.

Abstract

Poor river water quality as a result of rapid urbanization has led to various disease outbreak and destruction of wildlife ecosystem. Although continuous water quality monitoring has been proposed as the immediate solution, the complexity and expensive nature of such system often offset its purpose. Therefore, numerous studies have been made to forecast water quality utilizing different machine learning algorithms. In this paper, a comparative study was carried out to develop an efficient water quality index (WQI) prediction model based on more attainable monitoring parameters. Three different variation of ensemble decision tree models were analysed and compared, namely: Random forest regression (RF), extra tree regression (ETR), and decision tree + AdaBoost (BTR). These models were coupled with principle component analysis (PCA) and linear discriminant analysis (LDA) to reduce the dimensions of the input data. The results show that (ETR-LDA) model outperform the other ensemble tree models with an R^2 value up to 0.88. The ETR-LDA combination consistently score a higher R^2 values even when trained with a much smaller input dimension (i.e. 3) resulting in a faster training time. This model could positively contribute towards the long-term water quality management effort in a cost-effective manner.

Keywords: Water quality index, extra tree regression, linear discriminant analysis.

1. Introduction

Water utilized by domestic consumption and food production are primarily sourced from the surrounding river. Unfortunately, rapid urbanization and climate change has led to significant degradation in water quality which poses serious health risk (Imani et al., 2012). Poor water quality can give rise to multitude of health diseases such as polio, cholera, diarrhea, or typhoid which may directly affects human (Nawaz and Ali, 2018). Therefore, it is very important to continuously assess and monitor the river water quality. However, water quality measurement requires various biological, physical and chemical parameters, whereby some of the parameters are difficult and time consuming to measure. In Malaysia, the water quality measurement performed by DOE can be categorized into two groups. On site measurement, in which variable such as DO, SS, pH, NH₃-NL, Cl, Cd, Cr, Zn concentration conductivity, turbidity, and E coli can be easily recorded.

Whereas parameters like BOD and COD requires complex laboratory analysis and time consuming to calculate (5-7 days for BOD and few hours for COD) (Ahmad et al., 2016). The complexity and time constraints of BOD and COD measurements causes a major drawback in the overall WQI monitoring process, whereby it is impossible to alert the general public of the real-time WQI value. This has led to numerous studies being carried out to develop water quality prediction models based on various machine learning techniques. Furthermore, the size of water quality dataset fed into the machine learning model are often very large that it can cause enormous strain in the prediction model. High dimensional data could negatively impact the efficiency of the machine learning model, as the computational time increases exponentially with the dimensionality (Fan and Li, 2006). Therefore, performing dimensionality reduction (DR) is extremely crucial in order to improve the efficiency of the machine learning model. Mangai et al. (2020) developed a biological oxygen demand (BOD) prediction model coupled with principal component analysis (PCA) and correlation-features selection (CFS). Their work shows the two dimensionality reduction techniques, PCA and CFS did not compromise the performance of the BOD prediction models. In our study, only on-site monitoring parameters were utilized as the input features for the WQI prediction model. Three different variations of decision-tree based model were analysed and compared, namely random forest regression (FR), extra tree regression (ETR) and decision tree regression with AdaBoost (BTR). Additionally, principal component analysis (PCA) and linear discriminant analysis (LDA) were assessed to reduce the dimensions of the water quality dataset.

2. Methodology

2.1. Study Area and Data Collection

In this study, the data were collected from Malaysia's Department of Environment (DOE) in the span of four years from 2014 to 2018. The historical data represents water quality reading from 126 different monitoring sites within two major states in Malaysia namely Penang and Perak with an approximate area of around 10,800 km². The combined dataset has 2843 rows for 21 different parameters consisting of 4 location attributes, 3 date and time attributes, and 14 water quality attributes. The complete list of the water quality parameters can be observed from Table 1. The missing values from the dataset is relatively insignificant with highest observable percentage loss at only 1.20 % for WQI measurement and less than 1 % for all the other parameters. However, median value substitution was still performed to impute the missing values in order to fully utilize all 2843 rows of data. Out of the three location attributes, the states attributes were selected to train the water quality prediction model. As most machine learning algorithms prefers to work with numerical attributes, label encoding was performed to convert categorical value such as the states attribute to numerical value.

Table 1: List of input and output features for WQI prediction model.

List of all measured parameters	States, Basin, River, Station No, Days, Months, Years, DO (Dissolved Oxygen), BOD (Biochemical Oxygen Demand), COD (Chemical Oxygen Demand), SS (Suspended Solids), pH, NH ₃ -NL (Ammoniacal Solids), Conductivity, Turbidity, Cl, Cd, Cr, Zn concentration, E coli, WQI (water quality index)
Selected input feature	States, Days, Months, Years, DO, SS, pH, NH ₃ -NL, Conductivity, Turbidity, Cl, Cd, Cr, Zn, E coli

Selected output features	WQI (Water Quality Index)
--------------------------	---------------------------

Brief analysis on the WQI in each river basin shows that Beruas has the highest median WQI values at around 90, which falls under clean region of the Malaysia’s DOE water quality classification. The lowest median WQI values could be found in Perai river at 59 which falls under the polluted level. The rest of the locations falls under the slightly polluted range with WQI median values between 60 to 80.

2.2. Water Quality Index (WQI) Calculation

Water quality index (WQI) which was first introduced by Horton (1965), is a metric that represent multiple different weighted water quality parameters into a single numeric value. The main purpose of having such metric is to simplify the process of communicating water quality assessment to the general public and decision makers. Eq. (1) below shows how WQI is calculated by DOE in Malaysia (Mamun et al., 2009):

$$WQI = 0.22SIDO + 0.19SIBOD + 0.16SICOD + 0.15SIAN + 0.16SISS + 0.12SipH \quad (1)$$

Where: SIDO = Sub-index DO (% saturation); SIBOD = Sub-index BOD; SICOD = Sub-index COD; SIAN = Sub-index NH3-N; SISS = Sub-index SS; SipH = Sub-index pH.

As can be observed from Table 1, only on-site monitoring parameters that can be easily measured were selected as the model input parameters. Therefore, complex parameters such as BOD and COD which are time consuming to compute were excluded from the list of model input parameters. However, it could be observed from Table 2 that both BOD and COD are the third and the fourth most correlated variables towards WQI respectively (minus “-” sign depicts negative correlation). Excluding these parameters from the WQI model will inevitably affect the prediction performance. However, other highly correlated variables such as DO and NH3-NL would help minimize the performance impact.

Table 2: Pearson’s correlation analysis between input parameters against WQI.

Parameters	DO	States	Days	PH	Months	Years	Cd	Cr	Zn
Correlation	0.82	0.43	0.27	0.06	0.04	0.03	0.01	-0.07	-0.08
Parameters	Cl	Cond	Tur	SS	E. Coli	COD	BOD	NH3-NL	
Correlation	-0.10	-0.11	-0.12	-0.14	-0.14	-0.64	-0.64	-0.67	

2.3. Dimensionality Reduction

PCA is a very popular dimensionality reduction techniques, generally it performs a set of linear transformation on the original dataset into a smaller number of variables while explaining most of the variance. The transformed variables which are also called principal components (PC) are sorted in a descending order, whereby PC1 has the largest contribution of the explained variance. The equation for principal component is depicted as follow (Fahmi et al., 2011):

$$Y_{mn} = z_{m1}x_{1n} + z_{m2}x_{2n} + z_{m3}x_{3n} + \dots + z_{mi}x_{in} \quad (2)$$

Where y is the component score, z is the component loading, x is the measured value of a variable, m is the component number, n is the sample number, and k is the total number of variables.

On the other hand, LDA optimize the projection by preserving the discriminatory power of the dependent variable before transforming it into a lower dimensional space (Delac et al., 2005). This could be achieved as LDA seek to minimize the within class variance and maximize the between class variance which eventually lead to the greatest class discrimination. According to (Ngouna et al., 2020) water quality parameters can be divided into two main classes: compliant water quality and non-compliant water quality (which depicts water pollution). The between class scatter S_b matrix and within class scatter matrix S_w can be computed by eq. (3) and eq. (4) (Rupali et al., 2010):

$$S_b = \sum_{i=1}^C (u_i - u)(u_i - u)^T \quad (3)$$

$$S_w = \sum_{i=1}^C \sum_{j=1}^{M_i} (Y_j - u_i)(Y_j - u_i)^T \quad (4)$$

Where C is the number of distinct classes, M_i is the number of training samples in class i , u_i is the mean vector in class i , Y_j is the j th data of the set of samples in class i .

2.4. Prediction Model

As described in the earlier section, there are three ensemble decision tree-based regression models (FR, ETR, and BTR) that were analyzed and compared to predict WQI. Ensemble technique simply means that multiple decision trees are combined to improve the prediction performance. Two of the most widely known ensemble techniques are bagging and boosting. Bagging or bootstrap aggregation is generally performed to reduce the variance of the decision tree by generating multiple training dataset in parallel through random sampling. Each of the training set would be utilized to train their trees, resulting a more robust performance from averaging out the accuracy of all the trees. Boosting on the other hand generates series of decision trees sequentially with a goal of reducing the overall prediction error (Kotsiantis and Kanellopoulos, 2012). Random forest regression model (FR) is an example of decision tree model based on bagging technique. The advantages of FR compared to other machine learning models are: Robustness against parameters specification, powerful interactions against input variables, and tackling non-linear properties. ETR is similar to FR, but instead of subsampling the data with replacement, it utilizes the entire original dataset. Additionally, rather than selecting the optimum splitting point, it opted for randomization. Both FR and ETR compute the final prediction result as the average of all the generated decision trees (Geurts et al., 2006). BTR on the other hand is based on boosting ensemble technique, by which the decision tree is boosted using AdaBoost method. It works by building series of decision tree regressors in which larger weight is given to sample with higher degree of errors and vice versa. After numerous iterations, the resulting model would have a much lower overall prediction error (Drucker and Harris, 1997). The dataset was randomly distributed into 80 % of training set and 20 % of test validation set. The performance and efficiency of the prediction model was assessed by utilizing the R^2 , root mean square errors (RMSE) values, and training speed.

3. Results and Discussion

As shown in Table 3, the WQI prediction models were initially developed and compared without performing any dimensionality reduction techniques. The best model accuracy could be observed from both ETR and BTR models with an R^2 values 0.89 and RMSE scores of 4.632 and 4.688 respectively. FR model is not far behind at R^2 values of 0.87 and RMSE scores of 5.053. However, the efficiency of ETR is much better when compared to the FR model at 91 % faster training speed. This shows that ETR strategy of selecting random splitting point is much more efficient than that of FR.

Table 3: Prediction performance of different WQI prediction models for test dataset.

Model	Dimensions	Var	FR			ETR			BTR		
			R^2	RMSE	Speed	R^2	RMSE	Speed	R^2	RMSE	Speed
Base	-	1.00	0.87	5.053	1.3 s	0.89	4.632	91%>FR base	0.89	4.688	63%>FR base
Base + PCA	12	0.97	0.82	5.708	4%> FR base	0.86	5.151	10%> ETR base	0.87	4.921	3%> BTR base
	9	0.87	0.80	6.116	11%> FR base	0.82	5.780	26%> ETR base	0.83	5.672	8%> BTR base
	6	0.71	0.80	6.208	53%> FR base	0.82	5.856	54%> ETR base	0.82	5.819	51%> BTR base
	3	0.51	0.78	6.425	145%> FR base	0.79	6.323	113%> ETR base	0.77	6.570	135%> BTR base
Base + LDA	12	0.99	0.86	5.142	2%> FR base	0.88	4.860	10%> ETR base	0.88	4.811	1%> BTR base
	9	0.98	0.86	5.236	8%> FR base	0.87	4.918	31%> ETR base	0.87	4.887	5%> BTR base
	6	0.97	0.85	5.287	53%> FR base	0.87	5.147	62%> ETR base	0.86	4.929	43%> BTR base
	3	0.95	0.85	5.344	150%> FR base	0.85	5.339	127%> ETR base	0.85	5.396	129%> BTR base

Dimensionality reduction techniques were then performed to reduce the input dataset to 12, 9, 6, and 3 dimensions. In term of performance and efficiency, LDA reduced model consistently surpass that of PCA technique at any dimensional level. This could be observed from Table 3, whereby model trained with only 3-dimensional input data could still achieve an R^2 values of up to 0.85 and RMSE as low as 5.339 compared to that of PCA with the highest achievable R^2 values at only 0.78. The training speed for LDA reduced model is also much faster at up to 150 % faster compared to the respective base model without DR technique. This could be due to the fact that LDA has the ability to conserve majority of the discriminatory power from the original dataset when projecting the data into lower dimensional space, which allow LDA to maintain as much variance as possible. From Table 3, it could be observed that even at the lowest dimensional level, LDA could still explain 95 % of the variance in the original dataset. Whereas the cumulative variance explained by PCA technique dropped to as low as 51 %. Ideally, the final combination of prediction model and DR technique would be ETR + LDA (6-dimensions), where there is acceptable compromise between performance and efficiency with an R^2 values of 0.87 and 62 % faster training speed than base ETR model. After performing hyperparameter-tuning the performance and efficiency were further improved with an R^2 values of 0.88 and more than double the untuned training speed at 172 % faster than base ETR model.

4. Conclusion

In this study, three different type of decision tree-based regression model (FR, ETR, and BTR) were compared to predict WQI. The results of our study show that each of the decision tree model displayed satisfactory performance with R^2 values above 0.85 with

ETR being the most efficient model at up to 91 % faster training speed than the base FR model. Additionally, two dimensionality reduction techniques namely PCA and LDA were assessed. After performing hyperparameter-tuning, ETR + LDA (6-dimensions) was found to be combination with the best compromise between performance and efficiency with R^2 values of 0.88 and 172 % faster training speed than base ETR model. By utilizing only on-site measurements it is possible to develop a WQI forecasting system that could alert the general public almost in real-time. It could potentially be a more effective alternative than the existing WQI monitoring system.

Abstract

This paper proposes a novel method for synthesis, design and innovation of sustainable integrated processes that combines water, energy, waste treatment and carbon capture and utilization (CCU) networks together with the overall objective to minimize carbon emissions and wastes under uncertainty. Compared to the earlier deterministic method (Li et al, 2020), in this method, uncertainty of parameters, CCU as well as extended models for the process, water and energy networks have been systematically addressed in this work. The applicability of the extended method is demonstrated through a case study that considers the xylitol production process together with water, energy and CCU networks. Raw material prices, product prices and demand are considered as stochastic. The results show that the multi-network synthesis and design method is able to determine the optimal solution with high economic benefits and zero or low carbon emission under uncertainty for different scenarios.

Keywords: process synthesis, multi-network optimization, uncertainty, CCU

1. Introduction

Chemical processes convert selected raw materials to desired chemical products, while requiring also utilities such as water and energy and produce wastes and greenhouse gases emissions, thereby cause negative environmental impacts. Different sources and generation processes of water and energy may result in different investment costs, operating costs, carbon and pollutant chemical emissions as well as the synthesis-design of the chemical production process. Different processes of waste treatment and carbon capture and utilization (CCU) may also be used to reduce waste and greenhouse gases emissions. These problems should also be considered along with the production process.

Although some publications consider the water utilization, power integration or carbon capture during the systematic chemical process synthesis and design, the sources of the water and power have yet to be simultaneously considered. A framework for general chemical process synthesis that comprehensively considers the overall water and energy supply, waste and carbon emission is rare. In recent work proposed a framework of multi-network problem for process synthesis-design integrated with water sub-network and power generation sub-network (Li et al. 2020). It proves that the multi-network optimization problem can be used to find a more sustainable alternative with low emissions and high benefits. However, feasible solutions with zero carbon emission usually cannot be found. In order to obtain sustainable solution with zero carbon emission, we introduced a carbon capture and collection network to the multi-network problem to construct an extended multi-network optimization problem. Also, for the multi-network integration problem, since the uncertainty of any network will radiate to other networks, when parameters such as market prices and demands change, the optimal solution of the original model may perform poorly. To hedge against the uncertainty (Ning et al., 2019), the MILP model of multi-network optimization problem is extended to a stochastic mixed integer linear programming (SMILP) model. Therefore, by setting the discrete distribution of uncertain parameters and solving the new two-stage stochastic programming model, the sustainable alternatives with the highest economic expectation and zero emission can be obtained. The applicability of this extended method is demonstrated through by a realistic conceptual case study.

2. Framework and Modeling

We propose a framework together with modeling methods for integrating process, water treatment, power generation, and CCU networks to obtain the more sustainable alternatives with environmental constraints under uncertainty. A brief description of the systematic framework and associated methods and tools are given below.

2.1. Framework

The framework of integration is shown in Figure 1. The new framework has four sub-networks: chemical process, energy generation, water treatment, and CCU process. Chemical process converts raw materials to target product. Power sub-network supplies energy to all sub-networks. Water sub-network supplies water to other sub-networks. The carbon dioxide generated by process, power and water sub-networks are captured and utilized by the CCU sub-network.

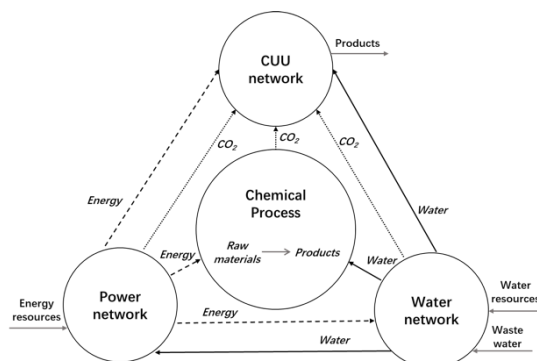

Figure 1. The integration framework of four networks.

2.2. Modeling

A superstructure-based optimization approach is employed to simultaneously synthesize and design a chemical process coupled with the power generation, water treatment and CCU sub-networks.

2.2.1. Superstructure

A superstructure is a visual representation to show all the feasible or allowed alternative routes of a decision-making design problem (Quaglia et al., 2012b). The superstructure for a process synthesis-design problem consists of columns, nodes, and arrows. They represent the processing steps, alternative processing techniques (intervals), and possible processing routes respectively. All sub-networks in Figure 1 will be represented using this process step-interval network superstructure (Bertran et al., 2017).

2.2.2. Generic interval model

The generic interval model gives the general form of the mathematical model for each interval to support the mathematical representation of the total network. As illustrated in Figure 2, the generic interval model has 5 operating units to convert the inlet flows to the outlet flows: a mixer, a reactor, a carbon emission calculation unit, a waste separator, and a product separation unit.

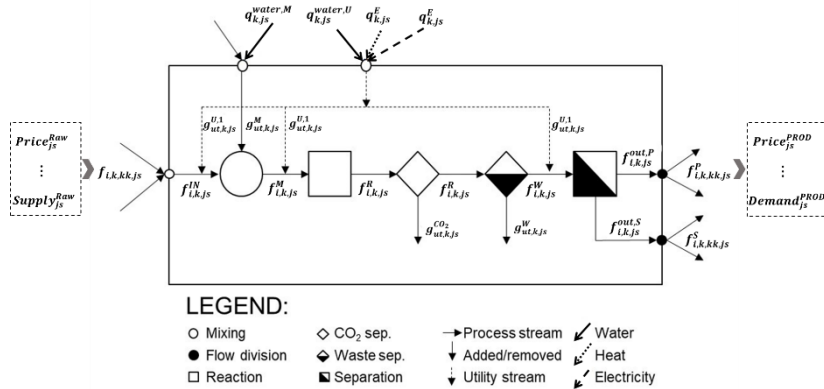

Figure 2. Generic interval model for multi-network stochastic programming.

2.2.3. Stochastic programming model

A two-stage stochastic programming approach (Birge et al., 1997) is considered to deal with the uncertainties of market prices of raw materials and products; and, market demand of products. The prices of raw materials and products will affect the selection of processes due to their different conversion and investment. On the other hand, market demand will affect the equipment scale. Here, the selection of production processing route and equipment scale (production capacity) are made “here-and-now” prior to the resolution of uncertainty for each-subnetworks, whereas the production rate of each sub-networks are made in “wait-and-see” mode after the uncertainties are revealed.

After setting the distribution of uncertain parameters, different scenarios js can be considered. In different scenarios, the general interval model has the following forms:

$$\text{Mixing} \quad g_{i,k,js}^M = \sum_{ii} f_{ii,k}^{IN} \mu_{i,ii,k,js} \quad (1)$$

$$f_{i,k,j_s}^M = f_{i,k,j_s}^{IN} + g_{i,k,j_s}^M \quad (2)$$

$$\text{Reaction} \quad f_{i,k,j_s}^R = f_{i,k,j_s}^M + \sum f_{react,k,j_s}^M \theta_{react,r,k} \gamma_{i,r,k} MW_i / MW_{react} \quad (3)$$

$$\text{CO}_2 \text{ separation} \quad g_{k,j_s}^{CO_2} = f_{co_2,k,j_s}^R \quad (4)$$

$$\text{Wastes separation} \quad g_{i,k,j_s}^W = f_{i,k,j_s}^R \delta_{i,k} \quad (5)$$

$$f_{i,k,j_s}^W = f_{i,k,j_s}^R - g_{i,k,j_s}^W \quad (6)$$

$$\text{Product-product separation} \quad f_{i,k,j_s}^{out,P} = f_{i,k,j_s}^W \sigma_{i,k} \quad (7)$$

$$f_{i,k,j_s}^{out,S} = f_{i,k,j_s}^W - f_{i,k,j_s}^{out,P} \quad (8)$$

$$\text{Utility consumption} \quad g_{ut,k,j_s}^U = \sum_i \beta_{ut,k}^1 f_{i,k,j_s}^{IN} + \sum_i \beta_{ut,k}^2 f_{i,k,j_s}^M + \sum_i \beta_{ut,k}^3 f_{i,k,j_s}^W \quad (9)$$

$$\text{Production rate} \quad f_{i,k,j_s}^M \leq F_{capacity} \quad (10)$$

The objective function of the multi-network optimization problem is determined as the expectation of the total economic benefits (Eq.11). P_{j_s} is the probability of each scenario. In addition, each scenario needs to meet environmental constraints (Eq.12, Eq.13).

$$Z = \sum_{n=1}^4 (P_{j_s} (S_{n,j_s}^{PROD} - C_{n,j_s}^{RAW} - C_{n,j_s}^C - C_{n,j_s}^E - C_{n,j_s}^H - C_{n,j_s}^{water}) - C_n^{CAP} / \tau) \quad (11)$$

$$\sum_{k_n} g_{k_n,j_s}^{CO_2} \leq CONS_{co_2} \quad (12)$$

$$\sum_{i_n} \sum_{k_n} g_{i_n,k_n,j_s}^W - Rec_{j_s} \leq CONS_{waste} \quad (13)$$

According to the above method, the SMINLP model of the multi-network optimization problem can be formulated and then simplified into the SMILP model through big-M method and capital piecewise linearization. Similar solution steps (Li et al. 2020) has been followed to obtain the optimal solution.

3. Case Study

3.1. Problem definition

The production of xylitol is considered as an illustrative example in this work. The raw material is corncob. Market price of corncob and xylitol, and market demand of xylitol are set as uncertain parameters. In this case, the multi-network optimization problem aims to find sustainable solutions with zero carbon emission, zero waste water emission and highest expected economic benefits.

3.2. Superstructure representation

The sub-networks of xylitol production, water treatment and power generation in this case follow the superstructure of previous work (Li et al. 2020). CCU sub-network is adapted from the case study of carbon dioxide utilization (Bertran et al. 2017). The superstructure of multi-network problem in this case is shown in Figure 3. The nodes (intervals) in each sub-network are set up using generic interval model.

3.3. Uncertain parameters distribution

Based on the market data collected in China, low, medium and high forecasts for prices of corncob and xylitol, and demands of xylitol are set as uncertain parameter values. The discrete distributions of uncertain parameters are listed in Table 1. Based on this distribution, 27 scenarios are generated.

Table 1. distributions of uncertain parameters.

Uncertain Parameters	Value	Unit	Probability
Price of corncob	97.5, 105, 112.5	\$/t	0.30, 0.40, 0.30
Price of xylitol	3900, 4200, 4500	\$/t	0.30, 0.40, 0.30
Demand of xylitol	10000, 12000, 14000	t/y	0.25, 0.5, 0.25

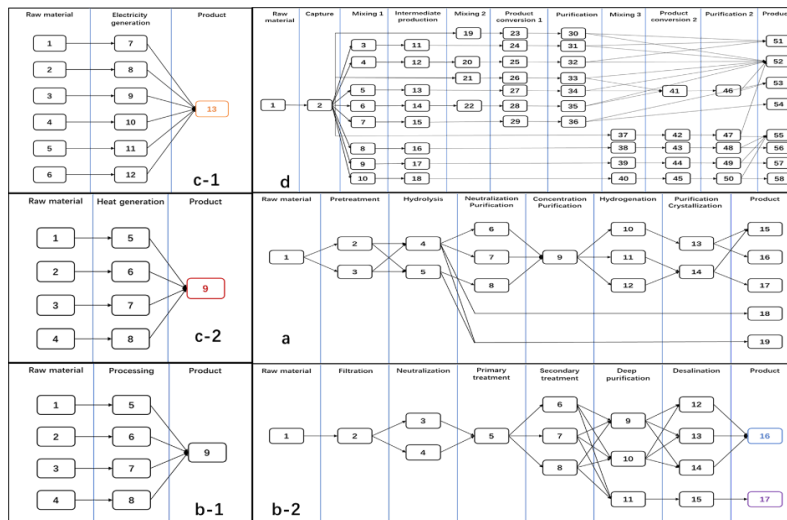

Figure 3. Superstructure representation of multi-network problem. a. Chemical process. b-1. Water plant. b-2. Waste water treatment. c-1. Electricity generation. c-2. Heat generation. d. Carbon capture and utilization.

3.4. Uncertain parameters distribution

After setting the uncertain parameter distribution, the SMILP model of multi-network optimization is established and solved simultaneously using the CPLEX optimizer. This model features 9,923,224 continuous variables, 10,178,711 equations and 381 binary variables whereas the deterministic model features 368,406 continuous variables and 378,062 equations. The optimal solution is obtained after 21186 iterations with 357 s CPU times. The results of the optimal routes are shown in Figure 4.

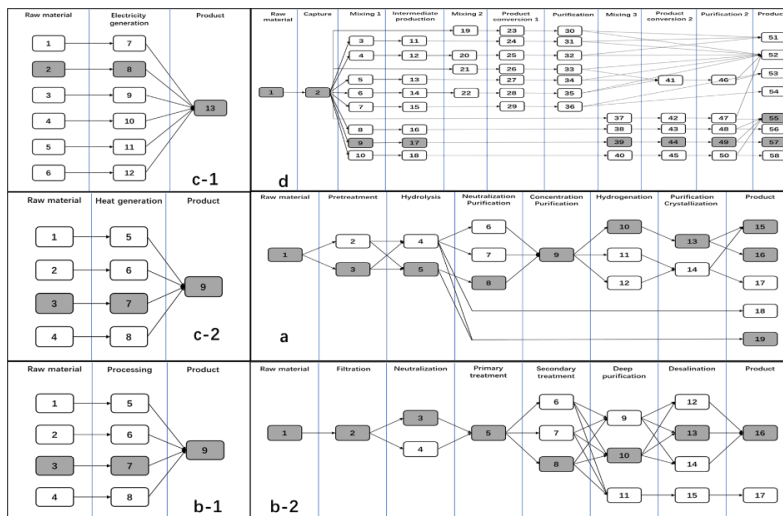

Figure 4. Result of optimal routes.

The optimal solution selects catalytic hydrogenation process to produce xylitol after hydrochloric acid hydrolysis. All waste water is deep purified and recycled. All carbon dioxide is captured by chemical absorption method and used to produce DMC. The optimal solution selects wind power and uses coal to produce steam. The mathematical results of the optimal solution and listed in Table 2.

Table 2. mathematical results of the optimal solution.

Term	Scenario	Value	Unit
Expected economic benefit	-	9,542,886	\$/y
Investment	-	172,892,655	\$
Output	1-9	10,000	t/y
	10-18	12,000	
	19-27	14,000	
CO ₂ capture	1-9	511,995	t/y
	10-18	614,394	
	19-27	716,793	
Steam consumption	1-9	853,325	t/y
	10-18	1,023,990	
	19-27	1,194,655	
Electricity consumption	1-9	172,566,400	kwh/y
	10-18	207,079,700	
	19-27	241,593,000	
Water consumption	1-9	2,341,356	t/y
	10-18	2,809,628	
	19-27	3,277,899	
Carbon emission	-	0	t/y
Waste emission	-	0	t/y

The results show that, in the face of market demand and price uncertainties, the multi-network stochastic programming model can help to obtain the optimal processing routes, equipment scale, and production rate for different scenarios with the highest economic benefit expectation. With the addition of the carbon capture and utilization sub-network, a comprehensive sustainable plan with zero carbon emissions can be obtained. However, in order to achieve zero carbon emissions, the scale of the CCU

sub-network is very large and leads to more investment, energy consumption and water consumptions, indicating the need for considering CCSU.

4. Case Study

An extended framework for integrating process, water treatment, power generation, and CCU networks has been proposed to obtain more sustainable alternatives with zero emission. In order to obtain the optimal solution under uncertainty, the stochastic programming of multi-network optimization problem has been implemented. The associated new methods are successfully applied to a multi-network problem of xylitol production under uncertainty and a sustainable optimal solution has been obtained.

Abstract

Rapid population growth has led to an increase in the demand for energy, water and food resources utilisation which results in environmental impacts and contributes to resource depletion. Therefore, it is necessary to design networks using various tools such as process integration and optimisation approaches, which have been applied to Energy-Water-Food (EWF) nexus studies. The main objective of the study is to design a systematic approach to capture the trade-offs between the economic and environmental metrics of sustainable design with industrial parks. It presents a novel superstructure and mathematical optimisation model that captures the synergies within EWF nexus considering interplants. Moreover, novel to this study, is the exergetic approach, which has not been previously applied to EWF nexus studies within industrial parks. The proposed nexus superstructure is applied to an eco-industrial park including wastewater treatment units, desalination plant, agricultural sub-systems, and a biomass gasification process for the recycling of biomass waste. The case study includes water-energy sources and sinks for chemical plants such as ammonia/urea and GTL processes in the State of Qatar which are simulated using the “what’sBest” Mixed-Integer Global Solver for Microsoft Excel by LINDO Systems Inc. Different cases with multiple optimisation objectives are evaluated in order to capture the trade-offs between the economic and environmental emission. Different indicators are used to assess the system resource efficiency such as exergy efficiency and global warming potential (GWP). The main focus is on capturing the synergic potential from utilising biomass from within the food sector and producing the syngas which decreases the natural gas consumption in other systems. Results of the study demonstrate clear benefits of water integration and biomass utilisation and contribute to the reduction of resource consumption. In the best scenario, the system demonstrates an 18 % reduction in the global warming potential, while the total annual cost of the design is increased by almost 9 %. The exergy efficiency of the system is enhanced reaching 53 %.

Keywords: Biomass, Wastewater, EWF Nexus, Optimisation, Integration.

1. Introduction

The growth in the global population affects consumption of energy, water, and food (EWF) resources. It has been estimated that the agriculture requires an increase of approximately 70 % in order to meet the population demand (Karan et al., 2018). Furthermore, the agriculture system consumes 70 % of the total global freshwater extraction, whilst food production accounts for nearly 30 % of the total energy consumed worldwide. Incidentally, there are significant interlinkages amongst EWF sectors, known as the 'nexus'. The integration and optimisation of the EWF nexus can lead to lower resource consumption and a more sustainable industry. Multiple studies have been conducted around the EWF nexus concept, for instance, a discussion on the decision making tools (Namany et al., 2019); a study based on a life cycle assessment (Al-Ansari et al., 2015); risk assessment studies within geospatial applications applied to food sectors (Haji et al., 2020); and studies on biofuels production (Alherbawi et al., 2020). The objective of this study is to apply the EWF nexus concept to the optimisation of industrial parks to support the transformation towards eco-industrial parks (EIP). The exchange of resources and wastes amongst various plants as advocated by industrial ecology can enhance the overall system efficiency. The majority of studies in this regard have focused on inter-plants integration, whilst others have adopted an intra-plants approach considering the integration of individual sectors such as energy and water. Lovelady and El-Halwagi developed a mathematical optimisation formulation to integrate the wastewater among number of plants (Lovelady and El-Halwagi, 2009). Alnouri et al. generated a water superstructure considering the direct and indirect water reuse for an EIP (Alnouri et al., 2014), where an optimisation model was developed to solve for the most cost effective and global optimum solution. In the concept of heat integration, different linear and non-linear programming models are proposed intra-plant and inter-plant (Nair et al., 2018). The energy-water integration is well studied within the EIP. Fouladi and Linke (2018) proposed an optimisation based model for a representative superstructure considering desalination, wastewater treatment, and cooling systems, and captures the trade-offs between the economic and environmental dimensions of the problem. Furthermore, Ghazouani et al. formulated a new optimisation model to integrate the mass and heat contents for multiple number of plants. Therefore, as mentioned previously, the concept of EIP within the EWF nexus needs to be further studied in order to explore the synergies between the two concepts which both aim to conserve resources. As such, the main objective of this study, is to generate and optimise a representative superstructure of EWF nexus which contributes towards the design of eco-industrial parks. A systematic approach is developed to search for the optimum design depending on economic and environmental objectives.

2. Network superstructure

In order to start the EWF nexus representation, a superstructure developed previously is used. The system boundaries are defined and sub systems are added to capture all the linkages between different sectors. In this work, some of the main sub-systems are considered in each sector, in which their integration and optimisation result in significant changes. The water sector consists of treatment units, desalination plants, and production units. Energy is considered to be in the form of a combined heat and power system, whilst the food sector includes the production of fertilisers and agriculture activities, all of which are connected to one another on a water-energy

sources-sinks basis. Figure 1 illustrates the systems and sub-systems of the proposed superstructure for the EWF nexus for a single plant.

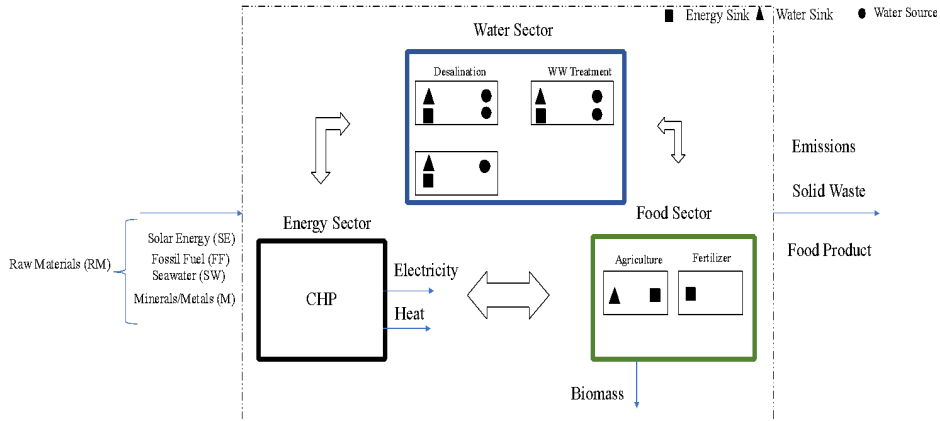

Figure 1: EWF Nexus representation systems and sub-systems

Moreover, Figure 2 captures the linkages among different sources and sinks.

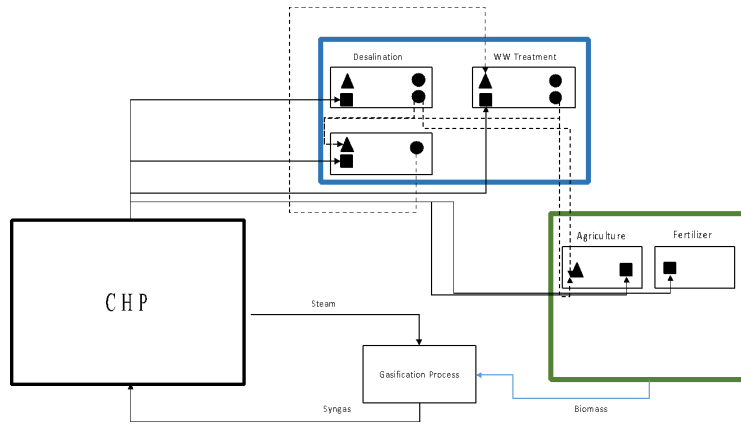

Figure 2: EWF Nexus with biomass utilization

An optimisation formulation is developed using network equalities (mass and energy balances), and inequalities (capacities, flow rates, and purities). The water network formulation is the expansion of an existing work (Alnouri et al., 2014). The “what’sBest” Mixed-Integer Global Solver for Microsoft Excel by LINDO Systems Inc is used to identify the global optimum solution of the network. The main objective of the problem is to minimise the total annual cost of the network as follows:

$$\text{Minimize: } C(\text{freshwater}) + C(\text{Treatment Units}) + C(\text{Fuel}) + C(\text{Biomass Utilisation})$$

Subject to:

$$g(x,y) < 0 \quad \text{Inequality constraints} \quad \square \quad \text{purities, flowrates, capacities}$$

$$h(x,y) = 0 \quad \text{Equality constraints} \quad \square \quad \text{mass balances, energy balances}$$

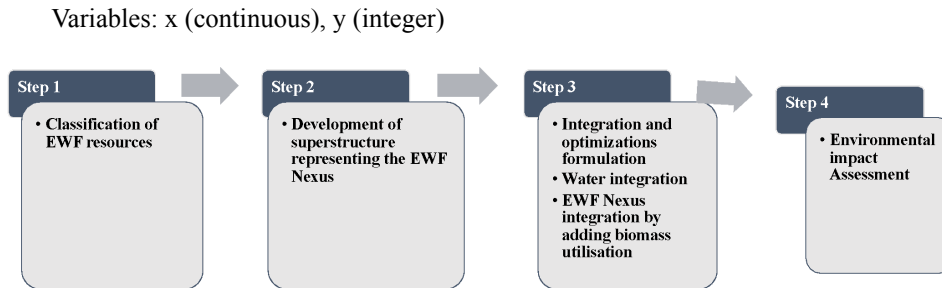

Figure 3: Modeling Procedures

Figure 3 illustrates the modelling procedures for the work which is all in terms of energy and water sources and sinks. Furthermore, to compare different scenarios and to support decision makers, a sustainability weighted return on investment metric (SWEIOM) developed by El-Halwagi (2017) is calculated using indicators such as energy, water, and waste reductions.

3. Results and discussion

A case study including two plants (GTL and Ammonia) with selected contaminants of TDS and TSS is solved to assess the proposed approach of EWF nexus. Water sources and sinks flowrates are taken from Aspen HYSYS results. HYSIS is a chemical process simulator which formulates the process mathematically. An air-stream gasification model developed previously to generate syngas is used for biomass utilisation scenarios (AlNouss et al., 2018).

Table 1: Simulation input data.

Flow rates (t/d)	GTL	Ammonia
Wastewater produced	9500	20000
Process water requirement	1625	31150

Four different cases are simulated and solved representing scenarios without any integration, with water integration, with water/biomass integration, and finally considering environmental objectives. In the first three cases, the optimisation objective minimises the cost, whilst in the final case the objective considers the minimisation of the environmental emissions. Table 2 summarises the main results from the optimisation solver.

Table 2: Results for the four selected cases.

Cases	Case 1 No Integration	Case 2 Water Integration	Case 3 Water-Biomass Integration	Case 4 Environmental Integration
Total Treated Water	0	19855	19855	19855
Total Annual Cost (M\$/year)	566	553	553	606

GWP (kg CO ₂ eq/year)	2.98E+10	2.98E+10	2.98E+10	2.43E+10
-------------------------------------	----------	----------	----------	----------

As illustrated from the results; the water network remains the same after case 1, which illustrates that wastewater treatment is chosen in both economic and environmental objective functions. The results in case 3 remains as case 2, which indicates that the biomass integration has been not selected as the optimum solution. For this reason, in the last case the objective function is changed. It can be noticed that the total annual cost is increased by approximately 9 %, while the global warming potential is decreased by 18%. The GWP remains constant until the final scenario since the energy integration is considered there by adding the sub-system which represents biomass utilisation.

Table 3 illustrates the exergy efficiency calculated for each optimisation case. It demonstrates that the exergy efficiency has the maximum value of 53 % with the biomass utilisation option and integrated wastewater sources.

Table 3: Exergy efficiency comparison for cases

Cases	Case 1	Case 2	Case 3	Case 4
Exergy Efficiency (%)	36.3	37	37	53

Moreover, to compare the cases and to select the most sustainable option, the SWROIM is calculated as illustrated in Table 3 below. Three different sustainability indicators are used; energy footprint, water footprint, and food waste footprint. The weighting factor for each indicator is varied in different scenarios to identify the best performing solution. As it is illustrated in Table 4, the findings demonstrate that for all indicators with different weighting factors, case 4 is selected as it has the largest SWROIM values.

Table 4: SWROIM results.

	Case 1	Case 2	Case 3	Case 4
SWROIM (%) (equal weights)	29	40	40	42.69
SWROIM (%) (0.5 water, 0.25 others)	31	53	53	54
SWROIM (%) (0.5 food, 0.25 others)	24	29	29	37
SWROIM (%) (0.5 energy, 0.25 others)	32	37	37	38

4. Conclusion

There are significant interactions amongst the EWF sectors which can be integrated to minimise consumption of resources. This study is novel as it considers an EWF Nexus approach within eco-industrial parks. It emphasizes on biomass utilization to capture the synergetic potential of integration of the EWF nexus concept with sustainability dimensions as applied to industrial parks. A case study to demonstrate this is developed accordingly and is evaluated from both economic and environmental perspectives. Evidently, biomass utilisation is an expensive process, however it can improve the environmental performance significantly. Finally, a sustainability metric is used to

compare different cases and to support decision makers in identifying the most sustainable configuration. As such, the results illustrate the significance of biomass utilisation as it enhances the exergy efficiency reaching 53 %. Generally, this work demonstrates the significance of the EWF nexus and its contribution towards resource management. The next goal is to study the seasonal effect on the optimised network and do some sensitivity analysis on different parameters. Moreover, adding more plants into the industrial park can also result in more significant outcomes where the pareto front curves are useful to capture the trade-offs between the economic and environmental dimensions.

A Study to Target Energy Consumption in Wastewater Treatment Plant using Machine Learning Algorithms

Akash Das, Piyush Kumar Kumawat, Nitin Dutt Chaturvedi

Process Systems Engineering Laboratory, Department of Chemical and Biochemical Engineering, Indian Institute of Technology Patna, Bihta, Patna, 801106, Bihar, India

Abstract

Wastewater treatment plants (WWTPs) are one of the world's largest municipal-level electricity users. Understanding the structure of the energy cost of WWTP is a challenge for planners, and its calculation could result in substantial saving capacity and cost estimation. The wastewater contains various organic materials, and the purpose of WWTP is to process these parameters to the appropriate parameter level. These input parameters are related to the demand for electricity but are challenging to model. The study utilizes some of the advanced machine learning models trained on real-world data to predict the energy consumptions of WWTPs. Four machine learning algorithms were leveraged on the available dataset to identify the model of best fit. The models' performance is evaluated based on standard metrics of mean absolute error (MAE), and root mean square error (RMSE). It shows that GRU is the model of best fit and is recommended for further future analysis.

Keywords: Wastewater treatment; Machine Learning; Data-Driven; Energy Consumption

1. Introduction

Wastewater treatment plants (WWTPs) may require about 1% to 3% of a country's total electrical energy output. Over 20% of public utilities' electrical energy consumption by municipalities is necessary for their operation (Capodaglio and Olsson, 2020). The energy requirements of water treatment and supply processes depend upon factors including the contamination of the water, water quality, geographical conditions, technology, and age of the industrial setup (Jian et al., 2014).

Energy is consumed at all levels of treating wastewater and is considered as a principal contributor to WWTPs expenses; to drive the influent pump, aerated grit chamber in the primary process, providing air in aeration process of biological treatment. Stillwell et al. (2010) stated that energy efficiency measures and treatment process modifications might reduce their energy cost. Machine learning applications are widely explored in recent years to carry out operations related to WWTPs. Guo et al. (2015) presented the study to predict effluent concentration in a WWTP using machine learning models. Li et al. (2019) used a radial basis function (RBF) neural network to forecast energy consumption.

In this study, machine learning algorithms are employed to estimate the energy consumptions from historical data. It is considered that the efficiency of WWTP is influenced by inflow loads, chemical oxygen demand (COD), and total nitrogen (TN). The available data set is trained using regression algorithms: support vector machines (SVM), artificial neural network (ANN), long-short term memory (LSTM), and gated

recurrent network (GRU). Further, error analysis has been performed to select the model with a minimum error corresponding to the data's best fitting. This study aims to find the best fitting model to estimate the approximate energy requirement for the process. This study assists the planner to intelligently select and utilize ML algorithms using the historical data of the influencing factors that can precisely model and estimate the energy consumption of WWTP given the influencing features.

2. Problem statement and data description

Given a set of historical data adapted from Li et al. (2019), each data point comprises influencing factors (inflow rate, COD removal, and TN removal) along with their subsequent energy consumption. A total of 360 data points are available over a period of one year. The influencing factors are the input parameters and energy consumption as an output parameter to develop and train the model.

The presented study's objective is to estimate energy targets using various ML regression algorithms using available historical data. These models were then compared to predict the best model to fit the model's data better.

3. Methodology development using machine learning algorithms

The proposed methodology uses a comparative approach among four machine learning algorithms. It compares them on standard metrics to conclude the algorithm that can best predict the data coming from WWTPs.

The input to RNN, LSTM, and GRU needs to be a 3D vector, typically consisting of the batch size, time steps, and features. Therefore, the data is segmented into a window size of 15 with three input features. The rolling window approach was utilized for this purpose. The input features were then normalized to get them within a definite range of values, enabling better training of the proposed models. After the datasets' preprocessing was completed, they were then divided into training sets (70%) and test sets(30%). The training datasets were used to develop the energy consumption models, and the test datasets were used to assess the accuracy and robustness of the developed models. The output predicted by the model was compared with that of the actual output on standard metrics of MSE and RMSE. The model that scores the least error in both the metrics was concluded to be the model of best fit. A graphical description of the proposed framework is provided in figure 1, and the machine learning models used are described in the following subsections.

Figure 1. Proposed framework flow chart

3.1 Feedforward Neural Network Model

The Feedforward neural network is one of the simplest types of ANN devised. The information flows in the forward direction through the input layer of several hidden layers and a final layer of output nodes. The neurons are interconnected by weights, which form probability-weighted associations between input and output. The network trains itself by computing differences between the processed output by the network and the actual target

output. The network then adjusts the weights associated with each connection according to a set learning rate and the error values. After many such successive adjustments as the network loops over each time in the ANN, this way tends to produce outputs that are increasingly similar to the target output (results). The output from the j th node of an ANN is given by Eq. (1). Here O_j is the output vector, σ is the activation function, w_{ji} are the weight vectors and x_i is the output vector from the previous layer

$$O_j = \sigma\left(\sum w_{ji}x_i\right) \quad (1)$$

For this study, an ANN with two hidden layers and one output node has been used.

3.2 Recurrent Neural Network Model

Recurrent Neural Networks (RNNs) are an extension of the typical Feed Forward Neural Networks described above, using their internal state to process variable-length input sequences. The RNN handles variable-length sequences by having a recurrent hidden state whose activation at each time is dependent on the previous time. At a given time-step, each non-input unit calculates its current activation (output) as the nonlinear function of the weighted sum of all the activations of all the connected units (Lipton et al., 2015). For a given sequence $X = (x_1, x_2, \dots, x_n)$, the RNN will have activations $a^{<t>}$ and may optionally have an output $Y = (y_1, y_2, \dots, y_n)$, which may again be of variable length. Typically the activation and output of the recurrent hidden state are given by Eqs. (2) and (3). Where W_{ax}, W_{ay} are weight metrics and W_{aa} is the memory of the RNN that it has been maintaining from the previous layers.

$$a^{<t>} = g(W_{aa} a^{<t-1>} + W_{ax} x^{<t>} + b_a) \quad (2)$$

$$y^{<t>} = g(W_{ya} a^{<t>} + b_y) \quad (3)$$

This study uses a model with two bidirectional RNNs and one layer of simple RNN fed to a dense network of five hidden layers through an attention layer.

3.3 Long Short-Term Memory Model

The Long-Short Term Memory (LSTM) structure was motivated by an analysis of error flow in existing RNNs, which found that long time lags were inaccessible to existing architectures because the backpropagated errors either blows up or decays exponentially. Unlike the recurrent unit, which computes a weighted sum of the input signal and applies a nonlinear function, each j^{th} LSTM unit maintains a memory c_j^t at time t . The output a_j^t , or the activation of the LSTM unit is then given by Eq. (4),

$$a_j^t = \tau_j^t \tanh c_j^t \quad (4)$$

The memory cell c_j^t is updated by partially forgetting the existing memory and adding a new memory content c_j^t , as shown in Eq. (5),

$$c_j^t = f_j^t c_j^{t-1} + i_j^t c_j^t \quad (5)$$

where the new memory content is given by,

$$c_j^t = \tanh(W_c[a^{<t-1>}, x^{<t>}] + b_c) \quad (6)$$

The extent to which the existing memory is forgotten is modulated by a forget gate f_j^t And the degree to which the new memory content is added to the memory cell is modulated by an input gate i_j^t . Thus unlike the traditional RNN, which over-writes its content at each step, an LSTM can regulate whether to keep the existing memory via the introduction of the gates, hence potentially capturing the long-term dependencies (Graves and Schmidhuber, 2005).

This research considers a model with two bidirectional LSTM layers and one layer of unidirectional LSTM, the output of which is fed to a dense network of five hidden layers.

3.4 Gated Recurrent Unit Model

A gated recurrent unit (GRU) was proposed by Cho et al. (2014) to make each recurrent unit adaptively capture dependencies of different time scales. GRU is similar to the LSTM, but it lacks the output gate and hence has fewer parameters. The activation $a^{<t>}$ of the GRU at time t is a linear interpolation between the previous activation $a^{<t-1>}$ and the candidate activation $a'^{<t>}$, given by Eq. (7), where an update gate τ_u decides how much the unit updates its activation or content.

$$a^{<t>} = (1 - \tau_u) a^{<t-1>} + \tau_u a'^{<t>} \quad (7)$$

The update gate is computed by Eq. (8), as,

$$\tau_u = \sigma(W_u [c^{<t-1>}, x^{<t>}] + b_u) \quad (8)$$

The reset gate is computed similarly to the update gate. This procedure of taking a linear sum between the existing state and the newly computed state is similar to the LSTM unit. The GRU, however, does not have any mechanism to control the degree to which its state is exposed but exposes the whole state each time. GRUs approximately maintain a similar performance and has fewer parameters that can help suppress overfitting.

The GRU for this study uses two bidirectional GRU layers and a unidirectional GRU layer passed on to a dense network with one hidden layer.

4. Results and Discussions

This study considers the influencing factors of inflow load, COD, and TN removal as feature vectors for predicting the energy consumption of the WWTP. Pearson's coefficient is calculated between the influencing factors and energy consumption is depicted in Table 1. It can be observed from the results that all the influencing factors display the least correlation with the target vector. This limits the developed models' performance and is considered a persistent problem in the data-driven approaches to model WWTP parameters. The table also lists the statistical details of the influencing factors and energy consumption.

Table 1. Details of the dataset preprocessing

	Pearson's Coefficient	Mean	Standard Deviation	Min	Max
Energy consumption	NA	22279.12	1884.362	5.39	9.52
Inflow load	0.391	7.642	0.624	16749	26913
COD removal	0.324	15.128	7.969	3.24	52.2
TN removal	0.385	1.856	0.543	0.52	3.42

The training process is carried out using ML algorithms with the training data. Each of the models' accuracy and robustness was then tested with the training data on standard metrics like MAE and RMSE. The model that yielded the least value of both the MAE and RMSE metrics was declared the model of best fit. Table 2 lists out the values that each of the models recorded when compared to the standard metrics.

The ANN model recorded the maximum MAE error of 0.77 results in the input data's poor fitting. Improved results are obtained with RNN, LSTM, and GRU models with MAE errors of 0.54, 0.54, 0.43, respectively. A similar trend is observed with RMSE errors presenting the edge they possess in modelling sequence data. The MAE error was reduced by 33% and RMSE error by 22% by changing the model architecture from the ANN layer to GRU layers. Analogous to the error values used to compare different models, Figure 2. represents the plot of energy consumption with the number of days. It compares energy predicted by the regression models trained in this study against the actual energy consumption by the WWTP. Figure 2(d) shows that the GRU model architecture could accurately predict the energy consumption of the WWTP as it fits the original energy consumption curve quite accurately. A lower precision of fitting is observed in the plots for the other ML models.

Figure 2. Energy predictions against actual energy consumption by the WWTP using (a) ANN, (b) RNN, (c) LSTM, (d) GRU

It can be seen from this study that all the sequence models (RNN, LSTM, and GRU) record a better performance from ANNs; this is because of the architecture of the sequence models that allows them to remember previous inputs while predicting the current ones. In RNN, it is difficult for it to learn to preserve the information over many timestamps due to vanishing gradient, which in turn affects the updated weights. Due to this, the network does not learn the effect of earlier input. GRU helps overcome this problem by the inclusion of update and reset gates in its architecture, where each gate has its weights and biases. This enables a better prediction of the target variable and achieves better accuracy than RNN.

The GRU model records the least error values on both metrics. Still, there is a noticeable difference between the output predicted by the model of best fit with that of the actual data. This difference can be reduced by using better quality data. However, it is challenging to model such data because of its increased non-linearity. Hence, an MAE error of 0.43 is acceptable even in the best fit model. Also, an increased number of available data would help in improving the accuracy of the models.

5. Conclusion

The energy consumption of a WWTP is a complex function and is influenced by several factors. In this paper, machine learning algorithms were used to create a suitable model that could predict the energy consumption of WWTPs. Historical data affecting energy consumption was taken into consideration for developing four different models. Developed models were compared based on MAE and RMSE for predicting energy consumption. GRU architecture gave the best results with the lowest error when tested on the entire dataset. The dataset's size and the data's complex characteristics became a significant hindrance in achieving greater accuracy. More parameters can be explored in future work, affecting energy consumption to predict outputs more accurately with a more extensive and well-correlated dataset. Also, significant developments in the model architecture, in terms of an ensemble model with a combination of ANNs, convolutional neural networks, and sequence models, will be explored as future research.

Abstract

With the objective to obtain more sustainable production processes, the biorefinery network is integrated with traditional pulp and paper industries. A systematic framework with computer-aided tools consisting of synthesis, design and innovation stages has been applied to determine the biorefinery-integrated pulping process. An integrated network of succinic acid production and black liquor gasification for dimethyl ether (DME) production linked to an existing Soda pulping process is identified as the best option for increased profit, which also reduces pollutant emissions through integration of innovative CO₂ capture and utilization (CCU) steps to form the biorefinery-integrated-Soda-pulping network (BIS). This paper aims at also designing a sustainable biorefinery-integrated-Kraft-pulping network (BIK). Three integration scenarios are considered for further study: (I) the production of gasification-based dimethyl ether (DME); (II) the co-production of DME and succinic acid (SA); and (III) the co-production of DME and SA coupled with CCU. The best scenario is found to be Scenario II, which exhibits the best economic performance with 74% increase in profit compared to the conventional process. Scenario III achieves the highest energy efficiency at 39% and improved environmental performance, a 65% reduction of CO₂ emission compared to the conventional process, with only 0.7% profit reduction. The BIK option shows improved performance in terms of economic and environmental improvements compared to the BIS network, confirming that the integrated biorefinery network can transform the conventional Kraft pulping process to a more sustainable process with increased profit.

Keywords: Biorefinery network, Process synthesis and design, Pulp and paper industries, Systematic framework with computer-aided tool

1. Introduction

The existing infrastructure, logistics system and know-how of mature pulp and paper industry provide a great opportunity to commercialize the multiple-product network of biorefinery by transformation of low profitability of traditional pulping processes. Ekbohm et al. (2006) studied the black liquor gasification (BLG) to produce different transportation fuels. Dimethyl ether (DME) production has the highest efficiency of fuel energy output per unit of product. Moreover, the BLG-based biofuels and chemicals production in a Kraft pulping process can provide significant economic returns (Larson et al., 2006). Fornell et al., (2013) proposed an integrated kraft pulping process-biorefinery producing both ethanol and DME. Their results point to a feasible but electricity deficit system. The carbon capture is suggested but has not been considered in their study.

In an earlier work, Mongkhonsiri et al., (2018), applied a superstructure-based process synthesis to define an optimal network of a biorefinery integrated with an existing pulp mill. They also performed a scenario-based sensitivity analysis to study the effect of product price and uncertainty. Based on the generated superstructure, the network of integrated succinic acid production (SA) and black liquor gasification based dimethyl ether production (BLG-DME) were identified to have excellent potential for improved profitability. As further work (Mongkhonsiri et al., 2020), the biorefinery integrated-Soda pulping network (BIS) was designed and evaluated in terms of energy, economics and environmental impacts. The results show that the BIS improves both economic and environmental aspects. Moreover, a CO₂ capture and utilization unit (CCU) step was included to further reduce the environmental impact.

This paper aims to design and evaluate the biorefinery-Kraft pulping network (BIK) where biochemical, biofuel and bioenergy productions are combined with an existing Kraft pulping process. The integrated network is rigorously simulated. Moreover, the Integrated network is designed for energy self-sufficiency by utilizing biomass residues for steam and electricity generation. The process performance is evaluated in terms of energy, economics, and environmental impacts. The integration of two conventional processes with a Tomlinson recovery boiler and a Black-Liquor-Gasification-Combined cycle (BLGCC) have been used for comparison. The CCU design is also applied in the BIK network. Three scenarios, which are extended versions of those studied previously (Mongkhonsiri et al., 2020) compare different types of pulping processes.

2. Methodology

2.1. Process Design

Material flows for the designed network is illustrated in Figure 1. The biorefinery network includes SA, DME, and BGCC processes. The design aims for an energy self-sufficient network. Energy consumption in a Kraft pulping process is considered to provide the biomass fuel required in the BGCC operation. For this work, feedstocks for the BIK network are assumed to have different composition compared to the studied BIS network, which provides higher pulp yield and more BL's organic compound but less biomass fuel. The performances of the networks are discussed in section 3: results and discussion.

2.2. Process evaluation

Process performance is evaluated in terms of economic aspects, energy consumption and environmental impacts, based on the rigorous simulations. The operation period is assumed to be 8,330 h/y and the eucalyptus feed rate is 100 kt/y. The indicator for an

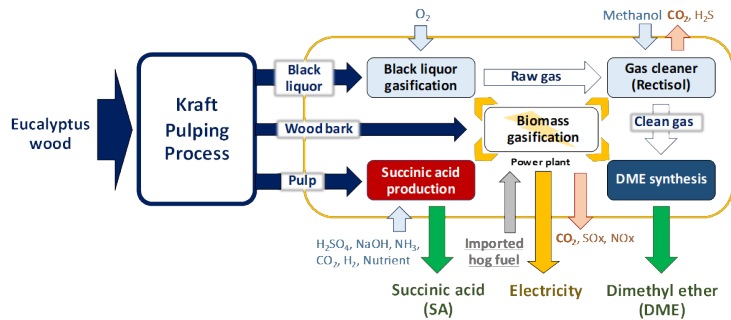

Figure 1. Material flow of integrated biorefinery-Kraft pulping network.

economic efficiency is the annual profit estimated from operating and capital costs based on 25 years of project lifetime. The capital cost includes only the new installation of integrated biorefinery process without the costs for the existing Kraft pulping facility. The environment impacts are evaluated by net emissions of pollutants: CO_2 , SO_x , NO_x and PM_{10} . The net gas emissions consider gas emissions from the processes estimated by emission factors (Larson et al., 2006) and the potential of gas reduction by the biomass utilization, the fossil-based products replacement, the diesel replacement by DME, the petroleum-based succinic acid and the fossil-based electricity generation based on the national grid of Thailand. Three different scenarios are considered.

Scenario I: Integration of the gasification-based DME production - This scenario considers only the integration of the BLG, the DME production and the biomass fuel utilization. Since the production of succinic acid was excluded; the unbleached pulp product was usually sold for paper making.

Scenario II: Integration of the DME and SA - This scenario includes the production of succinic acid (SA) from the unbleached pulp, together with the integrated network from Scenario I. The energy consumption of SA is included in the energy requirements.

Scenario III: Integration of innovative CCU - This scenario includes the CCU as part of the integrated network from Scenario II. CO_2 is captured from the flue gas by an existing Rectisol process without additional installation costs. CO_2 is utilized for methanol synthesis by the integrated CO_2 hydrogenation process. The performance of the methanol synthesis process has already been evaluated in terms of economic and environmental impacts by Frauzem (2017). The produced methanol is then supplied to the DME synthesis process; 30 ktons per year more of DME is acquired by the additional CO_2 -utilized methanol fed to the DME synthesis process.

3. Results and Discussion

3.1. Economic performance

The results of the economic assessment are reported in Table 1. The BIK network in Scenarios I, II and III point to profit over the conventional Kraft pulping process by 6, 40, 39 Million US dollars, respectively. Moreover, the excess power available in all integrated network scenarios provide additional income from the sale of electricity; as well as reduction of petroleum-based dependency. The integration of DME and SA processes (Scenarios II and III) do highly promote profitability of the existing Kraft pulping process. The CCU included in Scenario III decreases the profit by around 600 thousand US dollars per year or 1.1% compared to Scenario II. Although the integrated network in Scenario I yields half of the profit of Scenarios II and III, it still improves the

profit over the conventional Tomlinson boiler and BLGCC processes. Although capital cost of CO₂-utilized methanol production process and operating cost is increased by CCU (scenario III) comparing to scenario II, CO₂ capture and DME production process is an existing process for BLG-DME process. Compared to stand-alone process of CO₂ utilization, the integrated network of DME production from BL gasification and CO₂ utilization could reduce capital and operating costs.

3.2. Environmental impacts

The environmental impacts of the BIK network are calculated in terms of net pollutants: CO₂, SO_x, NO_x and PM10 emissions, reported in Table 2. The integrated DME and SA networks in Scenario II and the innovative CCU integration network in Scenario III discharge CO₂ and other pollutants by around 2 times more than Scenario I. Note that the conventional scenarios because of succinic acid production demands higher energy. Due to CCU integration, Scenario III achieves the highest net CO₂ emission reduction potential, thereby improving the potential of net CO₂ reduction by about 20% compared to BLGCC and 140% compared to Scenario II. Both Scenarios II and III with the integrated SA process can significantly reduce emissions of other pollutants due to the larger bio-based power generation replacing fossil-based fuel. Although, Scenario I has a smaller potential to reduce the net CO₂ than the BLGCC, it still could potentially lessen the total emissions of other pollutants with the produced DME substituting the use of diesel fuel. The net emissions of pollutants emissions for all scenarios of the BIK network are negative, indicating that the pollutions will be reduced in the global scale.

3.3. Comparison with the integrated biorefinery-Soda pulping network

The Soda pulping process has been previously considered as the receptor of the biorefinery-integrated network (Mongkhonsiri et al., 2020). The performance criteria of the BIK (Scenario I, II, III) and the BIS (Scenario IS, IIS, IIIS) networks are reported in Table 3. As can be seen from these results, the biorefinery concept is applicable to both types of pulping technology with comparable enhancement of the economic performance.

^a Negative value means the consumption of CO₂ in the process

More biomass utilization in BIK leads to more reduction of CO₂ and pollutants because it provides bio-based production and energy by replacing the fossil-based products. A reduction of 30% in the net CO₂ emission is observed in Scenario II compared to Scenario IIS and 4% observed in Scenario III compared to Scenario IIS. Regarding integrated CO₂ utilization, Scenario III and IIS can reduce the net CO₂ and other pollutants together with a drop in profit. However, Scenario IIS shows higher profit than Scenario III because of higher DME production. In Scenario III, the higher sulfur content in the syngas is due to Na₂S (used as Kraft-pulping chemical), which causes a lower flow rate of the pure CO₂ stream captured for CO₂ utilization, but the amount of DME is less than in Scenario IIS despite more CO₂ emission. Although scenarios with integrated CCU in BIK and BIS shows profit drop, it could point to more benefit if a carbon tax is considered.

4. Conclusion

The biorefinery-integrated networks with pulping processes have been studied and compared with conventional stand-alone pulping processes. They point to more sustainable alternatives and enhance the biorefinery concept. Extension of the biorefinery concept has been successfully achieved through integration with the Kraft-pulping process. The integrated biorefinery-Kraft pulping process shows great potential for transformation of the conventional pulping process into a more sustainable biorefinery system with higher profitability, less fossil fuel dependence and less environmental impacts. Based on the results of this work, the biorefinery-integrated Kraft-pulping network has been found to be superior to the biorefinery-integrated Soda-pulping network in terms of economic and environmental impact considerations due to larger environmentally friendly activities. As extension of this work, it is suggested that energy and water integration be considered to further optimize and gain benefit in economics and

Abstract

PEM is a mature technology to produce hydrogen using fluctuated renewable energy, but still utilization of oxygen from PEM has potential to integrate with reforming process. In this study, we proposed biogas autothermal reforming integrated with PEM and oxygen liquefaction system, to achieve continuous production of green hydrogen. The optimization is conducted to evaluate specific energy consumption. Conclusively, the proposed system produces green hydrogen of nominal 5596.7kmol/h in PEM section and constant 964.6kmol/h in ATR section based on fluctuated energy source.

Keywords: reforming, continuous operation, liquid oxygen storage, electrolysis, performance analysis

1. Main Text

Hydrogen is a promising energy source which has three times more heat than that of gasoline. Both electrolysis and reforming technologies could be considered as representative routes for hydrogen production. Integrating with renewable energy sources like wind, solar energy and biomaterial can make hydrogen close to complete clean fuel, the so-called “green hydrogen”.

In electrolysis, three different types of technology are studied for integrating with Renewable energy sources: alkaline electrolysis (AEL), polymer electrolyte membranes (PEM), and solid oxide electrolysis (SOEC). Of the technologies, PEM has fastest cold start time of seconds, and dynamic adjustment of operation load is possible. It has fast degradation and cost - ineffective as drawback, still it can be directly operated based on fluctuated renewable energy source, and most studies have been focused on operating PEM with renewable energy source. Clarke et al. (2010) proposed stand-alone electrolyser system consisted of PEM, hydrogen storage tank and renewable energy generator. In Barbir et al. (2005) study, grid independent and grid assisted PEM operation is compared conclusion revealed that PEM can be directly coupled with fluctuated energy source. However, in terms of economic feasibility, hydrogen production with PEM have potential to be integrated with other hydrogen production technologies as oxygen supplier.

Autothermal reforming (ATR), which is consisted of partial oxidation and steam reforming (SMR), requires oxygen supplier for hydrogen production, still its thermoneutral reaction is advantage compared with SMR required additional heat supply. In Timo et al. (2017), ATR combined with SMR has 27.7% more exergetic

efficiency than that of the SMR. Main source of inefficiency is at furnace of SMR which supplies heat and emits flue gas.

In this study, we proposed biogas ATR plant integrated with PEM and liquid oxygen storage plant (ATR-PEMLO) to produce hydrogen. ATR section in the proposed system is required to be operate steadily because of high operating temperature and pressure. To accomplish continuous oxygen supply from PEM to ATR, liquid oxygen production process in the proposed system acts as buffer from fluctuated renewable energy sources.

2. Process description

ATR-PEMLO system is comprised of three processes: (i) PEM stack operated by direct renewable energy source, (ii) cryogenic oxygen liquefaction system and liquid oxygen storage tank, (iii) ATR operated with biogas and oxygen continuously supplied from section (ii). Cold energy recovery in section (ii) and (iii) is accomplished by multi-stream heat exchanger (MSHE). Matlab R2017b is used to simulated PEM stack with governing equation of water electrolysis, and Aspen HYSYS V9.0 is used to simulate proposed system. Table 1 lists operating assumptions for the proposed system referred from Meng et al. (2008) for PEM, Sciacovelli et al. (2017) for cryogenic oxygen liquefaction system and conventional reforming operating range.

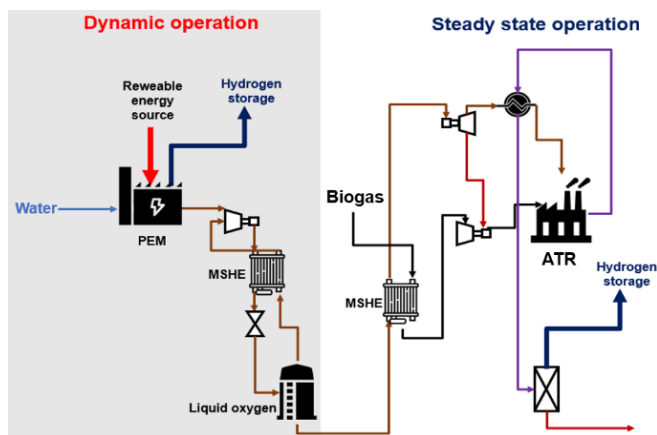

Figure 1. Schematic diagram of ATR-PEMLO system

Table 1. Operating assumption of ATR-PEMLO system

PEM current density	6000 A/ m ²
Thickness of the electrolyte membrane	50μm
PEM operating condition	80°C, 1bar
Compressor isentropic efficiency	85%
Turbine isentropic efficiency	85%
Cryogenic turbine isentropic efficiency	70%
Minimum temperature approach in MSHE	5°C

Minimum temperature approach in heat exchanger (HEX)	10°C
Liquid oxygen storage pressure range	1 to 18bar
Pressure range of reforming operation	7 to 10bar
Temperature range of feed in reformer	100 to 500°C
Carbon to oxygen (C/O) ratio range	1 to 3
Steam to carbon (S/C) ratio range	1 to 3

2.1. PEM modeling

During the water electrolysis operation, required power and heat can be determined by electro-chemical model.

$$E_{PEM} = JV \quad (1)$$

$$V = V_o + \eta_{act,a} + \eta_{act,c} + \eta_{ohm} \quad (2)$$

where V_o is the reversible potential determined by Nernst equation; η_{act} , η_{ohm} are activation overpotential of electrode, and ohmic overpotential of electrolyte, respectively.

In constant current density, activation overpotential can be calculated from Butler – Volmer equation expressed as;

$$\eta_{act,i} = \frac{RT}{F} \left(\frac{J}{2J_{o,i}} \right) = \frac{RT}{F} \ln \left[\frac{J}{2J_{o,i}} + \sqrt{\left(\frac{J}{2J_{o,i}} \right)^2 + 1} \right], \quad i = a, c \quad (3)$$

$$J_{o,i} = J_i^{ref} \exp \exp \left(- \frac{E_{act,i}}{RT} \right), \quad i = a, c \quad (4)$$

where J is current density; $J_{o,i}$ is exchange current density; J_i^{ref} is the pre-exponential factor; $E_{act,i}$ is the activation energy.

Heat supplied to PEM is calculated as;

$$Q_{PEM} = \frac{J}{2F} [T\Delta S - 2F(\eta_{act,a} + \eta_{act,c} + \eta_{ohm})] \quad (5)$$

Where ΔS is entropy increment of water electrolysis, and second term represents heat generation by irreversibility.

2.2. Cryogenic oxygen liquefaction process

Oxygen produced from PEM is sent to liquefaction section to store it as a liquid form. Heat recovery in two-stage compressor is conducted by pumped water with two HEXs. Thus, it enhances energy efficiency and heated water utilizes as feed in ATR section. After compressing, modified claud process is involved to liquify oxygen by renewable energy as electricity form. Two cryogenic turbines during MSHE produce cold energy

and remained cold energy is recycled to MSHE for complete liquefaction. Stored oxygen is continuously supplied to ATR section.

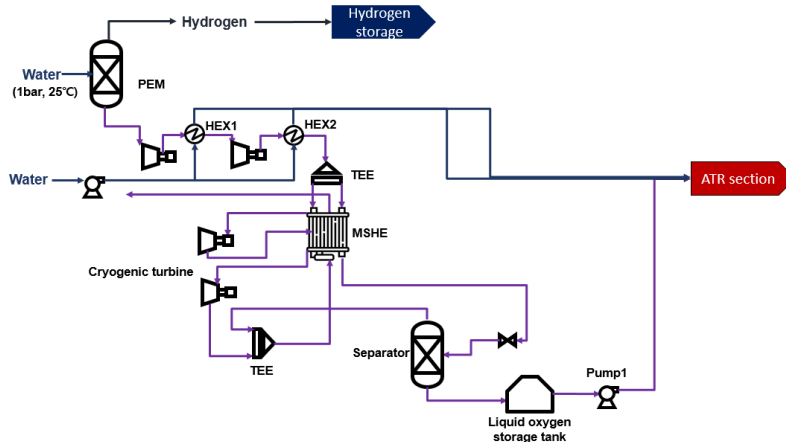

Figure 2. Cryogenic oxygen liquefaction process.

2.3. Biogas ATR process

ATR section is operated by cold energy stored in oxygen liquefaction section. High pressure liquid oxygen is vaporized by heat exchange with biogas and enters two-stage direct expand (DE) to meet operating condition of ATR. After reforming, high temperature product stream is decreased under 350°C for forward WGS reaction. This also means that thermal exergy of product stream can effectively heat turbine inlet temperature of DE process. Both cold energy utilization to biogas and DE process enables the system as complete standalone process. After purification, produced hydrogen is sent to storage facility with hydrogen from PEM section.

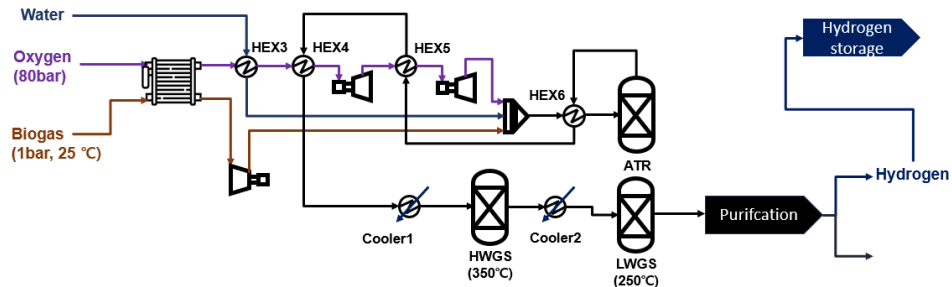

Figure 3. Biogas ATR process

3. Optimization of the proposed ATR-PEMLO system

To enhance energy efficiency of proposed system, the objective function is defined as specific power consumption with design variables as following equation.

$$\frac{P_{total}}{m_{H_2, total}} = \frac{P_{PEM} + P_{compressor} - P_{turbine}}{m_{H_2, PEM} + m_{H_2, ATR}} \quad (6)$$

where $X = (\gamma_{comp}, \chi_{oxygen}, T_{cryo1}, T_{cryo2}, T_{LO_2}, P_{storage}, \frac{C}{O}, \frac{S}{C}, P_{ATR}, T_{ATR})$

In the above variable set, γ_{comp} is compression ratio, and χ_{oxygen} is stream split ratio in liquefaction section, respectively; T_{cryo1} , T_{cryo2} are inlet temperature of first and second cryogenic turbine, and T_{LO_2} and $P_{storage}$ is storage temperature and pressure of liquid oxygen.; $\frac{C}{O}$ is carbon to oxygen ratio, $\frac{S}{C}$ is steam to carbon ratio, and feed stream composition is determined by these variables; P_{ATR} and T_{ATR} are operating pressure and temperature of ATR.

Subsequently, constraints determined by operating range in Table 1 as follows:

(1) The minimum temperature approach value of all MSHE should be higher than 5.0°C.
 $\Delta T_{min, MSHE} > 5.0^\circ\text{C}$

(7)

(2) The minimum temperature approach value of all HEX should be higher than 10.0°C.
 $\Delta T_{min, HEX} > 5.0^\circ\text{C}$

(8)

(3) The vapor fraction of the oxygen stream after MSHE should be lower than 1.
 $f_{vap, O_2} < 1.0$

(9)

(4) Because of safe operating range of oxygen storage tank and ATR, the temperature and pressure of corresponding unit should be placed in a specific range. Furthermore, S/C and C/O is also restricted in this study. Table 1 illustrated the constraints.

4. Result and discussion

For the optimization, `fmincon` in matlab which finds constrained minimum of function with constraints and interior-point algorithm is used to determine optimized variables. To evaluate objective function and constraints, HYSYS and matlab is linked during optimization procedure. Table 2 indicates the optimization results. In liquefaction section, 341.7kmol/h of liquid oxygen is stored with cold energy by consumption of renewable energy of 183.9kJ/mol. As a result of integration, ATR section is operated as standalone system because of power generation from DE process and utilization of cold energy from stored liquid oxygen.

Table 2. Optimization results for ATR-PEMLO system

Specific energy consumption for liquid oxygen	183.9kJ/mol
Liquid oxygen storage pressure and temperature	1000kPa, -153.6°C
Liquid oxygen production rate	341.7kmol/h
Hydrogen production in PEM	5596.7kmol/h
Specific energy consumption for ATR section	-1.8kJ/mol
C/O ratio	1.51

S/C ratio	2.53
Operating pressure and temperature	788kPa, 961°C
Hydrogen production in ATR	964.6kmol/h

5. Conclusions

A novel concept of continuous oxygen feed and cold energy using renewable energy, ATR-PEMLO system, is proposed in this study. To enhance the performance of hydrogen production, the independent variables in the entire system are optimized. As a result, ATR -PEMLO system shows 182.1kJ/mol specific energy consumption which is substantially low value compare to existing hydrogen production plant. Furthermore, the proposed system has advantage because direct coupling with renewable energy source is available without requirement of other facility to maintain energy source. By use of the proposed system, oxygen as byproduct of PEM can be effectively utilized as reforming agent. In conclusion, this study would contribute to efficient green hydrogen production from fluctuated renewable energy sources without additional energy input.

Abstract

In recent years, electricity demand has been increasing, according to the International Energy Agency, the energy sector is the biggest producer of greenhouse gas emissions (CO₂), having terrible environmental consequences. Various alternatives have been sought to reduce CO₂ emissions, highlighting the implementation of CO₂ capture and storage plants. In this work, it is shown an environmental and energetic analysis of a CO₂ capture plant coupled to a power plant. The analysis considered two different operating cases with different fuels in the power plant each case: biogas, coal, non-associated gas, and associated gas. The first one considers a constant fuel feed flow in the power plant. The second one, considers a constant energy demand. The results indicate that, for the first case, the fuel with the lowest environmental impact was the non-associated gas with 2.14 kEcopoints and 1083 MJ per kg of CO₂ recovered. For a constant energy demand, the fuel with the lowest environmental impact was the biogas with 0.57 kEcopoints and 193 MJ per kg of CO₂ recovered. For the systems here considered, those processes working with associated and non-associated gases remain the most efficient in terms of net energy produced.

Keywords: CO₂ Capture plant, biogas, coal, non-associated gas, associated gas.

1. Introduction

CO₂ is produced by diverse processes including the combustion of fossil fuels to produce electricity. According to the International Energy Agency, the 62% of the energy produced globally is obtained from burning fossil fuels, of which 27% comes from burning coal and 35% from burning natural gases such as: biogas, non-associated gas, and associated gas (IEA, 2019). In this way, electricity production is considered an unsustainable process according to the green chemistry principles and circular economy. However, current policies in both developed and developing countries still consider fossil fuel-based energies as the main source of energy. Several solutions have been sought to reduce CO₂ emissions, focusing on the implementation of CO₂ Capture and Storage plants (CCS) with post-combustion technology as the best alternative due to its high efficiency and easy implementation to existing power plants. During the capture, there are some technical aspects related to the process design and operation, for example, ensure enough

CO₂ capture, low energy requirements, low operating cost and low environmental load. Equally, the solvent selection for the CO₂ absorption, as well the required solvent gas ratio plays an important role on the process design. Pointing alkanolamines as a good solvent due to its high effectiveness, CO₂ capture also depends on the fuel used for electricity generation, because the flue gas composition greatly varies (Nagy, T. et al., 2013). Due to the growth of sustainability, green chemistry, and circular economy on the field of design and optimization processes, there is a clear need to analyze traditional processes. Even more the fossil fuel-based energies processes, focusing on the case of CO₂ capture plant coupled to power plant which it has been not reported yet. In this way, the intuitive benefit of CO₂ capture and reuse is apparently not so clear, and an analysis needs to be done in a critical and systematized manner.

In the present work, the environmental and energetic impact of coupling a CO₂ capture plant to power plant was analyzed according to an environmental perspective. Evaluating not only the possibility of reducing CO₂ emissions, but also turning electricity production in a sustainable process in accordance with the principles of green chemistry. It is important to highlight the environmental challenges involved to couple a CO₂ capture plant to a power plant. So, there are no work in the literature addressing the implementation of a CO₂ capture plant to a power plant from the perspective evaluated in this work. For the analysis made in this work, the use of four different fuels in the power plant was considered. Two operating scenarios were considered; in the first, the same fuel feed flow for all the plants and in the second, the same energy demand was specified. The design and simulation of the process plants were developed using the ASPEN Plus simulator, while the LCA was carried out with SimaPro software.

2. Study Cases and Methodology

In this work, two different scenarios of power generation plants coupled to a post-combustion CO₂ capture process are presented to analyze the environmental impact. The first case presents a constant fuel feed flow of 1 000 kmol/h and the second one presents a constant energy demand of 145 MW, each case was analyzed with the most used fossil fuels for power plants: biogas, coal, non-associated gas (NAG) and associated gas (AG). In both cases, for the simulation of the power plant coupled to a CO₂ capture plant the ASPEN PLUS process simulator is used (see Figure 1).

Figure 1. Representation of a thermoelectric power plant and the CO₂ capture plant in post-combustion using chemical absorption with monoethanolamine

For the power plant, the Peng-Robinson method is used to model the thermodynamic properties involved (Hasan, M. F. et al., 2012). For modeling the combustion chamber, it was considered the Gibbs free energy minimization by using a RGibbs block reactor. As operation specification it was considered a molar ratio of air to the fuel of 30: 1 with excess air ensuring complete combustion of each fuel and a pressure of 8 atm (Luyben,

2013). In first case the fuel feed flow it assigned to 1000kmol/h and for the second case the fuel feed flow was adjusted to achieve an energy production of 145 MW. For the simulation of the power plant the composition of the feed fuels was established as shown in Table 1.

Table 1. Flue composition in molar fraction

	CH ₄	C ₂ H ₆	C ₃ H ₈	i-C ₄ H ₁₀	N ₂	CO ₂
NAG	0.98	9E-3	1E-3	4E-4	4E-3	3E-3
AG	0.93	0.026	0.017	0.01	0.017	-
Biogas	0.8	-	-	-	0.015	0.185
	C	H	O	N	S	
Coal	0.51	0.41	0.066	7E-3	4E-3	

The flue gases obtained in the combustion were used as the feed flow to the absorption tower in the CO₂ capture plant. It was considered a chemical absorption using as solvent an aqueous solution of monoethanolamine (MEA) 30 % weight (Nagy, T., 2013). For modeling the absorption and regenerator columns it was considered the MESH equations by using a RadFrac equilibrium stage block. The reactions involved in the CO₂ capture involve the dissociation of the components involved in the absorption reaction, it is necessary to use a regenerator column to achieve high CO₂ recovery. For the regenerator column, the distillate flow and the reflux ratio were manipulated to achieve the biggest amount of CO₂ obtained in the combustion and thus reduce CO₂ emissions. For this reason, all the cases analyzed were standardized to a purity of 99 mol% CO₂ and a recovery of at least 95% of the CO₂ produced during the combustion. As a first step of the methodology applied, an optimization technique is employed to obtain the best design conditions for each case proposed in this work, then a LCA was made to the optimal design obtained in each case to analyze the environmental impact.

2.1. Optimization Methodology

For the optimization process, it was employed the stochastic optimization method of Differential Evolution with Tabu List (DETL) having as objective function the minimization of the energy requirement in the reboiler duty. The minimization of this objective was subject to the required recoveries and purities as is shown in Eq. 1.

$$\text{Min}(Q) = f(N_{TA}, N_{TR}, N_{FA}, N_{FR}, R_A, R_R, F_A, F_R, D_A, D_R) \quad (1)$$

Subject to:

$$\begin{aligned} \vec{y}_m &\geq \vec{x}_m \\ \vec{z}_m &\geq \vec{w}_m \end{aligned}$$

Where N_T are total number of column stages, N_R is the feed stage in column, R is the reflux ratio, F is the distillate/bottoms flux, and D is the column diameter. Where A and R represent the variables corresponding to the absorber and regenerator, respectively. Even though conventionally the diameter is calculated according to sizing equations, the main reason to consider the diameter as a decision variable lays on the fact of promoting a well hydraulic behavior. Eventually, the calculated diameter provokes flooding effects on the simulations which further may slightly influence the concentration profiles and the total mass balance. The multi-objective minimization considered 10 continuous and discrete variables. The optimization problem is subject to restrictions, the first restriction established is to achieve high CO₂ recovery, for this purpose \vec{y}_m represents the vector of CO₂ gases flow recovered in kg/h at the regenerator column, while \vec{x}_m represents 95 % of the flue gases fed to the capture section. The second restriction states that the

optimization problem is limited to ensuring CO₂ with a purity of 99 % molar, so \overline{z}_m represents the CO₂ purity in molar fraction at the exit of the regenerator column and \overline{w}_m represents a purity of 99 % molar fraction. The DETL method have shown being robust to optimize intensified separation systems. Srinivas & Rangaiah, (2013) showed that the use of some concepts of the metaheuristic tabu could improve the performance of differential evolution algorithm. The DETL algorithm is summarized in four steps: 1)Initialization, 2)Mutation, 3)Crossover and 4)Selection as is shown in Figure 2. The implementation of this optimization was made using a hybrid platform where the DETL method was coded in Microsoft Excel (ME). Initially, the method proposes a vector which is sent to Aspen Plus by means of dynamic data exchange (DDE). In there the separation process was rigorously simulated. For the optimization of process routes analyzed in this study, the following parameters for DETL method were used: 200 individuals, 500 generations, a tabu list of 50% of total individuals, a tabu radius of 0.0000025, 0.80 and 0.6 for crossover and mutation fractions, respectively.

2.2. Life Cycle Assessment

Once the optimal designs for each case were obtained it was applied a Life Cycle Assessment (LCA) to evaluate the environmental impact. According to ISO 14040, LCA has 4 phases: goal and scope definition, inventory analysis, impact assessment and interpretation. In the first one, the products to be studied shall be clearly defined in terms of the function that the product performs. The second, inventory analysis, involves data collection and calculation procedures to quantify the consumption of energy, raw material, air emissions, water discharges and solid wastes. The next phase is impact assessment, where the results of the inventory analysis are added up into environmental impacts using common equivalent units; for example, burning a fuel in a given process can be associated with effects on the impact category of global warming, which are measured by kilograms of CO₂ equivalent. The fourth phase of an LCA is interpretation, where the results obtained should be analyzed to establish understandable recommendations and decision arguments.

3. Results

In this section are presented the results of the two study cases. As mentioned earlier, the composition of the flue gases strongly depends on the type of fuel used during the combustion.

Table 2. Flue gas composition in molar fraction

	Case 1 – Fuel feed flow 1 000 kmol/h				Case 2 – Energy Demand 145 MW			
	Biogas	Coal	NAG	AG	Biogas	Coal	NAG	AG
N₂	0.767	0.786	0.767	0.766	0.749	0.781	0.765	0.766
O₂	0.168	0.189	0.144	0.139	0.135	0.162	0.139	0.139
CO₂	0.029	0.024	0.030	0.034	0.052	0.053	0.033	0.034
H₂O	0.035	0.002	0.059	0.062	0.064	0.004	0.064	0.062

Table 2 shows how the composition of the flue gases changes according to the fuel used during combustion. It is possible to observe that the CO₂ concentration increases in case two, where a specific energy demand must be achieved. This behavior can be explained as to achieve energy demand it is necessary to make an adjustment in the fuel flow. In case 1 the lower CO₂ concentration is obtained when coal is burned while the highest is obtained when Natural gases are burned. For case 2 is the opposite, the lower CO₂

concentration is obtained when natural gases are burned while the highest is obtained when coal is burned. These variations will have a direct influence on the capture effectiveness, energy requirements, amount of solvent as well as the CO₂ recovery (Nagy, T., 2013). Table 3 shows how CO₂ variations affect directly on operation conditions as the optimum ratios of solvent to flue gas (L/G), solvent to CO₂ recovered (L/CO₂ REC), reboiler duty to CO₂ recovered (QR/CO₂ REC), Net Energy per CO₂ recovered (E_{PP}/CO₂ REC) and environmental impact per CO₂ recovered (EI/CO₂ REC). In Case 1, it is needed more solvent to recover CO₂ in the capture process when CO₂ is obtained from coal, moreover when CO₂ is obtained from natural gasses the solvent to CO₂ recovery decreases. This behavior is consistent with the predicted from Table 2, as coal is the fuel with the lowest amount of CO₂ in case 1 will require more solvent during the capture and natural gasses will require less amount of solvent for CO₂ recovery. This trend changes in case 2, as coal and biogas are burned flue gases have a higher CO₂ concentration. This will require less solvent for CO₂ recovery. Moreover, reboiler duty in the regenerator column highly depends on the L/G ratio. In case 1 it is also coal the fuel that needs a higher energy requirement for the capture and natural gasses the fuels that require less energy. These results changed in Case 2, as the CO₂ concentration from burning coal increases, effectiveness also increase. The solvent and energy requirement involved in the capture decreases. For the net energy of the process per CO₂ recovered, in both cases the higher energy yield is when associated and non-associated gases are burned. Due to it is not an autonomous process, energy demand could be reduced, integrating heat from the combustion with the energy requirements of the regeneration column.

Table 3. Optimal operation conditions for both scenarios

	Case 1 – Fuel feed flow 1 000 kmol/h				Case 2 – Energy Demand 145 MW			
	Biogas	Coal	NAG	AG	Biogas	Coal	NAG	AG
L/G [kg/kg]	0.58	0.94	0.68	0.71	1.02	0.598	0.67	0.705
L/CO ₂ REC [kg/kg]	13.93	27.68	15.50	13.77	13.52	7.812	13.84	13.773
QR/CO ₂ REC [GJ/t CO ₂]	3.09	5.30	3.65	3.02	3.69	2.950	3.21	3.017
E _{PP} /CO ₂ REC [MJ/kg]	285	279	1083	990	193	311	1035	988
EI/CO ₂ REC [Ecopoint/kg]	4.11	354.2	4.25	9.14	0.22	2.34	4.45	4.96

The LCA analysis was conducted to evaluate the environmental impact during the generation of electricity, as well as the energetic and environmental implications of coupling a CO₂ capture process. As is shown in Figure 3, for case 1, the fuel with the lowest environmental impact is the non-associated gas with 2.14 kEcopoints. This can be explained as in this scenario, the non-associated gas is the fuel with the highest CO₂ concentration, improving capture efficiency. Also, is the one that requires less solvent and less energy for capture. These factors have a direct impact on environmental analysis. Iso, it is possible to see from Table 3 that the non-associated gas and the biogas are the fuels that have the lower environmental impact per kilogram of CO₂ recovered. For the case 2, the fuel with the lowest environmental impact is the biogas, with a score of 0.57 kEcopoints. In this case even though coal has better CO₂ capture, it is observed from the environmental analysis which is the fuel with the worst environmental indicators.

a) Best results for case 1, b) Best results for case 2

4. Conclusions

The implementation of the CO₂ capture process in power plants has been considered the most mature technology to reduce flue gas emissions associated to electricity production. Although capture plants help to reduce the environmental footprint of CO₂. However, before implementation it is necessary to make an analysis of the environmental implications that arise from the implementation, use of solvents and energy consumption. From the results obtained it can be concluded that the type of fuel and feed flow for power generation is a high weight variable during the capture process, impacting directly on solvent and energy requirements. As CO₂ concentration increases; CO₂ recovery and capture efficiency increases, so less solvent and energy requirements will be required during the capture process. Despite of the efforts in this field related to the efficiency of the capture process, it is essential to analyze the process considering not only the CO₂ capture as a strategy to reduce the negative effects of the power plant, but also by identifying new environmental effects due to the implementation of such capture process.

Abstract

Renewables can be used to supply the energy required for flexible CO₂ capture from fossil-fueled power plants, which in turn can act as an indirect energy storage to counter the intermittency of renewable energy. To that end, we propose a simultaneous design and operation scheme for the integration of renewables with dynamically varied flexible CO₂ capture connected to a fossil power plant. We develop a mixed integer linear program (MILP) to determine investment decisions for the integrated system in face of its high capital cost and the spatio-temporal variability of renewables. We also formulate a two-stage solution strategy to solve the resulting large-scale model by decoupling the design and time-dependent operational decisions. This framework is demonstrated through a nationwide case-study on coal power plants across the US.

Keywords: Clean Energy, Renewable Integration, Simultaneous Design and Operation.

1. Main Text

There is a significant push to adopt carbon-neutral energy sources to fulfill rising global energy demands. Although renewable energy is an inherently emission-free energy source, its intermittency and non-dispatchability pose several challenges in integration with electricity grids. To maintain grid reliability, cost-intensive infrastructure modifications are required including the installation of large-scale energy storage and increased cycling operations of fossil power plants. On the other hand, CO₂ capture and storage (CCS) can potentially reduce emissions from fossil power plants (Hasan et al., 2012); however, the high energy requirement for CO₂ capture, which can be 25–40% of the power plant output, restricts its widespread use. Renewables and CCS are different pathways for clean energy, and their limitations are traditionally addressed independently of each other leading to conservative integration costs and limited operational flexibility (Mac Dowell and Shah, 2014).

In this work, we propose that the synergy between the two technologies can be leveraged to counter their individual challenges. To this end, we evaluate the potential of a power generation system that integrates a coal power plant, a solar PV, a wind farm and a post-combustion CO₂ capture unit (Figure 1). The system delivers electricity to the grid using either fossil fuels, renewables, or a combination of both. The exhaust flue gas from the coal unit is directed to the capture system for CO₂ separation using a solvent-based absorption process. Steam is required to regenerate the solvent and can be extracted from

the steam turbines of the coal plant or using wind/solar generated power through an electric boiler. The capture system is flexible in a sense that it can dynamically vary the schedule and the steam demands for energy-intensive solvent regeneration, which is enabled via solvent storage (Zantye et al., 2019).

Such localized integration of renewables and CO₂ capture with existing coal plants presents several advantages as compared to the traditional grid-level integration. Firstly, renewable integration is facilitated without the need for costly grid modifications or the installation of additional transmission capacities. Secondly, time-varying flexible CCS operation using storage of the CO₂-rich solvent from absorption and the regenerated solvent from desorption improves the flexibility of the power plant without frequent cycling and steep ramping rates. CCS can utilize the excess renewable energy during off-peak demand periods, thereby keeping the power plant online for longer durations. Similarly, the capture operation can be turned down during peak load periods to increase the energy delivered to the grid. Thus, along with reducing the CO₂ emissions, flexible CCS operation acts as a form of energy storage to accommodate renewables.

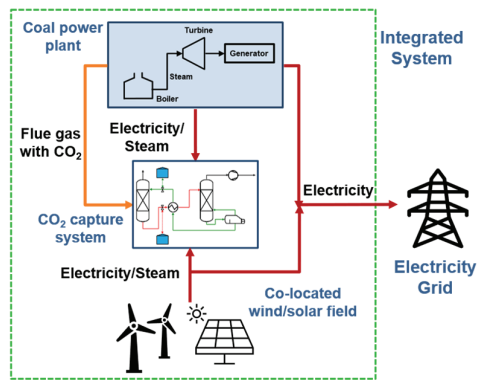

Figure 1: A schematic of the integrated system.

The concept of renewable-assisted CO₂ capture in fossil energy plants is relatively unexplored with the majority of the works in literature focusing primarily on the feasibility of the integration (Mokhtar et al., 2012). To meet the energy requirement of CO₂ capture using renewable energy, a medium to large-scale renewable farm is required. However, the high investment cost of renewables and its intermittency impacts the economic viability of the integration. To incorporate these trade-offs in optimal decision making, we describe a mathematical programming-based optimization model along with a computationally efficient methodology to solve the large-scale problem in Section 2. Lastly, we present a nationwide case-study and the potential for renewable-assisted CO₂ capture from coal power plants in the US in Section 3.

2. Model Formulation and Solution Strategy

The problem statement is as follows: for given time-varying electricity price, solar radiation intensity and wind speed profiles, determine the optimal design and operational schedules to integrate a CO₂ capture system with the coal-fired power plant and/or invest in a co-located renewable energy farm while maximizing the net present value (NPV) based on the projected costs and earnings from the overall system. The overall model (M0) is a large-scale mixed integer linear program (MILP) and has the general form as shown in Figure 2. On expansion of the general formulation M0, the design decisions x include: (i) the retrofit of the coal power plant with CO₂ capture given by the binary variable b^{ret} , (ii) the installed capacities of the co-located renewable field, denoted by

sz_{ren} , and (iii) the electric boiler capacity, designated as sz_b . The temporal variabilities in electricity price, wind speed and solar radiation are represented through deterministic scenarios, where $\omega \in \Omega = \{1, 2, \dots, NS\}$ denotes a scenario, and Ω is the set of all scenarios with hourly resolution. The objective function consists of two components: $f_d(\mathbf{x})$ representing the negative of the total investment cost which depends on design decisions \mathbf{x} alone, as shown in Eq. (2), and $f_o(\mathbf{y}_\omega, \mathbf{k}_\omega)$ representing the scenario-dependent operational revenue which depends on operational decisions \mathbf{y}_ω . Furthermore, $\mathbf{g}^{(d)}\mathbf{x}$ and $\mathbf{h}^{(d)}\mathbf{x}$ are the inequality and equality constraints on system design, while $\mathbf{g}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{k}_\omega)$, $\mathbf{h}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{k}_\omega)$ and $\mathbf{s}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{y}_{\omega+1})$ are operational constraints.

The objective function of net present value, denoted by Eq. (1), is expressed as the difference between the system's net yearly earnings PF^{net} discounted for the time value of money and the current investment cost CC^{tot} . The NPV is determined assuming each year to be identical by using the time series data for solar radiation, wind speed and electricity price. This data is based on NREL studies where 30 years of data is condensed to a single representative or "typical" year for each location and is widely used for energy systems analyses. Cycling conditions on solvent storage are imposed to ensure that each year is identical. The discount rate r^{disc} and the project lifetime t^{lf} are considered to be 10% and 25 years respectively.

The first term in the total investment cost expression of Eq. (2) denotes the capital cost of the renewable technologies, the second term represents the cost of the electric boiler and the final term denotes the cost of the CO₂ capture system. The projected annual profit denoted by Eq. (3) is determined as the difference between the cumulative operational revenue and cost over all scenarios in a year. This corresponds to the second term of the objective function in the general formulation M0. The operational revenue given by Eq. (4) includes the system's earnings from long-term bilateral contracts with power distributors, participation in the spot electricity market and through the sale of the captured CO₂ to enhanced oil recovery (EOR) fields. The cost denoted in Eq. (5) comprises the operating costs of the coal power plant, tax on CO₂ emissions, cost of storing the captured CO₂ and transporting to end-use sites and finally, the ramping cost of the coal plant.

$$NPV = -CC^{tot} + PF^{net} \left(\frac{1}{r^{disc}} - \frac{1}{r^{disc}(1+r^{disc})^{t^{lf}}} \right) \quad (1)$$

$$CC^{tot} = \sum_{m \in ren} CO_m sz_m + CO_b sz_b + \left(CO^{capt} p_{cl}^{max} \frac{E_{cl}}{E_{cl}^{ref}} + N^{tank} CO^{tank} sz^{tank} \right) b^{ret} \quad (2)$$

$$PF^{net} = (1 - r^{tax}) \sum_{\omega \in \Omega} t_\omega (Rev_\omega - Cost_\omega) = \sum_{\omega \in \Omega} p_\omega f_o(\mathbf{y}_\omega, \mathbf{k}_\omega) \quad (3)$$

$$Rev_\omega = p^l \pi^l + (P_{g,\omega}^{in} - p^l) \pi_\omega^s + M_\omega^{capt} \pi^{eor} \quad \forall \omega \in \Omega \quad (4)$$

$$Cost_\omega = P_{cl,\omega}^{out} C_{cl}^{gen} + M^{em} C^{em} + M_\omega^{capt} C^{ts} + \frac{RC_{cl,\omega}}{t_\omega} \quad \forall \omega \in \Omega \quad (5)$$

The design constraints $\mathbf{g}^{(d)}\mathbf{x}, \mathbf{h}^{(d)}\mathbf{x}$ in the general formulation translate to capacity constraints for the renewable technologies. The operational constraints $\mathbf{g}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{k}_\omega)$ and $\mathbf{h}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{k}_\omega)$ include the overall energy balance, capacity and ramping constraints for the coal power plant and energy balance for the CO₂ capture system. The constraint

$\mathbf{s}^{(o)}(\mathbf{x}, \mathbf{y}_\omega, \mathbf{y}_{\omega+1})$ is a time-coupling constraint, which results from the mass balance for solvent storage, and further complicates the formulation.

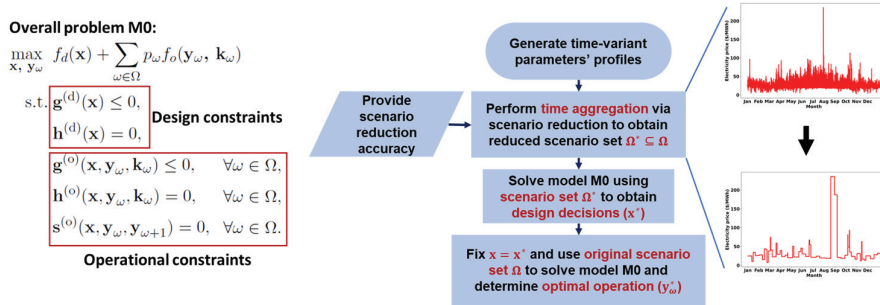

Figure 2: The general MILP formulation, and the proposed solution strategy.

The model M0, when used for large number of time points or scenarios, requires significant computation time to solve to determine the optimal long-term designs and short-term time-varying operating decisions. Therefore, we use a two-stage solution strategy as sketched in Figure 2. Specifically, the parameter profiles are first temporally aggregated using the SCENRED package (Dupacová et al., 2000) in GAMS environment. An example of such time aggregation is shown in Figure 2, where a yearly price profile with hourly resolution (8760 scenarios) is reduced to 53 scenarios while retaining a specified reduction accuracy of 94%. The reduced scenarios with reassigned frequencies are used to first solve the overall problem to obtain the optimal design decisions \mathbf{x} . The design decisions are then fixed and the problem is then solved using the original, unreduced scenario set to determine the optimal operational policy \mathbf{y}_ω . Although this strategy does not guarantee global optimality of the design decisions, it is effective in obtaining near-global solutions with a significant reduction in solution time (Arora et al., 2019).

3. Integration Case Study

The framework is demonstrated by a nationwide case-study across the US, through which we seek to identify coal power plants where it would be beneficial to invest in the integrated system to reduce CO₂ emissions. Data for 309 power plants with operational coal-based units shows a wide variation of capacities between 50 to 6000 MW, with 56% of the plants with capacities below 1000 MW. The CO₂ emission intensities of the standalone coal power plants vary between 0.5-2 ton MWh⁻¹, with the nationwide average being 1.11 ton MWh⁻¹. A full year of time-series data for wind speed and solar irradiation is obtained from NREL's NSRDB database.

Considering projected renewable energy prices of 300 \$ kW⁻¹ and a high carbon emission tax of 80 \$ ton⁻¹, the optimization results indicate that investment in a solar-assisted CO₂ capture system is beneficial for nearly one-third of the power plants across the US. Figure 4 shows the variation of the optimal co-located solar farm size. We observe a strong positive correlation between the co-located solar farm selection and the solar energy

availability represented by the capacity factor. Furthermore, the optimal PV farm size increases linearly with the power plant nameplate capacity, as can be seen from Figure 3a with the nationwide average size being 25.8% of the coal plant capacity. Figure 3b shows that the optimal capture system size is influenced by both the power plant nameplate capacity and its base-case emission intensity. The variation of the optimal levelized cost of electricity (LCOE) of the integrated system is displayed in Figure 4.

Figure 3: Optimal integrated (a) PV farm sizes, (b) CO₂ capture system capital costs.

We observe that the optimal LCOE is less than 40 \$ MWh⁻¹ or the cost of a new natural gas combined cycle (NGCC) plant, with higher LCOE reduction obtained for plants with solar integration. Furthermore, the reduction in CO₂ emission intensity obtained ranges between 87.5-91%. This indicates that it is economically profitable for the coal plant operators to invest in the integrated system as compared to replacing the plant with a natural gas unit to reduce emissions.

Figure 5a shows the distribution of solar output for a representative day in summer based on the full model optimization results. To evaluate the value of the CO₂ capture system in reducing renewable intermittency, we calculate the equivalent battery size required if the excess solar energy used in CO₂ capture is instead stored in a battery. Considering the high efficiency Li-ion battery type with a 2025 predicted total project cost of 362 \$ kW⁻¹, we observe the required battery capital cost to be linearly correlated with the co-located PV farm size as given in Figure 5b. Furthermore, the average battery capital cost to handle solar intermittency is found to be 4.4 times the solar PV farm size. The CO₂ capture system thereby avoids large investment while addressing renewable intermittency and directly reducing the CO₂ emissions of the coal power plant.

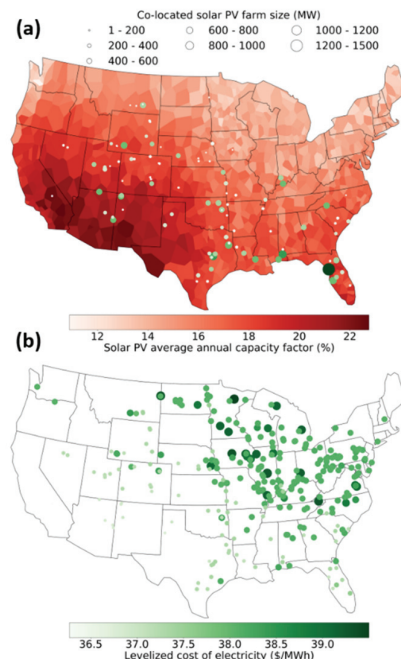

Figure 4: Nationwide integrated system design: (a) Selected co-located solar PV farms with optimal sizes, (b) Optimized LCOE of selected coal plants.

Figure 4: Nationwide integrated system design: (a) Selected co-located solar PV farms with optimal sizes, (b) Optimized LCOE of selected coal plants.

Figure 5: Equivalent battery size required to store excess solar energy. (a) Excess solar energy charged to battery, (b) Required battery size and capital cost for nationwide case.

4. Conclusions

A two-stage optimization framework using scenario-based time-aggregation was used to simultaneously determine the optimal design and operation decisions for clean energy. We found that the localized integration of renewables and CO₂ capture with coal power plants could compensate the CO₂ capture energy requirement as well as handle renewable energy variability. The results indicate that for a carbon tax above 80 \$ ton⁻¹ and renewable price below 300 \$ kW⁻¹, investment in a solar-assisted CO₂ capture is profitable for one-third of coal plants in the US. The resulting LCOE is lower than that of a new NGCC plant with 87.5-91% emission reduction. Thus, the integration can prove to be profitable despite the large capital investment. Furthermore, the CO₂ capture acts as an energy storage and avoids a battery investment of 4.4 times the capital cost of solar field to counter its intermittency.

Abstract

The current linear “take-make-waste” extractive models that have powered the tremendous growth of the last centuries, lead to the depletion of natural resources and environmental degradation. Circular Economy (CE) aims to address these impacts by building supply chains that are restorative, regenerative, and environmentally benign, through re-utilizing products and materials, using renewable energy sources, and closing any open loops. Process Systems Engineering (PSE) could play a critical role in this transition, providing the necessary analytical tools for a quantitative evaluation, and exploring alternative pathways for social and economic advancement. As such, we present here a novel framework for the modeling and optimization of CE food supply chains, along with a representative case study for the supply chain of coffee. First, the alternative pathways for the production of the desired product and the utilization of wastes are identified. Then, a Resource-Task-Network (RTN) representation that captures all these pathways is constructed. Since this analysis must be conducted holistically, a mixed-integer linear programming model that captures the entire supply chain, its objectives, and constraints is formulated, and it is solved to multi-objective optimality.

Keywords: circular economy, coffee supply chain, sustainability assessment, superstructure optimization, resource-task-network.

1. Introduction

Rising populations across the world seek to improve their standards of living, placing huge stresses on natural resources and supply chains. Energy and operational efficiency, improvement in manufacturing processes, and economic growth are vital to fulfill the increasing demand for goods, food and services. However, they still lead to natural resource degradation, substantial waste generation, water contamination, and surging greenhouse gas emissions. Thus, economic expansion shall be combined with sustainable development, ensuring the advancement of our societies while preserving the environment.

This requires a fundamental transformation of our economic model that promotes the “take-make-use-dispose-pollute” concept to a more “sustainable” one. Circular Economy (CE) has emerged as a potential solution for such a transition, with extreme emphasis being put towards improvement in reuse, remake, repair and recycling. CE aims to solve resource, waste, and emission challenges confronting society by creating a production - to - consumption total supply chain that is restorative, regenerative, and environmentally benign (MacArthur, 2015). The goals and key characteristics of CE (Reichel et al., 2016) are summarized as follows: a) minimization of material losses/residuals, b) reduction of input and use of natural resources, c) increase in the share of renewable resources and energy, d) reduction of emission levels, and e) increase the value durability of products.

CE can contribute to all dimensions of sustainable development, although the concept is relatively new, and there is little scientific guidance regarding its successful implementation and its effective evaluation. On top of that, significant challenges for the decision making are created from the interconnections among the diverse supply chain elements, stakeholders, and regulatory environments. Therefore, a holistic systems engineering approach is required to quantitatively navigate and thoroughly address the multi-scale, multi-faceted and interconnected CE supply chains (Avraamidou et al., 2020).

In this work, we present the foundations of a systems engineering framework and quantitative decision-making tool for the analysis and trade-off optimization of interconnected food supply chains. The framework utilizes mixed-integer modeling to establish the interconnections between different stages of the circular food supply chains as well as multi-objective optimization to consider all CE objectives and analyze trade-offs. The supply chain of coffee is used as a working example to illustrate the use and applicability of the proposed framework.

2. Coffee Supply Chain

Coffee is one of the most popular beverages globally with more than 167 million 60-kg bags of coffee being consumed yearly worldwide (ICO, 2020; Lombardini, 2017). The overall life cycle burdens of just one cup of spray dried soluble coffee (Humbert et al., 2009; Murthy and Naidu, 2012) are significant, as it is shown in Figure 1.

With the current linear supply chain model (Figure 2), only a small fraction of these burdens are reused or recycled, even though there are plenty of studies demonstrating sustainable alternatives (Murthy and Naidu, 2012; Chala et al., 2018; Blinová et al., 2017). Hence, as the coffee consumption increases, so does the amount of organic coffee waste and the amount of resources used, aggravating both the waste, water and energy management problems. A solution to this problem would be the transition to a circular supply chain (Figure 3) where renewable energy resources and more efficient processes will be utilized; water consumption will be reduced and wastewater treatment will be applied; waste generation will be minimized, and all wastes will be collected and utilized for the production of alternative products. The material flows ultimately shall be closed, while the energy flows shall be opened.

Figure 1: Life cycle burdens of 1 cup of spray dried soluble coffee

3. CE Systems Engineering Framework

The transition to a CE model while tackling the challenges from the multi-scale, multi-faceted and interconnected CE supply chains require a holistic systems engineering approach (Avraamidou et al., 2020). Therefore, and as an initial step, we have to identify and assess the alternative pathways for the production of the desired product, i.e. wet or dry method for the production of green beans (Chala et al., 2018). Coffee husk is the main pre-roasting by-product from the dry processing method, while coffee pulp, mucilage and parchment are the by-products of the wet processing method. Silver skin is the by-product from roasting the green beans, and spent coffee grounds are the final by-products from either brewing or extraction processes. Similarly, we have to identify and assess the alternative pathways for the waste utilization, i.e. utilization of pulp, husk, or spent coffee

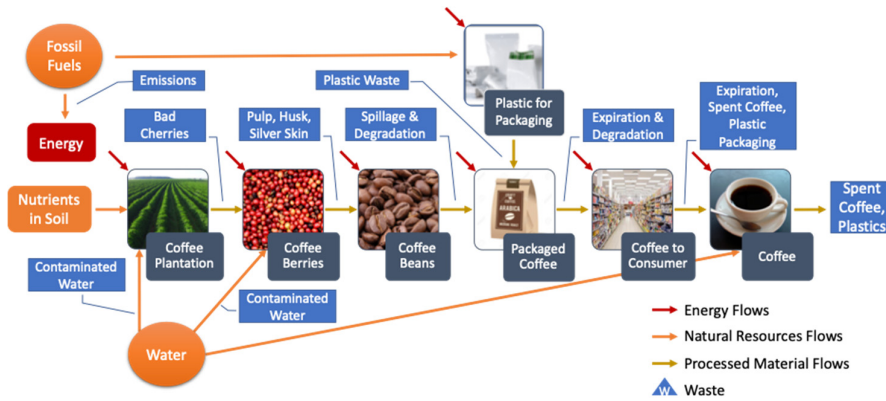

Figure 2: Simplified Linear Supply Chain of Coffee

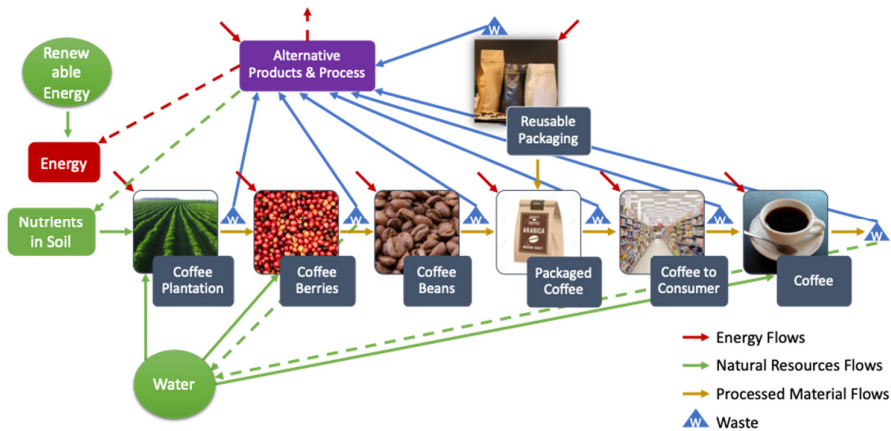

Figure 3: Simplified Circular Supply Chain of Coffee. Dashed lines refer to the energy and resource flows that return to the supply chain.

grounds for energy production (Murthy and Naidu, 2012; Gurram et al., 2016). This analysis, in conjunction with feedback from experimentalists, can help towards the identification of sustainable CE coffee supply chain alternatives. Then, a Resource-Task-Network (RTN) representation that incorporates all the alternative pathways is generated. Figure 4 illustrates such a RTN representation of the supply chain of coffee, capturing the sections in the production as well as in the consumption countries, the conversion coefficients, along with waste utilization alternatives for the production of energy. The next step is the formulation of a mixed-integer linear programming (MILP) model that reflects the entire supply chain, and includes the different objectives and constraints. Hence, binary variables are used for the selection or not of a process e.g. production of green beans through wet or dry method. Continuous variables are also defined for representing the amount of material used as input or output from each process as well as for the amount of material consumed or generated during each process. Moreover, the mass balances and the conversion equations are used to set the constraints.

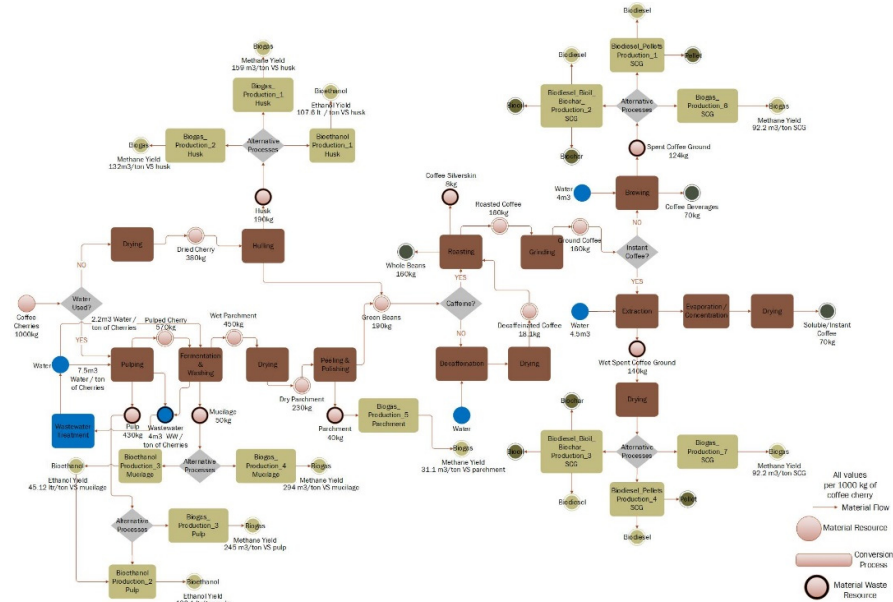

Figure 4: RTN of Coffee Supply Chain (Murthy and Naidu, 2012; Blinová et al., 2017; Ghosh and Venkatachalapathy, 2014; Braham and Bressani, 1979; Gathuo et al., 1991; ICO, 2011)

The final step involves a multi-objective optimization strategy to obtain trade-offs among multiple CE objectives, such as maximizing the energy output while minimizing the coffee cherries consumption, under different demand scenarios (Table 1) for the final products i.e. coffee beverages, instant coffee and whole beans. A variety of single or multi-objective functions can be optimized depending on the scenario under consideration. For the design of a CE supply chain, we select the objective functions by matching them with the CE goals and key characteristics. As such, by looking to increase the share of the renewable resources and energy, we will maximize the energy output of the supply chain, while by looking to reduce the input, we will minimize the coffee cherries consumption. Likewise, by targeting the reduction of natural resources, we will minimize the consumption of water, while the reduction of material losses and emission levels will be achieved through minimizing the waste generation and the CO₂ emissions respectively.

4. Discussion of Results

Utilizing the framework that was described in Section 3, we generate the pareto fronts (Figure 5) for the multi-objective optimization problem of maximizing the total energy output vs minimizing the consumption of coffee cherries, under five different demand scenarios (Table 1). The size of a bubble represents the normalized CO₂ emissions. Each colored line in the Figure 5 represents a different scenario. An upper bound of available cherries has been set at 100,000 tons for all 5 scenarios. Scenarios 1 and 2 require certain demands to be met for all 3 final products. As expected, the higher the consumption of cherries, the higher the energy produced. Once the target demands are

met, the excessive amount of cherries is converted to whole beans, while the excessive amount of coffee by-product is used to produce more energy. This is because even though whole beans can be sold as a final product to the market, they require further processing, either brewing or extraction, so as to yield the end coffee drink. Thus, producing just whole beans is favorable in terms of energy and environmental footprint.

Figure 5: Pareto Analysis

Table 1: Final Coffee Products Demand Scenarios

	Units	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5
Whole Beans	ton	$\geq 2,000$	$\geq 1,000$	= 0	= 0	> 0
Coffee Beverages	ton	$\geq 2,000$	$\geq 1,000$	> 0	= 0	= 0
Instant Coffee	ton	$\geq 2,000$	$\geq 1,000$	= 0	$\geq 6,000$	= 0

The operating profiles of scenario 1 (with higher energy demands) are more to the left on the graph than those of scenario 2, because the extra demand of coffee beverages and instant coffee requires more brewing and extraction, which are both energy intensive processes. The rest of the scenarios represent instances where the demand of only one final product is specified. In particular, scenario 5, even rather unrealistic since it refers exclusively to demand of whole beans and requires further processing to produce the coffee drinks, it demonstrates the best-case scenario in terms of both energy and environmental performance. On the contrary, scenario 4, with only instant coffee as a deliverable, is the worst-case scenario both in terms of energy and environmental efficiency. Just one operating profile is produced since the optimal solution for both

objectives refers merely to the satisfaction of demand. Finally, in scenario 3 that describes the case of demand solely coming from coffee beverages, the operating profiles demonstrate a steeper slope in comparison to the ones from the other scenarios. This is attributed to the different energy and environmental benefits that coffee beverages have versus the other products.

5. Conclusions

The transition towards a circular economy model introduces a plethora of challenges. Here, we presented a CE systems engineering framework for the analysis and trade-off optimization of interconnected food supply chains. We demonstrated the effectiveness of the framework in analyzing different demand scenarios, considering some of the CE objectives simultaneously within a multi-objective optimization approach for a coffee supply chain case study.

6. Acknowledgments

We are grateful to Professor Leonardo Lombardini and his student Amanda Birnbaum for providing us with data for the coffee supply chain. This work is based upon work supported by the National Science Foundation under grant no. 1739977 [INFEWS]. Financial support from Texas A&M Energy Institute is also gratefully acknowledged.

Abstract

Circular Economy (CE) aims to solve resource, waste, and emission challenges confronting society by creating a production-to-consumption total supply chain that is restorative, regenerative, and environmentally benign. A method for evaluating and comparing the “circularity” of different companies or scenarios is vital for effective decision making. A variety of metrics has been developed for measuring different aspects of CE. Despite the availability of metrics, CE has only been measured at the national/regional or product level with the main focus on material flows, while no metric is currently applicable at the company or product supply chain level. This work aims to address this research gap and provide i) a set of indicators and metrics with sector-specific dimensions, ii) a quantitative CE metric, iii) media for data visualization and analysis of CE indicators, and iv) an analytical tool to assess the multi-scale, multi-faceted and interconnected CE supply chains. Companies are able to track their transition towards CE, conduct temporal analysis, and compare their performance against their peers. The applicability and the capabilities of the developed CE methodology is demonstrated through a case study, where the Overall “Circularity” Index and the corresponding “Circularity” sub-indices of an industrial gas company are calculated over a period of 5 years.

Keywords: circular economy, circularity index, sustainability metric.

1. Introduction

The unprecedented economic development and the social advancement that occurred over the last centuries were inextricably linked to a “take-make-waste extractive” industrial model, which inevitably placed huge stresses on the natural resources and led to enormous environmental and socioeconomic impacts. The concept of Circular Economy (CE) has emerged as a potential solution to this challenging issue contributing to all dimensions towards sustainable development, promoting a transition to renewable energy sources, designing out waste and pollution, improving recycling while decoupling growth from the consumption of natural resources, and eventually regenerating natural systems (MacArthur et al., 2013). The effectiveness and the successful implementation of this transition on a global scale though, require systematic assessment of the alternative pathways and scenarios along with the development of holistic metrics to evaluate the different aspects of CE. A plethora of metrics have been proposed in the literature (Parchomenko et al., 2019; Roos Lindgreen et al., 2020; Elia et al., 2017; Cayzer et al., 2017; Saidani et al., 2017) to measure different aspects of CE; however, they capture separately the micro and macro level, without covering the meso level and without providing a holistic approach, whereas they rather focus on material flows (Avraamidou et al., 2020).

2. Circular Economy Metric Development

The proposed CE index takes into account a set of specific indicators and metrics based on the CE goals and key characteristics as well as the business sector that the company operates, and should not be confused with Life Cycle Assessment (LCA) which is an inherent attribute towards analysis, modeling, implementation and/or assessment of the CE (Avraamidou et al., 2020). Hence, five principal categories of indicators have been selected and matched with the goals and key characteristics of CE (Reichel et al., 2016) and are presented in Table 1.

Table 1: Matching of the Principal Categories with CE Goals

#	CE Goals & Key Characteristics		Principal Categories of Indicators
1	Reduction of material losses/residuals: Waste and pollutants minimization through the recovery and recycle of materials and products.	↔	Waste
2	Reduction of input and use of natural resources: The reduction of the stresses posed on natural resources through the efficient use of natural resources.	↔	Water, Procurement
3	Increase in the share of renewable resources and energy: Replacement of non-renewable resources with renewable ones, limiting the use of virgin materials.	↔	Energy
4	Reduction of emission levels: The reduction in direct and indirect emissions / pollutants.	↔	Emissions, Spillages
5	Increase the value durability of products: Extension of product lifetime through the redesign of products and high-quality recycling.	↔	Durability

An extra principal category, named “Organization” is also used for providing general information about a company’s business activity i.e. company’s revenue. As indicator, we define the information that must be measured and evaluated against a CE goal, e.g. total energy consumed within the company, while as metric we define the composite, normalized measure of an indicator against company’s level of business activity and productivity, e.g. total energy consumed within the company over company’s revenue. This is essential to capture the progress and efficacy of a company’s “circularity” year over year, as well as to conduct meaningful comparisons among companies (Herriott, 2016).

One or more indicators have been selected to evaluate the company’s performance against each CE goal or principal category. The indicators have been also matched with the Global Reporting Initiative (GRI) Standards (Global Sustainability Standards Board, 2016), ensuring uniformity in the reported results while providing a reference guide for those who want to use the proposed index. Similarly, one or more metrics have been chosen to standardize the indicators of each category. Different indicators and metrics are determined for each sector of the economy, in an attempt to reflect more accurately the specific characteristics and attributes of each sector. Tables 2 and 3 illustrate the indicators and metrics respectively, that are used for the analysis of the Industrial Sector for all principal categories.

The main sources of data are each company’s annual “Sustainability”, “Environmental-Social-Governance (ESG)” and “Financial” reports. Each company’s data from multiple years are collected and analyzed based on the proposed indicators and metrics, so as to calculate the annual Overall “Circularity” index and the annual “Circularity” index for each principal category (sub-indices) e.g. 2019 Overall “Circularity” Index, 2019

“Circularity” Index for Energy. Therefore, a company’s Overall “Circularity” as well as its “Circularity” versus every CE goal can be tracked on annual basis, and/or against its peers.

Table 2: CE Indicators for the Industrial Sector

Principal Categories	Indicators	GRI Standards Correspondence
Organization	Revenues [million \$]	GRI-201-1
	Products sold within the reporting period [# of products]	GRI-301-3
Waste	Waste generated - Hazardous [weight]	GRI-306-3
	Waste generated - Non-Hazardous [weight]	GRI-306-3
	Waste diverted from disposal [weight]	GRI-306-4
Water	Water withdrawal [volume]	GRI-303-3
	Fresh water discharge (<= 1,000mg/L TDS) [volume]	GRI-303-4
	Other water discharge (>= 1,000mg/L TDS) [volume]	GRI-303-4
	Water recycled or reused [volume]	GRI-303-3 (2016)
Procurement: Production & Packaging	Non-renewable materials used [volume or weight]	GRI-301-1
	Renewable materials used [volume or weight]	GRI-301-1
	Recycled Input material used [volume or weight]	GRI-301-2
	Packaging materials [# of products] reclaimed	GRI-301-3
Energy	Total energy consumed [joules or multiples]	GRI-302-1
	Renewable energy consumed [joules or multiples]	GRI-302-1
GHG Emissions	Direct GHG emissions (Scope 1) [tCO2e]	GRI-305-1
	Energy indirect GHG emissions (Scope 2) [tCO2e]	GRI-305-2
	Total use of products (Scope 3) [metric tons CO2 equivalent (tCO2e)]	GRI-305-3
	Emissions neutralized by carbon offset projects [tCO2e]	GRI-305-5
	Emissions of ozone-depleting substances (ODS) [metric tons of CFC-11 equivalent]	GRI-305-6
	Nitrogen oxides [NOx], sulfur oxides [SOx] & other significant air emissions [kg or multiples]	GRI-305-7
Spillages & Discharges	Volume of operational spills [volume]	GRI-306-3 (2016)
	No. of operational spills [#]	GRI-306-3 (2016)
	Environmental fines [\$]	GRI-307-1
	Notices of violation (NOVs) from spills [#]	-
Durability	Average lifespan of product or packaging [years]	GRI-306-2

Table 3: CE Metrics for the Industrial Sector

Principal Categories	Metric	Upper Bound	Formula Used
Waste	1a % of Hazardous waste over Total waste generated	100%	100%-1a
	1b % of Diverted waste over Total waste generated	100%	1b
Water	2a % of Recycled/reused water over Total water withdrawal	100%	2a
	2b % of Other water discharge over Total water discharge	100%	100%-2b
	2c % of Water consumed over Total water withdrawal	100%	100%-2c
Procurement: Production & Packaging	2d % of Recycled input materials used over Total material used	100%	2d
	2e % of Renewable material used over Total material used	100%	2e
	2f % of Reclaimed packaging materials over Total products sold	100%	2f
Energy	3a % of Renewable energy consumed over Total energy consumed	100%	3a
GHG Emissions	4a Net total emissions over Revenue [tCO2e over million \$]	10,000	1-4a
	4b Emissions of ODS over Revenue [metric tons of CFC-11 eq. over million \$]	0.05	1-4b
	4c NOx, SOx, and other significant air emissions over Revenue [metric tons over million \$]	0.5	1-4c
Spillages & Discharges	4d Notices of Violation (NOVs) from Spills [#]	50	1-4d
Durability	5a Average Lifespan of Product or Packaging [years]	20	5a

The target values of the Overall “Circularity” Index and its sub-indices are always 1 or 100%; thereby the formulas used for each metric have been designed to reflect to that target and are shown in Table 3. For example, metric 1a that captures the percentage of hazardous waste over total waste generated shall be preferably zero, but since our target is 1 then the formula $100\% - 1a$ is used.

The sub-index of each principal category is estimated as the weighted average of its metrics, using equal weights except from the GHG Emissions where the following weights are used: *4a* - 50%, *4b* - 20%, *4c* - 20%, *4d* - 10%. The overall index is calculated as the average of the sub-indices.

3. Case Study: “Circularity” Index of an Industrial Gas Company

The Overall “Circularity” Index along with the sub-indices of an industrial gas company, hereafter referred to as the “firm”, is calculated here. The data used for the subject calculations and analysis are taken from firms’ “Sustainability” reports (2016-2020) covering the period 2015-2019 (Air Products, 2016-2020). First, the annual metrics of each indicator are calculated using the methodology described in the previous section, and are summarized in Table 4.

Table 4: CE Metrics of the firm (2015-2019)

Principal Categories	Waste		Water			Procurement: Production & Packaging			Energy	GHG Emissions			Spillages & Discharges	Durability
	1a	1b	2a	2b	2c	2d	2e	2f	3a	4a	4b	4c	4d	5a
2015	0.604	0.228	0.0	1.0	0.0	0.0	0.85	0.0	0.017	0.678	1.0	0.560	0.84	1.0
2016	0.625	0.265	0.0	1.0	0.178	0.0	0.85	0.0	0.018	0.674	1.0	0.551	0.80	1.0
2017	0.653	0.282	0.0	1.0	0.179	0.0	0.865	0.0	0.069	0.682	1.0	0.578	0.72	1.0
2018	0.538	0.303	0.0	1.0	0.147	0.0	0.85	0.0	0.074	0.700	1.0	0.654	0.66	1.0
2019	0.649	0.201	0.0	1.0	0.186	0.0	0.85	0.0	0.071	0.695	1.0	0.649	0.74	1.0

The firm scores the maximum (100%) with regards to the durability metric (5a) throughout the years, since they supply most of their products in two-way bulk containers, semi-bulk containers or via pipelines with very long-life span. Even for small-scale supplies, they use returnable and reusable transportable pressure vessels with typical life spans of 20+ years. The energy metric (3a) demonstrated the highest improvement over this period (307.6%), but the renewable energy is still a tiny part of firm’s energy portfolio. A noticeable improvement of 15.9% was also shown in NOx/SOx emissions over Revenue (4c) with both parameters being improved over the years. On the contrary, the waste diverted as a percentage of the total waste generated (1b) and the number of violations from spills (4d) have deteriorated over the same period.

4. Results

The following figures illustrate firm’s annual “Circularity” Sub-Indices (Figure 1) and annual Overall “Circularity” Index (Figure 2) from 2015 to 2019, using the weights described in the previous sections. As it is shown, Durability is the best performing sub-index, having reached and maintained the target over the years, while in contrast, and despite the improvement over the years, Energy sub-index is still at the lower end of the scale. Thus, an increase in firm’s renewable energy footprint will boost the firm’s “circularity”. GHG Emissions & Spillages sub-index also improved slightly over the years, having reached 75.1% of the target. Waste and Water & Procurement sub-indices demonstrate a mixed picture, fluctuating year over year, but both have improved, even slightly, over this period. Consequently, firm’s “circularity” was at the highest level in

2017, after two consecutive years of improvement. Then, the index was barely reduced by 1.2% in 2018, mainly due to a 10.1% decrease in the Waste sub-index, before a marginal increase of 0.5% in 2019.

Figure 1: Firm's "Circularity" Sub-Indices (2015-2019)

Figure 2: Firm's Overall "Circularity" Index (2015-2019)

5. Conclusions

A quantitative CE index for assessing a company's "circularity" has been presented, in an effort to accurately measure the various aspects of CE and identify potential areas of improvement towards the transition to a CE economic model. It is noted that various sector-specific indicators and metrics have been established in order to effectively and holistically capture all CE aspects. This enables year-over-year comparisons, benchmarking against peers in the industry, and identification of key areas that require improvement. Also, the aforementioned tool is an integral part of a CE systems engineering framework to quantitatively evaluate different multi-scale supply chain pathways, assess CE tradeoffs, and aid in informed optimal decision making. The capabilities and applicability of the subject methodology was demonstrated through a case study for a firm operating in the industrial sector.

The proposed methodology can act as an organization's internal CE and Sustainability assessment tool and will be incorporated into a web-based index calculator that is accessible online. As soon as the required data are available, the user will be able within 5-minutes to i) measure firm's "circularity", ii) track firm's periodic progress, iii) benchmark against firm's peers, and iv) visualize the analysis online.

Abstract

Environmental regulations have always been an essential component of the natural gas supply chain. This study explores the challenges and opportunities associated with replacing heavy fuel oil used for maritime transportation with relatively cleaner and green fuels. The economic and environmental viability of alternative bunker fuels mainly liquefied natural gas, Ammonia, and hydrogen, is assessed. Additionally, the entire supply chain of natural gas is holistically evaluated by understanding the end-user requirements and exploring the feasibility of further processing the transported fuel (i.e., LNG) into the required form. The examination of supply-demand synergies constitutes the novelty of this study. With the aid of linear programming, the fuel-alternatives mentioned above are assessed on environmental and economic levels. A multi-objective optimisation model is developed considering the emissions constraints imposed on ship operators by regulatory authorities. The mathematical model also includes the possible transported fuel (i.e., LNG, Ammonia, and hydrogen) where both supply and end-user demand are factored into the formulation with the aim of achieving optimal value in an environmentally benign manner. The outcome of this study demonstrates the optimal combinations of transported and consumed fuels. The magnitude of each bunker fuel to be consumed indicates the best fuel to be used while considering both economic and environmental aspects. According to the result obtained from the developed model, Ammonia seems to be the most favourable, followed by HFO, LNG, and hydrogen, respectively. This is mainly attributed to the high cost associated with the consumption of hydrogen fuel. As for the transported fuel, the model suggests that LNG should be the main transported fuel followed by Hydrogen and Ammonia, respectively.

Keywords: LNG Supply Chain; Maritime Transportation; Clean Fuels; Bunker Fuels; Optimisation.

1. Introduction

In many businesses, a tradeoff is usually imposed between economic gain and environmental growth. Usually, a decision-maker will be in a situation that requires them to search for solutions/alternatives to reduce the environmental impact of their business yet still allow them to attain more monetary gains, thereby achieving sustainable development for their business. (Kumar, 2020) The shipping of hydrocarbons constitutes approximately 30% of the world's growing seaborne trade. (United Nations Conference on Trade and Development, 2018) According to LCA studies, the primary source of the

environmental impact during the life cycle of a ship is the operating stage. (Kameyama, Hiraoka, Tauchi) Moreover, traded natural gas is expected to increase from the recorded 25 % in 2017 to 28% of the global gas mix in 2022. (McKinsey. Global, 2018) Hence, efforts to reduce the environmental impact of oil and gas supply chains involve various measures, such as reduced flaring, process optimization, and the utilization of clean fuels, which have been extensively reviewed by many scholars in the fuel utilizing industries such as the aviation sector for over two decades. Today, policymakers and energy analysts worldwide believe that hydrogen has the potential to transform the world's energy outlook. Nevertheless, the complete transition to hydrogen as a replacement for fossil fuels is hindered by technical and economic challenges. (United Nations Environment Program, 2006) Meanwhile, Ammonia has been considered a potential alternative energy storage medium. It is a high-density carbon-free hydrogen carrier, providing a practical and clean alternative to fossil fuels. (Valera-Medina, Xiao, Owen-Jones, David, Bowen, 2018) A broad spectrum of applications in the industry entails the use of operation research to model and solve combinatorial optimization problems. Such applications include planning, scheduling, vehicle routing, and resource allocation. Moreover, to design an effective supply chain network, supply chain managers usually resort to using optimization modeling as it leads to determining the optimal mix of suppliers, production quantity/volume, and location of several facilities within the supply chain. Operation research practitioners normally use a modeling language to formulate and manage their developed mathematical models. Optimization Planning Language (OPL) is a computer-based modeling language concerned with solving optimization problems as it provides algorithms for mathematical integer programming, linear programming, and quadratic programming. (Hillier, Lieberman, 2001) The oil and gas industry have been utilizing the field of operation research as a scientific approach to help support refinery operations management. (Antunes, Gomes, 2008) In this particular study an optimization model was developed to look into the logistical aspect of the LNG supply chain. The objective function of this model is composed of two factors: (a). Economic: encompassing cost associated with bunker fuel in addition to transportation cost and revenue generated from selling the transported fuel. (b). Environmental: encompassing emissions generated by bunker fuel and emissions generated throughout the life cycle of transported fuel. This is to be governed by several restrictions such as the production capacity of the exporter and the emissions limits imposed by regulatory authorities (namely for CO₂, NO_x, and SO_x).

2. Problem Definition

Strategic level decisions are made when a natural resource is discovered and/or when producing a particular product is not as profitable as it used to be due to supply and demand interactions. Hence, exploring the possibility of making any particular modification to the pre-constructed processing facility becomes a necessary investment that enables the producer to maintain their position in the energy market. Also, from an operational perspective, ship operators are obligated to limit the emissions generated from their fleet in order to comply with emissions limits set by environmental regulatory authorities. This study is meant to address both of the aforementioned aspects while using the state of Qatar as a case study. Basically, the main questions to be answered by this study are: 1. Which bunker fuel is more economical and has the least environmental impact? 2. Is it more economically and environmentally viable for the state of Qatar to produce and ship another type of fuel instead of LNG? 3. Is there a possibility to create synergy between the bunker fuel consumed and the produced/transported fuel? Basically, the value of answering the first question lays in the fact that it will aid ship operators in

the fuel selection process while considering environmental and economic aspects. Moreover, on a strategic level, this model can be of use to decision-makers as it helps in evaluating current and future options for their fuel export. The model serves to assess the revenue gained from each Fuel and determine the strategy to be followed in terms of fuel production across a short and long timespan. The second question can be addressed by exploring the possibility of further processing natural gas into other forms of fuels required by customers. Lastly, the third question will examine the possibility of using the transported fuel as a bunker fuel, which will eliminate the need for ship bunkering and will significantly reduce operational costs.

The remaining sections of this paper illustrate the depiction of the problem in a mathematical language, which is then translated into a computer-based modelling language in order to facilitate the process of solving the model.

3. Mathematical Modelling

3.1. Governing Assumptions:

Due to the complex nature of the problem at hand, a set of governing assumptions had to be put in place in order to facilitate its representation by means of a mathematical language. These assumptions are listed below:

Table.1: A list of the pre-defined governing assumptions.

Governing Assumptions	
1.	Supplying LNG from the state of Qatar (i.e.one LNG loading port).
2.	One LNG-discharge port (Receiving terminal).
3.	Empty (return) voyages will not be considered.
4.	No partial unloading of ships. (i.e., a single loading port and a single discharge port per cargo).
5.	It is possible to have recurrent voyages (i.e., several cargos can be delivered to the same customer/ receiving terminal).
6.	All Ships are assumed to have the same capacity of 140,000 M3.
7.	All cargos are delivered using the operator fleet and sold at a fixed rate following a delivered ex-ship cargo transport system. A vessel is assumed to be available at the time of loading. (in this case, we need to assume an infinite fleet size).
8.	Both discharge and receiving ports are available at the time of loading/ unloading as unavailability of port can lead to an increase in total transportation costs as some delay penalties may apply. Cost of idle ships and cost of delays and demurrage costs are neglected.
9.	Fuel consumed for auxiliary system is constant and is neglected.
10.	All ship engines are assumed to be compatible with all of the suggested bunker fuels (i.e.no additional engine retrofitting measures are considered).
11.	Cost of receiving terminal regasification slot and canal charges are disregarded.
12.	All Ships are assumed to travel at a constant speed throughout the entire voyage.

3.2. Input Parameters

Table.2: Produced and Consumed Fuel related data.

Fuel i	Selling Price P_i	Consumed Fuel Cost $C_i^{Consumed}$	Produced Fuel Cost $C_i^{Produced}$	Produced Fuel Demand D_i	Fuel Production Capacity Cap_i	Specific Fuel Consumption $Consumption_i^{Specific Fuel}$	Fuel Density $Density_i$
Unit	\$/kg	\$/kg	\$/kg	Million kg/year	Million kg/year	Kg/km	kg/m ³
1.NH ₃	0.275	0.25	0.225	1980000	1275	200.941	696
2.LNG	0.385	0.35	0.315	700000000	9000	43.855	455

3.H ₂	0.88	0.80	0.72	28400000	450	3.177	71
4.HFO	0.308	0.28	0.252	0	0	124.611	905

Table.3: CO₂, NO_x, and SO_x emissions related data.

Emission Type (j)	GHG Emissions Limit (Per Voyage)			Fuel GHG Emissions Factor $Emissions Factor_i^j$			
	1.NOx	2.SOx	3.CO ₂	1.NOx	2.SOx	3.CO ₂	
Fuel (i)	Unit	Ton	Ton	Ton	Kg/Km	Kg/Km	Kg/Km
1.NH ₃	637	637	637	0.657277006	0	0	
2.LNG	99.4	99.4	99.4	0.061449948	0	135.0188511	
3.H ₂	974.4	974.4	974.4	0.011174968	0	0	
4.HFO	1267	1267	1267	4.1811	1.15×10 ⁻¹¹	5.1×10 ⁻¹⁰	

$Distance_{Qatar\ to\ k}$: Distance between exporting port located in Qatar and port k in km (in this case, only one case is considered Himeiji Terminal located in Japan where the assumed distance is 11693.528 km).

$Speed_{Ship}$: The assumed speed is 27.87 km/hr.

Cap_{Ship} : Capacity of the ship used for transportation in m³ is assumed to be 140,000 m³.

$Power_{Engine}$: Main engine power of the ship is assumed to be 15,006 KW.

3.3. Scenario Development:

The adopted approach of developing this model entails beginning with a very simple model then gradually increasing the level of complexity of the model until it nearly reflects the complexity of the real problem. (Hillier, Lieberman, 2001). Only the first scenario will be portrayed in this paper. This scenario is aimed at maximizing profit were bunker fuel type is independent of transported fuel type excluding receiving terminal regasification slot cost and canal charges.

Decision Variables:

N_i : Number of shipments delivered from fuel (i)

F_i : Amount of fuel (i) consumed per voyage as bunker fuel in kg

Parameters:

P_i : Selling price of fuel (i) in \$/kg

$C_i^{Consumed}$: Bunker fuel cost for fuel (i) in \$/kg

$C_i^{Produced}$: Transported fuel cost for fuel (i) in \$/kg

D_i : Demand for fuel (i) in kg

$Limit_i^j$: Limit of GHG emissions of type (j) for fuel (i) in kg

$Emissions\ Factor_i^j$: Emissions factor for GHG emissions of type (j) for fuel (i)

Cap_i : Production capacity of fuel (i) in m³

$Density_i$: Density of fuel (i) in kg/m³

$Distance_{Qatar\ to\ k}$: Distance between exporting port located in Qatar and port (k) in KM

$Speed_{Ship}$: Ship speed in km/hr

Cap_{Ship} : Capacity of the ship used for transportation in Kg

$Power_{Engine}$: Main engine power of the ship in kW

$Consumption_i^{Specific\ Fuel}$: Specific fuel consumption for Fuel (i)

where,

$i = 1,2,3,4$ refers to Ammonia, LNG, Hydrogen, HFO respectively.

$j = 1,2,3$ refers to NO, SOx, CO₂ respectively.

$k = 1$ refers to Himeiji Terminal located in Japan.

Objective:

$$\text{Max } \sum_{i=1}^4 (P_i \times \text{Cap}_{\text{Ship}} \times N_i \times \text{Density}_i - C_i^{\text{Produced}} \times \text{Cap}_{\text{Ship}} \times N_i \times \text{Density}_i - C_i^{\text{Consumed}} \times F_i) \quad \forall i \in i = 1, \dots, 4 \quad \text{eq.(1)}$$

Subject to:

4. Results

Based on the given input data, the model suggests that the optimal combination of Fuel resulting in the best revenue to be attained is as follows:

Figure.1: Summary of the obtained results.

5. Conclusions

This study presents Mixed Integer Linear Programming (MILP) as a means to provide an objective assessment of multiple potential maritime fuels. Based on the assumed input data, the results imply that Ammonia is the most favourable bunker fuel given the fact that it is an environmentally friendly fuel which is less costly than hydrogen. Moreover, the results also show that the most favourable Fuel to be transported is Hydrogen, given its relatively high selling price. However, any turbulence in the energy market might lead to a change in this result. Moreover, LNG was deemed as the least favourable bunker fuel due to its high CO₂ emissions. The use of CO₂ abatement technology while consuming LNG as bunker fuel can lead to a significantly different result. This can be further studied by conducting a thorough sensitivity analysis. Results and conclusions attained from this model can be of value to decision-makers when good demand and price forecasts are used.

as an input to this model. However, it should be noted that the quality of the forecasts used will dictate the reliability of the results obtained from this model. Future work involves extending the model to include a set of additional scenarios, which will, in turn, develop the complexity of the model.

Abstract

Farming is a complex and responsive business that considers types of soils and crops, topography, climate, etc., while minimising inputs like land and water for an optimal yield. Typically, a farm to be managed involves planting, irrigation, spraying of nutrients and pesticides, manual inspection when looking for signals of harvesting stress or pest infestation, etc. When these activities are unreliable, yields of crops fluctuate so do the enterprise margins. However, to reach higher levels of performance, today's agribusiness moves towards more sustainable and efficient operations within the so-called precision agriculture. From such a scenario, a process system engineering assessment is proposed to evaluate the impacts of industry 4.0 (I4) applications under circular economy (CE) concepts in the agricultural field. Particularly, we highlight drones or unmanned aerial vehicles as a tool in the agroindustry since numerous researchers and industries are designing and testing different principles and technologies that could be applied by replacing manpower with drones in engineering fields. A sensitivity risk analysis compares the I4 adoption and its CE impacts against an outdated agricultural-based production structure for corn production. It has been evaluated using subjective ratings for twenty sub-process components such as irrigation, monitoring, among others. The findings indicate that investments in agricultural drones' capabilities will modify sub-processes under CE principles, resulting in a process system re-engineering in this field. Agricultural drones can increase the economy of the processes coupled with environmentally friendly applications, whereby the impact on the social pillar of the CE is still debatable.

Keywords: Precision agriculture, circular economy, industry 4.0, society 5.0.

1. Introduction

Modern society has gone through three previous industrial revolutions, when workloads were still highly labour-intensive in comparison with the ongoing high-tech societies in the advent of the 4th industrial revolution, so-called industry 4.0. Industries 1.0 and 2.0 have brought human activities from focusing on hunting and agriculture (society 1.0) to industrial societies, when the combined inventions of mechanical movement (industry 1.0

and society 2.0) and electricity (industry 2.0 and society 3.0) replaced manpower from artesian/craft work to a mass production. Less than a century, industry 3.0 upgraded human activities to an extensive information age (society 4.0) of an automated and programmable production. Nowadays, industry 4.0 (I4) is reshaping communities into the so-called society 5.0 (S5) and enabling the creation of a new industrial society (within the augmented information age) where artificial intelligence (AI) will sense, calculate, and actuate to optimally support automated decision-making (Menezes et al., 2019). The I4-S5 combination within the smartness of everything is represented by the increasingly connected societies that are supported by automation of things (AoT) using high-performance computing and communication technologies in a cyber-physical system engine, whereby augmented information and pervasive communication technologies facilitate innovative industrial solutions that will completely reshape production systems.

However, these transformational industrial societies are facing severe social, economic, and environmental challenges to adhere to the concepts of the so-called circular economy (CE) within today's highly constrained sustainable process mandate. Moreover, the pressure in increasing levels of automation has been pushing the termination of a huge number of jobs. Therefore, such industrial societies are still not prepared for the onset of CE's disruptions on well-established processes of work and ways of well-being since there are unbalances between I4 technologies and CE strategies to be solved.

Nevertheless, despite the equilibrium of the I4-S5 to be determined for the next generation of industries and societies, the needs of improvements in the agricultural production go beyond economy. World population growth is expected to reach 9.7 billion in 2050 (UN, 2019) challenges the search for increased production of crops to meet food demands without significant impact on the environment and society. In such direction, as a case of I4 in agriculture, we evaluate the impacts in the CE by using unmanned aerial vehicles (UAV) or *agricultural drones*. These apparatuses have been providing sustainable values in increasing crop production, monitoring plant health, and collecting vital insights of soil and vegetation, since the speed and accuracy these data are gathered using drones allow tangible improvements in farming management (Al-Ansari and Chawla, 2020). From such scenario, we propose a process system engineering assessment in the corn value chain considering a quantitative operational-risk evaluation over the application of drones under CE's principles.

2. Unmanned aerial vehicle impacts in precision agriculture

Today's move in academia and industry towards researching, developing, and deploying novel apparatuses and operations within so-called precision agriculture is modifying farming businesses (Menezes et al., 2020). In this field, UAV or agriculture drones are one of the best I4 solutions to support the next generation of agriculture as it revolutionises operations and reduces its environmental impacts. It becomes enormously popular over the last five years due to its inexpensive rapidly improving technology in terms of battery, motor, and scientific know-how stabilisation. Several UAV models have been developed over the past years varying in purpose, size, weight, and design. Each design has its own benefits and drawbacks based on target application usage. UAV allows the sensing of the physical world by capturing aerial data to generate accurate maps and 3D models of their surroundings. By analysing these maps and 3D models, different industrial applications are enabling faster decisions that increase efficiency, improve safety, and reduce operational costs (Zhai et al., 2020). With such benefits, the UAV

usage rises across industries including engineering, mining, environment, agriculture, surveying, humanitarian, etc.

The modern technologies in agricultural fields facilitate and generate a significant amount of data that can be processed remotely enabling a variety of advanced analytics and solving real world problems for an efficient agribusiness. Collected data is stored and mined using supercomputers providing the foundation for developing data-driven applications and solutions utilising artificial intelligence (AI). The supercomputers store data from multiple sources such as sensors on the ground for soil and plant analysis, mobile sensors or images attached on drones, and satellite imaging. The streams of data are the basis for extracting key operational information about soil condition, crop nutrient uptake, crop yield forecasting, estimation of optimum harvesting times, gas emissions for monitoring, and soil contamination.

Many inputs and outputs to be considered for a precision agriculture in farming depend on the widespread application of I4. Traditional methods for planting, irrigation, inspection, spreading of pesticides, etc., can potentially waste time and resources as well as affect the environment negatively by misusing of soil, water, etc. These conventional farming activities are going to be replaced by autonomous engines to uniformly apply water, nutrients, and pesticides, to precisely plant the seeds within a perfect distance, and so forth. In terms of inspections, besides satellite imaging that became a revolutionary tool several years ago in the agriculture field, UAV offers an effective way to survey small to large scale operations, inspecting fields for signs of stress and pest infections as well as assessing crops management. Then, data analytics can be used to pinpoint areas of crop stress to determine when, where, and how much water, fertiliser, and pesticide is needed to sustainably produce healthy crops with upmost efficiency facilitated by I4 capabilities.

Considering the sustainable evolution of the industry and society, the interplaying of I4 technologies and CE fundamentals is a new frontline faced by engineering communities for their expansion. Although the underlying principles of CE have been included as an additional constraint in academia and industry since the last few decades, today's theories and applications of CE are systematically encapsulated in a wider and a detailed approach. In the broader, the relationships among economic, environmental, and social pillars are being considered from now to design, operate, and control manufacturing systems and supply chains. Furthermore, CE's details on re-do (or do-not) activities, behaviours, beliefs, etc., are transforming traditional industry and society towards their next generation. Hence, both CE concepts (pillars and R's) account for the expansion of the sustainable industry interrelating environmental and social concerns that involve I4 technologies within the society 5.0 (S5). Ritz et al. (2019) demonstrated that training in agricultural technologies in the AgTech program in France increased the profit in agricultural businesses among I4-trained farmers and defend that this should become a new prerequisite for smart farming. In such a context, we cover a case of I4 and CE interconnections in the agriculture industry that accesses operations and risks of I4 adoption and impacts in the CE in a PSE assessment.

3. Agricultural production operations and risks towards circular economy

We consider in the I4-CE operational-risk assessment the upstream or supply side of the system boundary in the agribusiness value chain seen in Figure 1. Although the business

model describes the full range of activities comprising all steps that involve agricultural processes and products from harvesting to retailing, covering inbound logistics, operations, outbound logistics, marketing, sales, and service, we focus on the production step only where I4 applications under CE principles can be assessed and evaluated.

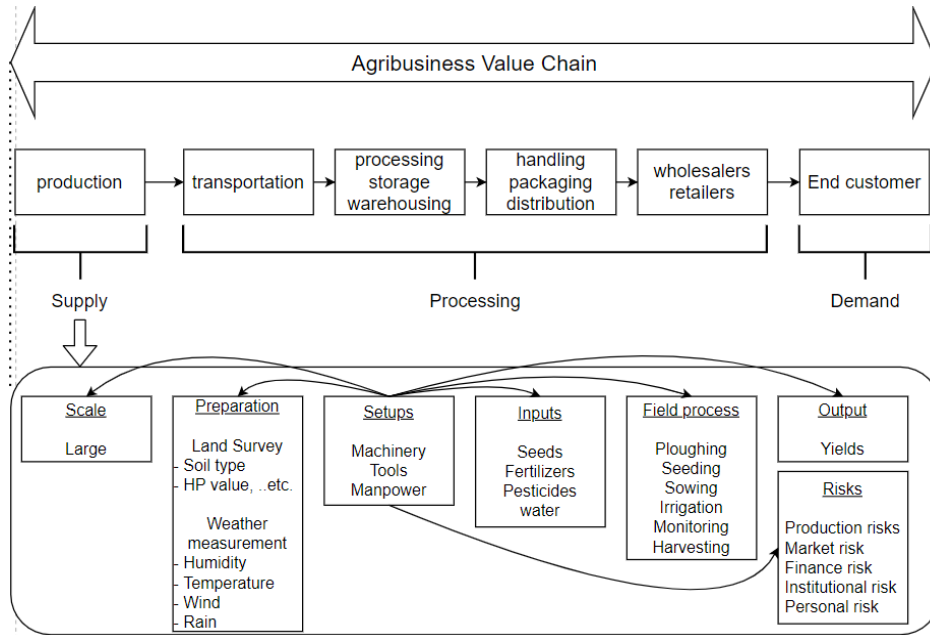

Figure 1: Agribusiness value chain.

According to Manitoba agriculture and resource development (Manitobia, 2020), the total cost for production of crops takes into account many setups, stocks and flows related to operations, fixed costs, and labour expenses. Operating costs are composed by seeds, treatment, fertiliser, herbicide, fungicide, insecticide, fuel, machinery operating, machinery lease, rental, custom, crop insurance, hail insurance, land taxes, drying costs, interest rate, and other minor costs. Fixed costs include land costs, machinery costs, storage costs. Labour cost is the hourly wage of the total number of needed labours per acre.

To evaluate the impact of I4 and CE in manpower towards precision agriculture, the type of I4 technology used in each production step is investigated and categorised into unmanned aerial vehicles (UAV), manned aerial vehicles (MAV), unmanned ground vehicles (UGV), and manned ground vehicles (MGV). In the methodology, every production step, associated with each I4 adoption, is subjectively evaluated using CE's detailed principles using the 9R model (refuse, rethink, reduce, reuse, repair, refurbish, remanufacture, repurpose, recycle, and recover), which is the extended form of the 3R on reduce, reuse, and recycle (Kirchherr et al., 2017). Then, the I4-CE impact in manpower is identified per each step, whereby labour involvement is clearly shown in land preparation, fertilising, irrigation, disease control, monitoring fields, and harvesting. As a labour-intensive industry, our proposition is to evaluate the impacts of I4 applications, under CE concepts, to manpower in agribusiness, in which drones participate as a sustainable and efficient manpower replacement tool in this field.

The operational-risk matrix methodology quantifies the possible risk level of each I4 option under CE pillars (economic, environment, and social) considering I4 adoption into CE impact risk values of 0.1, 0.3, and 0.6 for low, medium, high risks, respectively. According to the department of agriculture in the United States (Dohlman, 2020; Harwood et al., 1999), agricultural risks that impact farming are classified into five categories: production, market, financial, institutional, and personal. Production risks are factors that affect both the quantity and quality of produced commodities. It is driven by the uncertain natural growth processes of crops and livestock. Market risks refer to the uncertain prices that producers must pay for inputs used to grow different types of commodities. Financial risks are related to loans, rising interest rates, restricted credit availability, etc. Institutional risks have a major impact on agribusiness that results from uncertainties surrounding government actions such as price levels, waste disposal rules, taxes, chemical use regulations, etc. Personal risks include job profiles, human health, relationships that affect the agribusiness, illness, accidents, death, divorce, and any social crises that can threaten the agribusiness.

Pooling these risks in the I4-CE adoption-impact, we use the notation n for the number of processes, x denotes the CE pillar (economic, environment, social), P refer to the process itself. In the sensitivity risk analysis, the risk sum (Eq.1), its average (Eq.2) and the risk pooling (Eq.3) are defined to evaluate the environmental, economic, and social effects by adopting I4 in the agriculture processes.

$$\sum_{i=1}^n P_i^x \quad (1), \quad \frac{\sum_{i=1}^n P_i^x}{n} \quad (2), \quad \sum_{i=1}^x \frac{\sum_{i=1}^n P_i^x}{n} \quad (3)$$

4. Results

An integrated I4-CE sensitivity risk analysis against the base model has been evaluated based on subjective ratings for twenty agricultural subprocesses and summarised in Table 1. The summation and averages of risks for each CE principle (Eco, Env, Soc) for all agricultural subprocesses are calculated and then pooled. Results show that UAV risk pool value is the lowest with 0.49, which is close to the theoretical minimum risk pool. MAV score 1.25 and UGV 1.20, both around the theoretical medium risk pool. MGV yield 1.44 in the direction to the theoretical high-risk pool. The theoretical minimum, medium, and maximum risk pool values are 0.3, 0.9, and 1.8, respectively. Some subprocesses are kept unrated (as zero risk) when there is no effect by the adoption of I4.

Table 1: Summary results.

I4	UVA			MAV			UGV			MGV		
CE	Eco	Env	Soc	Eco	Env	Soc	Eco	Env	Soc	Eco	Env	Soc
Risk sum	2.3	1.5	3.1	4.9	7.2	3.4	5.4	6.9	4.5	7.9	8.7	5.6
Average	0.16	0.1	0.2	0.4	0.56	0.3	0.38	0.48	0.3	0.51	0.56	0.4
Risk pool	0.49			1.25			1.20			1.44		

5. Conclusion

The results in Table 1 show that the UAV adoption promotes the most efficient utilisation of resources since the agricultural subprocesses will be re-executed efficiently allowing CE principles to be reached while maximising yields, although the effects on manpower would result in either replacing or reducing of it. More precision predictive and prescriptive analytics facilitated by agricultural drones, with the use of machine learning and artificial intelligence, creates results to be delivered through several channels, including farmers' smartphones, farming servers, etc. Such augmented information enables farmers to make decisions or allows automated controls that manage drones to execute routine tasks such as fertiliser application, herbicide spraying, inspection, and monitoring in upmost efficient way. Drones facilitate fast and cheap inspections (descriptive and diagnostic data) for any potential issues such as lack of nutrients in certain areas of the land assets, indication of disease outbreaks, readiness of the crops to be harvested, etc. Moreover, collected data from drones can be visualised, interpreted to surface trends, and provide insights on the optimum solutions and segmentation of the tasks best carried out by either human labour or autonomous vehicles.

Farmers are inclined to be more receptive to the use of technology which supports to meet sustainable and efficient production pathways without significant perturbation on traditional practices as well as when this is not compromising quality of life, and the environment. Agricultural drones have been considered to bring economic prosperity coupled to environmentally friendly applications, whereby the impact on social equity is still debatable. Although a side effect of the automation wave in precision agriculture is closing jobs on the upstream side (production), it generates standard manpower's personal skills that will be upgraded and evolved in the so-called society 5.0 (S5).

Abstract

Renewable fuels generation and the elimination of fossil-fuel reliance are an important part of sustainable growth. As petrochemicals are a key economic cornerstone of contemporary society, an impetus exists to find potential supply routes so as to maintain scarce resources. In addition, waste utilisation to manufacture value-added products is essential to mitigate emissions of greenhouse gases. Biomass, which is a neutral CO₂ fuel, acts as a possible basis for the generation of energy and fuels. In addition, biomass gasification creates a syngas rich in hydrogen that can be used in the petrochemical industry for the production of value-added materials such as ammonia and methanol. Based on the existing developed biomass-treating infrastructure, incorporating large-scale biomass value-added products into the existing petrochemical generating network can give significant benefits. In addition, there is high possibility to utilise other undesired by-products such as CO₂ which exists within the same infrastructure network. In this research, Aspen Plus model is built based on the oxygen/steam gasification configuration for the production of H₂-rich syngas by different feedstock available in the State of Qatar. The resulting syngas is used with an external combined CO₂ source in the processing of methanol and urea. The results showed that the addition of the external CO₂ source to the biomass gasification system could save around 3% of the emitted stream and increase the production of methanol and urea by around 4% and 10%, respectively. Moreover, the economics of the integrated system are optimised to maximise the utilisation of CO₂ and minimise the capital and operating costs along with net environmental emissions.

Keywords: Biomass Gasification, CO₂ Utilisation, Economic Assessment, Optimisation

1. Introduction

Efficient utilisation of biomass, especially the landfilled waste biomass presents opportunities for significant reductions in global greenhouse gas (GHG) emissions, if used efficiently. Biomass is expected to contribute 120 to 155 exajoule (EJ) of the annual primary energy supply by 2050, which is substantial in comparison to the current total energy supply of 475 EJ (IPCC, 2011). Thermochemical conversion of biomass utilises catalysts and heat to convert solid materials into electric power, chemicals, or fuels. This is in contrast to biochemical biomass processing, that utilises microorganisms and enzymes for the same function. In reality, humanity has employed both thermochemical and biochemical methods for millennia. Interestingly, the prevalence for well over a century of fossil resources thermochemical conversion into energy, chemicals and electricity may be the cause for ignoring the thermochemical processing of biomass

(Zhang and Brown, 2019). Gasification offers variety of advantages as a commercial proven technology with a uniform intermediate product generation and diverse biomass feedstock options. The conversion of carbonaceous feedstock into liquid fuels has a long tradition of gasification. All these processes include the thermal oxidation of biomass to syngas at temperatures up to 1500 °C, producing a gas mixture of carbon monoxide, carbon dioxide, hydrogens, methane and small amounts of light hydrocarbons (National Academies of Sciences and Medicine, 2018). Up to 90 percent of the CO₂ emitted from fossil fuel installations can be permanently deposited with advanced carbon capture and sequestration (CC&S) technologies. Efficient CC&S demonstration and introduction will almost remove GHG emissions and contamination related to coal, boost the atmosphere, health and the economy. Techniques such ocean alkalinity and soil amendment using biochar, bioenergy with carbon capture and storage (CCS) and direct air capture are instrumental to achieve this goal. CCS is considered to have some drawbacks, including information gaps in cost, life-cycle impacts, storage capacity and efficiency between production and usage. However, it remains a valuable method for minimizing CO₂ pollution that is being captured and stored (Parvez et al., 2020). The method of carbon capture and utilisation (CCU) is similar where CO₂ is used instead of storage. As a means of lowering CO₂ emissions and gaining economic benefits at the same time, CCU strategies have recently gained interest. Accordingly, carbon capture utilisation and storage (CCUS) technology is known to be an economically viable means of minimizing GHG emissions before more intensive use is made of renewable energies. By CCUS, CO₂ waste streams become feedstock of marketable product synthesis. The CO₂ can be used as a source of carbon and an oxidant in many chemical reactions, replacing conventional feedstock products in the chemical, pharmaceutical, polymer and automotive industries. The gasification atmosphere of carbon and biomass has been used recently as complete or partial steam substitution. The H₂/CO ratio of generated syngas can be regulated by the CO₂ supply, which is a special feature in the use of CO₂ in the atmosphere. The CCU techniques were studied in the production of multiple value-added materials through fixed network architecture. The technological and economic study revealed a possible revenue of \$0.48 to \$4.35 billion from CO₂ use in the Gas-to-Liquid (GTL) process and a maximum revenue in the methanol processing process for 1.62 to 6 MT/y CO₂ use with a maximum utilisation level (Al-Yaeshi et al., 2020b; Al-Yaeshi et al., 2020a). As for CO₂ used as a gasifying agent in thermochemical conversion of biomass, a number of papers have been published but the knowledge on the basics of use of CO₂ in the thermochemical conversion reaction or the resulting biomass-based syngas is still missing in the processing of useful products. In an attempt to contribute to the reduction of GHG and recycling of biomass waste, this study investigates the integration of CO₂, which is primarily captured and utilised from fossil-based existing production facilities, within the biomass recycling and gasification plant is proposed as sustainable solution for the two problems. This integration can provide an added advantage for the production of chemicals and reducing the associated environmental impacts. In addition, the possible production volumes for fuel and green chemical products can also be improved, and potential beneficial results can thus be accomplished by addition of multiple biomass feedstock and refining the gasification process to yield high-quality syngas under working conditions, feed blending and increased parallel units. In this study, the steam/oxygen gasification of multiple biomass feedstock including food waste, date pits, sludge and manure is considered for the generation of hydrogen-rich syngas that is utilised along with captured CO₂ in the generation of methanol and urea products. The integrated system is then evaluated by means of economic and environmental assessments and sensitivity analysis to allocate the optimal utilisation of CO₂ stream.

2. Model development

Advanced process models are useful to derive accurate energy efficiency and cost-effective assessments of combined biomass gasification and CO₂ utilisation routes. A model of biomass gasification plant should be capable of imitating true plant behaviour, regardless of ability. For simulating a variety of plant implementations, the commercial Aspen Plus platform is appropriate. The base simulation established in this study is focused on a steam/oxygen gasification configuration of various feedstock available in Qatar for the development of H₂-rich product gas used in the production of methanol and urea with captured CO₂ flows. In an earlier work to improve waste to hydrogen generation through the optimisation of gasification processes, the base simulation model using steam and oxygen was established (AlNouss et al., 2020). The base model has then been expanded to explore other gasification mechanisms (AlNouss et al., 2020c), to assess the potential integration between the gasification combined cycle and post-combustion CO₂ removal (Ghiat et al., 2020), to optimise the superstructure representation of application sinks and biomass sources while incorporating energy-water-food nexus approach (AlNouss et al., 2019a; AlNouss et al., 2019b). In this paper, the steam/oxygen gasification model is integrated with downstream application of methanol and urea production while utilising an external CO₂ source to increase the production volume of the end products. Figure 1 illustrates the block flow diagram displaying the various processing steps of the integrated system. Aspen Plus simulation models are developed based on the assumptions of zero-dimensional simulation, neglected formation of tar with char is totally carbon, atmospheric operation with neglected pressure drop, steady-state and isothermal operation and instantaneous pyrolysis and drying. Three property packages, Peng Robinson with Boston-Mathias modifications, RKS-BM and NRTL are used to simulate the nonpolar and real species presented in the model. The multiple biomass feedstock with ultimate and proximate analyses presented in Table 1, is fed to the decomposition unit where they are converted from unconventional to conventional components. The impurities associated with biomass such as Ash and sulphur are separated before the actual gasification take place. The main carbon stream is sent to the gasification unit simulated as Gibbs reactor, where carbon reacts with steam and oxygen, at atmospheric pressure and a temperature of 850 °C, are carried out. Production lines for the processing of urea and methanol are further used with effluent syngas rich of H₂ and an additional CO₂ stream.

Classified as petrochemical plants; urea and methanol are produced in a series of reaction and separation sections yield fertilising, anti-freeze and solvent used materials. Urea production line starts with biomass gasification to yield syngas that is further purified from water and CO₂ before entering the loops of ammonia generation and urea production as illustrated in Figure 1. The urea generation loop assumes a total of 80% CO₂ and ammonia conversion to urea and a recovery of 90% for CO₂ and ammonia (Urea). Whereas, an ammonia separation of 75% and a 7% purging of unreacted recycle H₂ and N₂ stream are assumed in the processing loop of ammonia in general with a 19 percent conversion from N₂, and a 1:3 N₂ to H₂ ratio (Arora et al., 2016; Ammonia, 2. Production processes). The external CO₂ stream is injected in the urea production loop as an addition to the normal CO₂ utilised in the process in the ratio of 0.74:0.57 tonnes of CO₂:ammonia to produce 1 tonne of urea (Al-Yaeshi et al., 2020b).

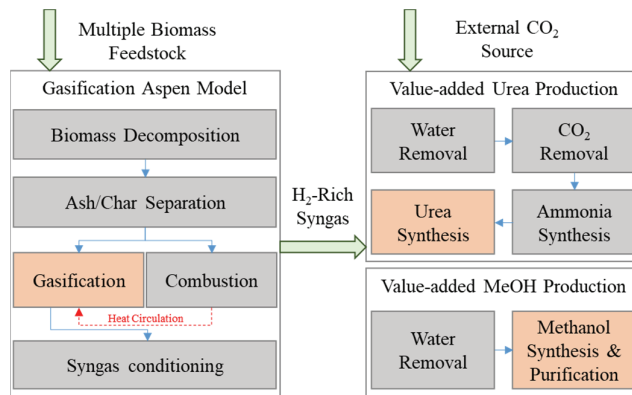

Figure 1: Block flow diagram of the GTL process.

On the other hand, methanol processing steps are simulated with the assumptions of a 9% purge of unreacted recycle gas stream and forward reaction mechanism. It utilises the hydrogen rich gas generated in the biomass gasification unit after removal of CO₂ and Water impurities to achieve the compulsory (CO₂+ CO):(H₂-CO₂) ratio of 2 as illustrated in Figure 1. Before entering the methanol convertor loop, a series of compressors and coolers bring the purified syngas to the required conditions which is then reacts with the external CO₂ injection to yield crude methanol. Further, methanol is purified from water and leftover gases using light ends and heavy ends distillation columns.

Table 1: Proximate and ultimate analyses of biomass feedstock as received basis.

	Date pit	Food Waste	Manure	Sludge
Mass Flowrate (t/y)	7.60x10 ³	7.0x10 ³	5.27x10 ⁵	3.65x10 ⁴
Ultimate analyses (wt %)				
Ash	1.0	6.2	21.4	71.8
S	0.0	0.0	0.5	0.1
Cl	0.0	0.0	1.0	0.0
O	37.9	37.4	31.4	5.7
C	49.8	46.4	37.1	19.1
H	6.8	6.9	5.1	2.3
N	4.5	3.1	3.7	1.1
Proximate analyses (wt %)				
Fixed carbon	17.2	7.7	13.5	19.4
Volatile matter	81.8	86.1	65.0	8.8
Ash	1.0	6.2	21.6	71.8
Moisture	5.0	75.1	27.4	8.3
LHV (dry basis) (MJ/kg)	34.07	19.12	19.40	20.50

To ensure optimal viability and enforcement, it is important to ensure the feasibility of any downstream development route by environmental and economic assessments. The different production lines under review are measured from an environmental and economic perspectives by first quantifying the optimum injection of CO₂ and calculating the net environmental pollution and the expense and income of the investment and operation. The combined economic and environmental research methods are used to analyse and accumulate relevant costs and pollutants of processes (AInouss et al., 2020).

3. Results and discussion

Aiming to quantify the optimal CO₂ utilisation, sensitivity analysis has been conducted by varying the amount of CO₂ injection and observing the trend of methanol and urea production as illustrated in Figure 2. The optimal CO₂ is approximated at 14,800 and 11,992 kg/h for the cases of methanol and urea production, respectively.

Figure 2: Trends of methanol and urea production with the increase in CO₂ injection.

Following the identification of optimal CO₂ injection, the material and energy balances associated with the optimal configurations are evaluated using Aspen Plus software. The results in Table 2 demonstrates higher requirement of steam in the methanol production route compared to the urea production line, necessary to generate the required (CO₂+CO):(H₂-CO₂) ratio along with lower oxygen requirement.

Table 2: Material and energy requirements of the integrated utilisation techniques.

Utilization technique	Urea	Methanol
Circulated Combustion Heat (MW)	104.2	68.4
Biomass Carbon content (kmol/h)	1.45 x 10 ³	1.45 x 10 ³
Air (kmol/h) (95 O ₂ , 1.6 N ₂ , 3.4 Ar)	1.00 x 10 ³	0.80 x 10 ³
Steam (kmol/h)	1.64 x 10 ³	4.00 x 10 ³
N ₂ (kmol/h)	2.37 x 10 ²	3.73 x 10 ²
Syngas (kmol/h)	5.45 x 10 ³	7.94 x 10 ³
H ₂ (kmol/h)	7.97 x 10 ²	1.19 x 10 ³
CO (kmol/h)	2.66 x 10 ²	2.20 x 10 ²
CO ₂ (kmol/h) after CO ₂ removal	0	2.49 x 10 ²
Product Mass Flow (t/y)	1.05 x 10 ⁵	8.61 x 10 ⁴
Production reactor (MW)	-0.17	-19.38

Moreover, the techno-economic and environmental assessment has been conducted to benchmark the addition of CO₂ to the normal production base cases. The results illustrated in Table 3 demonstrate an increase in the operating and capital costs with the addition of CO₂ stream. This is justified given the higher operating capacity of the subsequent units and the additional utility requirement. This increase is accompanied with an increase of 4% and 10% additional methanol and urea production for the optimal CO₂ utilisation case.

Table 3: The economic and environmental results of the integrated utilisation techniques.

Parameter	Methanol Production			Urea Production		
	Without CO ₂	Optimal CO ₂	Higher CO ₂	Normal CO ₂	Optimal CO ₂	Higher CO ₂
Total Capital Cost [\$]	2.50x10 ⁷	2.55x10 ⁷	2.58x10 ⁷	3.20x10 ⁷	3.22x10 ⁷	3.22x10 ⁷
Total Operating Cost [\$/y]	4.42x10 ⁷	4.57x10 ⁷	4.68x10 ⁷	3.40x10 ⁷	3.42x10 ⁷	3.43x10 ⁷
CO ₂ Utilisation [kg/h]	0	14,800	30,000	11,145	27,286	38,729
Methanol Production [kg/h]	13,163	13,634	13,568	10,912	11,992	11,192
Net CO ₂ Emissions [kg/h]	45,849	44,598	44,126	45,255	45,254	45,843
Total Annualised Cost [\$/y]	4.94x10 ⁷	5.09x10 ⁷	5.21x10 ⁷	4.06x10 ⁷	4.08x10 ⁷	4.09x10 ⁷
Revenue [\$/y]	5.65x10 ⁷	5.85x10 ⁷	5.82x10 ⁷	4.78x10 ⁷	5.28x10 ⁷	5.08x10 ⁷
Net Profit per kg Output [\$/kg]	0.062	0.064	0.052	0.076	0.113	0.096

From the optimal CO₂ injection results, it seems inefficient to raise the CO₂ injection by such a large amount for a negligible increase in methanol production. However, the net profit per kg output has increased by 4% and 50% for the methanol and urea production cases at optimal CO₂. In addition, a reduction in the net environmental emissions approximated at 3% for the case methanol production along with the fact that biomass and CO₂ are utilised as waste streams. These changes in the economic and environmental results are inverted at a higher CO₂ injection rates.

4. Conclusions

Based on the existing developed biomass-treating infrastructure, incorporating large-scale biomass value-added products into the existing petrochemical generating network can contribute significant benefits. Furthermore, there is a high scope for utilising the same infrastructure network by-products such as CO₂. In this research, the integrated system of the oxygen/steam gasification configuration and CO₂ utilisation is evaluated for the generation of H₂-rich syngas by different feedstock available in the State of Qatar. The resulting syngas is used with an external combined CO₂ source in the processing of methanol and urea. The results showed that the addition of the external CO₂ source to the biomass gasification system could save around 3% of the emitted stream and increase the production of methanol and urea by around 4% and 10%, respectively. Moreover, the economics of the integrated system are optimised to maximise the utilisation of CO₂ and minimise the capital and operating costs along with net environmental emissions.

Abstract

This contribution represents the synthesis of sustainable EU-27 energy supply networks, taking into account the production of renewable heat, alternative electricity, biofuel (first, second and third generation), hydrogen, food and other bio-products. A multi-period, mixed-integer linear programming (MILP) model is formulated, with the Sustainability Net Present Value (SNPV) as an objective. A gradual energy transition to 100 % renewable production of heat, electricity and fuels over a period of 40 years is examined. Efficient large-scale heat pumps, biomass cogeneration plants (CHP) and geothermal systems are considered for the heat generation. Taking these technologies into account, it is proposed that 58.2 % of renewable heat could be produced by biomass CHP plants, 40.3 % by large-scale heat pumps and a further 1.5 % using geothermal energy. However, storage technologies need to be integrated into the supply network to satisfy peak electricity and heat demand.

Keywords: supply network optimization, renewable energy transition, renewable heating, alternative electricity, biofuels

1. Introduction

To achieve the long-term reduction of greenhouse gas emissions and the goals of Paris Agreement, a major effort is required, as the consumption of renewable energy is still low in some sectors. At the end of 2018, the share of renewable energy in the EU in the transport sector was about 8.3 %, the share of renewable energy in the heating sector 21.1 %, while the share of renewable energy in total energy in electricity generation was 32.2% (Eurostat, 2020). Clearly, there is a large untapped potential, especially in the transport and heating and cooling sectors. Transition from fossil to 100 % renewable energy supply (Hansen et al., 2019; Bogdanov et al., 2021) requires an assessment of the local availability of renewable energy sources (RES), the use of appropriate renewable energy technologies and the system that can adequately integrate RES to meet daily, monthly and yearly demand (Østergaard et al., 2020). Moreover, the integration of storage technologies will play a very important role (Child et al., 2018). Biomass, wind, solar, geothermal and hydro energy are among the key resources in the transition to renewable production of heat, electricity and fuels. However, emphasis should also be placed on energy savings. There is great potential for increasing energy efficiency in the buildings, improving the linkages between electricity and heating systems and encourage the reuse of waste heat to ensure sustainable, secure and competitive energy supply at the EU level (European parliament, 2020).

This work is an extension of the production and supply of food, fuels and electricity (Potrč et al., 2020) to the 100 % production and supply of heat from renewable energy sources by 2060. In heat production, coal and natural gas are gradually being replaced by alternative electricity, using efficient large-scale compression heat pumps, biomass CHP and geothermal energy combined with heat pumps. To the best of the authors' knowledge, no study has so far examined the long-term transition to 100 % renewable production and supply of heat, electricity and fuels at EU level without compromising food production, and taking into account the sustainability objective. The aim of the study is to examine the economic viability, environmental friendliness and social benefits of a 100 % renewable heat supply over the next 40 years in addition to the supply of electricity and fuels from renewable energy sources, and to assess the associated production capability of the EU.

2. Approach to the sustainable synthesis of renewable supply networks

The synthesis of 100 % renewable energy supply networks was based on a four-layer superstructure (Čuček et al., 2010). The first layer contains the potential locations of the resources. The second layer considers the production of electricity and heat from RES, together with electricity storage, pre-treatment facilities (oil extraction, drying, etc...) and storage of the resources that are further used for biofuel production. On the third level biorefineries are considered and on the fourth layer the end users (demand), including logistics within and between the layers. For the production of electricity, wind farms, solar photovoltaics (PV) and geothermal power plants (GT plant) are taken into account, together with biomass cogeneration technologies. Renewable heat can also be produced with large-scale compression heat pumps (HP) using electricity generated from renewable sources, and geothermal systems combined with large absorption heat pumps. In the case of HP, the average practical coefficient of performance (COP) has a value between 3.5 and 4.5 (David et al., 2017), and this assumption has been used in this study. The use of intermittent sources (wind, solar) could be a bottleneck to meet peak electricity demand. Therefore, pumped hydro storage (PHS) systems with 80 % efficiency were integrated into the network to manage the supply at higher demand. Corn grain and wheat are primarily considered as raw materials for food supply, but the surplus can also be used for the production of biofuels, together with wheat straw, corn stover, forest residues, miscanthus, algae and waste cooking oil. Technologies used for the production of gasoline substitute (green gasoline, bioethanol), diesel substitute (FT-diesel, biodiesel), hydrogen and other bioproducts are: i) gasification and syngas fermentation, ii) gasification and catalytic synthesis of biomass, iii) Fischer Tropsch (FT) synthesis, iv) gasification and lignocellulosic hydrogen production, v) dry grind process and vi) production of biodiesel from waste cooking oil (WCO) and algal oil, with methanol or ethanol as catalysts (Martin and Grossmann 2013).

The optimization was performed using multi-period mixed-integer linear programming (MILP) model. It should be noted that non-linear investment terms were linearized with piecewise linear approximation. The model considers yearly, monthly, daily and hourly time periods. In the case of biomass and waste availability, and demand for biofuels and food, monthly periods are taken into account, while wind and solar energy availability, electricity demand, heat demand and electricity storage are modelled on an hourly basis. Yearly time periods are included to assess the gradual, steadily increasing transition to sustainable energy systems. In the present case study, the maximization of the Sustainability Net Present Value (*SNPV*) is used as an objective (Zore et al., 2018), which

is composed of the Environmental NPV (NPV_{Eco}), the Economic NPV ($NPV_{Economic}$) and the Social NPV (NPV_{Social}), as described by Eq. (1).

$$SNPV = NPV_{Economic} + NPV_{Eco} + NPV_{Social} \quad (1)$$

$NPV_{Economic}$ is calculated as the sum of annual net cash flows (the sum of revenues and salvage value reduced by expenditures and investments) over the project lifetime, with each annual net cash flow discounted to the present time. NPV_{Eco} is defined as the difference between eco-benefits and eco-costs, where the burdening and unburdening effects of raw materials, waste, technologies, transport, energy, products and additional land use are determined using the eco-cost coefficients (Delft, 2016). NPV_{Social} is determined as the sum of the social security contributions paid by newly employed workers and employers, and social unburdening effect from the creation of new jobs, reduced by the social costs incurred by the social support provided by the state and the company to the employees. The model includes energy and mass balances, conversion and production constraints, economic, environmental, and social constraints, and constraints on investment, pretreatment, operating, storage, and transportation costs. The restrictions for the model are also the area in each zone for food, biofuel, heat and electricity production, minimum and maximum capacities for facilities and storage, and maximum allowable distances between source sites, production facilities, and demand sites. Best available renewable heating technologies have been selected to be used and their specifications (costs, capacities, lifetime) were taken from (IRENA, 2013). All different kinds of data on the total area of each zone, yields per hectare and the availability of intermittent sources in each zone, conversion factors, costs and prices, demand (Eurostat, 2020), coordinates of each zone, coefficients used to determine the environmental impact, wages, transport losses, etc., were inserted into the optimisation model in a data-independent form, allowing the model to be applied to other large-scale case studies.

3. EU-27 case study

The methodology is applied to the European Union case study, in which the EU is divided into 47 zones. Larger Member States are divided into several zones to take account of differences in the availability of resources within a country. To achieve 100 % renewable energy supply, the following gradual transition is assumed: a) for 2020, the current share of renewable energy in electricity, heat and fuel production in each Member State is optimized, b) by 2040, a minimum of 50 % renewable energy should be achieved in each sector, c) by 2050, 75 % renewable energy should be produced, and d) 100 % renewable energy supply must be achieved in all sectors by 2060. Gradual electrification of the transport sector is assumed, up to 50 % by 2060, leading to increased demand for renewable electricity. The share of nuclear energy in total electricity generation is assumed to gradually decrease from the current 26 % to 15 % by 2060. The multi-period model that synthesizes sustainable renewable energy supply networks is formulated in GAMS modelling interface (version 27.2.0) and consists of 4,619,882 single equations, 146,827,714 single variables, and 25,286 discrete variables. The model is solved in about 10 hours with the Gurobi solver on the HPC server DL580 G9 CTO (4 processors - 32 core, Intel® Xeon® CPU E5-4627 v2 @ 3.30 GHz, 768 GB RAM).

3.1 Results and discussions

The main optimization results are presented in Table 1 and show the dynamics of the use of different technologies from 2020 to 2060, where the demand for renewable energy will increase from the current share to 100 %. The main technologies proposed for heat

generation in the early years are large-scale heat pumps (HP) (73 % of renewable energy demand), that use the surplus electricity from wind turbines and solar photovoltaic systems. The share of heat produced from biomass CHP is increasing over the years; for 2040, when the heat sector must reach 50 % renewable energy, 27.7 % of renewable energy needs will be covered by biomass CHP, while for the 100 % transition, it is proposed to produce 58.2 % of renewable heat using biomass CHP and 40.3 % from HP. In addition, it is proposed that 1.5 % of heat should be generated by geothermal systems using HP to increase the temperature of the heat. Wind farms are the most promising technology for alternative electricity generation, producing 64.1 % of the total renewable electricity demand in 2060. The share of solar PV will increase with the growing demand for renewable electricity, reaching 31.3 % when a complete transition is required. Small parts of the RES electricity demand are covered by biomass CHP and geothermal systems (4.6 %).

Table 1. Main results of the transition towards 100 % renewable energy production by 2060.

Items	Year 2020	Year 2040	Year 2060
Heat (renewable energy target, %)	22.1	50.0	100.0
Large HP (TWh/y)	872 (73.0 %)	1,955 (72.3 %)	2,179 (40.3 %)
Biomass CHP (TWh/y)	323 (27.0 %)	749 (27.7 %)	3,147 (58.2 %)
Geothermal+HP (TWh/y)	/	/	81 (1.5 %)
Electricity (renewable target, %)	34.1	50.0	100.0
Wind farm (TWh/y)	965 (97.3 %)	1,405 (78.7 %)	2,493 (64.1 %)
Solar PV (TWh/y)	10 (1.0 %)	337 (18.9 %)	1,217 (31.3 %)
Biomass CHP (TWh/y)	17 (1.7 %)	43 (2.4 %)	167 (4.3 %)
GT plant (TWh/y)	/	/	12 (0.3 %)
Biofuel (share in transport sector, %)	8.9	30.0	50.0
Bioethanol (kt/y)	8,483 (43.1 %)	25,398 (35.7 %)	49,088 (41.4 %)
Green gasoline (kt/y)	1,358 (6.9 %)	10,173 (14.3 %)	10,173 (8.6 %)
Biodiesel (kt/y)	9,841 (50.0 %)	10,600 (14.9 %)	13,280 (11.2 %)
FT-diesel (kt/y)	/	24,971 (35.1 %)	46,005 (38.8 %)
NPV_{Sustainability} (1.0•10⁶ €)	/	2,979,482	8,378,409
Area used (% of total)	11.10	12.90	24.86

With 50 % electrification of the transport sector expected by 2060, the demand for biofuels is expected to reach half of today's consumption of diesel and gasoline. Biodiesel is proposed as a diesel substitute in the near future, while for the long-term transition, it is proposed to produce FT-diesel in larger quantities. On the other hand, bioethanol is proposed as the most suitable replacement for fossil-based petrol in the coming years. Note that the use of wheat and corn and the associated production of first-generation bioethanol was not selected due to competition with the food supply chain. The results showed that the sustainability NPV increases over the years and amounts to 8,378,409 M€ by 2060, with the environmental and economic pillars making the highest contribution to the overall sustainability. Compared to our previous model, which considers the production of fuel and electricity from RES, the value of SNPV has almost

doubled due to the integration of heat into the renewable energy supply network. It should be noted that the integration of the energy storage system into the network has significantly contributed to this. The results indicate that it is economically advantageous to store excess electricity (most of the surplus electricity is generated at night and at weekends) using pumped hydro storage plants, and feed it back into the grid when demand for electricity and the selling price of the electricity are higher. The area dedicated to the production of food, renewable fuels, electricity and heat will increase over the years. To achieve 100 % renewable energy supply within the EU, almost 25 % of the total area is used, twice as much as is needed to meet 50 % of demand. Figure 1 shows the distribution of renewable heat generation between 2020 and 2060. For the first year (Figure 1a, optimized current demand), mainly large-scale HPs are proposed; in each zone it is proposed that the surplus electricity generated by intermittent sources is used for heat production. In addition, biomass CHP plants are proposed mainly in Finland and to a lesser extent also in Slovakia, Bulgaria, Spain, Estonia and Lithuania, as these zones have higher availability of forest residues compared to other sources.

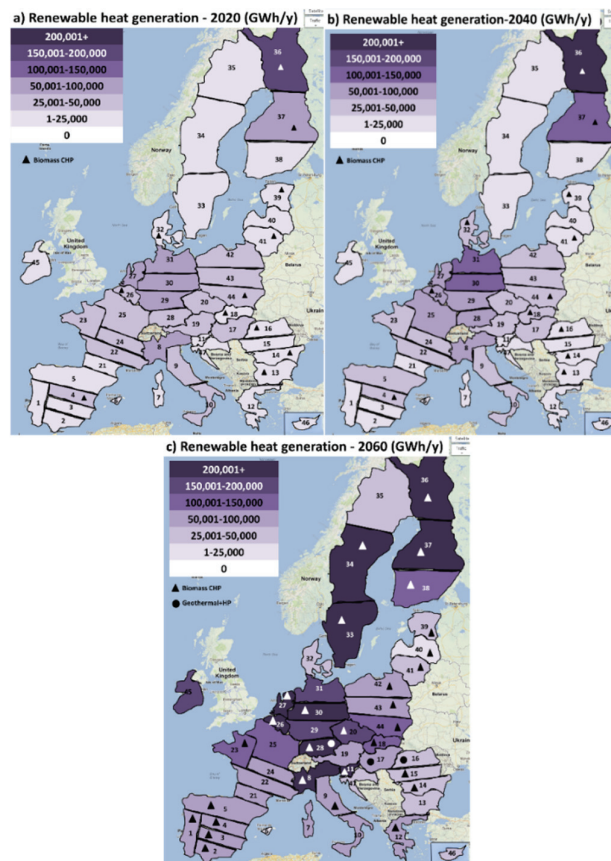

Figure 1. Distribution of renewable heat generation within EU-27 for: a) year 2020, b) year 2040 - 50 % renewable heat target, and c) year 2060 - 100 % renewable heat target.

For the year 2040 (Figure 1b), when renewable heat will have to cover 50 % of heat demand, higher capacities at existing sites are proposed. For the 100 % renewable heat supply (Figure 1c), biomass CHP plants are proposed to be installed additionally in Finland, Slovenia, Portugal, central Spain, France, northern Italy, Czech Republic, Romania, Poland and Germany. Geothermal systems are also suggested in Hungary, Romania and southern Germany. The production of renewable heat using large HP is proposed to be used in all zones in all periods considered.

4. Conclusions

A multi-period MILP model for the synthesis of sustainable renewable energy supply networks has been developed. Efficient renewable energy sources are considered, such as biomass, waste, residues, geothermal energy and intermittent sources (solar and wind energy). The results show under which conditions it would be possible to generate renewable heat in addition to renewable fuels and electricity within the EU in order to reach the zero-carbon emissions target. The most promising solution in the first years are large-scale heat pumps using an excess of alternative electricity, while in the following years biomass CHP plants will be very important for achieving the 100 % transition to renewable heat supply; it is proposed to achieve 58.2 % of renewable heat supply by biomass cogeneration plants and 40.3 % by large compression heat pumps. However, in order to achieve a complete supply of renewable energy in the electricity, heating and cooling and transport sectors, a large part of the area would have to be dedicated (almost 25 % of the total area). As we cannot afford to double the area dedicated to the renewable energy production, the emphasis should be oriented toward increasing energy efficiency, e.g. through cross-sectoral energy integration. The study will be further expanded to include uncertainties in costs, prices, yields, efficiencies, readiness of technologies, and other uncertainty issues to obtain an even more realistic design.

Simultaneous optimization and heat integration of a macroalgae-based biorefinery

Fernando D. Ramos, Andrés I. Casoni, Vanina Estrada, M. Soledad Diaz*

Planta Piloto de Ingeniería Química- PLAPIQUI (UNS-CONICET), Camino la Carrindanga km. 7, Bahía Blanca (8000), Argentina

sdiaz@plapiqui.edu.ar

Abstract

In this work, we address a simultaneous optimization and heat integration of a macroalgae biorefinery based on a previous study. As regards heat integration, it considers minimization of heat exchanging total annual cost, assuming isothermal mixing of the streams and overall heat balance within each stage. The resulting MINLP model has 1236 continuous variables, 339 binary variables and 1338 constraints. Hot and cold utilities were 43 % reduced signifying 53 % of savings. Moreover, it favored the environmental aspects of the process which disregarded though it may be, we consider it crucial.

Keywords: brown macroalgae, heat integration, MINLP.

1. Introduction

Macroalgae or seaweeds are photoautotrophic multicellular organisms grouped according to their photosynthetic pigments in green (Chlorophyta), red (Rhodophyta) and brown (Phaeophyta) algae. The main current applications of macroalgae, with a global market of USD 6 billion per year (FAO, 2018), are human food, hydrocolloids production (alginates, agar and carrageenans), fertilizers, biomass for fuel and wastewater treatment (Casoni et al. 2020).

The need of green processes has led to the study of the suitability of macroalgae as feedstock for sustainable production of fuels, chemicals, and materials within an integrated biorefinery concept (e.g. Ingle et al. 2018, Casoni et al. 2020). With 4867 km of coastline and the appropriate climatic conditions for macroalgae growth, Argentine Patagonia constitutes a key place for the macroalgae-based sustainable industry development.

In this work, we propose a mixed-integer nonlinear programming (MINLP) model for the optimization and heat integration (Nemet et al., 2020) of a macroalgae-based biorefinery based on two Argentinean brown algae (*Macrocystis pyrifera* and *Lessonia* sp.) to produce sustainable production of chemicals, materials, and biofuels. To our best knowledge, this specific kind of biorefineries have not been deeply studied. Therefore, incorporating heat integration aspects, contributes to constitute a useful model to evaluate the viability of brown macroalgae biorefineries.

Process Description

The proposed framework is based on a macroalgae-based biorefinery model developed in an early study (Casoni et al., 2020) which has been extended to handle and address heat

integration aspects. The optimum pathway was the production of isosorbide dinitrate from *M. pyrifera* depicted in Figure 1.

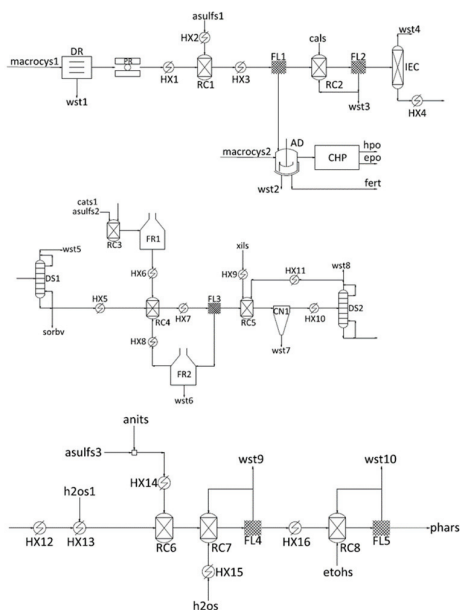

Figure 1. From top to bottom: Section 1, 2 and 3 showing the optimum pathway for the production of isosorbide dinitrate from *M. pyrifera*.

The process begins with drying the macroalgae up to obtain 20 % of moisture in the unit DR, followed by a press unit (PR) for macroalgae milling. Then, the process stream is heated up to 120 °C before feeding it into the reactor RC1 where the biomass is hydrolyzed. Afterward, the resulting stream is cooled down to 25 °C and filtered in FL1 separating the hydrolyzed solid and an aqueous stream containing hydrolyzed sugars. The hydrolyzed solid is fed into an anaerobic digester (AD), which is associated with a CHP unit to produce heat and electric power. Besides, AD produces fertilizers as by-products. The outgoing stream of FL1, constituted by aqueous sugar, is fed into the reactor RC2 where is mixed with calcium carbonate (in a 0.043:1 calcium carbonate-to-acid ratio) to neutralize the remaining acid. After that, the stream is filtered in FL2 to recover the calcium carbonate, which is redirected to RC2. Finally, the process stream is fed into a column containing a polymeric ionic exchange resin (IEC unit) to isolated sorbitol (70 wt.% aqueous solution). From the top of this column, a stream containing other sugars is considered as waste while the bottom one is led to section two: isosorbide production. Sorbitol stream from the first section is preheated up to 150 °C and enters to distillation column (DS1) to obtain pure sorbitol. The resulting stream is fed into the reactor RC4 and is mixed with sulfated zirconium as a catalyst in a 0.02:1 catalyst-to-sorbitol ratio. The sulfated zirconium is obtained in reactor RC3 by mixing zirconium with sulfuric acid (98 wt.%) in a 25:1 zirconium-to-acid ratio. Then this stream is calcinated in the furnace FR1 to obtain the catalyst, which is led to reactor RC4. RC4 outlet stream is cooled down to 120 °C and then is filtered in FL3 to separate the catalyst that is calcinated and

regenerated into FR2 and led back to RC4. The process stream outgoing FL3 unit, which contains isosorbide and other impurities, enters reactor RC5 where xylene is added in a 9.61:1 xylene-to-isosorbide ratio for impurity precipitation which are removed within centrifuge CN1. The outlet stream is heated up to 144 °C and fed into distillation column DS2. The top stream containing gaseous xylene is cooled down to 120 °C and redirected to reactor RC5. The bottom stream that is composed by isosorbide is cooled down to 25 °C and sent to section three as substrate of the final products: Isosorbide dinitrate (ISDN). This final section begins with diluting isosorbide with water in a 3.267:1 isosorbide-to-water ratio and cooling this stream down to 50 °C. Afterward, the main stream enters to reactor RC6 where isosorbide reacts with a mixture of nitric (63 wt.%) and sulfuric acid (98 wt.%) in a 7.315:1 sulfuric acid-to-nitric acid ratio. Acids are added to RC6 considering a 1.36:1 sulfuric acid-to-isosorbide ratio. The RC6 outlet stream is fed into RC7, where water is added to precipitate isosorbide dinitrate. The water is added in a 0.197:1 isosorbide dinitrate-to-water ratio. The resulting stream is filtered to recover isosorbide dinitrate while water is recirculated to RC7. The isosorbide dinitrate stream is heated up to 40 °C and mixed with ethanol in a 1.15:1 ethanol-to-isosorbide dinitrate ratio within the reactor RC8. Once this step is completed, the stream is filtered recirculating ethanol to RC8 and obtaining the final product.

2. Mathematical modeling

Firstly, the process units are modeled using mass and energy balances, equipment design equations, capital cost correlations, integer constraints and a process sustainability metric (RePSIM) is set as the objective function and maximized. Secondly, heat integration and the optimal heat exchanger network is performed using a modified SYNHEAT (Yee & Grossmann, 1990). In this sense, a new optimization problem is solved simultaneously with the heat exchanger network synthesis.

3.1 Mass balances

Non-reactive units mass balances are formulated as follows:

$$\sum_k^K f_{\theta,j}^k = \sum_r^R f_{r,j}^\theta \quad \forall \theta \in \vartheta \quad \forall j \in J \quad (1)$$

where $f_{\theta,j}^k$ is component j mass flowrate from the inlet stream k to unit θ in kg/h and $f_{r,j}^\theta$ represents component j mass flowrate from unit θ to outlet stream r in kg/h.

Reactive units mass balances are formulated as Eq. (2) describes.

$$f_{r,j}^\theta = \sum_k^K f_{\theta,j}^k + \sum_{\substack{h \\ \in J \quad \forall sh \in SH}}^H \xi_{j,sh}^h \cdot C_h \cdot \sum_k^K f_{\theta,sh}^k \quad \forall \theta \in \vartheta' \quad \forall r \in R \quad \forall j \quad (2)$$

where $f_{r,j}^\theta$ is the mass flowrate of component j from reactive unit θ to outlet stream r in kg/h. $f_{\theta,j}^k$ is component j mass flowrate from the inlet stream k to unit θ in kg/h. sh represents the limiting reactant while C_h is the conversion of the limiting reactant for reaction h . $\xi_{j,sh}^h$ denotes the mass coefficient between j and sh in kg/kg, which is positive

for products and negative for reactants. Finally, $f_{\theta,sh}^k$ is the component sh mass flowrate from the inlet stream k to unit θ in kg/h.

3.2 Energy balances

Linear relationships are assumed for energy consumption. In this sense, thermal and electrical energy consumption are calculated as follows:

$$\begin{aligned} \text{Thermal energy consumption: } Q_{\theta} & \\ &= \sum_k^K \sum_j^J f_{\theta,j}^k \cdot h_k - \sum_r^R \sum_j^J f_{r,j}^{\theta} \cdot h_r \end{aligned} \quad (3)$$

$$\forall \theta \in \vartheta \cup \vartheta'$$

where Q_{θ} corresponds to the heat exchanged in unit θ in kJ/h, h_k and h_r correspond to the enthalpies of inlet and outlet streams K and R of unit θ . $f_{\theta,j}^k$ and $f_{r,j}^{\theta}$ are the mass flowrates entering and leaving unit θ in kg/h.

$$\begin{aligned} \text{Electrical energy consumption: } EC_{\theta} &= ECR_{\theta} \cdot \left(\sum_k^K \sum_j^J f_{\theta,j}^k \right) \end{aligned} \quad (4)$$

$$\forall \theta \in \vartheta \cup \vartheta'$$

where EC_{θ} represents electrical energy consumption in kJ/h, ECR_{θ} is the energy consumption ratio per unit of mass flowrate relative to unit θ in kJ/kg.

3.3 Integer and mixed integer constraints

Potential units proposed in the former superstructure (Casoni et al. 2020) are associated with binary variables in order to determine the optimal technological pathway. These variables are included in the model using propositional logic and Big M formulation, and are represented by inequalities as it is shown in Eq. (5).

$$\sum_k^K \sum_j^J f_{\theta,j}^k - BM \cdot y_i \leq 0 \quad \forall \theta \in \vartheta \cup \vartheta' \quad \forall i \in I \quad (5)$$

where $f_{\theta,j}^k$ denotes the mass flowrate of component j in stream k of unit θ while BM is a large number that makes the constraint become redundant when $y_i = 1$. On the other hand, the mass flowrate is forced to be null when $y_i = 0$. It is worth mentioning that BM choice is made considering the maximum mass flowrate involved in the corresponding i technological alternative. Furthermore, binary variables are involved in the heat exchanger network design denoting the matches between hot and cold process streams and utilities.

3.4 Design and economic constraints

The nonlinearities of the problem appear in the equipment design equations and economics constraints, which were formulated following Ramos et al. (2019).

3.5 Objective function

RePSIM Eq. (6) is used as the objective function to evaluate the sustainability of the project. This metric aims at positive values, so that it is maximized. For further details please see Martin (2016).

$$RePSIM = -P + (M + B - F - RM - E - W)C_{CT} - I(C_{annual}) + JS + (F\&F_A + F\&F_B) \quad (6)$$

On the other hand, heat integration of the flowsheet is performed minimizing the annual cost for the network as it is shown below (Biegler et al., 1997).

$$NetCost = HU_{cost} + CU_{cost} + FC_{cost} + A_{cost} \quad (7)$$

Where HU_{cost} and CU_{cost} are the hot and cold utility cost, respectively. FC_{cost} is the fixed cost for heat exchanger and A_{cost} is the area cost of the exchanger.

3. Numerical Results

The MINLP model presented 5398 continuous variables and 13 binary variables and 5336 constraints and it was solved with DICOPT (CONOPT and CPLEX) (Grossmann et al., 2003). Besides, the energetic integration model possesses 1236 continuous variables, 339 binary variables and 1338 constraints. The heat integration reduced the number of cold and heat utilities (Figure 2) which directly impacted on the environmental pillar of RePSIM. Before the heat integration, the process required 828 kW while after heat integration this value was 470 kW (43 % less). These results are in agreement with the published literature (Chong et al., 2020; Song et al., 2018), which mention a 32.1 % and a 42.8 % of energy reduction in a macroalgae waste biorefinery and a cellulosic bioethanol plant, respectively. In term of cost, this represented a 54 % of savings. As regard RePSIM environmental pillar, it showed an improvement of 14 %. Finally, it is worth noting that not only does heat integration improve economic aspects of a process, but it also improves the environmental one.

Figure 2. Heat exchanger network

4. Conclusion

In this work, we propose a mixed-integer nonlinear programming (MINLP) model for the optimization and heat integration of a macroalgae-based biorefinery to produce chemical compounds from brown macroalgae biomass. The heat integration was effective in reducing heat requirements denoting how beneficial this type of analysis results in process design. Future work would involve a sensitivity analysis study and waste water treatment in order to keep focusing on environmental aspects.

Abstract

The growing interest in decarbonization promotes the spread of distributed generation and efficient load control approaches (demand-side management). In this framework, the definition of mathematical tools to tackle the integrated optimal management of energy resources and flexible loads is fundamental. This study addresses the optimal scheduling problem of a Multi-Energy System (MES) and thermal comfort management for buildings in a unified approach. Linearized simplified models of the buildings and district heating network (DHN) are included in the algorithm. The optimization can exploit thermal inertia of buildings and of DHN to increase the flexibility of the system. The proposed method is applied to a group of buildings of the Campus of University of Parma.

Keywords: Multi Energy Systems, demand-side management, MILP, district heating network.

1. Introduction

The current energy transition towards more environmentally sustainable solutions has boosted the employment of distributed energy resources, encompassing both distributed generation and controllable loads. Local energy production has to cope with fluctuating renewable energy sources (RES) availability and therefore the need of flexible solutions is of major importance. The building sector shows great potential in this direction, as thermal mass - readily available - can be exploited to shift loads. Moreover, buildings represent a large fraction of final energy consumption, accounting for approximately 40% in Europe (Rousselot, 2018). This work addresses the concurrent optimization of the thermal comfort management in buildings, operation of the district heating network and scheduling of the Multi-Energy System (MES) supplying their electrical and thermal power. An extension of the MILP (Mixed Integer Linear Programming) scheduling problem formulation proposed by Bischi et al. (2019) for MESs is proposed, by including a linearized dynamic thermal model of the buildings and a simplified linearized model of district heating network (DHN). The formulation allows optimizing not only the operation of the units (unit commitment and economic dispatch) but also the profiles of thermal energy supplied to each building, the dynamic evolution of their indoor temperature and

delivery and return temperatures of the DHN. This enables the possibility of exploiting the heat capacity of the system to shift energy consumption and find a more economic operational planning for the generation units. The proposed method is applied to the Campus of University of Parma considering two different MES designs (supplying heating, cooling and electricity) and the optimized strategies are compared with the conventional management strategy.

2. Problem statement

The optimization addresses the weekly scheduling of the generators with the possibility to exploit the heat capacity of the buildings and of the DHN in order to increase the operational flexibility of the units and reduce energy consumption (or increase revenues from electricity sales to the grid). Constraints on indoor temperature variations are included in occupancy hours, to guarantee that thermal comfort is not jeopardized. The general operation planning problem can be formulated as follows:

“Given:

- a set of dispatchable generation units \mathcal{M} , with performance curves and technical limits;
- a set of non-dispatchable units \mathcal{ND} ;
- a set of buildings \mathcal{K} , with defined construction parameters;
- forecasted electricity prices, forecasted electrical demand profile, forecasted occupancy profiles, forecasted outdoor air temperature and irradiance,

determine (for each time step t within the time horizon \mathcal{T}):

- the dispatchable units to be turned on and their load;
- the power exchanged with the grid;
- heating or cooling power supplied to buildings;
- the buildings indoor temperature;
- the delivery and return temperatures of the primary and secondary circuits;

which minimizes the operating cost subject to the following constraints:

- dynamic thermal balance of the building;
- heating, cooling and electrical balance of the whole system;
- technical limits of generating units;
- thermal comfort requirements (desired temperature range within occupancy hours and ASHRAE dynamic comfort constraints);

thermal propagation delay in pipes, limits on heat transfer in heat exchangers and heat balances across the heat distribution network.

3. Energy system and buildings modelling

Several studies have developed MILP models for the optimal operational planning of MES, where binary variables are required to include start-up/shut-down operation of units. However, a considerable number of papers deal separately with the energy system and the buildings supplied, either considering energy demand as an exogenous input or mainly focusing on buildings' perspective. The decoupling of these two aspects results in underuse of the load shift capability of the buildings and sub-optimal performance of the generating units (Darivianakis et al., 2019). For this purpose, a linearized differential model of the building is included in the algorithm, accounting for power input, heat exchange through walls, air infiltration losses and the contribution of air forced ventilation. When dealing with the management of buildings within an energy district, the thermal propagation delay in pipes cannot be neglected and therefore the linearized

dynamics of the district heating network are included in the MILP. In the following, we present the main features of the model.

3.1. Performance curves

The part-load performance curves (power input - output relationship) of the generating units have been linearized with minor approximations (<5%), as shown in Zatti et al. (2018). The effect of the outdoor air temperature T_{ext} is computed for the heat pump (HP) and the compression chiller (CC), through a linear function whose value affects the different load rates independently. As a matter of fact, the power output of these units is multiplied to the coefficient k_T , resulting from the best-fit of the performance data found in Yu et. al (2007) and Johnson (2013):

$$k_T = (m_T \cdot T_{ext} + q_T) \quad (1)$$

Where: m_T and q_T are the coefficients of the linear best-fit. Moreover, a penalty for start-up is included in the model as a reduction of machines useful output. To this end, we introduced a binary variable $\Delta(i, t)$ to state whether the unit has been switched on at a given timestep. This variable is linked to the unit commitment binary variable $z(i, t)$ by a set of inequality constraints, as described by Bischi et. al. (2019).

3.2. Building model

The model adopted in this work is a single state grey-box, derived from Gambarotta et al. (2017), where the coefficients of buildings are found trough best-fit of TRNSYS white-box model, by activating sequentially the contributions:

$$C_j \frac{dT_j}{dt} = UA \cdot (T_{ext}(t) - T_j(t)) + mc_{p,nat} \cdot (T_{ext}(t) - T_j(t)) + mc_{p,force} \cdot (T_{UTA}(t) - T_j(t)) + Q_{irr}(t) + Q_{occ}(t) + Q_j(t) \quad (2)$$

Where: $T_j(t)$ is indoor temperature, $T_{ext}(t)$ is outdoor air temperature, $T_{UTA}(t)$ is the temperature of the air coming from the air treatment unit, C_j is the total thermal capacity of the building, UA is the mean thermal transmittance of the envelope multiplied by its surface, $mc_{p,nat}$ and $mc_{p,force}$ are respectively thermal capacity of infiltration air and air forced ventilation, $Q_{irr}(t)$ and $Q_{occ}(t)$ are solar and internal gains, while $Q_j(t)$ is heat supplied to end-users. In particular, $T_j(t)$ and $Q_j(t)$ are the variables optimized by the model, in compliance with comfort requirements. In order to be implemented in the MILP, the differential equation is approximated using forward finite differences. We compared the approximated solution with the analytic one found for some test input profiles with a time step of 7.5 minutes (adopted for the optimization). The resulting absolute error in assessing the internal building temperature was lower than 0.05°C, sufficiently good for the purposes of the operational planning optimization.

3.3. District heating network model

The general scheme of DHN is depicted in Figure 1. The proposed approach can be applied to DHNs with radial configuration, where each building has a dedicated primary circuit connecting its internal secondary loop with the power generation site. The DHN is assumed to operate with a constant mass flow rate, while the heat transferred across the system is adjusted by changing the primary water delivery temperature T_p^D (equal for all buildings). Moreover, each building can decrease its input thermal power by opening the bypass valve of the heat exchanger. Assuming that the flow with minimum heat capacity rate is the primary loop during the heating season and the secondary loop in the cooling

season, the thermal power provided to each building j can be written as a linear function of the delivery temperature of the DHN (see Eq. (3)).

$$Q(j, t) \leq \varepsilon(j) \cdot c_w \cdot \dot{m}_{\min}(j) \cdot (T_H^{IN}(j, t) - T_C^{IN}(j, t)) \quad (3)$$

Where: ε is nominal effectiveness of the heat exchanger, c_w is heat capacity of water, \dot{m}_{\min} is the mass flow rate of the fluid with minimum thermal capacity, $T_H^{IN}(j, t)$ is the inlet temperature of the hot fluid and $T_C^{IN}(j, t)$ is the inlet temperature of the cold fluid. A constraint is included in the MILP to guarantee that the minimum thermal capacity is always on the same side of the heat exchanger. In order to consider the delay in heat propagation, we related the inlet $T_{in}(t)$ and outlet $T_{out}(t)$ temperature of the pipe, following the approach of Dobos et al. (2014). Assuming one dimensional flow, neglecting heat conduction in the axial direction and heat capacity of pipes, the solution of the energy conservation equation in the pipes is:

$$T_{out}(t) = T_{\infty} + (T_{in}(t - \Delta t) - T_{\infty}) \cdot (1 - \frac{4 \cdot k_p}{D_p \cdot c_w \cdot \rho_w} \cdot \Delta t) \quad (4)$$

Where: Δt is time delay, ρ_w is water density, k_p is the heat transfer coefficient between the pipes and the surroundings, D_p is the pipe diameter, T_{∞} is the temperature of the surroundings. This equation can be employed in the MILP model as long as the time discretization is sufficiently tight to capture the time delay in heat propagation (i.e. the time resolution has to be lower than the time the water needs to reach the closest building from the power plant). For this purpose, we considered a time resolution of 7.5 minutes in the case study.

Figure 1 – Scheme of the primary and secondary heating loops serving building j .

3.4. District heating network model

In the conventional management strategy, the thermal power provided to the buildings is adjusted to keep a set point of $20^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$ during the heating season, and of $25^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$ in the cooling season. The water delivery temperature of DHN is increased linearly as a function of the outdoor air temperature. The conventional optimization approach (without thermal comfort management where the heat demand profile is fixed) can be reproduced by imposing these binding constraints on the internal building temperatures. Instead, the Thermal Comfort Management (TCM) strategy, the building indoor air temperatures, the DHN water delivery and return temperatures and the thermal power supplied to each building are optimized in the MILP, in compliance with comfort requirements of the users during occupancy hours. In particular, we assumed that the users (students and university staff) accept to participate to a demand side management program, allowing a quality band of $\pm 2^{\circ}\text{C}$ around the summer and winter setpoints (18°C - 22°C in the cold season and 23°C - 27°C in the hot season). To avoid abrupt changes of temperature, ASHRAE standards (2004) constraints on ramps and drifts are included: the variation of temperature within an hour must be lower than 2.2°C , while the limit in 15 minutes is of 1.1°C . During non-occupancy hours, the building temperatures are free to vary outside the quality ranges.

4. Case study

The presented method has been applied to a group of 12 buildings of Campus of University of Parma. The area to volume ratio of the buildings varies from 33% to 55%, while time-constant (the ratio between thermal capacity and dispersions) ranges from 34 h to 158 h. Given the diversity of these features, the resulting indoor temperature profiles will differ between buildings. Thermal comfort requirements must be respected during working hours, i.e. from Monday to Friday from 8 a.m. to 6 p.m. The scenarios investigated encompass 3 different weeks of the year, representative of winter, mid-season and summer. The purchase price of electricity is derived from historical data of 2018 non-domestic users in Italian protected market (tri-hour tariff), while the purchase price of natural gas is defined on the basis of yearly average consumption of the university campus. We considered 2 different MES configurations: Design D1 features a boiler and a compression chiller, while design D2 comprises a HP - covering half of the heat peak - auxiliary boilers, a CC and PV panels.

5. Results

The optimizations have been formulated with Pyomo and the MILP has been solved with Gurobi solver. The solution of the large scale MILP (250160 continuous variables, 6725 binary variables, 384059 constraints) needs approximately 5 hours for optimizing the weekly operation with a time resolution of 7.5 minutes. If the optimization horizon is shortened to three days, the computational time reduces to only 20 minutes. With TCM, the algorithm can either decide to reduce the heat requirements of buildings or to store heat in their mass (i.e. when there is availability of RES). Figure 2 highlights the different thermal behavior (in design D2) of two buildings of the campus B0 and B1, respectively featuring a high and a low thermal capacity. The MILP can also exploit DHN thermal inertia, by varying water delivery temperature. As such, this temperature rises in the presence of RES (Figure 2) and it drops in the rest of the day, reducing the share of excess PV production sold to the grid at low price (from 84% in the reference strategy to 38% with TCM) and increasing the HP production (Figure 3). When there is a mismatch between thermal demand and low electricity price periods (i.e. with the CC), TCM enables production shifting. Furthermore, the flexibility provided by TCM slightly enhances machines performance, reducing boiler switching on/off and operation at partial loads, and advancing chillers start up in order to benefit from lower outdoor temperature (mean COP improves from 3.7 to 4.2). All these sources of flexibility explained so far operate concurrently and positively affect the total operating costs, as shown in Table 1, where the savings of TCM compared to the reference scenario are outlined in three weeks of the year (winter, spring and summer).

Figure 2. Temperature profiles (Saturday-Friday) of Design D2, in the reference strategy and with TCM. Right: indoor temperature profiles of buildings B0 and B1, with respectively high and low thermal capacity.

Figure 2. Unit commitment (Saturday-Friday) of Design D2, in the reference strategy and with TCM.

Total operating costs			
	W1	W2	W3
D1	-14.4%	-48.0%	-26.4%
D2	-2.8%	-21.6%	-7.6%

Table 1. Variation of total operating costs with TCM compared to the reference strategy in MES Design D1 and D2, in three weeks of the year (W1 = winter; W2 = spring, W3 = summer)

6. Conclusions and future works

The presented MILP approach appears to be effective not only for operational planning, but also to manage comfort in buildings. Its limited computational time allows solving weekly basis problems with very fine time resolution. It can be easily integrated into rolling horizon algorithms today used for optimizing the energy management strategy of multi-energy systems and energy districts.

Future extensions of the methodology may include more detailed models of the buildings and thermal energy comfort, as well as extending the optimization approach to cope with forecast uncertainty.

Abstract

Coupling of reaction and extraction, along with the ability to significantly increase reaction yields at milder conditions, makes liquid-liquid phase transfer catalysis an attractive intensified solution for many industrially important processes. Although there has been some work in terms of mechanistic modeling, solvent selection for such processes has remained a largely untouched topic by academia and industry. This work provides a path towards a systematic solvent screening or design framework by providing a quantum-chemistry-based evaluation method to find suitable green solvents for toluene in the process of hydrogen sulfide valorization from natural gas. From a pool of eight candidate alternatives, three are chosen to be suitable substitutes for toluene based on technical, economic, and environmental measures.

Keywords: green chemistry, sustainable engineering, reactive extraction, COSMO-RS, reaction path analysis.

1. Introduction

Liquid-liquid phase transfer catalysis (LL-PTC) belongs to an important class of intensified processes called multiphase reactive extraction. It has been reported to enable novel synthesis routes, higher yields, and faster reactions, while also facilitating the separation of certain species. Pudi et al. (2020) have shown a promising application of LL-PTC to offshore gas sweetening process as a replacement for the expensive and unsustainable triazine-based hydrogen sulfide (H₂S) removal method. In that work, the advantage of integrating quantum chemistry and Conductor-like Screening Model for Real Solvents (COSMO-RS) into process design has been clearly established. However, the emphasis of such studies has been put mostly on catalytic and mechanistic considerations with little attention paid to the choice of organic solvent. Due to the increasingly tight regulations and strong public opinion, a thoughtful selection for process-efficient and sustainable solvents in industrial activities has become an immediate requirement for chemists and chemical engineers alike. In an effort to meet

this need, this work shifts the focus towards the rational selection of green solvents to perform the biphasic production of benzyl mercaptan (BnMer) from benzyl chloride (BnCl) using tetrabutylammonium bromide (QBr) as the phase transfer catalyst. The specific chemical system and the reactions are reported by Pudi et al. (2020).

2. Methodology

2.1. Computational tools

The quantum chemistry program package, TURBOMOLE version 7.4, is employed for electronic structure calculations using density functional theory (DFT) and COSMO. The calculations are performed using the Becke-Perdew functional with the Ahlrichs basis set of triple-zeta valence plus polarization (BP-TZVP) to obtain the optimized structures, ground-state electronic energies, vibrational frequencies, thermal corrections to the free energy, and optimized reaction path. Based on the optimized DFT-COSMO molecular structures, the COSMO-RS solvation model implemented in COSMOtherm Release 19 is used to obtain liquid-phase thermodynamic properties, such as partition coefficients and free energies of solvation. In addition, the ProPred toolbox in the Integrated Computer-Aided System (Gani et al., 1997) is used to evaluate the environmental impact factors.

2.2. Solvent (pre-)selection based on published guides

Using the immiscibility of a solvent in water as a necessary requirement for the biphasic system, eight potential alternatives to toluene are selected from the vast pool of solvent candidates assessed in the CHEM21 selection guide (Prat et al., 2015) and Sigma-Aldrich's Greener Solvent Alternatives: 1-butanol, 2-methyl tetrahydrofuran (2-MeTHF), anisole, benzyl alcohol, butyl acetate, ethyl acetate, isopropyl acetate, and methyl isobutyl ketone (MIBK).

2.3. Reaction path optimization and free energies

Based on the approximation of a locally quadratic potential energy surface, reaction path at each step is optimized with the sole constraint of equally spaced structures using the reactants and products as the path boundaries (Plessow, 2013). An initial path is generated using a slight variation of the linear synchronous transit method (Halgren & Lipscomb, 1977). This iterative process is continued until one or more good initial guesses are obtained for the transition state (TS) optimization. Vibrational frequency analysis is performed on these initial guesses to find the closest approximation to the TS. This structure is then optimized to find the TS structure. The free energy of activation is equal to the free energy of reaction with the TS as the product of the reaction. Therefore, both free energies are calculated using the same procedure as reported by Hellweg and Eckert (2017).

2.4. Environmental impact

Four environmental impact factors (EIFs) are evaluated for each solvent: human toxicity potential by ingestion (HTPI), human toxicity potential by exposure (HTPE), aquatic toxicity potential (ATP), photochemical oxidation potential (PCOP). Using Eqs. (3)-(6), these EIFs for a chemical j are calculated based on the properties listed in Table 2. In the absence of experimental values for the properties, ProPred estimates them based on the combined group contribution and atom connectivity index method.

$$EIF_{j,HTPI} = \frac{1}{(LD_{50})_j} \quad (1)$$

$$EIF_{j,HTPE} = \frac{1}{(PEL)_j} \quad (2)$$

$$EIF_{j,ATP} = \frac{1}{(LC_{50}^{FM})_j} \quad (3)$$

$$EIF_{j,PCOP} = \frac{1}{(PCO)_j} \quad (4)$$

Table 1 Environmental properties obtained from ProPred to calculate the EIFs

Property	Unit	Description
-Log(LC ₅₀) ^{FM}	Log(mol/L)	50% lethal concentration for Fathead Minnow after 96 h.
-Log(LD ₅₀)	Log(mol/kg)	50% lethal oral dose for rat
-Log(PEL)	Log(mol/m ³)	Permissible exposure limit as defined by OSHA-TWA
-Log(PCO)		Photochemical oxidation potential from the reaction of NO _x and volatile organic compounds

Due to the differences in units and scales, EIFs are then standardized for each impact category using the following equation:

$$EIF_{j,k}^s = \frac{EIF_{j,k}}{\mu_k + 2\sigma_k} \quad (5)$$

where μ is the mean value, σ is the standard deviation, k is the impact category, j is the solvent, and s stands for standardized. The standardized EIFs are then weighted and summed to obtain the environmental impact of each solvent as a single score (SS) as shown in Eq. (8). The weights are chosen based on the offshore application, thus the weight for ATP was set the highest. Human exposure due to handling is important, so it followed closely, and photochemical smog is placed for a lower scaling.

$$SS_j = EIF_{j,PCOP}^s + 2EIF_{j,HTPE}^s + 3EIF_{j,ATP}^s + 4EIF_{j,ATP}^s \quad (6)$$

3. Results and Discussion

Choosing the best solvent for a specific application depends on several different factors, such as process performance, ease of product recovery, price, and environmental impact. For example, the initial selection criterion of water immiscibility among the green solvent candidates reported by the selection guides allows for higher yield, higher selectivity, etc., conforming to the advantages of a biphasic system in terms of process performance (Mąkosza & Fedoryński, 2003). In this context, the solvents are evaluated based on several important screening criteria relevant to the specific chemical system under consideration: partition behavior, reaction energy barrier, reaction free energy, organic product separation, solvent price, and environmental impact.

Figure 1 Partition coefficients (organic/aqueous) of the three catalyst species in all solvents

In LL-PTC, the partition behavior of the reactants, products, and the catalyst species is an important consideration. Partition coefficients for all the species are calculated in COSMOtherm with a value greater than 1 implying a preference for the organic phase and a value less than 1 implying a preference for the aqueous phase. A good organic solvent would result in high partition coefficients for BnCl and BnMer. Since all the considered solvents exhibit this behavior, this becomes irrelevant for screening. Proper partition behavior of the active and inactive catalyst forms is crucial for an efficient and effective LL-PTC. The active catalyst form, tetrabutylammonium hydrogen sulfide (QSH), must transfer to the organic phase to form BnMer, while the inactive catalyst forms, QBr and tetrabutylammonium chloride (QCl), must simultaneously transfer to the aqueous phase to form QSH. Ideally, the partition coefficient of QSH should be greater than 1 while that of QBr and QCl should be less than 1. Figure 1 shows (in log-scale) how the solvent candidates affect the partition coefficients of the three catalyst forms. All the three species have high partition coefficients in 1-butanol, 2-MeTHF, and benzyl alcohol, making them less favorable in terms of process performance. On the other hand, ethyl acetate, butyl acetate, and anisole cause the desired partition behavior.

Faster kinetics lead to a smaller reactor volume, while better thermodynamic favorability results in higher yield. The free energies of activation and reaction are a measure of kinetics and thermodynamic favorability, respectively. Figure 2 shows that, except for 1-butanol and benzyl alcohol, all the candidates result in an improved reaction performance in comparison to toluene with 3.4–7.8 % reduction in the reaction energy barrier. The two solvents with much poorer reaction kinetics also exhibit less favorable thermodynamics.

Ease of product recovery affects both the economics and the total environmental footprint of the process. Organic solvents with lower volatilities and higher boiling points correspond to lower emissions of volatile organic components. However, such solvents require a more expensive product recovery since the most common method for product recovery is distillation or evaporation of the solvent. In terms of the specific chemical

system under study, the boiling point of BnMer is 195 °C. Therefore, an easier product recovery requires the boiling point of the solvent to be lower to a satisfactory extent. However, it can't be too low since the reaction temperature is about 60 °C. Figure 3 shows that anisole, benzyl alcohol, and butyl acetate make bad candidates due to their high boiling points, while 2-MeTHF and ethyl acetate pose a slight risk since their boiling points are higher than the reaction temperature only by about 20 °C.

Figure 2 Free energies of activation and reaction in all the considered solvents

Figure 3 Comparison of toluene against the selected alternatives in terms of their environmental impact single scores (broken down by category), prices, and boiling points

Figure 3 also compares the prices and environmental impact scores (SS) of all the solvents. Although there is no considerable difference in the prices of the solvents,

environmental impact varies quite widely among the candidates. Anisole and butyl acetate have worse single scores than toluene, making them the only candidates that cannot be considered “greener” substitutes for this process. Ethyl acetate and isopropyl acetate perform significantly better than the other alternatives. Considering all the screening factors, ethyl acetate comes out as the best solvent with isopropyl acetate and MIBK doing quite well to warrant a further look into their capability to replace toluene.

4. Conclusion

Solvents are a major source of energy usage and waste generation in many chemical, biochemical, and petrochemical processes, including LL-PTC. In previous works, LL-PTC has been shown to substantially improve the economics and sustainability of offshore natural gas sweetening processes by replacing the existing triazine-based H₂S removal. In this work, the process is further improved by providing a quantum-chemistry-based screening method to find and evaluate green and sustainable alternatives to toluene in terms of technical, economic, and environmental factors. Based on the results, the three best solvents to replace toluene are ethyl acetate, isopropyl acetate, and MIBK. This work paves the way for a more systematic, optimization-based solvent screening or design framework in the future.

Abstract

Validated mathematical models were studied applying a multivariate analysis of relevant outputs in a wastewater treatment plant. Monte-Carlo based simulations permit to obtain enough responses of the outputs when varying relevant inputs. Uncertainty is incorporated into the flow rates of wastewater and the wind velocity. Results show the strengths and limitations of the models as well as the impact towards the reduction of H₂S. The dynamic variability is captured using a covariance analysis at different time intervals.

Keywords: hydrogen sulfide, mathematical modelling, parameter sensitivity.

1. Introduction

Wastewater treatment plants (WWTP) generate unpleasant odors due to the biological degradation of organic waste. The main influential compound is hydrogen sulfide (H₂S), and it has the potential to provoke the corrosion of wastewater infrastructure, odor nuisance in the community and possible health impact on the personnel. H₂S emissions are easily perceived by the human olfactory system because it detects odors at low concentrations over short time intervals. Growing environmental awareness and the search of better quality of life in urban areas drives the role of environmental control agencies. New policies or the revision of existing ones intend increase the control of odor emissions. In this sense, mathematical models developed for estimating the emission rates of WWTP, represent important decision-making tools when adequately exploited (Santos, et al., 2009)

Mathematical models require the definition of parameters and initial conditions for achieving a solution. Nevertheless, this information is not always available or there is a degree of uncertainty due to natural variations, measurement errors or simply the inability of measuring. Uncertainty and multivariate analyses permit to realistically assess the inherent variations of processes (Marino et al., 2008; Salas et al., 2007; Gonzalez, et al., 2020)

In this work, four validated models are studied applying a dynamic multivariate analysis in a WWTP. Initially, a Monte-Carlo based simulation permits to obtain samples of the outputs when changing five inputs. Uncertainty is incorporated to the flow rate of wastewater and the wind velocity. The results permit to observe the strengths and

limitations of the models as well as the impact towards the reduction of H_2S . Finally, the dynamic variations are captured using a covariance analysis at different time intervals.

2. Background

2.1. System description

The studied system corresponds to the experimental WWTP introduced by (Santos, et al.,2009). This unit treats the wastewater of a town in Brazil, with a fixed daily flow. It consists of a pumping, screening and grit removal station, an upward flow anaerobic sludge mantle reactor (UASB), three secondary biofilters (BF) and a tertiary biofilter, UV disinfection and sludge drying beds as illustrated in Figure 1. Regarding the mathematical model, (Santos, et al.,2009) proposed that the WWTP is treated as an homogeneous reactor, regardless the fluid flow and the mass transfer responsible of the distribution of the pollutant (H_2S) concentration inside. The H_2S can be accumulated, can passed through the reactor, or be affected by any of the following removal mechanism; volatilization of the wastewater-atmosphere interface, stripping because the diffusion into air bubbles, biodegradation, adsorption of solid particles or biomass, absorption for insoluble liquids and by chemical oxidation due to reactor aeration.

Figure 1: Experimental WWTP. Source: (Santos, et al.,2009)

2.2. Mathematical Model

The mathematical model under study (Corsi et al., 1992; Santos, et al.,2009) considers the WWTP as a single isothermal continuous stirred tank reactor. In this sense, the model is obtained through the mass balance of H_2S . Here, $[H_2S]$ represents the contaminant concentration after being mixed with the fluid inside the unit. The balance provides the initial value as a model: Find the function $[H_2S]: [0, +\infty) \rightarrow \mathbb{R}_+$ such that

$$V \frac{d[H_2S]}{dt}(t) = Q\{[H_2S]_0 - [H_2S](t)\} + \sum_{i \in I} R_i\{[H_2S](t); \theta_i\}; \forall t \in (0, +\infty) \quad (1)$$

subject to an initial condition $[H_2S]_0$ (at $t = 0$) that represents the contaminant concentration in the liquid phase entering the unit. Here, V is the volume of the unit, and Q is the sewage flow rate. R_i represents the constitutive relationship corresponding to the i -th removal mechanism that belongs to the set $I = \{v, s, b, ad, ab, q\}$, where v is the volatilization, s is the stripping, b is the biodegradation, ad is the adsorption, ab is the absorption, and q is the chemical oxidation. On the other hand, θ_i is a vector contains the parameters corresponding to the i -th removal mechanism, which has as many components as parameters appear in R_i . These relationships are taken from (Santos, et al.,2009).

Table 1 enlists the expressions of the chemical removal mechanisms that provide the four different mathematical models. Here, k is the specific rate, k_0 is the constant for oxidation of H_2S , k_1 is the constant for oxidation of HS^- , K_1 is the first dissociation constant for

H_2S , $[\text{O}_2]$, $[\text{S}]$ and $[\text{H}^+]$ are the oxygen, sulfur and hydrogen concentrations respectively, and T is the temperature in $^\circ\text{C}$. The model described in Eq. 1, together with each removal mechanism, is re-scaled and simplified using dimensionless variables and parameters. This provides an adequate handling of the model from the numerical perspective without the effects due to the scale differences. Also, it helps the multivariate analysis on the physical parameters.

Table 1: Mathematical expressions for the chemical removal mechanisms.

3. Multivariate analysis for a wastewater treatment plant

For a better insight regarding the dynamics of the aforementioned models, Monte-Carlo based simulations are carried out. First, the relationship between the operational variables and the outputs of the models is studied in order to identify those with greater influence on key variables. Second, we perform an analysis including uncertainty at the operational level by varying the possible disturbances of the WWTP, i.e., the wind velocity and the inlet wastewater flow rate. The proposed model-centric framework for the analysis of the different options for wastewater treatment are developed in a Python environment because it allows a versatile implementation. Libraries such as *Numpy*, *SciPy*, *Pandas*, *Matplotlib* and *Seaborn* facilitate obtaining and analyzing the results.

3.1. Monte-Carlo based analysis

To explore particularities of the relationships between the variables involved in the different models, Monte-Carlo based simulations are carried out. We generate a total of random uniform 1,000 samples varying the initial values of the following five variables: the gas phase temperature (T Gas Phase), the liquid phase temperature (Liq Phase), the level of pH, oxygen concentration ($[\text{O}_2]$), and the concentration of sulphur ($[\text{S}]$). The ranges of the initial values used in each variable are T Gas Phase $\in [17.8, 29.8]$, T Liq Phase $\in [13.7, 21.5]$, pH $\in [6.9, 7.5]$, $[\text{O}_2] \in [0.1, 8.5]$, $[\text{S}] \in [5, 300]$. The simulation of the models were run using the *solve_ivp* function available in the library module *scipy.integrate*. The variables and the parameters are properly dimensionless re-scaled, and the simulations run until the dimensionless time of 5.0. This value of time is chosen because the exploratory space of the process variables do not exhibit significant variation on its dynamics.

Once the results are obtained, a multivariate analysis of the output is performed by selecting the time steps $t = 1, 2, \dots, 5$. In this analysis, we look for insights about the relationship between the five operational variables and the reduction of the concentration of H_2S through the time stepping. Correlation matrices between the process variables for each model output are obtained at each time step. The dynamic multivariate analysis permits to observe the influence of certain variables along the dynamic process

simulation, and to determine which of these variables has a greater influence in the outputs.

3.2. Dynamic uncertainty analysis

In this study, uncertainty was incorporated to variables that appear to perform as disturbances and influence the dynamic response of the system. While the operational variables are set as T Gas Phase = 23.8, T Liq Phase = 17.6, pH = 7.2, $[O_2] = 4.3$, and $[S] = 152.5$, the disturbances, including uncertainty, correspond to the wind velocity (Wind V) and the inlet wastewater flow rate (Flux). An uncertainty class of 25% is considered as reasonable based on (Sin et al., 2009). Thus, Wind V = $4.025 \pm 25\%$ and Flux = $5.5 \times 10^{-4} \pm 25\%$. A total of 2,000 samples are randomly uniform generated.

4. Results

4.1. Monte-Carlo based analysis

For the multivariate analysis, 1,000 simulations run for each of the chemical oxidation removal models. The concentration value of H_2S for each operational variable is obtained at each of the chosen time steps.

Figure 2 portrays a series of the plots for the most significant variables, $[O_2]$ and $[S]$ for the model using the chemical removal model by (Jolley et al., 1985) at the times $t = 1, 2, \dots, 5$. The plots indicate a very strong inverse correlation between the $[O_2]$ and the concentration of $[H_2S]$ in each time step, and a direct inverse correlation between $[S]$ and $[H_2S]$.

Figure 2: Relationship between $[H_2S]$ and $[O_2]$ (upper plots) and the $[S]$ (lower plots) at the dimensionless time steps 1.0, 2.0, ..., 5.0, using the chemical oxidation removal model by (Jolley et al., 1985).

Table 2 enlists the correlation values between the operational variables at each time step for each chemical oxidation removal model. The values greater or equal to 0.1 are boldfaced. Figure 3 depicts graphically the information given in Table 2. These results permit to identify the variables that have more influence in the reduction of $[H_2S]$ when using a particular chemical removal model. For the utilization of the chemical removal model given by (Buisman et al., 1990) the variable $[O_2]$ and the output $[H_2S]$, in each time step, show a strong inverse correlation (~ -0.78) while $[S]$ and the output $[H_2S]$, in each time step, exhibit a very weak direct correlation. Regarding the use of the model given by (Wilmot et al., 1988) the scenario is similar, excluding that the correlation of $[H_2S]$ with $[O_2]$ becomes weaker while the correlation with $[S]$ stronger. When using the model by (Jolley et al., 1985) the trend is similar to the first one. The correlation gets

inversely stronger (~ -0.96) with respect to $[O_2]$ and directly weaker with $[S]$. Finally, regarding the model introduced by (Nielsen et al., 2004) the results show that the only significant variable in the output is the T Gas Phase, which depicts a very strong inverse correlation with $[H_2S]$.

Figure 3: Correlation matrix between parameters values of T Gas Phase, T Liq Phase, pH, $[O_2]$, $[S]$ and the dimensionless time steps 1.0, 2.0, ..., 5.0; for each of the different models used for oxidation chemical removal.

4.2. Dynamic uncertainty analysis

The uncertainty analysis aims to capture the dynamics of the outputs when incorporating variability to process inputs. Figure 4 depicts the results of stochastic simulations, using the four models and by varying $\pm 25\%$ the wind velocity and the wastewater inlet flow. The plots show the minimum and maximum values. The darker region corresponds to the percentiles 25 and 75. The results of the simulations show that by varying 25% the inputs a maximum variation of the $[H_2S]$ of 2.73%, 3.06%, 2.66%, 2.66%, for the simulations using the chemical oxidation removal models of (Buisman et al., 1990), (Jolley et al., 1985), (Wilmot et al., 1988) and (Nielsen et al., 2004), respectively.

5. Conclusions

A model-centric framework permits to exploit the capabilities of mathematical representations of dynamic systems. In this work, a WWTP was studied in detail using different modelling approaches towards the reduction of H_2S emissions. Depending on the final application or available data, the modeller could select a suitable system. The main influential variables correspond to the oxygen concentration, sulfur concentration, and the gas temperature. The oxygen concentration appears to be a reasonable control

variable through the aeration mode, capable of reducing the H_2S emissions. Additionally, the analysis under uncertainty with the selected class portrays important information regarding possible dynamic variations in the outputs. The output variations could be significant to the process and require special attention, specially when satisfying quality standards is desired. In terms of decision-making this provides insightful guidance to select the modelling strategy as well as further considerations for an adequate design and operation.

Abstract

This study aims to develop and evaluate new gas-to-liquid technologies for production liquid fuels, such as methanol, synthetic fuels, and dimethyl ether, using industrial residue gases. To resolve global energy and environmental issues, the upcycling of a coke oven gas (COG) which contains high-caloric chemicals of CH₄, CO, H₂ to value-added chemicals is one of the most promising strategies. In achieving the goal, we first developed for the upcycling processes of the residue gases to value-added chemicals and fuels (e.g., methanol, dimethyl ether, and Fischer-Tropsch fuels) through the gas-to-liquid framework. The COG-to-fuel processes involve three sub-processes: gas pre-treating, liquid fuels synthesis, and separation. In particular, the combined steam and CO₂ reforming (CSCR) was adopted to reform COG into H₂ and CO which is further adjusted to the optimal ratio for target products before entering the following synthesis stage. Here, the H₂/CO ratio of 2 is useful for methanol synthesis and Fischer-Tropsch synthesis while the ratio of 1 is better for dimethyl ether synthesis. We then developed process models using Aspen Plus simulator and performed a techno-economic evaluation to obtain technical (mass and energy flows) and economic (capital and operating costs) parameters. As a result, we identified the most energy-efficient, economic, and eco-friendly gas-to-fuel process under different market scenarios such as chemical prices and CO₂ reduction policies.

Keywords: Gas-to-liquid, Coke-oven gas, Methanol, Fischer-Tropsch, Dimethyl ether, Technoeconomic.

1. Introduction

The depletion of conventional energy resources, the growth of energy demand and climate change are the critical energy and environmental issues. To resolve such issues, many alternative technological routes for energy products from alternative feedstocks have been investigated. Recently, the reuse of industrial residue gas (e.g., coke-oven gas, Lintz-Donawitz) for heating or fuel products have received a lot of attention. A number of studies have been found for the upcycling of residue gases to high value-added chemicals and fuels (Kim et al, 2020). Therein, coke-oven gas (COG), which is one of the residue gases from the iron and steel making industry with high-caloric chemicals of CH₄, CO, H₂ can be utilized as a raw material for chemicals and fuels. In this study, we developed and evaluated the upcycling processes of coke-oven gas (COG) to liquid fuels such as methanol, dimethyl ether, and Fischer-Tropsch fuels through the gas-to-liquid

framework. The COG-to-fuel processes were firstly developed with three main sections of combined steam and CO₂ reforming for syngas, fuel synthesis, and separation. Therein, the combined steam and CO₂ reforming (CSCR) is flexible to adjust H₂/CO ratio for the specific following fuel synthesis (the ratio of 2 for methanol synthesis and Fischer-Tropsch synthesis, and 1 for dimethyl ether synthesis). We then evaluated a techno-economic (e.g., carbon and energy efficiency, unit production cost) and environmental performance (net CO_{2eq} emission). Consequently, the most energy-efficient, economic, and eco-friendly fuel production process were identified with the insight of major cost- and energy-drivers of COG-to-fuels to provide practical R&D targets and strategies.

2. Process simulation and analysis method

2.1. Process development

In this study, three process models were developed using Aspen Plus V10.0 according to the targeted products: COG-to-MeOH, COG-to-DME, and COG-to-FT. The proposed gas-to-fuel processes include three main stages of: 1) the pre-processing of a raw gas for syngas production, 2) synthesis to liquid fuels from syngas, and 3) separation and purification. Firstly, the combined steam and CO₂ reforming (CSCR) was adopted to reform CH₄ in COG into H₂ and CO, in which the H₂/CO ratio is flexible by adjusting the competitive steam reforming and CO₂ reforming reactions. Particularly, the methanol synthesis and Fischer-Tropsch synthesis prefers the syngas ratio of 2, while the favourable ratio between H₂ and CO for maximizing the dimethyl ether synthesis is assumed to be 1. The produced syngas is then fed into a reactor for the targeted fuels (MeOH, DME, or FT fuel):

- Methanol synthesis: catalyst of Cu/Zn/Al/Zr, at 250 °C, 50 bar (Do et al., 2019)
- Dimethyl ether synthesis: bi-function catalytic of CuO/ZnO/Al₂O₃ and γ -Al₂O₃, at 260 °C, 50 bar (Mevawala et al., 2017)
- Fischer-Tropsch synthesis: Ni/CaO/A₂O₃, at 210 °C, 38 bar (Han et al., 2019)

In the separation section, the outlet stream from reactors was cooled and separated the main product while the unreacted gas was recycled. For COG-to-MeOH, the simple flash tank and distillation was used to separate MeOH from water and recycle unreacted CO, H₂, CO₂. In COG-to-DME, the Restisol absorption unit was firstly operated to separate CO₂, which is produced together with DME. Then, the distillation column was used to purify DME from a small by-product MeOH. Finally, the flash tank and distillation were also adopted in COG-to-FT to separate liquid fuels (e.g., gasoline, diesel, and wax), from the water and light gas (sent to the reformer).

2.2. Analysis method

The COG-to-fuel processes were evaluated the techno-economic and environmental performance using many criteria. Firstly, the carbon efficiency (*CEF*) and energy efficiency (*EEF*) show how much carbon and energy were captured and utilized in the produced fuels (Do et al., 2020) as formulated in Eqs. (1) and (2).

$$CEF(\%) = \frac{\text{Carbon in product}}{\text{Carbon in feed}} \times 100 \quad (1)$$

$$EEF(\%) = \frac{\text{Heat of product}}{\text{Heat of feed} + \text{Utility}} \times 100 \quad (2)$$

For economic analysis, unit production cost (*UPC*) was calculated for fuels as expressed in Eq. (3). Here, the total production cost includes the capital expenditures (*CAPEX*) and operating expenses (*OPEX*) (Do el et al, 2020). The environmental performance of processes is performed in net CO₂ equivalent emission (*NEC*) which is expressed as the amount of CO₂ equivalent (CO_{2eq}) emit per unit of produced fuel, as presented in Eq. (4).

$$UPC(\$/\text{kg}) = \frac{CAPEX + OPEX}{\text{Amount of product}} \quad (3)$$

$$NCE(\text{kg}/\text{kg}) = \frac{\text{Direct emission} + \text{Indirect emission} - \text{Feed Inventory}}{\text{Amount of product}} \quad (4)$$

3. Techno-economic analysis

3.1. Process simulation and technical performance

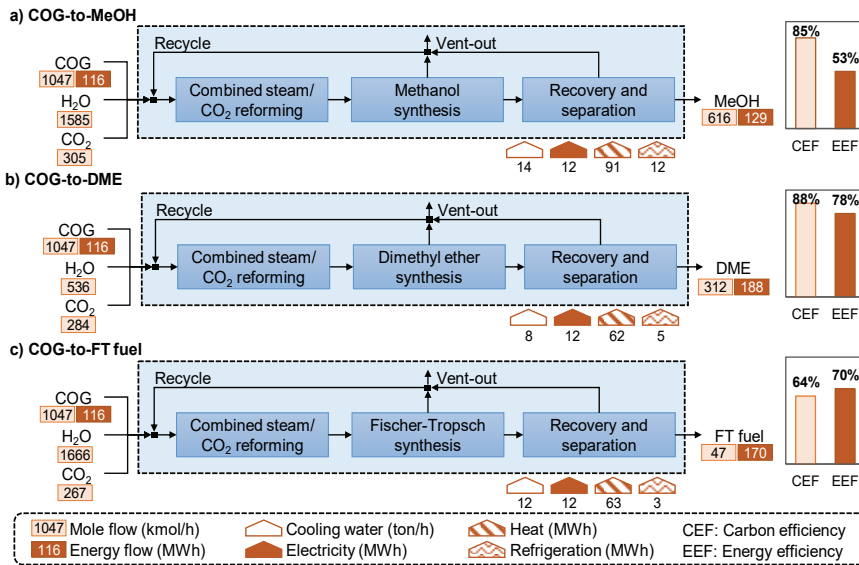

Figure 1. Block diagram with carbon efficiency and energy efficiency of COG-to-fuel processes

The process simulation of MeOH, DME, and FT fuel production was targeted to operate with the same feed rate (1,047 kmol/h of COG) and additional CO₂ and water, which are at different rates for adjusting the optimal syngas ratio, corresponding to the capacity of 158, 114, and 51 kt/y. Figure 1 presents the simplified block diagram with the mass and energy flows of each process as well as the carbon and energy efficiency. As shown in Figure 1, MeOH and DME production processes show relative high CEF of 85% and 88%

respectively, while the DME and FT fuel production routes was analysed to show high energy efficient of 78% and 70%, respectively.

3.2. Unit production cost

In the economic evaluation, the fuel production plants were assumed at annual 8,000-hours operability, 20 years of plant-life, and 8% of interest rate. The other assumptions and parameters for material and utility are presented in Table 1. Based on the obtained mass and energy flow information, the capital and operating costs were estimated using Aspen Process Economic Analyzer. The total production cost and UPC of fuels were estimated and presented in Table 2. The COG-to-MeOH is the highest expense plant. But due to the highest production rate (114 kt/y) compared to COG-to-DME and COG-to-FT plants, the MeOH production plant results in the lowest UPC for MeOH (0.46 \$/kg). To compare three different types of fuels, the UPC was further estimated into the unit of energy as gasoline gallon equivalent (\$/GGE). Consequently, the DME production process performs the lowest UPC at 1.92 \$/GGE.

Table 1. Assumption of raw material and utility price and CO_{2eq} inventory

	Unit price		CO _{2eq} inventory	
Coke-oven gas	2.5	\$/MMBTU	2.05	kgCO _{2eq} /MMBTU
CO ₂	35	\$/ton	1.00	kgCO _{2eq} /kg
Process water	1	\$/ton	0	kgCO _{2eq} /kg
Cooling water	0.03	\$/ton	0	kgCO _{2eq} /kg
Electricity	0.07	\$/kWh	0.62	kgCO _{2eq} /kWh
Fired heat	0.03	\$/kWh	0.34	kgCO _{2eq} /kWh
High pressure steam	14.5	\$/ton	0.19	kgCO _{2eq} /kWh
Low pressure steam	10.5	\$/ton	0.19	kgCO _{2eq} /kWh
Refrigeration	0.067	\$/kWh	1.50	kgCO _{2eq} /kWh

Figure 2. Breakdown of fuel unit production cost

Table 2. Total production cost and unit production cost of fuels

	COG-to-MeOH	COG-to-DME	COG-to-FT
<i>Capital expenditure (M\$/year)</i>			
(CAPEX=DC+IDC+WC)	16,169,041	15,548,946	22,866,501
Direct plant cost (DC)	9,441,496	9,079,408	13,352,307
Indirect plant cost (IDC)	4,816,310	4,631,601	6,811,298
Working capital (WC)	1,911,234	1,837,937	2,702,896
<i>Operating expenditure (M\$/year)</i>			
(OPEX=VOC+FOC)	56,277,886	42,300,327	45,620,557
Variable operating cost (VOC)	50,928,699	38,129,049	42,443,363
Raw material (RM)	11,892,086	11,481,053	11,059,361
COG	7,902,695	7,902,695	7,902,695
CO ₂	3,761,020	3,501,092	2,916,526
Process water	228,371	77,266	240,140
Utility (UT)	39,036,614	26,647,996	31,384,002
Cooling water	3,580,254	2,090,380	3,175,849
Electricity	6,358,806	6,109,776	4,141,934
Fired heat	20,820,159	13,048,426	21,369,119
High-pressure steam	0	2,192,372	1,136,703
Low-pressure steam	1,473,290	0	0
Refrigeration	6,804,105	3,207,042	1,560,397
Fixed operating cost (FOC)	5,349,187	4,171,278	3,177,194
Total production cost (M\$/year)	72,446,927	57,849,272	68,487,058
<i>Main Product</i>			
	<i>MeOH</i>	<i>DME</i>	<i>FT fuel</i>
Capacity (kg/y)	158,341,168	114,267,039	50,633,972
UPC (\$/kg)	0.46	0.51	1.35
Capacity (GGE/y)	30,946,586	30,125,292	19,160,394
UPC (\$/GGE)	2.34	1.92	3.57

Figure 2 presents the cost breakdown of the three fuel production plants with CAPEX, raw material cost, utility cost, and fixed operating cost. The lowest UPC of the DME production plant is primarily due to the lower utility cost which is the dominant component at around 45% over the others. Then, CAPEX is the second largest factor with 27-33% of UPC, followed by raw material cost at 16-20%. There are opportunities to lowering UPC of fuel with lower utility and raw material cost. Since COG feedstock is one of industrial residue gases, it is potential to receive incentive at zero cost.

3.3. Net CO_{2eq} emission

Table 3. Environmental performance of COG-to-fuels

	COG-to-MeOH	COG-to-DME	COG-to-FT
Feed inventory (kgCO _{2eq} /kg _{fuel})	0.72	0.93	1.77
Indirect CO _{2eq} emission (kgCO _{2eq} /kg _{fuel})	2.49	2.03	5.12
Direct CO _{2eq} emission (kgCO _{2eq} /kg _{fuel})	0.01	0.09	0.05
NCE (kgCO_{2eq}/kg_{fuel})	1.78	1.19	3.40

The net CO_{2eq} emission estimated to one unit of fuels as presented in Table 3. The indirect emission is the largest contribution to NCEs, which corresponds to the high consumption of utility in the processes. COG-to-DME process emits lower CO_{2eq} during its operation over COG-to-MeOH and COG-to-FT.

4. Conclusions

This study proposed new residue gas upcycling processes, and evaluated the technical, economic and environmental capability for the MeOH, DME, and FT fuel production. The COG-to-DME process achieved the highest technical metrics at 88% carbon efficiency, 78% of energy efficiency with the lowest cost at 1.92 \$/GGE, and the best environmental performance with NCE at 1.19 score. In addition, the major cost- and energy-drivers of COG-to-fuels was identified through the techno-economic evaluation. The strategy to lower utility cost and residue gas price is very helpful to achieve improved economic benefits of COG-to-fuels processes. As a future work, the sensitivity analysis using various scenarios, such as different market prices and CO₂ tax, can be performed to determine the debottleneck strategies.

Multi-Objective Optimization of Lignocellulosic Ethanol Production Based on Regional Land and Water Availability

Rashi Dhanraj^a, Varun Punnathanam^a, Yogendra Shastri^{a,*}
^a*Indian Institute of Technology Bombay, Mumbai 400076, India*
yshastri@che.iitb.ac.in

Abstract

The production design for lignocellulosic biofuels should incorporate both environmental and economic objective. This work suggests a multi-objective optimization model design for ethanol production, which includes the economic goal balanced by limited regional land and water availability. The allocation of agricultural land to selected crops is the key decision variable. The model has four objectives, namely, minimization of ethanol cost, minimization of the water footprint of ethanol, minimization of irrigation water and maximization of farmers' profit. The resulting multi-objective mixed-integer linear programming problem was applied to a case study of 33 districts in Maharashtra, India. Results indicated a significant trade-off between ethanol cost and irrigation water requirement. Sorghum, wheat, and cotton were the prominent crops recommended by the model. Ethanol cost varied from ₹ 47/L (\$0.63/L) to ₹ 81/L (\$ 1.10/L), while water footprint varied from 674 L/L to 301 L/L, irrigation water varied from 43 m³/ha to 2768 m³/ha, and farmers' profit from ₹ 21059/ha (\$ 281/ha) to ₹ 4,770 /ha (\$ 64.51/ha).

Keywords: Optimization, lignocellulosic biofuels, land availability, water availability.

1. Introduction

The annual surplus agricultural residue produce in India is approximately 234.5 million Mg (Hiloidhari et al., 2014). The potential in India to produce lignocellulosic bio-fuels by using agricultural residue has been studied in context with socio-economic impact (Purohit and Dhar, 2018). The studies of lignocellulosic biofuel were further extended to include environmental impact. Formulation of multi-objective optimization problems gives a better understanding of the trade-off between environmental and economic impact (Mandade and Shastri, 2019). The agricultural phase in the life cycle of biofuel is an important phase in land use and water footprint. The land and water resource availability are limited, thus incorporating them in the life cycle assessment of bio-fuel production could give better understanding of the long-term sustainability of bio-fuel production. However, the water footprint of agricultural residue does not give the actual water withdrawal in the region; similarly, the economic interest of bio-refinery is not enough. Thus, water consumed by crops and the economic interest of farmers has to be considered in agricultural planning. This work formulates a mixed-integer linear programming (MILP) problem considering four objectives and regional water availability constraints. The four objectives of the model are based on the factors mentioned above. The bio-refinery model considered in this work was developed earlier in the literature (Punnathanam and Shastri, 2020), and has been modified so that the model would suggest an optimum agricultural pattern. Water consumed at the

biorefinery is negligible compared to water consumed during the agricultural phase, and thus has been neglected. The article is arranged as follows. The second section details the optimization problem formulation. The third section describes the case study, followed by results and discussion in Section 4, and conclusion in Section 5.

2. Modeling framework

The scope of the model has been represented in the schematics in Figure 1. The model considers the balance between water consumed by crops and the regional availability of water during different seasons, as well as the economic aspect of ethanol production and agriculture. The time period is 1 year, and the water availability varies with the season; thus, the time period was divided into three seasons: kharif, rabi and zaid (summer) season. The constraints of the model are bio-fuel demand, and regional availability of land and water resources. These constraints are discussed in detail later. Rainfall and groundwater were the only sources of water considered in the model, while surface water was excluded.

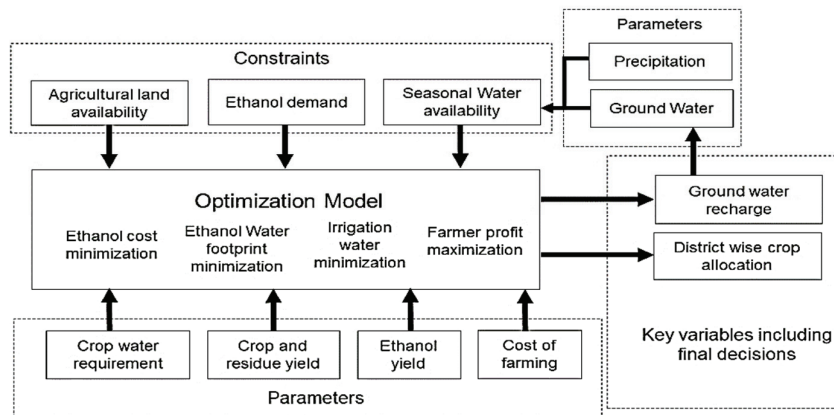

Figure 1: Schematics representing the scope of the model.

The water balance was done at district level (equivalent to a county). The crop water requirement (CWR) was calculated before the formulation of the model. CROPWAT 8.0, model developed by FAO (Clarke et al., 2000) was used for calculation of CWR. Rain is the primary source of water for crops, in case the rainwater is not sufficient irrigation is used to meet the water requirement. The part of rainfall consumed by crops is effective rainfall, rest of the rainwater either percolates deep in the ground or flows away as runoff (Allen, R. G. et al., 1998). The groundwater is replenished every year through rainfall and seepage to the canal, reservoir and dams. The groundwater recharged through sources other than rainwater was considered constant in the model. Data on soil moisture, runoff and groundwater recharge was obtained from the WaterBalance app developed by PoCRA moisture (Wankhade et al., 2019). It was assumed that the groundwater recharge water from one district doesn't flow to another district. Recharge from agricultural land was the only recharge considered in this work. The data generated for crop water requirement from CROPWAT 8.0 and groundwater recharge data from Waterbalance was used in the optimization model. The optimization model formulation is depicted in Subsection 2.1.

2.1 Optimization model formulation

The mixed-integer linear programming problem was formulated to solve the multi-objective optimization problem in General Algebraic Modelling System (GAMS) version 24.9.2 and solved using the CPLEX® MILP solver (Robichaud, 2010). This section discusses the constraints, decision variable and the objective functions of the model.

2.1.1 Constraints and decision variable

The primary decision variable in this model is $x(i, j, k)$, which the agricultural land is allocated to crops. Here index i , j , and k denotes the location of farm, crops and season, respectively. The first constraint in the model is ethanol demand. The ethanol demand is calculated by multiplying population of the region under study with per capita petrol consumption and the percentage blending of petrol with ethanol. The amount of agricultural residue converted to ethanol is denoted by $Re s_b(j, k, l)$, where index l indicates the location of bio-refinery.

$$E_D(k, l) = \sum_j Re s_b(j, k, l) \times x(i, j, k) \times E_c(j) \quad (1)$$

Here, $E_D(k, l)$ is the ethanol demand in of a bio-refinery at the location l , during the season k . $E_c(j)$ is the volume (L) of ethanol produced per unit mass (t) of feedstock. The constraint on land allocation is formulated as follows:

$$\sum_j x(i, j, k) \leq A_L(i, k) \times A_p(i, k) \forall i, k \quad (2)$$

Here, $A_L(i, k)$ is agricultural land available in the district i during the season k . The agricultural land available in a district is used for growing vegetables and fruits as well. Thus, $A_p(i, k)$ the is introduce in the equation. $A_p(i, k)$ Is fraction of total agricultural land allocated to crops. The water availability varies with the season, so does the water demand as crops are planted in different seasons and have different growth period. To capture this trend, water balance is done for different seasons. The water balance during kharif season is as follows:

$$\sum_j ER(i, j, k_n) \times x(i, j, k_n) \leq \{R(i, k_n)(1 - \delta)\} - \sum_j GWR(i, j, k_n) \times x(i, j, k_n) \quad (3)$$

Here, $ER(i, j, k_n)$ is the rainwater consumed by crop j in the district i during the kharif season (k_n), the subscript n denotes kharif. The rainwater is represented by $R(i, k_n)$, here δ represents the fraction of runoff, while $GWR(i, j, k_n)$ is the groundwater recharge. The groundwater balance is shown in Eq. (4)

$$\sum_j IR(i, j, k_n) \times x(i, j, k_n) \leq GW(i, k_n) + N(i, k_s) \quad (4)$$

Here, $IR(i, j, k_n)$, is irrigation water required by crops during the kharif season, $GW(i, k_n)$, is the groundwater available is kharif season. The groundwater which was not used during the kharif season and the groundwater recharge were passed down to the consecutive season. Here, $N(i, k_s)$ represents the water passed down from season before kharif season. Similarly, water balance is done for rabi and zaid seasons.

2.1.2. Multi-Objective optimization

There are four objectives in this multi-objective optimization model. The first objective is minimization of ethanol cost, and is formulated as follows:

$$\text{Min } J_C = \sum_{i,j,k} C_E(i, j, k) \quad (5)$$

Here, $C_E(i, j, k)$ is the cost of ethanol production. Cost of ethanol includes the cost of residue, cost of transport, cost of ethanol production process and storage cost. The objective of maximization of profit earned by farmers is formulated as follows.

$$\text{Max } J_P = \sum_{i,j,k} P_F(i, j, k) \quad (6)$$

The profit earned by farmers $P_F(i, j, k)$ the difference between the price of agricultural product and residue to the cost of cultivation. The third objective, minimization of water footprint of ethanol, is formulated as follow:

$$\text{Min } J_{WF} = \sum_{i,j,k} WF_R(i, j, k) \quad (7)$$

Here, $WF_R(i, j, k)$ is the water footprint of ethanol produced from different agricultural residue. The fourth objective, minimization of irrigation water consumption is formulated as follows:

$$\text{Min } J_{IR} = \sum_{i,j,k} IR(i, j, k) \times x(i, j, k) \quad (8)$$

Here, $IR(i, j, k)$ is the irrigation water required by the crop j in m^3/ha , which is multiplied by land allocated to the crop. The multi-objective optimization was solved using the ε -constraint method. In this method except for one objective function, all the objective functions are formulated as constraints, as shown in Eq. (9).

$$\begin{aligned} & \text{Min } J_C \\ \text{Subject to } & J_P \geq \varepsilon_1 \\ & J_{WF} \leq \varepsilon_2 \\ & J_{IR} \leq \varepsilon_3 \end{aligned} \quad (9)$$

Here, ε_1 , ε_2 , and ε_3 are the bound set on various objective functions. This single objective optimization problem is solved for various combinations of these bounds to obtain the trade-offs between different objective functions.

3. Case study of Maharashtra, India

The model was applied to the 33 districts of Maharashtra state (Mumbai city, Mumbai Suburban and Palghar districts were excluded from the study). The Maharashtra state has intensive water demand from the agricultural sector and suffers from water scarcity (Aayog et al., 2017). The crops chosen for the study were sugarcane, wheat, rice, cotton, and sorghum. The groundwater recharge data for the Solapur district was calibrated for different crops. Based on the data for the Solapur district, the correlation between rainfall and groundwater recharge was obtained using the linear regression method. This correlation was used for all districts. Results are discussed in Section 4.

4. Result and discussion

The model was run for each single-objective optimization followed by multi-objective optimization. For each single-objective optimization run, the number of constraints is 37,894, variables are 37,063, and the binary variables are 33. The values of the water footprint of biofuel, farmer's profit and irrigation water obtained from single-objective optimization runs was used to obtain the 20 values of ε_1 , ε_2 , and ε_3 . Thus, 8,000 independent single-objective optimization problems are solved to get the Pareto-front of multi-objective optimization. In order to make it easy to understand the results of the multi-objective optimization, the trade-off between irrigation water requirement and farmer's profit was explained at water footprint bound to various values. The model gave feasible solution for water footprints ranging from 674.28 to 398.24 L/L.

Figure 2. Plots of trade-offs between irrigation water utilization, farmers' profit and ethanol cost when water footprint ≤ 674.28 L/L

In this paper, we had discussed the Pareto-front when water footprint was bound to 674.28 L/L, as shown in Figure 2. The irrigation water was minimum at point A1, farmer's profit was maximum at point A2, and the ethanol cost was minimum at A3.

When the irrigation water requirement was minimum, 17% and 12% more land was allocated to sorghum than what was allocated when the farmer's profit was maximum and the ethanol cost was minimum, respectively. The profit earned by farmers depends on several factors such as the cost of cultivation, the price of the main product, as well as the price of residue. Wheat stalk and sorghum grain have relatively high prices, and thus wheat and sorghum accounted for about 28% and 47% of the total agricultural land utilized at point A2. The land was allocated to cotton to minimize the ethanol cost, but the cotton stalk is not enough to meet ethanol demand; thus, wheat stalk and sorghum stalk are used in the biorefinery. Wheat stalk reduces ethanol cost, while sorghum allows groundwater recharge, which passes down to the consecutive season, thus providing water for wheat production.

5. Conclusion

Amongst all the crops model showed favourability towards sorghum, stress on groundwater was less, also, ethanol yield and cost of sorghum stalk are moderate. The incorporation of regional water and land resource availability gave a better understanding of energy and water nexus. The model showed economic benefits earned by farmers comes at the cost of water stress in the region; thus, a balance has to be created between the two. The challenges associated with land allocation could further be studied by including flow across the district and surface water in the model.

Abstract

Around the world, 70% of the NG gasification volume of LNG regasification terminal is processed through ORV. First principle-based modeling studies have been conducted to improve the heat exchange efficiency and optimize the operation, but ORV is equipment in which the heat transfer coefficient is irregular according to time and space, and it undergoes a complex modeling process. In this study, FNN, LSTM, and AutoML-based modeling that predicts dynamic changes in NG and seawater discharged temperatures according to changing operating condition in ORV using actual operation data were performed to confirm the effectiveness of data-based modeling for complex systems. The MSE-based prediction accuracy was insignificant between LSTM and AutoML, and FNN showed twice the error in prediction. The performance of AutoML was superior to the manually developed FNN, and the training time took 27 times longer than the LSTM, but the total time required for model development was 1/25, which demonstrates the possibility of automated model design using AutoML, without manual intervention. The prediction of the NG and seawater discharge temperatures using LSTM and AutoML showed an error of less than 0.5K. The real-time optimization of the amount of LNG vaporization that can be processed through ORV in winter is performed with the LSTM model. It is possible to additionally process 19.7% of LNG compared to the previous operation, and by the effect of reducing operation cost, it is suggested that the optimal operation guideline of ORV can be provided using the developed dynamic prediction model.

Keywords: Machine learning, dynamic modeling, operations decision support, AutoML.

1. Introduction

The open rack vaporizer (ORV) of the LNG regasification process uses seawater as a heat source and is the most widely used due to its advantages such as low operating cost, ease of maintenance, and safety. In winter, however, when seawater temperature is below 5°C, which is the minimum requirement for ORV operation, a submerged combustion vaporizer (SCV) with a high operating cost is used to achieve the target NG production. If real-time optimization for more amount of LNG that can be vaporized through ORV in winter is possible, it reduces process operating cost by minimizing the use of SCV.

First principle-based modeling studies have been performed to improve the heat exchange efficiency of ORV and optimize the operating parameters. Wang et al. (2013) and Jin et al. (2014) performed heat exchange modeling reflecting the icing phenomenon of the tube

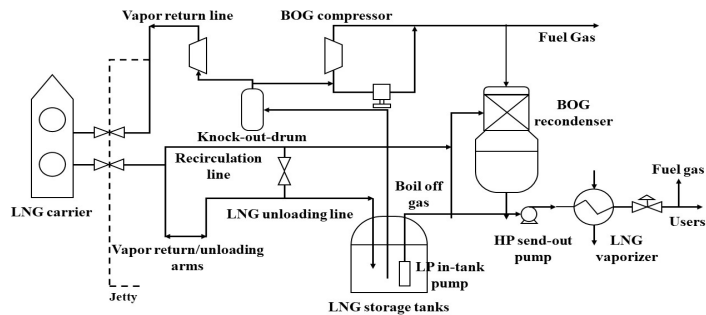

Figure 1. Onshore LNG regasification process (adapted from D'alessandro et al. 2016).

surface to present Super ORV design standards. Cheng et al. (2019) modeled the heat exchange phenomena to present the criteria for ORV design and analyzed the effect of operating parameters. However, first principle-based heat exchange modeling in ORV experiences a complex process because of the phenomenon of freezing seawater on the tube surface by -160°C LNG flowing and forming an irregular film on the tube surface, resulting in irregular heat transfer coefficients according to time and location.

In the case of a complex system, the first principle model contains many number of equations for high accuracy, which makes it tough to predict promptly and accurately. However, an artificial neural network, which reflects nonlinearity and has a low computational load, with the desired level of accuracy (Singh et al. 2013).

In this study, we developed a prediction model based on Feed-forward neural network (FNN), Long short-term memory (LSTM), and AutoML that predicts dynamic changes in NG and seawater discharge temperatures using actual operation data. The purpose of this study is to evaluate the feasibility of selecting an algorithm suitable for processing time series data by comparing the performance, including AutoML, automatically generating an optimal machine learning model for field engineers who are non-data science experts. Through real-time optimization of more amount of LNG vaporization that can be processed with ORV based on the suggested predictive model, especially for winter when the minimum operating conditions of ORV are not satisfied, we evaluate the applicability of the dynamic prediction model to reduce the operating cost of the LNG regasification process and provide operations decision support.

Table 1. Dynamic modeling results of FNN, LSTM and AutoML.

	Number of datasets	Network structure (L: LSTM layer, B: batch normalization layer)	Number of parameters	Test MSE	Training time (s)
FNN	1	320(input)-30-B-30-B-10(output)	10,990	0.000315	117
	2	320(input)-30-B-30-B-10(output)	10,990	0.000485	109

	Average			0.000207	290
AutoML	5	320(input)-256-32-64-10(output)	93,803	0.000253	7,918

2. LNG Regasification Process

Onshore LNG regasification process is a process of producing and supplying NG, the final product, by receiving LNG from an LNG carrier and storing it in a cryogenic liquid state and then vaporizing LNG through a vaporizer. Figure 1 is a diagram of the LNG regasification process. Various dynamic modelings of the widely used ORV based on artificial neural networks are performed during this research.

3. Dynamic Modeling Using ANN

3.1. LNG Regasification Process Dataset

Real operation data were obtained for the LNG regasification process. A prediction model was constructed using a data set with a total of eight features, such as seawater flow rate, LNG flow rate, incoming seawater temperature, discharge seawater temperature, LNG temperature, NG temperature, seawater pressure, and NG pressure.

3.2. Data Preprocessing

As data preprocessing, Min-Max normalization was performed to obtain the effect of reducing the prediction error and training time, and for the objective performance evaluation of the developed model, the entire data set was applied k-fold cross validation, a method of repeating training and validation by dividing into k of the same size. In this study, model training and validation were repeated 5 times (k=5).

3.3. Dynamic Modeling

The proposed ORV dynamics prediction model consists of 8 input variables and 2 output variables. Using process data in 40 time steps, from the past (t=-39) to the present (t=0), a model was designed to predict the dynamic changes of the future 5 time steps (t=1,...,5) of the discharge NG and seawater temperatures, which are constrained by environmental and process factors, according to changes in ORV seawater flow rate, seawater temperature, and LNG flow rate.

A network was constructed using Pytorch 1.5.0, and data were trained using GPGPU processors. FNN, LSTM and AutoML were applied, and the optimal values of the hyperparameters were determined using grid search method, which is the process of searching through a manually specified subset.

3.4. Deep Neural Network Modeling

To find the optimal network structure of the FNN, the initial structure was set as epoch=500, batch size=250, learning rate=0.1, and number of neurons=100. The optimal values were determined in the order of the number of hidden layers, the number of neurons in each layer, batch size, learning rate, and epoch. For LSTM, the initial structure was set to epoch=300, batch size=250, learning rate=0.1, hidden dimension=10, and number of neurons=50. The optimal values were determined in the order of the number

Figure 2. Model performance of FNN, LSTM and AutoML.

Figure 3. MSE according to the output sequence

Figure 4. Prediction results of (a) FNN, (b) LSTM and (c) AutoML.

of LSTM layers, hidden dimension, number of neurons, batch size, learning rate, and epoch. Table 1 shows the results of FNN and LSTM modeling for five datasets.

3.5. AutoML

Automatic design of a machine learning model using AutoML was performed. An automatic model generated by using the AutoKeras Python library (developed by Texas A&M University) has 3 hidden layers, and the total number of neurons is 352 (256-32-64), which is about 6 times more than the previous FNN model. Since the process of finding the optimal structure by Bayesian optimization is included, the training required 7918 seconds, which is 27 times longer than LSTM, but the test MSE showed better performance than the FNN with 0.000253. Table 1 shows the proposed structure by AutoML.

4. Performance of Dynamic Prediction Models

4.1. Model Performance Comparison

For the performance evaluation of the optimal FNN, LSTM and, AutoML, the test MSEs were compared. In the case of FNN, the average MSE was 0.000400, for LSTM, 0.000207, for AutoML, 0.000253. Figure 2 shows the model performances of FNN, LSTM and, AutoML. Figure 3 shows the prediction performance according to the future time step: LSTM performs the best with the lowest error in all predictions, more suitable for predicting process time series data. The performance of AutoML was superior compared to the FNN model, and especially the total development time was reduced to 1/25 compared to the LSTM model with a complex structure that required more than a week of work. Development of predictive models using AutoML only required domain knowledge at the level that can be designed by field engineers and shows similar performance to models designed by experts, thus the model development using AutoML was concluded as applicable.

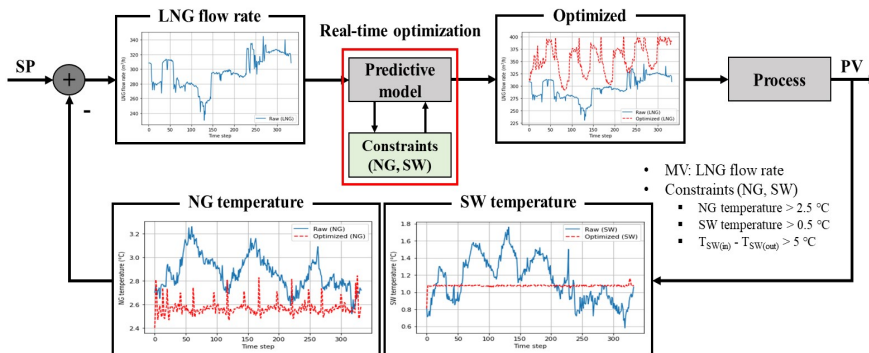

Figure 5. Result for real-time optimization of LNG flow rate.

4.2. Prediction Results

The real operation data were applied to the FNN, LSTM, and AutoML models to compare the prediction results. Figure 4 shows the prediction results for time step 2400 to 3100. FNN showed an error of 0-2.5K, LSTM of 0-0.42K, and AutoML of 0-0.38K. The prediction error of FNN was small, but it did not reflect the trend of the actual data. The model proposed through LSTM and AutoML well reflected the trend of actual data; and data-based modeling was outstanding for complex systems, which is smaller than the prediction error (0-6K) of the first principle-based ORV model proposed by Su et al. (2014).

5. Application of Developed Dynamic Model

5.1. Real-time Optimization

To present a guide for manual operation, especially for winter, the maximum amount of LNG that can be vaporized through ORV is calculated in real-time while effectively satisfying the constraints, to confirm the effect of reducing operating cost using the predictive model. The real-time optimization of the amount of LNG that can be processed through ORV was performed by the following equations.

$$\max \quad L(x) = \left(\sum_{i=0}^n x_i \right) / n \quad (1)$$

$$\text{s.t.} \quad F_{NN(NG)}(x_i) \geq 2 \quad (2)$$

$$F_{NN(sw)}(x_i) \geq 0.5 \quad (3)$$

$$T_{sw(in)} - F_{NV(NG)}(x_i) \leq 5 \quad (4)$$

$$0 \leq x_i \leq 450 \quad (5)$$

where x_i is the LNG flow rate in ORV at the time i , n is the total operating time, T_{sw} is seawater temperature, $F(x)$ is the output value of the prediction model.

The objective function, Eq. (1), is to maximize the average flow rate of LNG while satisfying all the constraints. The discharged NG temperature should always be higher than 1°C, which is the design condition of ORV. In the case of discharged seawater that is released to the sea after use, a constraint on the temperature difference between intake and drainage is enforced due to the influence of the marine ecosystem. For constraints, Eqs. (2)-(5), the discharged NG temperature was set to higher than 2°C, and the discharged seawater temperature and the temperature difference were set to more than 0.5°C, below 5°C.

5.2. Scenario: Reduction in LNG flow rate under 5°C of seawater

When the temperature of seawater decreases, the current (table-based) operation method excessively decreases the LNG flow rate to satisfy the constraints, as a result, the NG and seawater discharge temperatures rapidly increase. By performing real-time optimization through the LSTM model, it was intended to prevent a rapid rise in the discharged temperatures of NG and seawater and to avoid excessive LNG flow rate reduction. Figure 5 shows the results of real-time optimization. The LNG flow rate that can be processed through ORV increased by 19.7% per hour from the previous average of 296.62 to 355.19 m³/h. It vaporizes 24 tons of additional LNG per hour; operation cost of \$216 per hour can be reduced by maximizing the use of ORV instead of SCV usage.

6. Conclusions

To overcome the weaknesses of first principle modeling of ORV, complicated and requiring a lot of time, we developed a prediction model based on FNN, LSTM, and AutoML using real operation data. The test MSE of the LSTM model showed the best performance of 0.000207, and the AutoML-based model of 0.000253, which was higher than the FNN model of 0.0004. Besides the process of finding the optimal model through Bayesian optimization, it took 7918.42 seconds to train, but when comparing the time taken to manually develop the entire model with the LSTM through the complex modeling process, the whole design time demand was greatly reduced to 1/25. AutoML-based modeling requires domain knowledge only at the level of field engineers and shows similar performance to the models developed by experts, proposing that AutoML is effective in practical application.

In the actual data prediction, the FNN showed an error of less than 3K. The LSTM and AutoML models indicate high accuracy with an error of less than 0.5K, and the data-based model showed superior prediction accuracy compared to the first principle-based model. The LSTM model with high accuracy was used to predict the maximum amount of LNG vaporization in real-time within the range that satisfies the constraints of the NG and seawater discharge temperatures in winter. By real-time optimization of the LNG flow rate in ORV, it improved by 19.7%, and operating cost of \$216 per hour can be reduced by decreasing the SCV usage. Accordingly, by recommending the maximum LNG flow rate in real-time, the possibility of supporting the operations decision using the predictive models was validated.

Abstract

The increasing energy demand for mobility services and the growing concern about global warming have become significant drivers for these services' decarbonisation. In this regard, the production and use of fuels obtained from just water, air and renewable energies instead of conventional fossil fuels have caught much attention within the research community. Recently, nitrogen-based e-fuels have been praised for their potential to satisfy mobility and transportation services with a reduced carbon footprint compared to their carbon-based analogues, given their carbon-neutral nature. To evaluate this hypothesis, we conducted a location-based, techno-economic and cradle-to-grave environmental assessment for solar methanol (MeOH) and ammonia (NH₃) based on an optimisation model. Methanol and ammonia were considered for this study due to their relative ease of manufacture and lower production costs than complex fuels, *e.g.*, FT-fuels, and the growing interest in using them as transportation fuels. From this analysis, we concluded that ammonia could have similar production costs, *ca.*, 300 USD/GJ, but better environmental performance than methanol regarding global warming potential (GWP) and the three endpoint impact categories of the ReciPe 2016 LCA damage model, *i.e.*, human health, ecosystems and resources. These results are highly dependent on the hydrogen storage options available; their costs and carbon footprints.

Keywords: e-fuels, techno-economic assessment, life-cycle assessment, optimisation, carbon and nitrogen-based fuels

1. Introduction

The non-renewable nature of fossil fuels and the increasing demand for energy services, especially for power generation, heating, transportation, and rural energy services, have contributed to the depletion of oil reserves and global warming and its underlying effects. Recent studies (Dominković *et al.*, 2018; Brynolf *et al.*, 2018) affirm that the transport sector accounts for more than 20% of worldwide greenhouse gas emissions mainly due to the consumption of petroleum-derived fuels. Given the importance of sustainably meeting current and future demand for mobility services, recent research has focused on solutions that promote renewables' increasing utilisation. In this regard, e-fuels, *i.e.*, fuels produced from carbon (Brynolf *et al.*, 2018) or nitrogen (Ganzer and Mac Dowell, 2020) feedstocks, and "green" hydrogen, emerge as promising alternatives to tackle the environmental problems associated to the use of fossil fuels. As global warming is a

leading environmental concern, the study of carbon-based e-fuels has been prioritised owing to the possibility of employing atmospheric CO₂ as carbon feedstock. However, the potential of nitrogen-based e-fuels in deep decarbonisation scenarios may have been underestimated, given the carbon-neutral nature of these kinds of fuels. In this context, we conduct a thorough techno-economic and environmental evaluation of carbon and nitrogen-based e-fuels aimed at decarbonising the road transportation sector. Our assessment framework includes a broad range of tools, including process modelling and optimisation, heat integration, net production cost (NPC) calculation and cradle-to-grave LCAs. This framework was applied for the continuous production of MeOH and NH₃ in London, considering the hourly-based solar radiation of 2018, and targeting the same amount of energy output from both e-fuels. Based on the model results, we found that the production and utilisation of MeOH as fuel would have less environmental impacts than NH₃, even though their production costs are approximately the same. However, when we neglected the environmental impacts associated with the H₂ storage, *i.e.*, composite tanks, it was noted that NH₃ performed better than MeOH in all the environmental impact categories assessed. Summing up, we have shown the importance of including a detailed assessment of the intermittency of renewable energies and the corresponding energy storage means when evaluating the economic and environmental performance of e-fuels, which is often underestimated in this kind of studies.

2. Methodology

2.1. Model description

To evaluate the production of e-methanol (MeOH) and e-ammonia (NH₃), we followed the framework proposed by Ganzer and Mac Dowell (2020). This model takes the fluctuating nature of solar energy into account and allows determining the minimum net production cost (NPC) of the e-fuels based on optimal production routes, equipment sizing, heat integration and energy storage levels of chemicals and electricity. The implementation and solution of this MILP model were made via GAMS 32.1.0 with CPLEX 12.10.0.0 as the solver. We run this model for London with the hourly-based PV capacity factors taken from renewables.ninja for 2018.

2.2. Economic assessment

For the economic assessment, the total cost only includes the CAPEX of the processes and the storage options given that the cost of utilities, *i.e.*, heating, cooling and electricity, raw materials, *i.e.*, solar radiation, water and air, and labour costs could be considered negligible based on this model approach. The NPCs of the e-fuels were estimated considering the working capital to be 10% of the total capital investment (TCI); an interest rate of 10%, a plant lifetime of 20 years and an annual operation of 8600 h.

2.3. Environmental assessment

The environmental assessment was implemented in Simapro v9.0 interfacing with Ecoinvent 3.5, based on a cradle-to-grave approach and the life cycle impact model ReCiPe 2016, as described in a previous publication (Freire Ordóñez and Guillén-Gosálbez, 2020). The foreground system's LCA inventories were obtained from the model of Ganzer and Mac Dowell (2020) while the background data, *i.e.*, subprocesses involved in the provision of raw materials and utilities to the main processes, was retrieved from Ecoinvent. The composite tanks required to store H₂ were modelled based on the work of Benitez, *et al.* (2021), the Li-ion (LFP) batteries for the electricity storage according to (Majeau-Bettez *et al.*, 2011), and the utilisation-phase emissions of both e-fuels based on the study of (Al-Breiki and Bicer, 2021).

3. Results and Discussion

The optimal production routes for the given conditions are shown in Fig. 1 and Fig. 2.

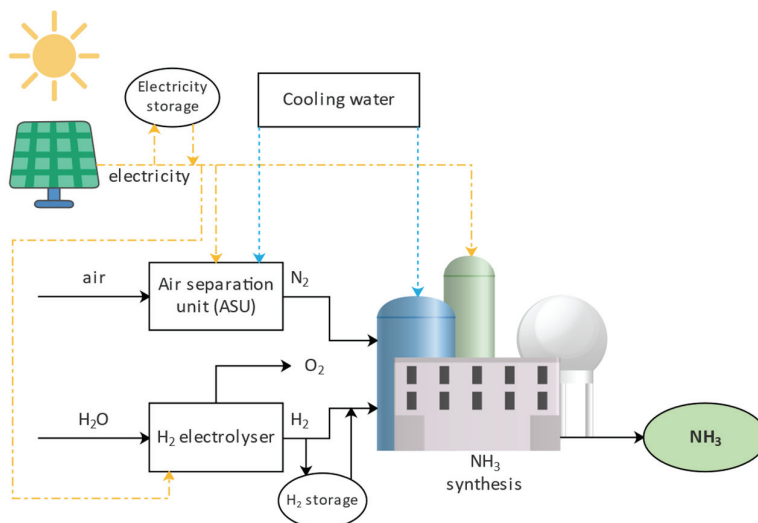

Fig. 1. NH₃ production process from solar electrolytic H₂ and N₂ from air separation. Only a cooling utility, *i.e.*, cooling water, is required after heat integration

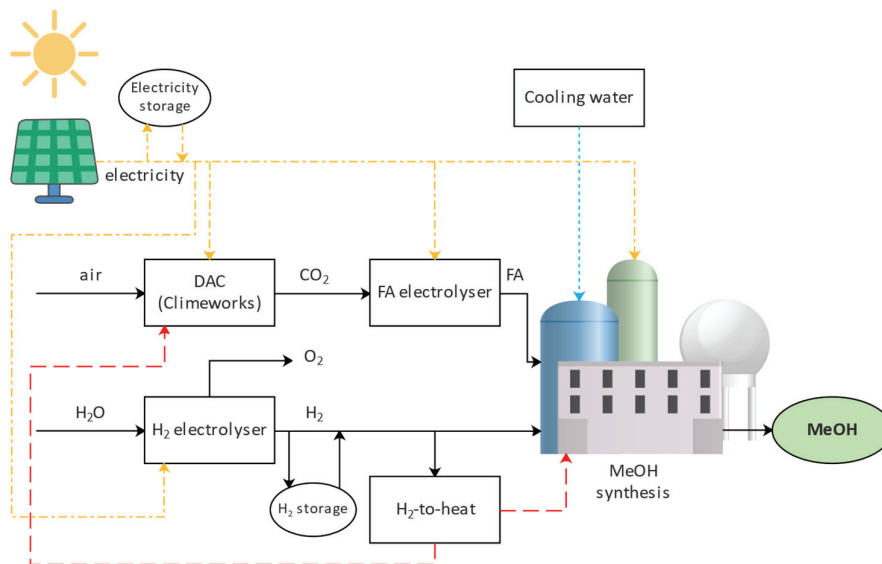

Fig. 2. MeOH production process from solar electrolytic H₂ and CO₂ from direct air capture (DAC) using the Climeworks technology. This production route includes the electrocatalytic reduction of CO₂ to formic acid (FA). A heating utility, *i.e.*, H₂-to-heat, and a cooling utility, *i.e.*, cooling water, are required after heat integration.

Fig. 3. NPC of the studied e-fuels, including all process and storage equipment required for the continuous operation of the chemical plant, compared with fossil petrol (BAU) + bio-energy with carbon capture and storage (BECCS) (Natural Resources Canada, 2014; Drax Group plc, 2020). Neither duty rate nor VAT is included in the given figure for fossil petrol. BECCS is regarded at the moment as the most mature carbon removal technology (IEA, 2020)

Fig. 3 shows the cost breakdown of the production routes of each e-fuel, while the required sizes of each subprocess are detailed in Table 1. It can be seen that both e-fuels have similar NPCs on an energy basis, *ca.*, 300 USD/GJ, and that the major contributors to the production costs are the solar PV and the H₂ storage processes. A large storage capacity for H₂ is required to guarantee the chemical plants' continuous operation due to the low level of solar radiation in London compared to other regions. Therefore, it is advisable to explore different energy alternatives, *e.g.*, wind power, depending on the production plants' location. It can be seen that, currently, the NPC of the studied e-fuels is approximately 30-fold higher than that of the BAU, when they are compared under the same cost basis, *i.e.*, excluding any taxes, tariffs or fees, added after the production stage. If direct offsetting of petrol CO₂ emissions via BECCS is considered, the NPC difference between the e-fuels and BAU would be about 20 fold.

Table 1. Process design required for the continuous operation of the chemical plant

Process	NH ₃	MeOH
PV [GW]	2.24	2.19
Battery storage [MWh]	40.43	204.85
H ₂ electrolyser [tonne-H ₂ /h]	17.60	17.92
H ₂ storage [tonne-H ₂]	4611.67	3077.11

Cooling water (MW)	18.14	16.36

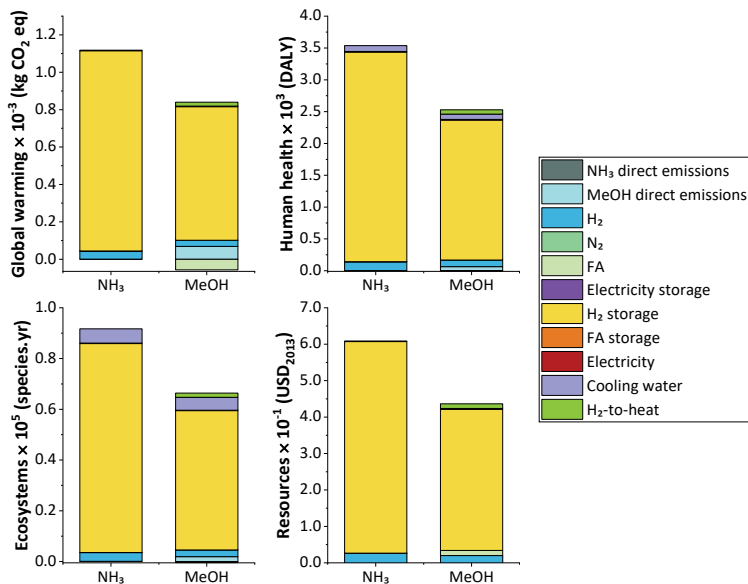

Fig. 4. ReCiPe 2016 LCIA per GJ of e-fuels: Cradle-to-grave results for GWP and endpoint impact categories, including environmental impacts and corresponding breakdowns.

As shown in **Fig. 4**, most environmental impacts come from H₂ storage. This is explained by the large storage capacity needed, and the complexity and energy-intensive nature of the processes required to manufacture carbon fibre. This fibre is the main component of the composite tanks used to store H₂ gas (Benitez *et al.*, 2021). Nevertheless, the production and utilisation of NH₃ might be a viable alternative over MeOH, if the costs and environmental impacts of H₂ storage are minimum or negligible (see **Fig. 5**), *e.g.*, if H₂ is stored in salt caverns (Sørensen and Spazzafumo, 2018).

Fig. 5. ReCiPe 2016 LCIA per GJ of e-fuels: Cradle-to-grave results for GWP and endpoint impact categories, when the environmental impacts of H₂ storage in composite tanks are omitted.

4. Conclusion

In this work, we have performed a comparative techno-economic and environmental assessment of two representative carbon and nitrogen-based e-fuels, *i.e.*, MeOH and NH₃, to evaluate the hypothesis that the production and utilisation of carbon-containing e-fuels have a higher carbon footprint than their nitrogen-based analogues when delivering the same amount of energy output. This hypothesis was proven to be not always correct since the production costs and environmental burdens associated with the e-fuels strongly depend on the steady-state plant's location, which has a marked effect on the design capacity of the storage means for chemicals and electricity. Based on our results for London in 2018, it was concluded that the composite tanks required to store H₂ for the continuous operation of the chemical plant were, in aggregate terms, major economic and environmental contributors of both solar e-fuels. This fact might not hold for other locations with different energy potentials. Furthermore, it was shown that conventional petrol is still substantially cheaper than both e-fuels, even when considering BECCS to offset its fossil CO₂ emissions. It means that significant cost reductions and technology improvements are still pending for e-fuels to be widely deployed.

This analysis demonstrated the importance of a location-based approach for this kind of studies and the need to keep investing in R&D to lower equipment costs and find alternative storage options that allow not only reducing the production costs but also the associated harmful impacts of e-fuels.

Techno-economic assessment of a renewable energy-based electric vehicle fast-charging station in Qatar

Abdulla Al Wahedi*, Yusuf Bicer

Division of Sustainable Development, College of Science and Engineering, Hamad Bin Khalifa University (HBKU), Education City, Doha 5825, Qatar

amalwahedi@hbku.edu.qa

Abstract

Electrical vehicles' (EV) deployment as an alternative eco-friendly transport solution has become a promising initiative worldwide to reduce greenhouse gas emissions and fossil fuel depletion. This fact triggers the need to roll out fast-charging stations to fulfill daily road charging demand. Securing the power requirement for those stations has become a significant challenge that would cause substantial load increase on the existing electricity generation system and distribution infrastructure if supplied from the conventional resources. Hence, grid-independent charging stations with renewable energy sources (RES) and multiple energy storage systems has become an alternative solution to overcome the raised challenge. This paper aims to assess the implementation of a stand-alone fast charging station technically and economically in the State of Qatar comprising of a wind turbine (WT), concentrated photovoltaic (CPV) system and a bio-generator as RES along with various storage systems. The proposed design is built, modelled, and simulated using Hybrid Optimization System for Electric Renewable (HOMER) software to determine the optimal techno-economic configuration to fast charge 50 EVs daily in a reliable manner. Predefined constraints such as space limitation, stochastic nature of EV demand, and site-specific metrological conditions are considered. Multiple sizing portfolios of incorporated subsystems are evaluated through simulation. Sensitivity analysis is used to evaluate the impact of selected decision variable values such as the WT height where the generated analytical results are compared from the technical and economic perspectives. The results show that a stand-alone micropower system consisting of 450 kW CPV, 250 kW WT with 60 m hub height, 100 kW bio generator, and 324 kWh batteries is the optimal configuration with minimal 2.378 million dollars net present cost (NPC), 0.284 \$/kWh cost of energy (COE) and 0.02 % unmet demand.

Keywords: Hydrogen, electrolyzer, fuel cell, clean energy, HOMER.

1. Introduction

The rising interest in clean energy and EV deployment increases the electricity demand to fulfil the associated charging power requirements causing generation fluctuations and grid tension in case it is supplied from the grid. Consequently, leading to political instability, economic variability, and environmental degradation in case conventional generation methods are used to supply the additional demand required. This made securing the needed power supply independently from the grid and based on renewable energies a global interest and motivation.

Many studies have investigated renewable energy utilization for power generation while others on electric mobility (Mazzeo, 2019). The combined research of employing stand-alone RES to supply electrical power for fast EV charging station has been insufficiently considered, and further research on grid-independent EV charging stations is required (Mehrjerdi, 2019).

In commitment to its long-term national sustainable development strategy, Qatar has embarked on the “Green Car Initiative” in 2017 (The Peninsula Qatar, 2017) to stimulate on the adoption of EVs to achieve 4 % share of its local share by 2020 (Qana, 2017). To fulfil EVs charging demand, it was declared that 400 EV charging stations would be accessible by the same year (Kumar, 2019).

Since the number of registered vehicles in Qatar in 2017 was 1.5 million and the average annual increase is 12 % (CEIC, 2019), the total number of vehicles will reach 2.7 million in 2022, out of which 100,000 shall be EVs. This fact raises the need to devise reliable nonhydrocarbon-based micropower systems to supply those charging stations with the necessary power without impacting or expanding the existing grid infrastructure.

2. Methodology

In this study, a micropower system which was designed and thermodynamically evaluated using Engineering Equation Solver (EES) program (Klein, 2018) in a previous study by the authors (Al Wahedi and Bicer, 2020a) is built using HOMER model from the National Renewable Energy Laboratory (NREL) (HOMER, 2018). The resources of the associated RES incorporated in the proposed design along with forecasted EV demand are modeled. Sensitivity analysis based on selected variables along with various parameters and sizing options for selected components are considered in the simulation process. HOMER Pro simulation and optimization results are analyzed thoroughly where multiple optimal configurations are investigated and compared to select the overall optimal design configuration and sizing based on predefined technical and economic decision criteria.

3. System description

Since Qatar is located in the Sun Belt region with plenty of annual solar irradiation, CPV solar system is selected as one of the two main RES for generating electricity. WT is selected as the second main RES since, based on the literature review the application of small to medium-size WTs is feasible to generate energy in Qatar (Moghbelli et al., 2011). Bio generator, electrolyzer, chemical storage tank, H₂ and NH₃ fuel cells (FC), DC/AC converter, and battery storage system (BSS) are the remaining components of the proposed stand-alone design.

Load-following (LF) and cycle-charging (CC) strategies are assessed for charging the incorporated BSS. In the former strategy, the battery system is charged by renewable sources but not by the incorporated bio generator. While in the latter strategy, the bio generator serves both the load and storage battery charging.

While H₂ is produced and stored in a tank on site, NH₃ is produced off site and stored in a tank on site in the proposed system.

The proposed design is built in HOMER and illustrated in Figure 1.

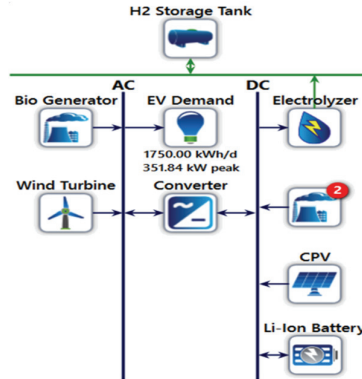

Figure 1: Proposed system configuration

Table 1 indicates the parameters to be investigated for each component in the design. Few components have predefined parameters, others have a range of parameters to be investigated, and others are determined by HOMER optimizer.

Table 1: Components and parameters investigated in the study

Component	Parameter	Remarks
CPV	450 kWp	Determined using PVSyst (PVsyst, 2018) software based on space limitation of 1,500 m ²
WT	250 kW	Determined considering space limitation and WT blade dimensions
H ₂ and NH ₃ FCs	50 kW / 100 kW	Both sizes are simulated for each FC
BSS and Converter	-	Calculated and selected by HOMER Optimizer
Bio Generator	50 kW, 100 kW and Auto size	Auto size is calculated and selected by HOMER Optimizer
Electrolyzer	50 kW / 100 kW	Both sizes are simulated
Chemical storage tank	50 kg / 100 kg	Both sizes are simulated
BSS charging strategy	LF / CC	Both strategies are simulated
WT Hub Height	40 m, 50 m, 60 m	Sensitivity analysis is carried out

4. Load profile and resources input modeling

Considering 20 % of the total EVs will need on-the-road fast charging service and the average energy required by each EV is about 35 kWh, the daily demand from a single charging station is estimated to be 1,750 kWh (Al Wahedi and Bicer, 2020b). The daily EV demand profile from the study (Bayram et al., 2016) is used here, after extrapolating the data using probability density function to represent 50 EVs daily demand. To model the demand more realistically, 10 % day-to-day and 20 % timestep randomness is added to the EV load data to represent 10 % daily variance and 20 % monthly variance. Figure 2 illustrates the daily and seasonal stochastic EV demand profile in HOMER.

Figure 2: EV demand generated by HOMER (a) daily and (b) seasonal

For the specific site selected in Qatar, the average monthly Solar Global Horizontal Irradiance (GHI), clearness index, and wind speed data are obtained from NASA Prediction of Worldwide Energy Resources (POWER) database included in HOMER Pro software, which is illustrated in Figure 3.

Figure 3: (a) Average monthly Solar GHI, clearness index, and (b) Wind speed at selected location in Qatar

The GHI data is for over 22 years from July 1983 to June 2005, and wind speed data is for over 30 years from January 1984 to December 2013 measured at 50 m height.

The economic analysis in HOMER is determined by assessing the life-cycle cost of a system, which is represented by calculating the NPC and COE of each configuration. Each component's costs within the project lifetime are reflected in Table 2 where electrolyzer and FCs costs are obtained from (Energy, 2015) and (Monterey Gardiner, 2014), respectively. Moreover, 5.7 % discount rate and 0.55 % inflation rate are used in this study (Bank, 2021).

Table 2: Life cycle cost of main components

Component	Capital Cost (\$)	Replacement Cost (\$)	O&M Cost (\$)	Fuel Cost (\$/L)	Lifetime
1 kW CPV	1,000	300	25/y	-	25 y
250 kW WT	250,000	250,000	1,000/y	-	25 y
1 kW NH ₃ FC	3,000	1,500	0.010/h	-	5,000 h
1 kW H ₂ FC	3,000	1,500	0.010/h	-	5,000 h
1 kWh Li-ion Battery	300	300	10/y	-	15 y
1 kW Converter	300	300	-	-	15 y
1 kW Bio Generator	200	200	0.030/h	0.50	15,000 h
1 kW Electrolyzer	380	95	20/y	-	7 y
1 kg H ₂ storage tank	700	700	-	-	25 y

5. Simulation and optimization results

The proposed stand-alone design is configured and simulated in HOMER Pro to identify the optimal configuration from the technical and economic perspectives. Based on the earlier predefined parameters such as components’ sizes, WT hub’s height, and battery charging strategy, all feasible options are simulated in HOMER Pro to determine the optimal configuration based on multiple decision criteria. Accordingly, 68,520 solutions are simulated, out of which 45,048 were found feasible while 20,400 were found infeasible due to capacity shortage constraint where the required capacity is found relatively more than the actual capacity that the system can deliver. For each WT hub height sensitivity case, nine different optimal configurations are identified with detailed associated parameters and components’ sizing.

For each WT hub height, the best configuration of each of the three suggested bio-generator capacities are listed in Table 3, along with associated components’ capacities and parameters. Techno-economic analysis is carried out by comparing NPC, COE and unmet demand among all the nine selected scenarios. As a result, 60 m WT height with 100 kW bio-generator and associated components and parameters scenario is found as the optimal configuration with minimum NPC and COE.

Table 3: Technical and cost analysis of selected optimization results

WT Hub Hight (m)	Bio Gen (kW)	H ₂ FC (kW)	NH ₃ FC (kW)	Li-Ion Battery (kWh)	Electro_lyzer (kW)	H ₂ Storage Tank (kg)	Conv_erter (kW)	Dispatch	NPC (Million \$)	COE (\$)	Unmet load (%)
40	100	50	50	344	50	50	226	CC	2.217	0.225	0.03
	500	50	50	709	50	50	281	LF	2.373	0.241	0.00
	50	50	50	817	50	50	272	CC	2.485	0.252	0.04
50	100	50	50	342	50	50	229	CC	2.206	0.224	0.03
	500	50	50	740	50	50	273	LF	2.341	0.238	0.00
	50	50	50	810	50	50	264	CC	2.464	0.250	0.04
60	100	50	50	324	50	50	253	CC	2.191	0.223	0.02
	500	50	50	729	50	50	281	LF	2.323	0.236	0.00
	50	50	50	810	50	50	253	CC	2.455	0.249	0.03

The total monthly electricity generated by the proposed configuration is illustrated in Figure 4, where WT, CPV, bio generator, and FC contributions are 41 %, 37 %, 17 %, and 5 %, respectively.

Figure 4: Monthly electricity production by the source in the optimal configuration

6. Conclusions

A techno-economic assessment is carried out in this study with HOMER Pro simulation software to model, simulate and optimize the proposed grid-dependent micropower

system consisting of multiple renewable sources and storage options to fast charging 50 EVs per day in the State of Qatar. Among many simulated feasible configurations, a system comprising of 450 kW CPV, 250 kW with 60 m height WT, 100 kW bio generator, 324 kWh batteries, 50 kg H₂ storage tank and 50 kW electrolyzer, H₂ FC and NH₃ FC is identified as the optimal configuration with 2.378 million dollars NPC, 0.284 \$/kWh COE and 0.02 % unmet demand where WT, CPV, bio generator and FC electricity contribution are found 41 %, 37 %, 17 %, and 5 %, respectively.

Abstract

This work proposes a simultaneous approach for the synthesis and design optimization of refrigeration cycles integrated with heat exchanger networks. The methodology includes a novel refrigeration cycle superstructure capable of reproducing a wide range of cycle architectures, and an effective solution algorithm (based on the decomposition of the problem on two levels) to tackle the challenging Mixed-Integer Nonlinear Program. In addition to optimizing the cycle and heat exchanger network structure, the methodology can optimize cycle pressures and temperatures (including superheating and subcooling degree of the working fluid). The application to a literature case study indicates that the proposed approach yields solutions that are considerably better in terms of economic than those published in the literature.

Keywords: Refrigeration Cycle Optimization, HEN Synthesis, MINLP, Heat Integration.

1. Introduction

The design of a refrigeration cycle represents a challenging task, mainly due to the wide range of designs and working fluid alternatives, resulting from the evolution of this technology during the last 100 years. All these possible alternatives have been developed to meet the needs of different applications, such as industrial refrigeration, heat pumps for industrial waste heat recovery and cryogenic applications like natural gas liquefaction. Thus, the optimal design of refrigeration cycles calls for the development of systematic optimization approaches capable of exploring all the alternative configurations and finding the best trade-off between cost and performance.

Many authors in the literature have addressed the optimization of refrigeration cycles, but to the best of the author's knowledge, only a few have considered a combination of technical, thermodynamic, and economic parameters in the process. In the study by Wallerand et al. (2018), a comprehensive literature review can be found, considering all the studies from the seventies. The main approaches adopted for optimization are Pressure and Temperature optimization approach and Synthesis approach. In the first one, a case-related structure is developed in an ad-hoc fashion, and then optimization is performed only on continuous variables since the structure is fixed. The second approach generates

the optimal structure together with the optimal operating conditions. This can be achieved by replicating multiple times a basic structure, or by selecting portions of a very general superstructure (synthesis based on reduction).

None of the approaches reported in the literature combines all the main optimization targets in one method, considering compression refrigeration cycle structure, heat exchanger network (HEN) structure, thermodynamic and economics. In contrast, the objective of this work is to develop a model that is able to consider all the alternatives available for compression refrigeration, and select the best ones for the selected purpose. In particular, the model considers:

- All the main configurations for the compression refrigeration cycles.
- The optimal configuration of the HEN: not only the general structure of the cycle, but also the heat integration is optimized, which means coupling in the best possible way hot and cold streams to guarantee a required refrigeration duty (and if necessary heating too).
- The optimization of thermodynamic properties, selecting optimal temperatures and pressures for condensations and evaporations, optimal heat exchange temperatures, and selecting the optimal values for all the technical solutions.

2. Problem Statement and Methodology

The problem addressed in this work can be summarized as follows.

“Given a set of hot and cold process streams with given mass flow rates, inlet and outlet temperatures, and a set of possible hot/cold utility systems (e.g., boilers, cooling water), and the superstructure of possible reverse Rankine cycle configurations, determine the optimal selection of utility systems, the design of the reverse Rankine cycle (selection of pressure levels, mass flow rates of each utility stream, temperatures at inlets and outlets of the evaporator/condenser/intercoolers, etc.), the HEN between process–process as well as process–utility, process–cycle and cycle–utility streams, minimizing the Total Annual Cost (TAC, sum of annualized capital cost and yearly operating costs) of the overall system (utility systems, reverse Rankine cycle and HEN)”.

The optimization of the Refrigeration Cycle and HEN is performed together with the thermodynamic and economic optimization with a synthesis approach based on a very general cycle superstructure containing all the major technological solutions from which the best configuration is selected. The superstructure is built as a series of headers representing the thermodynamic conditions (i.e., points in the p-h diagram), connected by streams and components, i.e., valves, compressors, and heat exchangers (HXs). This structure is then combined with a HEN superstructure and optimized minimizing TAC. The procedure also selects the optimal thermodynamic properties of all the streams and components. The problem is modelled and solved in GAMS.

3. Reverse Rankine Cycle and HEN Superstructures

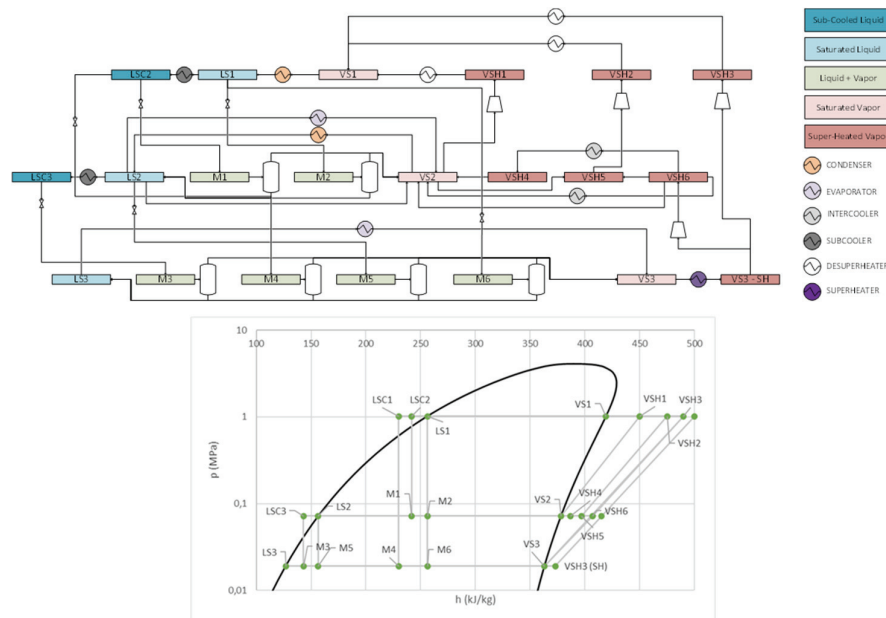

Figure 1. General Compression Refrigeration Cycle Superstructure with 3 Pressure Levels and corresponding p-h Diagram

The cycle superstructure (shown in Figure 1) is obtained by considering the most promising cycle schemes. For the sake of simplicity, Figure 1 shows a superstructure with up to 3 pressure levels, although this number can be easily increased. Indeed, in the test case, a superstructure with up to seven levels of condensation and evaporation is considered. The superstructure can model simple compression refrigeration cycles, compression refrigeration cycles with double throttling, multiple compression intercooling options (HXs, vapor mixing intercoolers and direct contact coolers), multiple condensation and evaporation levels, cascade refrigeration cycles (by replicating more than once the superstructure), liquid sub-cooling and vapor super-heating.

The corresponding p-h diagram is shown in the bottom part of Figure 1. Please notice that the p-h points reported in the diagram are optimized by the algorithm.

As for the HEN superstructure, the proposed optimization uses the SYNHEAT superstructure by Yee and Grossmann (1990) to optimize the HEN synthesis. Following the successful approach of Martelli et al. (2017) and Elsidio et al. (2019), the streams of the reverse Rankine cycle are included in the HEN in all stages and the overall structure obtained is optimized as a large scale nonconvex MixedInteger Nonlinear Programming model (MINLP).

4. Optimization Approach

The optimization problem resulting from combining the superstructure of the Reverse Rankine Cycle with the HEN synthesis is a nonconvex MINLP. It features binary variables for cycle components selection and HXs activation, and continuous variables for thermal power, areas, HEN stage temperatures, compressors power, mass flow rates of streams. The nonlinearities are bilinear products in energy balances ($m_i T_{i,j,k}$, where m_i is the mass flow rate of cycle stream i and $T_{i,j,k}$ is the HEN stage temperature), HXs areas calculation depending on the mean temperature difference (*LMTD*), economy of scale law in the capital cost of equipment units (compressors and HXs), products between mass flow rates and enthalpies of streams in energy balances, and functions $h(p, T)$ linking enthalpies h with temperature T and pressure p (or pressure and entropy for the compressor discharge stream) of each header. These functions $h(p, T)$ are evaluated using the “Extrinsic Functions” developed by Manassaldi et al. (2019) and implementing the Peng Robinson Equation of state. The isentropic efficiency definition was used to calculate the properties of the compressors outlets. Comparison with REFPROP indicates that the error incurred in the use of the Peng Robinson Equation of state in evaluating the enthalpies of the headers is lower than 1%, which is acceptable for the optimization purposes of this work.

Preliminary computational tests indicate that the nonlinear and nonconvex MINLP cannot be solved with general purpose MINLP solvers, such as BARON. Thus, a decomposition approach has been developed by adapting the bilevel decomposition approach proposed by Elsidio et al. (2019) for cases with fixed header p and T (i.e., fixed h). The adapted decomposition algorithm is shown in Figure 2. The initialization consists in guessing starting values of the headers pressures and temperatures, and then solving the problem with fixed header p and T using the same sequential initialization approach of Elsidio et al. (2019). Then, the bilevel algorithm starts with a linearized version of the problem (Mixed-Integer Linear Program, MILP) in which header enthalpies are fixed, but the capital cost functions are piecewise linearized, the area-LMTD relations are linearized using first-order Taylor approximation, and the bilinear terms $m_i T_{i,j,k}$ are linearized using the McCormick relaxation. Although of large scale, the MILP can be solved with commercially available solvers (CPLEX in our case). Once solved, the binary variables are fixed (fixing the HEN and Refrigeration cycle structure), and the lower level program optimizes the continuous variables (including headers pressures and temperatures) by solving a nonconvex Nonlinear Program (NLP). Due to the lack of the explicit algebraic expressions in the Extrinsic Functions used for $h(p, T)$, a solver with global convergence guarantee (like BARON) cannot be used for the NLP subproblem. Thus MSNLP (Multi Start Non-Linear Programming) is chosen to tackle the NLP subproblem (the risk of finding a local minimum is mitigated by considering multiple starting points). After the NLP is solved, the MINLP is linearized again around the newly found solution to derive an updated master level MILP for the subsequent iteration. “Nested integer cuts” (Elsidio et al. 2019) are added to the master level MILP to exclude already found binary solutions.

Since p and T of headers are fixed in the master level problem, its solution cannot be considered as a lower bound (useful for deriving an optimality gap and stopping criterion). Thus, as stopping criterion of the bilevel algorithm, we considered the condition of no solution improvement for 20 consecutive iterations.

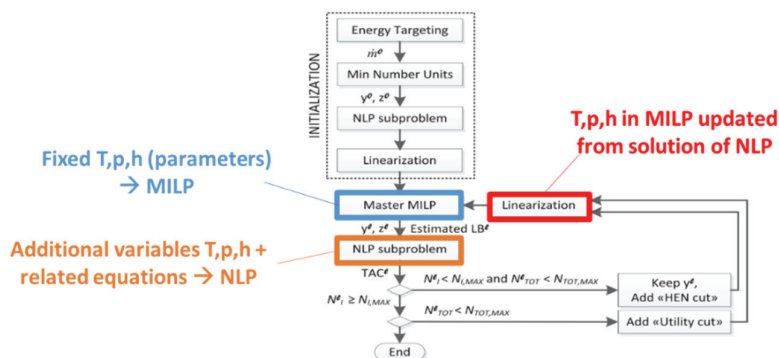

Figure 2. Schematic approach to the MINLP problem in the variable-headers optimization, adapted from Elsidó et al. (2019)

5. Case Study and Results

The proposed approach was applied to Example *E2* by Grossmann and Shelton (1986), where the synthesis and optimization of the refrigeration cycle is performed including two hot and two cold streams to be integrated in the HEN. The objective function is the Total Annual Cost (TAC) including both capital and operating costs. The bilevel decomposition algorithm converged in 33 iterations with a total computational time of 14480 s. The main results are summarized in Table 1, 2 and the optimized cycle and HEN structures are reported in Figure 3.

The results indicate major improvements in terms of economics (TAC), Coefficient of Performance (COP), and cycle simplicity (2 evaporation levels with 2 direct contact coolers and a total of 8 HXs vs. 2 evaporation levels, 4 intercoolers and 5 direct contact coolers with a total of 12 HXs of the reference solution). The key advantage of the proposed approach compared to the one adopted in Grossmann and Shelton (1986), is the possibility of optimizing the heat transfer temperature differences and the cycle pressure levels (this enables using more efficient heat integration options), the higher flexibility of the cycle superstructure (including more intercooling/throttling options) and the capability of considering simultaneously capital and operating costs.

Table 1. Main Results of Test Case Optimization

Reference TAC (k€/yr)	Optimized TAC (k€/yr)	Improvement
142,2	107,6	24,30%
Reference COP	Optimized COP	Improvement
5,73	9,59	67,36%

Table 2. Components of the TAC

	Reference Cost (k\$/yr)	Optimized Cost (k\$/yr)
Ann. CAPEX HEN	30,814	40,832
Ann. CAPEX COMP	57,135	27,011
Elect. purch. Cost	31,461	15,625
Steam import cost	22,822	24,147
TAC	142,232	107,615

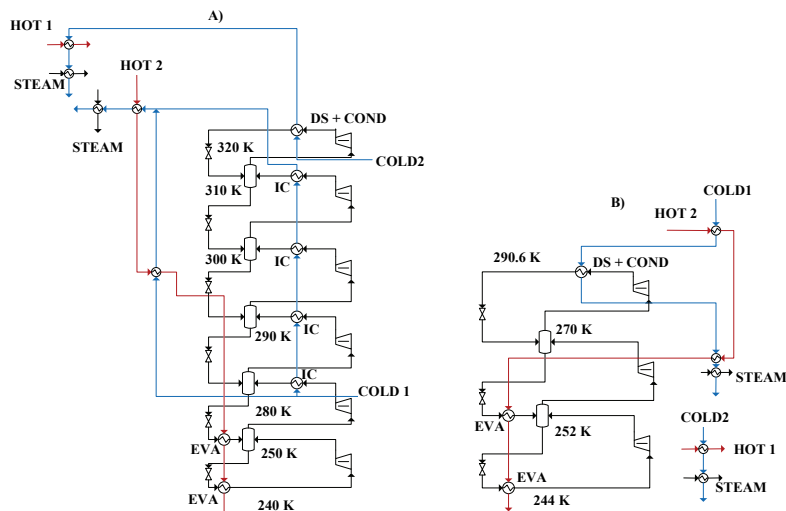

Figure 3. (A) Reference solution by Shelton and Grossmann (1986) and (B) optimized structure

6. Conclusions

The results of the test case show that the proposed approach is a very promising tool for the design of efficient and cost-effective refrigeration cycles. This is due to its capabilities of: (i) of integrating a flexible cycle superstructure with the HEN superstructure, (ii) optimizing cycle pressures and temperatures, (iii) considering both capital and operating costs in rigorous way, (iv) relying on an efficient (although without guaranteed global convergence) MINLP decomposition algorithm.

Future developments of the methodology will focus on the development of globally convergent decomposition algorithms.

Waste- to-DME: Process Synthesis and Sustainability Evaluation

Lefu A. Litheko^a, Bilal Patel^a

^aDepartment of Chemical Engineering, University of South Africa, Corner of Christiaan de Wet Road and Pioneer Avenue, Florida 1709, South Africa

Abstract

A macroscopic graphical targeting approach based on the C-H-O ternary diagram is proposed for the synthesis of waste-to-chemicals systems. Sustainability metrics are also considered to gain insight into the process efficiency and resource utilization. The process targets together with the sustainability metrics enable the screening, evaluation and comparison of various process routes. A case study for the conceptual design of a waste-to-DME facility is considered. The process includes waste gasification and DME synthesis. The DME production process has two main process targets, one based on the indirect synthesis route and the direct synthesis route, which require a syngas platform with compositions of $H_2/CO = 1$ and $H_2/CO = 2$ respectively. To achieve the syngas target required for the direct DME synthesis route, a mixture of H_2O and CO_2 or H_2O and O_2 is required as gasifying agents. A simplified input-output diagram of the overall waste-to-DME process was developed based on the process targets for the waste gasification and the direct DME synthesis process. The carbon efficiency, atom economy and global warming potential (GWP) is calculated. An additional source of hydrogen is required to achieve the syngas composition target for the indirect DME synthesis route (i.e. $H_2/CO = 2$). Introducing methane (from landfill gas) to the process results in a substantially higher carbon efficiency.

Keywords: waste biorefineries, sustainability, process synthesis, MSW, circular (bio) economy

1. Introduction

The rapidly growing consumption and commensurate depletion of the world's natural resources as well as the production of large volumes of waste has raised concerns regarding the sustainability of the current linear economy model. A shift to a circular economy model has been proposed to substantially improve resource efficiency and reduce consumption of fresh resources (Maina et al., 2017).

The valorisation of municipal solid waste (MSW) is an important aspect of a circular bioeconomy. In 2016, more than 2 billion tons of waste was generated with an increase of 70% to 3.4 billion tons in 2050 predicted (Kaza et al., 2018). Typical disposal methods like landfilling are no longer viable options due to stringent policies, limited space and environmental and health issues. The organic fraction of MSW (OFMSW) is the most abundant fraction of MSW (about 50 - 60%). The OFMSW has a relatively high carbon content (38- 51%) and calorific value (14-20 MJ/kg) (Campuzano and Gonzalez-Martinez, 2016). Waste biorefineries or waste-to-chemicals, that employ the OFMSW, play an important role in sustainably converting low-value streams to high value products (Carus & Dammer, 2018) and achieving a circular bioeconomy.

Thus, it is imperative to develop methodologies for the conceptual design of efficient and sustainable waste biorefineries that produce fuels, chemicals and other products. Insight-based approaches are useful to simplify the complexity of the waste biorefinery design problem, provide a fundamental understanding of design issues and identify holistic targets for processes (Kokossis et al., 2015). Tay et al. (2011) proposed a graphical approach, based on the C-H-O ternary diagram, for a gasification-based biorefinery to determine the syngas equilibrium composition. This study extends the use of the C-H-O ternary to waste biorefineries and presents a holistic approach to determine targets for the overall process that incorporate the downstream processes.

2. Modelling framework

Consider a waste biorefinery that converts Refuse Derived Fuel (RDF) into dimethyl ether (DME). Although the study presents an analysis for DME as the final product, any other product that contains carbon, hydrogen and oxygen can be analysed in a similar fashion. DME is used as an example to illustrate the methodology and may not represent the “best” product to produce from waste. However, the C-H-O ternary diagram (or the Van Krevelen diagram) may be applied to provide insights into which product should be produced based on carbon efficiency (Patel, 2015).

Since the system consist of inputs and outputs that consist mainly of carbon (C), hydrogen (H) and oxygen (O) atoms, a C-H-O ternary diagram is convenient graphical tool to synthesise and analyse processes at the conceptual design level (Tay et al., 2011; Litekho, 2017). For example, waste feedstock can be expressed as $C_xH_yO_z$, where x-z represent the atomic number of carbon (C), hydrogen (H), and oxygen (O) respectively, which can be obtained from the ultimate analysis of the feed material. The minor components of biomass such as nitrogen and sulphur are not considered. Possible process inputs for the biorefinery include RDF, H_2O , CO_2 , and O_2 . In this study, RDF has been specified with a chemical formula of $CH_{1.569}O_{0.541}$ (Onel et al., 2014). The thermodynamics properties of RDF are given as a function of composition according to the correlations developed for biomass (Peduzzi et al., 2016). By utilising the lever arm rule, the material balance targets for a process can be determined. By incorporating the first and second laws of thermodynamics, energy and work targets can also be obtained (Patel, 2015).

The overall material balance for the process can be written as follows:

$$a CH_{1.569}O_{0.541} + b H_2O + c O_2 + d CO_2 - 1 C_2H_6O = 0 \quad (1)$$

where a, b, c and d are the respective amounts of biomass, water, O_2 and CO_2 required (if the coefficient is positive) or produced (if the coefficient is negative) in the process for converting RDF into 1 mole of DME.

The process targets for the waste-to-DME process are assessed using sustainability metrics to determine the efficiency and/or the environmental performance of this process. Carbon efficiency, atom economy and global warming potential (GWP) in terms of CO_2 equivalence (Eq. (2)) are used to assess the process. Other sustainability metrics may also be applied to the process targets. For example, the WAR algorithm, inherent safety index and economic potential could be used to assess the process targets (Zeng et al., 2012).

$$CO_2 \text{ Equivalent} = \sum_{i=1}^n (Emissions \text{ to air})_i \times (GWP)_i \quad (2a)$$

$$\text{Atom Economy} = \frac{\text{Mass of desired product}}{\text{Total mass of feed}} \quad (2b)$$

$$\text{Carbon Efficiency} = \frac{\text{Moles of C in desired product}}{\text{Moles of C in feed}} \quad (2c)$$

The process targets developed represent an early-stage design of a waste biorefinery. These targets can be used to complement and enhance further detailed optimisation studies as well as detailed techno-economic and sustainability assessments (for example, life cycle analysis).

3. Results and Discussion

3.1. Process targets for overall system

The process target of the waste-to-DME process is represented on the C-H-O ternary diagram (Figure 1). The feed (input) line connects RDF and the H₂O/O₂ co-feed stream, while the product line joins CO₂ and DME. The reactant and product lines intersect at Point M which designates the target mixture of reactants (RDF, O₂ and H₂O) and products (DME and CO₂).

Figure 1. Material balance for the overall RDF-to-DME process

The overall material balance for the waste biorefinery process is

It is clear from Eq. (3) that producing 1 mole of DME from RDF requires oxygen and water as feed material. In addition, the process does not require an energy input ($\Delta H=0$) and it is thermodynamically feasible ($\Delta G < 0$). The process target show that the atom economy and carbon efficiency for the RDF-to-DME process are 55% and 70% respectively. The process also emits 0.825 tons CO₂ per ton of DME. The atom economy shows that just over half of the RDF fed to the process will be converted to DME. The

carbon efficiency indicates that of the carbon introduced to the process, 30% ends up as carbon dioxide.

3.2. Process targets for sub-systems

The overall waste-to-DME process involves two main processes - gasification and DME synthesis. DME can be produced via two process routes represented by the following material balance equations (Azizi et al., 2014):

The required syngas composition is $\text{H}_2/\text{CO} = 1$ for the direct route and $\text{H}_2/\text{CO} = 2$ for the indirect route.

Gasification of the RDF to produce syngas requires a gasifying medium, typically steam, oxygen, CO_2 or a combination of these. The C-H-O ternary diagram can be used to determine the process targets for the gasification process in which RDF is gasified using different gasifying agents to produce H_2 and CO as syngas product.

The input and output of the gasification process are plotted on the C-H-O ternary diagram (Figure 2). A product line is drawn by connecting the gasification products, i.e. H_2 and CO . The required syngas targets for the direct route ($\text{H}_2/\text{CO} = 1$) and the indirect route ($\text{H}_2/\text{CO} = 2$) are plotted based on their atomic composition as M1 and M2 respectively.

Figure 2. Evaluation of waste gasification (a) gasifying agents and (b) co-gasifying agents on a C-H-O ternary diagram

Feed lines that connect RDF with the three possible individual gasifying agents, i.e. H_2O , CO_2 and O_2 are drawn. These lines intersect the product line at points P, Q and R which represent syngas produced when RDF is gasified with H_2O , O_2 and CO_2 respectively. The gasifying agent that results in a gas composition that is on or closest to either M1 or M2 is considered optimum. From Figure 2, none of the points from the three gasifying agents is located on either M1 or M2. This means that gasifying RDF with H_2O , O_2 or CO_2 individually cannot produce syngas that is exactly $\text{H}_2/\text{CO} = 1$ or $\text{H}_2/\text{CO} = 2$. Therefore, the syngas compositions produced from the three individual gasifying agents do not meet the requirements for the intended downstream application.

It can, however, be deduced from Figure 2 that it is feasible to produce syngas with $H_2/CO = 1$ by co-feeding H_2O with either CO_2 or O_2 . Co-feeding H_2O with either CO_2 or O_2 shifts Point P toward M1. However, producing a syngas composition of $H_2/CO = 2$ from the gasification of RDF using any combination of the gasifying agents is infeasible. All possible co-feed streams of H_2O with CO_2 (H_2O/CO_2) and H_2O with O_2 (H_2O/O_2) are represented by lines that connect H_2O and CO_2 as well as H_2O and O_2 respectively. The optimum co-feed streams for the RDF gasification are determined by drawing a feed line from RDF point through the target syngas composition, M1. The feed line intersects the two co-feed stream lines at points labelled X and Y (Figure 2b). The two points represent the optimum co-feed streams that produce the target syngas composition of $H_2/CO = 1$. Point X represents the co-feed stream of H_2O with CO_2 whereas Y represents the co-feed stream of H_2O with O_2 . By identifying the atomic species of X and Y and using the lever arm rule on the C-H-O ternary diagram, the material balance of the two process targets can be determined.

The overall RDF-to-DME process integrates the gasification process and the direct DME synthesis process. Integrating the two gasification process targets with the DME synthesis process, results in the following material balances:

The process that involves RDF gasification with H_2O and O_2 (Eq. 4a) is exothermic ($\Delta H = -70.2$ kJ/mol). The excess heat can either be used for other purposes or is lost to the environment. On the other hand, the process involving the gasification of RDF with H_2O and CO_2 (Eq. 4b) requires additional energy ($\Delta H = 95.9$ kJ/mol). For the process to be energy self-sufficient, the required energy can be supplied through combustion of additional RDF. This would result in obtaining the overall target given by Eq. 3.

As shown in Figure 2a, producing syngas with a $H_2/CO = 2$ for the downstream indirect DME synthesis is infeasible from RDF gasification with all three oxidants (i.e. H_2O , O_2 and CO_2) as well as their combinations. The syngas platform is deficient in H_2 and therefore a hydrogen source is required to produce the syngas composition target of $H_2/CO = 2$. Methane (which can be obtained from biogas or landfill gas) can be introduced into the process as a source of hydrogen. The optimum amount of methane that meets the required gasification target composition is specified from the C-H-O diagram. Thus, the overall process targets of the RDF-to-DME through the indirect DME synthesis is giving by

Eq. 5 has a carbon efficiency and atom economy of 100% and CO_2 is utilised as a feed and is not emitted from the process.

4. Conclusions

A targeting approach based on the C-H-O ternary diagram and laws of thermodynamics is presented for a waste-to-chemicals systems. The C-H-O ternary diagram is a powerful graphical tool that enable quick and insightful for representing of the overall material balance targets for waste-to-chemical processes. Various process configurations can be considered by varying process parameters and these configurations can be rapidly evaluated by applying sustainability metrics such as carbon efficiency and atom economy.

A case study for the conceptual design of a waste-to-DME facility was considered. An overall material balance target is obtained that is energy self-sufficient. The carbon efficiency, atom economy and global warming potential (GWP) is calculated. Furthermore, ways of obtaining the overall target are explored by considering a process that includes waste gasification and DME synthesis. The DME production process has two main process targets, one based on the indirect synthesis route and the direct synthesis route, which require syngas platform with compositions of $H_2/CO = 1$ and $H_2/CO = 2$ respectively. To achieve the syngas target required for the direct DME synthesis route ($H_2/CO = 1$), a mixture of H_2O/O_2 or H_2O/CO_2 can be utilised. The requirements of these gasifying agents can easily be determined from the C-H-O diagram. An additional source of hydrogen is required to achieve the syngas composition target for the indirect DME synthesis route (i.e. $H_2/CO = 2$). Introducing methane (from landfill gas) into the process results in a substantially higher carbon efficiency and atom economy

Abstract

Liquid organic hydrogen carriers (LOHCs) can be used for long-term storage and long-distance transport of hydrogen. Here, hydrogen (H₂) is loaded into the organic molecule through a hydrogenation process and then unloaded through the reverse process (dehydrogenation). These organic molecules allow hydrogen to be handled at ambient conditions and transported using the existing crude oil-based infrastructure.

In the present work, the system toluene-methylcyclohexane was identified as being one of the most promising LOHCs. Simulations for the hydrogenation and dehydrogenation processes were performed in Aspen Plus[®] for a 50 ktonne H₂/year capacity. To increase the detail and reliability of the results, both reactions were modelled using kinetic laws and by-product formation was considered. The processes were optimized through heat integration, which enabled up to 60% savings of hot utilities. An economic analysis was held, from which the break-even price of hydrogen loading and release was found to be equal to 1.9 \$/kg-H₂.

Keywords: Hydrogen storage, Liquid organic hydrogen carrier, Toluene, Process integration, Techno-economic analysis.

1. Introduction

Public pressure has increased over the years to seek alternatives for fossil-based fuels and products while mitigating the adverse effects of climate change. Renewable energies have been contributing decisively to the decarbonization of power systems, but intermittencies associated with these energy sources have hindered their deeper incorporation into the energy mix. In this context, low-carbon hydrogen (green or blue) can play a key role as a clean energy vector because it can be stored and transported in many ways (e.g., liquified, pure or blended gas, and reversibly bonded with liquid or solid compounds), and deployed as a fuel or as a chemical. However, using hydrogen as an energy vector also faces important challenges, particularly those associated with long-distance transport and long-term storage due to its rather low volumetric energy density and extreme volatility (Usman, 2010). Recently, liquid organic hydrogen carriers (LOHCs) have been screened for hydrogen transport and storage. The concept, depicted in Figure 1, involves a two-step cycle: loading (hydrogenation) and release

(dehydrogenation). The efficiency of these two steps and the inherent aspects of the LOHCs supply chains affect the final delivery costs of hydrogen decisively.

The chemical compounds receiving more attention for hydrogen transport include naphthalene, formic acid, methanol, N-ethylcarbazole, toluene, and dibenzyltoluene. The toxicity of naphthalene, decomposition reactions of N-ethylcarbazole, and the slow kinetics of hydrogenation and dehydrogenation reactions associated with formic acid and methanol still limit the adoption of these compounds as LOHCs. Contrarily, recent results of techno-economic analyzes for toluene and dibenzyltoluene cases have shown they are economically viable for the long-range transport of hydrogen (e.g., Niermann et al., 2019). However, these studies do not consider the mechanisms involved in hydrogenation and dehydrogenation reactions, neither the occurring side reactions, particularly in dehydrogenation. Furthermore, simplified models were used to design most unit operations involved, preventing optimization studies from being conducted.

Figure 1: Two-way LOHC concept for hydrogen transportation.

This work reports ongoing research where various LOHCs are being screened for long-distance transport and storage of H₂. Here, the competitiveness of toluene as a LOHC is addressed, where hydrogenation and corresponding methylcyclohexane (MCH) dehydrogenation processes are analyzed. Kinetic models of the main reactions were used, and side reactions were considered to model the hydrogenation and dehydrogenation reactions with detail. The separation subsystems for the LOHC recovery and hydrogen purification were designed and operating conditions established using flowsheet optimization to minimize costs.

Next, the hydrogenation and dehydrogenation processes involved are described, and the modelling framework used for the techno-economic analysis presented (Section 2). In Sections 3 and 4, we show preliminary process simulation results using Aspen Plus[®] and the economic analysis. The paper closes in Section 5 with the final remarks.

2. Process overview and modelling

The toluene hydrogenation and methylcyclohexane (MCH) dehydrogenation processes, as simulated in Aspen Plus[®], are represented in Figure 2 and Figure 3, respectively. Peng-Robinson equation-of-state was used as the thermodynamic model because both processes involve hydrocarbons and are operated at moderate and high pressure. For the toluene hydrogenation reaction ($C_7H_8 + 3H_2 \rightarrow C_7H_{14}$) a non-commercial supported nickel catalyst (Ni/Al₂O₃) was selected from (Lindfors & Salmi, 1993), for which a kinetic law was derived for the range 120-200 °C:

$$r'_1 = \frac{k_1 K_{1,T} K_{1,H}^3 p_H^3}{(K_{1,T} p_T + (K_{1,H} p_H)^{0.5} + 1)^7}, \quad \text{mol}/(\text{g} - \text{cat. s}) \quad (1)$$

$$K_{1,T} = \exp K'_{1,T} \exp(-\Delta H_T/RT), \quad \text{atm}^{-1} \quad ; \quad (2)$$

$$K_{1,H} = \exp K'_{1,H} \exp(-\Delta H_H/RT), \quad \text{atm}^{-1} \quad (2)$$

$$k_1 K_{1,T} K_{1,H}^3 = A \exp K'_{1,T} K_{1,H}^3 \exp(-E_a/RT - \Delta H_T/RT - 3\Delta H_H/RT), \quad (3)$$

Where $\ln A = 69.254$, $\ln K'_{1,T} = -15.597$, $\ln K'_{1,H} = -39.666$, $E_a/R = 21288 \text{ K}$, $\Delta H_T/R = -7368.3 \text{ K}$, $\Delta H_H/R = -18097 \text{ K}$. Similarly, for the MCH dehydrogenation reaction, a single-site Langmuir-Hinshelwood kinetic model was developed for platinum supported catalyst (Pt/Al₂O₃) based on (Usman, 2010):

$$r'_2 = \frac{40.907 k p_M \left(1 - \frac{p_T p_H^3}{K_2 p_M}\right)}{1 + 40.907 p_M + 22.194 p_T + K'_2 p_T p_H^2}, \quad \text{mol}/(\text{g} - \text{cat. s}) \quad (4)$$

where

$$k = 4.064 \times 10^{-5} \exp \exp(7.652(1 - 617.2/T)), \quad \text{mol}/(\text{g} - \text{cat. s}) \quad (5)$$

$$K_2 = 3600 \exp \exp((-217650/R)(1/T - 1/650)), \quad \text{bar}^3 \quad (6)$$

$$K'_2 = 6.688 \exp \exp(-24.038(1 - 617.2/T)), \quad \text{bar}^{-3} \quad (7)$$

Here, subscript *T* represent toluene; *H*, hydrogen; and *M*, methylcyclohexane. At the conditions of MCH dehydrogenation (340-460 °C), the major side reactions reported include the formation of benzene (C₆H₆), xylene isomers (C₈H₁₀) and methane (CH₄):

For the abovementioned catalytic system, no kinetic data is available for reactions (8) and (9), but the observed reaction conversions were approximately 8.3E-4 and 2.7E-3, respectively (Usman, 2010).

Kinetic models were used to plot isobaric plots of single-pass conversion against temperature and adiabatic plots to determine the appropriate catalyst loadings and reaction conditions. Thus, the hydrogenation reaction was set to 30 bar and 170 °C, using a hydrogen molar excess equal to 6 and catalyst loading of 3065 kg, which led to a conversion equal to 99.98%. As for the dehydrogenation, the reaction occurred at ambient pressure and 450 °C, with a catalyst loading equal to 17000 kg, enabling 97.34% conversion. The fixed-bed reactors were simulated with a plug-flow reactor model (RPlug) in which the main reaction occurred and, for the dehydrogenation process, the side-reactions were modelled using the RStoic model (Aspen Technology, Inc., 2001).

Two scenarios of hydrogen compression in the toluene hydrogenation process were here considered: (i) compression from ambient conditions up to 30 bar; and (ii) hydrogen feeding at 70 °C and 30 bar, typical conditions at which it leaves the electrolyzer (David

et al., 2019). In scenario (i), the multi-compression section was designed by minimizing the energy consumption where per-stage compression ratios are adjusted, and the exit gas temperatures maintained below 204 °C to avoid exceeding equipment constraints (Luyben, 2011). Intercoolers were only used for the first two stages, as the excess heat from the last stage was used to vaporize the toluene feed. After the reactor, a distillation column, D101, is used to recover the unreacted toluene and the hydrogen excess. This equipment was initially designed using approximate methods to estimate the number of theoretical stages and feed stages and later optimized to minimize energy consumption using RadFrac rigorous distillation model (Aspen Technology, Inc., 2001).

In the MCH dehydrogenation process, H₂ is recovered by flashing the product stream and compressing it to the pressure swing adsorption (PSA) unit to obtain a hydrogen stream within fuel cell specifications (>99.97 mol%). Intercoolers and flash units are added to recover the hydrocarbon condensates and pre-concentrate H₂. The off-gas stream from the PSA containing the non-recovered hydrogen was recycled to the compression area feed, and a purge added to the accumulation of impurities. The purge stream feeds a burner unit which supplies heat to the reactor inlet stream.

Toluene, on the other hand, is recovered from the flash liquid stream through a three-distillation column scheme, which was required due to the close boiling points between toluene, MCH, benzene and xylene and also due to the high amount of MCH present in this stream. The first column, CD201, obtains the bulk of the toluene product stream and the second, which receives the distillate stream from the first column and the effluent stream from the PSA unit, separates the light contaminants (benzene and MCH) from the remaining toluene. Finally, the third column, CD203, was added to remove benzene from the MCH stream, which, in turn, is recycled to the reactor.

3. Process simulation results

The results for a delivery rate of 50 ktonne/year of H₂ and 8000 h of annual operation are now presented. In the hydrogenation process, a virtually complete reaction enables a simple purification scheme using a 7-stage distillation column, which operates at 25 bar with a reflux ratio equal to 0.175. This equipment was adjusted so that the minimum amount of MCH was contained in the recycle stream. The distillate from D101 removes most of the MCH, but still, 2.3% of MCH is recycled with hydrogen, which has a minor impact on the reaction rate, as expected from equations (1-3).

As for the dehydrogenation process, the analysis confirms the need for further purification, so that more concentrated product streams can be obtained, as both streams 209 and 216 only have 97.2 wt% hydrogen and 71.9 wt% toluene, respectively. The PSA scheme was well-suited for the hydrogen purification as the final product stream is within specifications. Regarding the toluene purification scheme, vacuum conditions were applied in all columns to facilitate the separation, while the operating pressure was estimated so that the temperature in the overhead condensers is not lower than 50 °C, to allow cooling water to be used (Turton et al., 2008). The molar reflux ratio (RR) and distillate to feed ratio (DF) parameters were determined through optimization. RR varied between 18 and 25 and DF between 0.1 and 0.15 in columns CD201-CD203. The number of theoretical stages in CD201 was 20, in CD202 was 12, and in CD203 was 10.

Figure 2: Toluene hydrogenation process.

Figure 3: Methylcyclohexane dehydrogenation process.

Globally, 1.38 % of MCH in the feed and 0.03% of the toluene exiting R201 are lost in the purification process. This purification scheme can be improved using other purification methods such as extractive distillation for benzene-toluene-xylene mixtures (Kim, 2016).

4. Heat integration and economical analysis

Heat integration was conducted for both processes using Aspen Energy Analyzer[®]. The minimum temperature difference (ΔT_{\min}) assumed was 5 °C. The optimal heat exchanger network (HEN) enabled a 63% reduction of the hot utility consumption in the hydrogenation process while increasing the number of heat exchangers (HEs) from 8 to 18 and the total area from 3948 m² to 8067 m². In the dehydrogenation, a 58% reduction of hot utility consumption was achieved, and the number of HEs increased from 15 to 23, as well as the total area from 17690 m² to 26270 m². The economical analysis was performed using the CapCost tool, and it estimates the fixed capital cost and total manufacturing cost of all plants previously simulated, according to the method developed by (Turton et al., 2008). The results are summarized in Table 1.

Table 1: Summary of fixed capital cost and utilities expenses.

Consumption (kWh/kg-H ₂)	Hydrogenation		Dehydrogenation
	Scenario (i)	Scenario (ii)	
Electrical	2.24	0.119	1.40
Heat	1.05	3.36	15.9
Total	3.29	3.48	17.3
CAPEX (M\$)	60.4	4.54	78.3

As the compressors account for 80% of the capital costs in scenario (i), it is already expected that the fixed capital costs scenario (ii) is drastically lower. Nevertheless, for the same reason, the decrease in the number of heat exchangers available for heat integration leads to an increase in heat consumption, which offsets the decrease in electrical consumption. The energy consumptions reported here for the toluene hydrogenation process in both scenarios (3.29-3.48 kWh/kg-H₂) are higher than 0.47 kWh/kg-H₂ estimated from (Niermann et al., 2019). This difference can be explained by the fact that in (Niermann et al., 2019) the hydrogenation reaction is taken to occur at the liquid phase and solvent recovery was not considered. For the dehydrogenation process, the total energy consumptions here reported (17.3 kWh/kg-H₂) is slightly lower than 17.85 kWh/kg-H₂ from Niermann et al., (2019). When considering both processes, the total operating costs obtained of H₂ loading and release was 1.3 \$/kg-H₂, and the total capital investment equal to 146.3 M\$, giving an estimated break-even price of 1.9 \$/kg-H₂.

5. Conclusions

In this paper, the hydrogenation and dehydrogenation process of the toluene-MCH system was simulated using kinetic laws to model the reaction, which increased the results reliability. For the toluene hydrogenation process, two scenarios were presented, and it was found that even though the absence of a compression zone significantly reduces the fixed capital cost, the utility cost is still maintained due to the decrease in the number of heat exchangers which heat can be integrated. As for the dehydrogenation process, the complex purification scheme leads to a significant increase in utilities and fixed capital costs compared to the hydrogenation. Additionally, the heat requirements of the reactor also contribute to the heat consumption increase. When comparing to the literature results, improvement opportunities were identified towards the purification scheme.

Abstract

The ceramic industry is a sector within process industry associated to a high energy intensity which is owe to the operation of thermal processes such as firing, drying, spray drying and boiling. These processes are associated to high thermal energy losses (waste heat). As such, the adoption of waste heat recovery (WHR) technologies and strategies may reveal as an excellent opportunity to improve the energy efficiency of ceramic plants by improving the operation of these thermal processes. In practice, such may be performed by applying principles of process integration through assessing the waste heat potential of all the plant material streams and furtherly elaborate a plan to use this waste heat in the several different processes. In this work, it will be assessed the energy efficiency improvement potential associated to the implementation of a WHR strategy in a case-study ceramic plant. Such is carried out by modelling and simulate the plant and the WHR strategy using the Modelica language. Through the simulation of the developed model the techno-economic assessment, it was possible to accomplish the viability of the conceptualized project, with 3508 MWh/year of energy savings corresponding to 0.2 years of payback time.

Keywords: energy efficiency, waste heat recovery, process integration, ceramic industry, Modelica.

1. Introduction

Waste heat recovery (WHR) is a set of measures with a high potential to improve energy efficiency in industry. Industrial thermal processes are associated to high energy demands and in consequence to considerable thermal energy losses (roughly representing 20 - 50 % of total energy consumption), being estimated the existence of a total 300 TWh/year waste heat potential in the European industry (Castro Oliveira et al., 2019).

The WHR strategy includes the selection of the most favourable WHR technologies, the application of process integration and energy system optimisation principles, taking into account the objective to reduce energy inputs by making use of some material streams, namely the outlet ones with considerable waste heat potential.

The ceramic industry is a high energy intensive sector. Such is due to the operation of energy intensive processes, such as firing (kilns), drying and spray drying. Some of the most implemented WHR technologies within the ceramic industry are air-gas heat exchangers to preheat the combustion air at the entrance of combustion-based processes

Organic Rankine Cycle (ORC) to produce electric energy and hot air recycling (from the cooling zone of kilns).

In this work, it will be assessed the energy efficiency improvement potential associated to the implementation of a WHR strategy in a case-study. Such will be performed by the assembling of a ceramic plant model (developed in the Modelica language) to simulate the implementation of a WHR strategy.

2. Modelling of Thermal Processes and Process Integration

The case-study is about a ceramic sanitaryware manufacturing plant, in which the most prominent thermal processes include 2 tunnel kilns, 1 intermittent kiln, 2 dryers and 4 hot water boilers. These are combustion-based processes using natural gas as fuel. It currently exists an interest to reduce the fuel consumption of the tunnel kilns and the boilers. As such, a new WHR strategy will be proposed, considering principles of process integration.

2.1. Conceptualization of the Study

This process integration study emerged within the scope of the study of industrial system retrofitting, in which most recent technologies are set to be implemented to improve the operation of the plant through the rationalization of the use of its resources such as energy and water. In this case, such is performed by integrating WHR technologies to improve the plant's overall energy efficiency. The result of such implementation is the conceptualization of a heat integration system, which encompasses the plant's thermal processes and the interdependencies which are created through the implementation of WHR technologies (such as in this case the recovery of the kiln's exhaust gas stream to be directed to two water-gas heat exchangers).

To perform a study on heat integration, several methodologies exist, such as pinch analysis, exergy analysis, use of heuristics and linear programming. This work uses a methodology based on numerical modelling: custom models for the plant's thermal processes are created and the system is created through the assembling of several component models. In practice, this methodology allows the conceptualization of new systems inserted within the operation of the plant processes (the simulation of the occurring phenomena in real time). The models for the thermal processes (tunnel kiln and boilers) and the whole system were created using the Modelica language. Two custom model were developed for the tunnel kiln and the boiler using adapting the source code present in the open-source ThermoPower Modelica library (Politecnico di Milano).

This work emerged on the scope of the objectives of the European Green Deal and the EU 2050 long-term strategy, namely on the strategy for energy system integration. In specific, it dwells with the first pillar of this strategy, which is the requirement to improve the circularity of the energy systems. The implementation of energy recovery approached in this work is in this sense a contribution to the promotion of circular economy in industry.

2.2. Case-study characterization and model

The conceptualized WHR strategy encompasses 1 tunnel kiln and 2 of the boilers of the plant. For the tunnel kiln, it is implemented the hot air recycling from the cooling zones to the combustion chambers, while for the two boilers two water-gas heat exchangers (economisers) are implemented for each one respectively, recovering the waste heat from the tunnel kiln exhaust gases to preheat the inlet water stream at both boilers. The conceptualized system is represented in Fig. 1.

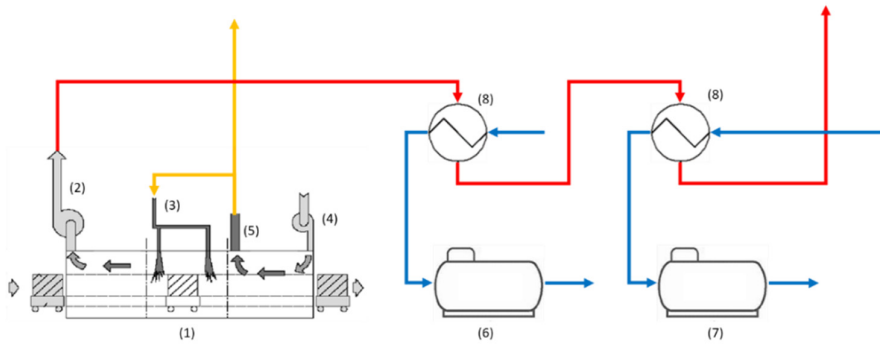

Fig. 1. Conceptualized heat integration system: (1) Tunnel kiln and its (2) exhaust gas chimney, (3) combustion chamber inlet, (4) cooling air inlet, (5) hot air chimney, (6) Boiler 1, (7) Boiler 2 and (8) Heat exchangers (Tunnel kiln scheme adapted from Dudam (2009))

The thermal process models were assembled considering the mass and enthalpy balances of a tunnel kiln and a boiler, respectively. In both cases, the total supplied heat (q_{supply} (kJ/h)) may be calculated considering the fuel's lower heating value (LHV), attending to equation (1). For the case in which more than one heat source exists to supply thermal energy to the kiln, it is necessary to consider an additional heat parcel ($q_{additional}$ (kJ/h)), as described by equation (2). In the case of the tunnel kiln, such corresponds to additional thermal energy contained in the combustion air stream ($q_{additional,kiln}$ (kJ/h)), as described by equation (3). In the case of the boiler, such corresponds to additional thermal energy contained in the inlet water stream ($q_{additional,boiler}$ (kJ/h)), as described by equation (4).

$$q_{supply} = M_{fuel,initial}LHV \quad (1)$$

$$q_{supply} = M_{fuel}LHV + q_{additional} \quad (2)$$

$$q_{additional,kiln} = M_{Comb.Air}C_{p,Comb.Air}(T_{Comb.Air} - T_{Comb.Air,initial}) \quad (3)$$

$$q_{additional,boiler} = M_{Water}C_{p,Water}(T_{Water} - T_{Water,initial}) \quad (4)$$

Where the variables above have the following meaning: $M_{fuel,initial}$ – Baseline case fuel mass flow rate (kg/h), M_{fuel} – Fuel mass flow rate (kg/h), $M_{Comb.Air}$ – Combustion air flow rate (kg/h), $C_{p,Comb.Air}$ – Air heat capacity (kJ/(°C.kg)), $T_{Comb.Air}$ – Combustion Air Inlet Temperature at the tunnel kiln (°C), $T_{Comb.Air,initial}$ – Baseline case Combustion Air Inlet Temperature (°C), M_{Water} – Water mass flow rate (kg/h), $C_{p,Water}$ – Water heat capacity (kJ/(°C.kg)), T_{Water} – Water inlet temperature at the boiler (°C), $T_{Water,initial}$ – Baseline case Water Inlet Temperature (°C).

The tunnel kiln model was assembled to allow the coupling of a PID controller, which controls the recycled air flow rate by receiving a set-point of the combustion air inlet temperature at the combustion chambers, thus simulating the recycling of hot air from the cooling zone of the kiln as a part of the total combustion air.

A set of assumptions were considered in the performance of the whole modelling:

- In respect to the tunnel kiln model, the air-to-fuel ratio is constant (not varying according to different conditions), as well as the enthalpy allocated to the ceramic product, the enthalpy allocated to the cooling air stream and heat losses;
- The ambient temperature is 25 °C and the ambient pressure is 1 bar;
- Pressure losses in the system are negligible.

The model created using OpenModelica 1.14.1, an open source distribution of Modelica, for the plant and the proposed WHR strategy is presented in Fig. 2.

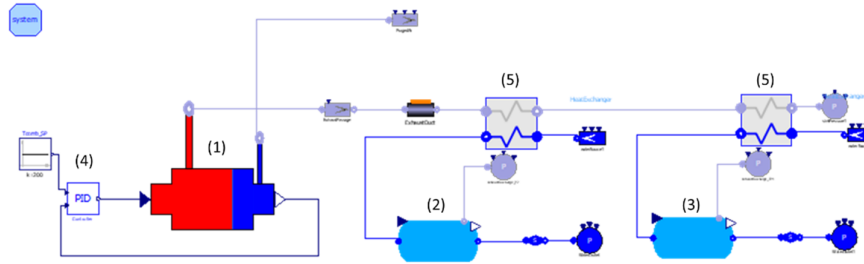

Fig. 2. Model for the ceramic plant and proposed WHR strategy: (1) Tunnel kiln, (2) Boiler 1, (3) Boiler 2, (4) PID Controllers, (5) Water-gas heat exchangers

2.3. Simulation Results and Model Validation

The model conceptualized for both components and plants are developed in a basis of dynamic simulation, although the simulation performed for the purpose of model validation was carried out in a steady state perspective – the simulation values tend to stabilize at a certain point of the simulation attaining constant values. The simulation results, real plant values and the respective deviations are presented in table 1.

Table 1. Simulation Results and Deviations from real plant values

Variable	Simulation Value	Real Plant Value	Deviation (%)
Flow rate of Exhaust Gases (Tunnel Kiln)	14455	14455	0.00
Temperature of Exhaust Gases (Tunnel Kiln)	159.4	159.3	0.09
Temperature of Hot Air (Tunnel Kiln)	93.0	93.73	0.79
Temperature of Hot Water (Boiler 1)	95.0	95.0	0.03
Temperature of Hot Water (Boiler 2)	95.0	95.0	0.03

Based on the results presented in table 1, it is possible to verify that the simulation results are overall consistent with the real plant measured data (the deviations for all the key parameters are lower than 1%).

2.4. Formulation of the Optimisation Problem

The process integration proposal may be adjusted to optimal operational conditions through the assessment of all the operational requirements needed to be considered and the energy consumption by thermal processes. This adjustment of operational conditions may be formulated as a simplified optimisation problem.

In the proposed optimisation problem, the constraints consist in limiting values for mass flow rates and temperatures of the exhaust gas and hot air streams. The hot air at the outlet of the tunnel kilns (the hot air that is purged to the environment and it is not recovered to the combustion chamber of the kiln) has associated minimum flow rate values, which is the hot air flow rate which have been recovered in the base case (5524.8 kg/h). Moreover,

as the exhaust gas must not be cooled down to the dew point temperature of the exhaust gas. Therefore, the exhaust gas stream obtain by the mixture of both kilns exhaust gas streams must be above 25 °C (a minimum temperature value). The objective-function is the minimization of fuel consumption (natural gas) in the tunnel kiln and boilers. The decision variable is the temperature of the combustion air stream at the inlet of the tunnel kiln (the set-point at the PID controller), which was set to 200°C. The decision variable is adjusted to achieve the objective while respecting the operational requirements. The mathematical formulation for the described optimization problem is presented in table 2.

Table 2. Mathematical formulation for the optimization problem

	Minimum Value	Variable	Maximum Value
Decision Variable	25°C	$T_{Comb,Air}$	200°C
Constraints	$M_{purged\ air} \leq 5524.8\ kg/h$		
	$T_{exhaust,outlet} > 25.0^{\circ}C$		
Objective-Function	$min(M_{fuel})$		

The implemented control system assisted on the implementation of the optimisation procedure (the decision variables are the PID associated controlled variables). Such allows the input of different values for the decision variable considering its variation with time, which is only possible since OpenModelica is dynamic simulation-based software. Due to the adopted steady state perspective adopted, the whole analysis performed for the techno-economic assessment is the minimum fuel consumption scenario.

3. Techno-economic assessment

The techno-economic assessment performed considers a simple payback, not considering an inflation rate of the capital costs associated to the technologies. As the system retrofitting approached in this work is essentially conceptualized in an energy efficiency improvement perspective, the overall aim is to optimise the associated plant energy costs. The capital expenditures, in its turn, correspond to the project overall investment cost (which includes the acquisition of ducts for the transportation of hot air, two water-gas heat exchangers and ducts for the transportation of the exhaust gases of the kilns). These are minimized in order to reduce the payback time associated to the implementation, although the values for the investment costs were fixed (considering the data from the catalogues of the technologies’ manufacturers).

The results for fuel savings obtained by the solving of the optimisation problem are presented in table 3. The savings were determined considering the natural gas price for Portugal of 13.28 €/GJ for industrial applications (INE-I.P./DGEG, 2018). The determination of payback time associated to the implementation of the proposed WHR strategy is presented in table 4. The calculation of this parameter was performed considering the results for the fuel savings obtained in the simulation and the total investment cost.

Table 3. Results for fuel savings

	Initial Case (kg/h)	Improved Case (kg/h)	Energy savings (MWh/year)	Savings (1000 €/year)
Kiln 1	103.5	81.4	2159	103.2
Boiler 1	10.95	4.21	659	31.5
Boiler 2	10.95	3.95	684	32.7
Total			3508	167.4

Table 4. Techno-economic assessment

Equipment	Investment Cost (€)	Savings (1000 €/year)	Payback Period (years)
Air Ducts	1754	167.4	0.2
Exhaust Gas Ducts	7700		
Two water-gas heat exchangers	25415		

Considering the payback time in which a measure is considered economically viable within the context of the European industry (2 – 3 years), the proposed WHR strategy may be considered highly economically viable.

4. Conclusions

The case-study analysed and assessed in this paper is inserted in a Portuguese ceramic plant. It is a plant with a high thermal energy consumption, with few implemented WHR strategies, currently existing an interest to reduce the fuel consumption of tunnel kilns and hot water boilers. In this sense, it was proposed and assessed the implementation of a new WHR strategy which included the hot air recycling from the cooling zone of the kilns and the installation of two water-gas heat exchangers.

Such study was performed by creating a model of the plant and WHR strategy using the Modelica language. The developed model was validated by comparing the simulation results with real plant measured data. It is verified that the simulation values are consistent with real values.

In a strategic perspective, this study revealed the significance of the use of a simulation tool for energy system-based decision making. In a technical perspective, it allowed to assess the viability associated to the project of heat integration system, having been obtained results of optimisation adding two water-gas heat exchangers, with a low payback time of 0.2 years.

Abstract

One way of simultaneously minimising the use of fresh resources and pollution reduction is the practice of industrial and urban symbiosis, implementing Circular Economy. In the current work, it has been shown that the circularity rate alone is not a sufficient criterion to achieve resource and footprint minimisation. It is necessary to evaluate the cost and the footprints in a combined way. The formulated conceptual model allows the evaluation of the trends of the total cost, water and Greenhouse gas footprints. The provided case study clearly demonstrates the usefulness of the model in evaluating the trade-offs between the considered process characteristics, showing a 10 % difference between the optimal circularity rates for Water footprint minimisation and cost minimisation.

Keywords: Resource Integration, Resource Recovery, Industrial-Urban Symbiosis, Network Optimisation

1. Introduction

Resource recovery and reuse methods have been developed to cope with the problems of resource depletion and pollution of the environment. The main categories include Circular Economy (CE) (Hartley et al., 2020), Industrial Symbiosis (IS) (Domenech et al., 2019) and Process Integration (PI) (Klemeš, 2013). The conservation of energy and materials (Klemeš, 2013) is the most effective strategy to achieve sustainability, making the task of fresh resource supply easier. Fan et al. (2019) reviewed the methods for energy saving and pollution reduction, identifying the synergy between CE, resource, utility, and waste management as the route to make this strategy economically viable. The European Commission adopted a new Circular Economy Action Plan (EC, 2020) and policy recommendations (Hartley et al., 2020) from the Life Cycle perspective, and a set of new targets (Morsetletto, 2020) were proposed to facilitate the transition to a CE.

IS (Domenech et al., 2019) is a practical way to implement CE by sharing resources – materials, energy, water. A good example is the application of urban and industrial symbiosis for formulating a cross-industry network of multiple supply chains (Tseng et al., 2018) and fundamentally the Total Eco-Site Integration (Fan et al., 2021).

Many circularity indicators are available (Saidani et al., 2019). They can be applied to a multitude of contexts, ranging from multiple chemical species evaluation and up to regional or global system boundaries. A standardised metric for characterisation is the “Circular Material Use Rate” (CMU), officially employed by Eurostat (2018), defined as the fraction of reused materials from the total material use.

Material circularity reflects only one of the key dimensions in industrial and urban symbiosis systems. The energy dimension is also crucial, often prompting the energy-water nexus (Ahmad et al., 2020) or multi-tier interactions (Wang et al., 2019) to be considered as a whole. The importance of energy is in driving all involved processes—thermally, chemically, electrically and mechanically. In assessing the energy inputs and efficiency, it is necessary to account for the energy forms—heat and power, and the entropy generation, especially by mixing. This consideration leads to the use of exergy (Selicati et al., 2020) as the unifying criterion. Recent research has used exergy to evaluate the efficiency of material recovery from Cd-Te photovoltaic modules (Abadías Llamas et al., 2020) and evaluation of the exergy efficiency of biogas upgrading processes (Vilardi et al., 2020). A key principle is the use of embodied exergy and the linked embodied emissions for evaluating the process performance (Almeida et al., 2017). Circularity alone cannot be used as an ultimate indicator of sustainability. Environmental footprints (Holmatov et al., 2019) are also needed to quantify the impacts of both inputs and outputs.

Industrial and urban symbiosis systems have degrees of freedom for making design and operating decisions, while footprints and cost are used as performance criteria. The reviewed state of the art shows the trend to use cost, footprints or exergy alone, and in some cases cost and exergy have been used together, leaving exergy input as an auxiliary screening tool. This leaves a research gap – the use of all three criteria simultaneously for evaluating the sustainability of the symbiosis systems against the degree of circularity. The current work presents a model optimising industrial-urban symbiosis system by minimising the cost and the footprints (Čuček et al., 2012) against the circularity.

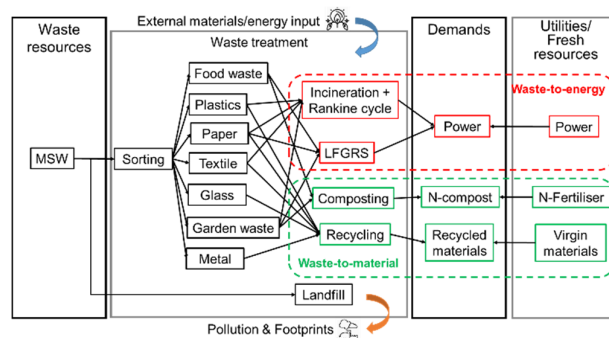

Figure 1. Concept Map of urban symbiosis waste reuse system

2. System representation, model and evaluation method

The symbiosis system can be seen as a set of paths from waste supply locations to demands for products and resources, which compete with the delivery of products from fresh resources (Figure 1). Each path includes different unit operations with varying efficiency. The processing paths also require fresh resources – energy, water, other materials, but they are often less intensive than the resource demands for new products.

The circularity is represented by the Total Circularity Index (TCI), which is the weighted sum of the CMU and a new circularity indicator – the Circular Exergy Use rate (CEU):

$$TCI = \omega_1 \times CMU + \omega_2 \times CEU; CEU = \frac{Ex_{recycle}}{Ex_{demands}} \quad (1)$$

CEU is defined (Eq.1) as the fraction of the exergy supplied from resource recycling and the overall exergy demands. The weights ω_1 and ω_2 are user specifications, modelling the importance of the material and exergy supply for each case. The model, summarised in (Eq.2), uses the material, energy and exergy balances, evaluating Total Annualised Cost (TAC) Greenhouse Gas (GHGFP) and Water Footprints (WFP). Additional constraints are stemming from the upper and the lower bounds on the stream flowrates. The optimisation variables include the flowrates of the recycle streams and those of the fresh resource supplies. The optimisations are run with three variants: minimising TAC, maximising GHGFP saving and maximising WFP saving.

$$\begin{aligned} & \text{minimise TAC} \quad \text{maximise GHGFP}_{\text{saving}} \quad \text{maximise WFP}_{\text{saving}} \quad (2) \\ \text{s.t.} \quad & TAC = f_{inv}(\text{equipment}) + f_{oper}(\text{throughput}) \\ & GHGFP_{\text{saving}} = f_{GHG1}(\text{demands}) - f_{GHG2}(\text{utilities}) - f_{GHG3}(\text{recycle}) \\ & WFP_{\text{saving}} = f_{WFP1}(\text{demands}) - f_{WFP2}(\text{utilities}) - f_{WFP3}(\text{recycle}) \\ & \text{Mass balances; Energy balances; Exergy balances} \end{aligned}$$

3. Case study

The system in Figure 1 has been evaluated on a set of sampling points of the TCI, running the optimisation model for each of the variants in Eq.2. The product demands and utilities prices are in Table 1, MSW properties in Table 2, where Degradable Organic Carbon is denoted as DOC. The maximum MSW flowrate is 137 kg/h. The unit operation characteristics and the cost data are shown in Table 3. The nitrogen content of the recycling compost is 30% (Fan et al., 2019). Table 4 provides the GHG factors, and Table 5 – the WFP factors.

Table 1. The data of the demands and utilities prices

Demands/Utilities	Demands value	Utilities Price
Power	60 kW	0.052 €/kWh
N-fertiliser	38 kg/h	0.133 €/kg
Paper	27 kg/h	0.033 €/kg
Plastic	29 kg/h	0.178 €/kg
Glass	6 kg/h	0.039 €/kg
Metal	5 kg/h	0.199 €/kg
Textile	10 kg/h	0.039 €/kg

Table 2. MSW properties

Sorting	Composition, %	LHV, MJ/kg	Carbon Content, %	DOC _F , %
Food waste	41.1	5.26	42.61	64

Landfill	1.2×10 ⁻⁶ m ³ /t	-

The TAC evaluation results are shown in Figure 2. Figure 3 shows in part (a) the variation of the GHG and the exergy input, and part (b) plots the WFP. The TAC curve features a minimum at TCI=0.465 (1) / TAC= 84.5 k€/y. The GHG emission trend implies that higher circularity rate is, the better. The WFP curve has a maximum for TCI= 0.353 (1) and WFP saving 827 k(m³/y). The reason for this is that for TCI ≥ 0.3, for increasing the CMU values, secondary resources are redirected from energy generation because the WFP saving for material recycling is higher than for energy generation which is also more costly. These discrepancies provide information to decision-makers for the approximate

cost ($\approx 0.6 \text{ €/m}^3$) of reduction of water pollution (by reducing circularity a little) or of the environmental cost of attaining the cost optimum. However, it should be noted that the reduced circularity also reduces the GHG savings, in addition to increasing the TAC.

(b) TCI $\in [0.4, 0.543]$

Figure 2. TAC variation with the circularity rate

(a) GHG emission reduction (with exergy)

(b) WFPs reduction

Figure 3. GHG and WFPs emission reduction as functions of the circularity rate

4. Conclusions

The current work presents a conceptual model for evaluating the sustainability of industrial-urban symbiosis systems. The proposed model captures the key circularity rate criteria – adding the definitions of CEU and TCI to CMU, followed by a combined evaluation of the TAC, GHGFP and WFP reductions, and total exergy input. The case study demonstrates the usefulness of the proposed conceptual model for evaluating the optimal circularity rate. It also reveals that besides not coinciding with the TAC trend (WFP optimum is $\approx 10\%$ higher TAC than the cost optimum), the emission reduction trends can be adversarial to each other, pointing to the need for improved modelling in the future. Such an improvement is to add a monetary representation of the footprints and join them to the TAC, leading to the concept of Eco-Cost as the objective function.

Abstract

Biomass gasification is one of the most promising solution for producing clean electricity. This technology option can reduce the use of fossil fuels and limit the exhaust CO₂ emissions in atmosphere. Moreover, by integrating different CO₂ separation technologies, the biomass gasification power plant is considered to have negative CO₂ emissions due to the CO₂ absorption during its growth. In this study, the physical absorption process deep eutectic solvent (DES) was used to retain the CO₂ from syngas. Subsequently, the treated synthesis gas was used in a gas turbine (ITG) plant. The flue gases expanded in the gas turbine were introduced into the heat recovery steam generator (HRSG) for steam production and utilization in a steam turbine for mechanical work and subsequent power generation. The biomass (poplar) gasification process was analysed for different air equivalent ratio (ER). The highest lower heating value of the synthesis gas was obtained for ER = 0.2. In the case of CO₂ capture based on DES, a thermal energy consumption of 1 GJ/tCO₂ was determined, this represents an electrical energy consumption of 0.4 GJ/tCO₂. In terms of electricity production, for a syngas flow rate of 20 t/h, the maximum power obtained was of 10.8 MW, and the net cycle efficiency of 30 %.

Keywords: Biomass gasification, DES-based CO₂ capture, Energy integration

1. Introduction

The biomass gasification with CCS (Carbon Capture and Storage) can be promising solution to reduce the carbon dioxide emissions (C. Dinca et.al, 2018). The biomass is considered a energy source with neutral CO₂ emissions. The biomass gasification with CO₂ capture generates the negative emissions, therefore it could decrease the level of carbon dioxide emissions in atmosphere on the long-term (J. Kemper, 2017). The CO₂ capture technology was studied intensively in the last decade to reduce the negative impact after integration into an energy or industrial process. Thus, it is needed to develop new solvents with higher CO₂ absorption capacity, solvents that requires lower thermal energy for regeneration, and with a lower corrosivity, comparative with the conventional amines. Several researchers studied primary, secondary, tertiary amines and amine blends in order to improve the performances concerning the CO₂ absorption capacity and to reduce the thermal energy consumption (C. Dinca, 2016). Also, it is observed that primary and secondary amines have a higher rate of reaction and higher energy consumption than the tertiary ones that need a lower amount of thermal energy for regeneration due to the carbonate and bicarbonate ions form during the hydrolysis of CO₂ in the absorption

process (K. Goto et.al, 2013). Deep eutectic solvents (DES) are the promising alternative for CO₂ separation, can replace the conventional chemical solvent based on amines. DES has many advantages, like as: the thermal energy needed for regeneration is lower compared to amines, due to the physical absorption of carbon dioxide; due to the low vapour pressure, the amount lost in the absorption and desorption process is smaller; DES degradation occurs at temperatures higher than 300 °C, no reactions with other impurities from flue gases, and are not corrosive; DES preparation allows the design of absorbents with specific properties for CO₂ separation. DES still have some drawbacks to integrating at a large scale for CO₂ separation, such as the difficult production process and the expensive raw material price (R.J. Isaifan and A. Amhamed, 2018). The aim of this study consists of the biomass gasification with CO₂ capture pre-combustion based on DES and syngas utilization for energy produce.

2. Gasification process

Gasification process consists of transforming of solid fuel in gaseous fuel, rich in H₂, in the presence of an oxidizing agent (air, oxygen, steam or mixtures of these). The main reactions that occur in the gasification process are presented by Equation 1-8.

The type of biomass used in this study was wood biomass – poplar. The biomass dry composition is presented in Table 1. The initial moisture content is of 6.35 %, and the oxygen content was determined by difference. The lower heating value (LHV) of biomass is 16,760 kJ/kg.

Table 1. Biomass composition

C [%]	H [%]	N [%]	S [%]	O [%]	Ash [%]
50.94	6.34	1.81	0.1	40.562	0.248

The gasification process simulation was carried out in the specialized software Chemcad. The Peng Robinson thermodynamic model was used in the gasification and power generation process. The oxidizing agent used in the gasification process was pure air. ER represents the ratio of the actual air amount introduced into the gasification reactor and the stoichiometric air amount. The maximum volume fraction of H₂ was obtained for ER = 0.4. The concentration of methane in the syngas decreases with a larger amount of air introduced the gasification reactor, and the CO concentration increases due to the combustion reactions (Figure 1). The lower heating value of the syngas decreases with

increasing the ER ratio, due to the decrease of CH₄ concentration. The heat energy contained by the syngas was determined as the product of the lower heating value and the syngas mass flow. Thus, even if the lower heating value has a descending allure, the thermal energy contained by the syngas has a maximum value for ER ratio of 0.4 (Figures 2). After the biomass gasification, the water gas shift reaction (WGS) and the syngas treatment, the carbon dioxide from syngas is separated by physical absorption used DES. The syngas composition considered for CO₂ separation is the one for that the highest value of the H₂/CO ratio was obtained. Thus, the syngas considered for the CO₂ separation has the following volumetric composition: H₂ = 27 %, CH₄ = 1 %, N₂ = 46 %, CO = 4 %, CO₂ = 22 %.

Figure 1. Syngas composition

Figure 2. LHV and thermal energy content

3. CO₂ capture process

The CO₂ separation process based on DES is described in the Figure 3. It can be observed that the process is similar to the separation process based amines, with the difference that in the case of use DES-amines, the absorption process can takes place at higher pressures (>2 bar, the pressure of the absorption process for amine is the atmospheric pressure) . In this study, the thermal energy for DES regeneration rich in CO₂, was determined by calculation based the model described by Y. Zhang et.al, 2016. The absorption pressure was considered of 1.013 bar to reduce the electric energy needed for the syngas compression, and the absorption temperature of 25 °C. The desorption pressure was considered of 1.013 bar and the desorption temperature of 50 °C. Due to the desorption temperature, the thermal energy consumption for solvent regeneration was resulted of 1 GJ/tCO₂, this is equivalence of 0.4 GJ/tCO₂ electric energy consumption, for CO₂ capture efficiency of 90 %. In the Figure 4, the thermal energy consumption is presented for DES, monoethanolamine and diethanolamine. The purity of dry CO₂ is more than 98 mol %.

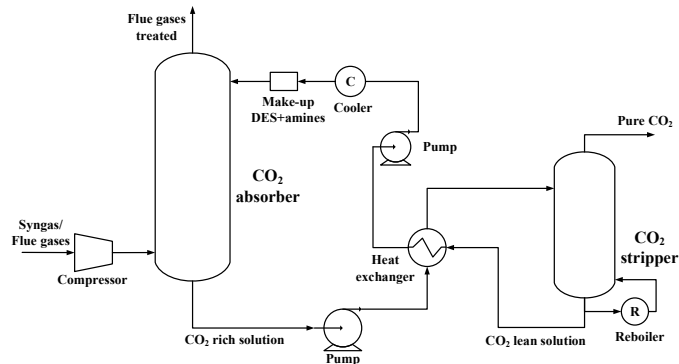

Figure 3. Schematic diagram of CO₂ separation process

Figure 4. Thermal energy consumption for solvent regeneration

4. Energy production

The schematic diagram of the energy production chain is presented in Figure 5. The syngas composition used for energy production is presented in Table 2 before and after CO₂ capture process integration. Syngas obtained after gasification process was used to produce electric energy in 4 cases. Cases studied are:

- Case 1: Gas turbine (GT) without CO₂ capture process;
- Case 2: GT with pre-combustion CO₂ capture;
- Case 3: GT with pre-combustion CO₂ capture and recovery a part of the flue gases heat to preheat the air-syngas mixture before entering GT;
- Case 4: GT with pre-combustion CO₂ capture, recovery the heat of the flue gases to use in the steam turbine (ST), and preheat the air-syngas mixture.

The efficiency process of the energy produced was determined with the following relationship:

$$Ef_{process} = \frac{P_{GT} + P_{ST} - P_C - P_R}{\dot{m}_s \cdot LHV_s} \quad (1)$$

where: P_{TG} - gas turbine power, in kW; P_{ST} - steam turbine power, in kW; P_C - air compressor power, in kW; P_R - regeneration solvent power, in kW; \dot{m}_s - syngas flow, in kg/h; LHV_s - lower heating value of syngas, in kJ/kg.

In order to maximize the energy produced, several parameters were varied, such as the air flow introduced into the combustion chamber (CC). It was determined the optimum temperature for that the maximum power is obtained and the maximum efficiency of the combustion process. For example, in the Case 1, when the syngas is used without CO₂ capture process, for a temperature of 1,200 °C, air flow of 40,000 kg/h is needed to produce 10.8 MW. In the Case 2, when syngas is used after CO₂ capture process, for a temperature of 1,200 °C in the combustion chamber, the air flow introduced was 50,000 kg/h, and the power produced was of 11.8 MW.

Figure 5. Biomass gasification with CO₂ capture process pre-combustion

Table 2. Syngas composition before and after CO₂ capture process

Composition (vol. %)	Before CO ₂ capture (vol. %)	After CO ₂ capture (vol. %)
H ₂	27	35
CH ₄	1	1.2
N ₂	46	57
CO	4	5
CO ₂	22	2.8
LHV (kJ/kg)	3,480	5,442

Further, it was analysed the process efficiency for a constant temperature in the combustion chamber, of 1,200 °C (Figure 6). Thus, with the heat recovery system integration of the flue gases significant improvements are known regarding the cycle efficiency. The optimal case, when it was obtained the higher process efficiency, it is Case 4 (integrated gasification combined cycle with CO₂ capture). Another important advantage of the CO₂ capture process integration consists in the amount of carbon dioxide emitted into the atmosphere with the flue gases resulting from the process. It can be observed that after the capture process integration the concentration of CO₂ in the flue gases decreases significantly, respectively from a percentage of 11 %, in the case of using of the syngas without CO₂ capture, to a maximum of 2 % for the cases when is integrated the CO₂ capture process (Figure 7). In Figures 8, there are shown the results obtained if the power is maintained constant. It can be observed, in terms of process efficiency, as in the previously hypothesis, the Case 4 has the highest efficiency, and the Case 2, the lowest efficiency. In Figure 9 is presented a comparative analysis of the process efficiency according to the type of solvent used for the CO₂ capture. The DES-based CO₂ capture is the most efficient solution due to the the lower amount of thermal energy required for solvent regeneration.

Figure 6. Process efficiency

Figure 7. CO₂ concentration in flue gases

Figure 8. Process efficiency

Figure 9. Comparative analysis of process efficiency

5. Conclusions

The biomass gasification with CO₂ separation process is a solution to produce thermal and electric energy with low emissions of carbon dioxide. The low heating value of the syngas obtained after air gasification process was of 3,480 kJ/kg before CO₂ capture, for an equivalent ratio of 0.4, and of 5,442 kJ/kg after CO₂ pre-combustion capture process integration. The thermal energy consumption for DES regeneration was obtained of 1 GJ/tCO₂, much lower than amines (MEA, DEA). In terms of the power produced, the combined cycle (gas turbine-steam turbine) with CO₂ pre-combustion capture and recovery heat flue gases system was optimum. In this case, it was obtained the maximum power produced.

Abstract

In this study, the energy efficiency of a novel integrated process including recovery of natural gas liquids (NGL), natural gas liquefaction and nitrogen removal unit (NRU) is investigated. This study designs a prevailing single column NRU, considered as the base case and a double-column NRU integrated processes in conjugation with boil-off gas (BOG) generation in the various process steps after acid gas removal unit. The BOG generated and nitrogen rich waste stream are utilized as fuel gas (FG) for gas turbine to generate power. A simulation based optimization paradigm deploying particle swarm optimization algorithm is implemented to minimize the specific power requirement with consideration of higher heating value (HHV) of LNG product, NGL Reid vapor pressure (RVP), Wobbe index (WI) and pressure of FG. The parity between FG heating value and fuel requirements ensures efficient and self-sustained LNG plant. The optimal process parameter and specific power requirement for the single column NRU conventional and double column NRU integrated process are compared.

Keywords: LNG, Nitrogen removal, integrated process design, Boil-off gas

1. Introduction

Natural gas (NG), owing to favorable heating values, relatively low fuel costs and significantly reduced emission of carbon dioxide and a negligible amount of CO, NO_x, SO_x and particulate as compared to combustion of oil and coal makes it a lucrative option to be the bridge between renewables and non-renewables. Practical storage and transport of NG as liquefied natural gas (LNG) is viable by liquefaction at 112 K, to reduce the volume occupied by methane by more than 600 times at ambient pressure.

The literature covers the progress in designing of efficient LNG liquefaction process and sheds light on potential improvements in specific energy requirement by the integration of LNG liquefaction, NGL recovery and NRU. (Ghorbani et al., 2016) With increasing concerns of climate changes, the BOG generation minimization and handling become of paramount importance to ensure LNG supply chain has reduced carbon footprints and detrimental impact on immediate surroundings. Although many studies are addressing the two aforementioned problems exclusively, to the best of our

knowledge there is no literature painting a holistic picture of existent LNG plant by incorporating an integrated LNG liquefaction, NGL recovery and multi-column NRU process with BOG generation at various process step accounting for the fuel gas. (Lee et al., 2019) The various process constraints on the HHV of LNG product, NGL RVP, WI and pressure of FG and parity between FG heating value and fuel requirements ensuring optimal and self-sustained LNG plant, remains briefly addressed in the literature.

This study aims to analyse and improve the energy efficiency of process steps after acid gas removal unit (AGRU) in an existent baseload LNG plant. This study carries out optimization and design of a prevailing single column NRU and a double-column NRU process, both integrating LNG liquefaction, NGL recovery and NRU processes in conjugation with BOG generation in the various process steps after AGRU. Particle Swarm Optimization (PSO) algorithm was implemented to minimize specific power requirement with consideration of LNG HHV, NGL RVP, and fuel gas WI and pressure and fuel gas generation-requirement balance. (Kennedy & Eberhart, 1995) Further, the optimized results of single column NRU conventional and double column NRU integrated processes are compared and results discussed.

2. Process Description

2.1. Single Column NRU conventional process design

Figure 1 illustrates integrated liquefaction, NGL recovery and one column NRU system, with an SMR cycle, regarded as the single-column NRU conventional system and the base case for comparing the improved system proposed in this study. The top product of NGL column after liquefaction makes the feed for the NRU column operating at 2 Bar pressure. The vapour fraction of reboiler stream controls the purity and recovery of methane in LNG product stream. The bottom product of NRU column is pumped to 6 Bar and flashed in the storage tank. The BOG generated in the storage tank and the nitrogen rich waste stream is compressed and used as fuel gas. A single mixed refrigeration cycle provides the requisite cold energy for liquefaction. The retrieval of cold energy from the BOG stream and nitrogen rich waste stream in a multi stream heat exchanger (MSHE) before compression, provide additional cold energy and improve the efficiency of the process.

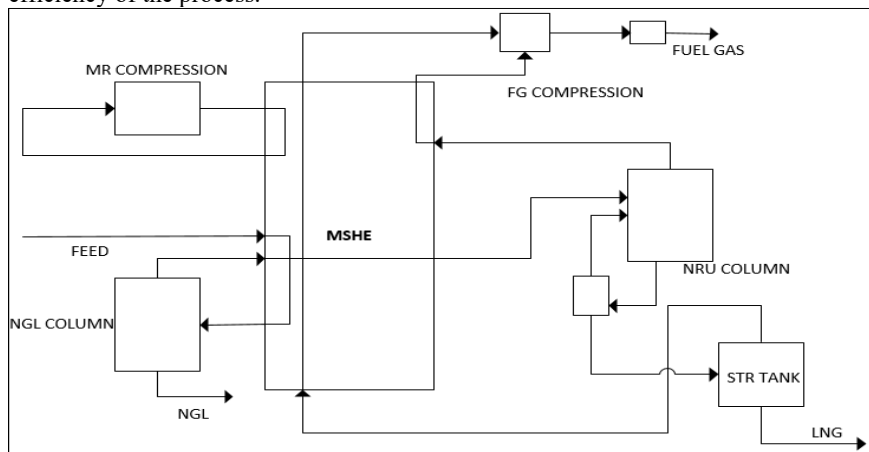

Figure 1 Schematic diagram of single column NRU conventional process

2.2 Double column NRU integrated process design

Figure 2 shows the double-column NRU process. The process along with integrated liquefaction and NGL recovery comprises of one high-pressure (HP) column and one low-pressure (LP) column in NRU. The compressed feed after AGRU is cooled and throttled before entering the NGL recovery column. The top product of HP NRU column enriched in nitrogen, divided into two streams in SPLIT-1 & 2 provide reflux to both HP and LP NRU columns after compression, splitting and cooling. A part of the bottom product of HP NRU column (SPLIT-3) contributes towards fuel gas requirement after Joule-Thomson expansion to 20 Bar and cold energy retrieval in MSHE. The feed to LP NRU column comprises of a part of the top product stream of HP NRU column. The HP and LP column operate at 26.8 and 5.3 Bar respectively. The bottom liquid stream from LP NRU is pumped to 56 Bar before sub-cooling and flashing to 2 Bar pressure. The BOG due to vapor displacement, HP flashing and heat leaks in STR-TANK and top product of LP-NRU column, after cold energy recovery in MAIN-MSHE and three-stage compression to 20 Bar, contribute to the fuel gas requirement.

3. Solution procedure

Simulation based optimization paradigm was deployed to find the optimal operating parameter of the processes. Aspen Hysys V.10 simulated each random design generated by PSO algorithm coded in MATLAB. A simulation-based optimization framework combining the accurate and fast thermodynamic calculation performed in Aspen Hysys and rigorous optimization algorithm implemented on an external platform like MATLAB can provide an accurate value for the decision variables while ensuring the constraints are met and specific power minimized. (Hamed et al 2019) The connection between MATLAB and Hysys established through component object model in ActiveX, allows direct two-way communication between Hysys and MATLAB. The process and stream data calculated in Hysys are sent to MATLAB, which performs optimization, levies constraints on variables, and sends back the values of calculated variables. This section further discusses the decision variables and constraints for the conventional and two-column NRU integrated design, which is optimized using PSO to find the minimum specific energy requirement for both cases.

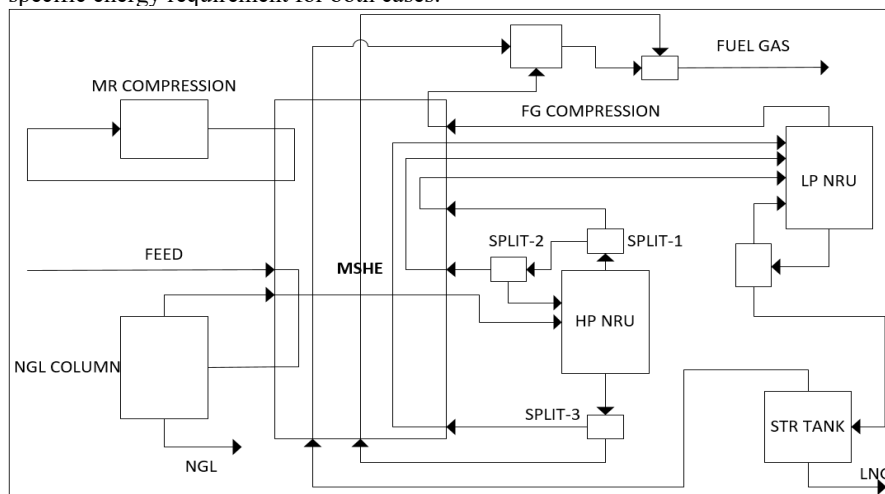

Figure 2 Schematic diagram of double column NRU integrated process

3.1 Single column NRU conventional process optimization

The major energy consumer in single-column NRU conventional process is the four-stage SMR cycle compressors. The three-stage compression of fuel gas streams generated by NRU column and BOG at the export terminal also contribute towards the energy requirements of the process. The feed compressor, SMR cycle pumps and LNG pump are other contributors towards energy consumption. The objective is to find the minimum specific energy requirement, calculated by dividing total energy consumption by LNG production in mega long tonnes per annum (Mty).

$$\text{Total power consumption by User 2} = W_{\text{FEED-COM}} + \sum_{\text{I=compressor}} (W_{\text{MR-COM-I}} + W_{\text{FG-1-COM-I}} + W_{\text{FG-2-COM-I}}) + \sum_{\text{I=pump}} (W_{\text{PMP-I}}) \quad (1)$$

Objective function, specific power consumption

$$= [\text{Total power consumption by User 2}] / [\text{PRODUCT LNG mass flow rate}] \quad (2)$$

W denotes power consumption by the compressor or pump described in the subscript. The single column NRU conventional process consists of 15 decision variables. The NGL recovery column operates at a fixed pressure of 54.7 Bar, hence the feed, reboiler and reflux temperature are the working variable to ensure the NGL flowrate and RVP specifications are met. The fuel requirement of plant before and including AGRU and post AGRU process are regarded as User 1 and User 2 fuel requirements respectively. The User 1 fuel requirement is considered same for both cases studies. The total fuel requirement for the process design takes into account the User 1 (fuel requirement before AGRU) and User 2 fuel requirements.

$$\text{Total fuel requirement} = \text{User 1 fuel requirement} + \text{User 2 fuel requirement} \quad (3)$$

$$\text{User 2 fuel requirement} = \text{Total power consumption by User 2} / 0.3 \quad (4)$$

The fuel requirement of process is satiated by the fuel gas stream available at 20 Bar.

$$\text{Total fuel generated} = (\text{Low heating value of FG}) * (\text{Molar flow of FG}) \quad (5)$$

The following specifications acting as constraints for the process:

$$\text{LNG product High heating value} \geq 39.86 \text{ MJ/m}^3 \quad (6)$$

$$\text{NGL molar flowrate} \geq 702 \text{ kmol/h} \quad (7)$$

$$\text{NGL RVP} \leq 23.9 \text{ Bar} \quad (8)$$

$$\text{Wobbe index of fuel gas} \geq 30 \text{ MJ/m}^3 \quad (9)$$

$$\text{Minimum temperature approach in MSHE} \geq 2 \text{ K} \quad (10)$$

$$\text{Total fuel requirement} / \text{Total fuel generated} \geq 0.99 \quad (11)$$

$$\text{Total fuel requirement} / \text{Total fuel generated} \leq 1 \quad (12)$$

The two inequality constraints (11) & (12), relax the equality constraint for fuel balance.

3.2 Double column NRU integrated process optimization

The double-column NRU integrated process has four compressors SMR cycle, contributing to major energy consumption and one expander at HP-NRU feed column, producing some energy. The NGL recovery column operated at a pressure similar to that of conventional design delineated in the previous section, hence the feed, reboiler and reflux temperatures of NGL recovery column are working variable to ensure NGL flowrate and RVP specification are met. The objective is to find minimum specific energy requirement containing 27 decision variables.

$$\text{Total power consumption by User 2} = W_{\text{FEED-COM}} + \sum_{\text{I=compressor}} (W_{\text{MR-COM-I}} + W_{\text{FG-1-COM-I}} + W_{\text{FG-2-COM-I}}) + \sum_{\text{I=pump}} (W_{\text{PMP-I}}) - W_{\text{EXP}} \quad (13)$$

Objective function, specific power consumption

$$= [\text{Total power consumption by User 2}] / [\text{PRODUCT LNG mass flow rate}] \quad (14)$$

The product specification and process constraints levied for the conventional process listed in section 3.1 (Equation 3-12) are active for double-column NRU integrated process optimization as well.

4. Results

The four-stage compression in SMR cycle is the major contributor towards the power requirement with 99.42 and 97.27 MW for single-column NRU conventional and double column NRU integrated process, respectively. This power requirement reduction results from lower entropy generation and lowered compression pressure. The fuel gas generated for the process design comprises of the nitrogen-rich waste stream from NRU column and BOG at low pressure and require compression. The double-column NRU integrated process has additional fuel gas stream sourced from the bottom stream of HP NRU column at high pressure. This leads to a reduction in FG compression power requirements by 56% and the absolute values are 9.64 and 4.24 MW respectively for single-column NRU conventional and double column NRU integrated process respectively.

Table 1 summarizes the values of parameters and constraints of the two process designs with fuel gas generation to satiate the process energy requirement. The NGL stream conditions are similar for the two process designs. The LNG product feed flow rate for the double column NRU integrated process increases by 4.8% as compared to the conventional case for the same feed flow rate. The total power requirement of the

Table 1
Summary of results and specific power consumption

		Single column NRU conventional design	Double column NRU integrated design
LNG	Product mass flow rate (Mty)	3.308	3.324
	Pressure (Bar)	1.2	1.2
	Temperature (K)	113.3	113.2
	Nitrogen content (mol %)	0.34	0.28
	LHV (MJ/m ³)	36.2	36.2
	HHV (MJ/m ³)	39.8	39.8
NGL	Molar flow rate (kmol/h)	703	702.5
	Pressure (Bar)	54.87	54.87
	Temperature (K)	314.8	327.8
	RVP (Bar)	23.9	23.8
Fuel Gas	Molar flow rate (kmol/h)	3815	3712
	Pressure (Bar)	20	20
	Temperature (K)	298	298
	Wobbee index (MJ/m ³)	30.78	30.36
Heat Exchanger Energy Calculation	MTA (K)	2	2
	Power requirement (MW)	109.6	104.3
	User 1 fuel requirement (MW)	210	210
	User 2 fuel requirement (MW)	365.3	347.6
	Total fuel requirement (MW)	575.3	557.6
	Total fuel generated (MW)	579.4	558.4
	Required/Generated fuel	0.993	0.999
Specific power requirement (MW/Mty)		33.13	31.3

double-column NRU integrated process witnesses a 4.8% reduction as compared to the single-column NRU conventional process. This reduction of power and fuel gas requirements lead to a reduction in required FG flow rate and higher LNG production for the former. The rigorous simulation-based optimization ensures the ratio of required and generated fuel value to be closer to unity. The objective function i.e. specific power consumptions are 33.13 and 31.13 MW/Mty for single-column NRU conventional and double-column NRU integrated process respectively. The decrease in optimal objective value can be attributed to a reduction in total power requirement and increase in LNG production.

5. Conclusions

The prevailing single column NRU conventional and double column NRU integrated processes are simulated, optimized and compared. The double column NRU integrated process shows a 5.5% reduction in specific power requirement as compared to the base case. This reduction in specific power requirement is attributed to lower power requirement leading to reduced fuel gas requirement and increased LNG production. The double column NRU integrated process witnesses a 16-kilo tonnes (long) per annum increase in production. The power required for SMR compression and fuel gas compression reduced by 2.1% and 56.1% as compared to the base case. The SPLIT-3 in double column NRU integrated process diverts 3.1% molar flow of HP-NRU bottom product to MAIN-MSHE for cold energy retrieval before utilising as fuel gas at high pressure, hence reducing the FG compression requirement. The high operating pressure of LP-NRU as compared to conventional design further contributes to the reduction in FG compression requirements.

Abstract

The aviation industry requires to reduce its carbon emissions. To do so, the fuel needs to be renewable-based as much as possible and have low life cycle emissions, hence be sustainable. Gas-to-Liquid (GTL) process through Fischer-Tropsch (FT) synthesis can be used to make aviation fuel. This process can be made more sustainable by lowering its carbon emissions. The addition of renewable power to the GTL process is investigated with the aim of reducing its CO₂ emissions. Two promising designs are considered which have very low CO₂ emissions: 1- Using Autothermal Reformer (ATR) to produce syngas and Solid Oxide Electrolysis Cell (SOEC) to produce H₂ and O₂; and 2- Production of syngas through electrically heated Steam Methane Reformer (E-SMR). In both designs, the addition of renewable power significantly reduces carbon emissions and increases carbon efficiency which means increased production for the same amount of natural gas feed. By assessing the two designs based on FT production, carbon efficiency, and FT catalyst volume, it is a better choice to add renewable power to the SOEC (case1) rather than using it in an E-SMR (case 2). These designs are considered in order to help us safely transit to a low-carbon society.

Keywords: Fischer-Tropsch synthesis, Renewable power integration, Low-carbon fuels, Low-emission Gas-To-Liquid process, Green Hydrogen.

1. Introduction

In order to reach the goals of the Paris Agreement (United Nations 2015) and the aims of the United Nations' Sustainable Development Goals (United Nations 2019), current industrial processes are required to move towards reducing their carbon emissions and hence becoming more sustainable. Decarbonizing the aviation industry is hard as there are few equivalent alternatives to kerosene and jet fuel, mainly because a fuel with high energy density is required. Fischer-Tropsch process produces a wide range of hydrocarbons including kerosene and jet fuel. Thus, liquid fuel production through this process is the focus of many investigations (Hillestad et al. 2018). Integration of renewable energy into chemical processes results in both increased production of chemicals and simultaneous reduction of CO₂ emissions (Agrawal et al. 2007). Hillestad et al. (2018) demonstrated that the carbon efficiency of a biomass to liquid (BTL) process can be increased by adding renewable power in the form of hydrogen and oxygen through electrolysis. The conversion of H₂ and CO₂ to liquid fuels via Power-to-Liquid

(PTL) processes is gaining attention (Dieterich et al. 2020). Van Bavel et al. (2020) proposed the hybrid “GTL-PTL” process where CO₂ and renewable H₂ are co-processed with natural gas to produce liquid fuel. Wismann et al. (2019) used electricity to drive the SMR reaction in an electrically heated wash-coated catalytic structure. As a result, the catalyst effectiveness factor is increased, production of side products is limited and a 100 fold volume reduction compared to a conventional SMR is observed (Wismann et al. 2019). In this paper, two options in reducing carbon emissions in the GTL process are investigated. Renewable power (from wind, solar, etc.) is integrated in both cases. As a result, the carbon emissions of both processes are considerably reduced. Moreover, with continued decline of cost of renewable power, these novel designs are considered to be cost competitive with the existing designs (Ostadi et al. 2015) in the future carbon-constrained world.

2. Process modelling

The specifications of natural gas feed are shown in Table 1. Aspen HYSYS V10 is used to simulate the process with Peng-Robinson as the thermodynamic model in this study.

Table 1: Specifications of the natural gas feed

Temperature [°C]	50
Pressure [bar]	30
Flow [MMscfd]	120.2
Molar flow [kmol/h]	6000
Mass flow [t/h]	104.7
Mole fraction	
CH ₄	0.95
C ₂ H ₆	0.02
C ₃ H ₈	0.015
n-C ₄ H ₁₀	0.01
n-C ₅ H ₁₂	0.005

2.1 Syngas production

For the syngas production step, two main reformer types are considered: Autothermal Reforming (ATR) and electrically-heated Steam-Methane Reforming (E-SMR). These units are modelled as Gibbs reactors within the process simulator. To avoid coke formation in the reformer, a pre-reformer is used. Pre-reforming is done adiabatically at 420 °C. In both cases, the produced syngas is almost inert-free, due to avoiding the use of air in the reforming step. Therefore, there is no need for a costly Air Separation Unit (ASU) or a membrane unit to produce oxygen (Ostadi and Hillestad 2017).

2.2 Fischer-Tropsch Synthesis

The main products of FTS are paraffins (or alkanes) (Eq. 1) and olefins (or alkenes) (Eq. 2). The polymerization reactions taking place are hydrogenation of CO to form n-paraffins, 1-olefins, and oxygenates. Oxygenates are formed in small amounts and therefore are neglected here.

In order to account for product distribution, a variable chain growth factor, α , is applied. This factor is greatly affected by H_2/CO ratio at the reaction site on the catalyst (Ostadi, Rytter, and Hillestad 2016). It is shown that under-stoichiometric H_2/CO is desirable for selectivity to higher hydrocarbons as a result of suppression of methane and light hydrocarbon formation (Ostadi et al. 2016). The H_2/CO selected here is 2.0 which is slightly below the stoichiometric ratio. With H_2/CO being lower than the consumption ratio, it decreases as the reaction proceeds. Therefore, hydrogen addition is required to avoid an exceedingly low H_2/CO ratio. This is done by the addition of hydrogen between FT stages. The Fischer-Tropsch synthesis is staged in 3 stages, with product withdrawal and hydrogen addition between the stages. This enables a high conversion of syngas and high selectivity to heavier hydrocarbons. Once-through conversion in each FT stage is limited to 60 % to have the maximum C_{5+} selectivity and also preserve catalyst lifetime (Schanke et al. 2001). Slurry bubble-column FT reactors used in this study are modelled as a completely stirred tank reactor (CSTR). Details of the reactor and kinetic models are provided in Hillestad et. al (2018). The syngas has a pressure of about 26 bar prior to the first FT stage and a temperature of 210 °C at the feed to all FT stages.

3. Considered cases

3.1 Case 1: ATR with SOEC

Natural gas is pre-reformed and then reformed in an Autothermal Reformer (ATR) to produce syngas. The block flow diagram is shown in Figure 1. Renewable power is used in SOEC to split steam into H_2 and O_2 (Hillestad et al. 2018). Oxygen from the SOEC is used in ATR as the oxidant to keep the ATR outlet temperature at 1050 °C and therefore the produced syngas is inert-free. As a result, the majority of the tail gas (90 %) is recycled to ATR which increases the carbon efficiency of the process. Carbon efficiency is defined as the amount of the feed carbon ending up in the products. The rest of the tail gas is sent to the fired heater to provide heat for the steam to SOEC.

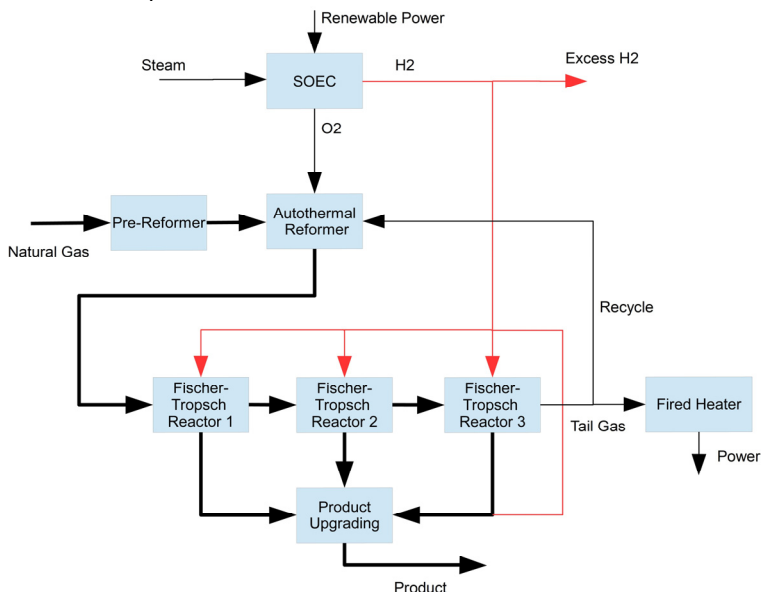

Figure 1: Block Flow Diagram of Case 1- ATR with SOEC

3.2 Case 2: Electrically heated SMR; E-SMR

In this case, renewable power derives the SMR reaction in an E-SMR. The block flow diagram is shown in Figure 2. The steam to carbon (S/C) ratio before the SMR is set to 2.0 which is a reasonable value considering the coking potential in the reformer. Natural gas is pre-reformed and heated to 500 °C prior to the SMR. The electric power input to the SMR is high enough to keep the SMR temperature at 850 °C. The H₂/CO ratio at the SMR outlet is high (> 3) which is more than the stoichiometric consumption ratio in FT process that is slightly above 2.0, as mentioned before. Therefore, part of H₂ needs to be separated to have the desired H₂/CO ratio prior to FT stages. Palladium membrane is used in this design to separate H₂. The temperature prior to the membrane needs to be at least 300 °C (Bredesen et al. 2011). There will also be excess H₂ in the process which can be used for product upgrading, provide extra heat in the fired heater or can be exported. In this design, 85% of the tail gas is recycled to the SMR.

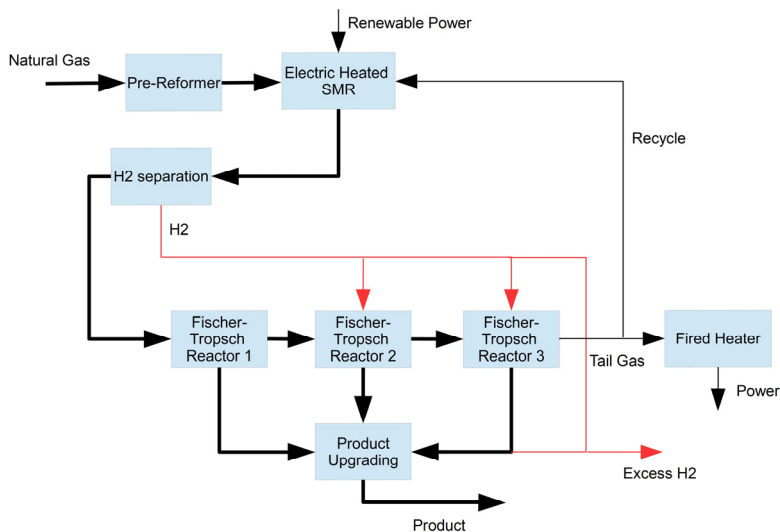

Figure 2: Block Flow Diagram of Case 2- E-SMR

3. Results

As mentioned earlier, in E-SMR case (case 2), excess H₂ is produced. In order to have a fair comparison between cases, the same excess H₂ is produced in both cases. Moreover, the same once-through conversion in three FT stages (i.e. 94 %) is used. The overall plant results in both cases are shown in Table 2. By assuming the density of syncrude (C₅₊) to be 800 kg/m³, the CO₂ emissions per liter syncrude produced are 0.20 and 0.43 kg CO₂/L_{syncrude} for case 1 and case 2, respectively. Comparing to the previous designs which had a CO₂ emission of 1.57 kg CO₂/L_{syncrude} (Ostadi et al. 2015; Ostadi and Hillestad 2016), case 1 and case 2 show 8 and 4 times less process emissions per liter syncrude produced, respectively.

Table 2. Carbon efficiency is considerably improved compared to the previous designs (Ostadi et al. 2015), from around 60% in previous designs to above 84 % and 91 %. The

power consumption in case 1 is slightly lower than case 2, while the FT production is higher. With the carbon efficiency being higher in case 1, this also indicates that the CO₂ emissions are lower in case 1. Moreover, the required FT catalyst volume is lower in case 1. The main reason for these differences is related to the higher reforming temperature used in ATR (case 1) than in the E-SMR (case 2) which are 1050 °C and 850 °C, respectively. The reforming temperature affects the CO₂ concentration out of the reformer which in case 1 and case 2 are 6% and 11%, respectively. Based on these results, it is a better choice to add renewable power to the SOEC rather than utilizing it in E-SMR. By assuming the density of syncrude (C₅₊) to be 800 kg/m³, the CO₂ emissions per liter syncrude produced are 0.20 and 0.43 kg CO₂/L_{syncrude} for case 1 and case 2, respectively. Comparing to the previous designs which had a CO₂ emission of 1.57 kg CO₂/L_{syncrude} (Ostadi et al. 2015; Ostadi and Hillestad 2016), case 1 and case 2 show 8 and 4 times less process emissions per liter syncrude produced, respectively.

Table 2: Overall plant results in both cases

	Case 1-SOEC	Case 2-ESMR
Electric power usage (MW)	633	635
FT production (t/h)	86.8	79.9
Carbon efficiency [%]	91.6	83.7
CO conversion per pass [%]	93.6	93.8
FT Catalyst volume [m ³]	1910	2680
Excess H ₂ production (kmol/h)	7908	7880
CO ₂ emission of the process (kg CO ₂ /L _{syncrude})	0.2	0.43

To get a better picture of the amount of heating and cooling required in the proposed processes, the energy composite curves for both cases are shown in Figure 3. In case 1, Figure 3a, there is a requirement for 85 MW of external heating and there is 492 MW of excess heat. In case 2, Figure 3b, the external heating and cooling requirements are 68 MW and 635 MW, respectively. The horizontal hot line at 210 °C represents the steam generated during cooling of the FT reactors. As can be observed, in both processes a large amount of excess heat is available mainly below 200 °C which can be utilized for preheating or be upgraded via heat pumps. Compared to the amount of extra heat required, there is a minor need for external heating in both designs, which can be supplied by changing important operating variables or combusting part of the excess hydrogen.

Figure 3: a) Composite curves for case 1; b) Composite curves for case 2

4. Conclusions

Two GTL designs with very low CO₂ emissions are presented and compared. In these designs, there is no need for a costly ASU or a membrane unit to produce oxygen. The generated syngas in both cases is almost inert-free because of avoiding the use of air, therefore allowing most of the FT tail gas to be recycled to the reformers. Adding renewable power increases the carbon efficiency and thus synthetic hydrocarbon production in both cases. Provided that cheap renewable power is available, it is a better choice to add power to the GTL process through SOEC (case1) rather than using it in an E-SMR (case2).

Abstract

The environmental benefits of switching to biomass-based feedstock have been demonstrated in numerous life cycle assessment (LCA) studies. Currently, most LCA research follows the process LCA approach, which is inevitably subject to missing flows and truncation errors. Hybridization methods have been developed to reduce truncation error by incorporating the economic input-output model into the traditional process LCA. In this work, the tiered and integrated hybrid LCA, along with their double-counting elimination methods, are applied to five different biomass-based chemical productions. The results demonstrate the effectiveness of the hybrid LCA in eliminating truncation error and the significance of hybridization method selection.

Keywords: Hybrid LCA, Double counting elimination, Biomass

1. Introduction

There is a growing interest in utilizing biomass feedstocks to replace traditional fossil-based chemical production (Athaley et al. 2019). The feedstock of the process itself does not guarantee a greener production than the conventional oil-based ones. Since the utility usage and other chemical demands could differ significantly, the conclusion should only be drawn after the comparative life cycle assessment (LCA).

Two common LCA methodologies are process LCA and Economic Input-Output LCA (EIO-LCA), which suffer from the truncation error and aggregation error, respectively (Pomponi and Lenzen 2018). Many hybridization techniques are developed to take advantage of the process LCA's accuracy and the EIO-LCA's completeness (Crawford et al. 2018). Under various scenarios of data availability, different hybrid LCA methodologies use the input-output table (Yang et al. 2017) that reflects the interactions between different industries to estimate missing activities in the supply chain. These strategies will ensure a more complete system boundary than the process LCA.

The tiered hybrid and integrated hybrid LCA are the most common choices for hybridization in the literature (Crawford et al. 2018). The matrix formulation of these two methods is described in Section 2. This work assesses the current hybrid LCA methods through case studies of biomass-based p-Xylene productions and lignin-based pressure-sensitive adhesive (PSA) production with two fractionation alternatives in Section 4.

2. Process LCA and Hybrid LCA

The matrix representation of the intermediary flow exchanges within different unit processes is well suited for LCA, especially in large systems with recycling loops (Heijungs and Suh 2002). In this framework, the element a_{ij} (row i , column j) of the technological matrix, A_p , represents the physical amount of raw material i used in process j . The environmental impacts are calculated from equation (1), where the f_p represents the final demand, I is the identity matrix, and B_p is the environmental intervention matrix that connects the productions with emissions.

$$g = B_p \cdot (I - A_p)^{-1} \cdot f_p \quad (1)$$

Similarly, the environmental impacts of the EIO-LCA model are calculated by equation (2). The main difference between these two methods is that the input-output direct requirement matrix A_{IO} and its corresponding input-output environmental intervention matrix B_{IO} are used instead of A_p and B_p . Moreover, each element in A_{IO} represents the monetary flow spent on different economic sectors, rather than the physical flow in A_p .

$$g = B_{IO} \cdot (I - A_{IO})^{-1} \cdot f_{IO} \quad (2)$$

The tiered and integrated hybrid LCA are the most common choices for process-based hybridization. In equation (3), missing flows in the final demand of process LCA are supplemented by input-output elements in the tiered hybrid LCA (Crawford et al. 2018). Alvarez-Gaitan et al. defined the depth of interface between the input-output and process models and used this to include additional elements in f_{IO} . (Alvarez-Gaitan et al. 2013).

$$g = B_p \cdot (I - A_p)^{-1} \cdot f_p + B_{IO} \cdot (I - A_{IO})^{-1} \cdot f_{IO} \quad (3)$$

The integrated hybrid LCA includes the interactions between the process system and the economy (Suh 2004). These interactions are captured in equation (4) by the upstream cut-off matrix C^u and downstream cut-off matrix C^d (which is often set to null) (Perkins and Suh 2019). Many double-counting elimination methods are developed, among which the binary correction (Agez et al. 2020) and SSM correction are discussed in this paper (Strømman and Solli 2008). If a process is already covered in A_p , the binary correction method will set its corresponding economic sector in C^u to zero. The SSM correction further eliminates the elements in C^u if some flows are known to be complete. To account for uncertainty in the completeness of the background database, three scenarios (min, base, and max) on which sectors are already included in process LCA (Acquaye et al. 2011) are considered in the SSM correction.

$$g = \begin{pmatrix} B_p & B_{IO} \end{pmatrix} \cdot \begin{pmatrix} I - A_p & 0 \\ -C^u & I - A_{IO} \end{pmatrix}^{-1} \cdot \begin{pmatrix} f_p \\ 0 \end{pmatrix} \quad (4)$$

3. Methodologies

Process simulations of p-Xylene (Athaley et al. 2019) and pressure-sensitive adhesive production are simulated using Aspen Plus v11. Yields from literature and experiments are used for reactor modeling. Missing physical property data are estimated by regression of experimental data and the group contribution method. Cradle-to-gate analysis is performed including the manufacturing stage of chemical products and emissions associated with the upstream raw materials and utility production. The functional unit is

selected as 1 kg of p-Xylene or PSA produced. Raw material and utility usages are collected from the simulation and utilized in the traditional process LCA. The background data for the process LCA are obtained from the Ecoinvent v3.3 database (Wernet et al. 2016), while the USEEIO including 388 economic sectors is chosen as the economic input-output model (Yang et al. 2017) for hybridization. TRACI 2.1 method is used in the USEEIO model for impact assessment; the environmental metrics include global warming potential (GWP), ozone depletion, acidification, eutrophication, respiratory effects, smog, human carcinogenics and non carcinogenics effects. GWP is one of the most used indices for LCA and is chosen in this study. The environmental impacts of the lignin production from black liquor are calculated from the life cycle inventory of Bernier et al. (Bernier et al. 2013). Multi-functionality is treated as follows: mass allocation of the environmental impacts is chosen for p-Xylene productions when furfural is the byproduct, while the generated electricity in p-Xylene production and biofuel in PSA production are treated as avoided burdens.

4. Case Study Results: Bio-based Chemical Production

4.1. Descriptions of Bio-based p-Xylene and Pressure-Sensitive Adhesive Production

Two hydrolysis technologies for biomass-based p-Xylene production are discussed in this work: the concentrated acid (CA) (Weydahl 2014) and molten salt hydrate (MSH) hydrolysis (Sadula et al. 2017). Glucose and xylose from the hydrolysis are used to produce p-Xylene and furfural, as shown in Figure 1 (Athaley et al. 2019). The humins and lignin byproducts are incinerated to provide electricity and steam. One particular MSH hydrolysis scenario that is unable to sell the excess electricity from the power generation section to the grid is also considered and referred to as ‘MSH no grid.’

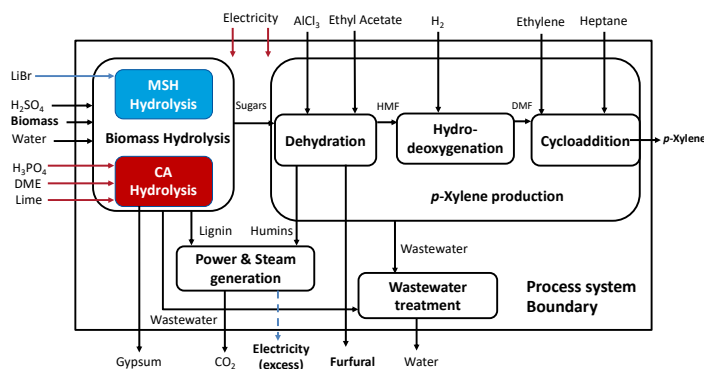

Figure 1: Process flow diagram of biomass-based p-Xylene production

The two alternatives for PSA production are illustrated in Figure 2. Using either glycerin or methanol as the solvent, lignin is depolymerized into a mixture of phenolics. Glycerin and methanol serve as the hydrogen donors for reductive catalytical fractionation, but typical processes using methanol or other low molecular weight alcohols employ hydrogen gas at high pressure (40 bar) to facilitate improved hydrogenation. Moreover, the glycerin fractionation process benefits from reactive distillation as the products are more volatile than the solvent. Unlike the pressurized methanol fractionation process, the glycerin process does not require cooling prior to separations and thus exhibits lower utility usage than the methanol fractionation process. Next, methacrylic anhydride (MAAH) functionalizes the phenolics with the help of 4-dimethylaminopyridine

(DMAP). After neutralization, monomers are polymerized with butyl acrylate (BA) by reversible addition-fragmentation chain-transfer polymerization in anisole with azobisisobutyronitrile (AIBN) as the initiator to produce the copolymer (PSA).

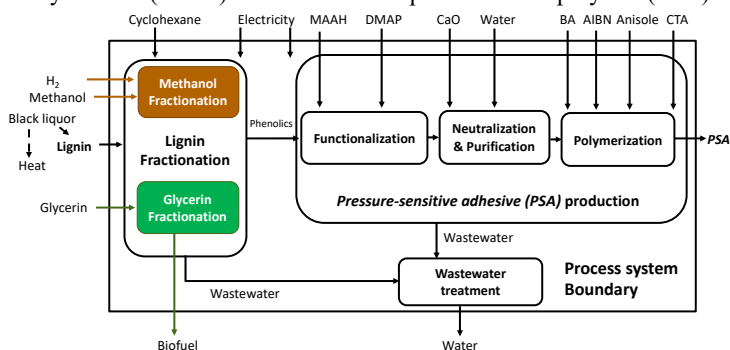

Figure 2: Process flow diagram of lignin-based pressure-sensitive adhesive (PSA) production

4.2. Truncation Errors in the Process LCA

The truncation errors in the process LCA comes from cutting off missing flows during the boundary selection. The extent of cut-off differs from case to case in process LCA studies, posing challenges to comparing different alternatives. The hybrid LCA has a more complete system boundary than the process LCA because it expands the system boundary by including previously missing upstream flows. It is often used to calibrate the truncation error in the process LCA (Mattila et al. 2010).

Table 1: Estimated truncation error (GWP) of process LCA based on hybrid LCA results

Estimated truncation Error (%)	p-Xylene production			PSA production	
	MSH	MSH (no grid)	CA	Methanol Fractionation	Glycerin Fractionation
Tiered hybrid	5.9	4.0	4.1	9.9	9.3
Binary-Integrated	14.6	13.0	12.6	26.6	21.4
SSM (min)	6.4	5.6	0.5	12.6	11.7
SSM (base)	6.7	5.9	0.9	13.7	12.1
SSM (max)	10.0	8.9	5.1	17.9	14.8

In Table 1, the truncation error estimated from missing upstreams varies based on the choices of hybridization methods and different technologies. For instance, glycerin fractionation for PSA production has a much higher estimated truncation error than the CA p-Xylene production. This is because many chemicals used in the PSA production processes are not captured well by the process LCA background database and need to be supplemented by the input-output analysis in the hybrid LCA. A high truncation error is an indicator of the original process LCA model's incompleteness, which encourages the use of hybrid LCA to replace the process LCA when comparing different alternatives.

The binary integrated hybridization estimates the highest truncation error among all methods as it removes the least amount of elements to avoid double-counting. The SSM correction is more conservative and acknowledges that irrelevant economic activities should be excluded in estimating missing flows. The minimum case of SSM only includes sectors highly probable to be neglected in the process database, while the maximum case accounts for all potential contributing sectors. These scenarios remove double-counting to different extents, reflecting the practitioner's confidence in the process LCA database.

The truncation errors vary by different magnitudes for different LCA metrics beyond carbon footprint. For instance, using the binary corrected integrated hybrid LCA as the reference, the truncation errors of PSA range from 0.11% (human non-carcinogenic effects) to 74.11% (ozone depletion).

4.3. Different Choices of LCA Methodologies in Comparative LCA

Figure 3: Effects of different hybridization methods on LCA results (Left: 1 kg biomass-based p-Xylene production; Right: 1 kg lignin-based pressure-sensitive adhesive (PSA) production)

Figure 3 shows that the MSH process of p-Xylene production without selling electricity to the grid has a lower global warming potential than the CA process according to the process LCA, tiered hybrid LCA, and binary corrected integrated hybrid LCA. After further eliminating double-counting by SSM corrections, the MSH process without selling electricity to the grid behaves similarly or even worse than the CA process. This comparison illustrates that the choice of hybridization method could lead to contradicting results. It is beneficial to choose SSM corrected integrated hybrid LCA for its flexibility. However, this method requires the practitioners to use their prior knowledge on the process and database to decide on the irrelevant economic activities. Tiered hybrid LCA should be applied if accurate technoeconomic analysis is available. If no extra information is available, the binary corrected integrated hybridization is the only option. Since the truncation errors for similar processes are very close, the binary corrected hybrid LCA and tiered hybrid LCA will still lead to reliable results in most cases. For example, glycerin fractionation outperforms methanol fractionation in PSA production, and the MSH process that sells the extra electricity to the grid behaves better than the CA p-Xylene process in all and hybrid LCA or even process LCA comparisons.

5. Conclusions

Both tiered and integrated hybrid LCA methods are applied in this work to achieve a more complete system boundary than traditional process LCA by incorporating the input-output model. In cases where the process LCA database does not sufficiently capture some inputs, the truncation error is effectively reduced through hybridization. Although different LCA methodologies generate similar results for the same process, the comparison between many technology alternatives could be affected by the hybridization method selection, as shown in Section 4.3. One limitation of the hybrid LCA, as with most of the current process LCA and EIO-LCA studies, is the model's static and linear nature, limiting its ability to assess future scenarios and significant changes (Yang and Heijungs 2019). Future studies should include more dynamic technological development features and consider the economy's complexity by nonlinear models.

Abstract

As the population continues to rise, the need for energy, water and food (EWF) resources are increasing in parallel. Accordingly, the EWF nexus has received considerable attention in previous years as a means to manage resources given the inherent interlinkages between them. The objective of this study is to expand on geospatial nexus approaches to support decision-making for EWF resources in non-resilience environments. A simple linear optimization model is applied to a geospatial representation of decentralised EWF systems to enhance the EWF nexus node approach and analysis of resilience. The methodology is applied to hydroponic greenhouses in Qatar, where the water is the core factor that affects the overall efficiency and AHP risk level. Thus, the optimization model introduces a new EWF node that operates at minimum cost whilst reducing the AHP risk level of existing EWF nodes. The objective function of the optimisation model accounts for three cost components; the cost of groundwater transportation, pumping and desalination, that is subjected to certain constraints; one constraint is suggested for the new EWF node to select a low risk area, hence ensuring low operating costs; three constraints assigned to identify a location for the new EWF node that will minimise risks of the three existing nodes, hence, reducing high AHP value of three farms; and the last constraint used to select one node only at an optimal location. The result demonstrates that with the allocation of a new EWF nexus node at an optimal location to be the main source of water supply, the risk level for all three existing nodes will reduce tremendously.

Keywords: Decentralization, Resource Management, EWF Nexus, Optimisation.

1. Introduction

In modern society, there are concerns related to the availability and accessibility of energy, water and food (EWF) resources. Hence, the EWF nexus approach to resource management has been heavily explored in the literature in recent years since its introduction in Bonn Conference (2011), to support resource management across these sectors whilst considering the inter-linkages between them (Al-Ansari et al., 2014; 2015). Recently, numerous scholars, academics and politicians have suggested various approaches to tackle uncertainties within EWF using different types of optimisation techniques and other intelligence algorithms (Li & Singh, 2019). Numerous studies demonstrated that computational modelling is an important way of quantifying WEF interactions and fostering sustainable decision-making (Bieber et al., 2018). It has been

considered as influential tool due to the ability in addressing resource optimisation problems with various objectives and combining several management features, goals and constraints into one system. Stamou & Rutschmann (2018) optimised energy, water and food resources using the parameterization-simulation-optimisation method, which is based on the WEF Nexus approach and by considering their related existence and interrelationships. The authors aimed to promote understanding of changes by decision makers as a consequence of the altered management policies through analysing the interchanges between hydropower and competing irrigating goals and to make water supply management more effective in the Nile region. The proposed Pareto optimisation based on WEF nexus method can be used to optimise water management with similar issues and at the same time having various goals. Additionally, Niu et al. (2019) suggested a linear objective linear fractional programming to model the interactions between WEA nexus. This study provides overall insights into agriculture and the management of water resources in arid areas and provides a new approach to tackle the complicated dynamic WEA nexus through a modelling technique. In general, mathematical modelling and other optimisation techniques have been primarily used to improve the overall food systems performance. Moreover, an integrated resource modelling with an EWF Nexus framework demonstrates useful results in a multi-objective and stochastic optimisation as they can cope with the complexities of Nexus related issues. As such, Namany et al., (2018) suggested an optimum energy-water mix model to reduce environmental burdens and costs related to food production in the State of Qatar. Specifically, the research evaluated the allocation of energy and water resources using a game-theoretical modelling approach, and by focusing on the impact that natural gas prices on the stochasticity of the market and competition in the power-generation business. Lately, Haji et al. (2020) introduced the EWF Node to describe the decentralisation of interconnected EWF Nexus systems. The study utilised the EWF nexus node, where every node represented a food sector sub-system that are influenced by external risks, such as climatic, water and soil factors. Then, spatial risk factors were gathered, digitalised, and incorporated into a single geo-processing framework from various data sources focused on the food industry, allowing the visualisation as well as the further processing of risks. Thus, a composite geospatial risk maps for the different food production scenarios were then generated using an analytical hierarchy process (AHP). Consequently, this study builds on recent work reported by Haji et al. (2020), expanding the geospatial Nexus framework developed to support decision-making within EWF Nexus, especially in hazardous non resilience environments, in order to reduce the effect of various risk factors, thus improving the national adaptability of EWF systems. This is achieved by integrating the computational modelling and optimisation approaches within the EWF nexus node.

2. Linear programming optimisation framework for EWF Nexus

Supporting objectives for sustainable food security in risky environments in this study is performed by means of a simple linear programming optimisation on the composite geospatial risk map for the hydroponic greenhouse case reported by Haji et al. (2020), which is the current state of Qatar's agriculture farms. To this point, the current state of existing nodes (four hydroponic greenhouses) has been detailed and analysed. Briefly, the risks were defined based on the chosen food sector. Thus, the main risk factors that have an impact on greenhouses in general are categorised into three: climate (temperature, humidity and solar radiation), water (groundwater depth, salinity, recharge rate and pH)

and soil factor (As and Fe concentration). However, since this study considers a hydroponic greenhouse, then the soil indicators are removed from the assessment. Then, a comparison between each indicator for the particular criterion is made in pair by classifying which of these indicators were extremely critical and by how much. The preferences are expressed on a semantical scale from 1 to 9, where 1 denotes equal importance between the two indicators, and the value 9 implies that first indicator is 9 times more critical than the second indicator. Finally, using the importance percentage of each factor from AHP, a composite geospatial risk map representing is generated from GIS. Thus, the primary purpose of the optimisation in this study is to minimise the risk of existing nodes located in high-risk areas. Figure 1 illustrates that 3 out of 4 existing nodes are located in high-risk areas, and includes Al Safwa, Global and AGRICO farms with a risk level of 28.91, 22.60 and 24.29 respectively. The objective of this optimisation is to allocate a new EWF node at an optimal location, which will operate at minimum cost, whilst minimising the risk of existing nodes especially those located in high risk areas. Hence, the three main cost components are considered in this case study. The first component is the cost to transport groundwater from new to existing EWF nodes. The second component is the cost associated with pumping groundwater to the surface, and the final component is the cost of desalinating pumped water having certain groundwater salinity. The decision variables comprise of 3 parameters, including the transportation and the groundwater variables, which are elaborated in Table 1. The optimal decisions of the selected variables will minimise the operating cost of the new node locating at the optimal location and overall risk of existing nodes. The mathematical formulation for the optimisation model is presented below, where spatial (distance) and economic related data are used to run the optimisation model, along with weights associated with each risk factor. Since the optimisation process involves many decision variables and various calculation steps; then, a computer model such as Excel Solver is valuable in performing these steps, and to solve the optimisation formulation by ensuring that all functions and variables are sufficiently expressed. In terms of the spatial and temporal scales, the proposed approach will vary under various geographical characteristics and will differ over different seasons. In this study, the optimisation model is applied for hydroponic greenhouse distributed within the State of Qatar for Summer season data.

Table 1: Mathematical formulation for the optimisation model.

Objective Function:	
$\text{Min Cost} = \sum_{i=1}^{28} \sum_{j=1}^3 d_{ij} C_T x_i + \sum_{i=1}^{28} D p_i C_p x_i + \sum_{i=1}^{28} S_i C_D x_i$	Identifies the optimal distance and groundwater characteristics that minimises the total operating cost of the new EWF node that will supply the required water demands to the existing EWF nodes.
Subject to:	
$\sum_{i=1}^{28} x_i (w_s S_i + w_{ph} p H_i + w_{rr} R R_i + w_d D p_i + w_t T_i + w_h H_i + w_{sr} S R_i) \leq 17$	This constraint is suggested for the new EWF node in order to select a low-risk location with an AHP value less than 17, hence ensuring low operating cost
$\sum_{i=1}^{28} x_i (w_s S_i + w_{ph} p H_i + w_{rr} R R_i + w_d D p_i) + w_t T_1 + w_h H_1 + w_{sr} S R_1 \leq 28.9100$	This constraint is assigned in order to identify a location for the new EWF node that will minimise risks of the existing node; thus, reducing the high AHP value of Al Safwa Farm to a value less than 28.91
$\sum_{i=1}^{28} x_i (w_s S_i + w_{ph} p H_i + w_{rr} R R_i + w_d D p_i) + w_t T_2 + w_h H_2 + w_{sr} S R_2 \leq 22.6039$	This constraint is assigned in order to identify a location for the new EWF node that will minimise risks of the existing node; thus, reducing the high AHP value of Global Farm to a value less than 22.60

$\sum_{i=1}^{28} x_i (w_s S_i + w_{ph} p H_i + w_{rr} R R_i + w_d D p_i) + w_t T_3 + w_h H_3 + w_{sr} S R_3 \leq 24.2957$	<p>This constraint is assigned in order to identify a location for the new EWF node that will minimise risks of the existing node; thus, reducing the high AHP value of AGRICO Farm to a value less than 24.29</p>
$\sum_{i=1}^{28} x_i = 1$	<p>This constraint used so as to select one node only at an optimal location</p>
$d_{ij}, D p_i, S_i, x_i \geq 0$	<p>It implies that all decision variables must be strictly positive.</p>

The optimisation begins with the initialisation of the database, including the distance and cost matrix between new and existing EWF nodes, the groundwater salinity value and the cost associated to desalinate such salinity level, in addition to the groundwater depth value along with the cost associated with pumping groundwater. It is then followed by the simulation steps to calculate the operating cost of the initial data. The SAIC farm is excluded from the analysis; as it is the only farm located in a low-risk area. However, in order to calculate the capacity of the new RO desalination plant, it is assumed that the same RO characteristics installed in the SAIC farm is applied to the new EWF node. Currently, SAIC farm has two RO plants with a total capacity of 1070 m³/day that fulfilled 10,223 L/kg/year of water requirements for hydroponic farming, in addition to other water requirements within the farm. Hence, the new node should have an RO plant with an approximate unit size of 19,000 m³/day, in order to satisfy the three existing farm total water requirements, which is equivalent to 176,091.25 L/kg/year. However, by considering new EWF node water requirements satisfaction, the total capacity of the new RO plant is assumed to be 24,000 m³/day. Furthermore, the electricity consumption for RO desalination with a unit size of 24,000 m³/day is almost 2.10 kWh/m³ for brackish water with a salinity of approximately 5000 ppm (Manju & Sagar, 2017). Noting that the groundwater salinity in Qatar varies between 2206.12 and 5639.81 ppm, and the subsequent energy required in order to desalinate using RO desalination will range from 0.93 to 2.37 kWh/m³. Hence, the cost of desalinating groundwater using the RO desalination process is approximately between 1467.12 \$ and 9588 \$; where the rate associated with electricity consumption for productive farms in the State of Qatar is 1.68 QAR/kWh (KAHRAMAA, 2020). The other cost component in the objective function is the transportation cost, a previous study demonstrated that the approximate cost is 0.061 \$/m³ per 100 km to transport water, thus it is equivalent to 0.00061 \$/m³/km (Zhou & Tol, 2005). Therefore, the distance between the new node and the existing node is calculated using the distance formula. Finally, the operating cost of lifting groundwater to the surface using an electrical motor is 0.1780 \$/kWh, where 2.725 kWh is required for pumping groundwater per each meter (Robinson, 2002). Thus, the groundwater pumping costs at various locations were then calculated. Ultimately, all the previous data for the minimisation of the objective function and set of constraints required to perform optimisation are inserted into Excel Solver, where Simplex LP is used.

3. Geospatial optimisation model application

A simple linear optimisation is conducted to determine the optimal location for the new EWF node to be allocated and established. The chosen location minimised the risk of existing EWF nodes whilst operating at minimal operating costs. In this study, hydroponic greenhouses represent the food element of the nexus, where the water is the core factor that affects the overall efficiency and AHP risk level. Thus, the objective of the optimisation is to identify a location for new EWF nodes, with better water quality; in order to reduce the operational cost, such as the cost of pumping and desalinating

groundwater, and hence supply good water quality to existing EWF node to reduce their overall risk. Figure 1 illustrates the optimal node with respect to 28 potential nodes. Although the potential EWF nodes are distributed randomly, including high risk area, the four constraints assigned to the optimisation model contribute to enhancing its ability to select optimal EWF nodes located at low-risk areas with better groundwater quality. Moreover, outcomes from the linear programming optimisation validated the trade-offs between cost components. Though, the location of the new node (north-east) is slightly far from existing nodes, which implies a larger transportation cost. However, the location with better groundwater salinity and less depth is selected. This demonstrates that through the allocation of a new node in an optimal location, the risk of existing nodes decreased tremendously. Initially, Al Sawfa, Global and Agrico farms are located in high-risk areas indicating poor water qualities with an AHP risk value of 28.1, 22.6 and 24.3 respectively. However, with the allocation of a new EWF nexus node to be the main source of water supply, the risk level reduces to approximately 10 for all three existing nodes. Therefore, the optimisation result proves the necessity to use groundwater with improved qualities within EWF nodes.

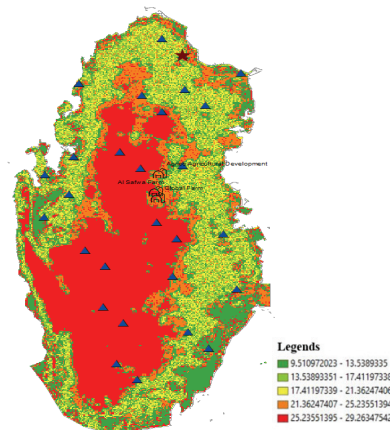

Figure 1: The location of the optimal selected EWF node corresponding to the 4 hydroponic farms and 28 potential nodes.

4. Conclusion

This study implements a simple linear optimisation model to introduce a new EWF node that will reduce the AHP risk level of existing EWF nodes. The objective function of the optimisation model accounts for three cost components; the cost of groundwater transportation, pumping and desalination. Hence, by running the optimisation model into an excel solver, a location in the north-east of Qatar is selected as an optimal location in order to allocate the new EWF node, which will operate at the least cost whilst reducing the AHP risk of three existing nodes. In conclusion, the approach of EWF nexus node deployed in this study can be utilised to reflect various farming industries that have different spatial and temporal characteristics. For instance, a dairy, fodder or combined farm are affected by various geospatial risk factor, thus it can be analysed using the same approach. Evidently, the geospatial optimisation of EWF nexus node is promising as it classifies nodes that are performing well in a methodological risk analysis, thus paving

the way for further optimization and decision-making with a view to reducing the effects of risk factors, and therefore, improving the national resilience of the EWF systems.

Abstract

In response to climate change concerns, there has been an increasing global commitment to reduce carbon dioxide emissions. Circular economy pillars have been proposed as a means to conserve resources, limit emissions and maintain sustainable revenue streams. Most CO₂ emissions stem from stationary sources, which are largely due to industrial processes (IPCC, 2005). In an attempt to reduce these emissions, there has been an increased focus on carbon capture utilization and storage solutions, e.g. integrating carbon dioxide in industrial parks to create value-added products. Ahmed et al. (2020) introduced a method that can represent any resource, material or energy, within a cluster to identify integration potential. In this work, we utilize the mixed integer linear program to synthesize waste reuse clusters at zero carbon footprint. The work mainly assesses the potential benefits of utilizing waste resources such as CO₂ emissions, free resources such as seawater (H₂O and its minerals), air (N₂, and O₂) and sunlight as an energy source to produce various value-added products to create carbon neutral industrial parks. This attempt demonstrates circular economy values on an industrial park level by conserving fresh resources, maximizing reuse of materials and creating valuable products. The system studied was able to generate profits while adhering to emission and material constraints.

Keywords: Climate Mitigation, Renewable Energy, Water Reuse, Optimization, Integration

1. Introduction

In recent years, there has been an alarming increase in greenhouse gases in the atmosphere, the most notable of these gases being carbon dioxide (CO₂). Thus, there is an urgent need to minimize these emissions and alleviate the climate change concerns that result from them, identified as one of the United Nations Sustainable Development Goals for 2030. One possible solution for CO₂ reduction is the generation of energy from renewable sources (such as solar or wind power) in place of non-renewable sources such as through burning fossil fuel with a large CO₂ footprint. Another way to reduce CO₂ emissions is through carbon capture and utilization (CCUS) systems. This involves the capture and use of CO₂ from emissions in order to produce value-added products. Both of these methods are being studied extensively to determine their applicability in industry. The concept of an eco-industrial park (EIP) where sustainable practices are incorporated into industrial processes can be used to achieve sustainable development goals. An EIP, as defined by Côté and Hall (1995) is “an industrial system which conserves natural and

economic resources; reduces production, material, energy, insurance and treatments costs and liabilities; improves operating efficiency, quality, worker health and public image; and provides opportunities for income generation from use and sale of wasted materials.” The principle governing the operation of EIPs is industrial-ecology, where they operate much like natural systems in which resources are conserved or reused (Valenzuela-Venegas, 2016), while also gaining economic, environmental, and social benefits that would be otherwise be unachievable by a stand-alone facility.

Numerous works have been applied to promote sustainability through material integration. This includes research by Lovelady and El-Halwagi (2009), whose work presented an approach to water integration in industrial parks through optimization. Al-Mohannadi and Linke (2016) uses optimization to integrate CO₂ in industrial parks. Alnouri et al. (2018) established a brine management water integration approach through a mathematical modeling program. El-Halwagi et al. (2003) developed a procedure to minimize the amount of fresh feed required for a source sink system using a set of linear algebraic equations modeling the mass balance of fresh feed and contaminants. While these works all focused on one aspect of integration, multiple resources must be integrated to achieve maximum reduction in CO₂ emissions. Ahmed et al. (2020) developed an optimization-based mixed integer linear program (MILP) for this purpose. The representation allows the exchange of any resource, material or energy within a cluster. Thus, this work uses the Ahmed et al. (2020) resource integration model to design a profitable carbon neutral industrial park from natural sources (seawater, air, sunlight, and CO₂). The aim is to use material and energy integration to have the same the amount of CO₂ emitted from the park as that entering the park.

2. Methodology

The methodology used in this work to achieve the objective involves multiple steps. First, the inputs in to the city are defined, then a database of possible reactions and processes to convert the raw materials is created. Finally, the resource integration model is applied to optimize for maximum profit while meeting the emission constraint. As seawater and air are inputs to the cluster, various desalination and air separation technologies were assessed to choose that which was best suited for the application. Next, a number of processes were chosen as potential candidates to be selected as part of the EIP. An ideal candidate is one that can utilize the raw materials or products produced by other plants, is profitable, and is feasible in the geographical location of the industrial cluster. A database was created containing the mass balances, energy requirements, capital costs, and operating costs. In addition, other relevant information for each of the specified candidate plants such as material and utility prices and market sizes, were also included. The candidate city was then optimized using the resource integration model. This gives specified optimal operational capacities for each plant and determined the connections between them. The model used was developed by Ahmed et al. (2020) and the system equations can be found in their work. The model constraints were the minimum and maximum possible capacities and the allowable inputs.

$$\begin{aligned} \text{Max} \quad & \text{Profit} = f(\text{Resources flows}) \\ & g(x_1, x_2, \dots, x_n) \leq 0 \\ & h(x_1, x_2, \dots, x_n) = 0 \end{aligned}$$

3. Case Study

The approach developed here is applied to a case study where the objective is to design an EIP that is carbon neutral and profitable as illustrated in Figure 1.

Figure 1: Illustration of the case study objective

Through the process selection phase, 12 candidate plants were determined. These include production units for hydrogen (H₂), ammonia (NH₃), sodium chloride (NaCl), formalin (CH₂O), methanol (CH₃OH), soda ash (Na₂CO₃), urea (CH₄N₂O), nitric acid (HNO₃), and sodium bicarbonate (NaHCO₃), along with a seawater reverse osmosis (SWRO) unit, an air separation unit (ASU) that gives oxygen (O₂) and nitrogen (N₂). Of these, the CH₃OH, NaHCO₃ and CH₄N₂O units have their own carbon capture units since they release emissions. A sequestration unit is also present to store any pure CO₂ that is not converted. The capital cost requirement or CAPEX parameter for each of the units was calculated by assuming a reasonable maximum capacity limit and an operational life of 20 years utilizing the CAPEX estimation techniques found in Peters et al. (2002). Table 1 lists these calculated CAPEX parameters along with the maximum allowed capacities.

Table 1: Selected processes, their reference products and CAPEX parameters

Process	Reference Product (RP)	CAPEX Parameter (\$/ton RP)	Maximum Allowed Capacity (t/y)
Sequestration	CO ₂	20.00	120,000
SWRO	H ₂ O	0.02	800,000
H ₂ Production	H ₂	779.00	100,000
Air Separation	O ₂	7.70	500,000
NH ₃ Production	NH ₃	20.00	200,000
CC Unit	CO ₂	8.00	20,000
NaCl Production	NaCl	5.65	200,000
CH ₂ O Production	CH ₂ O	52.88	200,000
CH ₃ OH Production	CH ₃ OH	14.67	200,000
Na ₂ CO ₃ Production	Na ₂ CO ₃	140.56*	200,000
CH ₄ N ₂ O Production	CH ₄ N ₂ O	7.53	200,000
HNO ₃ Production	HNO ₃	5.30	200,000
NaHCO ₃ Production	NaHCO ₃	27.46	50,000

*It should be noted that the Na₂CO₃ unit is assumed to produce sodium hydroxide (NaOH) needed for its own consumption and the capital and operating expenses for this production are reflected in the Na₂CO₃ CAPEX parameter. This NaOH production does not require any additional imports into the cluster.

The mass and utility resource parameters for these processes were obtained through mass and energy balances performed on data obtained from an extensive literature review. A negative parameter indicates that the resource is utilized in the process while a positive parameter indicates that it is an output of the process. The parameters used for the ASU, sequestration and production units for H₂, NH₃, CH₃OH and CH₄N₂O were taken from Ahmed et al. (2020), while the parameters for the capture units were calculated using the capture units in their work as a basis. Data for the SWRO and NaCl production units were obtained from Nayar et al. (2019). The data for the CH₂O unit was obtained from Millar and Collins (2017) and Bahmanpour et al. (2014). For Na₂CO₃, NaHCO₃ and HNO₃, the data was collected from Yusuf et al. (2019), Lee et al. (2019) and Wiesenberger (2001). The resource parameters for the remaining units are summarized in Table 2 where all parameters are given in t/t RP except for electricity and cooling water parameters which are given in kWh/t RP and m³/t RP respectively.

Table 2: Selected processes and their process parameters

SWRO		Sodium Chloride		Formalin	
Brine	1.41	Brine	-59.31	Air	-1.17
Seawater	-2.41	NaCl	1.00	Emissions*	0.84
H ₂ O	1.00	Wastes*	54.16	CH ₂ O	1.00
Electricity	-2.53	H ₂ O	4.15	CH ₃ OH	-0.42
		Electricity	-102.00	H ₂ O	-0.25
				CW	-42.00
				Electricity	-49.00
Soda Ash		Nitric Acid		Sodium Bicarbonate	
CO ₂	-0.66	Air	-4.48	CO ₂	-1.02
Na ₂ CO ₃	1.00	NH ₃	-0.28	Emissions*	4.49
NaOH	-0.35	Emissions*	3.96	N ₂	-3.97
Wastes*	0.02	HNO ₃	1.00	Na ₂ CO ₃	-1.59
Wastewater	0.83	H ₂ O	-0.20	NaHCO ₃	1.00
H ₂ O	-0.83	CW	-105.00	Wastes*	0.91
CW	-37.52	Electricity	-8.50	Wastewater	3.90
Electricity	-23.24	LP Steam	-0.05	H ₂ O	-3.72
		HP Steam	0.80	Electricity	-78.91
				LP Steam	-0.30
				Process Water	-0.25

*Emissions** refers to the emissions from a production unit, *Emissions*** refers to fugitive emissions from the capture units, and *Wastes** refers to process wastes from a unit.

Constraints were set to only allow seawater, air, and imported CO₂ into the cluster, while the RP material outputs can be sold. Energy requirements for the cluster are met by utilizing solar energy through a photo-voltaic system that is built outside the cluster and low-pressure (LP) steam obtained from geothermal sources. 50,000 tpy of CO₂ is imported into the system while no constraint is placed on the imported energy. The limit for the seawater and air feeds are restricted by the maximum capacity limits of the SWRO unit and the ASU. The utility prices for electricity, cooling water and LP steam were obtained from Ahmed et al. (2020) along with the prices of NH₃, O₂, and H₂O. The prices for HNO₃ and N₂ was obtained from Intratec (Intratec, 2019), while those of Na₂CO₃ and NaCl were obtained from Lee et al. (2019) and Nayar et al. (2019) respectively.

The EIPs determined for these cases are shown below where both networks activate the same candidate plants with the exception of the soda ash plant which is only activated when there is a CO₂ import. The activated units are represented by the white blocks while

those in grey are inactive. The solid lines show the material flows into and out of the cluster while the dashed lines show the exchange of resources within the cluster. Scenario 1 was able to achieve 100% utilization of all the CO₂ imported into the system at no cost making the cluster carbon-negative while achieving a profit of \$178 M/y (with selling nitrogen) and \$113 M/y (without selling nitrogen). Scenario 2 achieves a profit of \$171 M/y (with selling nitrogen) and \$109 M/y (without selling nitrogen). The capital costs of scenario 1 and 2 are \$805 M and \$716 M respectively.

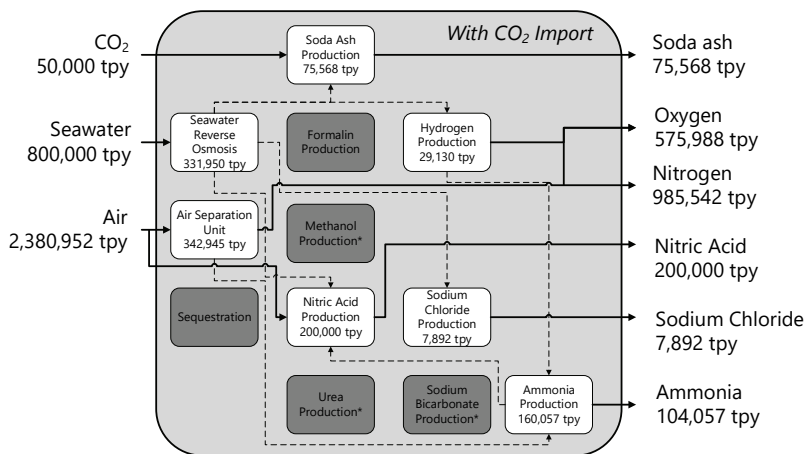

Figure 2: Scenario 1 - Industrial cluster design with CO₂ import

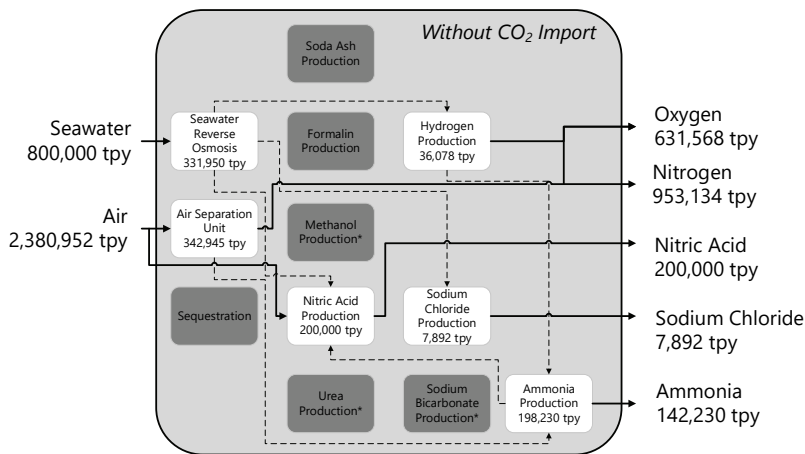

Figure 3: Scenario 2 - Industrial cluster design without CO₂ import

It was observed that a profitable carbon-neutral EIP is possible even with CO₂ as input. In fact, the importing pure CO₂ increased the profit. It should also be noted that this profit is achieved when the production capacities of the hydrogen and ammonia units were decreased. This was due to the ability to convert CO₂ with water and sodium chloride to produce soda ash. This observation encourages the expansion of the case to include more CO₂ converting processes for future work.

4. Conclusion

The profitability and environmental performance of an industrial clusters whose sole material inputs were seawater and air were investigated through the use of a MILP tool. Two scenarios were modelled, one with and the other without an import of CO₂, that activated the same units with the exception of the soda ash plant when CO₂ was allowed into the cluster. The soda ash plant serves as a sink for the CO₂, thereby generating considerable profits of \$178 M/y and \$113 M/y, with and without selling nitrogen, while achieving a carbon-negative system. Multiple scenarios can be further studied to analyze the impact that environmental restrictions have on profitability.

Abstract

The need to use clean sources for producing electricity has been a great topic of discussion in recent years. Many countries have begun to take advantage of solar energy through the production of solar panels for electric power generation. In addition, knowing people's preferences allows predicting their behavior to propose better planning at macroscopic level. This work presents a mathematical programming model to address the conduct of people. The objective is to know their inclinations using the matching law, which involves the actions of users through different scenarios considering economic incentives and punishments. It includes a strategic planning of the production and distribution of solar grade silicon that is used for the construction of solar panels to meet the demand of electricity in the residential sector of Mexico as a case study. Process intensification was used to enhance different ways to obtain solar grade silicon such as an Intensified Fluidized Bed Reactor and a hybrid, which is a combination of Siemens and conventional FBR processes. Also, the Siemens process was considered the most common process to produce silicon. Results show that the difference between the analyzed scenarios lies in the behavior of people while profit maintains constant.

Keywords: Matching Law, Solar Grade Silicon, Strategic Planning, Process Intensification, Economic Incentives.

1. Introduction

In recent decades, photovoltaic systems have evolved and have been adapted to various applications of daily life. That way, large-scale manufacturing of photovoltaic cells capable of providing energy has become economically viable. It is important to produce large amounts of polysilicon due to the high demand by the solar sector. The production of polysilicon from quartz consists of two main stages: obtaining metallurgical grade silicon and purifying it to transform it into solar grade silicon (Ranjan et al., 2011). Attention has been drawn to update processes to obtain this component in order to achieve not only cost reduction but also improving safety of the process. Due to the exceeding cost of photovoltaic panels, it is necessary to look for alternatives in order to reduce the production cost of the solar grade silicon (SiSG). The photovoltaic industry relies on high-

purity silicon produced in the Siemens process; however, it requires a high power consumption. Another process is the Fluidized Bed Reactor that saves between 80-90 percent of the energy consumed compared to the Siemens process (Jiao et al., 2011) but the operating conditions are more difficult to achieve. Different alternatives have been proposed, one of them is an intensified FBR's process by substituting the conventional reactors and separation zone with a reactive distillation column to improve the chemical conversion. An additional alternative process is based on both, the Siemens and the conventional FBR attempting to reduce the use of raw material (Ramírez-Márquez et al., 2018).

The behavior of the population under various circumstances has not been addressed in a proper way. Considering the human behavior is especially important due to the high dependence of the energy system on it, this because the demand for each type of energy depends on the preference of the end user (population). Matching law is a mathematical approach that describes the relationship between the relative rate of response and the relative rate of reward in the face of a concurrent stimulus; from this law and respecting what is established, it is possible to give different interpretations and use it under diverse scenarios (Herrnstein, 1961). This way, in this paper is proposed a mathematical model that involves behavior through matching law and planning a supply chain of an important value-added compound.

The main difference with other works is that the planning of photovoltaic systems has not considered users in the system, they only included ways to evaluate costs or improve the processes but not to consider how the decision of a person could affect the whole system. Also, it has not been studied the behavior of the population through the matching law together with the strategic planning of solar grade silicon (Si_{SG}). The use of matching law is related to the economic flow of incentives and penalties that will influence the consumer's decision to select the type of solar panel to use depending on the addressed case. Matching law provides a good tool to model consumer response to incentives. This allows optimizing the supply chain and planning of poly-silicon used to yield solar panels involving producers, government and end-users.

2. Problem statement

The addressed problem seeks to meet the demands of electric power of the residential sector. One of the main limitations is the production and distribution of the raw material to produce solar grade silicon, which can be implemented through the Siemens processes, intensified FBR Union Carbide and a combination of both (Hybrid).

Matching law is adapted in a mathematical optimization model and the problem consists in determining the preference of the end user at a maximum profit. In the presented case study, the Government is the decision maker because it is responsible to pay incentives or implement economic punishments. The considered perspective is to study the effect of the government over producers and consumers. There are different studied scenarios, where it is intended to analyze those perspectives. The consumer can choose between two options: (a) use solar panels interconnected to the network, (b) use isolated solar panels. The final decision will be influenced by the incentives and punishments that the government will provide. Following those ideas, the behavior can be predicted.

3. Optimization model

The proposed mathematical model is based on the superstructure shown in Figure 1, which represents the problem to be addressed and involves all the possibilities to solve it. It considers the raw material available for using in different cities of the country. The raw material is transported to the different processes to produce solar grade silicon (Siemens, intensified FBR Union Carbide and Hybrid). This raw material must meet the compositions requirements for its processing. Once the Si_{ISG} is obtained, it is used to produce solar panels isolated or solar panels interconnected to the existing network and will subsequently be used to meet the electricity demand of the country's residential sector.

Figure 1. Proposed superstructure.

3.1. Problem behavior

Eq. (1) is used to calculate economic incentives (rewards, $R^1_{pis,t}$) and economic punishments ($P^1_{pis,t}$). The producer is asked to propose a certain amount that he considers he can meet, knowing that by meeting that amount he will obtain an economic incentive, but if he does not meet it, he will be financially punished. In this way, both the stakeholder and the producer are involved. It is necessary to involve the receiver in establishing the targets to assure that they will try their very best in order to achieve the production target and earn the incentives but also they need to be aware of their limits and do not propose more than they can do, that is why punishments are also included. $P^{is-p}_{pis,t}$ represents the number of panels proposed by the CEO of the company or the final user, according to the case. Those are the panels that CEO/user mean to achieve, it is a hypothetical situation because that number represents the number of panels that is easy to use for them but also the number must be reliable and achievable. They commit to reach the number and based on that the incentives/punishments are calculated. $P^{is-oc}_{pis,t}$ is the target quantity of solar panels established by the stakeholder. IE^{R1} is the base economic incentive that can be obtained. u^{is} , x^{is} and v^{is} are required parameters.

$Y^{R1}_{A_{pis,t}}$ will be activated if the number of produced panels is equal to the number of proposed panels. The reward is the base economic incentive and there is no punishment. $Y^{R1}_{B_{pis,t}}$ will be activated if the number of produced panels is greater than the proposed panels. The reward will be greater than the base economic incentive and there is no punishment. $Y^{R1}_{C_{pis,t}}$ will be activated if the number of produced panels is lower than the

proposed panels. There is no reward, and the punishment will be greater than the base economic incentive.

$$\left[\begin{array}{l} Y_{A_{pis,t}}^{R^1} \\ P_{pis,t}^{is} = P_{pis,t}^{is-p} \\ R_{pis,t}^1 = IE^{R^1} \cdot u^{is} \cdot \frac{P_{pis,t}^{is-p}}{P_{pis,t}^{is-oc}} \\ P_{pis,t}^1 = 0 \end{array} \right] \vee \left[\begin{array}{l} Y_{B_{pis,t}}^{R^1} \\ P_{pis,t}^{is} > P_{pis,t}^{is-p} \\ R_{pis,t}^1 = IE^{R^1} \cdot x^{is} \cdot \frac{(P_{pis,t}^{is} + P_{pis,t}^{is-p})}{2 \cdot P_{pis,t}^{is-oc}} \\ P_{pis,t}^1 = 0 \end{array} \right] \vee \left[\begin{array}{l} Y_{C_{pis,t}}^{R^1} \\ P_{pis,t}^{is} < P_{pis,t}^{is-p} \\ R_{pis,t}^1 = 0 \\ P_{pis,t}^1 = IE^{R^1} \cdot v^{is} \cdot \frac{(3 \cdot P_{pis,t}^{is} - P_{pis,t}^{is-p})}{2 \cdot P_{pis,t}^{is-oc}} \end{array} \right], \forall pis, \forall t \quad (1)$$

The equation of matching law developed by Borrero and Vollmer (2002) was adapted to the current problem statement (Eq.(2) and Eq. (3)).

$$\frac{B_{pis,t}^1}{B_{pis,t}^1 + B_{pin,t}^2} = \frac{R_{pis,t}^1 - P_{pis,t}^1}{(R_{pis,t}^1 - P_{pis,t}^1) + (R_{pin,t}^2 - P_{pin,t}^2)}, \forall pis, \forall pin, \forall t \quad (2)$$

$$\frac{B_{pin,t}^2}{B_{pis,t}^1 + B_{pin,t}^2} = \frac{R_{pin,t}^2 - P_{pin,t}^2}{(R_{pis,t}^1 - P_{pis,t}^1) + (R_{pin,t}^2 - P_{pin,t}^2)}, \forall pis, \forall pin, \forall t \quad (3)$$

The response rates B1 and B2 are reflected with the flow of money in the case of isolated and interconnected to the network solar panels:

$$B_{pis,t}^1 = IE^{R^1} \cdot P_{pis,t}^{is}, \forall pis, \forall t \quad (4)$$

$$B_{pin,t}^2 = IE^{R^2} \cdot P_{pin,t}^{in}, \forall pin, \forall t \quad (5)$$

3.2. Objective function

The considered objective function corresponds to maximize the profit, which is calculated through the sale of Si_{SG} minus all costs involved in the production and transport of the raw material and the different processes to obtain silicon, as well as rewards and punishments related to using solar panels:

$$Profit = \left[\begin{array}{l} Sale^{Si} - \\ Cost^{p-SiO_2} - Cost^{p-C} - Cost^{p-HCl} - Cost^{p-H_2} - Cost^{p-SiCl_4} - \\ Cost^{p-Sie} - Cost^{p-FBR} - Cost^{p-Hyb} - \\ Cost^{t-raw} - Cost^{t-Si} + \\ \sum_{pis,t} (R_{pis,t}^1 - P_{pis,t}^1) + \sum_{pin,t} (R_{pin,t}^2 - P_{pin,t}^2) \end{array} \right] \quad (6)$$

4. Case study

The case study is applied in Mexico. The raw material must be transported from its production point of the different plants to the silicon production plants for either the Siemens, the intensified FBR or the Hybrid process. It is necessary to meet the required

compositions for each process. For the installation of solar panels, 20 cities are selected which represent the cities where entrepreneurship is being promoted in the country. The contemplated time horizon is 30 years divided in periods of a year. According to the current consumption of electric energy, the necessary solar panels are determined if the total demand is covered, and his way the basis for subsequent calculations is obtained. Solar panels of 270 W are used. Different scenarios were proposed.

Scenario A: Government pays economic incentives and implements economic punishments to the CEO. Scenario B: CEO pays economic incentives to the final user. Scenario C: Government pays economic incentives and implements economic punishments to the CEO at the same time that CEO pays economic incentives to the final user. Under this background, it was determined the preference of population between isolated or interconnected solar panels.

5. Results

The profit obtained in scenario A is 7.9188×10^8 \$/y. Silicon production is mainly satisfied from the hybrid process (70.1%). Siemens process has the lowest cost but also the lowest silicon production rate. Intensified FBR has the highest cost but a large production. On the other hand, the hybrid process has the largest production rate with the middle production cost compared with the other two. It was shown that the Hybrid process is the most cost-effective one.

The values B1 and B2 represent the flow of money that is directed to each option considered, it means that where there is greater flow of money is the largest number of households that select that type of panel. In scenario A, results show that population is more inclined to use panels interconnected to the grid to produce electricity and to meet the demand for residential sector (Figure 2). Only Tlaxcala and Monterrey received economic punishments. Results in scenario B show a greater profit (7.9223×10^8 \$/y) than scenario A (7.9188×10^8 \$/y), because scenario B does not consider economic punishment although the incentives granted are lower than the incentives given by government in scenario A. Profit in scenario C is 7.9214×10^8 \$/y and in 40% of the cities, more than 50% of the users prefer to install isolated panels. In scenario A, 25% of the cities prefer isolated panels. In contrast, in scenario B, all cities prefer to install interconnected panels.

It should be noted that in the addressed case study there were analyzed various scenarios to see how the whole system will react under different targets proposed by different entities and the presented scenarios are only cases to show the applicability of the proposed approach. This work is the first attempt to understand the relationship with matching law and planning under the fixed parameters.

6. Conclusions

This work has presented a mathematical optimization model capable of involving the conduct of people with the planning for the construction of solar panels isolated and interconnected with the network. The proposed approach has been tested in a national case study in Mexico, taking into account the greater profit and preference towards the solar panels of the involved users.

By using the matching law to study the human behaviour, it is possible to predict preferences of population. Also, it can be created hypothetical scenarios to understand the

main factors that change the final decision of the user and to help the stakeholder to decide according to their objectives and interests.

In the presented case study, the profit remains similar between scenarios A, B and C (7.9188×10^8 , 7.9223×10^8 and 7.9214×10^8 \$/y). However, the difference lies in the behaviour of the users, the preference for which they lean. Using models that predict behavior makes possible to control or manipulate the response expected from consumers under various established situations. The proposed model is general, and it can be applied to different case studies by making the appropriate changes in the involved parameters.

Abstract

Supply chain management is an interconnected problem that requires the coordination of various decisions and elements across long-term (i.e., supply chain structure), medium-term (i.e., production planning), and short-term (i.e., production scheduling) operations. Traditionally, decision-making strategies for such problems follow a sequential approach where longer-term decisions are made first and implemented at lower levels, accordingly. However, there are shared variables across different decision layers of the supply chain that are dictating the feasibility and optimality of the overall supply chain performance. Multi-level programming offers a holistic approach that explicitly accounts for this inherent hierarchy and interconnectivity between supply chain elements, however, requires more rigorous solution strategies as they are strongly NP-hard. In this work, we use the DOMINO framework, a data-driven optimization algorithm initially developed to solve single-leader single-follower bi-level mixed-integer optimization problems, and further develop it to address integrated planning and scheduling formulations with multiple follower lower-level problems, which has not received extensive attention in the open literature. By sampling for the production targets over a pre-specified planning horizon, DOMINO deterministically solves the scheduling problem at each planning period per sample, while accounting for the total cost of planning, inventories, and demand satisfaction. This input-output data is then passed onto a data-driven optimizer to recover a guaranteed feasible, near-optimal solution to the integrated planning and scheduling problem. We show the applicability of the proposed approach for the solution of a two-product planning and scheduling case study.

Keywords: Integrated planning and scheduling, bi-level programming, data-driven optimization, mixed-integer optimization.

1. Introduction

Planning and scheduling belong to different levels of supply chain management, yet their coordination is essential for feasible decision making. The former determines the production targets by observing the market considerations (i.e., product demands), whereas the latter decides on the sequencing of tasks and their respective assignment to specific units such that the production targets set by the planning level are met.

Typically, these planning and scheduling problems are solved sequentially: initially, the planning level decides on the production targets of finished goods by observing the

demand profiles for the products; later, the production targets are set for the scheduling problem, and the respective optimal schedules are calculated. However, such a sequential approach, where the planning decisions are solely based on the product demand profiles are optimistic estimates and may lead to infeasible schedules (Grossmann, 2005). In other words, the process of converting raw materials to finished goods cannot be realized within the given capacity of the scheduling level. Henceforth, the production target set by the planning level cannot be met, and consequently, the demand is not satisfied. This interconnected network of decision making requires an integrated approach where the interdependencies among planning and scheduling levels need to be addressed simultaneously to achieve globally optimal solutions (Maravelias and Sung, 2009).

Bi-level programming enables the integration of planning and scheduling levels and creates holistic models that explicitly account for the inherent hierarchy between different levels of the supply chain. Unfortunately, many algorithmic difficulties arise when solving bi-level programming problems including, NP-hardness, nonconvexity, and discontinuity, even in the most simplistic formulations (Sinha et al., 2018). Especially the mixed-integer formulations in the scheduling level prohibit the use of the KKT transformation at the lower level, creating a necessity to tackle these problems with an algorithmic approach that can guarantee feasibility to bi-level formulations. An approach based on multi-parametric programming has been proposed to address this (Avraamidou and Pistikopoulos, 2018), but it cannot handle a relatively high number of variables. Recently, the DOMINO algorithm is introduced as a data-driven methodology for solving constrained bi-level mixed-integer nonlinear programming (B-MINLP) problems with a higher number of variables and a feasibility guarantee (Beykal et al., 2020). In this work, our goal is to (1) further advance the DOMINO framework for solving integrated planning and scheduling problems with multiple followers; and, (2) utilize this framework to provide guaranteed feasible solutions to integrated supply chain management problems.

2. The DOMINO Algorithm and its Extension to Multi-Follower Systems

DOMINO is a data-driven optimization algorithm that is tailored to solve single-leader single-follower constrained B-MINLP problems by approximating them as single-level grey-box optimization problems through series of sampling, optimization, and surrogate modeling steps (Beykal et al., 2020). It postulates candidate sampling points for the upper-level decision variables and solves the lower-level problem deterministically to global optimality at each sampling point. The collected input-output data is then passed onto a data-driven optimization step where the solver retrieves the optimal solution of the bi-level program. DOMINO ensures the feasibility of a candidate solution by evaluating the constraint violations of grey-box constraints and the optimality of the lower-level problem. If these two conditions are satisfied, the candidate solution is deemed a guaranteed feasible solution of the bi-level program. Previously, DOMINO is shown to locate near-optimal solutions to varying types of single-follower bi-level programming problems in series of benchmark problems (Beykal et al., 2020) and a case study (Avraamidou et al., 2018).

In the case of integrated planning and scheduling problems, the lower-level problem is composed of multiple scheduling problems (i.e., multiple followers) that need to be solved sequentially over the entire planning horizon. For that reason, the DOMINO

algorithm cannot be directly implemented, and a subroutine needs to be devised to collect the input-output data. The production targets for the planning horizon are the upper-level decision variables, which are used to create the input data for the sampling stage. To account for the multi-follower nature of the lower-level problem, these input production targets will be fixed at the scheduling level and the schedules for each planning period will be solved sequentially while accounting for the inventories and production cost per period. Finally, the total cost of planning will be calculated from the total inventory and production cost across the planning horizon and this value will serve as the output information that is required to be minimized in the data-driven optimization stage.

3. Case Study for Bi-level Production Planning and Scheduling

The computational case study for the bi-level production planning and scheduling problem is adapted from Li and Ierapetritou (2009) with an implementation of the continuous-time formulation of Example 2 (Ierapetritou and Floudas, 1998) at the lower-level scheduling problem. An overview of this bi-level program is provided in Eq. (1).

Total Cost of Planning

s. t. Inventory and Balance Equations (1)

Production Cost for Each Planning Period

s. t. Scheduling Constraints

3.1. The Upper-Level Problem: Planning Model

The planning level objective minimizes the total inventory and production cost over the entire planning horizon. The decision variables for the bi-level program are the production targets (Prd_s^t) of the desired products (i.e., states $s \in S_p$) per planning period t . The inventory accounting is performed at every planning period using Eq. (2), where Inv_s^t is the inventory level of the product state s at the end of planning period t , Prd_s^t is the production level of the product state s in the planning period t , and Dmd_s^t is the demand level for the product state s in the planning period t .

$$Inv_s^t = Inv_s^{t-1} + Prd_s^t - Dmd_s^t \quad \forall s \in S_p, t \quad (2)$$

If the inventory becomes negative at any period, the minimum inventory of each product is calculated, and all respective inventories are penalized by adding this minimum level of inventory. Also, the total amount of products given by the production target, and the inventory level at the beginning of each planning period should be greater than or equal to the demand to satisfy the need. The planning horizon is set to be 7 days, and the demand for the two products is assumed to be known for the entire week. Besides, the planning problem is assumed to be cyclic where the last day production target should meet the last day demand and produce the 1st day inventory of the next planning cycle. The upper-level problem contains 14 production target constraints, 14 demand constraints, and 28 positive variables (14 inventory and 14 decision variables). The upper bound on the decision variables is set to be 80-unit materials per product per planning period.

3.2. The Lower-Level Problem: Scheduling Model

In the selected case study, the scheduling problem (Figure 1) considers the production of two products through three reaction steps, a heating step, and a separation step. Three feed and four intermediate components are considered in the production schedule. The scheduling formulation considers material balances, allocation, capacity, storage, duration, time horizon, and sequence constraints (Ierapetritou and Floudas, 1998). To guarantee feasibility to the integrated multi-follower problem, a constraint on the final states of the products is added to ensure the production targets set by the upper-level problem are met at the scheduling level. The objective function of the scheduling problem minimizes the fixed cost of operating tasks in units, as well as the variable cost coming from handling raw materials, intermediates, and final products within the process. The lower-level problem contains 285 continuous variables, 160 binary variables, and 712 constraints. The detailed model equations and parameters can be provided upon request.

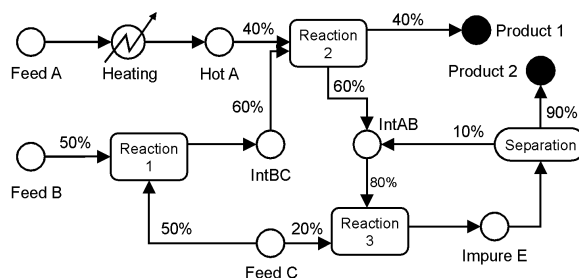

Figure 1 State-task network of the scheduling case study. Adapted from Ierapetritou and Floudas (1998).

3.3. Other Considerations for the Problem Formulation

The integrated bi-level mixed-integer program is solved for two cases: (1) assuming linear inventory and production cost, leading to an LP-MILP bi-level problem; and, (2) assuming cubic inventory cost at the planning level and quadratic production cost at the scheduling level, creating an NLP-MIQP problem. Compared to other bi-level optimization algorithms, DOMINO allows us to solve highly nonlinear systems using its data-driven optimization strategy and retrieve guaranteed feasible near-optimal solutions (Beykal et al., 2020). Specifically, this capability of DOMINO is advantageous because the nonlinear objective functions allow for a more realistic estimate of the variable cost in the integrated planning and scheduling formulation, as linear cost estimates are approximations of the nonlinear behavior. Also, the inclusion of the nonlinear terms in the bi-level formulation yields a very challenging optimization problem which the exact methods like multi-parametric programming cannot address. Data-driven evolutionary algorithms can handle nonlinearities but they fail to provide guaranteed feasible solutions.

To assess the consistency and accuracy of the DOMINO algorithm in finding the best solution for the integrated planning and scheduling problem, the algorithm is randomly executed 10 times with the NOMAD algorithm (Le Digabel, 2011) chosen as the data-driven optimizer. The results retrieved from DOMINO are presented in the next section.

4. Results

4.1. LP-MILP Solution

The best solution of the 10 random runs for the LP-MILP integrated planning and scheduling formulation is summarized in Figure 2. The results show that the demand for both products is satisfied over the 7-day planning period where the corresponding production targets are met with globally optimal schedules. We also observe that at the start of the planning period (Day 1), the system produces more than the minimum required level to sustain the inventory levels for Product 1 whereas a lower production target is set for Product 2 and the remaining demand is supplemented from the starting inventory. On Day 2, both production targets are relatively higher than the demand. This higher level of production enables Product 1 to sustain its starting inventory levels whereas Product 2 makes up for the lost inventory on Day 1. Later, when peak demand is expected on Day 4 for both products, the production target is supplemented with this accumulated inventory to satisfy the demand. On Day 6 as the demand is lower, the production can meet this demand without requiring any extra supply from the inventory. On the final day of the planning period, the production levels are increased to satisfy the 7th day demand as well as to produce the starting inventory of the 1st day of the next planning cycle.

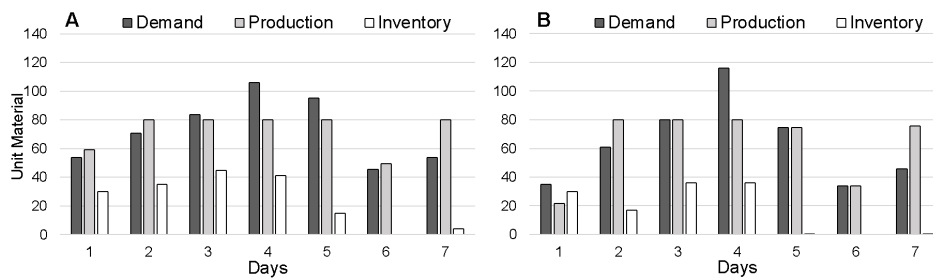

Figure 2 Demand, production, and starting inventory profiles for (A) Product 1; and (B) Product 2.

The results of the other 9 random cases also showed very consistent production and inventory levels in Days 3-7 for Product 1 and in Days 4-5, 7 for Product 2. Some variability is observed in the early days of the week where in one instance a significantly higher production is observed for Day 1 for both products which led to no production in Day 2, essentially pushing the system to spend the accumulated inventory more quickly than the best solution. In the other two instances, Day 1 production is observed to be zero where the system relied on having a higher start inventory by producing more at the end of the planning period when the demand is lower. Nonetheless, the final cost objective value for all runs was within ± 0.0386 standard error and all final solutions were guaranteed feasible with globally optimal schedules.

4.2. NLP-MIQP Solution

The best solution of the 10 random runs for the NLP-MIQP formulation is summarized in Figure 3. The nonlinear integrated planning and scheduling results show very similar production and starting inventory profiles to the LP-MILP case study where the demand is satisfied for the entire planning horizon of 7 days with a globally optimal lower-level solution. Only on Day 7, a slightly higher starting inventory level is observed for Product 1 because the production target of the prior day is higher in the NLP-MIQP

solution. Furthermore, the DOMINO solution is very consistent across all runs for the NLP-MIQP formulation. For Product 1, we observe that the same starting inventory and production levels are determined for Days 1-5 whereas a slight deviation is observed for Days 6 and 7. For Product 2, some variability is observed at the start and end of the planning period, but the production and inventory levels are consistent for Days 3 and 4. The consistency of the solutions is also reflected in the final objective values where for all runs the objective value was within ± 0.1465 standard error.

5. Conclusions and Future Work

In this work, we present a data-driven approach to solve bi-level multi-follower mixed-integer formulations of integrated planning and scheduling problems. By extending the DOMINO algorithm to solve multi-follower bi-level optimization problems and utilizing the data-driven and deterministic optimization capabilities of this framework, we solve the integrated problems to guaranteed feasibility. For all the tested cases, DOMINO identified solutions that meet the product demand and have globally optimal schedules at the lower level, which ensures meeting the production targets, DOMINO also found consistent feasible solutions for both the linear and nonlinear formulations. In the future, the results of the linear formulation will be compared to the deterministic algorithm developed by Avraamidou and Pistikopoulos, 2019. This research was funded by the U.S. National Institutes of Health (NIH) grant P42 ES027704.

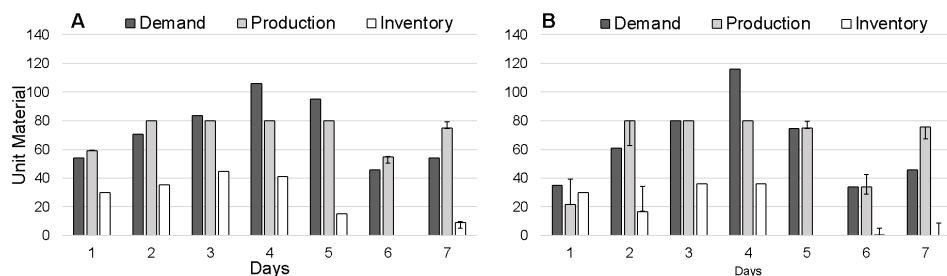

Figure 3 Demand, production, and starting inventory profiles for (A) Product 1; and (B) Product 2 in the NLP-MIQP solution. The error bars indicate the minimum and maximum deviation observed across all runs with respect to the best-found solution.

1. Abstract

On a global scale, the main usages of wood are energy production and materials. Wood chemistry offers a broad range of potential outlets, and the whole supply chain around it. The latter is made up of a set of actors (suppliers, producers, etc.), processes and financial, informational and material flows. Designing the supply chain is therefore a complex activity. It is therefore important to determine the different variables that will influence the design of the supply chain. From this perspective, this research focuses on the valorization of the lignin fraction, by addressing the various aspects of the development of new products and by determining the variables that will impact the design and implementation of the future supply chain.

Keywords: supply chain, prospective analysis, lignin.

2. Context

Nowadays, oil consumption accounts for 90% of the energy consumed and alternatives to replace oil are still poorly developed. In France, for example, renewable energies (hydraulic, wind, solar, geothermal or biomass energy) account for 10% of energy consumption (Arion et al. 2018). The increasing scarcity of oil could therefore require a reconsideration of the entire energy supply chains and stimulate the exploitation and development of innovative products from natural renewable resources, like lignocellulosic biomass. Nevertheless, the success of these new products and their supply chains will depend on technological progress and cost control (de Cherisey 2015). It is therefore necessary to anticipate and design the product, the process and the supply chain jointly (Hilletoft et al. 2010; Sharifi et al. 2006; Primus 2017). At any given moment, the supply chain can be characterized by its actors, processes, flows, and the value it generates described by its structure and operating dynamics (Marche et al. 2017). In general, the pathways considered to develop products derived from lignocellulosics include the following elements: biomass cultivation, storage, and treatment plants (biorefineries); intermediate product storage; final product production plants, and demand centers. Raw materials and intermediate products circulate between the elements (Panteli et al. 2017; 2018). However, this structure depends on the decisions of each actor, which

are interdependent, but also on collective decisions. Therefore, this research is a holistic and prospective approach in order to anticipate the design of future lignin supply chains.

3. Research approach

To better understand the influence of the variables on the future supply chains, as well as the effects of the decisions of the actors involved, a prospective analysis was carried out using the MICMAC (Cross Impact Matrix and Multiplication Applied to Ranking) method. This method has already been used in prospective supply chain design approaches (Attri et Grover 2017; Agarwal, Tyagi, et Garg 2021). It allows a systematic identification of the key variables determining the evolution of the supply chain and examining the combinations of hypotheses that can be excluded a priori (Elmsalmi and Hachicha 2014). Based on the influence/dependence plan, it is possible to identify 9 areas, as shown in Figure 1.

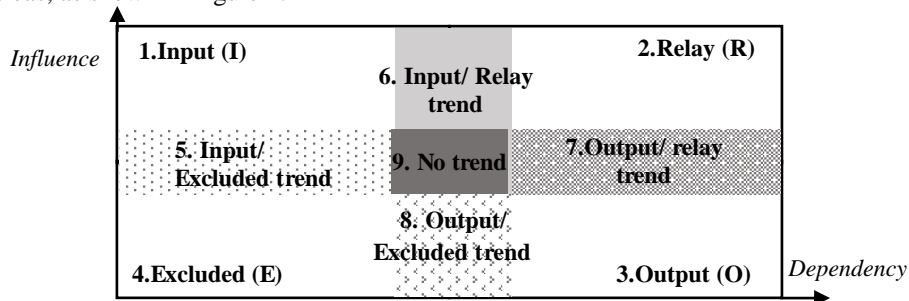

Figure 1: Zones of the influence/dependence plan

A confrontation with 8 experts made it possible to identify 29 variables, which have a higher impact on the future supply chain design. Then, these experts evaluated the impact of each variable on all other variables (0: no impact; 1: low impact; 2: medium impact; 3: high impact; 4: potential impact). According to these assessment, the MICMAC method classifies variables into four typologies (Godet and Durance 2011):

- Input variables: They are explanatory of the system under study, and condition the overall dynamics. They guide and explain the development of the system.
- Relay variables: They are inherently unstable. They play a central role in the dynamics of the system and are the main issues at stake. Any action on them will have repercussions on the other variables and a feedback effect on themselves.
- Output variables: Their behaviour can be explained by analysing (or acting on) the input and relay variables. They are the variables most dependent on others.
- Excluded variables: They have little impact on the system, either because their inertia does not alter the dynamics of the system, or because of their reduced connection with it and develop relatively autonomously.

Three types of analyses were carried out: (i) unweighted analysis and considering the pool of experts in the panel (ii) analysis with a weighting of the self-rated level of expertise (1: low expertise; 5: high expertise), and (iii) analysis with a weighting of the level of expertise (same scale) evaluated by the researchers.

4. Results

The different analyses made it possible to identify 7 variables on which there is a consensus among all the stakeholders. A strong trend may emerge for certain variables but for the majority, it seems impossible to determine the type of each variable. On the basis of the representation of Figure 1, it is possible to position the variables more accurately, as shown in Table 1.

Table 1. Variables classification

Variable	I	R	O	E	I/E	I/R	O/R	No trend
1. Minimal scale of processability			X					
2. Diversification of raw materials						X		
3. Added value of final product			X					
4. Sales volume of final products							X	
5. Transformation cost			X					
6. Source configuration	X							
7. Pre-treatment capacity			X					
8. "Purity" of the lignin				X				
9. Lignocellulosic source prices								X
10. Availability of lignin								X
11. Production capacity							X	
12. Sales price of lignin			X					
13. Cost of the final product			X					
14. Price of energy					X			
15. Geographical location	X							
16. Technological maturity	X							
17. Type of products								X
18. Type of wood	X							
19. Supply risk								X
20. Weight of suppliers								X
21. Type of processes		X						
22. Weight of biorefineries							X	
23. Potential competition								X
24. Quality of wood				X				
25. Pedological & climatic variables				X				
26. Shape and structure of the tree				X				
27. Type of solvents			X					
28. Environmental impact of products			X					
29. Presence of alternatives products	X							

Thus, Table 1 presents the classification of the 29 variables, as follows:

- Dominant trend for one of the typologies (more than 70% of identical answers from the experts): zone 1, 2, 3 and 4;
- Dominant trend for two typologies (more than 70% for the two majority typologies): zones 5, 6, 7 and 8;
- No dominant typology (total disagreement between the experts or the two majority typologies below 70%): zone 9.

4.1. Input variables

Our qualitative analysis characterizes the following variables as input variables: the source configuration; geographical location; Technological maturity; wood type; and the presence of alternative products. The source configuration, the geographic location, and the wood type are all related to lignin and its suppliers are globally dispersed, so their activities depend on the raw material available to them. The lignin source and their locations will have a direct impact on the choice of biorefinery according to their specialty or proximity. Technological maturity refers to the degree of completion of a technology with a view to making it available on the market. It is a measure of whether the technology is capable of delivering the expected services and quality of service under real operating conditions. This variable is particularly important in our study, as lignosulphonates, Kraft or soda lignins are obtained from mature and mastered technologies, but organosolv lignins are rather emerging. Thus, the technological maturity being classified as an input variable seems relevant, as the choice of technology will condition the supply chain (production capacity, supply capacity, type of suppliers, etc.). The presence of alternative products plays a key role in the supply chain if one considers supply chains competing with each other, the alternative product chains will condition the functioning of the future supply chain being created. Indeed, if the innovative product arrives in a highly competitive market, the supply chain must make its place and adopt a more aggressive behavior or develop a particular strategy, turned towards the customer's demand. In the case of the future supply chain, it should compete with similar petroleum-based product chains. These products are omnipresent on the market, the future supply chain must therefore adapt its strategy to gain market share.

4.2. Relay variables

The type of process was the only variable classified as relay. It plays an important role in the creation of the future supply chain for the product, as it characterizes the biorefineries that will be involved in the supply chain. The choice of a process for obtaining lignin will lead to other decisions in terms of the supply chain, related to the output variables.

4.3. Output variables

The output variables are the result of the decisions taken within the supply chain. In our study these are the minimum scale of processability, the added value of the final product, its transformation cost, pre-treatment capacity, selling price of lignin, cost of the final product, type of solvents and environmental impact of the product.

4.4. Excluded variables

Some variables were excluded as these are considered to be less influential or not very dependent. Variables directly related to the growing condition of the plants (wood quality, pedological and climatic variables and wood form/structure) were considered as having no impact on the creation of the future supply chain. The "purity" of lignin, on the other hand, could be considered as a strong trend. This means that it could have an impact on the supply chain in the future. Indeed, lignins exhibit different properties according to the process chosen and therefore. Probably in the future, the purity of lignin could become an important variable in the supply chain, because it would condition the processes to be favored to obtain lignin-based products with very precise and differentiating properties.

4.5. Input/Excluded variables

Energy prices and weight of suppliers are classified as input/excluded (zone 5) variables in the supply chain. The energy price variable can be very influential depending on the location one wishes to set up the supply chain in. Indeed, in order to minimize energy costs, it is in the interest of companies to deploy their supply chain in countries where energy is easily accessible and at affordable costs.

4.6. Input/Relay variables

The diversification of the raw material is found to be in the zone 6 of the Figure 1. This variable can cause the type of processes/solvents used to change, if the lignin composition goes beyond the established limits. In this case, suppliers of different types of wood can gain weight along the supply chain.

4.7. Output/Relay variables

In the zone 7 we found the volume of sales of final products, production capacity and weight of biorefineries. For example, the volume of sales of final products can be considered as a relay variable before the product launch on the market because it can be difficult to assess how customers will welcome the new product. Once the supply chain has been set up, the volume of sales becomes a known variable and is the result of decisions taken within the supply chain. Similarly, before the future supply chain is set up, it may be possible to assess the production capacity of the supply chain and the processing costs based on the individual capacities of each stakeholder and the costs generated. However, it may be difficult to estimate the evolution of demand once the product is launched, and thus to ensure that the supply chain has the capacity to keep up with changes in demand and to manage processing costs when changing the scale of production.

4.8. Dissensus

Several variables remain unclassified (zone 9) for several reasons. Firstly, when the four typologies are proposed by the experts, as it was the case for the price of lignocellulosic sources, the availability of different types of lignin, and the weight of suppliers. Secondly, when the experts' visions are antagonistic (input variable for some VS result variables for others). This is the case for the variables type of products and presence of alternative products. For the weight of biorefineries or the supply risk there was a slight trend towards relay variables, but it was not confirmed by all the experts. No trend emerged for the potential competition. Note that our qualitative analysis did not characterise any of the variables of the supply chain as outcome/excluded variables (zone 8).

The MICMAC analysis underlines that the supply chain created is influenced by relay variables, making it unstable. In order to anticipate and facilitate its creation, it is necessary for the stakeholders of the supply chain to be able to "control" the impacts of these variables. The relay variable clearly identified for this is the type of process, whose importance was illustrated in a parallel study using poplar as a basis for producing a range of products in a sustainable way thanks under the biorefinery concept (Solarte-Toro et al. 2020).

5. Conclusions

The study of the supply chain for a lignin-based product highlighted the complexity of setting up a supply chain. The mobilization of experts was an important step to describe the future supply chain scenarios that could support the industrialization of a lignin-based product. However, the analysis of the results underlines the difficulty for individuals to project themselves in a situation where the system, in this case the supply chain, does not yet exist. How can the sales volume of the future product be estimated? How can the weight of the players be assessed? Several questions arise. It is therefore necessary to develop a maximum number of scenarios to anticipate all possible situations. The choice of the lignin extraction process seems to be a relevant basis for developing different scenarios, as it has a direct impact on sales volumes, prices, production capacities and the location of biorefineries, which will give information on the type of wood or on energy prices.

Abstract

During the last decades, design under uncertainty has become one of the key aspects in the Process Systems Engineering with widely spread applications to technological and economic aspects. In particular, the supply chain design is seeing a constantly increasing interest and flexibility could be an added value of critical importance for the supply chain management domain. The purpose of this research work is then to define a thorough procedure able to describe flexibility in the operational research domain taking advantage of established indicators. The most commonly used deterministic and stochastic flexibility indices are then adapted to the traveling salesman problem, an NP-hard problem in combinatorial optimization, widely studied in theoretical computer science and operations research. It can be seen as the most general problem formulation in this field and as a preliminary test before extending the flexibility assessment to more specific applications. According to existing methodologies for chemical processes, the economic and flexibility analyses have been coupled over a certain flexibility range. This approach resulted in a correlation between flexibility and costs represented by the total traveling distance. Moreover, the additional costs vs. flexibility trend can be plotted both for both the indicators showing analogies and differences with respect to the results previously obtained for chemical processes. In conclusion, the methodology provided a useful tool to quantify the parameter deviations that can be withstood keeping the solution feasible. The combined costs-flexibility graphical representation allows a more conscious decision and could be further exploited in more specific applications such as the supply chain network design.

Keywords: flexibility, supply chain, operational research, travelling salesman problem.

1. Introduction

With the increasing interest toward the replacement of the conventional sources of energy by renewables and the need to deal with the fluctuating market demand, operational research and the supply management in particular belong to the research fields in the process system engineering domain for which the flexibility assessment is of critical importance.

Design under uncertainty represents a useful and reliable tool mainly used for process unit design during the last decades by means of a thoroughly defined procedure and dedicated flexibility indices (Di Pretoro et al. (2019)). In the last years, some articles focusing on supply chain design under uncertainty have been proposed in literature as well (Govindan et al. (2017)). However, this is a more recent application field and they aim at the analysis of specific case study by considering different scenarios and uncertain

parameters without providing a detailed procedure of general validity in analogy with the processes related research works.

The Traveling Salesman Problem (TSP) can be seen as the most basic formulation of operational research problem. It was first mathematically formulated by Hamilton and Kirkman in the 1800s and mathematically considered in 1930 by Flood for the solution of the bus routing problem.

It is a NP-hard problem and, in its decision version it is also NP complete, i.e. it could be solved in polynomial time on a deterministic Turing machine. The exact algorithm to solve this problem implies the calculation of all permutations with a running time lying within a polynomial factor $O(n!)$ as a consequence, where n represents the number of cities. Therefore it is evident that this approach can be employed for problems involving a small number of cities only (Applegate et al. (2006)).

For this reason, heuristic algorithms or specific cases analysis are often used to provide a reliable approximation of the optimal solution in a reasonable time. The application of several optimization methodologies such as branch-and-bound, branch-and-cut, dynamic programming, Lin-Kernighan heuristic, ant-colony optimization, genetic algorithm etc. have been proposed during the last century in order to effectively approximate the optimal solution with good results both from the accuracy and from the computational effort perspectives for case studies of practical interest.

The purpose of this research work is then to adapt the well-established flexibility assessment procedure employed for process equipment to the TSP in order to analyse the impact of input parameters uncertainties on the optimal solution and the corresponding additional distance to be travelled. Moreover, this analysis is extended to uncertainties weighted with respect to their likelihood by means of the stochastic flexibility index in order to find the probability corresponding to the different optimal pathways and provide a more reliable tool.

The obtained results, of general validity, could be then applied to more complex operational research problem by adding the desired constraints and weight functions in order to have a design procedure for each specific supply chain management case study.

Further details about flexibility analysis and the TSP under uncertainty case study as well as a thorough description of the design procedure are discussed in the following sections.

2. Flexibility assessment

Flexibility assessment is a powerful tool usually employed in process engineering in order to assess the ability of a system to accommodate a set of uncertain parameters. This property can be effectively quantified by means the several flexibility indices proposed in literature during the last decades.

In particular, two main categories of indices can be distinguished, namely deterministic and stochastic. The difference between them is that the former evaluates the magnitude of the maximum disturbance load that can be withstood by the system without becoming infeasible while the latter accounts for the deviation likelihood as well and evaluates the probability that a given set of uncertain parameters is accommodated or, equivalently, the percentage of accommodated perturbations.

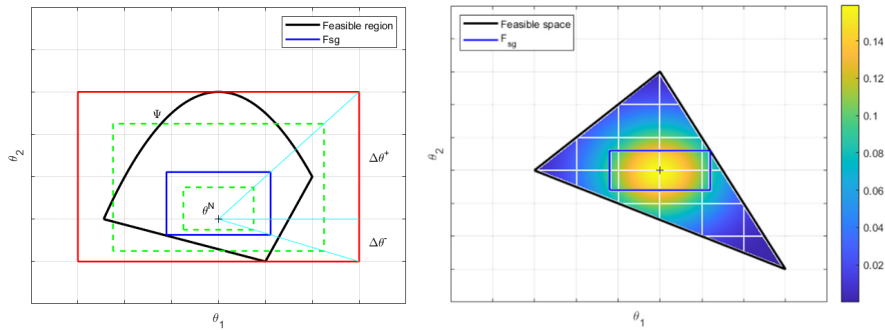

Figure 1 - Deterministic (left) vs stochastic (right) flexibility indices

The geometrical representation of both the indices typologies is reported in Figure 1.

Among the deterministic flexibility indices, the most used by far is the one proposed by Swaney and Grossmann (1985) that is the solution of the optimization problem:

$$F_{SG} = \max \delta \tag{1}$$

$$s. t. \max_{\theta \in T(\delta)} \min_z \max_{j \in J} f_j(d, z, \theta) \leq 0 \tag{2}$$

where θ refers to the uncertain variables, d to the design parameters, z to the control variables and finally δ is the scaling factor of the hyperrectangle

$$T(\delta) = \{\theta: \theta^N - \delta \cdot \Delta\theta^- < \theta < \theta^N + \delta \cdot \Delta\theta^+\} \tag{3}$$

represented in Figure 1 (left).

On the other hand, the most frequently used stochastic flexibility index was defined by Pistikopoulos and Mazzuchi (1990). Given the uncertain parameters Probability Distribution Function $P(\theta)$, the Stochastic Flexibility (SF) is evaluated as:

$$SF = \int_{\psi(d, \theta) \leq 0} P(\theta) \cdot d\theta \tag{4}$$

where ψ is the feasible domain boundary. Differently from the F_{SG} index, the value of SF is bounded between 0 and 1 and might have a non-zero value in correspondence of the nominal operating conditions.

In this research work both the indices will be used and compared in order to provide a complete overview of the TSP flexibility analysis. Although the results concerning the SF index depend on the selected PDF for the uncertain parameters, the proposed methodology has a general validity and can be applied to whatever probability function.

3. The TSP under uncertainty case study

“Given a set of cities along with the cost of travel between each pair of them, the traveling salesman problem is to find the cheapest way of visiting all the cities and returning to the starting point” is the standard formulation of the TSP.

Figure 2 – The TSP case study (left) and sensitivity analysis results (right)

In this study, a set of n cities is generated randomly while the starting point is fixed at the center of the 2D space. In order to show the results with a 3D plot two uncertain parameters have been selected, namely the distances between the starting point and the closest (L_1) and furthest (L_2) cities respectively since they have been detected as the most critical points affecting the length and the shape of the optimal traveling path.

The results discussed in this paper refer to a case study with $n = 10$ whose general scheme is shown in Figure 2 (left). This value for n allows the solution of the TSP with a computational time of the order of seconds by means of the exact algorithm and does not restrain the general validity of the proposed procedure. The study of other optimization algorithms does not serve the purpose of this research.

The distances L_1 and L_2 uncertain interval for the deterministic flexibility analysis was set equal to $[L_i - 1.5, L_i + 1.5]$. On the other hand, for the stochastic flexibility analysis, a Gaussian PDF was used by setting $\mu_i = L_i$ and $\sigma_i = 0.5$ so that the 99.7 % of the deviations fall within the uncertain interval.

4. Results

The flexibility assessment was then performed by using the exact algorithm to solve the TSP case study. Hundreds of runs with ten random cities were performed to estimate an average computational time of about 6 minutes for a 31×31 discretized domain.

The sensitivity analysis results for the presented case study are shown in Figure 2 (right). As it can be noticed, the reason lying behind the relatively high computational time is the impossibility to perform the deterministic flexibility assessment by means of the vertex analysis since the traveling distance is not a quasi-convex function in the uncertain domain. Thus, all the points on the perimeter of the hyperrectangle should be evaluated to assess the flexibility index. This irregular trend can be explained by the fact that not only the length but also the shape of the optimal path can change for some values of the uncertain parameters deviations.

In fact, in Figure 2 (left) it can be noticed that, if points 5 and 10 are displaced over the uncertain domain, the shortest path (red dotted line) takes a different shape with respect to the optimal path under nominal operating conditions (the blue dashed line).

Figure 3 – Deterministic (left) and stochastic (right) flexibility assessment results

The results obtained for both the deterministic and stochastic flexibility analysis are then presented and discussed here below in the corresponding section.

4.1. Deterministic Flexibility Assessment

The flexibility analysis performed with the F_{SG} index results in an original trend worth to be analysed in detail. After an expected initial linear growth, deviations in the interval [0.3 0.5] have a lower impact on the travel path. The slope change of the trend is the indicator proving that the optimal traveling sequence between the ten cities has changed. This flexibility index behaviour can be also detected in Figure 2 – right where it corresponds to the optimal trajectory represented by the dashed line. After that, for more relevant deviations (yellow region in Figure 2 - right) the cost function restarts increasing again but with a lower slope with respect to the beginning.

In addition, from the sensitivity analysis results, it can be detected that the deviation Δd_{close} of the closest point (i.e. point 10) affects the results in a much more relevant way than the furthest one Δd_{far} and results to be the most critical parameter for the expectations concerning the travelling distance under uncertainty.

4.2. Stochastic Flexibility Assessment

The additional travel distance vs. SF index trend (Figure 3 - right) results show a couple of analogies with the main features obtained for the process units with the same PDF, namely a non-zero value in correspondence of the nominal operating conditions and an asymptotical behaviour towards $SF=1$. The first phenomenon is due to the fact that the travel path under nominal operating conditions already overestimates the value obtained for a given set of perturbed conditions, while the second one is a consequence of the residual probability and summation constraint of the PDF.

However, some relevant difference are worth to be remarked for the SF index as well. First of all a faster initial increase is observed due to the relatively limited deviation range included in an expected traveling additional distance lower than 6.65 %. On the other hand, an accumulation of points in the proximity of the same value can be observed even before approaching the vertical asymptote. In analogy with the F_{SG} results, this behaviour is somehow explained by the fact that an additional distance of 6.65 % already includes the majority of the possible deviations, with poor margins of improvement whether a higher value was taken into account.

5. Conclusions

The application of the flexibility assessment to the TSP case study was successfully achieved. The outlined procedure allows to estimate the additional travel distance with respect to nominal operating conditions as a function of the expected deviation magnitude or the withstood deviation likelihood.

Differently from flexible process equipment, where an additional flexibility usually corresponds to a proportional oversizing, in the TSP case study the change in the optimal traveling path form causes some discontinuities in the derivative of the travel distance vs flexibility plot. On the other hand, the definition of the stochastic flexibility index implies that, for a given travel distance value, the feasible domain might result by the combination of topological regions in the uncertain domain that are not connected.

However, in both cases the obtained results allow a deeper understanding of the optimal results and provide a useful decisional tool and the associated graphical representation. Nonetheless, the proposed procedure could be used in the reverse way: for a given data set, the flexibility analysis is performed by considering uncertain one city position at a time in order to detect which is the most critical one for the optimality of the solution.

In future works travel cost functions between each pair of cities and further constraining conditions could be included in order to be able to characterise each specific supply chain management problem and find the associated solution under uncertainty.

Production scheduling of continuous make-and-pack processes with byproducts recycling

Apostolos P. Elekidis,^a Georgios P. Georgiadis,^a Michael C. Georgiadis^{a,*}

^a *Department of Chemical Engineering, Aristotle University of Thessaloniki, University Campus, Thessaloniki, 54124, Greece*

Abstract

In this work, the scheduling problem of continuous make-and-pack industries is considered. A continuous precedence-based MILP model is proposed for multistage continuous processes, considering flexible intermediate storage. Extending previously proposed precedence-based MILP models, multiple campaigns of the same recipe can be stored simultaneously in a storage tank. Explicit resource constraints related to the generation and recycling of byproduct are introduced, to achieve a better utilization of the available resources. Several case studies, inspired by a large-scale consumer goods industry have been solved, to illustrate the applicability of the proposed frameworks. It is illustrated that good quality schedules are obtained in reasonable solution times.

Keywords: scheduling optimisation, MILP, make-and-pack, continuous processes

1. Introduction

Within the current climate of business globalization, modern process industries have to produce a plethora of final products that can address the needs and demand of multiple customers. Hence, scheduling optimization is becoming a vital process and decision-makers tend to exploit recent advances in computer-aided optimization methods (Harjunkoski et al., 2014). Nowadays, several companies from various industrial sectors, such as food and beverages, pharmaceuticals, chemicals and fast-moving consumer goods (FMCGs), have adopted make-and-pack production processes. Due to variable production rates, a challenge typically met in continuous make-and-pack processes is the necessity to synchronize the production rates of consecutive stages (Klanke et al., 2020). Thus, continuous stages are often decoupled by deploying intermediate storage vessels (Méndez and Cerdá, 2002). Furthermore, product-dependent changeovers, mainly occurred by cleaning operations, have to be minimized to increase the productivity of production facilities. In cases when cleaning with water can affect the quality of products, an undesirable amount of byproduct waste is generated between two consecutive campaigns. Usually, the byproducts can be recycled into the next production campaigns. This industrial policy is typically met in liquid detergents industries. (Elekidis et al., 2019).

2. Problem statement

The scheduling problem under consideration has been inspired by a continuous make-and-pack process of a real-life, large-scale consumer goods industry (Elekidis, Corominas, and Georgiadis, 2019). Several intermediate products are produced through a continuous formulation stage (stage 1), while a plethora of final products is processed in the packing stage (stage 2), to satisfy multiple customer orders. Due to the different production rates of the two stages, a varying production bottleneck can be detected in

both stages depending on the specific product characteristics. To overcome this limitation and to achieve a better synchronization between the two stages, flexible intermediate buffer tanks are utilized. If an intermediate product is temporally stored in an intermediate vessel both stages operate at their maximum speed. Otherwise, the production rate is determined by the slowest stage. Furthermore, multiple changeovers take place between consecutive production campaigns due to the necessary cleaning operations. However, cleaning with water is not allowed, since water can affect the quality of the products, while the generation of an undesirable amount of foam also occurs. Under these circumstances, cleaning is implemented by generating an amount of byproduct waste. According to industrial policies, the waste can be temporally stored in tanks and it can then be recycled and utilized into the next intermediate products. The plant layout is also depicted in Figure 1.

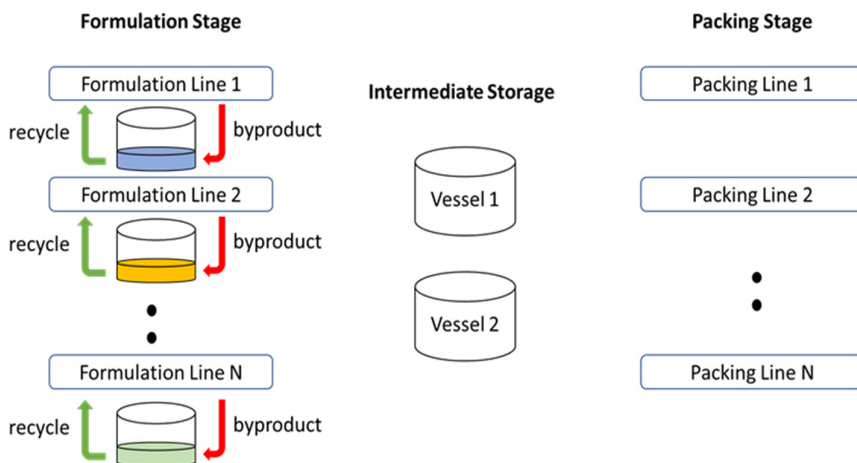

Figure 1 Plant layout

3. MILP model

A continuous-time, precedence-based, MILP model for continuous make-and-pack processes is proposed, considering intermediate storage tanks. The model consists of assignment, timing and sequencing constraints, similar to relevant frameworks (Elekidis et al. 2019). Mass balance constraints for the storage vessels are also imposed based on the framework of Méndez and Cerdá, (2002). Immediate precedence variables are used for sequencing operations in the processing units, while general precedence variables are utilized to define the sequence of storage operations. In comparison with discrete-time formulations, only a binary variable is introduced for handling the mass balance constraints. This auxiliary binary variable defines if the packing operation of a product order starts before or after the completion of its formulation process.

In the MILP model of Méndez and Cerdá (2002), it is assumed that each product can be stored in a vessel only if the packing operations of the previously stored products have been completed. However, this assumption is not in full agreement with industrial practice, since product orders produced by the same intermediate could potentially share the same storage tank. The proposed MILP model differs from the model of Méndez and Cerdá, (2002), since by integrating additional mass balance constraints and introducing a new set of auxiliary binary variables, multiple production orders, produced by the same

intermediate product type, are allowed to be stored in the same storage tank simultaneously.

The synchronisation of stages is achieved via proper timing constraints. An intermediate product can either be temporarily stored into a buffer tank or routed directly to a packing line, bypassing the storage vessels. Timing constraints guarantee that if a product bypasses the storage tank, the process of the two stages will start simultaneously.

Additionally, efficient resource-constraints, related to generation and recycling of byproduct waste are proposed to consider potential benefits by their utilization in the plant. The main objective is the minimization of the total cost, taking into account the costs of changeovers, the idle time, the processing time and the cost of the generated byproduct waste.

3.1. Mass balance constraints for product orders produced by the same intermediate product type (recipe)

Production campaigns which are made by the same intermediate product, can be stored simultaneously in the same buffer tank for some period of time. Due to the varying production rates, a production bottleneck can be posed in both stages depending on the specific product features. To prevent the overloading of storage vessels, mass balance constraints have to be enforced at two time points for each product. The first time point corresponds to the end of each formulation operation while the second one corresponds to the starting time of each packing operation (Méndez and Cerdá, 2002). Extending the work of Méndez and Cerdá (2002), a new set of auxiliary binary variables is introduced to accurately handle mass balance constraints. In case multiple intermediate campaigns are stored simultaneously at the same storage tanks, the proposed binary variables define if an operation (formulation or packing process) starts before or after the time point under consideration. The new binary variables are determined via a set of big-M constraints.

The total stored amount at a specific time point is defined as the total inserted amount minus the total amount exported from the buffer tank. The inserted and exported amounts are efficiently defined via a set of big-M constraints. It should be noted that the vast majority of scheduling approaches for make-and-pack processes rely on discrete-time formulations to handle material balances around storage equipment thus, resulting in computationally intractable models.

3.2. Modelling of byproducts

In scheduling problem under consideration, a set of product orders $i \in I$ is allocated to a set of production units $j \in J$, at each production stage $s \in S$. A subset of units j is able to process product order i , ($j \in JI_i$) at stage s ($j \in JS_s$). Additionally, a subset of processing units $j \in J$ is able to process product orders i , given by subset IJ_j . The maximum production rate of each product i , at stage s , is given by the parameter $r_{i,s}$.

The vast majority of product-dependent changeovers, usually take place among the production of consecutive production campaigns, i and i' , are related to cleaning operations. In liquid detergents industries, a significant amount of waste is generated during the changeover time, $n_{i,i'}$, which can be recycled into the next production campaigns if the quality of products is not affected. Each processing unit j of formulation stage ($j \in JS_{s=1}$), is connected with a dedicated storage vessel, in which the generated waste can be temporarily stored. Since the capacity of byproduct vessels have to be fully satisfied, a set of mass balance constraints are introduced, without utilising further binary variables or considering any discretisation of time.

$$O_i = LI_i + \sum_{i' \in I: i' \neq i} \sum_{j \in (JS_1 \cap JI_i \cap JI_{i'})} X_{i,i',j} n_{i,i'} r_{i',1} - W_i \quad \forall i \in I \quad (1)$$

$$LI_i \geq O_{i'} - dm_i \left(1 - \sum_{j \in (JS_1 \cap JI_i \cap JI_{i'})} X_{i',i,j} \right) \quad \forall i \in I, i' \in I: i' \neq i \quad (2)$$

$$LI_i \leq O_{i'} + dm_i \left(1 - \sum_{j \in (JS_1 \cap JI_i \cap JI_{i'})} X_{i',i,j} \right) \quad \forall i \in I, i' \in I: i' \neq i \quad (3)$$

$$LI_i \leq iw_j Y_{i,j} + dm_i \sum_{i' \in Ij_j: i' \neq i} X_{i,i',j} \quad \forall i \in I, j \in (JS_1 \cap JI_i) \quad (4)$$

$$LI_i \geq iw_j Y_{i,j} - dm_i \sum_{i' \in Ij_j: i' \neq i} X_{i,i',j} \quad \forall i \in I, j \in (JS_1 \cap JI_i) \quad (5)$$

$$W_i \leq dm_i a_i \quad \forall i \in I \quad (6)$$

$$W_i \leq L_i \quad \forall i \in I \quad (7)$$

$$O_i \leq cp_j Y_{i,j} \quad \forall i \in I, j \in (JS_1 \cap JI_i) \quad (8)$$

$$RW_j \geq O_i - cp_j (1 - Y_{i,j}) - cp_j \sum_{i' \in Ij_j: i' \neq i} X_{i,i',j} \quad \forall i \in I, j \in (JS_1 \cap JI_i) \quad (9)$$

The accumulated amount of byproduct O_i is calculated at the end of each changeover. According to mass balance constraints (1), the variable O_i is equal to the previously accumulated byproduct amount LI_i , plus the waste generated by the cleaning operations that take place ($n_{i,i'} r_{i',1}$), minus the recycled amount during the production of product i , W_i . In particular, it is assumed that during the changeover time $n_{i,i'}$, between two consecutive campaigns i and i' , the production rate of byproduct is equal to the maximum production rate of campaign i' ($r_{i',1}$). According to constraints (2) and (3), if product i' is produced immediately before product i , ($X_{i',i,j} = 1$), the accumulated byproduct is equal to variable $O_{i'}$. Constraints (4) and (5) ensure that the accumulated amount of byproduct at the beginning of the first campaign ($X_{i',i,j} = 0$), is either equal to zero or equal to the initial byproduct (iw_j) only if the product i is allocated at unit j ($Y_{i,j} = 1$). The demand parameter, dm_i plays the role of the big-M value in constraints (4) and (5). The maximum percentage that can be recycled is expressed by the parameter a_i . Constraints (8) ensures that the stored amount of byproduct, will not surpass the related capacity (cp_j) of each tank. The remained amount of waste RW_j at the end of the time horizon, is equal to the generated waste of the last production campaign O_i of each unit.

4. Application studies

In order to evaluate the efficiency and applicability of the proposed MILP model, 4 case studies are considered. They include 3 formulation lines, 3 packing lines and two

intermediate storage tanks. Due to the large number of final products, the decomposition algorithm of Elekidis et al. (2019), is utilized to solve the large-scale MILP model. To assess the benefits of the intermediate storage tanks, two case studies have been solved, with (decoupled layout) and without (coupled layout) the utilization of intermediate storage tanks. The minimization of total operational time is the main objective. The results are summarized in Table 1. It is illustrated that the utilization of flexible intermediate buffer tanks leads to a better synchronization of the production stages resulting in increased productivity. In particular, depending on the case study, the productivity gain ranges within 4.43% (case 2) and 17.29% (case 1).

Furthermore, the case studies have been also solved considering the minimization of total cost. Near-optimal solutions are obtained within a total CPU time of 3600s, while a zero-optimality gap is achieved at each iteration. Results are summarized in Table 2. The individual costs represent relative monetary units (rmu) and they are also presented in Table 2. It is observed that the biggest percentage of the total cost, reflects the idle time as it valued by 30 rmu/h. Although the percentage of the changeover cost is gradually decreased in larger cases, from 17% (case 1) to 8% (case 4), the percentage of idle time cost is steadily increased, from 47% (case 1) to 77% (case 4).

Figure 2 Total produced and recycled amount in each case

Table 1 Comparison of the total operational time of the two layouts

	Products	Coupled layout*	Decoupled layout*	Difference (hours)*	Productivity gain (%)
Case 1	20	186.63	225.63	39.00	17.29%
Case 2	50	355.34	371.82	16.48	4.43%
Case 3	70	422.14	442.70	20.55	4.64%
Case 4	100	596.23	680.88	84.64	12.43%

*the values represent the total operational time of all production units of both stages in hours

Table 2 Results for larger problem instances – Cost distribution

	Products	TC*	COC*	ITC*	PTC*	WC*
Case 1	20	1301	221 (17%)	614 (47%)	385 (30%)	79 (6%)
Case 2	50	1999	231 (12%)	1224 (61%)	470 (24%)	72 (4%)
Case 3	70	3505	299 (9%)	2592 (74%)	541 (15%)	72 (2%)
Case 4	100	5455	422 (8%)	4193 (77%)	757 (14%)	82 (2%)

*TC=Total cost, COC=Changeover cost, ITC=idle time cost, PTC=processing time cost, WC=waste cost

**COC= 10 rmu/h, ITC= 30 rmu/h, PTC= 1 rmu /h, WC= 0.5 rmu /kg

Figure 2 shows, the total produced amount and the amount of recycles as well, for each case. It is illustrated that the byproduct recycles constitute a significant percentage of the total produced amount, which ranges from 6.1% (Case 3) to 7.57% (Case 4). Hence, it is evident that the utilization of this recycling policy and the consideration of the proposed byproduct constraints lead to better utilization of raw materials and a significant reduction of material cost.

5. Conclusions

In this work a precedence-based MILP model, for the scheduling of continuous, make-and-pack industries is presented. The utilization of intermediate buffers can provide a better synchronization between the two production stages. The integration of byproduct recycling constraints leads to a better use of the available raw materials and to a significant reduction of waste. The proposed MILP model can constitute the basis of an optimization tool to assist decision-makers with rigorous scheduling solutions under a dynamic environment.

Abstract

A plethora of contributions have appeared in the literature over the past decade in the area of production planning of a single machine with sequence-dependent changeovers. Most of them, however, deal with the deterministic optimization model where all the parameters are considered known, which render optimal schedules, sub-optimal, or even infeasible in practice. In this paper, we first develop a new deterministic model based on a hybrid discrete- and continuous-time mixed-integer linear programming model for the production scheduling of a single machine with sequence-dependent changeovers. The proposed model (i) considers a time interval in which the processing machine is unavailable due to some maintenance jobs, and (ii) monitors inventory levels over shorter time scales, rather than at the end of predefined long-term periods. Then, the robust counterpart of the deterministic model is devised using the Γ -robustness approach that considers uncertainty in processing and changeover times. The objective is to find robust production schedules such that the sum of holding and changeover costs is minimized. We demonstrate the performance of the proposed model with a real-world case study.

Keywords: Scheduling, Changeovers, Robust optimization, Uncertainty.

1. Introduction

Scheduling is an important planning function in the process industries and lies at the very heart of the performance of manufacturing (Stood, 1996). It is a highly dynamic process and is characterized by a high level of uncertainty, such as raw material availability, prices, machine reliability, processing times, and client demand, which vary with respect to time and are often subject to unexpected deviations (Li and Ierapetritou, 2008; Georgiadis et al. 2019). Two primary methods to address scheduling under uncertainty are stochastic programming and robust optimization (Grossmann et al. 2016). In the former (Birge and Louveaux, 2011), the uncertainty is modeled through several scenarios, using probability distributions, which is often difficult to describe in practice. Another drawback is that the number of scenarios increases exponentially with the number of uncertain parameters, which limits the application of this approach to solve practical problems. Robust optimization (Bertsimas and Sim 2004), on the other hand, defines an uncertainty set of possible realizations of the uncertain parameters and selects a solution

that can cope best with the various realizations, while keeping the problem tractable. The other advantage of robust optimization is that it only requires defining bounds for uncertain parameters, rather than their probability distribution.

There is a plethora of publications that have addressed the production scheduling of a single machine with sequence-dependent changeovers (Gupta and Magnusson, 2005; Liu et al., 2008; Mostafaei et al., 2020). Compared to its deterministic counterpart, the literature on the robust optimization of the single machine scheduling problem is still very scarce. To this end, this paper develops a novel robust optimization model for single machine scheduling with sequence-dependent changeovers (SMSSDC) to generate reliable solutions that are immunized against uncertainty. The contributions of this work are twofold: First, we develop a continuous-time mixed-integer linear programming (MILP) formulation using generalized disjunctive programming (Castro and Grossmann, 2012; Mostafaei and Harjunkoski, 2020) for SMSSDC that allows us to (i) consider the machine unavailability during the time horizon, (ii) monitor the inventory over shorter time windows, and (iii) meet customer demands over multiple intermediate due dates. Second, by means of the Γ -robustness approach, the proposed deterministic MILP model is extended to a robust counterpart propose schedules that are immunized against variability in processing and changeover times. The reason why we select the Γ -robustness approach is that it keeps the problem tractable and does not change the structure of the original problem, meaning that if the deterministic model is an MILP, its robust counterpart will also be an MILP

2. Problem statement

We focus on the production scheduling of a single machine, where a set of products p should be manufactured during a time horizon of duration H . The aim is to find the optimal sequence of production so that the costs related to backorder, changeover, and inventory are minimized. Given are the following: $[v_p^{min}, v_p^{max}]$: minimum and maximum production size during every process run; ρ_p : processing time of one unit of product p ; $\sigma_{p,p'}, c_{p,p}$: changeover time and cost; τ_t : absolute time of period t ; $d_{p,t}$: the product demand for product p at time period t ; $[S_{stop}, E_{stop}]$ idle time interval for the machine.

3. Deterministic optimization model

Here we present a deterministic MILP model for SMSSDC that is derived from generalized disjunctive programming (GDP). The model involves three sets: (i) production runs $r, r' \in R = \{1, 2, \dots, |R|\}$, in which a run r should always be performed after the completion of run $r - 1$; (ii) set of products $p, p' \in P$; (iii) set of time periods $t, t' \in T$. Note that the cardinality of set R is a tuning parameter, and to find the optimal solution, we start with an initial guess for $|R|$ and keep increasing it until no improvement is observed in the objective function.

3.1. Allocation and product size

First, let us define the binary variable $X_{p,r}$ denoting that the production run $r \in R$ processes product $p \in P$, whenever $X_{p,r} = 1$. The exclusive OR (\vee) in disjunction below states that exactly one product can be processed in the machine during each run. The size of product p processed in the machine during the run r ($V_{p,r}$) is restricted to the interval $[v_p^{min}, v_p^{max}]$. The duration of run r (L_r) processing product p is a function of $V_{p,r}$ and the

processing time of one unit of product p . The convex hull reformulation of the disjunction leads to the equations (1)-(3).

$$\bigvee_{p \in P} [X_{p,r} v_p^{\min} \leq V_{p,r} \quad \Rightarrow \quad \sum_{p \in P} X_{p,r} = 1 \quad \forall r \quad (1)$$

$$\leq v_p^{\max} L_r = \rho_p V_{p,r}] \quad \forall r \quad \Rightarrow \quad v_{p,r}^{\min} X_{p,r} \leq V_{p,r} \leq v_{p,r}^{\max} X_{p,r} \quad \forall p, r \quad (2)$$

$$L_r = \sum_{p \in P} \rho_p V_{p,r} \quad \forall r \quad (3)$$

3.2. Changeover times and costs

Changeover times and costs occur when two different products p and p' are processed in two consecutive runs $r - 1$ and r ($r \geq 2$). The changeovers are often associated with changing the operating conditions or with the cleaning of the machine. If the continuous variables CT_r and CC_r are the changeover time and cost at the start of run r , respectively, we have the following Eqs. (4)-(7). Note that the binary variable $X_{p,p',r}^{ch}$ ($= 1$ if the changeover $p - p'$ occurs at the start of run r) can be treated as a 0-1 continuous variable.

$$X_{p,r-1} \wedge X_{p',r} \Rightarrow X_{p,p',r}^{ch} \quad \forall p, p', r \quad \Rightarrow \quad X_{p,p',r}^{ch} + 1 \geq X_{p,r-1} + X_{p',r} \quad \forall p, p', r \quad (4)$$

$$\bigvee_{p \in P} \bigvee_{p' \in P} [X_{p,p',r}^{ch} CT_r \quad \Rightarrow \quad \sum_{p,p' \in P} X_{p,p',r}^{ch} = 1 \quad \forall r \geq 2 \quad (5)$$

$$= \sigma_{p,p'} CC_r \quad \Rightarrow \quad CT_r = \sum_{p,p' \in P} \sigma_{p,p'} X_{p,p',r}^{ch} \quad \forall r \geq 2 \quad (6)$$

$$= cc_{p,p'}] \quad \forall r \quad \Rightarrow \quad 2$$

$$\geq 2 \quad \Rightarrow \quad CC_r = \sum_{p,p' \in P} cc_{p,p'} X_{p,p',r}^{ch} \quad \forall r \geq 2 \quad (7)$$

2

3.3. Sequencing production runs

Let continuous variable C_r be the completion time of production run r . The beginning of the production run r should not be before the end of the completion of $r - 1$ plus the changeover time at the start of run r . Furthermore, the completion of each run is always inferior to the time horizon length (H):

$$(C_{r-1} + L_r) + CH_r \leq C_r \leq H \quad \forall r \quad (8)$$

3.4. An unavailable time interval due to maintenance jobs

Let us assume that the machine should be stopped during the time interval $[S_{stop}, E_{stop}]$ due to, e.g., maintenance. The binary variable W_r is equal to one if the production run r is completed during the time interval $[0, S_{stop}]$, i.e., earlier than time S_{stop} . If $W_r = 1$, then (i) the previous run $r - 1$ must be completed in the same interval too ($W_{r-1} = 1$), and (ii) the completion time of run r (C_r) must less than or equal to S_{stop} . Notice the inclusive OR (\vee) since multiple runs can end before the time S_{stop} .

$$W_r \Rightarrow W_{r-1} \quad \forall r \geq 2 \quad \Rightarrow \quad W_r \leq W_{r-1} \quad \forall r \geq 2 \quad (9)$$

$$\bigvee_{r \in R} [W_r C_r \leq S_{stop}] \quad \Rightarrow \quad \sum_{r \in R} W_r \geq 1 \quad (10)$$

$$C_r \leq S_{stop} + (H - S_{stop})(1 - W_r) \quad \forall r \quad (11)$$

Now let the binary variable W_r^{last} be 1 if run r is the last one completed during the time interval $[0, S_{stop}]$. If $W_r^{last} = 1$ then (i) $W_r = 1$ and $W_{r+1} = 0$, meaning that run r ends earlier than time S_{stop} ($W_r = 1$) whereas the completion of run $r + 1$ is after time S_{stop} ($W_{r+1} = 0$), and (ii) the starting time of run $r + 1$ should be after the maintenance interval $[S_{stop}, E_{stop}]$, i.e., after time E_{stop} . Notice the exclusive OR (\vee) since only one run can be the last one completed before time S_{stop} . We have thus the following conditions.

$$W_r \wedge \neg W_{r+1} \Rightarrow W_r^{last} \quad \forall r \quad \Rightarrow \quad W_r^{last} \geq W_r - W_{r+1} \quad \forall r \quad (12)$$

$$\Rightarrow \quad \sum_{r \in R} W_r^{last} = 1 \quad (13)$$

$$\bigvee_{-r \in R} [W_r^{last} C_{r+1} - L_{r+1} \geq E_{stop} W_r^{last} \quad \forall r] \quad C_{r+1} - L_{r+1} \geq E_{stop} W_r^{last} \quad \forall r \quad (14)$$

3.5. Meeting demand and inventory level

Let the binary variable $Y_{t,r}$ indicate if the production run r completes during period t . If $Y_{t,r} = 1$, it should be imposed $\tau_{t-1} \leq C_r \leq \tau_t$, where τ_t is the absolute time of period t . Notice that the disjunction in (23) is exclusive, meaning that each production run r should be completed in exactly one of the periods.

$$\bigvee_{-t \in T} [Y_{t,r} \square_{t-1} \leq C_r \leq \tau_t] \quad \forall r \quad \Rightarrow \quad \sum_{t \in T} Y_{t,r} = 1 \quad \forall r \quad (15)$$

$$\leq \tau_t] \quad \forall r \quad \Rightarrow \quad \sum_{t \in T} \tau_{t-1} Y_{t,r} \leq C_r \leq \sum_{t \in T} \tau_t Y_{t,r} \quad \forall r \quad (16)$$

Now, let us introduce the binary variable $Y_{t,r}^{last}$, indicating that run r is the last one completed in the period t . If $Y_{t,r} = 1$ and $Y_{t,r+1} = 0$, the run r is the last one that ends in period t ($Y_{t,r}^{last} = 1$). Note that $Y_{t,r}^{last}$ can take one for only one run r during each period t , as imposed in (18).

$$Y_{t,r} \wedge \neg Y_{t,r+1} \Rightarrow Y_{t,r}^{last} \quad \forall t, r \quad \Rightarrow \quad Y_{t,r}^{last} \geq Y_{t,r} - Y_{t,r+1} \quad \forall r, t \quad (17)$$

$$\bigvee_{-r \in R} Y_{t,r}^{last} \quad \forall t \quad \Rightarrow \quad \sum_{r \in R} Y_{t,r}^{last} = 1 \quad \forall t \quad (18)$$

If $Y_{t,r}^{last} = 1$ and to meet product demands, the amount of product p sent to customers during period t computed through the continuous variable $CP_{p,r}$ should be as large as $d_{p,t}$. Otherwise, the backorder demand ($BC_{p,t}$) will cause penalty costs (e.g., customer dissatisfaction). Note that $BC_{p,t-1}$ on the right-hand side of Eq. (19) indicates the shortage of product p to the customers during the period $t - 1$ to be tardily met at period t .

$$\sum_{r \in R} CP_{p,r} + BC_{p,t} - BC_{p,t-1} \geq \sum_{t' \in T} Y_{t',r}^{last} d_{p,t'} \quad \forall p, t, r \quad (19)$$

Let $IP_{p,r}$ be a continuous variable denoting the inventory level of product p at the end of run r . The stock of product p is increased by the production of the product and decreased by sending it to local customers. Note that at the start time of the planning horizon, the initial inventory of product p is known i.e., ip_p^0 . To prevent stock overloading and empty conditions, $IP_{p,r}$ should lie within the feasible range, as imposed in Eq. (21).

$$IP_{p,r} = IP_{p,r-1} + V_{p,r} - CP_{p,r} \quad \forall p, r \quad (20)$$

$$ip_p^{min} \leq IP_{p,r} \leq ip_p^{max} \quad (21)$$

3.6. Objective function

The objective is to minimize the backorder, inventory, and changeover costs.

$$z = \sum_{t \in T} \sum_{p \in P} cb_{p,t} BC_{p,t} + \sum_{r \in R} \sum_{p \in P} cip_p IP_{p,r} + \sum_{r \in R} C_r \quad (22)$$

4. Robust counterpart

4.1. Changeover time

Let us assume that the changeover times, represented by $\sigma_{p,p'}$, are subject to uncertainty, and thus are represented by the random variable $\tilde{\sigma}_{p,p'}$ with support given by the interval $\tilde{\sigma}_{p,p'} \in [\underline{\sigma}_{p,p'} - \hat{\sigma}_{p,p'}, \underline{\sigma}_{p,p'} + \hat{\sigma}_{p,p'}]$. We follow the approach in Bertsimas and Sim (2004)

in which we would like to immunize constraint (6). For that, first notice that can be equivalently rewritten as:

$$\sum_{r \in R} \sum_{r \geq 2} CT_r \geq \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} \tilde{\sigma}_{p, p'} X_{p, p', r}^{Ch} \quad (23)$$

Constraint (23) can then be restated in a robust sense, as

$$\sum_{r \in R} \sum_{r \geq 1} CT_r \geq \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} \underline{\sigma}_{p, p'} X_{p, p', r}^{Ch} + \Phi(\Gamma) \quad (24)$$

where $\Phi(\Gamma)$ is the protection term defined as

$$\Phi(\Gamma) = \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} \hat{\sigma}_{p, p'} X_{p, p', r}^{Ch} \times Z_{p, p', r} \quad (25)$$

$$\text{subject to: } \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} Z_{p, p', r} \leq \Gamma \quad (F) \quad (26)$$

$$0 \leq Z_{p, p', r} \leq 1 \quad (Q_{p, p', r}) \quad \forall p, p', r \quad (27)$$

The terms in brackets represent the associated dual variables, used to state the equivalent dual formulation (28)-(30) for (25)-(27), which is given by

$$\Phi(\Gamma) = + \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} Q_{p, p', r} \quad (28)$$

$$\text{subject to: } F + Q_{p, p', r} \geq \hat{\sigma}_{p, p'} X_{p, p', r}^{Ch} \quad \forall p, p', r \quad (29)$$

$$F, Q_{p, p', r} \geq 0 \quad (30)$$

The robust counterpart can be stated by replacing (6) with the following set of constraints

$$\sum_{r \in R} \sum_{r \geq 2} CT_r \geq \sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} \underline{\sigma}_{p, p'} X_{p, p', r}^{Ch} + \Gamma F + \quad (31)$$

$$\sum_{r \in R} \sum_{r \geq 2} \sum_{p, p' \in P} Q_{p, p', r}$$

$$CT_r \geq \sum_{p, p' \in P} \underline{\sigma}_{p, p'} X_{p, p', r}^{Ch} \quad \forall r \geq 2 \quad (32)$$

$$F + Q_{p, p', r} \geq \hat{\sigma}_{p, p'} X_{p, p', r}^{Ch} \quad \forall p, p', r \quad (33)$$

4.2. Processing time

In a similar vein, let us assume that the processing time ρ_p is represented by a random variable $\tilde{\rho}_p$ with support $[\underline{\rho}_p - \hat{\rho}_p, \underline{\rho}_p + \hat{\rho}_p]$. Following the same reasoning as in §4.1, the robust counterpart considering protection in the processing time can be thus obtained by replacing (3) with the following constraints:

$$\sum_{r \in R} L_r \geq \sum_{r \in R} \sum_{p \in P} \underline{\rho}_p V_{p, r} + \Gamma' F' + \sum_{r \in R} \sum_{p \in P} Q'_{p, r} \quad (34)$$

$$L_r \geq \sum_{p \in P} \underline{\rho}_p V_{p, r} \quad \forall r \quad (35)$$

$$F' + Q'_{p, r} \geq \hat{\rho}_p V_{p, r} \quad \forall p, r \quad (36)$$

5. Real-world case study

The proposed deterministic and robust approaches for SMSSDC are applied to a real-world paper machine that was obtained by slightly modifying Example 1 previously studied by Mostafaei et al. (2020). The aim is to meet customer demands of P4₁₂₀, P6₁₇₀, P7₄₀, P8₄₀, P9₈₀, P13₂₁₈, P14₅₁, P15₄₅, P18₄₀, and P20₈₃ (with the subscripts indicating the number of paper reels to be produced during a time horizon of 11 days) at minimum backorder and changeover costs. It is assumed that: (i) the paper machine should be stopped for 12 hours during the time interval [100, 112] h, and (ii) backorder has a unit

cost of 200 \$, one hour changeover has a fixed cost of 100 \$, (iii) the processing and changeover times are uncertain parameters and have variability in $[\underline{\rho}_p - 0.02, \underline{\rho}_p + 0.02]$ and $[\underline{\sigma}_{p,p'} - 0.1, \underline{\sigma}_{p,p'} + 0.1]$, respectively.

The example was solved on a Quad 1.60 GHz Intel Core i5-8365, 16 GB RAM Laptop using GAMS/CPLEX with 8 parallel threads as the MILP solver. Figure 1 shows the Gantt chart for the deterministic model and its robust counterpart (with $\Gamma, \Gamma' = 1$). The deterministic model corresponded to a cost of \$166.47 was solved in 20.15s while the robust model with the objective function of \$6514.30 was solved in 364.12 s. As can see from the figure, the production sequence is slightly different, and some products cannot be produced when processing and changeover times are subject to uncertainty. For example, product 18 it not produced in the robust model.

Figure 1: Solutions found for the case study

6. Conclusions

This paper has presented a continuous-time optimization formulation for the short-term scheduling of a single machine with sequence-dependent changeovers. We first developed a deterministic MILP model derived from GDP that considers the machine unavailability during the time horizon, and customer demands on multiple due dates. Then we derived the robust counterpart of the model using the Γ -robustness approach to tackle uncertain processing and changeover times. We validated the proposed model using a real-world case study from the paper-making industry, and a robust schedule for production scheduling of 11 days was successfully found in a reasonable CPU time.

Abstract

Increase in the cost of process water and stringent environmental norms result in the requirement for water reducing technologies in process industries. Batch processes have been widely used in process industry (such as pharmaceuticals, fine and specialty chemicals, etc.) as batch processing is appropriate to produce a specialized low amount of production and is flexible to adjust according to the dynamism of the market. In recent years, significant research efforts are made to minimize resources such as energy and water in batch processes. Optimizing the storage requirement is an essential aspect while considering capital investment and space availability.

This paper focuses on minimizing freshwater and storage requirement simultaneously. In this paper, a mathematical formulation is proposed to solve the proposed bi-objectives problem. The primary objective of this work is to generate a Pareto optimal front for these two objectives via using a ϵ -constraint method. The proposed linear programming formulation includes demand satisfaction, source availability and quality constraints. The trade-off between storage and resource requirements is captured through a Pareto optimal front. This Pareto optimal front facilitates decision-makers to select an appropriate operating point as per suitability.

Keywords: Batch process, Storage capacity, Resource minimization, Pareto optimal front, Water Allocation Network.

1. Introduction

The batch process is utilized for production of specialized products in several industries such as food, pharmaceutical, fine chemical, etc. Impurity concentration and time are two important constraints for resource recovery in operation of a batch process. Mathematical optimization and physical-insight based techniques are used to minimize freshwater and storage requirements in industries (Wang and Smith, 1994). Earlier, Majozi (2005) presented a continuous-time model for minimizing wastewater and freshwater with or without central water storage facilities in batch process. As water is essentially required in several operations of the process industry, so freshwater needs to be used efficiently which reduces the discharge of wastewater (Shenoy and Bandyopadhyay, 2007). Later, Gouws and Majozi (2008) presented the effect of several storages for wastewater reduction in batch process. It is reported that the optimization of the storage requirement is an essential aspect upon considering capital investment and space scarcity. Similarly, Gouws et al. (2010) reviewed and compared various methodologies of water minimization for batch processes in process industries. Mitigation of water footprint is important for enhancing profitability and reducing

environmental degradation; hence, optimization of water resources for industrial processes is essential for water management (Begatin et al., 2014). Similarly, Chaturvedi and Bandyopadhyay (2014) examined a model for optimal production scheduling and usage of freshwater. The trade-off between freshwater minimization and production maximization is presented via Pareto optimal front. Later, Adekola and Majozi (2017) presented a mathematical model for optimization of batch production and minimization of wastewater for a static mass load problem simultaneously. The minimization of wastewater is attained by exploring the order of jobs in a unit. The results depict that water utilization is minimized via suitable selection of jobs arrangements in a unit. Later, Hesran et al. (2019) studied waste minimization techniques for waste minimization. Recently, Duhbaci et al. (2020) reviewed water minimization approach via a mathematical programming in industrial process.

Earlier, Chaturvedi and Bandyopadhyay (2012) presented a pinch analysis-based approach to target minimum storage capacity and maximum freshwater requirement for a Water Allocation Network (WAN) in batch process. In this work, trade-off between storage capacity and freshwater requirement is captured by solving a mathematical programming optimization model. The proposed algorithm can be applied to any fixed flow rate and fixed scheduled batch process involving single or multiple qualities. The proposed linear programming formulation includes demand satisfaction, source availability and quality constraints.

2. Problem Statement

The general problem statement for minimizing freshwater and storage requirements for WAN in a batch process is as follows:

- For a fixed time interval (T_k), a set of internal sources (M_{sTk}) is provided. A known flow rate F_{sITk} is produced by each source which have a concentration of impurity as q_{sITk} .
- For a fixed time interval (T_k), a set of internal demands (M_{dTk}) is given. A known minimum flow rate (F_{dTk}) is required with concentration of impurity as q_{dTk} .
- The freshwater flowrate requirement is F_{wITk} with concentration of q_{wITk} .

Objective: Overall aim of this work is to minimize freshwater and storage requirements in process industry. Primary objective of the proposed model is to generate a Pareto optimal front by varying storage limit. Pareto optimal front accounts for a trade-off between freshwater and storage capacity requirement in batch process. For generating points of Pareto optimality, ϵ -constraint technique (Mavrotas, 2009) is implemented in the model. The model is evaluated for a single objective and another objective is stated as inequality constraint. The minimum storage requirement is fixed at a specified value and added as a constraint.

3. Mathematical Formulations

Let x_{ij} depicts the transfer of flow from i^{th} source to j^{th} demand. From the conservation principle, the equation for demand constraint is given by Eq. (1). The concentration of every stream and freshwater is equal to concentration of the demand which is shown in Eq. (2). The release of water from sources should be lesser than the limit of source in

any time interval. Eq. (3) presents inequality constraint for the i^{th} source in a time interval.

$$\sum_{T_{m \leq k}} \sum_i (x_{ij}) + F_{wjT_k} = F_{djT_k} \tag{1}$$

$$\sum_{T_{m \leq k}} \sum_i (q_{siT_k} * x_{ij}) + q_{wjT_k} * F_{wjT_k} = q_{djT_k} * F_{djT_k} \tag{2}$$

$$\sum_{T_{m \geq k}} \sum_i (x_{ij}) \leq F_{siT_k} \tag{3}$$

Eq. (4) represents minimizing objective function for storage requirement (Z_1):

$$Z_1 = \sum_{T_{m \neq k}} \sum_i x_{ij} \tag{4}$$

Eq. (5) represents minimizing objective function for freshwater requirement (Z_2):

$$Z_2 = \sum_k \sum_j F_{wjT_k} \tag{5}$$

These modeling equations are solved for minimizing freshwater and storage requirements in a WAN. The trade-off between storage and resource requirement are captured through the Pareto optimal front. The Pareto optimal front facilitates decision-makers to select an appropriate operating point as per its suitability.

4. Illustrative Example

For a batch process operation, considering a batch WAN. Table 1 (Chaturvedi and Bandyopadhyay, 2012) shows flow-rate and concentration of streams in batch WAN.

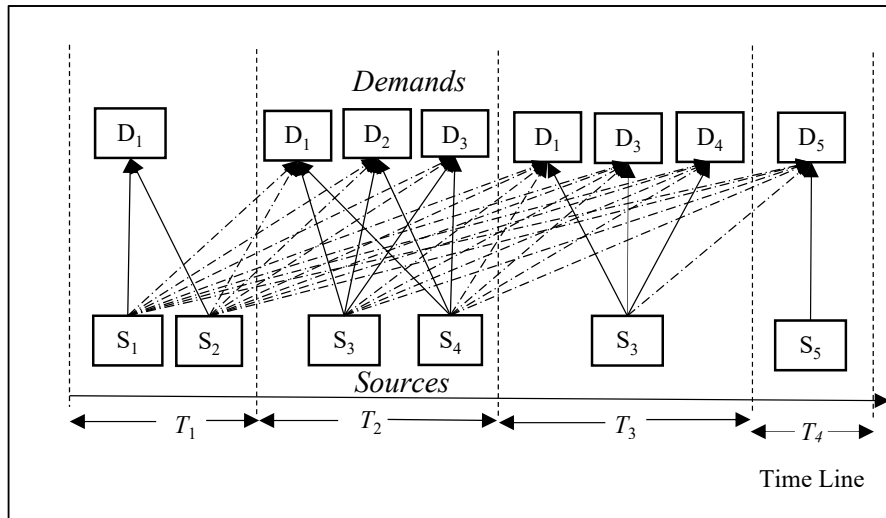

Figure 1: Schematic diagram of the Water Allocation Network.

Table 1: Demand and source availability in different time intervals
(Chaturvedi and Bandyopadhyay, 2012)

Source	Flow rate (t/h)	Conc. (ppm)	Duration (h)	Demand	Flow rate (t/h)	Conc. (ppm)	Duration (h)
S ₁	5	25	0.0-1.0	D ₁	10	0	0.0-3.0
S ₂	5	15	0.0-1.0	D ₂	40	27.5	1.0-2.0
S ₃	10	40	1.0-3.0	D ₃	5	15	1.0-3.0
S ₄	50	30	1.0-2.0	D ₄	5	25	2.0-3.0
S ₅	50	10	3.0-4.0	D ₅	20	5	3.0-4.0

Table 2: Time-interval wise flow and their concentration for the WAN problem
(Chaturvedi and Bandyopadhyay, 2012)

T ₁ (0.0-1.0) h		T ₂ (0.1-2.0) h		T ₃ (2.0-3.0) h		T ₄ (3.0-4.0) h	
Flow (t)	Conc. (ppm)	Flow (t)	Conc. (ppm)	Flow (t)	Conc. (ppm)	Flow (t)	Conc. (ppm)
25	5	10	40	10	40	50	10
15	5	50	30	-5	25	-20	5
0	-10	-40	27.5	-5	15		
		-5	15	-10	0		
		-10	0				

The streams are segregated in four time intervals as shown in Table 2. Figure 1 shows schematic diagram of sources and demands presence in several time intervals. Based on data of sources and demands of Table 2, the optimization problem is solved using GAMS with CPLEX solver for linear programming. A Pareto optimal front is generated between storage and freshwater requirement. This optimality front is generated by using ϵ -constraint method. The ϵ -constraint methodology provides the non-dominated solution for proposed mathematical model for minimizing freshwater and storage requirements in WAN.

In ϵ -constraint method, bi-objective model is solved for an objective function and another objective is expressed in form of an inequality constraint. For this inequality condition, maximum storage capacity is fixed at a certain value which is added as a constraint. For generating other optimal points, methodology is repeated with scalarly placed variations on storage requirement. The mathematical model is solved as linear programming model. The developed model is solved for minimizing freshwater and storage requirements. Thus, trade-offs between storage capacity and freshwater requirements are determined for WAN which is represented as Pareto optimal front in Figure 2.

Figure 2: Pareto optimal front for bi-objective problem

As storage capacity increases from zero to 5 ton (t), fresh water requirement decreases from 50.833 t to 47.70 t. With further increase in storage capacity from 5t to 10 t, freshwater requirement decreases up to 45.833 t. A constant fresh water requirement is observed upon further increase in storage capacity. Thus, target value for minimum freshwater requirement is obtained to be 45.833 t and maximum required storage capacity is obtained to be 10 t. Note that, this targeted value equates with the problem discussed in Chaturvedi and Bandyopadhyay (2012). The developed model provides a trade-off between two objectives via Pareto-optimal front.

5. Conclusions

This paper focuses on minimizing bi-objectives problem of freshwater and storage requirements simultaneously. A mathematical model is developed to solve this bi-objectives problem and a Pareto optimal front is generated by using ϵ -constraint methodology. The proposed methodology can be applied to any fixed flow rate and fixed scheduled batch process involving single or multiple qualities. The proposed linear programming model includes demand satisfaction, source availability and quality constraints. The trade-off between storage and resource requirements are captured through a Pareto optimal front. For generating points of Pareto optimality, ϵ -constraint technique is implemented in the model. The model is evaluated for a single objective and another objective is stated as inequality constraint. This Pareto optimal front facilitates decision makers to select an appropriate operating point as per its suitability.

Nomenclatures

x_{ij}	Transfer of flow from i^{th} source to j^{th} demand
F_{djT_k}	Flow rate requirement of j^{th} internal demand in T_k time interval
F_{siT_k}	Flow rate of i^{th} internal source in T_k time interval
F_{wjT_k}	Freshwater flow rate of j^{th} internal demand in T_k time interval
M_{dT_k}	Set of internal demands in T_k time interval
M_{sT_k}	Set of internal sources in T_k time interval

q_{djT_k}	Impurity concentration of i^{th} internal source in T_k time interval
q_{siT_k}	Impurity concentration of i^{th} internal source in T_k time interval
q_{wjT_k}	Freshwater concentration of j^{th} internal demand in T_k time interval
T_k	Time interval
Z_1	Minimizing objective function for storage requirement
Z_2	Minimizing objective function for freshwater requirement

A Hybrid Solution Approach for Large-scale Batch Scheduling with Quantum Computing

Akshay Ajagekar, Fengqi You

Cornell University, Ithaca, NY 14853, USA

asa273@cornell.edu

Abstract

In this work, we demonstrate the applicability and efficiency of hybrid quantum computing (QC) based techniques for solving large-scale batch scheduling problems. We propose a novel solution approach that integrates classical and quantum techniques to overcome their individual shortcomings. The hybrid solution framework allows us to take advantage of the complementary strengths of the two methods. We demonstrate the use of this hybrid approach in developing efficient solution algorithm for an intractable batch scheduling problem formulated as mixed-integer fractional program. We then propose a novel QC-based parametric decomposition algorithm for solving large-scale batch scheduling problems. The performance and efficiency of the developed hybrid models and methods are validated by performing several computational experiments and comparing the obtained computational results with those of the state-of-the-art classical off-the-shelf optimization solvers..

Keywords: Quantum computing, batch scheduling, hybrid techniques, optimization

1. Introduction

Scheduling is a critical issue in systems operations and has a major impact on the productivity of a system. Complex scheduling problems span a wide variety of areas, especially in the chemical process industries (Kallrath, 2002). Analytical approaches based on mathematical programming are plagued by the computational complexity of scheduling problems and may demonstrate exponential time complexity (Aytug et al., 1994). While heuristic and hybrid heuristic methods (Chu et al., 2013) can be used to solve large-scale problems in a reasonable time, they tend to trade off optimality for speed. Therefore, there arises a need to develop novel solution approaches capable of overcoming limitations of current solution approaches carried out on classical computers for complex scheduling problems.

The ability of quantum computing (QC) to offer large speed advantages over classical methods (Nielsen and Chuang, 2010) has proven to be a powerful tool in solving optimization problems (Martonosi and Roetteler, 2019), as QC becomes commercially available (Mohseni et al., 2017). There are a number of QC applications in process systems engineering (Ajagekar and You, 2020). For detailed preliminaries on QC-based computational optimization, specifically adiabatic quantum optimization, we refer interested readers to theoretical background in (Kadowaki and Nishimori, 1998) and practical implementation in process systems optimization (Ajagekar and You, 2019) and power systems scheduling (Lau et al., 2009). The goal of this paper is to demonstrate

the applicability and efficiency of hybrid QC-based techniques for solving large-scale scheduling problems, building upon previous work by Ajagekar et al. (2020). To overcome the shortcomings of the purely classical and purely quantum approaches, we propose novel solution methods that integrate both approaches by decomposing the problem into smaller subproblems. The hybrid solution framework allows us to take advantage of the complementary strengths of the two methods. We demonstrate the use of this hybrid approach to developing efficient algorithms for an intractable scheduling problem, the multi-purpose batch scheduling problem.

2. Quantum Computing Background

Quantum computing, which follows the rules of quantum mechanics, has emerged as the next frontier in computation. Analogous to the bit in classical computers, the quantum bit (qubit) is the fundamental unit of information in quantum computers. This work is restricted to quantum annealing-based computers, which are purposefully built for discrete optimization applications. Quantum annealing uses quantum fluctuations to tunnel through local minima and converge to an optimal state (Kadowaki and Nishimori, 1998). The advantage of the quantum annealing model is that it uses quantum fluctuations to efficiently find the minimum-energy state of the Hamiltonian, which corresponds to the objective function in the context of an optimization problem. The annealing process begins by initializing the system to the lowest-energy state of the initial Hamiltonian, which means that all qubits are in a superposition of 0 and 1. Throughout the quantum annealing process, the influence of the initial Hamiltonian is reduced, and a user-defined problem Hamiltonian is introduced. Quantum fluctuations are used to evolve the system towards the lowest-energy eigenstate of the problem Hamiltonian as shown in Figure 1a, which represents the solution to the optimization problem (Kadowaki and Nishimori, 1998).

Figure 1. a) Quantum annealing and b) Chimera graph on the quantum processing unit

State-of-the-art implementations of quantum annealing are available from D-Wave Systems, which provides cloud access to users. The D-Wave system solves problems that are formulated as a quadratic unconstrained binary optimization (QUBO) model. A QUBO model can be represented by a graph, where the nodes represent the binary variables, and the edges represent the connections between these variables. On the D-Wave quantum processing unit (QPU), this graph maps to another graph where the nodes are qubits and the edges are internal couplers that connect the qubits. This lattice of interconnected qubits forms a topological structure known as the Chimera graph as shown in Figure 1b. Solving a problem on the QC system involves embedding graph of

problem QUBO on the QPU, performing quantum annealing to return the lowest-energy solutions of the problem Hamiltonian before returning the unembedded solution.

3. Multi-purpose Batch Process Scheduling

A significant scheduling problem that is typical in batch manufacturing is the multi-purpose batch scheduling problem. This operational problem pertains to determining the optimal batch sizes, the assignment of tasks to equipment resources, and the sequence of tasks on each equipment unit. In this paper, we consider a Resource Task Network (RTN)-based formulation (Castro et al., 2001) with a fractional objective, as in You et al. (2009). To solve the mixed-integer fractional programming (MIFP) model of the multi-purpose batch scheduling problem efficiently, we propose a novel approach that integrates a hybrid QC-MILP decomposition strategy (Ajagekar et al., 2020) with an inexact parametric algorithm, which was developed for general MIFP problems (Zhong and You, 2014). Consider a version of the RTN-based continuous-time batch scheduling problem modified to have a fractional objective. The binary variables of this model are $W_{S_{in}}$, $W_{f_{in}}$, and $R2_{rn}$. $W_{S_{in}}$ indicates whether task i starts at time point n . At time point n , $W_{f_{in}}$, and $R2_{rn}$ indicate whether task i finishes and whether equipment resource r is being utilized. The problem also has six continuous variables. Bs_{in} and Bf_{in} represent the batch size of task i as it starts and finishes at time point n , respectively. $R1_{rn}$ is the amount of material resource r at time point n . T_n is the time corresponding to time point n , and H is the variable scheduling horizon, or make-span, of the network. The objective (1) describes the maximization of profit per unit time, which calls for the MIFP formulation presented here.

$$\max \frac{\sum_{r \in M} price_r (R1_{rN} - init_r)}{H} \tag{1}$$

$$s.t. \quad b_i^{\min} W_{S_{in}} \leq Bs_{in} \leq b_i^{\max} W_{S_{in}} \quad \forall i \in T, \forall n \tag{2}$$

$$b_i^{\min} W_{f_{in}} \leq Bf_{in} \leq b_i^{\max} W_{f_{in}} \quad \forall i \in T, \forall n \tag{3}$$

$$b_i^{\min} \left(\sum_{m < n} W_{S_{im}} - \sum_{m' \leq n} W_{f_{im'}} \right) \leq Bp_{in} \quad \forall i \in T, \forall n \tag{4}$$

$$Bp_{in} \leq b_i^{\max} \left(\sum_{m < n} W_{S_{im}} - \sum_{m' \leq n} W_{f_{im'}} \right) \quad \forall i \in T, \forall n$$

$$Bs_{i(n-1)} + Bp_{i(n-1)} = Bp_{in} + Bf_{in} \quad \forall i \in T, \forall n \tag{5}$$

$$R1_{rN} \geq demand_r \quad \forall r \in M \tag{6}$$

$$R1_{rn} = R1_{r(n-1)} + \sum_{i \in TO_r} \rho_{ir}^O \cdot Bf_{in} - \sum_{i \in TI_r} \rho_{ir}^I \cdot Bs_{in}, \quad \forall n > 1, r \in M \tag{7}$$

$$R1_{rn} \leq storage_r^{\max} \quad \forall r \in M, \forall n \tag{8}$$

$$R2_{rn} = R2_{r(n-1)} + \sum_{i \in E_r} (W_{S_{in}} - W_{f_{in}}) \quad \forall r \in E, \forall n \tag{9}$$

$$T_m - T_n \geq \sum_{i \in E_r} (fd_i \cdot W_{S_{in}} + vd_i \cdot Bs_{in}) \quad \forall r \in E, \forall n \tag{10}$$

$$\sum_n W_{S_{in}} = \sum_n W_{f_{in}} \quad \forall i \in T \tag{11}$$

$$W_{S_{iN}} = W_{f_{i1}} = 0 \quad \forall i \in T \tag{12}$$

$$T_1 = 0, T_N = H \quad (13)$$

$$R2_{rN} = 0 \quad \forall r \in E \quad (14)$$

$$Bs_{in}, Bf_{in}, Bp_{in}, R1_{rn}, T_n, H \geq 0 \quad \forall i \in T, \forall r \in M, \forall n \quad (15)$$

$$Ws_{in}, Wf_{in}, R2_{rn} \in \{0, 1\} \quad \forall i \in T, \forall r \in E, \forall n \quad (16)$$

Constraints (2)-(4) are batch size constraints. Constraint (5) models the logical relationship between Bs_{in} , Bf_{in} , and Bp_{in} for a given task. Constraint (6) enforces required demand by the end of the scheduling horizon. Eq. (7) expresses the mass balance of chemical resources, where ρ_{tr}^O and ρ_{tr}^I represent rates of consumption and generation of resource r by task i , respectively. Eq. (8) enforces the storage capacity limitation. The equipment unit eq. (9) does not allow an equipment unit to be utilized by more than one task at any time, where I_r is the set of tasks that utilize equipment unit resource r . The timing eq. (10) ensures that the processing time of tasks on each equipment unit is not greater than the duration between two consecutive time points. Eq. (11) expresses that tasks that have started must finish. Eq. (12) prevents tasks from finishing at the first time point and does not permit tasks from starting at the end of the scheduling horizon. Eq. (13) and (14) represent the initial and final conditions at end of scheduling horizon. To solve the MIFP model of the multi-purpose batch scheduling problem efficiently, we propose a novel approach that integrates a hybrid QC-MILP decomposition strategy with an inexact parametric algorithm, which was developed for general MIFP problems (Zhong and You, 2014).

3.1. Hybrid QC-MIFP Parametric Decomposition Algorithm

We propose a novel algorithm that integrates hybrid QC-based decomposition with a computationally efficient parametric method (Zhong and You, 2014). We first discuss the QC-based decomposition and further show how to integrate it with the parametric algorithm. Consider the simplified problem that results from replacing the fractional objective in (1) by the linear objective: $\max \sum_{r \in M} price_r (R1_{rN} - init_r) - \lambda \cdot H$, where λ is a penalty parameter that is initialized to zero and is iteratively updated. We introduce a hybrid QC-MILP decomposition method that efficiently solves this MILP scheduling problem formed by replacing fractional objective with the above linear objective, in two phases. The first phase determines the start times, finish times, and batch sizes of tasks that optimize the objective function. The second phase balances equipment unit resources and searches for an optimal schedule on each unit such that the start times, finish times, and batch sizes determined in the first phase are feasible. The main idea is that if the equipment resources cannot be balanced, then the partial solution returned from the first phase is infeasible. Linear objective, constraints (2)-(8), and constraints (10)-(13) form the relaxed MILP that is optimized in phase one of this hybrid strategy.

$$\min H_r = \sum_n R2_{r(n-1)} \cdot (1 + 2K) + R2_{rn} \cdot (1 - 2K) - 2R2_{r(n-1)} R2_{rn} \left. \vphantom{\sum_n} \right\} \text{QC Step} \quad (17)$$

where $K = \sum_{i \in I_r} (Ws_{in}^* - Wf_{in}^*)$

Constraints (9) and (14) are concerned with balancing equipment unit resources and are reduced to the QC step shown in (17). During each iteration, the relaxed MILP problem is solved using the classical deterministic solver Gurobi to return partial optimal solutions. The second phase involves taking in partial optimal solutions and solving the

QC step on a quantum processor to search for a feasible schedule. If the QC step returns an infeasible solution, integer cuts are added to the relaxed MILP. This process is repeated iteratively until the QC step returns a feasible schedule or the relaxed MILP problem is proven infeasible. If the QC step returns a feasible schedule, this schedule is returned as the optimal solution for the batch scheduling problem. Each r for which the task scheduling W is infeasible, could be identified. The assignment for these specific tasks can then be excluded. This is accomplished by adding an integer cut. To tackle the intractability stemming from the fractional objective of the multi-purpose batch scheduling problem, we integrate a hybrid QC-based decomposition with an efficient parametric algorithm. To initialize the algorithm, the dynamic parameter λ should be set to zero, and a tolerance value must be defined. During each iteration, the parametric MILP problem is solved using the hybrid QC-MILP decomposition method described above. If the MILP is infeasible, the hybrid QC-MIFP parametric decomposition algorithm stops, and the original batch scheduling problem is infeasible. The algorithm updates λ to take the value of the last computed fractional objective, and it moves on to the next iteration. Convergence is achieved when the absolute difference between the fractional objective and λ is lower than the tolerance level.

Table 1. Computational results of the batch scheduling problem

Tasks	Time points	BARON v20.4		Hybrid QC-MIFP parametric decomposition method

a. Run time exceeds 24 h

3.2. Computational Results

To illustrate the effectiveness of the proposed hybrid QC-MIFP parametric decomposition method, we carry out computational experiments with batch scheduling problems of various sizes, which were taken from Dow Chemical originally (Wassic et al., 2012). A RTN as reported in Chu et al. (2013) was used for modelling the batch scheduling problem. This MIFP problem can be solved using the general-purpose MINLP solvers BARON v20.4 on a classical computer. BARON is a robust global optimization solver and consistently demonstrates fast performance on benchmarks. Comparing the computational times and objective values reported in Table 1, the hybrid parametric algorithm obtains near-optimal solutions within reasonable computation times. The performance of BARON v20.4 deteriorates beyond problems with 18 tasks, and it takes more than a day without returning any feasible solution for problems with more than 40 tasks. BARON is unable to yield solutions for large-scale problems with 24 hours of computation time. The hybrid QC-MIFP parametric decomposition method, on the other hand, obtains high quality solutions for problems with 52 tasks in under 900 seconds. The proposed hybrid QC-MIFP parametric decomposition method not only performs competitively against state-of-the-art MINLP solvers for small-scale scheduling problems, but also dominates classical solvers for medium and large-scale

batch scheduling problems. Based on the computational times observed for several batch scheduling problem instances, the hybrid QC-MIFP parametric decomposition method demonstrates better scalability than BARON. Due to its computational advantage and its high-quality solutions, the hybrid QC-MIFP decomposition method is expected to yield economic advantage for multi-purpose batch scheduling problem.

4. Conclusions

In this paper, we proposed hybrid QC-based optimization methods for solving large-scale batch scheduling problems. The proposed algorithms exploited the complementary strengths of established classical computing methods and novel QC-based solution strategies. For the multi-purpose batch scheduling problem, we proposed a novel algorithm that integrates a hybrid QC-MILP decomposition method with a fractional parametric algorithm. Computational results showed that the proposed hybrid QC-based solution strategies were orders of magnitude faster than state-of-the-art MINLP solvers.

Abstract

An integrated framework for building a virtual replica of business transactional processes in supply chains is presented. The framework consists of two main components: a simulation module and an optimization module. Business processes are modeled as networks of queues through which requests (internal or external to the enterprise) can flow. The digital replica of the business processes creates value by providing a simulation platform upon which to: 1) test optimization strategies, 2) forecast potential delays in requests based on the current state of the real process and the historical data, 3) identify and mitigate bottlenecks, and 4) provide more accurate fulfillment dates to customers. The optimization can be performed offline or in real-time in a feed-back loop as the simulation is being executed. As an integrated simulation and optimization environment, the framework bridges and extends the literature in business process simulation and business process optimization, building upon previous work by the authors that was restricted to only business process scheduling in static deterministic environments. A case study is presented in which three mathematical programming models and a greedy heuristic are compared. A sensitivity study shows the value in using simulation to mitigate operational bottlenecks.

Keywords: Business process optimization, digital supply chain, order-to-cash, digital twin

1. Introduction

Optimization of supply chains provides significant value to enterprises that seek to reduce costs, increase customer satisfaction, and streamline operations. For this optimization to be achieved, each of the areas in the supply chain need to be improved. These areas include those governed by material flows, financial flows, and information flows. Inefficiencies in any of these areas affect all other areas in the supply chain. Traditionally, work in supply chain optimization has focused on the physical processes that are governed by material flows. This work has been led by the Operations Research community (Pourhejazy and Kwon, 2016). However, the transactional business processes that are governed by information flows have received limited attention in supply chain optimization. Previous work by the authors has shown the potential in applying scheduling models from the chemical process industry to improve the operation of

business processes (Perez et al., 2021, 2020). However, this work was limited to perfect information systems that ignore the stochastic nature of the transactional flows and future customer demands in the supply chain. Although not applied in the context of supply chain, relevant work includes that of workflow scheduling of cloud-based systems from the computer science and systems community. Both heuristic and mathematical programming approaches are presented in a handful of works in this field (Cai et al., 2016; Hoenisch et al., 2016; Li et al., 2018). However, these works are limited to static deterministic systems. To improve the applicability of scheduling models in supply chain business process optimization, the authors present a business process digital twin for supply chain. Although the digital twin is general for other business processes, it is presented in the context of the order-to-cash process.

2. Methods

The proposed digital twin uses a queuing network representation of the order-to-cash processes as shown in Figure 1. From a manufacturing perspective, the business process queuing network is represented as a multi-stage batch plant, where customer orders are analogous to batches. Discrete event simulation is used to model orders flowing through the process. Each processing stage or transaction on an order is represented as a service node with an unknown service time that is sampled from a known probability distribution, which can be determined from real process data. At these service nodes, one or more resources can be made available to perform the necessary transactions. Resources can be shared between transactions as well. Thus, each transaction has a queue, with one or more service nodes representing the resource used. As the simulation marches forward in time, optimization events can be triggered at discrete intervals, or when certain conditions occur. A snapshot of the system state is sent to an optimization algorithm that schedules active orders and assigns the resources involved in the process transactions. The resulting schedule sequences are translated into order priorities for each queue in the network. These priorities are returned to the discrete event simulation to reorganize the positions of the orders in each of the active queues. Since the optimization is an event in the simulation, the computational time spent performing the scheduling is accounted for in the duration of the optimization event. The simulation does not pause for the optimization to occur, but keeps marching forward in time, allowing for a more realistic implementation of optimization in the business process environment. Furthermore, the optimization frequency and solution time plays an important role in the simulation-optimization integration.

The digital twin framework is developed in the Julia programming language (v1.5), which brings the advantages of using several simulation and optimization libraries available within the Julia environment. As an integrated platform, the framework reduces the need for creating interfaces between different programming languages, GUIs, and databases required for simulation and optimization. The framework is designed such that transactional processes of any scale and complexity can be modeled by it. It is general in that it allows building simulation and optimization models for business processes based on four key inputs: 1) the network structure of the activities in the business process, 2) the assignment of resources to activities, 3) the resource capacities, and 4) the probabilistic distributions of the processing times for each activity or task. These

processing times can be specific to the resource type, order type, and/or customer. Making modifications to the underlying business process structure or parameters is relatively easy to make. As a unified system, any changes are automatically translated to the queueing network structure for simulation and the mixed-integer programming (MIP) models for optimization.

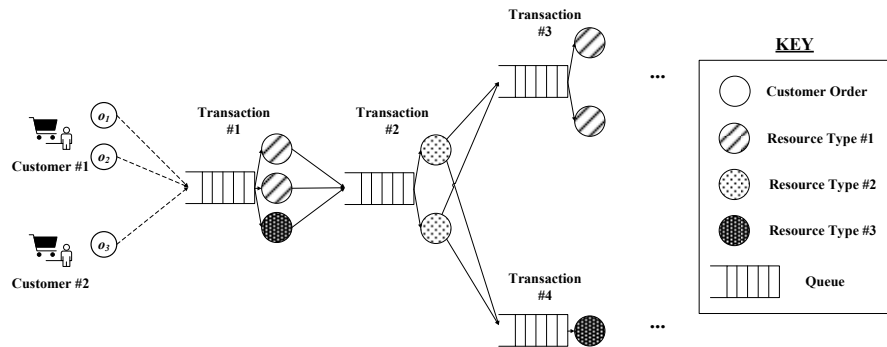

Figure 1. Queueing network representation for a business process

Two scheduling paradigms are used for optimization within the framework: a continuous-time general precedence model (Méndez and Cerdá, 2003) and discrete-time task network models. The latter include the Resource-Task Network (Pantelides, 1994) and the State-Task Network (Kondili et al., 1993). As discussed in another work by the authors, the general precedence model provides the benefits of reduced model sizes and temporal accuracy, whereas the task network models provide the benefits of reduced solution times for large systems due to tight model relaxations (Perez et al., 2021). As an alternative to mathematical optimization, a greedy heuristic is also provided, in which the order sequencing in the queueing network is determined by the order price, where orders that bring in higher revenue take priority. The benefit of using optimization over heuristics is that the mathematical models capture the different features in the system (e.g., order prices, backlog penalties, processing times, and due dates) to yield a holistic view when assigning order priorities.

3. Case Study

The digital twin is applied to an extended order-to-cash process with 11 steps as shown in Figure 2. Transactional steps (1-5, 7-9, and 11) are processed by a single agent with processing times sampled from a uniform distribution in the 15-30 min time range. The goods loading step (6) can be processed by one of two agents with processing times sampled uniformly from the 1-2 hr. range. The goods transportation step (10) has four available agents with processing times sampled uniformly from the 8-24 hr. range. 10 orders enter the system with arrival times occurring randomly within the first 28 hrs. Order due dates are set at random, ensuring that all orders are given at least the average total processing time between their arrival times and due dates. Order sales revenues vary from \$0-1K with a backlog penalty of 30% for late orders.

Queue re-prioritizing is performed at hourly intervals in the simulation. A time limit of 10 min is placed on the optimization algorithms, which are solved using CPLEX 20.1 on

a 2.11 GHz, 24 GB RAM, Intel i7 PC. The case study is run under two modes: deterministic and stochastic. The difference between the two is that the stochastic mode samples transaction times from the processing time distributions, whereas the deterministic mode uses the average values of such distributions. However, both modes are stochastic in the sense that, at any time in the simulation, future orders are unknown. Six operating models are compared: FIFO (first-in, first-out), Greedy Priority Heuristic, GP (General Precedence), D-RTN (Discrete-time Resource-Task Network), D-STN (Discrete-time State-Task Network), and PI (Perfect Information). The FIFO mode represents a simulation without any queue priority optimization. The greedy priority heuristic mode assigns order priorities in each queue according to the order value. The PI mode is an offline optimization that yields a tight upper bound on the total revenue possible when all information about present and future orders is known beforehand.

Figure 2. Order-to-cash process structure for case study

3.1. Deterministic Mode

Table 1 shows the normalized total revenues for each of the simulation modes when processing times are deterministic. The results show that performing no queue optimization yields the lowest total revenue. On the other hand, the greedy priority heuristic and the mathematical programming models produce a 57% and 105% improvement relative to the FIFO system, respectively. The superior performance of the MIP models (GP, D-RTN, and D-STN) relative to the greedy heuristic results from the fact that the assignment of order priorities in the queues is not based solely on the order prices. Instead, the MIP models provide a mathematical description of the system that accounts for processing times, backlog penalties, resource availabilities and due dates. The total revenue of the MIP models is 15% below the highest possible revenue (i.e., the perfect information model). As the optimization frequency increases, the gap in the total revenue with respect to the perfect information model is expected to decrease. The total revenue from the perfect information model serves to highlight the potential gains of having accurate demand forecasting. In terms of on-time order fulfillment, the MIP models process 5 orders on time, which is a 25% improvement with respect to the FIFO system. Despite its improved revenue relative to the FIFO mode, the heuristic does not improve the number of orders fulfilled on time. The results from the MIP models show that using mathematical optimization can improve not just the total revenue by prioritizing which orders to focus on, but can also increase the order fulfillment rate in the system.

Table 1. Results for each simulation mode with deterministic task durations

Simulation Mode	<i>FIFO</i>	<i>Heuristic</i>	<i>MIP</i>	<i>PI</i>
Cumulative Revenue	1.16	1.82	2.37	2.79
On-time Fulfillment	40%	40%	50%	80%

3.2. Stochastic Mode

Table 2 shows the results from 100 simulations in the stochastic environment. For comparison purposes, a unique random seed is used for each of the 100 runs with all simulation modes having the same seed in each run. The results show an average revenue increase on the order of 10% for the MIP models and 16% for the heuristic, relative to the FIFO system. The 95% confidence intervals correspond to a 4-6% uncertainty in the average revenues obtained. The number of simulations required is dictated by the allowed error tolerance. For a 10% tolerance, approximately 30 simulations would be required. For a 2% tolerance, the number of required simulations is in the 500-800 range. The MIP models suffer in environments with task durations that exhibit significant variance, as is the case with the uniform distributions used here. The deterministic models rely on the mean processing times, which results in a mismatch between the mathematical models and the simulations when the task durations are uncertain. However, as the variability in the processing time distributions becomes less pronounced, the MIP models should begin to outperform the Heuristic, as was observed in the deterministic case.

Table 2. Results for simulation models in a stochastic environment (95% confidence)

Sim. Mode	<i>FIFO</i>	<i>Heuristic</i>	<i>GP</i>	<i>D-RTN</i>	<i>D-STN</i>
Cum. Rev.	1.74 ± 0.10	2.01 ± 0.09	1.92 ± 0.10	1.89 ± 0.10	1.90 ± 0.11
On-time	47 ± 2%	51 ± 2%	50 ± 2%	51 ± 2%	50 ± 2%

4. Sensitivity Analysis

Besides serving as a testing ground for optimization strategies, the digital twin provides a framework upon which to identify bottlenecks and test design alternatives to mitigate these bottlenecks in a computationally inexpensive way. In the case study above, a major bottleneck is the lack of agents to perform transactional steps. A sensitivity study is performed in which the number of transactional agents is increased from 1 to 4. Table 3 shows that if the number of agents available for transactional events is doubled from the single agent in the original case study, the total revenue can be increased on average by 36% without any queue optimization. The on-time order fulfillment rate increases by 20 points. Further additions of agents do not result in increments that are statistically significant. It should be noted that performing the simulations in Julia is computationally inexpensive, with run times of less than 0.2 seconds for each simulation in this case.

Table 3. FIFO Results as the number of transactional agents increases (95% confidence)

Number of Agents	1	2	3	4
Cumulative Revenue	1.74 ± 0.10	2.37 ± 0.09	2.44 ± 0.08	2.44 ± 0.08
On-time Fulfillment	47 ± 2%	67 ± 2%	71 ± 3%	71 ± 3%

5. Conclusions

A simulation-optimization framework for supply chain transactional processes is presented. Optimization via mixed-integer linear programming is coupled in a feedback loop to a discrete event simulation of the process, which is modeled as a queueing network. The feedback loop assigns priorities to orders in each queue in the network. A greedy prioritization heuristic is compared against three mathematical optimization models in a case study. Two simulation modes are used, a deterministic and a stochastic mode. In the latter, the processing times for transactions are sampled from probability distributions. Under the deterministic scenario, the MIP models outperforms the heuristic by 30%, doubling the total revenue of the un-optimized FIFO system. Under the stochastic scenario with large uncertainty in the processing times, the heuristic slightly outperforms the MIP models, which are limited due to their deterministic representation. A sensitivity study is also presented to illustrate the value of using discrete event simulation to identify and mitigate bottlenecks in business process operations. Future work includes extending the MIP models to better respond to uncertainty in transaction times, while maintaining model tractability when executing the simulations. Reducing the uncertainty in the processing times by incorporating supply chain business rules is also expected to improve the performance of the mathematical programming models. Overall, the digital twin framework presented has promise in paving the way for industrial applications where business processes execute a very large number of transactions.

A Data-Driven Approach to Plan Electricity Production from Diesel Engines with Constrained Parameters

Piyush Kumar Kumawat, Nitin Dutt Chaturvedi

*Process Systems Engineering Laboratory, Department of Chemical and Biochemical
Engineering, Indian Institute of Technology Patna, Bihta, Patna, 801106, Bihar, India*

Abstract

Optimum energy utilization and constraint release of greenhouse gases are essential considerations in any production process. This challenge is generally observed in large energy extensive plants or processes involving fossil fuel combustion. Diesel engines are widely used to convert some of the chemical energy, contained by the diesel fuel, to mechanical energy through combustion. This mechanical energy can be converted into electrical energy using an alternator. Researchers claim that using alternate fuels having similar chemical properties or using foreign fuel as a fractional substance with diesel in these engines could result in a significant reduction in emissions or can alter the concentration of different pollutants. In this study, a methodology is suggested to create a feasible design space for operation with capped emission limits and energy consumption. A data-driven machine learning approach is implemented to classify feasible data points from the data set to create design space. Further, optimization is performed in the defined region to address an optimization problem associated with constrained energy and emission limits.

Keywords: Energy Consumption, Electricity Production, Machine Learning, Emissions;

1. Introduction

Energy consumption and emissions of harmful gases are of increasing concern in the world, and alternative options are continuously being explored having a reduced effect on the environment. Traditional electricity production process principally depends upon critically limited fossil fuels. The process of electricity generation by means of these fuels, several poisonous by-products adversely affect the conservation of natural eco-system.

Diesel engines are mainly used for decentralized power generation. The major drawback of these engines is the emanation of harmful gases. However, various studies claim that using other similar fuels or dual-fuel (using foreign fuel as partial substance) in these engines can significantly affect the emissions and can produce power from a few kilowatts up to several hundred kilowatts. R. Uma et al. (2004), stated that dual-fuel operation reduces NO_x and SO₂ emission without increasing particulate emission at the expense of an increase in carbon monoxide emission. Saleh (2008) studied the effect of variation in LPG composition on emissions and performance in a dual fuel (LPG-diesel) diesel engine. B.B. Sahoo et al. (2012) discussed the effect of H₂: CO ratio in syngas on the performance of a dual fuel diesel engine operation. H. Ambaria (2017) elucidated

performance and emission characteristics of a small diesel engine run in dual-fuel (diesel-biogas) mode. An appropriate trade-off between the operating diesel engine on different fuel mode will result in balanced emissions and energy consumption.

To address this challenge, support vector machines (SVM), a machine learning tool is adopted to classify feasible data from the data set in order to define a design space to operate the engine with constrained objective limits to produce electricity. The model can be used to classify the data from the embedded dataset and considered to be more reliable as it encompasses a data-driven approach. The aim of this paper is to obtain a design space for constrained energy consumption and different emission limits. The study is based on emission and energy consumption characteristics of the electricity generation system using a diesel engine. The proposed methodology is explained using literature example. The diesel engine can be operated in two different modes i.e. diesel alone and dual fuel (diesel-producer gas). In order to operate similar engines parallelly in two different modes, a design space is created using an SVM classifier. This will assist the planner to make decisions in a defined area and to optimize several objectives within the calculated predefined area using classifier algebraic equation.

2. Problem statement

Given a set of historical/simulated data with varying target load of diesel engine operated using different fuels. Each targeted load will have its respective specific energy consumption (SEC) and emission information of different gases as by-products. The energy consumption and emission of different harmful gases vary with different load conditions.

The aim of the model is to project the feasible region satisfying the capped limits of energy consumption and emissions of gases onto the space of production targets. Additionally, to generate an algebraic equation to attain objective-based optimization in the feasible region.

3. Methodology

To identify the feasible design space for the presented problem, support vector classification (SVC) technique is used. It attempts to find an optimal hyperplane or a sequence of hyperplanes in high dimension space that separates one class from those of the other class. The ideology for the classification is that the hyperplane has the largest distance from the nearest training data points in each class conducts a good separation and, in general, the larger the margin, lower the generalisation error of the classifier.

Given training vectors $x_i \in \mathbb{R}^p$, $i = 1, 2, \dots, k$ in two classes, and a vector $O \in \{-1, 1\}^k$, the goal is to find $w \in \mathbb{R}$ and $b \in \mathbb{R}$ such that the prediction given by $sign(w^T \phi(x) + b)$ is correct for most samples. Support Vector Classification (SVC) solves the following primal problem (Eqs. 1-3):

$$\frac{1}{2} w^T w + C \sum_{i=1}^k \xi_i ; s. t. \quad (1)$$

$$O_i (w^T \phi(x) + b) \geq 1 - \xi_i \quad (2)$$

$$\xi_i \geq 0, \forall i \quad (3)$$

Intuitively, to maximize the margin (by minimizing $\|w\|^2 = w^T w$), while incurring a penalty when a sample is misclassified or within the margin boundary. Ideally, the equation $O_i (w^T \phi(x) + b) \geq 1$ would be true for all data, which indicates a perfect

prediction. The problems are usually not always perfectly separable with a hyperplane, so some samples are allowed to be at a distance ' ϵ_i ' from their correct margin boundary.

The penalty term ' C ' controls the strength of this penalty, and as a result, acts as an inverse regularization parameter. The dual of the primal problem (Eqs. 4-6) is:

$$\frac{1}{2} \delta^T Q \delta - e^T \delta; \text{ s. t.} \tag{4}$$

$$O^T \delta = 0 \tag{5}$$

$$0 \leq \delta_i \leq C, \forall i \tag{6}$$

where ' e ' is the vector of all ones, and ' Q ' is a $(k \times k)$ positive semidefinite matrix $Q_{uv} = z_u z_v K(x_u, x_v)$, where $K(x_u, x_v) = \phi(x_u)^T \phi(x_v)$ is the kernel. The terms δ_i are called the dual coefficients, and they are upper-bounded by ' C '. This dual representation highlights the fact that training vectors are implicitly mapped into a higher dimensional space by the function ' ϕ '. Commonly used kernel functions are the linear kernel, polynomial kernel, radial basis function kernel (RBF) kernel with bandwidth and sigmoid kernel.

Once the optimization problem is solved, the output of decision function for a given sample ' x ' becomes:

$$\sum_{u \in SV} z_u \delta_i K(x_u, x) + b \tag{7}$$

The sum of the support vectors will be of the samples that lie within the margin because the dual coefficients are zero for the other samples. This classification using SVM is performed and practised in Python 3.0 using the library scikit-learn (Pedregosa, 2011) to process input data and to classify them on the basis of feasibility.

4. Case Study

To clarify the methodology, a case study is adapted from R. Uma et al. (2004). Biomass feedstocks are available in huge amounts in rural areas and could be an appropriate option for decentralized power generation using biomass gasifier-based systems. Producer gas from a biomass gasifier can be used either as a partial substitute for diesel in diesel engines or can be used alone in a gas engine. The mixture is known as dual fuel and considered as another fueling option to produce electricity. It is also assumed that the mixing ratio is fixed in dual fuel.

Table 1. Concentration of pollutants and SEC from diesel engine in diesel alone and dual fuel mode

Parameter	Load							
	10 kW		20 kW		30 kW		40 kW	
	Single	Dual	Single	Dual	Single	Dual	Single	Dual
CO (ppm)	175.6	656	219	669	284.3	710.6	320.6	922.3
SO ₂ (ppm)	4.234	1.167	5.4	1.234	7.367	1.667	9.834	2.167
SEC (MJ/kW)	22.8	34	15.5	18	14.0	15	13.1	16

The diesel engine system consists of a turbocharged, four-stroke I.C. engine coupled with an alternator. Table 2 describes the concentration of pollutants and SEC in diesel alone engine for four different load conditions. It is being observed that the emission of carbon monoxide (CO) in the dual fuel mode is greater than that of CO in the diesel mode alone. It indicates incomplete combustion results in the high CO content in the dual fuel exhaust, whereas, CO concentration improves at partial load condition. This suggests the need for a lower load limit for dual fuel operation. It can also be observed from the data that dual-fuel operation reduces SO₂ emissions. The SEC increases with decreasing load both in diesel alone and dual-fuel mode. This implies the considerable efficiency loss at the low-load condition. In dual fuel mode, SEC is greater than the diesel-only mode throughout the load condition tested. Increased SEC indicates a decrease in the efficiency of the dual-fuel mode, which could be caused by a decrease in the heating value of the producer gas-air mixture, a decrease in the gas pressure entering the air inlet and a decrease in the flame velocity. Due to contradictory performance of diesel engine for different parameters, it is suggested to operate diesel engine in both models parallelly with a cap over aggregate emission and energy consumption to generate a cumulative load.

A set of historical data could be useful and more accurate, however, for this study simulated data is used to train the classification model. Simulated data comprises combinations of the load to be produced by operating diesel engine in two different modes and is obtained by interpolating four load points (Table 1) using non-linear regression. A data set of 150 random production combination is generated and divided into two categories; feasible (-1) if the characteristics (emissions and energy consumption) are below the capped value for the selected combination output target, otherwise infeasible (1). Further, the input data is trained using SVC to classify the data on the basis of feasibility and to predict a feasible region in production space.

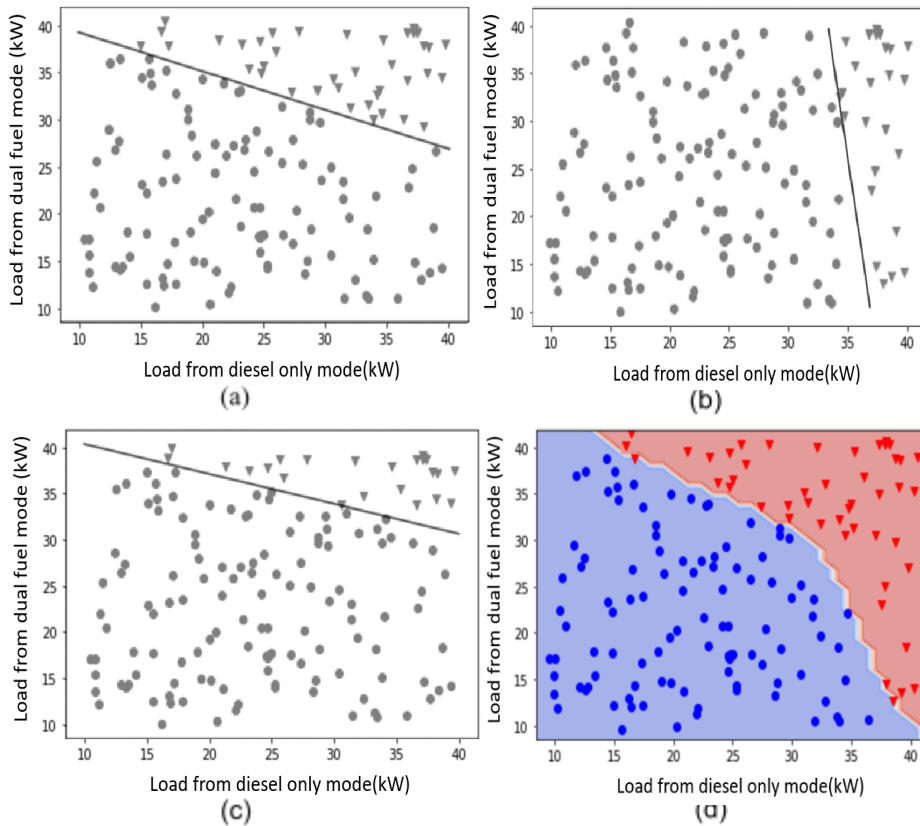

Figure 1. Performance of SVC in predicting the feasible region for (a) energy consumption, (b) CO, (c) SO₂, (d) overall (•: feasible points, ▼: infeasible points).

Figure 1 depicts the feasible region (area having feasible points) for production under specified limits. In Figure 1(a), a line is generated using SVC which separates the feasible data points. The criteria for the classification is that the total energy consumed by two engines operated on two different modes should be less than 850 MJ. Similarly, Figure 1(b) presents the feasible area lies on the left side of the generated line for SO₂ concentration to be less than 10 ppm. In the same way, data points are separated in a region with production combinations producing emission less than 1000 ppm (Figure 1(c)). Linear kernel function is used with SVC to classify input data because these data points are linearly separable in scatter plot. All the data points which resulted to be infeasible for any criteria are clustered and assigned as infeasible for overall performance. Further, a design space is obtained encompassing all the limitations over parameters, the generated curve for classifying feasible space is shown in Figure 1(d). It is generated using RBF kernel function in SVC, a hyperplane is created by mapping the data points to a higher dimension, in order to make non-linear classification possible. Table 2 summarizes the prediction result of additional 100 points generated by the model. Precision can be seen as a measure of a classifier's exactness; recall is a measure of the classifier's completeness. The F1 score is a weighted harmonic mean of precision and recalls such that the best score is 1.0 and the worst is 0, support is the number of actual occurrences of the class in the specified dataset.

Table 2. Results for the case study

	Precision	Recal	F1-score	Support
		l		
Feasible (-1)	0.90	1	0.95	65
Infeasible (1)	1	0.8	0.89	35
Accuracy			0.93	100
Macro avg	0.95	0.90	0.92	100
Weighted avg	0.94	0.93	0.93	100

This study will assist the planner to plan the generation of electricity within the specified limits or following the government norms. An algebraic equation can also be created using the fitted model parameters, i.e. support vectors, coefficients. Using this equation several objectives can be attained in the feasible design space. An example is performed to maximize diesel production can be solved using Eq. (8) as objective and Eqs. (9)-(10) as constraints.

$$P_D + P_{DF} \quad (8)$$

$$\sum_{u \in SV} z_u \delta_i \exp(-\gamma \|x_u - P\|) + b \leq 0 \quad (9)$$

$$P_D, P_{DF} \leq 40 \quad (10)$$

Here, P is the vector of production targets, $P = \{P_D, P_{DF}\}$ i.e. production using diesel-only mode and dual-fuel mode. γ be the parameter for RBF kernel function and x_u is the set of support vectors used to design classification boundary.

The resultant NLP model using support vectors from the trained model is solved using GAMS/CONOPT solver. The maximum aggregate production in the feasible region is approximately calculated to be 64.1 kW ($P_D = 32.16$ kW, $P_{DF} = 31.94$ kW). To generate this load, 893.94 MJ of energy is required with the resultant concentration of pollutants as 998 ppm CO and 9.7 ppm SO₂.

5. Conclusion

With an objective to produce electricity from diesel engine under capped emission and energy consumption, a data-driven approach is proposed. The methodology is based on classification of feasible data points using SVC and to create a design space for feasible production combinations. The proposed study is supported by a case study to use a mixture of producer gas and diesel as dual fuel. In order to operate two engines with two different fuel (diesel and dual-fuel) parallelly, a design space is created for production combination from each mode. Parameters like total CO, SO₂, and total energy consumption were considered and capped below a certain value. For individual parameters, the data was linearly separable and for the overall classification, RBF kernel was used to classify nonlinear data and are demonstrated graphically. Optimization is also performed in the feasible area to calculate maximum production satisfying capped parameters. In future work, the methodology can be implemented to other combinations for dual fuel and can be extended to scheduling and planning to satisfy the continuous electricity demand.

Abstract

In this work, we propose a decomposition strategy to solve a large-scale MILP model that seeks to optimize the monthly schedule of the Omsk lubricant plant. The proposed algorithm consists of sequential solutions of two sub-problems. First, we solve a relaxed sub-problem where the integer variables representing the amount of packed lubes and their inventories are treated as positive continuous variables. The solution of the first approximate problem provides decisions on feedstock purchases and daily capacities of the continuous process units that produce oil components from vacuum residues and distillates. In the second stage, we solve the full-space sub-problem with the fixed values of the process capacities and utilization of the raw materials. By comparing with rigorous solution of the problem we demonstrate numerical efficiency of the method. The proposed algorithm provides near optimal solutions with significant reductions in CPU time as compared with the rigorous solution.

Keywords: scheduling, MILP, relaxation, refinery management.

1. Introduction

Plant-wide planning and scheduling systems play a crucial role in achieving greater profitability for oil companies. Since 2016 Gazprom-neft, a leader in the Russian oil business, has been developing own in-house optimization solutions for its refineries and lubricant plants located in Omsk and Moscow. Such planning and scheduling modules linking together will eventually compose a unified environment for supporting a decision-making process across the company’s supply chain.

In this work, we describe one of the modules -- the monthly scheduling problem of process activities within the Omsk lubricant plant. In a hierarchical planning process, the production plan is cascaded down to a more detailed production schedule (Hadidi et al., 2012). The aim of a scheduling phase is to construct the optimal sequence of production tasks, such that:

- all decisions made on the first planning stage (i.e., capacities of production units, monthly volumes of supplies, customers’ orders to deliver) should be executed with minimal deviations,
- product deliveries should be done according to the customer rating system,
- several large-capacity production units must be uniformly loaded during a month,

- blending operations must be sequenced with the minimal number of switches between incompatible oils to prevent unnecessary cleaning operations and generation of low-value oil mixtures,
- allocation of oil inventories to the tanks should be also done taking into account compatibility with preceding tank content.

Such scheduling task is formulated as a discrete-time MILP model which main equations are described in Section 2 of the paper. To reduce the computational burden associated with solution of the resulted large-scale MILP we develop a decomposition strategy, which consist of sequential solutions of two sub-problems. Details of our solution approach can be found in Section 3. Computational performance of the proposed algorithm is demonstrated by the case study of the Omsk lubricant plant in Section 4.

2. Discrete-time mathematical formulation

The scheduling model formulated as an MILP includes material balance equations, capacity constraints for every production unit and mixer, production plan limitations, and specific constraints setting preferable delivery days according to a product priority, uniform daily loads of certain production units and penalizing objective function when preparations or storing of incompatible products occur at the same mixer or tank.

The overall mass balance is determined for every stream s in a day p of a month. Thus, for every stream s its purchases $supply_{s,p}$ and initial inventories ($inventory_s$ for the first day of a month or $stock_{s,p-1}$ for other days) must be equal to the amount produced or consumed at production units ($process_{s,p}$) plus the amount delivered to customers ($demand_{s,p}$) and stored in tanks or warehouses ($stock_{s,p}$):

$$supply_{s,p} + stock_{s,p-1} + process_{s,p} - demand_{s,p} - stock_{s,p} = 0 \quad \forall s \quad (1)$$

$$supply_{s,p} + inventory_s + process_{s,p} - demand_{s,p} - stock_{s,p} = 0 \quad \forall s \quad (2)$$

The mass balance equations for the packed oils and greases (denoted as the subset of streams PS_s) are represented by Eqs. 3-4. The only difference from Eqs. 1-2 is that the amount of the packed lubes stored ($stockpack_{s,p}$) and the amount delivered to customers ($demandpack_{s,p}$) have integer nature since they are counted in pieces:

$$stockpack_{s,p-1} + process_{s,p} - demandpack_{s,p} - stockpack_{s,p} = 0 \quad (3)$$

$$inventory_s + process_{s,p} - demandpack_{s,p} - stockpack_{s,p} = 0 \quad \forall s \quad (4)$$

The amount of stream s produced or consumed in a plant ($process_{s,p}$) is calculated from the daily loads of operating modes m ($modeload_{m,p}$) and the material balance coefficients $processcoeff_{s,m}$ of a corresponding stream in an operating mode m :

$$process_{s,p} = \sum_m modeload_{m,p} processcoeff_{s,m} \quad \forall s, p \quad (5)$$

The material balance coefficients $processcoeff_{s,m}$ have a negative sign for the streams that are consumed in an operating mode m and a positive sign for the streams produced in this operating mode.

The daily loads of operating modes $modeload_{m,p}$ are limited by the minimum and maximum daily capacities ($capmin_m$ and $capmax_m$) associated with a corresponding mode m :

$$usecap_{m,p} capmin_m \leq modeload_{m,p} \leq usecap_{m,p} capmax_m \quad \forall m, p \quad (6)$$

The binary variable $usecap_{m,p}$ takes the value of 1 if a mode m is used in a day p and 0 otherwise.

The sum of all daily loads $modeload_{m,p}$ over all days p should not deviate from a monthly value $monthcap_m$ that was obtained during a planning phase:

$$\sum_p modeload_{m,p} = monthcap_m + Dcap_m^{plus} - Dcap_m^{minus} \quad \forall m \quad (7)$$

The slack variables $Dcap_m^{plus}$ and $Dcap_m^{minus}$ are incorporated in the model to guarantee finding feasible solution (Mendez at al., 2006). In Eqs. 8-10 similar slack variables are used to penalize deviations from the monthly supply and demand requirements:

$$\sum_p supply_{s,p} = monthsupply_s + Dsupply_s^{plus} - Dsupply_s^{minus} \quad \forall s \quad (8)$$

$$\sum_p demand_{s,p} = monthdemand_s + Ddemand_s^{plus} - Ddemand_s^{minus} \quad \forall s \quad (9)$$

$$\sum_p demandpack_{s,p} = monthdemand_s + Ddemand_s^{plus} - Ddemand_s^{minus} \quad (10)$$

The binary variable $usecap_{m,p}$ is used to restrict number of switches from one operating mode to another one assigned to the same process unit during the same day p at the same production unit u :

$$\sum_{m \in MU_u} usecap_{m,p} \leq switchmax_u \quad \forall u, p \quad (11)$$

where MU_u is a subset of operating modes m which can be executed at a process unit u . The amount of oil s that can be prepared in a mixer b ($VO_{b,s,p}$ in Eq. 12) is limited by the volume restrictions of a mixer b :

$$Vmin_b usemix_{b,s,p} \leq VO_{b,s,p} \leq Vmax_b usemix_{b,s,p} \quad \forall b, p, s \in BS_b \quad (12)$$

In Eq. 12 the subset BS_b represents the only oils s that can be prepared in a mixer b . The binary variable $usemix_{b,s,p}$ is 1 then an oil s is mixed in a blender b during a day p and 0 otherwise. It is used to count the number of blending operations at a mixer b during a day p and to restrict it by the maximum allowable number of blending operations NBO_b :

$$\sum_{s \in BS_b} usemix_{b,s,p} \leq NBO_b \quad \forall b, p \quad (13)$$

The binary variables $X_{b,s,s',p}$ denotes an occurrence of preparing two incompatible oils s and s' at the same blender b during period p . Another binary variable $Y_{b,s,s',p}$ is equal to 1 if a blender b prepares an oils s in a current period p and an incompatible oil s' during the next period $p+1$. Such logical variables are used to count all occurrence of blending of incompatible oils at the same blender and penalizes such schedule, because shifts to incompatible products causes additional cleaning operations and generation of low-value oils:

$$penalty^{clean} = penaltycost^{clean} \left(\sum_{b,s \neq s',p} X_{b,s,s',p} + \sum_{b,s \neq s',p < P} Y_{b,s,s',p} \right) \quad (14)$$

The aforementioned binary variables $X_{b,s,s',p}$ and $Y_{b,s,s',p}$ are derived from the binary variable $usemix_{b,s,p}$ using the procedures of disjunctive programming that translate logical expressions to inequality constraints (Grossmann, 2009). In the interest of brevity, detailed definitions of $X_{b,s,s',p}$ and $Y_{b,s,s',p}$ are not presented here.

Slack positive variables from Eqs. 7-10 are used to compute penalties for deviating from a production plan for a given month:

$$penalty^{supply} = penaltycost^{supply} \sum_s \left(Dsupply_s^{plus} + Dsupply_s^{minus} \right) \quad (15)$$

$$penalty^{cap} = penaltycost^{cap} \sum_m \left(Dcap_m^{plus} + Dcap_m^{minus} \right) \quad (16)$$

$$penalty^{demand} = penaltycost^{demand} \sum_s \left(Ddemand_s^{plus} + Ddemand_s^{mir} \right) \quad (17)$$

Every product item has its own priority according to ABC analysis (Gudehus and Kotzab, 2009). The products with a mark ‘‘A’’ should be prepared and delivered during the first days of three decads in which a month is divided. The ‘‘C’’ products should be delivered during the last days of 10-day periods, and ‘‘B’’ has no preferable days of delivery. It is modeled using the bonus coefficients $coeff_{s,p}^{bonus}$. For products s with ‘‘A’’ rating, parameter $coeff_{s,p}^{bonus}$ has the highest value for the first day p of every decad and monotonically decreases till the first day of the next 10-day interval. The bonus coefficients for the ‘‘C’’ lubes are constructed in a similar way with the only difference that they reach their maximum values at the last days of every decad. The values of $coeff_{s,p}^{bonus}$ for ‘‘B’’ items do not vary depending on a day p . Using these bonus coefficients, we compute the bonus part of the objective function:

$$bonus^{priority} = \sum_{s,p} \left(demand_{s,p} coeff_{s,p}^{bonus} + demandpack_{s,p} coeff_{s,p}^{bonus} \right) \quad (18)$$

The objective function obj to be maximized is formulated as follows:

$$obj = bonus^{priority} - penalty^{clean} - penalty^{demand} - penalty^{su} \quad (19)$$

3. Solution strategy

The MILP model includes variables of different nature. The complexity of this formulation is mainly given by the integer variable $demandpack_{s,p}$ representing amount of packed oils and greases. Our solution strategy exploits the fact that the relaxation of

these integer variables does not greatly affect the production and supply schedule. The overall MILP model can therefore be decomposed into a pair of the smaller sub-problems that are solved sequentially.

We first construct the approximate sub-model by relaxation of the integer variables $demandpack_{s,p}$ and $stockpack_{s,p}$. After solving the first sub-problem, we fix the values of the binary variables defining the optimal production schedule, i.e. the binary variable $usecap_{mp}$ denoting selection of a particular operational mode m in a day p and the binary variable $usemix_{s,b,p}$ representing a usage of a blender b for preparing a product s . Finally we solve the second sub-model in which variables $demandpack_{s,p}$ and $stockpack_{s,p}$ have their original integer nature and the values of the binary variables $usecap_{mp}$ and $usemixer_{sb}$ are fixed at the values from the solution of the first relaxed sub-model.

4. Case study

The structure of the Omsk lubricant plant is depicted in Figure 1. The plant involves a continuous processing of vacuum residues and distillates into oil components and batch operations of blending and packing. Vacuum residues from the Omsk refinery are separated from asphaltenes at three propane-deasphalting units. Two aromatics extraction units remove aromatic hydrocarbons from deasphalted oils and refinery oils cuts, thus producing dearomatized oils called “raffinates”. Finally, base oils are generated at 3 dewaxing units after removing dissolved long chain paraffines. By blending these base oils with various additives, the desired properties of lubricants are achieved. Special mixers and tanks conduct blending operations, and final products are delivered to customers by either rail cars or trucks. The Omsk lubricant plant has its own 13 packing lines that can fill oils and greases into 43 different types of packings. Most of these packings are manufactured using own extruders and injection molding machines.

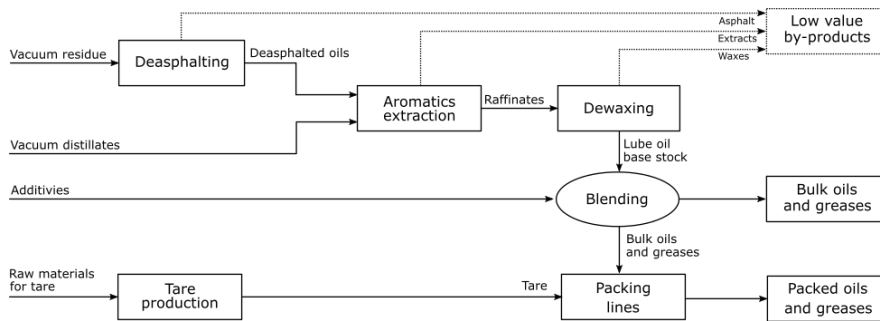

Figure 1. Structure of the Omsk lubricant plant

The mathematical model also includes several tank farms and storages. In total, there are 86 process units with 1404 different operating modes, 31 mixers, 216 tanks and 12 storages.

The model was written in GAMS 32.2 (McCarl et al., 2016) and solved with the MILP solver CPLEX 12 on a desktop PC with Intel Core I5-6500, 3.2 GHz and 8Gb of RAM. The dataset of process coefficients, supply and demand constraints used in the case study corresponds to the actual plant conditions at the beginning of August 2020. The original full-space model (i.e., without any relaxation of the integer variables) comprises 2,754,281 equations with 2,899,767 variables. 405,950 of the model variables are

discrete. The relaxed sub-problem, which we solve first according to the proposed strategy, contains 58,962 discrete variables less than the original problem.

To compare the numerical performance of our relaxation strategy and the computational results of solving the full-space model, we first attempted to solve the original scheduling MILP problem allowing the solver to use as much time, CPU and RAM resources as needed to close the optimality gap to zero. Unfortunately, after 2h and 19 minutes a memory issue interrupted the solving process at the integer solution with objective equal to -586,341,137 and the best bound of -562,994,661. The optimality gap was therefore 3.98%. The best bound we found during solving the full-space model is later used to assess the tightness of the solution of the proposed relaxation method.

Both sub-problems involved in our method were successfully solved without numerical issues in 506 seconds. Solving of the first approximate sub-problem with the relaxed integer variables took 343 seconds whereas the second sub-problem with the fixed production schedule was solved in 163 seconds provided the integer solution with the objective of -565,120,963. Thus, the proposed algorithm was able to find the better optimal solution with the optimality gap of 0.38% significantly faster than the rigorous solution of the original full-space MILP model.

5. Conclusions

In this work, we describe how the relaxation of integer variables can be exploited to effectively solve the large scheduling problems. The proposed algorithm involves sequential solution of the approximate sub-model constructed by relaxing integer variables representing delivery decisions and the second sub-problem that receives a production schedule from the solution of the first sub-model. The capabilities of the proposed method were shown through a case study of the Omsk lubricant plant. The proposed algorithm provides near optimal solutions with significant reductions in CPU time as compared with the rigorous solution.

Abstract

This paper addresses the design of the hydrogen supply chain (HSC) with a focus on the its decentralization degree. For this purpose, the superstructure used for HSC modelling is split into six echelons, i.e., primary energy source, H₂ production, conditioning and centralized storage, distribution, conditioning and decentralized storage, final usage. The originality of this work is also the diversification of H₂ production, conditioning and distribution methods for the H₂ supply both for the industry and mobility sectors. The problem is formulated in a mono-optimization framework, where the total cost of the HSC is minimized. The model involves a multi-period (2020-2040) mixed-integer linear programming (MILP) formulation that is implemented in the General Algebraic Modelling System (GAMS) environment, using CPLEX as a solver. The optimization results highlight some significant applications of the developed methodological framework. The assessment of the decentralization degree of the system, the diversification of the final H₂ demand, the share between liquid and compressed gaseous form are some of the Key Performance Indicators (KPIs) that can characterize a scenario. The scalability and replicability of the tool indeed allow to make forecasts on different geographical and temporal scales.

Keywords: hydrogen supply chain, multi-period optimization, mixed integer linear programming, GAMS, decentralization.

1. Introduction

The deployment of a hydrogen infrastructure constitutes one of the most challenging tasks due to the complexity and large spectrum of energy sources and technological bricks involved (e.g. water electrolysis technologies, liquid or gaseous conditioning and transport of H₂, Hydrogen Refuelling Station (HRS) options) serving a multitude of end uses. In this paper, the structure of the energy supply chain is studied with an innovative vision based on “think global, act local”, rather than “think local, act local” (Devine-Wright, 2013), emphasizing the decentralization degree of the hydrogen supply chain (HSC).

The pioneering work carried out by (Almansoori and Shah, 2006) has been followed by almost 15 years of active research in the field (Talebian et al., 2019). This work enlarges the scope of previous studies by considering the possibility for one production site to simultaneously satisfy different hydrogen demands coming from industry and mobility

via the development of a superstructure that can embed a large set of technological bricks for the construction of the HSC.

Following this introduction, the problem formulation and the key points of the methodology will be presented. A case-study will then be analysed with the most relevant results. Finally, the conclusions and critical analysis of the model will be highlighted, thus opening perspectives in terms of methodology and scenario definition.

2. Text

2.1. Main assumptions

A great challenge for modern day energy systems models is to capture the high degree of variability and complexity that exists in energy systems and represent the involved technologies. Several formulations have been developed including simulation vs. optimisation, top-down vs. bottom-up (e.g. MARKAL) (Pfenninger et al., 2014). The core innovation of this work lies in the modelling of the HSC with a spatial and temporal resolution adapted for addressing:

- the discretization of a territory into grids, each grid being characterized by demands targeting industry and mobility markets;
- the simultaneous satisfaction of both demands;
- various technical solutions for H₂ logistics, i.e. gaseous and liquid, corresponding to the final conditions of usage in industry or mobility (i.e., pressure level);
- interconnection between grids in order to valorise the energy produced from one grid to another grid (primary energy sources);

The skeleton of the model was taken from the works developed by (De-León Almaraz et al., 2014; Guilarte and Azzaro-Pantel, 2020). This work aims to show all the different solutions and scenarios that can be implemented in the extended tool. No investment cost has been considered for the HRS on the industrial site which suggests that the structure already exists. The advanced model focuses mainly on two KPIs, on the one hand, the diversification of the energy source, status and utilization of hydrogen, and on the other hand, the centralization degree of the production and storage facilities. The replicability and scalability of the tool make it flexible and usable for any type of scenario.

The problem is presented as a multi-period mono-optimization model in which the time slots are divided into 4 periods “t” of 5 years “n” each. The investment costs related to H₂ technologies are reduced at the beginning of each period due to a learning rate factor. Furthermore, the investment costs are involved only at the beginning of each period (i.e. end of year 0,5,10,15). The parameters of the years belonging to the same period, including the H₂ demand have been kept constant, except for the costs, which are discounted as explained in Eq. (3). The model aims finally to minimize the yearly cost of HSC.

In line with the majority of the works analysed in the literature, this formulation of the HSC design problem is based on a mixed-integer-linear-programming (MILP) approach. The model is developed in the General Algebraic Modelling System (GAMS) environment, using the CPLEX solver in a computer with Intel® Core™ i5-6200U processor with CPU @ 2.30GHz and 16GB RAM. A comprehensive explanation of all the parameters, formulas and constraints can be found in (De-León Almaraz et al., 2014; Guilarte and Azzaro-Pantel, 2020).

The design of the HSC is represented by a 6-echelon superstructure: primary energy source, hydrogen production, conditioning and centralized storage, distribution, conditioning and decentralized storage, final usage. A schematic view (Fig. 1) gives additional information on the energy sources and technologies that have been analysed in this work. Two options for H₂ production have been considered, i.e., electrolysis powered by renewable electricity sources (RES) (or by the grid if RES is not sufficient) or by Steam Methane Reforming (SMR).

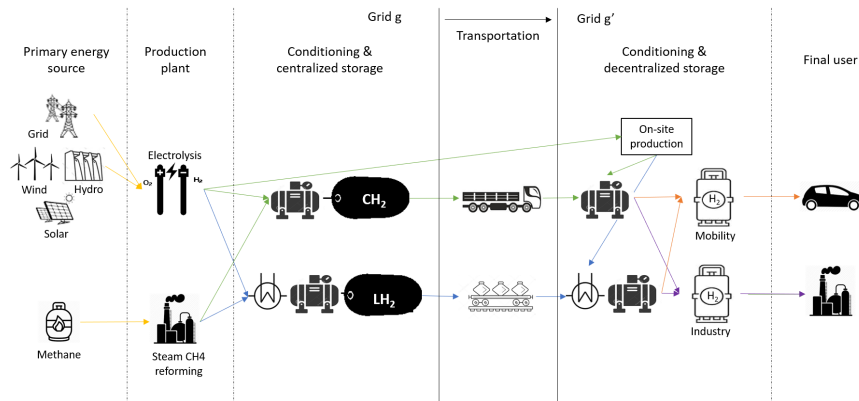

Figure 1: Definition of the H₂ supply chain superstructure

The discretization of the territory allows each area (the so-called grid) to be represented with its own characteristics (e.g. availability of RES, different H₂ demands, etc.). Furthermore, all possible exchanges between grids, both internal and external to the system have been considered (Fig. 2): primary energy sources can be imported/exported from any grid and/or bought from a source outside the system; the H₂ produced, including the one produced on-site, can be transported to any grid where it will be conditioned and made ready for end-use (i.e. mobility or industry).

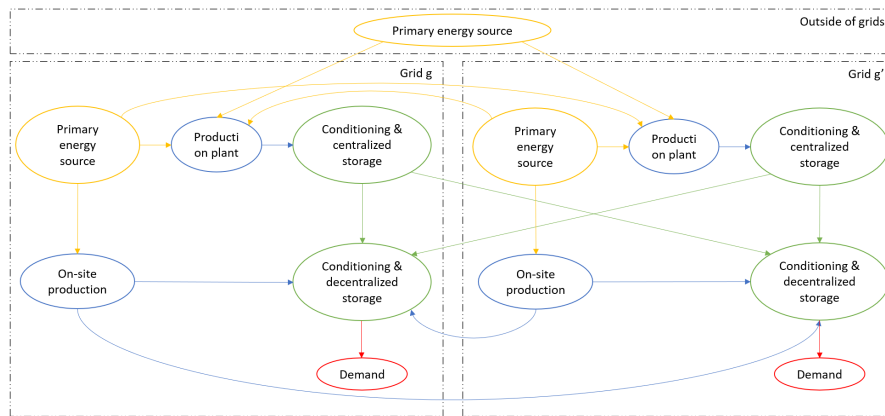

Figure 2: Interconnection between the grids of the HSC superstructure

2.2. H₂ and primary energy sources mass balance

The new mass balance constraint is shown in Eq. (1): the total H₂ production (PT) in all "g" grids, independently of its form "i" (i.e. compressed or liquid) and of the size of the plant "j" (i.e. centralized or on-site production), must satisfy the different H₂ demands (DT) "k" (i.e. mobility and industry) in each "g" grid.

$$\sum_{ijg} PT_{ijg} = \sum_{kg} DT_{kg} \quad \forall i, j, g, k \quad (1)$$

The calculation of the primary energy costs (ESC, €/day) is composed of two parts. The former considers the costs of the energy present in the territory including the transportation costs, whereas the latter considers the costs due to the purchase of energy from an off-grid source.

2.3. Economic parameters

The investment cost of the facilities (FCC) (see Eq. (2)) includes the facility capital costs (i.e. production "p" (PCC), storage "s" (SCC) and fuelling station "f" (FSCC)) respectively for the installed number of each facility (i.e. number of production plants (NP), storages (NS) and refuelling stations (NFS)). All these factors are then divided by a learning factor (LearnF) to consider cost reduction of some technologies with mass production and market penetration (e.g. electrolyzers). The facility capital costs and the learning factor are defined at the beginning of each period "t".

$$FCC_t = \frac{1}{LearnF_t} \sum_{ig} \left(\sum_{pj} PCC_{pij} NP_{pijgt} + \sum_{sj} SCC_{sij} NS_{sijgt} + \sum_{fj} FSCC_{fkj} NFS_{fkjgt} \right) \quad \forall t \quad (2)$$

2.4. Actualization factor

All the economic variables (e.g. PCC) are discounted to year "n" see Eq. (3), where "i" is the discount rate.

$$PCC_n = PCC_0 \frac{1}{(1+i)^n} \quad \forall n \quad (3)$$

2.5. Optimization variable

The total cost (TCTotal) as expressed in Eq. (4), representing the costs of the whole HSC over the timeframe analysed, is the objective function to be minimized. The TCTotal consists of the sum of investment costs for facilities and transportation means (TCC) and the sum of the total yearly operating costs (TOC) that are discounted (see Eq. (3)).

$$TCTotal = \sum_t (FCC_t + TCC_t) + \sum_n TOC_n \quad (4)$$

3. Case study

As a first case study for the validation of the model, the deployment of the HSC in the Occitania region in France was analysed considering the availability of energy sources and the H₂ demand as presented in (De-León Almaraz et al., 2014). The Occitania territory was discretized into 8 grids and in this scenario, the H₂ demand for industry and mobility has been set as an equal level corresponding to 23.5 tons per day (t/d) of H₂ at

the beginning of the study and progressively increasing up to roughly 600 t/d at the fourth period.

4. Results

Two important KPIs of the HSC design have been further analysed, i.e., the decentralization degree and the share between compressed and liquid H₂. Due to the increasing demand for H₂ in the Occitania Region, the model has to make trade-offs between centralized and decentralized H₂ production, mitigating the cost between production and distribution logistics. Starting in period 1 with 100% of H₂ produced on a decentralized basis, more than 50% of the production becomes centralized at the end of period 4 as shown in Figure 3 (a). This can be explained by the scaling effect on the investment cost of H₂ production technologies that reduces the H₂ production cost. Nevertheless, this should be in contradiction with the reduced CO₂ footprint of H₂ that was not yet considered in the first scenario.

Figure 3: KPI analysis, centralized vs. decentralized (a) and CH₂ (compressed gas) vs. LH₂ (cryogenic liquid) (b)

Another result of the model concerns the mode of H₂ distribution, i.e. either as compressed gas (CH₂) or as cryogenic liquid (LH₂) (Figure 3 (b)). Despite the higher energy density of LH₂ allowing the distribution of larger volumes of H₂, the investment and operating costs for liquefaction and cryogenic tankers remain prohibitive over the fourth periods. CH₂ distribution is preferred because of the good share between centralized and decentralized production which reduces distribution distances. However, other issues have to be considered such as the availability of space for the storage of gaseous H₂ compared liquid H₂. It is interesting highlight that the solution with liquid H₂ is not considered for a centralized solution because of the currently high investment and operating costs of LH₂ vessels. Nevertheless, the bulk and footprint of the solution cannot be ignored. Road transportation is mainly dependent on the available H₂. In the first 2 periods, only tanker trucks are considered, while in the last period there is a higher number of tube trailers (14), even though the amount of H₂ that the tanker trucks (8) transport is higher (71% LH₂ vs. 29% CH₂).

HSC investment costs supporting the development of H₂ in the Occitania region integrate the contribution of H₂ production plants, centralized storage with conditioning and transportation modes, decentralized storage and refuelling stations as shown in Figure 4 (a). Around 54% of the investment costs of the HSC are related to centralized storage, conditioning and distribution due the development of centralized production plants over the fourth time periods. Concerning operating and maintenance costs, the cost of electricity and natural gas needed for the production of H₂ represents the main operating costs (76.7%) as shown in Figure 4 (b).

Figure 4: Share of the investment (a) and maintenance costs (b)

5. Conclusions

The model developed for the optimization of hydrogen supply chains was used for the case of the Occitania region. The optimal design of HSC was implemented on the basis of total cost minimization and some KPIs such as the decentralization degree of the production and storage plants or the share between liquid and compressed hydrogen. The model is scalable and replicable to forecast and understand where, how and in which conditions the H₂ market will evolve. The methodology can be further improved with a multi-objective analysis, including the minimization of CO₂ emissions to assess the trade-offs between low-carbon technologies (electrolysis powered by renewable electricity or SMR with CCS, Carbon Capture and Sequestration) as well as the scale-up effect of large-size electrolyzers which is a key driver for cost reduction. Furthermore, few technology solutions such as H₂ pipelines or hydrogen importing from another region, could also be implemented.

Abstract

This contribution addresses the optimal design and operation of a reverse supply chain of empty agrochemical containers. The problem is tackled by means of a multi-period MILP model, which relies on a superstructure that includes all the potential/existing collection centers and possible/existing plastic treatment plants, as well as the farms. Its decisions involve selecting the new facilities, their sizes, and installation periods, along with the operation of the facilities and the material flows among the various nodes in each planning period. A realistic case study has been solved under several scenarios in order to analyze the model scalability and to test its response to changing conditions.

Keywords: Reverse Logistics, Supply Chain Design, Empty Agrochemical Containers.

1. Introduction

In recent years, reverse logistics has become a field of importance for many organizations due to growing environmental concerns, legislation, corporate social responsibility and sustainable competitiveness (Agrawal et al., 2015). The importance increases significantly when the products handled are harmful to the health of people, animals, and the environment, and must be treated in a special way prior to disposal or recovery. Reverse logistics refers to the process of planning, implementing and controlling backward flows of raw materials, in-process inventory, packaging and finished goods, from a manufacturing, distribution or use point, to a point of recovery or point of proper disposal (Dekker et al., 2004). The definition of reverse logistics has been changing over time and widening its scope with the interest of researchers. The number of scientific publications related to the field has steadily grown during last decade (Govindan et al., 2014), showing the attention that the subject entails. However, regarding the reverse supply chains of empty agrochemical containers, few contributions have been found. Recently, Sorichetti et al. (2018) reported a preliminary approach to address the design of the reverse network of empty agrochemical containers in a region of Buenos Aires, Argentina. Various aspects of relevance are not taken into account, such as the operation and installation costs of facilities and the transportation from farms to collection centers. The optimal configuration of the reverse supply chain network of empty agrochemical containers is a challenging problem that deserves attention and will be addressed in the remaining sections of this contribution, which is organized as follows. The mathematical model is presented in Section 2. In Section 3, a realistic case-study, which allowed testing the formulation, is described. Computational

results associated with various scenarios are also presented. The contribution ends with concluding remarks and a summary of future work.

2. Mathematical Programming Formulation

The multi-period mixed-integer linear programming (MILP) model presented in this section allows making the following decisions: (i) the number and location of collection centers – intermediate points for collecting containers –, as well as plastic treatment plants to be built, (ii) the time period in which each facility will be installed and the ones in which it will operate, (iii) the capacities of the various storage and processing facilities, (iv) for each time period, which are the flows of materials between farms, which generate the containers, and the collection/treatment points, as well as the flows between collection centers and plastic treatment plants, with the goal of minimizing the total actual discounted cost of the network.

2.1. Sets/indices

F/f	farms
J/j	collection centers
P/p	plastic treatment plants
J^i/P^i	subset of collection centers/treatment plants that are already installed at the beginning of the planning horizon
M/m	set of available sizes of collection centers
N/n	set of available sizes of treatment plants
$T/t, t'$	time periods

2.2. Parameters

g_{ft}	number of containers to be generated by farm f during period t
$d_{ff}/d_{fp}/d_{jp}$	distance between the different types of nodes
k_m^{min}/k_n^{min}	minimum capacity of a collection center/treatment plant of size m/n
k_m^{max}/k_n^{max}	maximum capacity of a collection center/treatment plant of size m/n
nt^j / nt^p	number of time periods required by a new collection center/treatment plant to start operating from the period it is installed
$c^{fj}/c^{fp}/c^{jp}$	transportation cost per distance unit between the different nodes
ir	interest rate
fc_m/fc_n	fixed cost of operation of a collection center/treatment plant of size m/n
vc	variable production cost of plastic treatment plants
cc_m^j/cc_n^p	construction cost of a collection center/treatment plant of size m/n , including the cost of infrastructure and in the case of treatment plants, the equipment cost.
cap	loading capacity of the trucks that travel between collection centers and treatment plants
nf_{ft}	number of trips required to transport the total generation of containers of farm f during period t
$nmax$	$\max(nt^j ; nt^p)$ number of periods that must be considered previous to the beginning of the planning horizon for the installation of facilities

2.3. Binary variables

Y_{jt} / Y_{pt}	equal to one if collection center j /treatment plant p operates in period t
I_{jmt} / I_{pnt}	equal to one if collection center j of size m /treatment plant p of size n is installed in period t

2.4. Positive variables

$S_{fjt}/S_{fpt}/S_{jpt}$ number of containers sent between nodes of different type in period t

2.5. Equations

$$g_{ft} = \sum_{\forall j \in J} S_{fjt} + \sum_{\forall p \in P} S_{fpt} \quad \forall f \in F, \forall t \in T, t > n_{\max} \quad (1)$$

$$\sum_{\forall f \in F} S_{fjt} = \sum_{\forall p \in P} S_{jpt} \quad \forall j \in J, \forall t \in T, t > n_{\max} \quad (2)$$

$$\sum_{\forall m \in M} \sum_{\forall t' \in T, t'+nt' \leq t} I_{jmt'} \geq Y_{jt} \quad \forall j \in J, j \notin J^i, \forall t \in T \quad (3)$$

$$\sum_{\forall n \in N} \sum_{\forall t' \in T, t'+nt' \leq t} I_{pnt'} \geq Y_{pt} \quad \forall p \in P, p \notin P^i, \forall t \in T \quad (4)$$

$$\sum_{\forall m \in M} \sum_{\forall t \in T} I_{jmt} \leq 1 \quad \forall j \in J \quad (5)$$

$$\sum_{\forall n \in N} \sum_{\forall t \in T} I_{pnt} \leq 1 \quad \forall p \in P \quad (6)$$

$$\sum_{\forall f \in F} S_{fjt} \leq k_{m=\max}^{\max} Y_{jt} \quad \forall j \in J, \forall t \in T, t > n_{\max} \quad (7)$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \leq k_{n=\max}^{\max} Y_{pt} \quad \forall p \in P, \forall t \in T, t > n_{\max} \quad (8)$$

$$\sum_{\forall f \in F} S_{fjt} \leq \sum_{\forall m \in M} \sum_{\forall t' \in T, t'+nt' \leq t} k_m^{\max} I_{jmt'} \quad \forall j \in J, \forall t \in T, t > n_{\max} \quad (9)$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \leq \sum_{\forall n \in N} \sum_{\forall t' \in T, t'+nt' \leq t} k_n^{\max} I_{pnt'} \quad \forall p \in P, \forall t \in T, t > n_{\max} \quad (10)$$

$$\sum_{\forall f \in F} S_{fjt} \geq k_{m=1}^{\min} Y_{jt} + \sum_{\forall m \in M} \sum_{\forall t' \in T, t'+nt' \leq t} (k_m^{\min} - k_{m=1}^{\min})(Y_{jt} + I_{jmt'} - 1) \quad \forall j \in J, \forall t \in T, t > n_{\max} \quad (11)$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \geq k_{n=1}^{\min} Y_{pt} + \sum_{\forall n \in N} \sum_{\forall t' \in T, t'+nt' \leq t} (k_n^{\min} - k_{n=1}^{\min})(Y_{pt} + I_{pnt'} - 1) \quad \forall p \in P, \forall t \in T, t > n_{\max} \quad (12)$$

$$\begin{aligned}
TC_t = & \sum_{\forall m \in M} \sum_{\forall t' \in T, t'+nt^j \leq t} fc_m(Y_{jt} + I_{jmt'} - 1) + \sum_{\forall j \in J} \sum_{\forall m \in M} cc_m^j I_{jmt} + \\
& \sum_{\forall p \in P} \sum_{\forall n \in N} cc_n^p I_{pnt} + \sum_{\forall n \in N} \sum_{\forall t' \in T, t'+nt^p \leq t} fc_n(Y_{pt} + I_{pnt'} - 1) + \\
& \sum_{\forall p \in P} vc \left(\sum_{\forall f \in F} S_{fp} + \sum_{\forall j \in J} S_{jpt} \right) + \sum_{\forall f \in F} \sum_{\forall j \in J} c^{fj} 2d_{fj} \frac{S_{fjt}}{g_{ft}} nf_{ft} + \\
& \sum_{\forall f \in F} \sum_{\forall p \in P} c^{fp} 2d_{fp} \frac{S_{fpt}}{g_{ft}} nf_{ft} + \sum_{\forall j \in J} \sum_{\forall p \in P} c^{jp} 2d_{jp} 1.2 \frac{S_{jpt}}{cap} \quad \forall t \in T
\end{aligned} \tag{13}$$

$$\min \sum_t \frac{TC_t}{(1+ir)^{t-1}} \tag{14}$$

Eq. (1) prescribes that all the containers generated by a farm in a certain period, must be sent to a collection center and/or a treatment plant in the same planning period. In turn, Eq. (2) states that all the containers that are received by a collection center in a given period must be sent to a plastic treatment plant in the same period. Expression (3) assures that a collection center can operate in a certain period only if it has been installed in a previous one. Expression (4) forces treatment plants to obey the same restriction. Expressions (5) and (6) force every facility to be installed at most once with a unique size. According to Expressions (7) to (10), the number of containers sent to a given collection center/treatment plant in each period should not overpass the maximum storage capacity corresponding to the installed size. Following analogous ideas, the minimum capacity of each collection center or plastic treatment plant to be installed is given by expressions (11) and (12), respectively. Eq. (13) comprises the different costs involved in the design and operation of the logistics network in each period of the planning horizon. In order to determine how much future projected cash flows are worth at present, these cost components are affected by an annual interest rate, according to the multi-period total discounted cost formula given by Expression (14).

3. Computational Results

The model has been implemented in GAMS 23.6, running on an Intel Core i8 computer, with 3.4 GHz, 8 GB of RAM, and using CPLEX as a solver. As shown in Table 1, a base case (Case 1) has been initially tackled. It takes into account a super-structure composed of 300 farms, 20 potential collection centers, 8 potential treatment plants and no existing facilities that are already installed. Two different capacity modules for collection centers and treatment plants have been allowed for. The planning horizon considers 5 years of operation, plus an initial year for the installation of the first facilities. Thus, during the initial year the system does not operate, but the required facilities are being built. This base case has been extended to test the scalability of the model, analyzing different dimension scenarios presented in Table 1. In a second stage, the sensitivity of the formulation to parameter disturbances has been assessed, analyzing the scenarios presented in Table 2, which consider the same super-structure as the base case. All the model instances were run to optimality and the obtained results are presented in Table 3.

Table 1. Dimensionality of some of the analyzed scenarios.

	Farms	Collection centers/ available sizes	Treatment Plants/available sizes	Periods
Case 1	300	20/2	8/2	5
Case 2	450	20/2	8/2	5
Case 3	600	20/2	8/2	5
Case 4	300	20/2	8/2	10
Case 5	300	20/3	8/3	5

Table 2. Scenarios associated with perturbations of the base case parameters.

	Disturbed parameter	Disturbance type
Case 6	Containers generation	Gradual decrease from period 3 onwards
Case 7	Transportation costs	10% increase
Case 8	Transportation costs	20% increase
Case 9	Installation costs	10% increase
Case 10	Installation costs	20% increase

Table 3. Computational results corresponding to the analyzed scenarios.

	Total variables	Binary variables	Total constraints	Objective Function	CPUs	Centers/ plants
Case 1	54,447	504	2,799	1,513,663.31	717	7/2
Case 2	77,647	504	3,549	2,288,839.52	1,670	3/4
Case 3	102,847	504	4,299	2,833,478.15	3,459	3/4
Case 4	96,152	870	5,444	2,307,106.48	487*	9/4
Case 5	52,615	672	2,799	1,238,574.16	1,880	7/1
Case 6	54,447	504	2,799	1,478,809.46	1,301	7/2
Case 7	54,447	504	2,799	1,542,416.85	608	7/2
Case 8	54,447	504	2,799	1,571,170.39	410	7/2
Case 9	54,447	504	2,799	1,618,496.74	883	7/2
Case 10	54,447	504	2,799	1,723,330.16	1,208	7/2

*Base Case solution taken for the five initial periods

As shown in Table 3, the optimal solution of Case 1 comprises seven collection centers and two treatment plants, which are all installed before the start of the planning horizon and operate during all the periods. Two collection centers are of the smallest size, allowing a maximum capacity of 5,000 containers per period, while the remaining five double this capacity. Regarding treatment plants, one small and one large are chosen, with a maximum capacity of 60,000 and 100,000 empty containers, respectively. The solutions of Cases 2 and 3, which correspond to an increase in the number of farms, comprise 3 collection centers and 4 treatment plants. All the treatment plants associated with the solution of Case 2 have the smallest size, while two small and two large correspond to Case 3. In both situations, two collection centers are installed with the highest capacity. A comparison of these results reveals that the effect of managing a greater number of farms is to increase the investment in treatment plants, allowing more direct shipments to them. Case 4 takes into account the same superstructure as Case 1, but doubles the length of the planning horizon. This scenario has been tackled with two different solution approaches. The first one considers the solution obtained in Case 1 as given, and extends the horizon to evaluate potential new facilities. In this case, the optimal solution has been found in only 487 s. The second approach does not resort to any initial network and the 10 periods are taken altogether. A solution with a gap of

10% has been reached in 2,530 s. The solution obtained is the same in both cases; it comprises 12 facilities: 9 collection centers and 3 treatment plants. A comparison of the solutions corresponding to Cases 1 and 4 shows that the effect of having a longer planning horizon is to increase the investment in the installation of facilities. The aim is to reduce transportation costs along a longer planning period, that otherwise would have been much higher. Whereas Case 1 solution has installation (59.15%) and transportation (19%) costs as the main components, the solution of Case 4 has the following cost participation: installation (61.42%) and transportation (11%). Case 5 also considers the same superstructure as Case 1, but allows three different capacity modules for collection centers and treatment plants, instead of two. The obtained solution includes 7 collection centers and only one treatment plant of the largest size, with a capacity of 200,000 containers per period. With respect to the sizes of collection centers, only one has the smallest capacity and four are installed with the largest size (20,000 containers per period). These results indicate that, when larger facility sizes are allowed, economies of scale are taken advantage of. Case 6 considers a reduction in the number of empty containers starting from period 3. The solution reports the same initial network as Case 1, but starting periods 4 and 5 two collection centers stop operating in order to cope with the reduction of empty containers to be handled. As seen in Table 2, Cases 7 to 10 take into account different increments in the installation and operation costs with respect to Case 1. Since the increases are not significant, the obtained networks remain the same as in Case 1 and only augment the value of their objective function. Finally, Table 3 reveals that the proposed model always exhibits a satisfactory computational behavior.

4. Conclusions and future work

An MILP model for a multi-period reverse logistics network design problem has been presented, taking into account several realistic features. The model has been applied to the case of empty agrochemical containers and has been tested under various scenarios, exhibiting a very good computational behavior. The proposed approach can be easily adapted to address other recyclable waste collection systems (electronic and electric devices, household plastic waste, cardboard and paper, etc.) having two tiers: collection centers and disposal/recycling facilities. The incorporation of environmental and social objectives, in addition to the economic ones, will be considered in the future. Further testing will be done to better study scalability and sensitivity issues.

Designing a Rectification Strategy for Managing Disruptions in LNG Supply Chain

S.V.Ramanan,^a and Rajagopalan Srinivasan^{a,*}

^a*Indian Institute of Technology Madras, Chennai 600036, India*

raj@iitm.ac.in

Abstract

Global LNG trade continues to grow owing to increasing energy demand, especially from the Asia-Pacific region. However, the trade of LNG has inherent vulnerabilities that can eventually manifest as disruptions. Typical consequences of disruptions include excess or shortfall of inventory, and plant shutdown, all of which can significantly impact profit. In this paper, we seek to develop a systematic methodology that can be used by an LNG receiving terminal to mitigate the effects of disruptions. We develop an agent-based dynamic model of the LNG supply chain and use it to systematically design operational interventions that can ameliorate the adverse consequences of disruptions. As a case study, we focus on a sudden decrease in demand. The disruption is managed through fire sales of a product. We demonstrate that a key parameter in this rectification strategy, the fire sale price, can be systematically determined using the proposed agent-based model.

Keywords: LNG supply chain, Agent-based model, disruptions management, rectification strategies.

1. Introduction

Supply Chains are highly interlinked networks that involve a set of companies collaborating with one another for the timely delivery of products to end customers. Given the complexity of interactions, supply chains are susceptible to various disruptions that can inhibit the routine and systematic operations, leading to overall inefficient performance. There is always a trade-off to consider while designing for the reliable and unhindered operation of any supply chain (SC). This trade-off can either choose the right location of sourcing raw-materials, the best mode of transport for safe and faster delivery to the buyer, and the understanding of the internal operational processes to deliver the right products at the right place and at the right time. While nearby sourcing can always be a better option considering shorter lead times, resource constraints largely inhibit the development of proximate SC networks. Most present-day supply chains are globalized mainly due to increased customer demands, high competitiveness, improved communication, and reduced transit times leading to a highly interlinked and complex SC. With the increased dependence on imports, the SC becomes vulnerable to disruptions.

The LNG SC involves NG extraction and liquefaction at an export terminal, transportation through LNG carriers, and receiving and regasification at an import terminal. The receiving terminal is attached to a regasification plant that sells natural

gas (called Regasified LNG) in large quantities through conventional gas pipelines or in small quantities (called Retail-LNG) through road or rail-based virtual pipelines to various customers. Some receiving terminals also cater to maritime customers like FSRUs and LNG cooling services; this product is called Reload-LNG. The material flow diagram in a typical LNG supply chain is depicted in Figure 1.

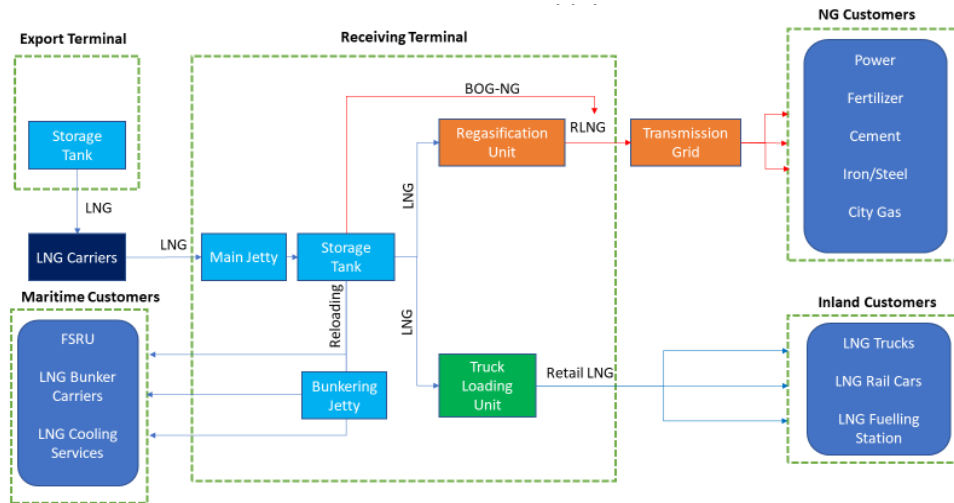

Figure 1. Overview of LNG Supply Chain

1.1. LNG Supply Chain Disruptions

Each section of the supply chain is exposed to various disruptions. Disruptions in LNG supply can happen due to political/economic situations, unplanned maintenance, or strikes at the liquefaction terminal. Marine transport of LNG can be affected by strait closure, marine accidents, piracy, and other exogenous factors like hurricanes, tsunami, etc., leading to either delay or loss of shipment. Unexpected orders or order cancellations by customers can also perturb the normal operation of the supply chain.

While an exhaustive description of real-world instances of LNG supply chain disruptions is beyond the scope of this work, the present glut in the global supply of LNG and the fall in demand due to the covid-19 pandemic is a good instance that illustrates the potential effects of supply-demand disruptions. As an example, Indian LNG import terminals were forced to declare force majeure as their customers shut down operations owing to a nation-wide lockdown (Jaganathan, 2020). Such abnormal situations can lead to major financial implications and motivate a systematic approach to disruption management.

1.2. Literature review

Significant research has been conducted on techniques for managing disruptions in supply chains. Most of them involve qualitative reasoning, relying on expert opinions to manage disruptions (Urciuoli et al., 2014). Only a few quantitative studies have reported quantitative methods such as simulation and modeling. An integrated procedure to handle disruptions in a supply chain was developed by (Behdani et al., 2012), consisting of separate pre-disruption and post-disruption considerations. The pre-disruption steps involve risk identification, risk quantification, risk evaluation & treatment, and risk

monitoring. The post disruption steps involve disruption detection, reaction, recovery, and learning. A survey of the literature suggests that there is very limited research on post-disruption recovery procedures. Also, managing the ripple effect arising from low frequency-high impact disruptions has attracted limited attention. Based on the modeling paradigm, approaches for modeling disruptions can be classified into optimization-based, simulation-based, control-theory based (Dolgui et al., 2018) schemes. Given the limited research towards managing disruptions in LNG supply chains, in this paper, we propose an agent-based dynamic simulation for disruption management in the LNG SC.

We consider a major LNG receiving terminal in India to test the effectiveness of our approach. We take up a case study of an unexpected decrease in RLNG demand and study its impact on the receiving terminal. We devise rectification strategies to counteract the effect of the disruption and as well provide insights on a key decision parameter involving the recovery action that will lead to economic benefits for the focal company. The rest of the paper is organized as follows. Section 2 gives an overview of the agent-based modeling technique. An application of the developed model is analyzed with an illustrative case study in section 3. Finally, section 4 provides some concluding remarks and future areas of research.

2. Agent-Based Model of LNG Supply Chain

Agent-based modeling is a widely used technique used to capture the various entities and their interactions in the supply chain. An agent is described as any entity that can make decisions, initiate or perform activities, manage resources, and interact with other agents in the system. Each agent has a set of behavioral attributes. The heterogeneous nature of the supply chain makes agent-based modeling a suitable simulation paradigm to capture the various dynamics inherent in the system.

We have developed a dynamic simulation model of the LNG SC. Eight distinct agents interact, exchange information and make decisions leading to the overall operations of the supply chain. The various entities in the supply chain, including LNG supplier, LNG carrier, receiving terminal, and customers, are modeled as agents that interact with one another. The various internal departments of the LNG receiving terminal, which is the entity in focus in this study, including the sales, operations, procurement, and jetty, are also modeled as rational, self-interested decision-making agents. The sales agent keeps track of customer demands, the operations agent oversees the regasification process, the procurement agent makes decisions regarding when to procure LNG and the requisite quantity, and the jetty agent oversees the cargo unloading. We implemented the agent-based model using AnyLogic® Simulation Modelling Tool, version 8.6.0 (AnyLogic, 2020)

We performed the simulations for the normal operation of the LNG supply chain using the parameters listed in Table 1. The overall simulation horizon is 365 days with each time tick corresponding to an hour of operations. The demands for the various products are stochastic and drawn from normal distributions with a standard deviation of 5% of the nominal value. Various KPIs, including profit, customer satisfaction index, capacity utilization, number of unloaded cargos, and demurrage period, are calculated for each run of the simulation. Due to the stochastic nature of the demand and disruptions, we use Monte Carlo simulation to arrive at statistically significant results. All results are

reported as average over 1000 runs of the simulation. The computational time for conducting a set of Monte Carlo simulations is 60 minutes. For the normal operation, the receiving terminal makes a profit of \$798 million, with 242 cargos procured annually.

Table 1. LNG SC Simulation Parameters

Parameter	Value
Simulation Horizon (days)	365
Demand Cycle (days)	7
LNG Procurement Cost (\$/MMBtu)	4.16
Nominal Product Demand (10^3 m ³) [RLNG Retail-LNG Reload-LNG]	[647 6 70]
Product Sales Price (\$/MMBtu) [RLNG Retail-LNG Reload-LNG]	[5.0 10.0 5.43]

The LNG supply chain is subjected to a number of disruptions. We used the HAZOP analysis based approach proposed by (Adhitya et al., 2009) to identify the possible sources of deviation from normal operations, their causes, and consequences. The study requires the development of a comprehensive supply chain flow diagram and analyzing the activities of each agent. Each activity involves performing a sequence of tasks that can be subject to deviations. Each deviation is generated using a set of guidewords. For example, the sales department collates product demand from various customers. Any deviation from the nominal demand towards a "high" or "low" (guidewords) value can have consequences on the receiving terminal leading to "low" or "high" storage tank inventory. This can further propagate both upstream and downstream of the supply chain, as illustrated below. We then analyze the existing safeguards available that can help the SC recover from the deviation (for example, safety stocks). If the safeguards are inadequate, we propose additional mitigative actions to manage the disruption, as illustrated next using a demand disruption case study.

3. Demand Disruption Case Study

Consider the case of a significant decrease in demand of RLNG by 75% due to exogenous factors affecting the customers' businesses for a long duration (average of 6 months). This leads to challenges to the supply chain, specifically related to LNG inventory. The existing inventory management policy of the terminal uses the traditional fixed reorder level (ROL) based replenishment strategy. This policy works well during normal conditions where the demand is close to the nominal values. Here, we seek to evaluate its suitability during demand decrease disruptions. Various disruption scenarios are generated stochastically with both the time of disruption initiation and the total duration of disruption sampled from a uniform distribution (Behdani et al., 2019). During each disrupted case, when the RLNG demand reduces drastically, there is a supply-demand mismatch due to the underlying ROL-based LNG procurement policy. As the quantity of LNG procured is aligned with the nominal situation, it is much greater than the actual customer demand during the period of the disruption.

Consequently, there is an issue of inadequate ullage space in the receiving terminal. This causes a ripple effect when LNG carriers arrive at the terminal for unloading and are forced to wait until the inventory in the LNG storage tanks falls to a level sufficient for the unloading of the cargo. This leads to demurrage charges and a continuous domino effect on all subsequent LNG carriers.

Our simulation studies of this scenario reveal that the decrease in demand would lead to a reduction of profit for the terminal to \$536 million (a decrease of \$260 million) due to the demand decrease. However, the loss is exacerbated by \$2.2 million due to demurrage charges. While little can be done about the exogeneous demand disruption, the impact due to demurrage can be tackled by triggering a suitable rectification strategy when the terminal becomes aware of the demand reduction. Among the various options, we chose the RLNG fire sale as a possible rectification strategy. In this rectification strategy, the receiving terminal sells the excess LNG inventory at a very low price (called the fire-sale price) to facilitate smooth unloading of arriving cargo. To evaluate the economic implications of this, we performed a simulation-based study by varying the key decision parameter, i.e., the RLNG fire-sale price, to identify the point of economic break-even. If the fire-sale of the RLNG is possible at any price above this break-even price, the terminal will make a higher profit compared to the unrectified case. By evaluating the entire supply chain performance for various RLNG fire-sale prices, we arrive at the break-even plot depicted in Figure 2. It can be concluded that at any RLNG fire sale price above \$3.52/MMBtu, the terminal will be economically better-off. For instance, at an RLNG fire-sale price of \$3.75/MMBtu, the demurrage dropped drastically by 98%, as shown in Table 2. The mean profit with the rectification increases by \$4 million as compared to the unmanaged case.

Figure 2. Effect of RLNG Fire Sales price on mean profit

Table 2. Effect of rectification strategy on performance

KPIs	Nominal Operation	Disrupted operation	
		Unrectified	Rectified
Overall Profit (Million \$)	798 (± 7.27)	536 (± 13.76)	540 (± 10.7)
Demurrage (h)	-	658 (± 209.05)	11 (± 20.1)
RLNG Fire Sales Quantity (10^3 m^3)	-	-	628 (± 45)

4. Concluding Remarks

This paper addresses the management of disruptions in LNG supply chains using an agent-based dynamic simulation technique. The model can be used to design rectification strategies that can be triggered when a disruption occurs in the supply chain. Various disruptions that can occur in the LNG supply chain are demand decrease, demand increase, reduction in production, and transportation delay. We have focused on an RLNG demand decrease case study in this paper. The consequences of this disruption are increased waiting time of LNG carriers, which can be ameliorated by RLNG fire sales to prevent a tank ullage shortfall. This recovery strategy requires the determination of a break-even price for the fire sales of RLNG. If the LNG terminal is able to find new customers willing to buy RLNG above this break-even price, the resulting profit would be higher compared to the unrectified case. Our simulations show that, against a normal RLNG sales price of \$5/MMBtu, fire-sales at any price higher than \$ 3.52/MMBtu would be advantageous to the LNG terminal. Similar insights for designing rectification strategies for other disruptions can be obtained using the proposed agent-based model. This work did not consider various operational aspects of the LNG regasification plant tanks, such as boil-off gas generation, which can play an important role in terminal operations. These would be incorporated in the future. Further, we plan to include strategic mitigative actions like additional buffer stock, capacity expansion, and multiple sourcing in our future development.

Abstract

The world has witnessed an increase in the level of investments for renewable energy technologies in the past decade mainly owing to the pressure for mitigating greenhouse gas (GHG) emissions, whilst addressing the issue of climate change. According to recent statistics, global investments edged up by 2 % in 2019 to \$301.7 billion, taking the value of cumulative investments since 2004 to \$3.5 trillion, which has been attributed to the falling costs of solar and wind technologies. With the commissioning of additional capacities from renewable energy sources each year, there is a growing need for managing the associated risks and uncertainties from the perspective of different stakeholders throughout the planning, development and operational phases. Renewable energy sources entail considerable technological and financial risks exposure, depending on the location where the technologies are implemented, and thus needs to be managed using techniques that would provide both the quantification of risks and optimal decisions that lead to risk mitigation. The objective of the proposed research is to develop a probabilistic framework which broadly includes: (a) statistical modelling of financial risks - such as variability of revenue due to electricity price, demand fluctuations, generation costs, or other market conditions; and (b) evaluating options that maximise the stakeholders' utility/reward functions, or minimise risks, for a given technology mix. This research demonstrates the implementation of binomial lattice model in real options analysis (ROA) for the valuation of investments on diversified energy portfolios. The framework is applied to analyse the impact of risks and uncertainties on capital budgeting decisions relating to project size (expand or contract); project life and timing (initiation, deferment or abandon); and project operation (flexibility in the technology mix) for scenarios involving large-scale deployment of renewable energy sources.

Keywords: Binomial lattice model, Cogeneration, Real options analysis, Renewable energy, Risk management.

1. Introduction

Investment in the renewable energy sector continues to increase globally for the fulfilment of the Paris Agreement obligation of sustaining global temperature rise to well below 2 degrees Celsius. The amount of renewable energy provision in 2019 was the highest recorded at 184 GW of which 118 GW was through solar energy and 61 GW through wind turbines. This can primarily be attributed to the ever decreasing levelised

cost of energy (LCOE) for both solar and wind technologies due to continuous technology improvements and economies of scale. The current LCOE levels for solar and wind energies are lower by 83 % and 50 %, when compared to the last decade (FS-UNEP, 2020). Prior to committing to a project, investors need to evaluate all the associated risks in terms of risk probability and impact. Some risks are intolerable leading to a no investment decision and some to the other extreme are very low impact and are ignored entirely. However, the majority of risks fall in the middle where a formal evaluation is required to determine what is acceptable and what is not. Risk mitigation measures are usually implemented to reduce the risk level or to eliminate it altogether at a premium that need to be factored into the project overall cost. In the energy domain, fluctuations of fossil fuel, carbon and electricity market prices cause undesirable uncertainty that impacts future investment predictions and, in general, a portfolio of production technologies are mixed together to mitigate the risk and lower the overall impact. For large power projects, project economics and investment decisions are typically based on metrics such as the net present value (NPV) and the discounted cash flow (DCF). These metrics are well suited and have been long established for the conventional power projects. Recently, real options methods gained wide spread and are considered more appropriate for renewable energy projects where project flexibilities such as flexible project designs and flexible investment timings are possible during the planning phase.

Several studies were conducted previously to either address the weaknesses of traditional project assessment tools using basic ROA methodology or propose improved ROA techniques. Yang and Blyth (2007) developed a computational model to address the impacts of climate change policy including energy and carbon price uncertainties on power projects investment using ROA. Stochastic variables were used to map volatile energy and carbon prices and optimisation techniques were developed to search for the best time to invest. The model was applied on twelve case studies all with satisfactory results. The aim of the model is to assist policy stakeholders in the process of decision-making and critical comparison of the effects of different policy designs, and the impacts of climate change policy and market uncertainty on power project investments. Martinez-Cesena and Mutale (2011) employed an advanced real options methodology for the renewable energy generation projects. The scheme was implemented on a simplified hydropower plant as a case study in which the results demonstrated higher expected profits compared to conventional investment assessment tools. Santos *et al.* (2014) proposed a case study for a small hydropower plant where a comparison between traditional project evaluation methods and ROA was conducted. The analysis involved the development of real options and investment decision flexibilities based on ROA using the binomial decision tree. The results show that when the traditional methods support an immediate investment decision, ROA provides more flexibility to the investor in terms of project re-evaluation or redefinition of the project strategy. Pringles *et al.* (2020) applied ROA to determine the value of investment deferral while awaiting favourable market conditions in terms of system acquisition costs. Some of the conducive flexibilities that were valued are site location/relocation, network accessibility and regulatory policies. A stochastic valuation framework based on the least square Monte Carlo method was developed and applied to a proposed photovoltaics (PV) facility where site relocation and alternative tariff schemes were the more attracting options.

Based on the review above, the majority of the analyses focus on policy changes or uncertainties in fuel and carbon prices. Also, integrated power and water production facilities, co- and polygeneration in general, don't receive the same attention as single output facilities which are usually less complex with a lower risk profile. The aim of this paper is to develop a statistical based risk framework for the economic evaluation of integrated electricity and water cogeneration facilities to identify potential future expansion options where electricity market prices are uncertain in an unregulated electricity market.

2. Methodology

The integrated facility configurations are based on proposals previously made by Al-Obaidli *et al.* (2019, 2020) for a utility-scale production of electric power and freshwater. A base configuration and 4 expansion options are selected and presented in Figure 1. The base configuration is composed of: natural gas combined-cycle gas turbine (CCGT) for power generation and seawater desalination based on the multistage flash (MSF) process. Two additional technologies are considered: PV and seawater reverse-osmosis (SWRO). The base plant capacities are 500 MW for power and 100 km³d⁻¹ for water and the expansion capacities are the same except for the PV farm which has a higher capacity (1385 MW) due to the lower plant efficiency and the requirement to maintain the same level of energy throughput for an impartial assessment of the 4 options.

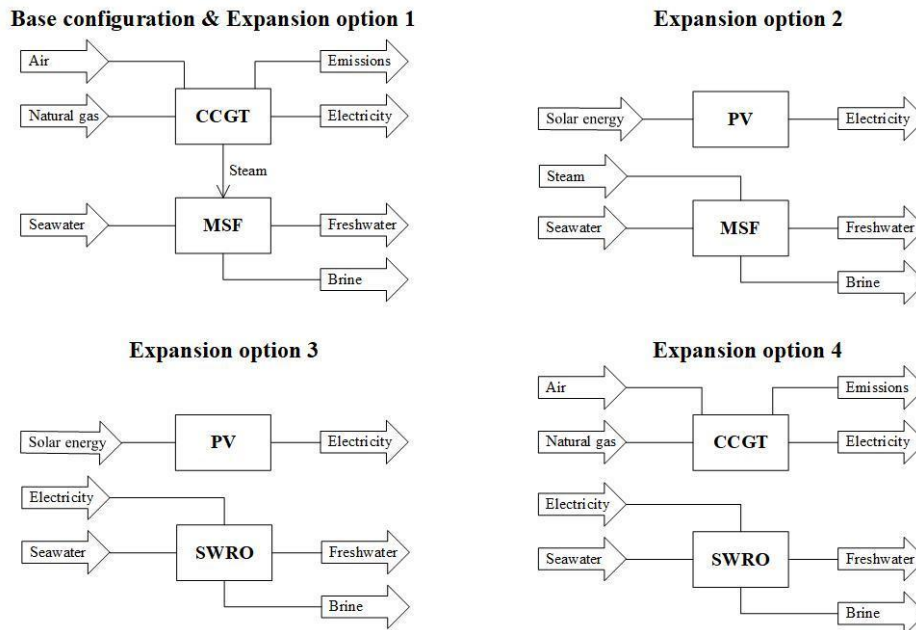

Figure 1. Facility block diagram of base configuration and expansion options.

The NPV is determined using:

$$NPV = -Capex + \sum \frac{Rev-Opex}{(1+d)^T} \quad (1)$$

where *Capex* is the total capital expenditure for each expansion option, *Rev* is the annual revenue, *Opex* is the total operating expenditure, *d* is the discount rate, and *T* is the facility lifetime. For the power block, the gas section is composed of multiple H-class combined-cycle turbines in a typical 1×1×1 configuration. The PV farm is fitted with a single-axis tracking system. In this case, battery storage was not considered due to the nature of the power mix and the operating philosophy since CCGT and PV are mixed to supply base and peak demands based on weather conditions and seasonality. For the water block, typical MSF and SWRO configurations suitable for the Middle-East region are used. The financial parameters for each of the production technologies are listed in Table 1. The discount factor and facility lifetime are estimated at 10 % and 25 years and the capacity factors for CCGT and PV are 67.4 % and 24.3 %, respectively.

Table 1. Financial parameters for the production technologies.

	CCGT	PV	MSF	SWRO
Capex (\$/kW, \$/m ³ d ⁻¹)	1,084	1,313	2,100	1,500
Fixed Opex (\$/kW, \$/m ³ d ⁻¹)	14.10	15.25	79.20	140.30
Variable Opex (\$/kWh, \$/m ³)	2.55	-	30.80	89.70

Source: EIA (2020) and World Bank Group (2019).

A binomial lattice model is developed for each of the options and is based on the exponential Brownian motion using the electricity market price as the stochastic variable:

$$\frac{\delta S}{S} = e^{\mu(\delta t) + \sigma \varepsilon \sqrt{\delta t}} \quad (2)$$

where μ is the price escalation rate and σ is the market price volatility. The asset value based on the deterministic NPV of each option is escalated across 6-time steps where each of the steps is equivalent to 2.08 years. At the end of the 6th step, equivalent to 12.5 years or half facility lifetime, the option is to be exercised in a European-like options system. The payoff value is compared across different market price evolutions and the decision to expand or not to expand is based on the difference between the escalated asset value and the payoff. The payoff values are then discounted across all evolution branches from step 6 back to the starting point resulting in the extended NPV for each option. The extended NPVs and the option values are then compared to identify the rank of the options from most attractive to least.

3. Results and Discussion

The binomial lattice model evolution was first applied to expansion option 1 which resulted in the binary tree depicted in Figure 2. At time step 0, deterministic NPV of the option is escalated through 6-time steps using different price escalation rates based on Equation 2. The upper branches represent higher escalation rates compared to the lower branches. As shown in Figure 2, expansion option 1 offers more positive results at multiple branches of electricity market price evolutions at half facility lifetime. This provides an incentive for a more likely “Expand” decision with a predicted payoff value of around \$45.6 billion at the highest anticipated price escalation branch. Also, the extended NPV at \$5.1 billion provides another indication regarding the feasibility of this particular option.

Figure 2. Binomial lattice model evolution and valuation (expansion option 1).

Evolution and valuation of the other 3 expansion options is also applied and similar to expansion option 1, the results in general are positive with the exception of PV based expansion options (2 and 3) where price escalation evolution must lean towards the higher escalation rate branches for the options to become feasible. A positive option value does not necessarily mean that the option is feasible as both sides of the tree should be investigated together with current price escalation rates at the facility half lifetime, when a decision must take place. Furthermore, the extended NPV for all of the options together with the option values are presented in Figure 3. An informed decision is possible once all the options are properly ranked from the most feasible to the least based on current market data.

Figure 3. Comparison of extended NPV and option value for all expansion options.

The poor financial performance of renewable energy technologies can be attributed to the higher initial capital costs compared to conventional technologies. Moreover, the lower plant efficiencies that are characteristic to renewable energy technologies also amplify the financial gap especially when a persistent energy throughput is in demand. From a pure financial perspective, CCGT technology is privileged when compared to PV and for water MSF process is slightly better than SWRO. In order to overcome these shortcomings with renewable energy technologies, additional criteria must be included in the assessment such as natural gas and carbon market price fluctuations.

4. Conclusions

Future expansion pathways for existing CCGT-MSF electricity and water production facility were evaluated using ROA. A discretised binomial lattice model was developed for 4 possible configurations composed of CCGT, PV, MSF and SWRO technologies. The results show that all of the options were feasible at half the existing facility lifetime with expansion option 1 providing more attractive financial results across various future electricity market price scenarios. Since only a single risk factor was considered in this study, renewable energy-based systems might have been at a disadvantage due to the higher capital costs and the lower throughput owing to the inherent lower energy efficiencies. Future work will focus on the introduction of variability in other risk factors including but not limited to natural gas and carbon market prices and the application of Bayesian based methods.

Abstract

In this work, we address a problem of optimal production and distribution planning of industrial gas supply chains and the associated truck allocation. Two different optimisation models, a multi-objective optimisation (MOO) model and a mixed integer linear fractional programming (MILFP) model, are developed. The proposed models simultaneously determine the purchasing schedule for raw material, transportation schedule, network structure of supply chains, and optimal allocation of truck resources. To solve the problem, we employ the ϵ -constraint method for the MOO model, while a literature approach based on the Dinkelbach algorithm is adopted for the MILFP model as a solution method. Finally, an industrial case study is presented to demonstrate the applicability of the proposed optimisation models.

Keywords: Mixed-integer linear fractional programming, multi-objective optimisation, integrated supply chain planning, vehicle allocation

1. Introduction

Industrial gas supply chains involve domestic and/or international transportation systems between multi-site production plants, intermediate storage locations and several customers (Chima, 2007). Consequently, a large portion of supply chain costs come from transportation, and improving transportation efficiency has become increasingly important to improve overall profitability. Transportation efficiency can be improved by optimally allocating vehicle resources. Furthermore, there is a need for considering not only the transportation efficiency but also the economic performance, such as total cost or profit, in an integrated manner. There are existing works in literature, which address the production and distribution planning for the gas industry. Campbell and Savelsbergh (2004) addressed combined vehicle routing with scheduling problems for industrial gas distribution, and more recently by Dong et al. (2014). Concerning the integrated production and distribution planning, Marchetti et al. (2014) developed a mixed integer linear programming (MILP) model which coordinates production and distribution decisions. The production model considers plants operating at various production modes, while the distribution model accounts for a combined vehicle routing and inventory management. You et al. (2011) developed an MILP model accounts for planning decision of tank sizing at customer locations, inventory and truck routing decisions of industrial gas supply chain simultaneously. Zhang et al. (2017) proposed an MILP model and an iterative heuristic approach for the multi-scale production routing problem which combine production, distribution, and inventory decisions. Additionally, Lee et al. (2020) developed an MILP model which integrates supply contracts, production and transportation scheduling, and inventory management. They also proposed a relaxation approach to tackle computational limitation when dealing with large-size problems.

However, to the best our knowledge, none of works has considered the issue on improving transportation efficiency. In this work, we investigate a problem for the production and

distribution planning involving truck allocation of industrial gas supply chains, with total cost and total number of allocated truck resources as objectives. The aim is to develop optimisation frameworks which integrate the decision on the truck allocation into our previous model (Lee et al., 2020), and to adopt two solution approaches for the developed models; ϵ -constraint method and Dinkelbach algorithm.

2. Problem Statement

This work addresses the integrated optimisation of the industrial gas supply chains, including the production and distribution planning, and truck allocation. Figure 1 shows the network of the industrial gas supply chains considered in this work. On the production side, each plant purchases raw material from an external supplier and transform into liquid product at high purity. This liquid product can also be purchased from third-party suppliers. On the distribution side, the customer demand is satisfied through two primary transportation modes. The trucks deliver the product from plants, depots, and third parties to customers, whereas the rail-cars transport the product from plants and third parties to depots.

Figure 1: Network of industrial gas supply chains

Overall, the optimisation problem is described as follows:

Given (a) maximum available supply of raw material and purchasing cost; (b) plant location, production capacity, and production cost; (c) third party location, maximum purchasing amount from third party, and related cost; (d) unit outsourcing cost (e) initial, minimum, and maximum inventories; (f) loading capacities, available quantities, and transfer unit costs for both rail-car and truck; (g) total number of available truck resources.

Determine (a) production schedule; (b) purchasing schedule of raw material and product from external suppliers; (c) product allocation; (d) rail-car schedule; (e) allocation of truck resources to plants, depots, and third parties.

so as to (a) minimise total cost; (b) minimise total number of allocated truck resources.

3. Mathematical Frameworks

In this section, brief outlines of two different optimisation models are presented based on our previous work (Lee et al., 2020).

3.1. MOO model

Firstly, we formulate the problem as an MOO model, which comes with two objective functions. The first objective, total cost which is comprised of raw material cost, production cost, plant start-up cost, third party cost, truck cost, rail-car cost, and outsourcing cost, is minimised:

$$\min TC^{total} \quad (1)$$

$$TC^{total} = TC^{raw} + TC^{prod} + TC^{st} + TC^{third} + TC^{rail} + TC^{truck} + TC^{os} \quad (2)$$

The second objective considers the minimisation of total number of truck resources allocated to plants, depots, and third parties:

$$\min NT^{total} \quad (3)$$

$$NT^{total} = \sum_i NT_i^{new} + \sum_j NT_j^{new} + \sum_m NT_m^{new} \quad (4)$$

where NT_i^{new} , NT_j^{new} and NT_m^{new} are the number of allocated trucks to each plant i , depot j , and third party m , respectively.

Inventory mass balance. Inventory of each customer k in time period t is given by:

$$I_{kt} = I_{k,t-1} |_{t>1} + I_k^{ini} |_{t=1} + \sum_i Q_{ikt}^{truck} + \sum_j Q_{jkt}^{truck} + \sum_m Q_{mkt}^{truck} + Q_{kt}^{os} - D_{kt} \quad \forall k, t \quad (5)$$

The inventory at the end of time period t (I_{kt}) is equal to the inventory at previous time period ($I_{k,t-1}$) plus incoming product delivered by trucks from any plants, depots, and third parties ($\sum_i Q_{ikt}^{truck}$, $\sum_j Q_{jkt}^{truck}$, $\sum_m Q_{mkt}^{truck}$) plus outsourcing product (Q_{kt}^{os}), which can be used when existing plants and third parties can not satisfy customer demand, minus customer demand (D_{kt}). Here, the initial inventory is defined by I_k^{ini} . The similar equation returns to plant i and depot j for inventory mass balance of each plant and each depot (I_{it} and I_{jt}).

Truck constraint. The formulation to limit both the total product amount delivered and total travel time performed by trucks during each period follows our previous work (Lee et al., 2020):

$$\sum_k \frac{\gamma Q_{ikt}^{truck}}{CAP_i} \theta_{ik} \leq NT_i^{new} \Delta_t \quad \forall i, t \quad (6)$$

Here, the summation of the delivery amount/capacity ratio (Q_{ikt}^T/CAP_i) multiplied by the duration of the round-trip between the plant and customer (θ_{ik}), estimates the total travel time executed by trucks during the period. The γ multiplied to the delivery amount/capacity ratio is the tuning parameter to avoid underestimating the total travel time. The total travel time is restricted by the length of each time period (Δ_t) and the number of allocated trucks at each location (NT_i^{new}).

3.2. MILFP model

In MILFP model, the objectives are formulated as a fractional objective function:

$$\min \frac{TC^{total}}{AUR^{total}} \quad (7)$$

As we minimise both objectives, total cost and total number of trucks, we can not directly adopt one of them as a denominator. Here, we introduce the overall truck utilisation rate (AUR^{total}) as a denominator, which is maximised as the total number trucks is minimised.

Overall truck utilisation rate. The overall truck utilisation rate is calculated by:

$$AUR^{total} = \frac{\sum_i UR_i + \sum_j UR_j + \sum_m UR_m}{\sum_i X_i + \sum_j X_j + \sum_m X_m} \quad (8)$$

where UR_i , UR_j and UR_m are the truck utilisation rates for truck resources which are allocated at each plant, depot and third party. The binary variables, X_i , X_j and X_m , are 1 when at least one truck is allocated to each plant, depot and third party.

Eq. (8) includes the bilinear term; thus, it is linearised with an auxiliary variable, a big-M value, and additional constraints:

$$AUR^{total} = \sum_{l=1}^q \frac{TUR_l}{l} \quad (9)$$

$$\sum_l^q \overline{TUR}_l = \sum_i UR_i + \sum_j UR_j + \sum_m UR_m \quad (10)$$

$$\sum_i X_i + \sum_j X_j + \sum_m X_m = \sum_l^q l \cdot Y_l \quad (11)$$

$$\sum_l^q Y_l = 1 \quad (12)$$

$$\overline{TUR}_l \leq M \cdot Y_l \quad \forall l = 1, \dots, q \quad (13)$$

where Y_l is the binary variable to express the integer variable in the denominator of eq. (8) by its decimal representation. q is the maximum value of the number of plants, depots, and third parties which have at least one truck resource. i.e., q is the total number of plants, depots, and third parties considered in the problem.

Truck utilisation rate. The truck utilisation rate at each plant i during a given planning horizon is calculated by:

$$UR_i = 100 \cdot \left(\frac{\sum_k \sum_t \gamma Q_{ikt}^{truck}}{CAP_i NT_i^{new}} \theta_{ik} \right) / T \quad \forall i \quad (14)$$

where T is the number of time periods. As eq.(14) also includes the bilinear term, it is linearised by the linearisation scheme applied in eqs.(9)-(13). For the truck utilisation rates at each depot and third party (UR_j and UR_m), the similar equation and linearisation scheme are adopted.

Finally, the total number of allocated trucks is limited by the maximum number of available truck resources:

$$\sum_i NT_i^{new} + \sum_j NT_j^{new} + \sum_m NT_m^{new} \leq NT^{max} \quad (15)$$

4. Solution Approaches

4.1. ϵ -constraint method

To solve the developed MOO model, we employ the ϵ -constraint method (Haimes, 1971), where one of objectives is kept as an objective function and the other objective is considered as a constraint. The MOO model is transformed as follows:

$$\begin{aligned} & \min TC^{total} \\ & s.t. NT^{total} \leq \epsilon; \\ & \quad Eqs. (2), (4) - (6); \\ & \quad \text{Supply chain production and distribution planning constraints.} \end{aligned}$$

Here, ϵ is the user-defined upper bound for the total number of allocated truck resources.

4.2. Dinkelbach algorithm

For the MILFP model, we implement the Dinkelbach algorithm (Liu et al., 2014), which iteratively solve an MILP model given below:

$$\begin{aligned} & \min TC^{total} - f \cdot AUR^{total} \quad (16) \\ & s.t. Eqs. (2), (5) - (6), (9) - (13), (15); \\ & \quad \text{Linearisation constraints for the truck utilisation rates;} \\ & \quad \text{Supply chain production and distribution planning constraints.} \end{aligned}$$

The procedure of the Dinkelbach algorithm implemented for the problem is as follows:

- Step 1. initialise f ;
- Step 2. solve the MILP model (16), and denote the optimal solution as TC^{total*} and AUR^{total*} ;
- Step 3. If $|f - \frac{TC^{total*}}{AUR^{total*}}|/|f| \leq \delta$ (stopping criteria), the optimal solution for the MILFP model is TC^{total*}/AUR^{total*} ; otherwise, update $f = TC^{total*}/AUR^{total*}$, and go to Step 2.

5. Case study and Results

To demonstrate the applicability of the developed models, an industrial case study is conducted. The supply chain network considered for the case study consists of total 30+ of plants, depots, and third parties, 700+ customers, 300+ rail-cars, and 100+ trucks. A planning horizon is one month and it is divided into 30 days.

The developed models are implemented using Gurobi 9.0.0 in GAMS 30.3 on Intel 3.60 GHz, 32.0 GB RAM computer. For the MOO model, the optimality gap is set to 1%, while 98% of optimality gap and 0.01 of stopping criteria (δ) are set for the MILFP model.

Firstly, we solve the problem with the developed MOO model by fixing ϵ to 7 values between 50 and 80 of the total number of allocated truck resources. The resulting MOO model includes 137,268 equations, 160,146 continuous variables, and 5,415 discrete variables. The entire process to get Pareto optimal solutions with different values of ϵ takes 3,575 s CPU time.

Figure 2: Pareto optimal solutions obtained from the MOO model

Figure 2 shows the optimal solutions and the piecewise linear approximation of the Pareto curve, together with the overall truck utilisation rate calculated by eq.(4) using obtained optimal values. The total cost remains relatively stable when the total number of trucks is decreased from 80 to 65, while the total cost is increased significantly as the total number of trucks is reduced from 55 to 50. We can also see that the overall truck utilisation rate is improved as the total number of truck resources is decreased. Furthermore, we can find a “good choice” solution marked with a blue circle, which dramatically reduces the total number of trucks and improves the overall truck utilisation rate with only a small increase in total cost.

Secondly, we solve the problem with the proposed MILFP model using the Dinkelbach algorithm. The model consists of 141,389 equations, 160,511 continuous variables, and 5,777 discrete variables, and it takes 1,914 s CPU time to gain an optimal solution. The red point shown in figure 2 is the optimal solution, and the point lies on the “good choice” solution which was identified by comparing the Pareto optimal solutions obtained from the MOO model. This result reveals that the proposed MILFP model can find an optimal solution, which is evaluated as the “good choice” solution by the MOO model. Figure 3 presents the number of allocated trucks at each plant and the cost breakdown gained from the MILFP model. As observed, the number of allocated trucks to each plant varies,

and the number lies on the values between 1 to 7. The result of cost breakdown shows that truck cost accounts for the highest percentage of total cost (41%), followed by raw material cost (26%) and production cost. The outsourcing cost and plant start-up cost show the lowest percentages of the total cost (2% and 1%, respectively).

Figure 3: (A) The number of allocated truck resources and (B) the breakdown of the total cost obtained from the MILFP model

6. Conclusions

This work has addressed a problem of optimal production and distribution planning involving truck allocation for industrial gas supply chains, through the development of two different optimisation models; the MOO model and the MILFP model. The models have considered both economic performance (i.e. total cost) and truck efficiency simultaneously. To solve the MOO model, we applied the ϵ -constraint method, whereas the Dinkelbach algorithm was employed as a solution method for the MILFP model. The proposed models successfully solved an industrial case study. The results from the MOO model showed the trade-off between total cost and the total number of trucks. The decision-makers can select their preferred planning from the obtained Pareto optimal solutions. Finally, the MILFP model found a "good choice" optimal solution, which was identified by examining optimal solutions gained from the MOO model.

Optimal Day-Ahead Load Curtailment for Central Chiller Plants

Gustavo Campos,^a Yu Liu,^a Nael H. El-Farra,^a Ahmet Palazoglu^a

^aDepartment of Chemical Engineering, University of California, Davis, One Shields Ave, Davis, CA 95616, USA

Abstract

Demand Response (DR) programs with the goal of maintaining the electricity grid's generation-load balance and ensuring transmission reliability have been on the rise in the last few decades. Services such as load shifting and curtailment have become economically attractive alternatives for large end-users with flexible operation. Different ways exist for providing these services, one of them being the Day-Ahead (DA) bidding as a generator in the energy or ancillary services market. In this work, we propose an optimization-based framework for performing DA bidding of load curtailment services, specifically in the context of large-scale central chiller plants with Thermal Energy Storage (TES) used for District Cooling. The framework integrates the two problems of real-time load shifting and day-ahead load curtailment bidding. Using the proposed framework, we evaluate the techno-economic feasibility of providing load curtailment services. The case-study is performed with real data from the central chilled water plant located on the campus of the University of California, Davis. Simulation results of the closed-loop implementation provide insights into the potential benefits from providing load curtailment.

Keywords: Demand Response, Load Curtailment, Process Scheduling, Energy Systems, HVAC.

1. Introduction

With the advent of deregulated electricity markets in the last few decades, there has been a push for increasing competitiveness in the generation and consumption of electrical energy. Unlike traditional commodities, electricity exhibits a few unique characteristics; among the most important are its continuous generation and delivery as opposed to batch-wise, and the need to balance generation and demand on a second-by-second basis. In the case that there is such an imbalance, or the transmission capacity exceeds its limit, there is a high risk of blackout followed by a restoring process that could take up to days (Kirschen and Strbac, 2019). To help mitigate these issues, system operators have been intensifying the use of Demand Response (DR) services, which have become especially useful to offset the impact of growing renewable penetration. From 2017 to 2018, participation of DR services in wholesale markets in the US increased by approximately 8 percent, while the California Independent System Operator (CAISO) had the greatest increase on a regional basis (FERC, 2019). The most common types of DR services include load shifting, load curtailment and the dispatching of controllable distributed generation systems.

The topic of load curtailment has been addressed in the literature mostly from the power generator or provider's perspective (e.g., Tsimopoulos and Georgiadis, 2019), which frequently makes use of oversimplified models for the consumer side (Zhang and

Grossmann, 2016). However, more recently the user's perspective has been addressed more heavily in the literature. Vujanic *et al.* (2012) considered the flexible schedule of cement milling plants using robust optimization. The provision of load curtailment was treated as a preliminary step in which the jobs having flexible starting times were selected arbitrarily. Zhang and Hug (2015) proposed a day-ahead bidding strategy using stochastic programming for aluminum smelters participating in both energy and spinning reserve markets. The continuous scheduling problem was solved daily and generated bidding curves for both markets for the following day. Zhang *et al.* (2015) assessed the benefits of adding cryogenic energy storage to air separation plants, including the provision of spinning reserve in ancillary services (AS) markets. The scheduling problem was solved weekly and uncertainty was assumed to arise mainly from the spinning reserve demand, which was addressed using robust optimization. Zhang *et al.* (2016) extended the work by considering recourse decisions using adjustable robust optimization. In these works, it was assumed that the reserve provider is rewarded based on the accepted bids, even if no actual dispatch is required. The authors highlighted the existing trade-off between load shifting and curtailment, favored by a low and high level of plant utilization, respectively. More recently, Chalendar *et al.* (2019) proposed a planning approach for bidding load reduction in the form of long-term capacity for HVAC plants. The bids are submitted 25 days before the start of each month, which results in a planning problem with long-term horizon and uncertain forecasts.

Most works in the literature address the open-loop schedule and consider bids that are either submitted a long time in advance or are valid for a long time into the future (week or month). The shorter-time interactions between load shifting and curtailment, specially under closed-loop operation, thus, remain mostly unexplored. In this work, we develop a framework for assessing the provision of load-curtailment services through bidding in a DA market, either energy or AS, specifically for large-scale central chilled water plants with TES used for District Cooling. The optimal load curtailment bidding problem is solved once every day and calculates the magnitude and duration of the load curtailment for the following day. In contrast, load-shifting is performed hourly and generates the production profiles that minimize the operating cost and implements the accepted curtailment bids. Emphasis is given on the following features: (i) the integration of the load curtailment bidding with real-time load shifting; (ii) the derivation of results from the closed-loop implementation of the framework, as opposed to the open-loop; (iii) the modeling of a large-scale chilled water plant using real operational data; and (iv) the consideration of DR programs that allow demand resources to bid as generators in the DA market.

2. Methodology

This paper considers the central chiller plant located on the campus of the University of California, Davis. The university has two separate plants at different locations, referred to here as plant 1 (P1) and 2 (P2). Plant 2 contains a TES tank with a maximum capacity of 5 million gallons of water. Each plant has four centrifugal chillers, all of them in parallel except for chillers 7 and 8 in Plant 2. The chillers have different maximum cooling capacities varying between 2,000 and 2,500 ton, adding up to a total of 18,000 ton maximum cooling capacity. The water inside the TES tank is distributed into two layers, a bottom layer of cooler water (supply) and a top layer with warmer water (return), separated by a thermocline. In addition, the tank operates full of water at all times. An important constraint particular to this system is that only the chillers at Plant 2 are allowed

to charge the TES tank, due to the configuration of the distribution system. A simplified representation of this system is presented in Figure 1.

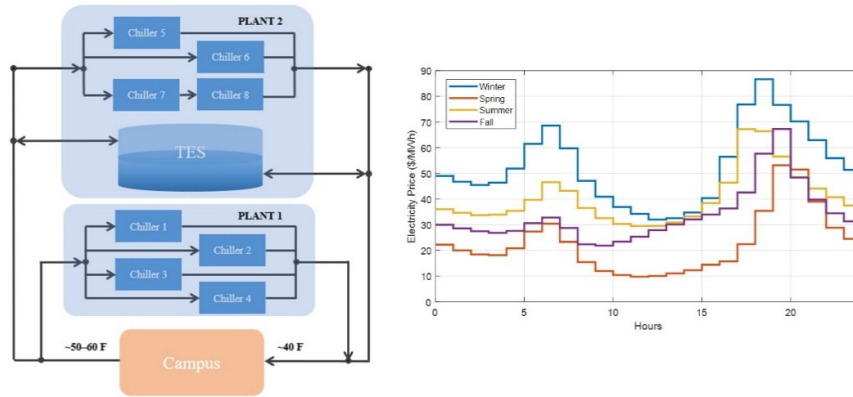

Figure 1. A schematic of UC Davis central chilled water plant (left); CAISO seasonal average day-ahead energy prices in 2019 (right).

The campus participates in the wholesale energy market from CAISO under a DA program, in which hourly electricity prices for a period of 24 h of the next day (from 00:00 to 23:00) are supplied to the customer one day ahead at 13:00. It is assumed that the real-time rate is equivalent to the DA price. The seasonal-average DA prices from CAISO in 2019 are also shown in Figure 1. In addition to the participation in the wholesale energy market for purchasing electricity, in this work we consider that the resource can also offer load curtailment capability as a generator in a DA market, either as energy or AS (e.g., spinning or non-spinning reserve). Bidding in the energy DA market as a generator provides an economic incentive to the user when the prices for purchasing and providing energy are settled using different node regions. Since the market prices vary considerably according to the location and system operator, here we focus on the unifying feature regarding the timing of the DA program. In the case of CAISO, bids for load curtailment are submitted before 10:00 on the day before the operating day. The market results are known at 13:00, along with the DA energy purchasing prices for the following day. This means that at the moment the bid is made, the prices for both services (load shifting and curtailment) are not known. Here we assume that the baseline (normal energy consumption profile without curtailment) is calculated by solving the optimal scheduling problem without load curtailment, instead of statistical historical averages. Real examples of economic-based DR programs include CAISO's Proxy Demand Resource (PDR), NYISO's Day-Ahead Demand Response Program (DADRP), and ISONE's Price-Responsive Demand (PRD).

2.1. Optimization Framework

The optimal load-shifting (LS) problem is formulated as follows:

$$\min \sum_{t \in T} (\psi_t^{opr} + \psi_t^{swi} + \psi_t^{rlx}) \quad (1)$$

$$\text{s. t. } \psi_t^{opr} = \sum_{c \in C} P_{c,t} C_t \quad (2)$$

$$P_{c,t} = (\beta_0 + \beta_1 T_t^S + \beta_2 T_t^{WB}) y_{c,t} + \beta_3 Q_{c,t} \quad (3)$$

$$ST_{t+1} = \left(ST_t + \sum_{c \in C_{P_2}} Q_{c,t} - D_t^{P_2} \right) \frac{(T_{t+1}^R - T_{t+1}^S)}{(T_t^R - T_t^S)} \quad (4)$$

$$\sum_{c \in C_{P_1}} Q_{c,t} = D_t^{P_1} \quad (5)$$

$$D_t^{P_1} + D_t^{P_2} = D_t \quad (6)$$

$$y_{c,t} Q_{c,t}^{min} \leq Q_{c,t} \leq y_{c,t} Q_{c,t}^{max}, ST_t^{min} \leq ST_t \leq ST_t^{max}, \sum_c P_{c,t} \leq P_t^{max} \quad (7)$$

where the parameters (both known and forecasted) include the electricity price C_t , the chilled water supply and return temperatures T_t^S and T_t^R , the wetbulb temperature T_t^{WB} , the campus cooling demand D_t , and the upper and lower bounds. Decision variables include the cooling load of chiller c at time t , $Q_{c,t}$, the on-off status $y_{c,t}$, the power consumption $P_{c,t}$, the storage level in cooling load equivalent ST_t , the portion of total demand supplied by plants P_1 and P_2 , $D_t^{P_1}$ and $D_t^{P_2}$, the operating cost ψ_t^{opr} and the penalties for switching and constraint relaxation ψ_t^{swi} and ψ_t^{rlx} (omitted in the model). A time horizon of 48 hours was employed.

The load-curtaiment (LC) problem is formulated as follows, in addition to Eqs. (2)-(7):

$$\min \sum_{t \in T} (\psi_t^{LS} - \psi_t^{LC}) \quad (8)$$

$$\text{s. t. } \psi_t^{LS} = P_t^{eff} C_t \quad (9)$$

$$\psi_t^{LC} = P_t^- C_t^{LC} \quad (10)$$

$$P_t^{eff} = P_t^{BL} - P_t^- + P_t^+ \quad (11)$$

$$P_t^{eff} = \sum_{c \in C} P_{c,t} \quad (12)$$

$$y_t^+ P_t^{+,min} \leq P_t^+ \leq y_t^+ P_t^{+,max}, y_t^- P_t^{-,min} \leq P_t^- \leq y_t^- P_t^{-,max} \quad (13)$$

$$y_t^+ + y_t^- \leq 1 \quad (14)$$

where C_t^{LC} is the price/reward for load curtailment, P_t^{BL} is an auxiliary variable that is fixed as the baseline during the bidding period, P_t^- and P_t^+ denote the negative and positive deviations from the baseline (only negative deviations are rewarded as load curtailment), P_t^{eff} is the effective power consumption after applying the negative and positive deviations, and ψ_t^{LS} and ψ_t^{LC} denote the economic cost and gain from load shifting and curtailment. Binary variables y_t^+ and y_t^- and Eq. (14) are employed to avoid increasing both P_t^+ and P_t^- by the same amount.

2.2. Integration

To effectively integrate the solution of the two problems, we can divide the time horizon of problem (LC) into three periods. In the first period, from 09:00 to 23:00 of the current day (first 15 hours), the problem reduces to a regular (LS), in which the bids from the previous day are implemented (setting an upper limit for power consumption) and load shifting is performed with the remaining load. The load deviation variables P_t^- and P_t^+ are set to zero by adjusting their lower and upper bounds in Eq. (13), making the effective power consumption P_t^{eff} equal to P_t^{BL} , both free decision variables. This step is important because it will determine the available storage at the beginning of the next day, which in turn determines the available load curtailment capacity for bidding. In the second period, from 00:00 to 23:00 of the following day (next 24 hours), the time and magnitude of the load curtailment bids for the following day are calculated. Prices are unknown and must be forecasted, and the base power consumption P_t^{BL} is fixed and set equal to the baseline

previously calculated by solving the (LS) problem. The load deviation variables P_t^- and P_t^+ are now allowed to vary freely by relaxing their upper and lower limits. The third period consists of the consecutive time steps. If a time horizon of 48 h is used, this period corresponds to the last 9 hours. This additional step is important to diminish the effect of the finite horizon approximation or the associated terminal constraint on the generated schedule or bids, e.g., to avoid storage depletion by the end of the following day, which could incur in demand and curtailment constraint violations. For this period, one can either solve a pure (LS) problem, in which case the problem becomes analogous to the first period, or also consider load curtailment bids, in which case the problem becomes analogous to the second period. The integration of the solution of problem (LC) into (LS) is easily done by enforcing upper bounds on the power consumption P_t^{max} in Eq. (7).

3. Case-Study Results

As a case-study, we generate and implement load curtailment bids for an average week from summer 2019. Seasonal average profiles were generated for DA electricity cost and building cooling demand, as shown in Figure 2. We assume that the load curtailment incentive C_t^{LC} has a magnitude proportional to the DA energy purchase cost (e.g., 10%), and that it only assumes a nonzero value during peak hours (e.g., 12 highest values in each day), as is typically the case for reserve prices. Furthermore, the price profiles are assumed to be known ahead of time for this analysis.

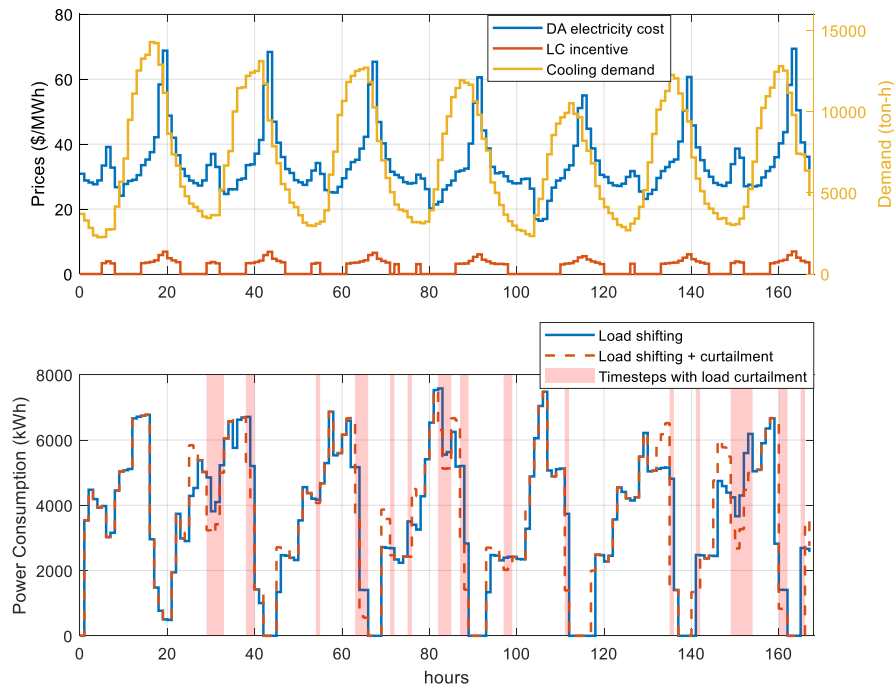

Figure 2. Energy prices and cooling demand (top), and power consumption profile with and without load curtailment (bottom).

Power utilization profiles are shown in Figure 2 for two cases; the first considering only load shifting and the second integrating load shifting and curtailment. It can be observed that most of the economic gains derive from the load shifting, while the curtailment

algorithm implements finer corrections to maximize the curtailment rewards. Providing load curtailment reduced the operating cost by approximately 2% considering a reward profile with a magnitude of 10% of the DA energy price. Naturally, the extent of the achievable economic gains will depend on the local cost profile and may or may not suggest the provision of load curtailment services. It can also be observed that periods with a higher level of plant utilization (i.e., higher power consumption) do not necessarily correspond to higher curtailment when performed together with load shifting. This can be attributed to the fact that the load shifting algorithm acts first by assigning the bulk of power consumption to low-cost regions, which in turn provide low to zero rewards for curtailing.

4. Conclusions

In this work, we presented a framework for the optimization of load-curtailment services in the DA market for large-scale central chilled water plants with TES. The framework integrates the DA bidding of load curtailment with real-time load shifting, and addresses closed-loop implementation. The results of a case-study demonstrated the potential benefits of providing load curtailment services, and provided insights into the interactions between load shifting and curtailment when implemented in a closed-loop fashion. Future research will focus on using real prices from DR programs, analyzing how price and demand forecasts and storage size affect the potential load curtailment benefits, and assessing the impact of aggregating loads.

Abstract

With today's rapid growth of human populations along with environmental concerns worldwide, it becomes increasingly difficult to meet future requirements for food, specifically in meat production systems (fish, poultry, cattle, etc.), to satisfy protein dietary demands of humans. The necessity of increasing the production of food, in both quantity and quality aspects, pressures the utilisation of natural resources (fresh water, land, etc.) and other inputs (as fertilisers) to fulfill demands of higher yields and improved properties of crops and livestock. Therefore, it is important to develop a sustainable model or framework integrated to the state-of-the-art technologies that helps to satisfy efficient use of natural resources in a consistent path by addressing food security issues without compromising food quality and the environment. To achieve sustainable processes within such limited resource world, the agri-food sector must move towards zero waste generation or at least minimise environmental impacts by (1) creating value in the agri-food manufacturing and supply chains and (2) recovering resources from by-products if techno-economically viable. Furthermore, considering novel technologies from the industry 4.0 (I40) age, it can be reached by efficient utilisation of resources via optimisation and integration of processes of production management among agri-food producers, traders, retailers, etc. Towards sustainable development in agri-food systems and supply chains, every operation must focus on closing loops to reduce, reuse, and recycle of material, energy, etc., without losing quality, within the concepts of the so-called circular economy (CE). These food supply chains, and agriculture productions can be improved using I40 solutions, yielding optimal operations, higher amounts of food, better quality of products, among others. An example in the poultry production and market is given considering interconnections of the triple of supply chain resilience, industry 4.0 and sustainability.

Keywords: Food supply chain, poultry market, industry 4.0, sustainability, resilience.

1. Introduction

Industry 4.0, supply chain resilience and sustainability have rapidly become strategic milestones for various industries, as they play into the competitive advantage of the chains and their overall efficiency. The three mentioned frameworks address the topics of sustainable processes in excellence and exchange value transformation between the two ends of the chain. Supply chain resilience (SCR) is an assessment of how prepared the chain would be for sudden disruptions. Supply chains must be designed to incorporate event readiness, provide an efficient and effective response, and be capable of recovering to their original state or even better post the disruptive event (Ponomarov and Holcomb, 2009). Industry 4.0 (I40) is identified as the framework that allows artificial autonomous machines to inspect, model, and visualise critical decisions based on mass data, wirelessly fed through electronic collectors that are distributed across the value chain. Moreover, this I40 element permits intelligent data-based decision-making to be done rigorously while considering the impact of the decision on the totality of the supply chain. This is achieved by using internet-of-things (IoT), radio frequency identification (RFID) technologies, big data and data analytics, advanced robotics, cloud computing, etc.

On the other hand, sustainability (SUS) focusses on the utilisation of current resources and assets to meet the demands of the present while accommodating the future generations' ability to do the same (Brandenburg and Rebs, 2015). Additionally, sustainability is the accountability measure of the negative externalities caused by the chain on the environment, society, and economy in the present and the future under the so-called circular economy fundamentals. Luthra and Mangla (2018) discuss the criticality of incorporating sustainability factors in the decision-making environment. They foresee that the framework's exclusion of those variables will intensify the damage of ecological imbalances like resource over-consumption, global warming, climate change problems and energy requirements for supply chains as their demand grows. Therefore, the design of a model that balances the efforts spent on the three frameworks would be the best approach for the business, consumer, and environment.

This work evaluates one major food supply chain that is found in the poultry industry. The significance of such study lies in the inevitable increasing demand of food due to the ever-growing human population. This continuously increasing demand pressures governments to ensure the availability of sufficient supplies through imports and local production, without damaging the source of their natural biological ecosystems. Assessing the relationship between supply chain resilience (SCR), industry 4.0 (I40), and sustainability (SUS) throughout the value chain of the poultry products will allow for a holistic analysis of the critical parameters in this specific market (Wang et al., 2018). As an example of the optimisation element of the I40, Menezes et al. (2020) consider a poultry production planning for both feed (ration, vitamins, etc.) and number of animals (from the hatchery) to be placed into appropriate cages for their proper growth. The animals are assigned to unit-places modelled as batch-processes with limited capacity and variate time-of-growing of the livestock batches. How the I40 elements can assist in the reduction of bottlenecks throughout a chain will define how such novel states of technologies may impact SCR and SUS in the chains. Various processes in the food supply chains are interlinked, allowing for some multi-dimensional surpluses with minimal improvements.

2. Supply chain resilience and sustainability connections

Many researchers have addressed the connection between sustainability and supply chain resilience, as they seek to understand how external and internal disruptions would impact a sustainable supply chain and how quickly can it recover to normal state. Derissen et al. (2011) affirmed that there are four possible relationships between the two frameworks: *a) resilience of the system is necessary, but not sufficient, for sustainability; b) resilience of the system is sufficient, but not necessary, for sustainability; c) resilience of the system is neither necessary nor sufficient for sustainability; and d) resilience of the system is both necessary and sufficient for sustainability.* Fahimnia et al. (2015) conducted an in-depth trade-off analysis between the supply chain costs incurred while minimizing environmental degradation. They found that when it comes to lean versus green directions, not all lean interventions at the planning level will result in a greener chain and that a flexible chain (resilient chain) is the most efficient alternative to balancing the focus on greenness and leanness.

Mari et al. (2014) tested the relationship between sustainability and resilience through a network design and optimisation. Differently to Azevedo et al. (2013) who assigned an index for the *ecosillient* relationship and Fahimnia et al. (2015) with their trade-off analysis approach, they created a multi-objective programming model that optimises sustainability (SUS) through carbon emission reduction and resilience through location-specific risks at each node in the network. Taking into consideration other conflicting goals like supply chain costs, carbon emissions and disruption costs, this research will attempt to use the different previously addressed models for well-rounded relationship testing.

This study will shed the light on various links and opportunities on the ability to retain mutual utility from the two far ends of the chain as the chain converges towards the equilibrium balance of prioritizing each framework. If the suppliers' ability to transfer value through their chains becomes highly responsive and visible through industry 4.0 components, then it would enhance the chains' absorption ability to external disruptions. This in turn would increase the resilience of the chain. The strategic strength of a more resilient chain will allow for better matching of supply and demand. In an ideal theoretical space, where a perfect match between supply and demand occurs, the reduction of food waste while meeting the nutritional demands of the consumers, can be reached. The sustainability value could be reflected when industry 4.0 systems consider the present and future tensions caused on the external environment of a supply chain. With a valid link between the frameworks, firms can focus on the optimization of resources, which will be travel in a sustainable efficient network. Eventually this would accommodate for the present and the future, without any decrease in retained utility of the firm and society. In other words, the ideal match between supply and demand could be more attainable as the supply chain management moves towards the equilibrium between all frameworks.

3. Interplaying of food supply chain resilience, industry 4.0 and sustainability

This research targets on using the previously developed concepts, metrics, indices, and models to calculate the impact factor of industry 4.0 (I40) integration on supply chain resilience (SCR) and sustainability (SUS). Most of the studies discuss thoroughly each framework exclusively as a major strategic focus, then propose one or multiple directions

for supply chain managements to consider. Some of the researchers suggest the link between resilience and sustainability is due to the implicit benefits between the two terms. However, a thorough comparative study that addresses the concept of a resilient sustainable supply chain with industry 4.0 integrated components (in short, RSSC4.0) has not been conducted in the food sector. The goal of this research is to (1) validate the triangular connection between the frameworks, (2) conceptualise the benefits and limitations of adopting RSSC4.0 in the supply chain operations. Firstly, contributing to the introduction of the concept of interplay between the three studied frameworks, and the business value of taking the strategic directions to reach the equilibrium. Secondly, contributing to an in-depth study of how industry 4.0 integration can solve or ease various bottlenecks in food supply chains. This would allow for enhanced, sustainable, and resilient networks that satisfy their fiduciary duties to all their stakeholders. The points to be raised in the SCR-I40-SUS triple as show in Figure 1 to be applied in the food industry or more precisely in the poultry market are:

- Visualize the supply network design of a *farm-to-fork* poultry firm.
- Identify and extract the critical parameters that cause bottlenecks for each process across the chain.
- Identify industry 4.0 technologies that can resolve or ease the bottlenecks.
- Compare the previously address models like the *ecosillient* index of the supply chains before and after the industry 4.0 integration.
- Divide the impacts of the industry 4.0 integration to two categories:
 - Direct or indirect impact demonstrated on the resilience score (R)
 - Direct or indirect impact demonstrated on the sustainability score (S)
- Express through the findings the future implications and trends of the study of RSSC4.0.

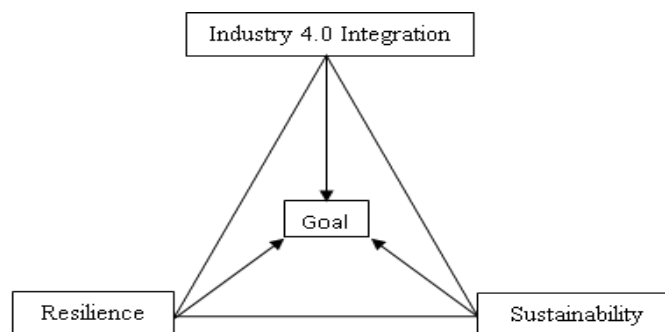

Figure 1. Supply chain resilience (SCR), industry 4.0 (I40) and sustainability (SUS) triple.

4. Poultry market value chain

As an example, we consider in the analyses of segment of the poultry supply network, where farms regularly place orders to suppliers of feed (like corn) to satisfy chickens' nutritional needs. The selection of the supplier is based on the ideal balance between pricing, quantity, and quality of the feed to ensure that the standard food conversion rate

(FCR) is met the livestock production in the farmyards. Variables that allow farms to decide on the quantity and quality of the feed would be mass inputted in cloud-based machine, which would be analysed and the resulted information would be shared to:

- (1) allow cameras or other optical-verification technologies to flag the rating of the quality of the feed when an order is received for quality assurance.
- (2) optimise the order point thresholds by balancing the increase of FCR obtained with a higher quality feed, allowing for a reduced quantity ordered and variable cost per chicken.
- (3) allow for a swift well-rounded decision on the procurement selection that is most ideal for the farm's sort and long-term needs.

This cloud-based system would be integrated with the remainder of the information flowing through the network possibly assisting in an optimised decision elsewhere in the network. If all farms aim to optimise the balance of variables in their procurement selection, it will allow the feed suppliers to focus on the metrics that they require if made public to them, which enhances the suppliers' ability to categorise farms based on their quality needs and direct existent and future products to the farms with a high likelihood of acceptance.

With the implementation of some of I40 components in the poultry market for a sustainable supply chain in Figure 2, the total SCR of the feed procurement process will increase through helping the two-ends effectively predict the versatility of each other's demand and supply patterns. Furthermore, by enhancing their cooperation and data visibility, an efficient production schedule will be made, reducing the amount of waste and pollution caused by unnecessary oversupply of poultry feed, enhancing the supply's network SUS and circularity. Similar practices could be implemented on agribusiness value chain yielding optimal operations, higher amounts of food, better quality of products, among others.

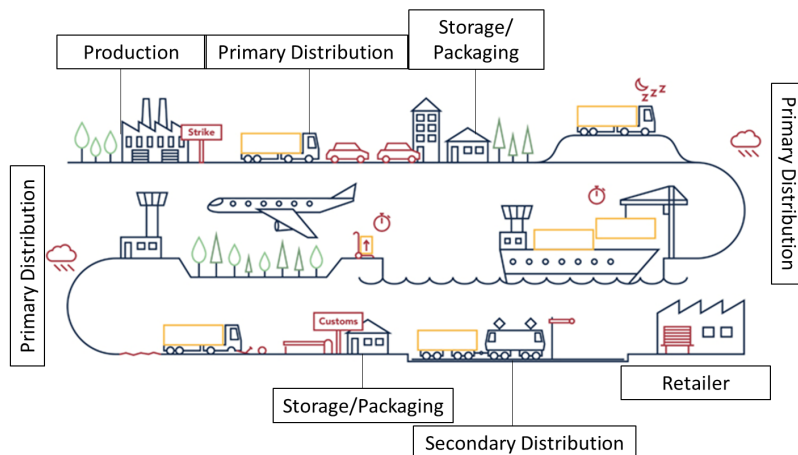

Figure 2. Poultry market components for a sustainable supply chain.

5. Conclusion

The improvements and changes that could be done to the current processes in the poultry production industry using the triple SCR-I40-SUS framework could enhance the value added from farm-to-fork to the businesses, governments, people, environment, and economy. The matching of supply and demand is the fundamental goal for each player in the supply network as it enhances their short-term profitability and long-term financial security. I40 would support in attaining that ideal matched point of supply and demand, while also allowing the firms in the network to consider other environmental, social, and economic impacts that could be easily overlooked when decisions are focused on short-term outcomes. The future objectives of this study would be to identify an ideal equilibrium point or optimisation model to balance the benefit and cost of a RSSC4.0 focused supply network.

Abstract

An integrated biofuel supply chain (SC) system, from field to product, has the potential to help fuels from second generation bioenergy crops become competitive with fossil fuels and grain-based fuels. Landscape design, deciding where to plant bioenergy crops and how to manage that land, has been shown to improve the environmental impact of farm-scale biomass production (including soil carbon sequestration) but has been studied largely separately from biofuel supply chain network design (SCND). This paper proposes methods for the spatially explicit and simultaneous optimization of landscape design and SCND to explore their economic and environmental tradeoffs. Field scale data methods are described, key constraints for a two-stage stochastic mixed-integer linear model are introduced, and results from a realistic case study in southern MI, USA are presented that show economic and environmental benefits from the proposed approach.

Keywords: Mixed-integer Stochastic Programming, Biofuels, Landscape Design

1. Introduction

Efficient design and operation of cellulosic biofuel production systems are crucial factors for the future scale up and competitiveness of renewable fuels (Puigjaner et al., 2015). In the context of biofuel production, mathematical programming methods such as mixed-integer linear programming (MILP) and stochastic programming can simultaneously account for tradeoffs between decisions needing to be made under uncertainty that span a range of both time and spatial scales. Researchers have applied a variety of techniques to the biofuel supply chain network design (SCND) problem. Osmani and Zhang (2013) developed an optimization model that considers supply chain (SC) strategic and tactical decisions at the county level and the minimization of total cost. Ng et al. (2018) presented a high-resolution SC model for corn stover with preprocessing depots (referred to subsequently as depots) and demonstrated that the spatial distribution of biomass influences the optimal SC configuration and operation. Gao and You (2017) presented a modelling framework that optimized the SC environmental impact in addition to the economic impact through a functional-unit-based life cycle approach under uncertainty.

One of the primary ways cellulosic crops achieve sustainability is through soil organic carbon (SOC) sequestration (Gelfand et al., 2013). Both biomass yield and SOC

sequestration potential depend on where in the landscape a specific crop is established. The term 'landscape design' refers to the process of choosing where in the landscape to establish crops and how to manage that land to achieve a specific goal. Some recent studies applied optimization techniques to landscape design, usually with environmental objectives that consider SOC sequestration. Cobuloglu and Büyüktaktakin (2017) developed a two-stage stochastic MILP model for landscape design around a fixed biorefinery that makes crop establishment decisions, considers environmental objectives, and analyses the competition between food and fuel. Field et al. (2018) simulated crop growth at different management conditions on lands around a fixed biorefinery and 'optimized' the landscape design by aggregating the lowest cost and greenhouse gas (GHG) parcels to meet a specific demand. Nguyen et al. (2019) developed a high-resolution MIP model that includes crop establishment and management decisions to optimize a set of environmental objectives around a pre-existing biorefinery.

The SCND problem and the landscape design problem have been studied largely separately in the literature. Landscape design studies typically do not make strategic or tactical SCND decisions (e.g., facility location, inventory planning) and SCND studies assume fixed crop locations and availability. Integrating these two aspects of biofuel production by including crop location and management as decision variables, rather than parameters as in most SC studies, offers an opportunity to optimize their spatially explicit tradeoffs and provide a tool for decision makers to design holistically sustainable systems.

In this paper we present methods for integrating the biofuel SCND and landscape design problems. In section 2 we present methods for gathering necessary high-resolution data, flexible spatially explicit model features, and selected model equations for landscape design. In section 3 we report results from a case study in southern MI, USA over a range of model instances at varying levels of detail. Finally, in section 4 we present conclusions and discuss application opportunities for the integrated model.

2. Spatially explicit two-stage stochastic model

2.1. Model Parameters and Data Methodology

Spatially explicit environmental and economic interactions among many of the SCND and landscape design decisions motivate the integration of high-resolution data sources with optimization models that can capture those tradeoffs. For example, the landscape design decision of where to plant crops will affect, among other things, both the SOC sequestration and the transportation cost.

Because yield and SOC sequestration potential is highly field specific, we model the available land for planting biomass on the field level and choose lands with United States Department of Agriculture Land Capability Classifications (LCC) V-VIII in southern Michigan, USA as our study area; although any set of geographically identifiable fields are compatible with the model equations presented in section 2.2.

Field-specific SALUS biogeochemical crop model simulations are used to obtain yield and SOC sequestration data for switchgrass grown on the available land (Basso et al., 2006). SALUS uses a daily time step approach to simulate crop growth and harvest including the flows of carbon and nitrogen. Simulations were performed over thirty years (1989 – 2018) with the stand re-planted every ten years at two levels of nitrogen fertilization (0, 50 kgN/ha) for each of the ~40,000 fields within our study area. SALUS

accounts for local weather at a 4 x 4 km resolution and, with thirty years of simulation, provides an estimate of the spatially explicit year-to-year uncertainty in biomass yield.

The two-stage stochastic model is solved for a representative year. Establishment years for which crop yields are artificially low are removed and uncertainty scenarios are sampled from the remaining 24 simulation years. The sampled yield years are taken as uncertainty scenarios $s \in S$ with an equal probability of occurring.

As the number fields within the study area grows, large model instances are unable to be solved in a reasonable amount of time. To maintain tractability of the integrated model while still accounting for the uneven distribution of biomass yield and the spatially explicit nature of landscape design, we introduce a gridded approximation. A grid of user defined resolution is overlaid on the study area. Grid cells containing no fields are discarded. The yield and SOC sequestration of fields within a cell are aggregated and the location of the new ‘harvesting site’ is defined as the yield-weighted average location of the fields it contains. Finer grid resolutions better approximate the uneven distribution of yield and SOC sequestration but lead to instances that are computationally difficult.

2.2. Integrated Landscape Design and SCND Model

To integrate the SCND and landscape design problems, we propose a spatially explicit two-stage stochastic model. The SC structure largely follows the deterministic approach of Ng et al. (2018) with extensions for the stochastic biomass yield uncertainty. Compounds $i \in I$ move through the SC according to material balance and capacity constraints defined over the harvesting sites, depots, and biorefineries with second-stage operational decisions made for a representative year divided into time periods $t \in T$.

Extending the work of Ng et al. (2018), we introduce a set of landscape design constraints to model crop establishment at high-resolution harvesting sites (from the gridded approximation) in addition to land management decisions that affect biomass yield and SOC outcomes. The binary variable $W_{i,j,r'}$ is equal to one if crop $i \in I^F$ is planted at harvesting site $j \in J$ using discrete management (e.g., harvest method, tillage method) $r' \in R^D$. Eq. (1) enforces no more than one crop may be established at each harvesting site and only one discrete management option may be chosen. A combination of discrete management options can be considered if each element of R^D is taken as a unique combination of discrete management options.

$$\sum_{i,r'} W_{i,j,r'} \leq 1 \quad \forall j \tag{1}$$

Landscape design decisions also involve continuous land management considerations (e.g., N-level, residue removal rate). Because the yield and environmental responses to land management are often non-linear, we introduce non-negative Special Ordered Set II (SOS2) variables to approximate the response to management as linear combinations of the available simulated data points for each field described in section 2.1. SOS2 variables are an ordered set of variables such that no more than two may be non-zero and they must be adjacent. SOS2 variables $Z_{i,j,r',r}$ are defined for each feedstock, harvesting site, discrete management option, and continuous management data point $r \in R$ (SOS2 on index r). Eq. (2) enforces the constraint that the SOS2 variables must sum to one if the harvesting site is selected for crop establishment and zero otherwise.

$$\sum_r Z_{i,j,r',r} = W_{i,j,r'} \quad \forall i \in I^F, j, r' \tag{2}$$

Eq. (3) constrains the yield $Y_{i,j,t,s}$ of crop i at each harvesting site j at each time period t and uncertainty scenario s to the linear combination of the SOS2 variables, the simulated yield potential $\alpha_{i,j,t,s,r,r'}$ (Mg/ha) from SALUS, and the area for establishment σ_j (ha).

$$Y_{i,j,t,s} = \sum_{r,r'} Z_{i,j,r,r'} \sigma_j \alpha_{i,j,t,s,r,r'} \quad \forall i \in I^F, j, t, s \quad (3)$$

$$D_j = \sum_{i,r,r'} \chi_r Z_{i,j,r,r'} \quad \forall j, r' \quad (4)$$

The level of continuous management D_j at each harvesting site is given by Eq. (4), where χ_r are the levels of the continuous management option at each data point $r \in R$. A two-stage stochastic formulation is implemented to account for the year-to-year uncertainty in biomass yields. Because the SCND decisions involving facility locations, technology selection, and capacity are capital intensive and difficult to change, model solutions should behave well in expectation over the lifetime of the SC in the face of the uncertain biomass yields which are influenced by variations in local weather, soil quality, and farming practices. The SC specific first stage decisions are biorefinery and depot location, technology, and capacity. The landscape design specific first stage decisions are crop establishment location and management level. Second stage decisions made after the realization of uncertainty include the SC operational decisions (inventory, shipment, and production management) and the landscape design decision, harvest amount. The optimization objective is the minimization of the expected value of the total annualized cost, TAC , of biofuel production defined by Eq. (5).

$$TAC = C^{CAP} + \sum_s p_s (C_s^F + C_s^{PR} + C_s^{INV} + C_s^{TR} + C_s^{SFALL} - C_s^{BY} + C_s^{ENV}) \quad (5)$$

where C^{CAP} , C_s^F , C_s^{PR} , C_s^{INV} , C_s^{TR} , C_s^{SFALL} , C_s^{BY} are the capital cost, feedstock cost, production cost, inventory cost, transportation cost, shortfall from unmet demand, and revenue from by-products respectively; p_s represents the probability for uncertainty scenario s to occur; and C_s^F defines the cost of landscape design (Eq. (6))

$$C_s^F = \sum_{i,j,t} \lambda_i H_{i,j,t,s} + \sum_j D_j \rho \sigma_j + \sum_{i,j,r'} \phi_{i,r'} W_{i,j,r'} \sigma_j \quad \forall s \quad (6)$$

which includes the per-ton cost λ_i for harvesting biomass $H_{i,j,t,s}$, the per-unit cost of continuous land management ρ , and the annualized per-area cost $\phi_{i,r'}$ of establishing and managing a crop. Finally, C_s^{ENV} defines the environmental impact of the landscape design and SCND on a cost basis by using the social cost of carbon (SCC) (\$/MgCO₂e). We model the emissions from transportation, production, and landscape activities (GT_s^{LAND}). The spatially explicit modelling approach described in section 2.1 allows us to include field-level SOC sequestration as negative landscape emissions (Eq. (7)).

$$GT_s^{LAND} = \sum_{i,j,r'} W_{i,j,r'} \sigma_j GHG_r^{HARV} + \sum_{i,j,t} H_{i,j,t,s} GHG_i^{MG} + \sum_j \sigma_j D_j GHG^{MAN} - \sum_{i,j,r,r'} \sigma_j GHG_{i,j,r,r'}^{SOC} Z_{i,j,r,r'} \quad \forall s \quad (7)$$

GHG_r^{HARV} is the per-area emissions from establishing and harvesting crops, GHG_i^{MG} is the per-ton emissions from harvest operations, GHG^{MAN} is the per-unit emissions from continuous land management, and $GHG_{i,j,r,r'}^{SOC}$ is the potential for sequestering SOC at a harvesting site under management options r and r' . A baseline value of 50 \$/MgCO₂e is used for the SCC (ToI, 2011), but by adjusting from the base value, a decision maker can determine how much emphasis to put on reducing emissions versus SC specific costs.

3. Case study results

To demonstrate the capabilities of the combined SCND and landscape design model and the methods used to integrate the two, we present the results of a case study located in southern MI, USA. Figure 1. displays the configuration of a detailed instance considering 5 uncertainty scenarios randomly sampled from the simulated years described in section 2.1, a spatial resolution of 4 x 4 km, and considering nitrogen fertilization 0 – 50 kgN/ha.

Figure 1. Optimal first-stage decisions for an instance considering 5 uncertainty scenarios and a 4 x 4 km grid resolution. Large centralized biorefinery and 13 depots located far from the refinery.

The model solution finds a large centralized biorefinery with 13 depots located far from the refinery. Landscape design, including crop establishment locations and fertilization, is driven by both the proximity to the refinery and depots and the SOC sequestration potential at each harvesting site. Computational results for instances at different spatial resolutions and number of uncertainty scenarios are detailed in Table 1. Implementation is with GAMS 32.2 solved via CPLEX 12.10 on 2.4 GHz Linux cluster machines with a time limit of 24 hours. Each row represents the average of 10 runs with different uncertainty scenario samples. High-resolution instances with many scenarios are difficult to solve to optimality. The value of the stochastic solution (VSS) is reported in Table 1. for instances able to be solved to a 1% optimality gap. The VSS represents the benefit to the objective value re-evaluated over the course of 10 years with first-stage decisions from solving the stochastic solution as opposed to a solution assuming the biomass yield at each field is that field's average yield. Table 1. also shows the average percent decrease of total annualized emissions (MgCO_2e) from the corresponding county level instance.

4. Conclusions

The spatially explicit and stochastic methods described in section 2 contribute to capturing the effect of landscape scale decisions on the SC outcomes to find solutions that perform well in expectation compared to the average information case. Instances with a higher spatial resolution lead to solutions with much better environmental performance largely due to better control of crop establishment, leading to higher SOC sequestration. The high-resolution instances rely on the availability of high-resolution and realistic data. The data methodology combining field-level crop model simulations with a gridded approximation enables tractable simultaneous landscape design and SCND optimization.

Table 1. Computational results for model instances at resolutions: county – 16 km² and uncertainty scenarios 1 – 12. Each row is the average 10 model runs for that number of scenarios.

# of Scenarios	Resolution	Soln. time (s)	Gap	VSS (\$)	GHG Benefit
1	County	64	1%	N/A	0%
	400	94	1%		-103%
	100	316	1%		-125%
	16	6,281	1%		-151%
3	County	406	1%	1.05 E7	0%
	400	779	1%	1.02 E7	-138%
	100	5,232	1%	1.67 E7	-151%
	16	64,336	1%	1.48 E7	-155%
5	County	1,204	1%	9.88 E6	0%
	400	2,447	1%	1.32 E7	-136%
	100	25,071	1%	2.04 E7	-128%
	16	86,400	15%	N/A	-142%
12	County	13,333	1%	1.46 E7	0%
	400	39,838	1%	1.58 E7	-180%
	100	68,517	9%	2.07 E7	-182%
	16	86,400	40%	N/A	N/A

An integrated landscape and SCND model paves the way for impactful system level analyses. The model generality, features, and data methodology allow for future analysis of SCND outcomes resulting from inputs such as alternative definitions of marginal land, uncertainty associated with future climate, and coarse regional study areas as well as small field-level systems through the flexible spatial approach. Insights will aid decision makers in designing efficient, cohesive, and sustainable field-to-product systems.

Abstract

Natural gas is expected to grow faster than oil or coal with predictions that it will be the leading primary fuel between 2020 and 2030. Technically, there are a number of ways to monetize the natural gas resource depending for example on the resource location, quantity, and quality. Beside the conventional way of transferring natural gas through pipelines, other options considered promising include: liquefied natural gas (LNG), compressed natural gas (CNG), gas to solid (GTS), gas to wire (GTW), gas to liquids (GTL) and gas to commodity (GtC). The utilization ways vary as being physical compression and mixing process like the case of LNG, CNG, and GTS or chemical conversion process like the case of GTL. Some of these utilization options are described as mature, while others are developing or prospective options that need more investment. In this study, the gas to methanol option is explored considering the methanol to gasoline (MTG) production route and compared to GTL process and products. The objective of this work is to conduct rigorous simulation models for two NG utilization routes namely, GTL and MTG in order to help the decision-maker in gas processing industry. Given a natural gas feedstock, it is desired to assess economically and environmentally the two production routes of gasoline product. In addition, the study aims to investigate the comparative and sensitivity analyses to incorporate the sustainability perspectives between GTL and MTG production routes. The results indicate a higher overall yield for the MTG process with a net economic value of around \$568 per tonne of gasoline produced and 0.2 tonne of CO₂-e emitted per tonne of product. Furthermore, increasing the percentage of methanol being processed to gasoline indicates to have more net economic profitability but with increased amounts of CO₂ emissions. These results indicate the significance of MTG process and can be further studied to identify the optimal percentage of methanol being processed to gasoline as a trade-off between economic and environmental benefits.

Keywords: MTG, GTL, Process simulation, Techno-economic-enviro, Natural gas

1. Introduction

Fossil fuels are dominating the major energy sources worldwide and serve as the prime feedstock in the production of a wide variety of chemicals. Reserves of natural gas are larger than other fossil-based fuels; coal and oil. However, with the significant depletion of fossil-based sources and the increasing demand for energy, especially liquid fuels, there is a critical need to establish alternative routes that archive higher sustainability in the generation of liquid fuels. Conversion of natural gas to liquid fuels through what is known as gas to liquid (GTL) process is technically mature and considered economically promising for large-scale production. Alternatively, liquid fuels generation through

methanol production route known as methanol to gasoline (MTG) is considered a feasible pathway. Methanol can be generated through reforming of natural gas to produce syngas intermediate. The first discovery of MTG technology was in 1970's by ExxonMobil in which zeolite catalysts were used due to their well-defined structure, acidity and surface areas (Li et al., 2015). After that, MTG process has received significant interest from industry and research. Most of the previous studies in literature focused on analysing a single natural gas conversion pathway and less attention was given to comparative studies that present the trade-offs between the different routes to support decision making. Aspen Plus process simulation along with published data were used to establish a basis for the techno-economic analysis of shale gas-to-methanol production. The results of the techno-economic analysis demonstrate that production of methanol from shale gas would be profitable for a broad range of methanol selling prices and shale gas costs. For example, a desirable 31% ROI is achieved for a methanol selling price of \$2.00/gal and shale gas price of \$3.50/kSCF (Ehlinger et al., 2013). Sequential process simulation and optimization techniques were implemented through a developed framework to natural gas processing and production networks, consisting of LNG, GTL, and methanol facilities. Initially, a steady state simulation using Aspen Plus software was used to determine accurately mass and energy balances, operating conditions, and equipment specification. Several benefits obtained by simulating the network, for example, determining accurate product yields and feed-gas requirements, capital and operating cost estimates linked to plant capacities, environmental impacts in terms of quantified emissions. The yields and costs obtained from the simulation are then used as inputs for the optimization step. The formulated linear programming (LP) optimization model with the objective function set to maximize profitability, evaluates the processing and production network over a wide range of forecasted economic changes (i.e. product prices) (Al-Sobhi and Elkamel, 2015). The same has been also applied in other studies to support the techno-economic decision making in process synthesis such as the different LNG liquefaction process routes (AlNouss et al., 2018) and to assess sustainability of production pathways (Al-Sobhi and AlNouss, 2018). The objective of this research proposal is to address and identify ways to increase the value of NG resource in Qatar by considering more utilization option such as methanol to gasoline (MTG) process. The MTG option is explored considering the methanol to gasoline (MTG) production route and compared to GTL process and products. The novelty of this approach is the economic and environmental comparison of two different routes for generating the same final product that is originating from the same energy source. This can be achieved by considering rigorous simulation and advanced mathematical optimization models while taking into account market information (i.e., supply and demand curves, product prices) for liquid fuels and methanol products. This presents a comparative analysis framework which benefits addressing the grand challenges currently facing Qatar and any NG-rich county worldwide through identifying the potential downstream value-added products to be generated and the right investment decisions. It is worth mentioning that the developed framework can be applied to different processing sectors such as oil refining, petrochemical, etc. One of the main expected outcomes of this study is to present a state-of-the-art NG processing and production planning tool to help the decision maker to assess the current monetization and identify any emerging/potential technologies to be considered to improve the economic portfolio of the country.

2. Model development

The application and implementation of integrated simulation-optimization approach proved to be helpful in utilizing the data from process simulation to deliver decision outcomes through optimization models. This study focuses on the assessment and the comparative analysis of synthesis gasoline produced from GTL and MTG processes. GTL is a process that convert natural gas into more valuable liquid products such as gasoline. It has three major steps; reforming of natural gas to produce syngas, Fischer-Tropsch (FT) synthesis to generate liquid fuels, and lastly, product upgrading to refine the generated products into different cuts. Natural gas reforming is reaction of the feed with oxygen and steam to produce H_2 and CO . Auto-thermal reforming (ATR) is selected in this study to be the method of syngas production since it has the ability to control large-scale production rates. ATR is endothermic reaction utilizing both oxygen and steam, and has the most suitable hydrogen to carbon monoxide ratio for cobalt-based catalyst operation (Iandoli and Kjelstrup, 2007). Air separation unit is utilized in the process to provide the required oxygen for syngas production unit. Hydrogen to carbon monoxide ratio ($H_2:CO$) is a significant parameter in GTL process, and it can be adjusted by water gas shift reaction to obtain the optimum ratio for the process. For cobalt-based catalyst process the ratio should be between 1.8:2.1 and in this study its equal to 2.1 (Steynberg et al., 1999). The produced syngas is then fed into FT reactor to convert it into long-chain hydrocarbons which are upgraded using hydrocracked into more valuable products such as naphtha, gasoline, kerosene, and wax. The final step of the GTL process is to refine the generated liquid fuels through series of distillation columns into the different cuts by means of difference in boiling points. Figure 1 illustrates the block flow diagram of the process.

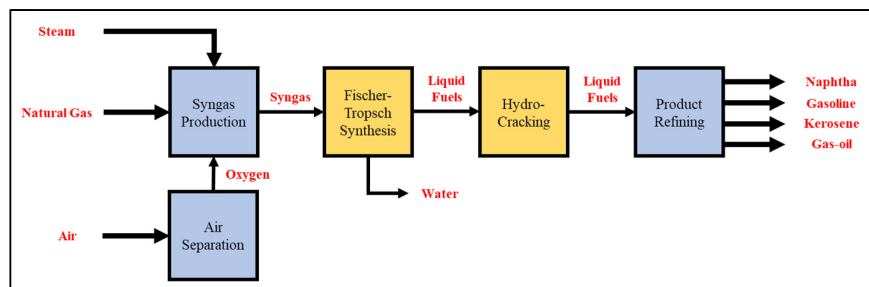

Figure 1: Block flow diagram of the GTL process.

Methanol to gasoline conversion is a modern process for generating gasoline from natural gas and it is considered as an alternative route to GTL process. The process starts by converting natural gas to syngas (CO and H_2) in the presence of steam, then converting this syngas into methanol followed by MTG. MTG process normally take place into two steps, first methanol is transformed into a mixture of dimethyl-ether (DME) and water with some unreacted methanol over a non-zeolitic catalyst usually. Secondly, this mixture is introduced into a zeolite catalyst to be converted to gasoline. This process was developed in the early 1970 by Mobile and it was commercialized later, and now other technologies are introduced in the area of MTG such as Topsoe integrated gasoline synthesis (TIGS) (Galadima and Muraza, 2015). Figure 2 illustrates the block flow diagram of the MTG process.

Figure 2: Block flow diagram of the MTG process.

The steady state simulation of the GTL and MTG process flowsheets is carried out using Aspen HYSYS software and taking into account the feed specifications presented in Table 1. The simulated flowsheets have been then analysed from technical, environmental and economic perspectives. Aspen Process Economic Analyzer and Aspen Process Energy Analyzer have been used to estimate the capital and operating costs of the two models along with the environmental emissions in terms of CO₂ equivalent. Moreover, a sensitivity analysis has been applied on MTG process to study the effect of changing the NG feed flowrate on the generated gasoline product and the associated CO₂ emissions. Another sensitivity analysis has been applied on GTL process to the effect of chain growth probability (α) on the products distribution according to Anderson-Schulz-Flory model.

Table 1: Feed specifications for the GTL and MTG models.

Parameter	GTL	MTG
NG molar flowrate (kmol/h)	37540	37540
NG Composition (mol%)		
Methane	92%	92%
Ethane	3%	3%
Nitrogen	5%	5%
NG feed Temperature (°C)	500	345
NG feed Pressure (bar)	25	30
Air to NG molar ratio	0.60	
Air Temperature (°C)	144	
Air Pressure (bar)	25	
Air Composition (mol%)		
Nitrogen	6%	
Oxygen	94%	
Steam to NG molar ratio	0.20	3.00
Steam Temperature (°C)	500	345
Steam Pressure (bar)	25	30

3. Results and discussion

The results of the techno-economic and environmental study demonstrate a higher overall product yield for MTG compared to GTL process with a higher net profit per product and CO₂ emissions. The detailed results of the two models are presented in Table 2. The raw material costs are calculated based on a NG feed price of \$137.2 per and the total product sales are calculated following a liquid fuels price of \$775.4 per tonne. The product distribution in GTL process is generated at an α value of 0.75 following Anderson-Schulz-Flory equation. The product distribution indicate a high share for gasoline with more than 50% followed by Naphtha 25%, Kerosene 22.5% and wax 1%. Whereas, the product in MTG process is totally gasoline with an overall yield of around 11% compared to 6% in the case of GTL process. The capital and operating costs are higher in the MTG process compared to the GTL process which was compensated by the higher production yield and sale. The raw material cost is the same for both cases as the same amount of NG is utilized. As a result, the net profit per product is higher for MTG process with \$568 per tonne of

product compared to \$558 for the GTL case. Similarity, the CO₂ emissions per product for MTG process is lower with 0.2 tonne of CO₂-e emitted per product compared to 1 for the GTL process.

Table 2: Summary of the main results for GTL and MTG processes.

Parameter	GTL	MTG
Liquid fuels product (kmol/h)	2151.43	4121.50
Liquid fuels product (tonne/y)	3.77x10 ⁶	4.20 x10 ⁶
Product distribution (wt%)	25.1% Naphtha	100% gasoline
	51.1% Gasoline	
	22.5% Kerosene	
	1.3% Wax	
Product yield	6%	11%
Total capital cost (\$)	2.20 x10 ⁸	4.62 x10 ⁸
Total operating cost (\$/y)	4.48 x10 ⁶	7.26 x10 ⁶
Total raw materials cost (\$/y)	7.70 x10 ⁸	7.70 x10 ⁸
Total product sales (\$/y)	2.92 x10 ⁹	3.25 x10 ⁹
Total annualized cost (\$/y)	8.20 x10 ⁸	8.72 x10 ⁸
Net profit (\$/y)	2.10 x10 ⁹	2.38 x10 ⁹
Net profit per product (\$/T product)	558.10	567.55
CO ₂ emissions (T CO ₂ -e/h)	433.07	93.45
CO ₂ emissions per product (T CO ₂ -e/T product)	1.0	0.2

The distribution of the liquid fuels generated from the GTL process are highly affected by the characteristics of the FT reactor and α probability following Anderson-Schulz-Flory equation (Al-Yaeeshi et al., 2019). The effect of α on the products distribution has been studied to determine the trend of gasoline production. Figure 3 demonstrate that the gasoline production increases with the increase in α until a certain peak point at around 0.75 which beyond the trend decreases. The curves of kerosene and wax indicate an increasing trends in general while the trend of Naphtha production decreases with the increase in α .

Figure 3: Effect of chain growth probability (α) on the products distribution of the GTL process.

Similarly, the effect of changing the NG feed flowrate on the generated gasoline product and the associated CO₂ emissions has been studied for MTG and GTL processes. The trends presentenced in Figure 4 indicate an increasing gasoline production and CO₂ emissions with the increase in NG feed. This increasing trend become less signification after 60,000 kmol/h of NG feed.

Figure 4: Effect of NG feed flowrate on the gasoline product and the associated CO₂ emissions.

4. Conclusions

The importance of transportation fuels is growing rapidly while the downstream investment in its production indicates critical operational costs. Hence, there is a need to establish alternative routes that archive higher sustainability in the generation of liquid fuels from fossil fuels. This study investigates the methanol to gasoline (MTG) production route as a GTL process alternative. The objective is to conduct rigorous simulation models for two NG utilization routes namely, GTL and MTG in order to help the decision-maker in gas processing industry. The results indicate a higher overall yield for the MTG process with a net economic value of around \$568 per tonne of gasoline produced and 0.2 tonne of CO₂ -e emitted per tonne of product. As a future work, the optimal percentage of methanol being processed to gasoline can be investigated as a trade-off between economic and environmental benefits.

Abstract

The main goals of retrofitting strategies are focused on addressing fundamental improvements in energy, environmental, and cost performance. This paper presents a novel formulation model aimed at determining optimal configurations for integrating a multi-energy type system to the process industries. The design and operation tasks are posed in mathematical terms as a bi-criteria mixed-integer linear programming problem (bi-MILP) that seeks to maximize the net present value (NPV) of the process supply chain while minimizing its environmental impact. Hence, the major contribution is the adoption of a mathematical approach to capture the cause-effect relationship between material/energy consumption/demand and the associated environmental impacts. The model capability is validated through a case study based on the Argentinean sugar cane industry and the benefits of integration are demonstrated.

Keywords: Retrofitting, MO optimization, sustainability, energy integration.

1. Introduction

Optimization strategies should be improved within the framework of industrial symbiosis systems to meet sustainability goals. Besides, the development of sustainable design and planning models for the process industries has strongly stimulated academia during the last three decades. Hence, the main goals of retrofitting strategies are focused on addressing fundamental improvements in energy, environmental, and cost performance. These strategies can be implemented in different levels as a unit, process segment, and overall system. For the case of process industries, the following challenges must be addressed (i) The integration of material/energy strategies in process industries; (ii) The integration of economic and environmental aspects within the framework of supply chain management; (iii) The development of efficient retrofit techniques to production processes. These challenges can be tackled by adopting a holistic systems-based analysis. Such an approach is supposed to propose an integrated solution by minimizing the global impact while considering feasibility constraints introduced by universal physical laws and current regulations. Particularly, multi-objective optimization is applied to the sustainable design and planning of a wide variety of industrial systems (Grossmann and Guillén-Gosálbez, 2010; Arora, 2012).

Subsequently, the incorporation of environmental concerns in SCs optimization models leads to Green Supply Chain Management. Hence, an approach has gained wider interest in recent years about combining mathematical programming and life cycle assessment and economic performance of the network. For instance, (Sabio et al., 2014) proposed an integrated LCA model via multi-objective mathematical programming to demonstrate that the combination of optimization techniques and LCA provides a powerful tool for balancing the environmental and economic performance of the production system.

However, very few types of approaches have been addressed multi-objective optimization of an integrated material/energy supply chain with considering economic and environmental impact factors. Hence, a general model that simultaneously optimizes the economic and environmental benefits of single-energy resource integration in process industries, particularly, exploiting bioenergy to run the production process, is the novelty proposed through this work. The proposed MILP model extends the traditional multi-objective approaches by considering the energy cogeneration, as a particular case, and its impact on the conflicting objectives of the whole system.

2. Problem statement

The production network retrofitting considers both its economic performance and the environmental impact (see Fig. 1). The network contains a set of raw materials and energy suppliers, production system utilizing various technologies, storage facilities, and final markets. For a more sustainable option, a penalty cost is assigned to the landfill. A standard high-level network is considered to determine the mathematical formulation, encompassing material resources that play the role of suppliers.

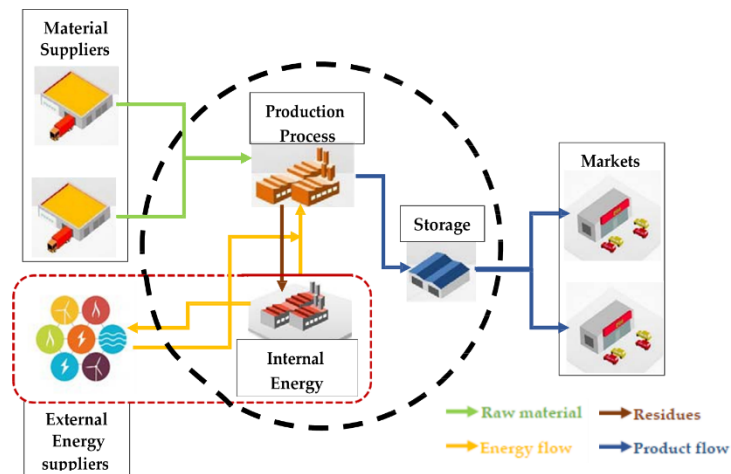

Fig. 1. Integrated energy/material SC Network

The network also includes process industries with different production technologies, acting as raw material consumers along with potential sites for storage technologies. The goal is to identify the best design and planning decisions about the system configuration and operation in terms of economic performance along with the environmental impacts.

3. Mathematical Model

The following equations formulate the network shown in Fig.1. In particular, mass and energy balances, as well as capacity constraints for each part of the network, are next described. A mixed-integer linear programming model is used to optimize sustainable supply chains. The proposed MILP is extended from the model introduced by (Mele et al., 2011). The emissions and wastes generated during the production tasks are considered in the model formulation. Any excess of energy can also be marketed.

3.1. Material balances and constraints

The mass balance for each potential site is defined by Eq.1. Hence, for each material type i , the initial inventory $ST_{i,s,g,t-1}$ maintains in region g from the previous period plus purchased raw material $PU_{i,g,t}$, the total produced material $PT_{i,g,t}$ and input material flow rate $Q_{i,l,g,g',t}$ is equal to the current inventory $ST_{i,s,g,t}$ added to delivered product $DT_{i,g,t}$ plus the output material flow $Q_{i,l,g,g',t}$, and generated waste $W_{i,g,t}$.

$$\sum_{s \in IS(i,s)} ST_{i,s,g,t-1} + PT_{i,g,t} + PU_{i,g,t} + \sum_{l \in (i,l)} \sum_{g' \neq g} Q_{i,l,g,g',t} = \sum_{s \in IS(i,s)} ST_{i,s,g,t} + DT_{i,g,t} + \sum_{l \in (i,l)} \sum_{g' \neq g} Q_{i,l,g,g',t} + W_{i,g,t} \quad \forall i, g, t \quad (1)$$

3.2. Energy balances and constraints

Due to single source energy generation, total energy demand is defined as follows:

$$\sum_{ei} [EnIJ_{ei,g,t} \times EfIJ_{ei}] + \sum_{ex} [EnXJ_{ex,g,t} \times EfXJ_{ex}] = TotalDemand_{g,t} \quad \forall g, t \quad (2)$$

Here, it is assumed that different types of energy are generated internally and purchased from external resources, reflected by ei and ex indices, respectively. The total amount of energy demand $TotalDemand_{g,t}$ of a process plant located in region g is equal to the summation of all different types of energy flows $EnIJ_{ei,g,t}$, generated inside the system, plus the total energy flow that comes from the external resources $EnXJ_{ex,g,t}$. The conversion efficiencies between energy resources and the process plant are represented by $EfXJ_{ex}$ and $EfIJ_{ei}$.

3.3. Objective functions

The model includes two objective functions, being the Net present Value (NPV) as the economic objective function whereas the environmental impact quantified regarding the Life Cycle Assessment (LCA) principles. The NPV can be determined from the discounted cash flows (CF_t) generated in each of the time intervals in which the total time horizon is divided, updated according to the interest rate (ir)

$$NPV = \sum_t \frac{CF_t}{(1+ir)^{t-1}} \quad (3)$$

In the current application, the total environmental damage is simplified to only consider the Global Warming Potential, through the GWP100 metric and calculated through the summation of damages could be caused in each stage of SC: the production of the main

feedstock GWPPU, the manufacturing and storage tasks GWPPE, and the transportation of materials between regions GWPQ. Hence,

$$DAM = GWPPU + GWPPE + GWPQ \quad (4)$$

$$GWPPU = GWP100PU \times \sum_i \sum_g \sum_t PU_{i,g,t} \quad (5)$$

$$GWPPE = \sum_i \sum_p \sum_g \sum_t GWP100PE_p \times PE_{i,p,g,t} \quad (6)$$

$$GWPQ = \sum_i \sum_l \sum_g \sum_{g'} \sum_t GWP100Q_l \times EL_{g,g'} \times Q_{i,l,g,g',t} \quad (7)$$

Here, $GWP100PU$, $GWP100PE_p$, and $GWP100Q_l$ represent the heat absorbed by any greenhouse gas (as a multiple of the heat that would be absorbed by the same mass of carbon dioxide) in the atmosphere by the feedstock production, main products operations and material transportation process, respectively. The environmental impact, as an objective function, is defined through the variable DAM as an environmental metric to be minimized.

$$DAM = GWPPU + GWPPE + GWPQ \quad (8)$$

3.4. Multi-objective equations

The mathematical model presented herein capitalizes on the mixed-integer linear programming (MILP) formulation and seeks to optimize simultaneously the NPV and DAM objectives described in the bi-dimensional objective function as presented in model M . The overall bi-MILP formulation can be expressed briefly as follow:

$$(M) \quad (9)$$

s.t. constraints 1-7

$$x \in R, X \in \{0, 1\}, N \in Z^+ \quad (10)$$

Note that, despite being the work by Mele et al. (2011) the basic model, particularly in those equations regarding production, it is extended to consider the energy section to amplify solutions borders and create more opportunities to make more flexible decisions.

4. Case Study: Retrofitting of integrated Sugar-bioethanol SCs

The proposed formulation is illustrated through its application to a case study based on the sugar-bioethanol industry of Argentina. The country is divided into 24 regions with associated ethanol, raw and white sugar demands. We use the data in Mele et al. (2011).

4.1. Cogeneration power plant

Cogeneration power plant is considered as a single source of energy generation to produce two types of energy (heat and electricity). It is assumed that the energy output per ton of sugarcane is 66 kW/t and the minimum energy generation coefficient is equal to 1. It is also assumed that the capacity of the power plant is 50 GW , and power

generation is available continuously for 7800 hours annually. On the basis of IEA (2010), the estimated installation costs of the cogeneration plant is $800 \frac{\text{€}}{\text{kW}}$.

5. Results

Regarding the aim of proposing a quantitative tool, we target at determining the optimal integration of renewable technologies to meet the energy (in this particular case electricity) demand in order to produce the main products (particularly sugar and ethanol) and cover the market demand over 12 months and during 4 years of planning horizon. The bi-criteria model was written in GAMS and solved with the MILP solver CPLEX 12.9 on an Intel® Core™ i7-3770 Octa-core Processor 3.40 GHz and 7.88 GB of RAM. The results include the environmental sustainability of the network to illustrate the environmental impacts minimization simultaneously with maximization of NPV. It takes approximately 1200 seconds to identify the global optimum in every instance. 12 Pareto points were generated, as shown in Fig. 1, in which nadir and utopia points have been also included.

Fig. 1. Pareto set of solutions NPV vs GWP100

The decision on the optimum configuration of the system mainly depends on its local resource (energy/raw material) availability and the installation and operational costs. In this, the SC consists of three sugar mills and five distilleries. In the maximal NPV solution, all the production plants are implemented in 10 regions, 4 of them having sugarcane plantations. This optimality comes from the raw material availability and stability regarding climatic conditions during a year. There are cogeneration power plants in 4 regions that have the most sugarcane plantation capacity. The installed production technologies and the number of the power plants can be seen in Table 1 for both cases of maximal NPV and the minimal GWP100.

Table.1 Output data for the two extreme solutions

	NPV, €	GWP100, CO ₂ KG	Retrofitted Regions	Non Retrofitted Regions	Distillery Production Technology	Sugar Mill Production Technology
Maximal NPV	3.20×10^9	-1.56×10^0	4	6	T3, T4	T1, T2
Minimal GWP100	2.380×10^9	-1.8×10^0	10	0	T3	T1

Table 2. Regional Installed power capacity (kW) of power plant

Region	G13 (Salta)	G16 (Tucumán)	G17 (Jujuy)	G18 (Santa Fe)
Cogeneration power plants	2.5	2.5	58.6	378.8

Hence, they are autonomously able to provide their energy demand and Tucumán (G16) sells its exceeded energy to the grid. The results assure that for all demand levels, an energy surplus of 10% to 40% especially in lower demands create possibilities to market it. Hence, regions with constant climatic condition such G16, G17 and G18 may implement cogeneration plants and so advantage results in a high contribution of residue to energy in the energy/material SC and as it has the most effective share of 60% in the integrated energy/material SC and the NPV improves to 43% than stand-alone system.

6. Conclusions

In this work, we introduced a general model to optimize an integrated energy/material SC with economic and environmental concerns. The model includes four segments of equations: material production, energy generation and integrated energy/material equations and objective function. It is aimed to show the quantitative profitability of integration for both economic and environmental issues.

The model has been validated in a country size case study of Argentinean sugar cane industry that is considered 24 regions of Argentina as potential sites. For this case, several system configurations proposed and analyzed the exploitation benefits of renewable energies to generate different energy types required in a production process system.

Compared to Mele et al. (2011) work as an initial model, by considering a single type energy provider as an internal resource, the economic criteria represented by NPV, is increased 20% in a deterministic condition (Morakabatchiankar et al., 2017). Furthermore, by developing the model to a multi type energy generation, results show an increase of 43% in NPV. In the particular case study, not only we can satisfy the internal energy demand to produce main products that can satisfy 97%, 37% and 40% of the whole country demands for ethanol, white sugar and raw sugar respectively, but also there is generated 64 GWh of exceeded energy to sell.

Abstract

The rising share of renewable energy sources in power supply and the shut-down of conventional power plants lead to a need for new providers of balancing power. Balancing-power could be newly provided by the flexibilization of decentralized energy systems. In this contribution, we propose flexibility-expansion planning for decentralized energy systems to account for investments in additional units for flexibilization. Flexibility-expansion planning leads to a stochastic optimization model for optimal investment decisions towards increased operational flexibility. The stochastic optimization model consists of a design optimization and a two-stage stochastic program. In a case study, the method is applied to a decentralized energy system participating in the German tertiary balancing-power market. Savings of up to 5.9 % can be achieved with additional investments in heat storage. Thus, flexibility-expansion planning allows operators of decentralized energy systems to optimally invest in flexible technologies for improved balancing-power market participation.

Keywords: Ancillary service, utility system, stochastic optimization, control reserve

1. Introduction

Balancing power settles short-term imbalances between supply and demand in the electricity grid. Balancing power is an ancillary service offered by electricity providers or consumers. Positive balancing power is provided by increasing the demand or decreasing the supply; negative balancing power works vice versa. Today, conventional power plants supply most balancing power. However, many conventional power plants are shut down due to political, ecological, and economic reasons. These power plants no longer provide balancing power, while studies show an increasing demand for balancing power (DENA, 2014). Hence, new balancing-power providers are needed.

Deciding to provide balancing power is challenging due to the inherent uncertainty. Zhang et al. (2015) therefore use robust optimization to model the balancing-power market participation of an air-separation unit with cryogenic energy storage. The number of balancing-power requests is specified exogenously and the system is scheduled to the worst case of balancing-power requests. Kumbartzky et al. (2017) demonstrate savings for a combined-heat-and-power plant with heat storage participating in the German electricity and balancing-power market. Stochastic optimization is used to account for market uncertainties. However, the model excludes the actual request of balancing power. For a production system with an on-site utility system, Leenders et al. (2019) model the participation in the German tertiary balancing-power market. The operation of the overall

system is explicitly modeled if balancing power is requested. Schäfer et al. (2020) and Bohlayer et al. (2020) demonstrate savings from balancing-power market participation for an energy-intense aluminum mill and cement plant, respectively. However, only a few studies investigate investments in additional units to increase the flexibility of decentralized energy and production systems. Muche et al. (2016) optimize a combined-heat-and-power plant participating in the tertiary balancing-power market in Germany. The investment in heat storage is studied to increase flexibility. The investment decision itself is not part of the optimization problem and is only considered *a posteriori*. Hence, the sizing of storage is suboptimal and turns out to be non-profitable. Teichgräber and Brandt (2020) design a chlor-alkali electrolyzer with real-time electricity market data using stochastic optimization. Large differences in system design are shown depending on the shape and magnitude of the used market price data. The authors point out that other short-term markets should be considered in design optimization besides the real-time electricity market. Commonly, decentralized energy systems are designed only to cover exogenous demands of, e.g., heating, cooling, electricity. As reviewed, the balancing-power market participation is often studied for a given energy system design. Thus, the energy system is not designed for participation in balancing-power markets. In this work, a method is proposed for flexibility expansion of decentralized energy systems to increase balancing-power provision. The method employs a stochastic optimization model that combines long-term investment decisions with short-term operational decisions from participation in balancing-power markets. The operational model is based on Leenders et al. (2020). We extend this model with investment decisions and time-coupling storage equations.

2. Flexibility-expansion planning for balancing-power markets

The goal of flexibility-expansion planning is the optimal long-term investment for participation in the balancing-power market (Figure 1). Long-term investment decisions are considered by the design optimization. Therein, the investment in flexibility options is modeled to increase the flexibility of the decentralized energy system. The design optimization chooses the optimal capacity CAP_u of units $u \in U$, e.g., heat storage or electrode boiler. Short-term operational decisions are considered by a two-stage stochastic mixed-integer linear program. The stochastic program models the course of the information revelation in the balancing-power market and covers the uncertainty from the request of balancing power. Bids in the balancing-power market need to be made one day before operation. The 1st stage of the stochastic program models the pay-as-bid balancing-power market auction for the decentralized energy system. Bids in the balancing-power market consist of an amount of positive and negative balancing power $BP_{s,t}$, the capacity price $cp_{s,t}$ and the energy price $ep_{s,t}$ for each request scenario $s \in S$ and time step $t \in T$. The capacity price is paid for the provision of capacity in the balancing-power market. The energy price compensates for the respective request of balancing power. The energy price bid is discretized as in Leenders et al. (2019) with a Big-M formulation to avoid nonlinearities from the bidding decision. The 2nd stage of the stochastic program is the scenario-dependent operation $OP_{s,t,u}$ of the decentralized energy system. Since the request of balancing power is uncertain in each time step $t \in T$, three request scenarios $s \in S = \{ 'no', 'pos', 'neg' \}$ can occur with their probabilities $\omega_{s,t}$: no request of balancing power ('no'), and request of positive or respectively negative balancing power ('pos' / 'neg'). In each time step, the operation of the decentralized energy system depends on the request scenario for balancing power. In the scenarios 'pos' / 'neg', the produced electricity increases/decreases by the offered amount of balancing power $BP_{pos,t}$ and $BP_{neg,t}$, respectively. Hence, the operation of the decentralized energy system $OP_{s,t,u}$ is different for each request scenario and in each time step.

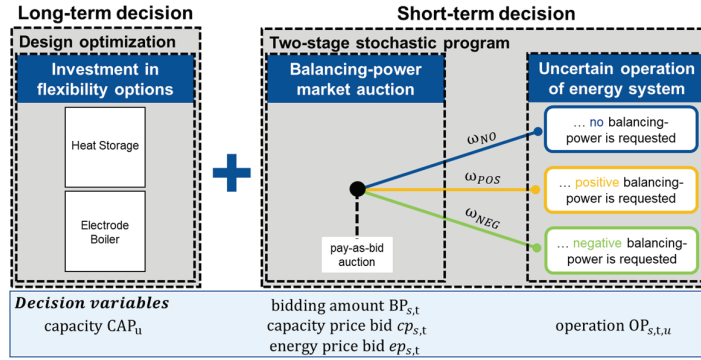

Figure 1: Flexibility-expansion planning combines a design optimization determining long-term investment decisions with a two-stage stochastic mixed-integer linear program for optimal operational decisions in the balancing-power market. Long-term and short-term decision variables are listed below the figure.

The long-term investment decisions cannot be taken independently without considering the short-term decisions. Hence, we combine both optimization models for long- and short-term decisions in the flexibility-expansion planning problem. The flexibility-expansion planning minimizes the total annual costs TAC subject to energy balances, storage equations, and other operational constraints of the energy system:

$$\begin{aligned} \min TAC &= CAPEX + OPEX & (1) \\ s.t. \text{ energy balances } &\forall p \in P, t \in T, s \in S & (2) \\ \text{ storage equations } &\forall p \in P, t \in T, s \in S & (3) \\ &\vdots & \end{aligned}$$

The total annualized costs TAC consider annualized capital expenditures $CAPEX$ in newly installed units $u \in U$ with capacity CAP_u and the yearly operational expenditures $OPEX$. The operational expenditures $OPEX$ arise from the scenario-based operation of the decentralized energy system $OP_{u,s,t}$. At each time step t , the operational expenditures $OPEX$ consider the costs for all three scenarios $s \in S$ weighted with the respective request probability $\omega_{s,t}$. The operational expenditures $OPEX$ consist of costs for gas and electricity purchase and revenues from the sale of electricity and the participation in the balancing-power market.

The energy balance needs to be fulfilled for all products $p \in P$, e.g., heating, cooling, electricity, in each time step $t \in T$ and request scenario $s \in S$. Details about the formulation of the operational expenditures and the energy balance formulation are given by Leenders et al. (2020).

2.1. Modeling of time-coupling energy storage

Energy storage is used to store a product in a specific time step and withdraw it at a later time step. Hence, energy storage couples the time steps in an optimization problem. Modeling energy storage in stochastic optimization increases complexity. In each time step, storage can operate in 3 modes, since the three request scenarios lead to different storage levels in general. In result, the number of possible storage levels grows with $3^{|T|}$. Hence, the problem gets computationally intractable with already a few time steps.

Here, we propose a method to restrict the possible storage level in each time step. To keep the problem tractable, we consider only one distinct storage level in the next time step. For this purpose, we propose two formulations based on different assumptions (Figure 2).

Same-storage-level formulation

In the same-storage-level formulation, the storage is operated the same regardless of the request of balancing power. This formulation leads to an operational schedule of the decentralized energy system, which is always feasible but restricts operational flexibility. Storage level $LEV_{p,t+1,s}^{st}$ of the next time step $t + 1$ is derived by withdrawing product $OUT_{p,t,s}^{st}$ or adding product $IN_{p,t,s}^{st}$ to the storage level $LEV_{p,t,s}^{st}$ in time step t

$$LEV_{p,t+1,s}^{st} = LEV_{p,t,s}^{st} \cdot \eta_p^l + \Delta_t \cdot \left(\eta_p^{st} \cdot IN_{p,t,s}^{st} - \frac{1}{\eta_p^{st}} \cdot OUT_{p,t,s}^{st} \right) \forall t \in T, s \in S, p \in P. \quad (4)$$

The storage losses η_p^l in each time step t are assumed to be a constant share of the storage level $LEV_{p,t,s}^{st}$. Furthermore, constant charge and discharge efficiencies η_p^{st} are assumed. In the same-storage-level formulation, the storage level $LEV_{p,t,s}^{st}$ is the same in each scenario $s \in S$ and, thus, the operational variables for charging $IN_{p,t,s}^{st}$ and discharging $OUT_{p,t,s}^{st}$ are the same in each scenario $s \in S$. Hence, the storage operation has no recourse. However, the problem remains a two-stage stochastic optimization as the other units $u \in U$ adapt to the respective scenario that materializes.

Lowest-storage-level formulation

In the lowest-storage-level formulation, the storage operates independently in each request scenario, but only the lowest storage level is considered in the next time step $t + 1$. Thereby, we avoid the exponential growth of scenarios but have to allow for overproduction if the storage is fully charged. The storage-level equation Eq. (4) is changed to an inequality:

$$LEV_{p,t,s}^{st} \cdot \eta_p^l + \Delta_t \cdot \left(\eta_p^{st} \cdot IN_{p,t,s}^{st} - \frac{1}{\eta_p^{st}} \cdot OUT_{p,t,s}^{st} \right) \geq LEV_{p,t+1,s}^{st} \forall s \in S, t \in T, p \in P. \quad (5)$$

In this formulation, no non-anticipativity constraints are needed for the operational variables $IN_{p,t,s}^{st}$ and $OUT_{p,t,s}^{st}$, but the non-anticipativity constraints for the storage level $LEV_{p,t,s}^{st}$ are kept. Each time step, the storage operates differently for each request scenario, but the storage level is equal to the lowest storage level. This formulation offers more operational flexibility of energy storage, but the energy storage might be sized too small in some unfavorable cases as overproduction is allowed.

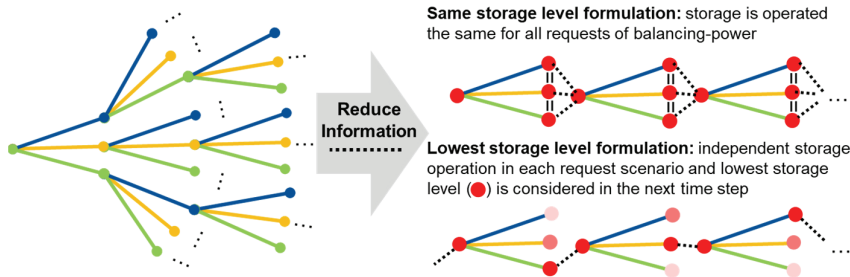

Figure 2: The scenario tree for an energy system with energy storage in stochastic optimization (left). The scenario tree grows exponentially due to time-coupling constraints. To keep the problem tractable, we propose 2 formulations (right) to reduce the information, i.e. storage level, considered in the next time step.

3. Case study

3.1. Description

Flexibility-expansion planning is applied to a real-world case study of a decentralized energy system based on Baumgärtner et al. (2019) with 3 combined-heat-and-power engines (2, 2.25, 3 MW), 2 boilers (5, 2 MW), 2 absorption chillers (1.4, 0.3 MW), and 3 compression chillers (2.2, 2.2, 1.3 MW) to cover a time-varying demand of heating, cooling, and electricity. Investments in heat storage and electrode boiler are considered. The energy system participates in the German tertiary balancing-power market while considering hourly fluctuating electricity and gas prices. We use market price data in the current balancing-power market design from 01.08.2019 to 31.07.2020. Capacity prices, discrete energy prices, and request probabilities are derived similarly to Leenders et al. (2019). The maximum amount of balancing power to be offered is set to 5 MW. Bids in the balancing-power market need to be the same for four hours to comply with the current market rules. The time-sensitive data are derived as time series of one year with an hourly resolution. We aggregate the time series with the TSA-module from Kotzur et al. (2018) using hierarchical clustering to receive one typical day with 24 time steps. Four cases are compared: No balancing-power market participation and no possibility to invest (*no market*), balancing-power market participation and no possibility to invest (*no invest*), balancing-power market participation and possibility to invest in an electrode boiler and heat storage using the same storage level formulation (*same*) or the lowest storage level formulation (*flexible*). All optimization problems are solved with the solver Gurobi on an Intel Xeon W-2155 @3.30 GHz with 128 GB RAM with an optimality gap of 1 % and a time limit of 7200 s. The 4 cases needed the following time to solve the problem to the predefined gap: 3 s (*no-market*), 13 s (*no invest*), 7200 s with a gap of 1.4 % (*same*) and 7200 s with a gap of 2.0 % (*flexible*).

Table 1: Expected costs (positive) and revenues (negative) for the four cases *no market*, *no invest*, *same* and *flexible* (upper part). Average offered amount of positive and negative balancing power at the typical day for the four cases *no market*, *no invest*, *same* and *flexible* (lower part).

<i>In 1000 €</i>	<i>No market</i>	<i>No invest</i>	<i>Same</i>	<i>Flexible</i>
Investment costs	0	0	12	11
Expected gas costs	2653	2687	2790	2831
Electricity costs	274	232	96	60
Balancing-power market revenues	0	-81	-97	-146
Total annual costs	2927	2838	2802	2756
Savings	0.0 %	3.0 %	4.3 %	5.9 %
Average positive balancing power [in MW]	0.0	0.33	0.67	2.0
Average negative balancing power [in MW]	0.0	4.5	4.5	4.5

3.2. Results

In the case study, flexibility-expansion planning saves 4.3 % (*same*) and 5.9 % (*flexible*) compared to the case *no market* (Table 1). Participation in the balancing-power market without investment saves 3.0 % compared to the case *no market*. Balancing-power market participation decreases electricity costs while gas costs increase. More electricity is produced to reduce electricity production upon request of negative balancing power.

In the case *same*, the optimal heat storage capacity is 2.9 MWh and in the case *flexible* 2.6 MWh. The smaller heat storage capacity in the case *flexible* than in the case *same* indicates that additional heat is not necessarily profitable to store when overproduction is possible. Instead of using the excess heat in other time steps, the heat storage is sized smaller in the case *flexible* than in the case *same* to reduce capital expenditures. Neither the case *same* nor the case *flexible* regard an investment in electrode boilers as beneficial.

The decentralized energy system offers an average amount of 4.5 MW of negative balancing power for the cases *no invest*, *same* and *flexible* (Table 1). Hence, the decentralized energy system has sufficient flexibility to provide negative balancing power. The average amount of offered positive balancing power increases with heat storage installation from 0.33 MW in the case *no invest* to 0.67 MW in the case *same* (Table 1). In the case *same*, heat storage gives heat-controlled combined-heat-and-power engines more flexibility since heat production is shifted to time steps with higher electricity demand. In the case *flexible*, the average offered amount of positive balancing power increases to 2.0 MW, as heat storage enables the combined-heat-and-power engines to be even more flexible.

4. Conclusions

The proposed flexibility-expansion planning combines long-term investment decisions with short-term operational decisions in one stochastic optimization model. For the flexibility-expansion planning, we proposed two methods to model energy storage in a stochastic optimization model for balancing-power market participation. In a case study of a decentralized energy system, flexibility-expansion planning achieves cost savings of up to 5.7 %. Thereby, flexibility-expansion planning supports participation in the balancing-power market.

Abstract

Refined products supply chain optimisation is a crucial issue in the oil industry. The task is to transport refined products from refineries to storage depots and retail markets through multiple transport modes. The optimisation of the refined products supply chain has been mostly based on maximising the total profit. However, each company, along with the supply chain, pursues their own maximum profit. The solution obtained by the total chain method may not satisfy all the participants in the refined products supply chain. Bargains have existed between these companies, and steps are required to adjust the transport plan, which may affect the optimality of the plan. Also, the bargain abilities of these companies are different. A mixed-integer nonlinear programming (MINLP) model considering both cooperative game theory and transfer prices to simulate the behaviours of stakeholders is proposed to solve this problem of the optimal refined products distribution planning. Material balance, production rate, transport modes and capacities are developed as constraints. Nash bargaining solutions for the multi-player bargaining game are obtained via maximising a tailored objective function. In this way, a refined products distribution plan with more fair profit allocation can be obtained, and the bargaining ability of each participant can be considered. The model is applied to a refined products supply chain in China as a case study to show its validity and applicability. This method can also be used in the optimal planning of other refined products supply chain and help to enhance their performance.

Keywords: Refined Products Supply Chain (RPSC), fair profit allocation, mixed-integer nonlinear programming (MINLP), Nash bargaining.

1. Introduction

As a sort of primary energy, the consumption of the refined products achieved 325.14 Mt in 2018, with 6% year-on-year growth in China (National Development and Reform Commission, 2019). Refined products supply chain (RPSC) plays an important role in linking refineries and retail markets. Optimisation of the RPSC is widely studied from many aspects to reduce the operating cost and improve efficiency (Sule et al., 2011). Wang et al. (2019) developed a mixed-integer linear programming (MILP) model that considered both RPSC distribution and new pipeline route planning to achieve the goal of minimising annual transport and pipeline investment costs. Lima et al. (2018) developed a multistage stochastic programming model for the optimal distribution of

refined products. Yuan et al. (2019) developed a framework that coupled a mathematical programming technique with the energy-economy-environment (3E) assessment method to quantify the impacts of pipeline network reform on the downstream oil supply chain of China. Zhang et al. (2019) proposed a stochastic linear programming model for the reliable design of the oil products supply chain. The stochastic hub disruption and the demand uncertainty were considered, and the effect of uncertainties on the supply chain design was analysed. Wang et al. (2020a) proposed a framework for reliability assessment of a regional RPSC under several scenarios. Yuan et al. (2020) evaluated the province- and region-level supply security of refined products in China by an integrated assessment framework. Wang et al. (2020b) developed a framework for the optimisation of downstream oil supply chains with emission-cost nexus using P-graph model (Friedler et al., 1992).

However, the majority of companies in the supply chain pursue their maximum profit. The solution obtained by the current methods may not satisfy all the participants in the RPSC. Bargains have existed between these companies, and steps are required to adjust the transport plan. In this case, it is practical to optimise the operation of RPSCs, considering the profit allocation. Gjerdrum et al. (2001) proposed a MILP model for fair and optimised profit distribution between members in a supply chain. Liu and Papageorgiou (2018) developed a MILP model framework with the consideration of fair profit distribution to optimise an active ingredient supply chain. Zheng et al. (2020) studied the fair profit allocation problem in third-party take-back waste cooking oil-to-biodiesel supply chain, and they also compared different policy impacts on integrated and opening markets. In this paper, a MILP model is developed for the fair profit allocation of an RPSC. A Nash-bargaining solution is solved to obtain the distribution plan. Results of total profit maximisation and Nash-bargaining solution are compared to show how the proposed model can lead to a fair profit allocation between participants in the RPSC.

2. Problem description

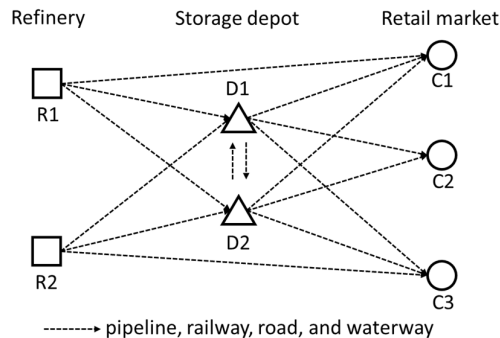

Figure 1 Schematic diagram of an RPSC

The RPSC in China has 3 echelons: refinery, storage depot, and the retail market. Refineries produce refined products and sell them to storage depots and retail markets. Storage depots purchase refined products from refineries and sell them to retail markets. Storage depots usually have advantages of lower transport cost. Some have pipelines link from the upstream and link to the downstream. Some have access to water transport. The unit transport prices of these two ways are lower than transport by rail and road. Retail markets purchase refined products from refineries and storage depots to satisfy the

demand. If the demand is not satisfied, a lost sale cost would be counted. The schematic diagram of the RPSC is shown in Figure 1.

3. Mathematical model

Two models are developed, one is to maximise the overall profit of the whole RPSC, and the other is to maximise the profit based on the fair profit allocation. In this study, Nash-bargaining is applied to get a fair profit solution. The objective function of the Nash-bargaining is shown as follows:

$$\text{maximize } F = \sum_{i \in I} \ln Pr_i^I + \sum_{j \in J} \ln Pr_j^J + \sum_{k \in K} \ln Pr_k^K \quad (1)$$

Where Pr_i^I , Pr_j^J , and Pr_k^K are the profit of refinery i , storage depot j , and retail market k .

The basic constraints for supply chain optimisation include material balance and capacity constraints. These constraints can be referred to Wang et al. (2019).

In this model, there are three parts of profit constraints. The first is for refineries, the second for storage depots, and the third for retail markets. For the refineries, their profits are obtained according to sales revenue, depreciated investment, construction cost, purchasing cost of crude oil, and inventory cost. For the storage depots, their profit equations consist of sales revenue, refined products purchasing cost, inventory cost, and transport cost. For the retail markets, sales revenue, refined products purchasing cost, inventory cost, transport cost, and cost for lost sales make up the profit equations.

For the cooperative bargaining mode, Nash bargaining is adopted in this model. Except for the basic constraints for the RPSC optimisation, following transfer price constraints should be modelled.

$$TP_{i,p}^I = \sum_{e \in E} TPL_{p,e}^I \cdot X_{i,p,e}^I, \forall i, p \quad (2)$$

$$TP_{j,p}^J = \sum_{e \in E} TPL_{p,e}^J \cdot X_{j,p,e}^J, \forall j, p \quad (3)$$

$$\sum_{e \in E} X_{i,p,e}^I = 1, \forall i, p \quad (4)$$

$$\sum_{e \in E} X_{j,p,e}^J = 1, \forall j, p \quad (5)$$

Where $TP_{i,p}^I$ is the transfer price for refined product p from refinery i , $TP_{j,p}^J$ is the transfer price for refined product p from storage depot j , $TPL_{p,e}^I$ and $TPL_{p,e}^J$ are parameters that indicate the transfer prices when price level e is selected for refineries and storage depots, $X_{i,p,e}^I$ is a binary variable which indicates if the price level e is chosen for refined product p from refinery i , and $X_{j,p,e}^J$ is a binary variable which indicates if the price level e is chosen for refined product p from storage depot j . Constraints (2) and (3) obtain the transfer prices, and constraints (4) and (5) ensure that only one price level should be chosen for each refinery and storage depot.

4. Case study

In this section, an RPSC in East China is studied as an example. As shown in Figure 2, the supply chain includes refineries (represented by dot i), storage depots (represented by triangle j) and retail markets (represented by diamond k). Refined products can be transported between each individual by pipeline, railway, road, and waterway. The production capacities of refineries and storage capacities of storage depots are shown in Table 1 and Table 2. In this case, a total of 10 periods are selected as the study period; each period is one month long.

Figure 2 Locations of facilities in the studied RPSC

Table 1 Production capacities of refineries

Refineries	Petrol (kt/month)	Diesel oil (kt/month)
i1	6,250	9,500
i2	8,500	16,500
i3	2,600	4,900
i4	6,600	7,850
i5	9,000	5,700

Table 2 Inventory capacities of storage depots

Storage depots	Inventory capacities of petrol (kt)	Inventory capacities of diesel oil (kt)
j1	66.5	90.25
j2	95	114
j3	95	171
j4	38	58.9
j5	3.8	53.2
j6	47.5	57.95
j7	76	86.45
j8	142.5	209

The profit allocations of different individuals are shown in Figures 3, 4 and 5. It can be seen from Figures 3 and 4 that in the profit allocation of refineries and storage depots, the effect of the Nash bargaining solution to make a fairer profit allocation is not obvious. This is because refineries and storage depots handle a relatively large quantity of refined products in the RPSC than retail markets. To satisfy the demand for retail markets, these

upstream facilities has to be used. Also, it can be observed that the profit allocation of refineries and storage depots are more related to their handling capacities.

As shown in Figure 5, in the maximising total profit model, the profits of some individuals will be sacrificed to achieve the goal of maximising the profit of the whole supply chain. Taking retail market k17 as an example, it obtains a negative profit around $-4,800 \times 10^6$ CNY, but under this circumstance, the entire supply chain achieves the largest total profit. The distance between k17 and refineries is quite far. The solved model suggests a shortage in this retail market to increase total profit. In the Nash bargaining solution, the profit of k17 is closer to other retail markets.

The maximising total profit model can also lead to some individuals to make more profit, such as k52, k53, and k54. Their profits are significantly higher than in other retail markets. In the Nash bargaining model, the profit allocation tends to be fair.

Figure 3 Profit distribution among refineries

Figure 4 Profit distribution among storage depots

Figure 5 Profit distribution among retail markets

5. Conclusions

This paper studies the fair profit allocation in the RPSC, and a mathematical model is developed. A case is studied to test the proposed method. The results of the Nash-bargaining solution are illustrated. Results show that the Nash-bargaining solution will reduce the profit of markets by 19.3% compared to the integration, while a fairer profit allocation can be achieved. Future studies will focus on the performance evaluation of RPSCs, indicators including the supply rate of refined products and operating costs would be proposed. The sensitivity of alternative fuel prices, as well as the products purchasing, processing, and sale prices, should be further analysed.

Abstract

The decisions on synthesising a process network are often to optimise the payback periods based on investment cost. In addition to the core investment and the cost of used resources, the long-term reliable operation of the process is also crucial. Given available states and technologies of the assets, this study aims to identify the long-term optimal asset planning policy. Markov Decision Process (MDP) is a promising tool in identifying the optimal policy under different states of the assets or equipment. The failure probability of the unit is modelled with the ‘bathtub’ model and each of the condition states are incorporated in the MDP. The decisions to implement the redundant units in the process with variety of technologies are allowed. This paper applied the MDP into an equivalent Mixed Integer Non-linear Programming (MINLP) to solve for the optimal long-term assets decision and the maintenance policy. The applicability of the method is tested on a real case study from Sinopec Petrochemical Plant. The capital and expected operational cost that accounts for equipment maintenance for an infinite time horizon are determined.

Keywords: Markov Decision Process, Asset Optimisation, Reliability, Maintenance Planning, Mixed Integer Non-linear Programming (MINLP)

1. Introduction

The availability, reliability and maintenance planning are significant factors in the project economics when designing the process plant in the early stage. Goel et al. (2003) mentioned that the operating and the capital cost should be affected by the inherent availability of the system. The recent review by Chin et al. (2020) analysed different strategies of maintenance considering individual process plants.

Vassiliadis and Pistikopoulos (2001) derived a MINLP model with a two-step strategy to identify optimal maintenance policies in continuous process operations. The first step involves generating structural design based on availability threshold values and maintenance time, while the second step involves operative-failed state-space model to determine the optimal policies. Several studies on improving the equipment availability can be found in Godoy et al. (2015) for hydropower or Süle et al. (2019) for petrochemical system. industry or Andiappan et al. (2019) in biomass trigeneration system. Ye et al. (2018) provided a general mixed-integer framework for selecting the

standby processing units to achieve optimal availability and cost. Ye et al. (2020) recently applied the Markov Decision Process (MDP) approach in synthesising the design optimisation, storage sizing and maintenance policy for the air separation process.

A variety of studies using MINLP frameworks to address asset availability issue have been proposed. However, there are still lacking system availability design considering different asset technologies, i.e. different reliability parameters or different sizes. The expected benefits of installing different asset technologies should be analysed by considering their long-term effects on the system efficiency and availability. Markov Decision Process (Bellman, 1957) is a framework that evaluates the optimal policies under different equipment states by optimising the long-term benefits (value functions) of each state. This method provides suggestions on actions for the equipment regardless of the equipment initial states. This means the optimal actions determined should be carried out for a specific equipment state to achieve expected long-term benefits.

Realising from the research gaps identified, this work aims to adapt the MDP formulation from Ye et al. (2020) to model the system availability design. The inspection intervals, the selection of the optimal technologies and the redundancy design are incorporated into the MDP with MINLP formulation. The stage interdependencies are considered within the state transitioning probability matrix.

2. Methodology

As most of the chemical processes are production systems with serial structures, a generic serial process structure is used to evaluate the reliability of the system. Each stage $i \in \mathbf{I}$ is dedicated to the subsystem/individual process unit with parallel units. The parallel units or redundant units are used as the standby so that when the operating unit is failed, the standby unit can be used immediately as a replacement to avoid downtime. One of the goal of this study is to determine the optimal number of redundant components in each stage. For each stage there are finite numbers of redundant design $j \in \mathbf{J}$, for which $j=2$ indicates there are 2 units installed in the stage. Each subsystem can also be implemented with assets technology $z \in \mathbf{Z}$ that has different reliability parameters, capacity or efficiency. Figure 1 shows the overall structure of the model.

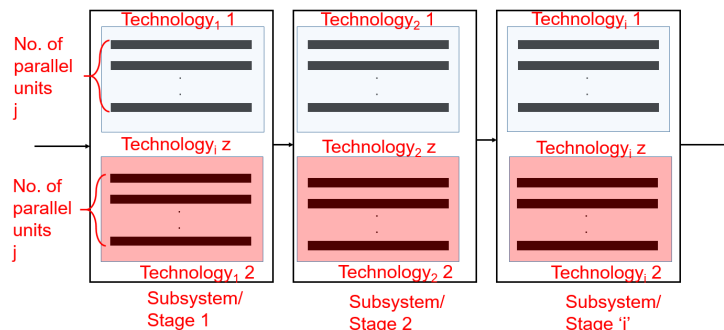

Figure 1: A generic structural representation of the problem

In this work, the condition of the equipment is modelled with the 'bathtub' model as the asset undergoes different period where their failure rates vary with time. As proposed by

Barlow and Proschan (1975), the deterioration of the asset is usually distinguished into three periods: ‘Infant’, ‘Stable’ and ‘Worn-out’.

Along with the three states as mentioned, the condition state of the equipment also includes states ‘Stopped’ and ‘Stand-by’. These states form the finite sets of condition states of the equipment $s \in \mathbf{S}$. Under different states, there are finite sets of possible actions $a \in \mathbf{A}$ that can be performed on the equipment: ‘None’, ‘Inspect’, ‘Maintain’ or ‘Stop’. The common approach to model asset maintenance plain using Markovian approach is to formulate the Continuous-time Markov Decision Process. For this approach, all of the equipment states in each stage are incorporated into the model. The approach is comprehensive; however, the applicability is hindered by the curse of dimensionality. Consider just two states exist for a piece of equipment: ‘Operating’ or ‘Failed’, if there are total of ‘k’ subsystems in the process, the number of available states is 2^k , and this is excluding the redundant units. If there are ‘n’ redundant units installed in each subsystem, the problem grows exponentially huge as the number of available states increases, as shown in Ye et al. (2020).

To overcome this issue, the MDP can be modelled in another way. The state-action representation can be modelled with each equipment in each stage and can be linked together with their transitioning probability, adopted from Ye et al. (2020). Figure 3 shows the state diagram for a single stage, with two redundant units installed in this work. It is assumed that the interdependency between units is affected by the failure of other subsystem or stage. For example, if one of the unit in any stage is failed, the other stages are not functional as well due to the serial structure. If any redundant is used, the stages go into ‘Standby’ state and resume to functional using the redundant equipment.

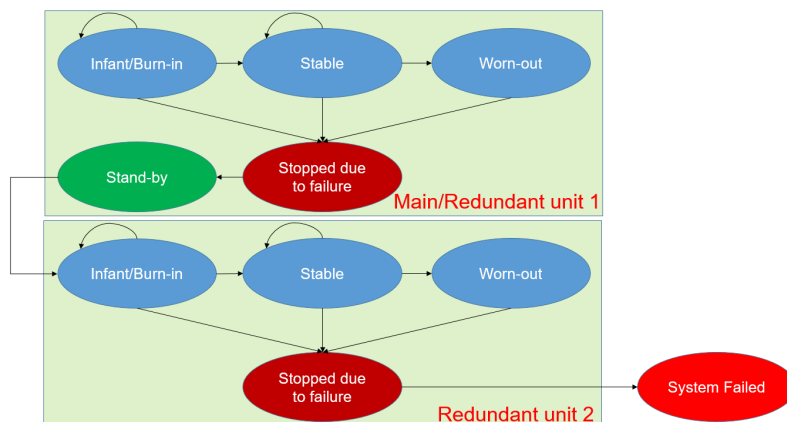

Figure 2: A state diagram MDP for a single stage, with two redundant units

3. Model formulation

The most common approach to solve a MDP is based on the Bellman Expected Optimality equation (Bellman, 1957) using value iteration or policy iteration. As the problem becomes complicated, these two approaches are not suitable and the problem can be converted to an optimisation formulation. The expected long-term cost to be minimised for the MDP is shown in Eq (1), with the constraint in Eq (2). These two equations are the basis for equivalent optimisation model for a MDP.

$$\sum_{i \in I, j \in J, z \in Z} y_{i,j,z} Cap_{i,j,z} + \sum_{i \in I, j \in J} \sum_{s \in S} \pi_{i,j}(s) v_{i,j}(s) \quad (1)$$

$$v_{i,j}(s) \geq \sum_{s' \in S} P_{i,j}(s, a, s') \sum_{z \in Z} y_{i,j,z} R_{i,j,z}(s, a, s') + \gamma \sum_{s' \in S} P_{i,j}(s, a, s') v_{i,j}(s') \quad (2)$$

$\forall i \in I, j \in J, s \in S, a \in A$

The variable $y_{i,j,z}$ is the binary variable indicating the selection of redundant numbers ‘j’ and technology ‘z’ for stage ‘i’; $Cap_{i,j,z}$ is the capital cost for the stage ‘i’ with ‘j’ numbers of redundant units using technology ‘z’. $\pi_{i,j}(s)$ is the probability distribution of state ‘s’ for the stage ‘i’ that is determined by the model. The variable $v_{i,j}(s)$ is the value function of each state ‘s’ in the MDP which it represents the ‘discounted’ rewards in state ‘s’. The rewards in this case is the maintenance cost for the system. $P_{i,j}(s, a, s')$ is the state transitioning probability from state ‘s’ with action ‘a’ to state ‘s’’, where this corresponds to the stage ‘i’ and redundant design ‘j’. $R_{i,j,z}(s, a, s')$ is the instant rewards when transitioning from state ‘s’ to state ‘s’ by action ‘a’, with selected asset technology ‘z’. As the problem involves minimisation of the total cost, the instant reward parameters are the instant maintenance cost associated with the actions. The γ is the discount factor which is fixed at 0.1 for this work. The constraint for $y_{i,j,z}$ is fixed with Eq (3), where only one redundant design and one technology can be selected. Eq (4) represents only one action is selected only for state ‘s’, for stage ‘i’ provided redundant number ‘j’ is selected. $x_{i,j}(s, a)$ is a binary variable indicating the selection of action ‘a’ in state ‘s’, for stage ‘i’ and redundant ‘j’.

$$\sum_{j \in J, z \in Z} y_{i,j,z} = 1 \quad \forall i \in I \quad (3)$$

$$\sum_{a \in A} x_{i,j}(s, a) = \sum_{z \in Z} y_{i,j,z} \quad \forall i \in I, j \in J, s \in S \quad (4)$$

Eqs (5) to (7) below indicate the constraints for the stationary probability distribution of the MDP, $\pi_{i,j}(s)$. Eq (6) is introduced as the sum of probability distribution for any state ‘s’ should exist only if the redundant unit ‘j’ and technology ‘k’ is selected. $\pi_{i,j}^{policy}(s, a)$ indicates actions ‘a’ is preferred in the state ‘s’ if its value > 0. Eq (7) indicates the total selected policy for a single state is equal to the probability distribution of state ‘s’.

$$\sum_{s \in S, a \in A} x_{i,j}(s, a) \pi_{i,j}^{policy}(s, a) P_{i,j}(s, a, s') = \pi_{i,j}(s') \quad \forall i \in I, j \in J, s' \in S \quad (5)$$

$$\sum_{s \in S} \pi_{i,j}(s) = \sum_{z \in Z} y_{i,j,z} \quad \forall i \in I, j \in J \quad (6)$$

$$\sum_{a \in A} x_{i,j}(s, a) \pi_{i,j}^{policy}(s, a) = \pi_{i,j}(s) \quad \forall i \in I, j \in J, s \in S \quad (7)$$

The states transition probability and the instant rewards adapted from Ye et al. (2020) are defined by Eqs (8) to (9). In this work, the maintenance cost involves a certain fixed cost plus the downtime cost due to maintenance duration. The inspection cost is based on fixed labour cost, and the shutdown cost is calculated with the production loss cost due to stopping the operation. The probability from ‘stopped’ to ‘standby’ is if more than one redundant unit is used.

$$P_{i,j}(s, a, s') = \{1 - e^{-\left(\frac{T_{infant}}{\theta}\right)^{b_1}}\} \quad \text{if } (s, a, s') = (Infant, None, Stopped), \quad e^{-\left(\frac{T_{in}}{\theta}\right)} \quad (8)$$

$$R_{i,j}(s, a, s') = \{C_{maintain} \quad \text{if } a = 'Maintain' \text{ and } s \neq 'Stopped' \quad C_{inspect} \quad (9)$$

4. Case study and results

The methodology is applied to a real case study from Sinopec Luoyang Petrochemical Plant from Hu et al. (2009). It is a naptha reforming reaction system that process 2,500 t/d of refined naptha, with subsystems of reactors, heat exchangers, compressors and pumps and absorbers. The full documentation of the maintenance records, as well as the inspection, shutdown and maintenance cost parameters for the equipment in the plant can be found in the reference source. The case study allows maximum of three redundant units to be installed in each equipment position. Different technologies are available by varying the shape parameter of the failure function by multiplying a random number, i.e. $\mu_1 \times b_2$, where μ_1 is a random number between 0 and 1. The capital cost for each technology of the unit is also assumed to be varied by the equation: $(1 - \mu_2) \cdot Base\ capital_i$, where μ_2 is a random number between -0.5 and 0.5. The MINLP model is solved using GAMS software with random number seed generator set as zero. The total expected optimal cost is \$ 2.4 M, with long-term risk cost as \$ 0.19 M/y (\$ 0.25 M/y from Süle et al. (2009)). The inspection intervals for each equipment range from 2 to 4 months.

5. Conclusion

A discrete-time Markov Decision Process has been proposed to evaluate the long-term economic benefits of different assets technologies and redundant unit allocation in a chemical process. The discrete decisions and the inspection periods are translated to MINLP model to optimise the long-term discounted cost. The method is tested on a real case study from Sinopec petrochemical plant. This approach is regardless to the initial state of the subsystem, which means that the optimal policies identified can be followed regardless of the states of the equipment. However, the approach suffers computational complexity due to the high number of binary variables and non-linear terms in the transitioning probability. This might be inconvenient if quick maintenance decision is to be made as data are updated. Future research can be focused on the linearisation or enumeration algorithm of the structural network to reduce the binary variables during operational optimisation, while generating multiple near-optimal solutions for industrial practitioners. The ‘bathtub’ model also could not represent all type of equipment accurately. Future research should consider real data-driven estimation of the failure rate.

Cost, environmental and exergy optimization of hydrogen and methane supply chains: application to Occitania region, France

Eduardo Carrera, Catherine Azzaro-Pantel

Laboratoire de Génie Chimique, Université Toulouse, CNRS, INPT, UPS, Toulouse, France

Abstract

This paper presents a methodological framework for the design of Hydrogen and Methane Supply Chains (HMSC), mainly focusing on Power-to-Gas (PtG) with low-carbon sources to spur the energy transition. The scientific objective is to perform mono and multi-objective optimizations of the HMSC to provide effective support for the study of deployment scenarios, with the Occitania region (France) as a case study. The formulation developed is based on a Mixed Integer Linear Programming (MILP) approach with augmented ϵ -constraint, implemented in the GAMS environment following a multi-period approach (2035-2050). The three objectives to be minimized are the Total Annual Cost, the Total Global Greenhouse Gas emissions, and Total Exergy Lost/Destroyed, which are related to the whole HMSC over the entire period studied. The results show that hydrogen can be competitive with SMR with carbon rates below 270 €/tonCO₂, whereas other drivers (i.e., ambitious policies to reduce GHG emissions) are expected for synthetic methane. Furthermore, coupling with other energy systems and processes is essential to increase the exergetic performance of HMSC.

Keywords: Power-to-Gas, hydrogen, methanation, MILP, exergy analysis, supply chain optimization.

1. Introduction

Power-to-Gas (PtG) is a promising solution to drive the penetration of low-carbon energy sources into the energy mix. These systems allow the use of electrical power, and CO₂ to produce gas (i.e., hydrogen or methane). Faced with the intermittency of renewable energy sources, they provide a low-carbon fuel supply and promote CO₂ recovery (Götz et al., 2016). Despite their advantages, PtG systems face some challenges. Typical Levelized Cost of Energy (LCOE) values for hydrogen and methane from PtG are stated at 64-74 €/MWh (2.1-2.5 €/kgH₂), and 95 to 150 €/MWh in 2030 (E&E consultant et al., 2014), respectively. In this regard, other options such as Steam Methane Reforming and natural gas are economically more advantageous (IEA - International Energy Agency, 2019)). In addition, the factors that favor the use of low-carbon technologies are decisive, since GHG emissions for SMR and natural gas are approximately 327 kgCO₂-eq/MWh and 202 kgCO₂-eq/MWh, respectively (Reiter and Lindorfer, 2015). For hydrogen produced from PtG, typical GHG emissions values range around 18-90 kgCO₂-eq/MWh and 22-191 kgCO₂-eq/MWh for renewable hydrogen and methane, respectively (Reiter and Lindorfer, 2015).

Another issue to be addressed is the destruction and loss of exergy throughout the Hydrogen and Methane Supply Chains (HMSC). Exergy is destroyed or lost when a process is irreversible (second law of thermodynamics) or due to by-products (Dincer

et al., 2014). Thus, the overall exergy efficiency of the HMSC can vary considerably depending on the feedstock and technologies involved (Khosravi et al., 2018).

Given the set of technologies, energy sources, and services involved, energy supply chains have been extensively studied, particularly for hydrogen (Li et al., 2019). However, only a few studies (Mesfun et al., 2017), (Bramstoft et al., 2020) consider simultaneously several fuel demands through PtG concepts. This issue has also been tackled in (Carrera Guilarte and Azzaro-Pantel, 2020) by also considering the geographical and logistical aspects of the entire HMSC over a multi-period horizon. Many researchers have carried out exergy analyses especially for power generation and cogeneration (Dincer et al., 2014). To the best of our knowledge, very few studies have been developed on the exergy analysis of a HMSC based on PtG concepts. The scientific objective of this study is to propose a comprehensive optimization model that can determine the design and deployment of an HMSC with total cost, GHG emissions and exergy loss as objective functions to be minimized. The main contribution of this study is thus to address the typical features of the HMSC (i.e., primary resources, production units, hydrogen transportation, storage, and refueling stations), considering the evolution of its configuration over time according to these different criteria. The paper is divided into three sections following this introduction. The methods and tools are presented in Section 2 with a focus on the problem formulation, presentation of the case study, the key points of the mathematical model for the HMSC, and the solution strategy. Finally, the main results (i.e., mono and multi-objective optimizations, and decision variables) are analyzed in Section 3, followed by the conclusions and perspectives presented in Section 4.

2. Methods and tools

2.1. Problem formulation

The problem formulation is based on prior studies, and follows the guidelines proposed by (Carrera Guilarte and Azzaro-Pantel, 2020; De-León Almaraz et al., 2015). It can be summarized as follows:

Given:

- Spatio-temporal demands for hydrogen and methane, availability of feedstocks.
- Characteristics of each technology.

Assuming:

- A division of the territory into grids.
- SMR, PtG, and natural gas are used to satisfy the methane and hydrogen demands.
- Direct injection of the methane produced into the natural gas network.
- Limited availability of primary energy and CO₂ sources.
- Possibility of importing primary resources.
- Possibility of transporting hydrogen only between grids by tanker-trucks for liquid hydrogen transportation.
- A constant carbon price over the period studied.

Determine:

- The location, number, capacity, and rate of production, storage and transport units as well as of refueling stations for hydrogen and methane.
- Transport flows between the grids.

Subject to:

- The satisfaction of the hydrogen and methane demands.
- Conservation of mass and energy, and other physical laws.

Objectives to be minimized either separately such as:

- Total Annual Cost.
 - GHG emissions.
 - Total Exergy Loss and Destruction.
- or with a combination through ε -constraint method.

2.2. Case study

The case study is the Region of Occitania, located in the south of France. Its energy transition strategy is framed within the REPOS (Positive Energy Region, in French) scenario (Région Occitanie / Pyrénées-Méditerranée, 2017). Hydrogen demand has been determined based on the expected use of fuel cell electric vehicles (FCEVs), for buses, private and light-good-vehicles. It corresponds to 5 TWh in 2050. The demand for methane includes the residential, industry, transport, and service sectors (1 TWh in 2050) (ADEME, 2018). A five-year period is used for time discretization (2035 to 2050). The territory is divided into 13 grids that correspond to the departments of this region. An average inter-district distance has been considered for transport purpose. Three sources of renewable energy have been identified, namely solar, wind, and hydro-power. Hydrogen is produced in the form of gas. Cryogenic storage is assumed for hydrogen with liquid transportation by tanker-trucks. Synthetic methane is assumed to be produced from hydrogen in a catalytic methanation process. Different sizes of electrolyzers, SMR, and catalyst reactors are considered. The CO₂ sources stem from methanization and gasification processes. The cost of electricity varies depending on the source. The natural gas needed to produce hydrogen by SMR or to meet part of the demand for methane is imported from abroad. A discount rate of 5.25% (E&E consultant et al., 2014), and an average constant carbon price of 270 €/ton_{CO₂} (Li et al., 2019) have been adopted respectively.

2.3. Key items of model development

The methodological framework is based on Mixed Integer Linear Programming (MILP). The formulation aims to satisfy the demands of both energy vectors “i” (hydrogen and methane), through fossil or renewable energy sources “b”, considering the potential of each grid “g”. The availability of energy source “e” and CO₂ “c”, production of hydrogen “p”, storage option “s”, transport option “l”, methane production type “q”, and refueling station “f” for each period “t” are taken into account. Only the key points are discussed below.

2.3.1 Cost objective function

The Total Annual Cost (*TAC*, €) (Eq. (1)) takes into account the capital cost (*FCC_{it}*, €/year), operating cost (*FOC_{it}*, €/year), the Annual Carbon Price (*ACP_{it}*, €/year), the cost of imported natural gas (*INGC_{it}*, €/year) and the discount rate (*r*):

$$TAC = \sum_{it} \left(\frac{MFCC_{it} + MFOC_{it} + ACP_{it} + INGC_{it}}{(1+r)^t} \right) \quad (1)$$

2.3.2 Environmental objective function

The Total Greenhouse Gas emissions (TGHG, gCO₂-eq) (see Eq. (2)) generated by the different echelons of the supply chain have been considered as the environmental impact objective function, with the following contributions all expressed in gCO₂-eq/year: *GHG_{it}* related to the hydrogen (*HGHG_{it}*), and methane (*MGHG_{it}*) production, the hydrogen storage (*SGHG_{it}*), hydrogen transport (*TGHG_{it}*), and methane import (*IMGHG_{it}*).

$$TGHG = \sum_{it} (HGHG_{it} + SGHG_{it} + TGHG_{it} + MGHG_{it} + IMGHG_{it}) \quad (2)$$

2.3.3. Exergy objective function

The Total Exergy Loss and Destruction (TELD) corresponds to the exergy objective function (Eq. (3)). Each flow of mass and energy in the processes involved in HMSC is identified as a resource, product, or waste. Subsequently, the exergy destroyed and lost in each process was calculated considering the typical exergetic yield of each stage using the values presented in (Khosravi et al., 2018). The lost/destroyed exergy related to hydrogen ($HELD_{it}$), and methane ($MELD_{it}$) production, hydrogen storage ($SELD_{it}$), hydrogen transport ($TrELD_{it}$), and methane import ($IMELD_{it}$) can be expressed as follows (all expressed in MWh/year:

$$TELD = \sum_{it} (HELD_{it} + SELD_{it} + TrELD_{it} + MELD_{it} + IMELD_{it}) \quad (3)$$

2.4. Solution strategy

The model is solved by CPLEX 12 in the GAMS environment. An Intel Xeon E3-1505MV6, 3.00 GHz computer with 32 GB RAM was used. A mono-objective analysis of each criterion (TAC, TGHG, and TELD) is first performed for a better understanding of the problem. A multi-objective optimization strategy with the three objective functions is then conducted to reach the Pareto front using the augmented ϵ -constraint method (AUGMECON)(Mavrotas, 2009). Since AUGMECON uses the lexicographical optimization, a priority is established for the objective functions. In this case, TAC is first ranked, then TGHG, and finally TELD. The modified-TOPSIS (m-TOPSIS), a variant of the Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) is applied to choose the best compromise configuration from the Pareto front, assigning equal weight to each optimization criterion.

3. Results and discussion

The optimal values of the decision variables of the mono-objective approach for each objective function (TAC, TGHG, and TELD), and the TOPSIS solution are presented in Table 1. The production, storage and transport units are installed progressively throughout the period. The minimization of exergy implies the absence of hydrogen transport, due to the large amount of exergy destroyed. The LCOE for hydrogen is between 130-285 €/MWh, which is the acceptable range of values to be economically viable (Hydrogen Europe, 2018). However, only the “min TGHG” and TOPSIS solutions propose methane production from methanation, where a significant reduction of CO₂-eq emissions is imposed. For “min TAC” and “min TELD”, the methane demand is met through natural gas, since its cost is half that of methane produced by methanation. The GHG for both vectors corresponds to the range of values reported from the literature (see Section 1), and varies according to the energy sources used in each period. The exergy lost and destroyed over the period varies between 55 and 92%, mainly due to the exergetic yield associated with energy production (i.e., 11 and 30% for PV and wind power plants, respectively). The HMSC configuration in 2050 can be visualized in Figure 2. The main source of electricity used is solar followed by wind. Due to the capacity factor associated with each energy source, the HMSC is decentralized, with on-grid production of hydrogen and methane. Depending on the scenario and decision criteria applied, the total hydrogen demand is fully satisfied by electrolysis while 68% of the methane demand is provided by methanation and the remaining part by natural gas import. The main

characteristics and computational effort of the solution found by the optimization model are summarized in Table 2, corresponding to each mono-objective optimization and the TOPSIS solution chosen.

4. Conclusion and perspectives

In this paper, a general methodology for the design and deployment of an HMSC was developed and used for a baseline case study devoted to the Occitania region in France. Each mono-objective minimization proposes a drastically different configuration. The LCOE for hydrogen and methane was obtained from the optimization strategy. The results show that with electricity prices close to 31 €/MWh and a carbon price below 270 euros/ton CO₂, hydrogen can play an important role as an energy carrier. As for synthetic methane, its cost remains prohibitive to play a significant role in the energy mix. The total satisfaction of the expected methane demand through methanation could only be justified

in a scenario of massive reduction of greenhouse gas emissions. In addition, coupling this PtG ecosystem with other energy systems is necessary to reduce the exergy losses (i.e., with the cement industry or with methanization processes).

The methodology and the results found can be useful to enrich the decision-making process, especially to promote the deployment of specific technologies. The model is general enough to incorporate other criteria. The methodological framework paves the way for further extensions to other types of processes and energy vectors, creating a synergetic effect with other energy systems, thus exploring the scale-up potential for increased efficiency and cost reduction.

Abstract

This paper presents a mathematical optimisation model for the planning of non-conventional gas field development, considering multiple impurities in natural gas streams and uncertainties in gas quality and technological parameters. The model consists mainly of mass balance equations and fuzzy constraints. A modified literature example is presented to illustrate the proposed approach.

Keywords: natural gas sweetening, mathematical programming, fuzzy optimisation.

1. Introduction

With growing demand for natural gas (NG) as a low-carbon energy source, developing non-conventional gas fields has become common in the oil and gas industry. NG streams produced from such fields are sour with high concentrations of CO₂ and H₂S, requiring treatment or “sweetening” before processing and downstream applications. Planning the development of non-conventional gas fields involves determining how much gas should be produced and treated at each source, and which gas sweetening technology should be used. Process integration techniques have been extended to address the gas field planning problem, which is analogous to the effluent treatment problem.

The gas field planning problem can be solved using pinch analysis and mathematical programming. Foo et al. (2016) developed pinch-based graphical and optimisation approaches to determine the minimum extent of CO₂ removal and the minimum sweet gas supply. Parand et al. (2018) later developed a pinch-based algebraic technique that overcomes the limitations of the graphical technique of Foo et al. (2016). Lee et al. (2018) developed a multi-period mathematical model that considers time-varying gas production and demand. However, none of these previous works has considered other impurities such as H₂S in NG streams as well as uncertainties in technical and economic parameters.

In this paper, a mathematical programming model is developed for optimal planning of gas field development. The formulation considers multiple impurities in NG streams, and incorporates fuzzy optimisation to allow for parametric uncertainties. An example is used to illustrate the proposed approach.

2. Problem Statement

The problem addressed in this paper is formally stated as follows. Given:

- A set of gas sources $i \in \mathbf{I}$ (e.g. gas fields). The NG streams produced from these sources contain a set of impurities $k \in \mathbf{K}$ (e.g. CO₂ and H₂S), and need to be treated, or sweetened, before proceeding to the gas processing plant (GPP).
- A set of gas sweetening technologies $j \in \mathbf{J}$ (e.g. amine absorption and membrane separation). Each technology is characterised by its product (NG) recovery factor, impurity removal ratio and cost.

The objective is to determine the optimal strategy that minimises the total operating cost associated with (a) gas sweetening to meet the product specifications and (b) gas transport for processing, while considering uncertainties in cost and performance parameters.

3. Model Formulation

Figure 1 shows a schematic diagram of gas sweetening at source i . The gas from source i can be partially treated with available gas sweetening technologies. The purified stream is sent to the GPP along with the bypass stream, while the reject stream may be used for enhanced oil recovery (EOR). Two scenarios are considered. Scenario 1 represents the deterministic case assuming that all cost and performance parameters are known precisely, while scenario 2 accounts for parametric uncertainties using fuzzy optimisation.

Figure 1. Schematic of Gas Sweetening

3.1. Scenario 1: Deterministic Case

Eq. (1) describes the flowrate balance for source i .

$$\sum_{j \in \mathbf{J}} f_{ij}^{\text{in}} + f_i^{\text{b}} \leq F_i \quad \forall i \in \mathbf{I} \tag{1}$$

where f_{ij}^{in} is the inlet flowrate to the gas sweetening unit using technology j at source i ; f_i^{b} is the bypass flowrate of gas from source i ; F_i is the available gas flowrate of source i . Eq. (2) states that at each source only one gas sweetening technology can be used.

$$\sum_{j \in \mathbf{J}} y_{ij} \leq 1 \quad \forall i \in \mathbf{I} \tag{2}$$

where y_{ij} is a binary variable indicating if technology j is used at source i . Eq. (3) sets an upper limit on f_{ij}^{in} , while ensuring that no gas is treated by unused technologies ($f_{ij}^{\text{in}} = 0$ if $y_{ij} = 0$).

$$f_{ij}^{\text{in}} \leq F_i y_{ij} \quad \forall i \in \mathbf{I}, j \in \mathbf{J} \tag{3}$$

Eqs. (4) and (5) describe the flowrate and impurity balances around the gas sweetening unit using technology j at source i , respectively.

$$f_{ij}^{\text{in}} = f_{ij}^{\text{p}} + f_{ij}^{\text{r}} \quad \forall i \in \mathbf{I}, j \in \mathbf{J} \quad (4)$$

$$f_{ij}^{\text{in}} C_{ik} = f_{ij}^{\text{p}} c_{ijk}^{\text{p}} + f_{ij}^{\text{r}} c_{ijk}^{\text{r}} \quad \forall i \in \mathbf{I}, j \in \mathbf{J}, k \in \mathbf{K} \quad (5)$$

where f_{ij}^{p} and f_{ij}^{r} are the flowrates of the purified and reject streams, respectively; C_{ik} is the concentration of impurity k in the gas from source i ; c_{ijk}^{p} and c_{ijk}^{r} are the impurity concentrations of the purified and reject streams, respectively.

The gas sweetening process is also characterised by the impurity removal ratio (RR_{jk}) in Eq. (6) and the product recovery factor (RF_j) in Eq. (7).

$$f_{ij}^{\text{p}} c_{ijk}^{\text{p}} = f_{ij}^{\text{in}} C_{ik} (1 - RR_{jk}) \quad \forall i \in \mathbf{I}, j \in \mathbf{J}, k \in \mathbf{K} \quad (6)$$

$$f_{ij}^{\text{p}} \left(1 - \sum_{k \in \mathbf{K}} c_{ijk}^{\text{p}} \right) = RF_j f_{ij}^{\text{in}} \left(1 - \sum_{k \in \mathbf{K}} C_{ik} \right) \quad \forall i \in \mathbf{I}, j \in \mathbf{J} \quad (7)$$

Eqs. (8) and (9) impose flowrate and concentration constraints for gas processing.

$$\sum_{i \in \mathbf{I}} f_i^{\text{b}} + \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}} f_{ij}^{\text{p}} \geq F^{\text{GP}} \quad (8)$$

$$\sum_{i \in \mathbf{I}} f_i^{\text{b}} C_{ik} + \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}} f_{ij}^{\text{p}} c_{ijk}^{\text{p}} \leq F^{\text{GP}} C_k^{\text{max}} \quad \forall k \in \mathbf{K} \quad (9)$$

where F^{GP} is the required gas processing flowrate; C_k^{max} is the maximum allowable concentrations of impurity k for gas processing.

The objective function in this scenario is to minimise the total operating cost associated with gas sweetening and gas transport (f_{TOC}), as given in Eq. (10).

$$\min f_{\text{TOC}} = \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}} OC_j f_{ij}^{\text{in}} \delta + TC \left(\sum_{i \in \mathbf{I}} D_i f_i^{\text{b}} \delta + \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}} D_i f_{ij}^{\text{p}} \delta \right) \quad (10)$$

where OC_j is the operating cost of technology j ; δ is the operating duration; TC is the gas transport cost coefficient; D_i is the distance from source i to the GPP.

The model for scenario 1 (Eq. (10) subject to Eqs. (1)-(9)) is a mixed integer nonlinear programme (MINLP) due to bilinear terms in Eqs. (5)-(7) and (9).

3.2. Scenario 2: Planning under Uncertainties

In this scenario, uncertainties in C_{ik} , OC_j and RR_{jk} are considered and handled using fuzzy optimisation. For conservative (low-risk) planning, higher values of the estimated impurity concentration and operating cost are more desirable, as given in Eqs. (11) and (12). Similarly, a lower value of the estimated removal ratio is more desirable, as given in Eq. (13).

$$C_{ik} \geq C_{ik}^{\text{L}} + \lambda (C_{ik}^{\text{U}} - C_{ik}^{\text{L}}) \quad \forall i \in \mathbf{I}, k \in \mathbf{K} \quad (11)$$

$$OC_j \geq OC_j^{\text{L}} + \lambda (OC_j^{\text{U}} - OC_j^{\text{L}}) \quad \forall j \in \mathbf{J} \quad (12)$$

$$RR_{jk} \leq RR_{jk}^{\text{U}} - \lambda (RR_{jk}^{\text{U}} - RR_{jk}^{\text{L}}) \quad \forall j \in \mathbf{J}, k \in \mathbf{K} \quad (13)$$

where fuzzy parameters C_{ik} , OC_j and RR_{jk} are redefined as variables; superscripts L and U denotes lower and upper limits, respectively; λ represents the overall degree of satisfaction of these fuzzy constraints. The value of λ ranges from 0 (unsatisfactory) to 1 (completely satisfactory), as stated in Eq. (14).

$$0 \leq \lambda \leq 1 \quad (14)$$

With parametric uncertainties, the objective of minimising the total operating cost in Eq. (10) is reformulated as an additional fuzzy constraint in Eq. (15), which indicates that a low value of f_{TOC} is desirable.

$$f_{\text{TOC}} \leq f_{\text{TOC}}^{\text{U}} - \lambda (f_{\text{TOC}}^{\text{U}} - f_{\text{TOC}}^{\text{L}}) \quad (15)$$

The objective function in this scenario is to maximise the overall degree of satisfaction of the fuzzy constraints, as given in Eq. (16).

$$\max \lambda \quad (16)$$

The model for scenario 2 consists of Eqs. (1)-(9) and (11)-(16) and is also an MINLP. In the following section, a modified literature example is solved to illustrate the proposed approach. The MINLP models for both scenarios are implemented and solved in GAMS using solver BARON. Results were obtained with negligible processing time.

4. Illustrative Example

Table 1 shows the data for the example, which is adapted from Foo et al. (2016). A total of four gas fields are to be developed. The maximum allowable concentrations of CO₂ and H₂S for gas processing and downstream applications (e.g. power generation) are 3% and 5 ppm, respectively. Amine absorption and membrane separation are available for gas sweetening. Table 2 shows the cost and performance parameters. It is assumed that the GPP is designed to process 1000 MMscfd of gas to meet the demand. The transport cost is taken to be 0.003 USD/MMscf/km.

Two scenarios are analysed in this example. Scenario 1 assumes that all the parameters are known precisely as given in Tables 1 and 2, while scenario 2 considers uncertainties in CO₂ concentrations, operating costs and CO₂ removal ratios.

Table 1. Data for the Gas Sweetening Example

Source	Flowrate (MMscfd)	Concentration (%)		Distance to GPP (km)
		CO ₂	H ₂ S	
Gas field 1	300	10	0.1	400
Gas field 2	450	20	0.2	300
Gas field 3	500	30	0.5	350
Gas field 4	600	35	1	150

Table 2. Cost and Performance Data for Gas Sweetening Technologies

Technology	Operating cost (USD/MMscf)	Product recovery factor (%)	Removal ratio (%)	
			CO ₂	H ₂ S
Amine absorption	0.4	92	90	99.9
Membrane separation	0.7	96	95	99.99

4.1. Results for Scenario 1

Scenario 1 aims to minimise the total operating cost associated with gas sweetening and transport. Solving the corresponding MINLP model gives the minimum cost of 559,044 USD/y. Table 3 shows the technologies used and the associated stream flowrates. Amine absorption is used at gas fields 1, 2 and 4 because of its lower operating cost. Membrane separation is needed at gas field 3 for its higher removal ratios. Gas fields 1 and 2 produce higher quality gases (with lower CO₂ and H₂S concentrations) and are fully developed; in

other words, the flowrates of gas produced are equal to the available amounts. Gas fields 3 and 4 produce lower quality gases and are only partially developed. Furthermore, the flowrate of gas produced from field 3 is less than that from field 4 because of the longer distance from gas field 3 to the GPP. All the gases produced are completely treated and there are no bypass streams. These results may be used to determine the sizes of gas sweetening units and pipelines. Figure 2(a) illustrates the optimal gas sweetening system for scenario 1.

Table 3. Technology Selection and Stream Flowrates for Scenario 1

Gas field	Technology	Flowrate (MMscfd)			
		Inlet stream	Purified stream	Reject stream	Bypass stream
1	Amine	300	251.124	48.876	0
2	Amine	450	339.373	110.627	0
3	Membrane	264.904	180.717	84.186	0
4	Amine	366.755	228.785	137.969	0

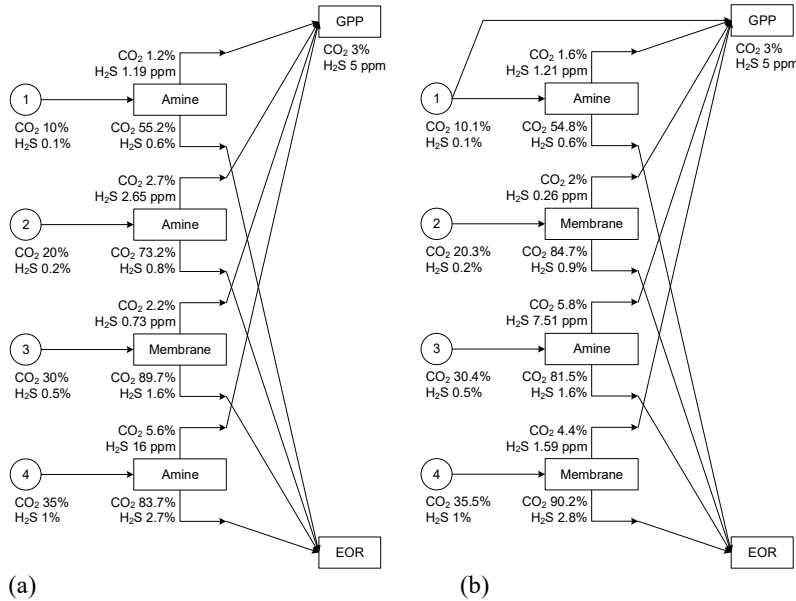

Figure 2. Gas Sweetening Systems for (a) Scenario 1 and (b) Scenario 2

4.2. Results for Scenario 2

In scenario 2, parametric uncertainties are considered, and the objective is to maximise the overall degree of satisfaction of the fuzzy constraints for a conservative, low-risk planning. The fuzzy ranges for the uncertain parameters in this example are given in Tables 4 and 5. In addition, the minimum cost of 559,044 USD/y in scenario 1 is taken as the lower limit for the total operating cost, while the upper limit of 752,091 USD/y is determined by solving the model for scenario 1 with operating cost coefficients at the upper limits and CO₂ removal ratios at the lower limits.

Solving the MINLP model for scenario 2 gives the maximum λ value of 0.568, meaning that each fuzzy constraint is at least 56.8% satisfied. The total operating cost is estimated

at 642,484 USD/y, which corresponds to a 14.9% increase from the lower limit. Table 6 shows the technologies used and the associated stream flowrates. Amine absorption is used at gas fields 1 and 3, and membrane separation at gas fields 2 and 4. Fields 1 and 2 with higher quality gases are 98.8% and 91.6% developed, respectively. With lower quality gases, field 3 is only 13% developed due to its long distance to the GPP, while field 4 is fully developed because it is the closest to the GPP. Figure 2(b) illustrates the optimal gas sweetening system for scenario 2.

Table 4. Fuzzy Limits for Impurity Concentrations

Source	CO ₂ concentration (%)	H ₂ S concentration (%)
Gas field 1	9–11	0.09–0.11
Gas field 2	18–22	0.18–0.22
Gas field 3	27–33	0.45–0.55
Gas field 4	31.5–38.5	0.9–1.1

Table 5. Fuzzy Limits for Operating Costs and Removal Ratios

Technology	Operating cost (USD/MMscf)	CO ₂ removal ratio (%)
Amine absorption	0.4–0.48	85–90
Membrane separation	0.7–0.84	90–95

Table 6. Technology Selection and Stream Flowrates for Scenario 2

Gas field	Technology	Flowrate (MMscfd)			
		Inlet stream	Purified stream	Reject stream	Bypass stream
1	Amine	296.371	248.606	47.765	3.629
2	Membrane	412.392	321.394	90.998	0
3	Amine	65.006	43.856	21.15	0
4	Membrane	600	382.515	217.485	0

5. Conclusion

A mathematical programming model for gas field development planning has been developed in this paper. The formulation considers multiple impurities in NG streams, with fuzzy constraints account for parametric uncertainties. A modified literature example was solved to illustrate the proposed approach. Future work will consider a more comprehensive energy system with hydrogen production and utilisation.

Abstract.

Woody biomass has been proposed as a versatile raw material to be upgraded in energy vectors and value-added products. Nevertheless, most studies have focused on the cellulose and hemicellulose conversion reducing the potential of lignin as a value product that can be commercialized or upgraded. Thus, this paper aims to evaluate the influence of the lignin extraction process on the economic performance of a woody-based biorefinery addressed to produce lignin and levulinic acid as products. Kraft, Soda, and Organosolv extraction methods were assessed and compared. After a simulation procedure and economic assessment using experimental information and kinetic models reported in the open literature, the results show the Kraft process as the most suitable option to produce both lignin and levulinic acid. The simulation process results show that the organosolv process requires higher processing scales than Kraft and Soda processes to reach economic feasibility. In conclusion, the further valorization of lignin in other high value-added products is necessary to increase the economic performance of extracting lignin. Moreover, the inclusion of high added-value products such as levulinic acid reduces processing scale and increases the possibility of implementing this type of process.

Keywords: Biorefineries, Lignin extraction, Process Design, Woody Biomass, Levulinic acid, Economic assessment.

1. Introduction.

Woody biomass has been defined as a potential raw material to be upgraded through either thermochemical or chemical pathways. Thermochemical processing of woody biomass has been preferred over other biomass sources. This renewable resource has some advantages related to easy handling, high energy content, and relative-high fixed carbon content. Indeed, woody biomass has supplied 9% of the energy consumption in 2019. Despite the suitability of woody biomass for energy production purposes, several studies have focused on converting this raw material into a series of value-added products through the biorefinery concept. Nevertheless, most of these studies have been addressed to convert the cellulose and hemicellulose, leaving aside the lignin content of woody biomass (Solarte-Toro et al., 2021).

Lignin is considered the most important renewable aromatic source in the world. Moreover, this biopolymer can be upgraded into a series of value-added products (e.g., vanillin, benzene, toluene, xylene, quinones, eugenol) able to be used in the chemical, pharmaceutical, cosmetic, and textile industries. Lignin isolation can be done in several ways, such as mechanical, chemical, physical, and enzymatic. However, the most common methods applied at the industrial level involves the use of chemical agents. In this way, extracted lignins can be classified as sulfur lignins and sulfur-free lignins, depending on the chemical agents used to isolate lignin. Sulfur free lignins are obtained through Organosolv and Soda, while sulfur lignins are obtained via Kraft and lignosulfonate pulping. The chemical composition of woody biomass before and after implementing the lignin extraction methods has been reported in the open literature (Tian et al., 2017). Nevertheless, few studies have been focused on the economic analysis of these processes. For instance, Carvajal et al. (2016) report the comparison of the stand-alone lignin extractions processes. These authors proposed the Kraft process as the most economical process for lignin extraction. Even so, these authors do not include the lignin isolation step. Moreover, few studies have analyzed the effect of the lignin extraction process on the economic performance of a biorefinery. In this way, this paper aims to evaluate the influence of the lignin extractions process on the economic performance of a woody-based biorefinery addressed to produce lignin and levulinic acid as products.

2. Methodology.

2.1. Conceptual design and process description.

The proposed biorefinery involves two processing stages. The first stage is related to the lignin extraction process. Kraft, Soda, and Organosolv processes were simulated. Kraft pulping conditions were active alkali 26 %, sulfidity 30 %, solid to liquid ratio 1:4, process temperature 172 °C, and residence time 2 hours (Przybysz et al., 2018). In contrast, Soda pulping was performed at 93 °C using an 8 %w/v NaOH solution. The soda process was simulated considering a residence time of 2 hours (Saber et al. 2020). Finally, the organosolv process considered a 60 %v/v ethanol solution and 1.25% w/w sulfuric acid solution as a catalyst. The process temperature and residence time were 180 °C and one h, respectively (Meng et al. 2020). For Kraft and Soda processes, the lignin recovery was made using CO₂ and H₂SO₄ as precipitating agents (Öhman et al. 2013). Finally, the organosolv lignin recovery was made following the downstream processing described by Solarte-Toro et al. (2018). The levulinic acid production stage involves (i) cellulose degradation and (ii) glucose conversion. The cellulose degradation process was achieved considering a process temperature of 220 °C for 30 min at an initial cellulose loading of 29 %w/w. The remaining solid was recycled to increase glucose concentration in the outlet liquid stream. Rich-glucose stream was upgraded to levulinic acid at 160°C, 5.5 MPa, and catalyst (Amberlyst 70) loading of 0.035 kg/L (Weingarten et al., 2012a). The residence time was less than 3 minutes. Humins and a liquid mixture composed of levulinic acid, formic acid, and water are the glucose decomposition products. Humins are separated by filtration, and levulinic acid is purified by distillation. The distillation process was designed to produce a levulinic acid solution at industrial grade.

2.2. Simulation procedure.

The simulation of the three scenarios using poplar (*Populus sp.*) as lignocellulosic feedstock was done using the simulation software Aspen Plus v9.0 (Aspen Technology

Inc. USA). The feedstock flow rate was set at 1 t/h on a wet basis. The vapor-liquid equilibrium in the simulation was estimated through the gamma-phi method by selecting the Non-Random Two Liquids (NRTL) activity coefficient model and the Peng-Robinson equation of state. The thermodynamic properties of cellulose, hemicellulose, and lignin were specified in the simulator. Temperature-dependent properties were introduced as reported by the National Renewable Energy Laboratory (NREL). Besides, constant thermodynamic properties such as enthalpy of formation and free energy of formation were estimated using the equations reported by Peduzzi et al. (2016). The chemical characterization of raw poplar (*Populus sp.*) on a dry basis is given in Table 1.

Table 1. Chemical characterization of poplar (*Populus sp.*)

Compound	Share %
Cellulose	51.10
Hemicellulose (Xylan)	21.40
Lignin	22.70
Extractives	4.40
Ash	0.40
Moisture	45.00

The chemical characterizations of poplar (*Populus sp.*) after Kraft, Soda, and Organosolv processes were used to estimate the mass balances of the lignin extraction process in each scenario. Thus, experimental results reported in the open literature were used as input data. Kraft process was simulated considering the data given by Buzala et al. (2017), Soda process was assessed according to the yields stated by Saber et al. (2020), and Organosolv lignin extraction was designed involving the information reported by Meng et al. (2020). Lignin recovery from black liquor was simulated following the process described by Öhman et al. (2013). The Kraft and Soda processes flow diagrams were based on the schemes reported by (Carvajal et al., 2016). The Organosolv process flowsheet was based on the reported figure by Solarte-Toro et al. (2018). The levulinic acid production process was simulated in three stages. The first stage comprised the cellulose hydrolysis to produce glucose. The mass balances of this stage were estimated considering the experimental cellulose conversion reported by Weingarten et al. (2012b). The second stage is related to glucose dehydration. The kinetic parameters (i.e., pre-exponential factor and activation energy) estimated by Weingarten et al. (2012a) were introduced to model a continuous stirred tank reactor (CSTR) in the simulation software. The third stage is addressed to the levulinic acid purification by distillation. Topologic thermodynamics was applied to identify the best way to separate levulinic acid mixture. Shortcut methods were used to estimate the number of theoretical stages, reflux ratio, and distillate to feed ratio. Finally, the information mentioned above was used to specify the rigorous distillation module in Aspen Plus to estimate material and energy balances.

2.3. Economic evaluation.

The economic assessment of the proposed scenarios was done using the Aspen Process Economic Analyzer v9.0. This software was used to estimate the total capital investment (TCI) of the proposed processes. The profitability analysis was accomplished following the methodology reported by Towler and Sinnott (2013). The cost of raw materials, utilities, and labor were used as input data (see Table 2). Besides, the following conditions were involved in the economic analysis: (i) the straight-line depreciation method with a salvage value of 10% was applied, (ii) the cash flow analysis was done considering a corporate tax rate value of 28% and an interest rate value of 1.64%, (iii) the proposed

biorefineries are conceived as continuous processes working 8360 hours in a year, (iv) The proposed scenarios consider the creation of eight operator jobs and two supervisor positions, and (v) the project lifetime was set in 10 years. Finally, all the proposed scenarios were compared using the net present value (NPV) and payback period (PBP) as economic metrics. This metrics estimation was done to assess the biorefinery profitability and the best extraction method to reach economic feasibility.

Table 2. Input data used to estimate the cash flow of the proposed scenarios.

Item	Price	Units	Item	Price	Units
Poplar	0.0358	USD/kg	MP steam	0.0081	USD/kg
NaOH	0.37	USD/kg	Electricity	0.076	USD/kwh
Na ₂ S	0.95	USD/kg	Operator labour	22.66	USD/h
Ethanol	0.92	USD/L	Supervisor labour	45.71	USD/h
H ₂ SO ₄	0.064	USD/kg	Organosolv lignin	0.60	USD/kg
Process water	2.95	USD/m ³	Kraft lignin	0.48	USD/kg
Cooling water	0.45	USD/m ³	Soda lignin	0.51	USD/kg
LP steam	0.0079	USD/kg	Levulinic acid	8.56	USD/kg

3. Results and Discussion.

The yields of lignin and levulinic acid production are summarized in Table 3.

Table 3. Production yields of lignin and levulinic acid production.

Scenario	Lignin extraction process	Lignin yield (kg/kg db.)	Levulinic acid yield (kg/kg db.)
1	Kraft	0.276	0.229
2	Soda	0.020	0.239
3	Organosolv	0.244	0.216

The lignin yield was estimated considering the resulting mass balances of each scenario. Kraft process offers a high lignin yield on a dry basis than the other options since more lignin can be isolated from the raw material. However, this yield is similar to the lignin extraction yield of the organosolv process. Indeed, both processes allow separating more than 80% of the lignin content in the raw material. In contrast, Soda extraction did not have a good mass performance since less than 10% of the lignin was isolated. This low extraction yield can be improved by increasing the temperature of the process. For instance, Lehto and Alén (2013) evaluated the lignin removal of wood chips using an 8 % w/w NaOH solution at different temperatures. The highest lignin removal (i.e., 72.5 %) was found at 150°C. Levulinic acid production yields are similar in all three scenarios since the cellulose content is not upgraded in monomeric sugars. The highest levulinic acid yield was obtained in scenario 2 (i.e., Soda process). Nevertheless, this value should be analyzed carefully since the biorefinery objective is not accomplished due to the low lignin production. In this way, the low yield of the lignin extraction in the Soda process makes the biorefinery a stand-alone process. The economic results suggest the Soda process as the most feasible option since the payback period is the lowest value reported in Table 4. Nevertheless, the low lignin production did not contribute to the process cash flow. Thus, the best option to upgrade woody biomass involving a lignin extraction stage is the Kraft process. Organosolv process did not reach economic feasibility at the proposed scale. Thus, a sensitivity analysis was carried out to find the Minimum

Processing Scale for Economic Feasibility (MPSEF) (Serna-Loaiza et al., 2018). After this analysis, the MPSEF of the organosolv process is about 2 t/h. Thus, higher scales are required to obtain positive cumulative cash over the lifetime of the project.

Table 4. Economic metrics estimated using a feedstock mass flow rate of 1 t/h.

Scenario	TCI (M.USD*)	PBP (years)	Cumulative cash over the lifetime of the project (M.USD*)	MPSEF (t/h)
1	4.51	6.61	1.58	0.95
2	3.55	4.04	3.67	0.89
3	5.75	0.00	-21.61	2.00

M.USD*: Millions of dollars.

In contrast, the proposed scale gave a positive cash flow at the end of the project in scenarios 1 and 2. Regarding the TCI, the Soda process has the lowest value since the capital investment required to isolate lignin contributes less than 5 % of the TCI. This low share in the lignin isolation process is attributed to the low input flow to this stage after the Soda process. Similarly, the lignin isolation process in the Kraft process accounts for 20 % of the TCI. This difference is attributed to the material flow of black liquor obtained after the Soda and Kraft processes. Finally, the Organosolv process is the most expensive since this lignin extraction method involves an additional step related to the ethanol recovery after lignin isolation. This stage (i.e., lignin isolation + ethanol recovery) accounts for more than 35% of the TCI of scenario 3. Therefore, the Organosolv process requires higher scales to reach economic feasibility. The economic evaluation results allowed us to determine the effect of the lignin extraction process on the economic performance of a woody-based biorefinery. Indeed, the organosolv process decreases the economic feasibility of the process, while Soda and Kraft processes have similar positive behaviors. Even so, the upgrading of lignin to other high value-added products can increase the economic performance of the process and reduce the required raw material mass flow.

4. Conclusions.

The comparison of three methods to extract lignin was done to evaluate the effect of these processes on the economic performance to produce lignin and levulinic acid as products. The product yield obtained in the simulation procedure allows proposing Kraft and Organosolv processes as the best ways to isolate lignin from poplar (*Populus sp.*). The soda process requires further research to find optimal conditions to increase lignin extraction. Regarding the economic perspective, the Kraft process offers the best economic performance since high lignin and levulinic acid production yields are allowed. Nevertheless, the low cost of lignin compared to other possible lignin-derived products limits the biorefinery potential. Indeed, the production of high-valued added compounds such as vanillin and eugenol plus the valorization of cellulose and hemicellulose to platform products can boost the real implementation of woody biomass applications at the industrial level using feasible and reliable raw materials input.

Abstract

This work focuses on the performance analysis and life cycle assessment of two BHD production processes from waste cooking oil coupled with a reformer. The first process produces hydrogen from gas flare from the oil and gas industry, while the second process produces hydrogen from by-product propane. It was revealed that the second process requires less hydrogen by 15.27%, compared to the first process. However, its heating and cooling utilities were 22% and 10% higher than the first process. The economic assessment showed that the first process has a net present value of 2.39 times higher than the second one. Life cycle assessment is evaluated in terms of carbon footprint and other environmental impacts by using LCSof program. It was found that the carbon footprint released by the second process was higher than the first process by 0.45 kgCO₂ eq. The second process was also found to have higher environmental impacts in most categories. Thus, it can be concluded that the first process is preferable.

Keywords: Bio-hydrogenated diesel, Waste cooking oil, Process simulation, Economic assessment, Environmental assessment

1. Introduction

Bio-hydrogenated diesel (BHD) is considered a potential alternative energy source to replace petroleum diesel. The production process involves the hydrotreating of vegetable oil to enhance long-chained hydrocarbons. Four main reactions are involved in the process, which are hydrogenation, decarboxylation, decarbonylation, and hydrodeoxygenation. The reactions take place in a liquid phase under severe conditions (i.e., 350°C of temperature, 10 MPa of pressure in the presence of Ni catalyst) (Srifa et al., (2014)).

The gaseous by-products obtained are typically CO, CO₂, methane, and propane. One major problem of this process is that it requires a very high hydrogen to oil ratio (1000 Ncm³/cm³) to operate to complete the reaction (Hsu et al., 2018). It results in excessive unreacted hydrogen to handle and thus a high production cost.

Many researchers were concerned with the process design and evaluated the BHD process under economic criteria. Cheah et al. (2017) reported that raw material cost had the highest impact on profitability and selling price. Furthermore, the vegetable oil price, hydrogen gas price, and plant capacity were sensitive to the net present value (NPV), so waste cooking oil was preferable. Environmental impact assessment is another essential issue because energy utilization and waste disposal affect the environment and human health. The assessment of the BHD process is typically performed through a life cycle assessment (LCA). Boonrod et al. (2017) studied the processing and environmental impacts of raw materials, including crude palm oil, palm oil fatty acid distillate, and fatty acid methyl ester. The results showed that fatty acid methyl ester was the most suitable raw material due to low GHG emission.

There were only a few studies that concerned about hydrogen sources for the BHD production process. For example, Sungnoen et al. (2015) studied the combination of biodiesel, glycerol reforming and BHD process. The integrated process of hydroprocessing, gasification, and Fischer-Tropsch of by-product propane from hydroprocessing was performed for the bio-jet fuel (Alherbawi et al., 2020). However, none of them considered the technical, economic, and environmental aspects altogether. This work proposes two BHD production processes from waste cooking oil integrated with a reforming process. The first process produces hydrogen from a gas flare from the oil and gas industry, which is assumed as a waste but contains a considerable amount of hydrogen. The second process, however, produces hydrogen from the by-product propane. The best process would be considered in terms of economics and environmental impacts.

2. Methodology

The waste cooking palm oil used in this work consisted of 82.67% of triglycerides, 7.6% of free fatty acids, 2% of diglycerides, and 7.8% of dimers (J. Riera, and R. Codony (2000)). The composition of fatty acid content was following Srifa et al. (2014). The composition of gas flare was following Emam (2015). Simple triglyceride consisting of the same three fatty acids was assumed. A Non-random two-liquid model (NRTL) was used to predict thermodynamic properties. The sequence of unit operations in the model was arranged through thermodynamic properties analysis. The model simulation of both processes is performed by using the Aspen plus program. An economic analysis was then evaluated in terms of net present value (NPV), total production cost, payback period, and internal rate of return (IRR). Finally, the environmental impacts of both processes were analyzed by LCA.

2.1 BHD process with gas flare reforming

The flowsheet of the BHD process with gas flare reforming is shown in Figure 1(a). A gas flare from oil and gas industry is fed, together with steam, into a reformer, followed by a water-gas shift reactor with a temperature of 450°C. The effluent stream is sent to a pressure swing adsorption to obtain pure hydrogen (99.95%). It is then mixed with the excess hydrogen recirculated back from the process and waste cooking palm oil and enter

a hydrotreating reactor, operating with an H_2/oil ratio of $1000 \text{ Ncm}^3/\text{cm}^3$, a pressure of 50 bar, and a temperature of $300 \text{ }^\circ\text{C}$. The product is sent to a flash separator, operating at 20 bar and $130 \text{ }^\circ\text{C}$, to separate the vapor phase (i.e., methane, propane, H_2 , CO , and CO_2) and the liquid product. The separated gases are sent back to the reactor while the liquid product is sent to the first distillation column to remove the remaining gas and water. The bottom product containing the BHD is purified further in the second distillation column to produce the BHD with high purity (99wt% on dry basis).

2.2 BHD process with propane reforming

The flowsheet of the BHD process with propane reforming is shown in Figure 1(b). The configuration of this process is similar to the first process. However, the hydrogen feed used in this process is partly produced from the by-product propane from the hydrogen separator from an external source. Specifically, the gas stream from the flash separator is sent through an expander to reduce the pressure to 1 atm before sending it to a reformer. Then, it is followed by a water-gas shift reactor with a temperature of 450°C before recirculating back to the process.

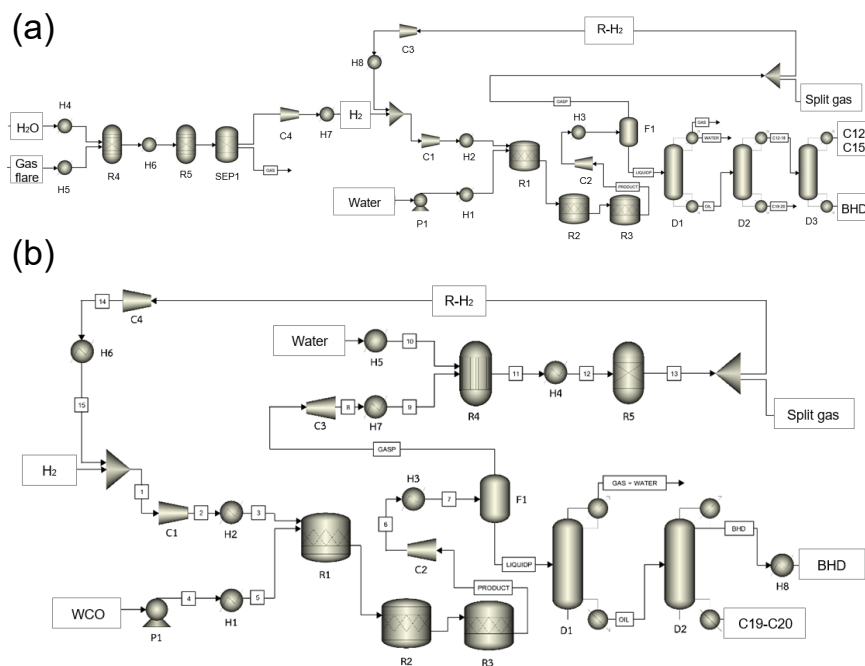

Figure 1 (a) stand-alone BHD process (b) gas-flare reforming (c) BHD process with by-product propane reforming

3. Results and Discussions

3.1 Process performance analysis

The process performance was determined in terms of BHD yield, H_2 consumption, and utility requirements. They are compared and illustrated in Table 1. The amount of waste

cooking oil feed at 56048 kg/hr and the BHD purity of 99 wt% were given for both processes. It can be seen that both processes provided the same yield of BHD at 75.16%. However, the second process could save hydrogen consumption by 15.27%, compared to the first process. For utility consumption, the second process used a higher heating utility by 22% due to the presence of the propane reforming process. Likewise, the cooling utility of the second process was also higher by 10% because of the larger volume of gases to be processed after the flash separator.

Table 1 Process performance of BHD processes

	BHD production with gas flare reforming	BHD production with by- product propane reforming
BHD yield (%)	75.16	75.16
H ₂ consumption (kg/hr)	1925	1631
Heating utility (x 10 ⁸ Btu/hr)	3.2	4.1
Cooling utility (x 10 ⁸ Btu/hr)	3.6	4.12

3.2 Economic assessment

Process data such as plant capacity, equipment sizing, amount of raw materials and chemicals, and utility consumptions were used to calculate the economics of the process. The total production cost for both BHD processes is summarized and shown in Figure 2. It was revealed that the raw material cost of both processes was a dominant factor of total production cost, taking about 82% - 90% of the total. The use of pure hydrogen as feed in the second process resulted in its raw material cost much higher than the first process. Although some hydrogen can be produced from the by-product propane, it is still not enough to compensate for the high cost of pure hydrogen feed (99.95%). The capital cost was represented in terms of the depreciation cost and, of which, about 40.56% came from a gas compressor. The presence of a gas compressor also required very high energy to operate, increasing the operating cost of the process. Another source of high energy-intensive units included the distillation columns and the heat exchanger used for preheating the feeds before entering the reformer and reactor. Comparing with a stand-alone BHD process (baseline scenario), the first process and the second process can reduce the cost by 18.96% and 2.75%, respectively.

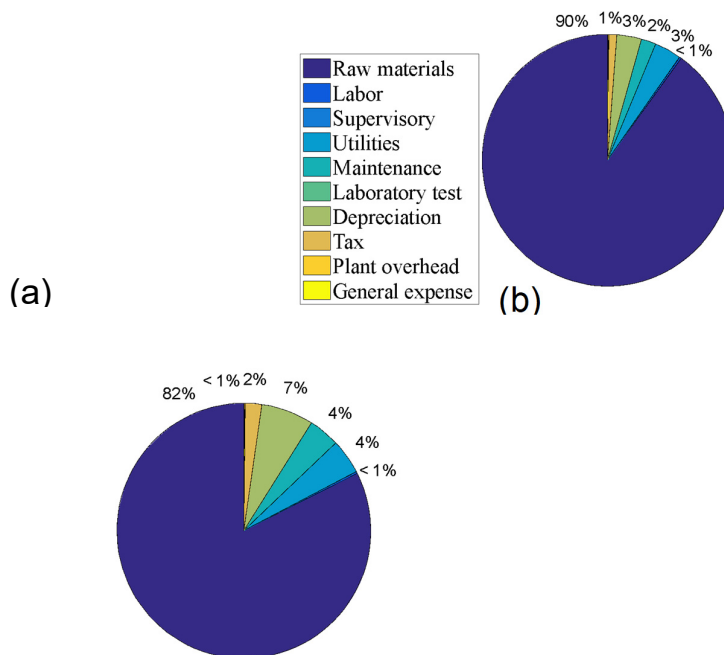

Figure 2 Total production cost contribution of (a) BHD process with gas flare reforming (b) BHD process with by-product propane reforming

The economic viability of the processes was evaluated through net present value (NPV), return on investment (ROI), and payback period. They were calculated and presented in Table 2. Noted that the plant lifetime of 10 years was assumed, and the income cash flow was derived from the selling price of the BHD at 1.1 \$/kg. It was found that both processes delivered the profit when the BHD selling price was higher than the cost of the raw materials by approximately 1.8 times. In conclusion, the first process offered better economics in all aspects. The main reason is that the second process used pure hydrogen as an additional feed, which is very costly. Therefore, it is clear to this point that to make the BHD process more competitive, a low-cost hydrogen supply source is necessary.

Table 2 Economic indicators of both processes

	BHD production with gas flare reforming	BHD production with by-product propane reforming
Return on investment	0.23	0.19
NPV (\$x10 ⁸ /year)	3.55	1.34
Payback period (year)	4.35	5.21

3.3 Environment impact assessment

In this section, the environmental impacts of both BHD processes were investigated by using LCSofT software. The gate-to-gate system boundary was assumed. In addition to carbon footprint, other environmental impact indicators were evaluated, namely, human toxicity noncarcinogenic impact (HTNC), Global warming potential (GWP), acidification potential (AP), human toxicity carcinogens (HTC), photochemical oxidation potential (PCOP), photochemical ozone formation, aquatic toxic potential (ATP), ecotoxicological potential (ET), particulate matter, and ozone depletion potential (ODP). The results were normalized in the same scale and illustrated in Figure 3. It was found that the carbon footprint of the first and second processes was 0.77 and 1.22 kg CO₂ eq., respectively which were higher than the baseline scenario (0.31 kg CO₂ eq.). The propane reformer was the most carbon footprint producer because it consumed the highest energy and released the most CO₂, accounting for 37.43% of the total carbon footprint. Heat exchangers and distillation columns were also the primary sources of CO₂. It was revealed that the reaction section was the main contributor to many environmental impact indicators in the first process. The gas flare reforming section notably contributed to ozone depletion potential (ODP) while, in the second process, the propane reforming contributed specifically to ET, HTNC, and ODP. HTNC was found to be the most significant environmental impact of the process. The hydrotreating section generates the highest amount of HTNC, followed by the separation section. The separation section, however, generates a relatively small amount of it. For example, in the first process, the HTNC generated from the hydrotreating, reforming, and separation sections were 1.5, 0.8, and 0.1 kg toluene eq., respectively.

4. Conclusions

The feasibility analysis of BHD processes from waste cooking oil integrated with a reformer was performed. Hydrogen sources from gas flare from the oil and gas industry and by-product propane were considered. Both processes were analyzed based on

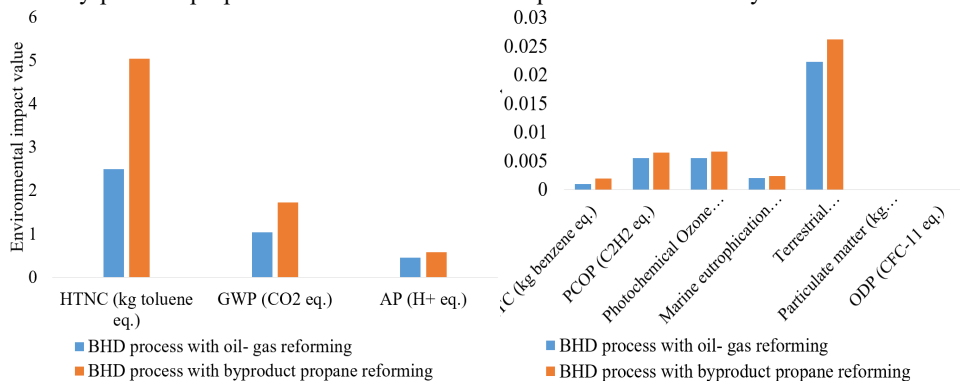

Figure 3 Environmental impacts BHD process with oil – gas reforming and BHD process with by-product propane reforming

economics and environmental impact indicators. The BHD process that used hydrogen from the gas flare was preferable. It consumed not only fewer utilities but also its economics and environmental impacts were more superior.

Abstract

Renewable aviation fuel is the most promising alternative to reduce emissions in the aviation sector; its production is technically feasible, but not its cost respect to fossil jet fuel. Then, novel pathways need to be developed. One option is the processing through a biorefinery scheme, where biomass is completely converted to several products. Thus, in this work the computer-aided design and analysis of an integrated biorefinery for the conversion of *Jatropha curcas* fruit, castor bean plant, microalgae biomass and cooking oil is presented; the biorefinery is planned to produce aviation biofuel and other biofuels. The conversion processes are modelled and simulated using Aspen Plus. The assessment of the biorefinery is realized through the estimation of total annual cost, released CO₂ emissions, and the net gross profit. Results indicated that biojet fuel represents 33% of net gross profit, with 5.52 kW invested per kW of energy delivered by the products.

Keywords: biorefinery, biojet fuel, process simulation, Aspen Plus.

1. Introduction

Besides the recent challenges on human health, satisfying the energy demand is still a priority theme. The estimated energy requirements for 2040 will be 25% more than the amount required in 2019, and an increase up to 130% has been forecasted for 2050 in the main sectors involved in the energy consumption, such as the transport sector (BP, 2019). Among the transport ways, the aviation sector has presented the major growth rate, projecting an increase up to 40% for 2040 (Zhang et al, 2020). To achieve its sustainable development, the use of biojet fuel has been identified as the most appropriate strategy (Gutiérrez-Antonio et al, 2016). The biojet fuel can be obtained from any kind of biomass through different conversion routes (Gutiérrez-Antonio et al, 2020). However, its production is still not competitive regarding the fossil jet fuel. For this reason, research about novel alternatives to produce biojet fuel is highly needed. In this context, integrated biorefineries are considered a feasible option to produce a variety of products, including

chemicals, power, heat and steam from biomass (Energy, 2019). Few works about biorefineries to produce biojet fuel have been reported (Tongpun et al, 2019; Romero-Izquierdo et al, 2019; Neves et al, 2020); in most of them, only one kind of biomass is used. Nevertheless, the use of mixtures of raw materials could help to strengthen the industrial implementation of the production of this biofuel. Therefore, in this work an integrated biorefinery scheme to produce biojet fuel is presented, using *Jatropha curcas* (JC) fruit, castor bean (CB) plant, microalgae biomass (MA) and waste cooking oil (WCO). For this biorefinery, all the fractions of the raw materials (husk, oil, etcetera) are used, achieving the diversification of processes and biofuels. The computer-aided design of the biorefinery scheme is realized using Aspen Plus. The assessment of the scheme is performed through the estimation of total annual cost (TAC), the counting of CO₂ emissions, as well as the estimation of net gross profit of the products obtained. These estimations allow to analyse the biorefinery scheme by the use of energetic and environmental indicators, detecting the main opportunity areas for enhancing the scheme.

2. Process design and simulation

The biorefinery feedstock is defined as a mixture of JC seeds (19 wt%), CB seeds (58.5 wt%), MA (*Chlorella vulgaris*) after harvesting stage (22.4 wt%), and WCO without solid traces (0.1 wt%). The amount of each raw material was defined based on the potential cultivation (Zamarripa-Colmenero et al, 2009), the productivity of microalgal strain (Vera-Morales et al, 2017), and the recollection data in México (Romero-Izquierdo et al, 2019), respectively. The biorefinery was decomposed in four processing zones: oil extraction (Z1), press cake processing (Z2), oil conversion (Z3), and biojet fuel separation (Z4). The flow diagrams for Z1 and Z2 are presented in Figure 1, while in Figure 2 are showed the Z3 and Z4. The process starts in Z1, wherein the oil extraction is performed. The mechanical extraction of JC and CB seeds is carried out in two stages; heating up to 100°C using saturated steam, and mechanical pressing by *Crusher* module to obtain vegetable oil and press cake. In the case of MA, ultrasound technology is used. The oil is separated from press cake using a *Split* module as filter. Then, 20 wt% of JC press cake and 20 wt% of MA press cake are fed to anaerobic digestion process (AD) in Z2. The degradation of biomass in AD was described by the Buswell equation (Huun-Nguyen et al, 2014) and performed at 55°C and 1 atm, using a *RStoic* reactor module. The obtained biogas is used to produce electricity by a gas turbine (*Comp* module). The JC and MA press cake remaining enter two separated hydrolysis and fermentation processes (SHF), using two consecutive reactors modelled by *RStoic* modules. The operating conditions of acid hydrolysis are 121°C, 1 bar and H₂SO₄ solution 1 wt%; whilst the fermentation reactor operates at 30°C, 1 bar with an urea-to-biomass mass ratio of 0.1 (Ho et al, 2013; Dimian and Sorin, 2008). Roughly 7% ethanol yield is obtained, along with other co-products (furfural, lactic acid, succinic acid, glycerol). Ethanol is purified through 3 distillation columns (*RadFrac* modules) to reach 98 % mass purity. The first column (38 stages) separates the CO₂; while in the second column the ethanol is preconcentrated until 90% mass purity. Finally, in the last column (15 stages), glycerol is used as extractive entrainer to break the ethanol-water azeotrope. 70 wt% of ethanol is sent to ATJ process, and 30 wt% to transesterification processes. Z2 continues with the pyrolysis of CB press cake, modelled with the *RBatch* module at 623 K, using the kinetic model reported by Santos et al (2015). The biochar is removed by a *Filter* module; the condensable gases are the bio-oil product, whilst the non-condensable gases could be used as heating source.

In ATJ process, 3 reactors are modelled with *RStoic* modules: 1) ethanol dehydration at 450 °C and 11.4 bar (Ristic et al, 2017); 2) ethylene oligomerization at 120°C and 35 bar (Heveling et al, 1998); 3) hydrogenation at 100 °C and 15 bar (Gounder et al, 2011).

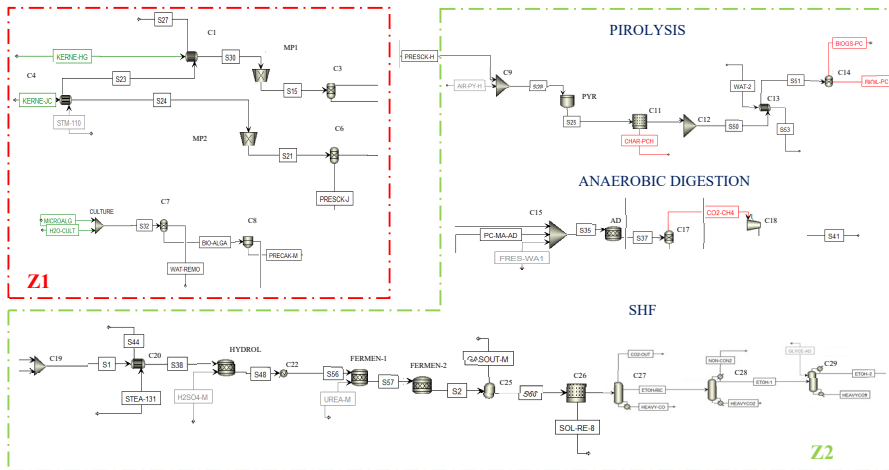

Figure 1. Flow diagram for Z1 and Z2 from Aspen Plus.

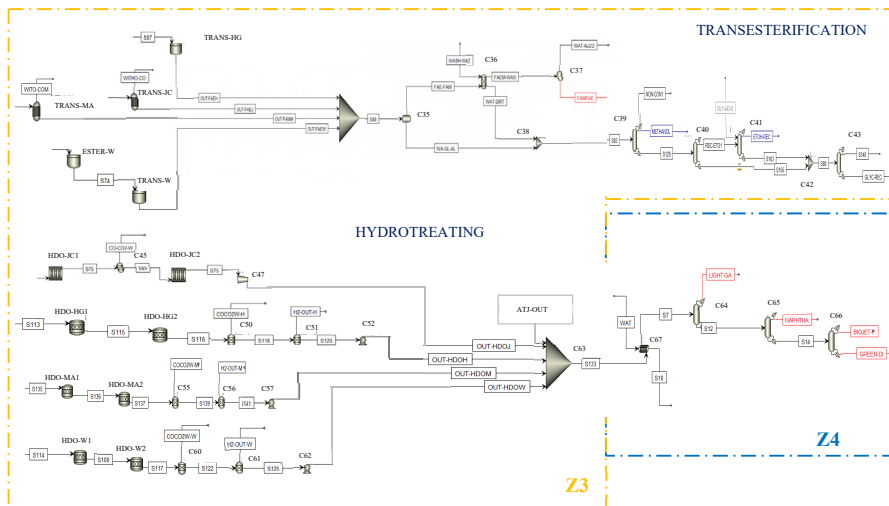

Figure 2. Flow diagram for Z3 and Z4 from Aspen Plus.

In Z3, 30 wt% of the oil flow is devoted to biodiesel production, and 70 wt% to the hydrotreating process. The production of biodiesel is carried out by transesterification reaction at 50 °C and 1 bar, using *REquil* modules for JC and MA, whilst *RBatch* modules are used for CB and WCO. For JC, CB and WCO the reaction uses ethanol (Abduh et al, 2013; Nivea et al, 2006; Romero-Izquierdo et al, 2019); for MA, the methanol is the reactant (Farooq et al, 2016). The obtained biodiesel is a mixture of ethyl and methyl esters. The separation of biodiesel starts with a *Decanter* module at 15 °C, followed by a wash-column and a *Flash* module to remove the excess of water. Then, the methanol,

ethanol and glycerol are separated using 4 distillation columns, modelled by *RadFrac* modules, reaching 0.958, 0.974 and 0.857 of mass purity, respectively. In the hydroprocessing (HDO), modules *RStoic* are used for CB oil, MA oil and WCO. The HDO for CB oil operates at 320 °C and 80 bar (Liu et al, 2015); while it operates at 350 °C and 50 bar for MA oil (Verma et al, 2011) and WCO (Romero-Izquierdo et al, 2019). Regarding to JC oil, two consecutive reactors (*RPlug* modules) at 80 bar are implemented, operating at 320 °C and 420 °C, respectively (Gutiérrez-Antonio et al, 2016). In order to reach 1 bar after the hydrotreatment for each oil, 4 turbines are used. After the turbines, the output streams from HDO are mixed with the hydrocarbons stream from ATJ process in Z4. This mixture is fed in a train of 3 distillation columns, modelled by the *RadFrac* module, reaching for each product 99% mass purity. In the first column (24 stages), light gases (C1-C4) are separated; while in the second one (38 stages), naphtha is purified (isoC5-C7). Finally, in third column (91 stages), biojet fuel (isoC8-C16) at top, and green diesel (C17-C21) at bottom are obtained. It is important to mention that sensibility analysis for decreasing the energy requirements were applied at separation zones (Z3 and Z4), varying reflux ratio and stages number. The biorefinery scheme is modelled with Peng-Robinson for the reactive zones, NRTL for SHF process, and BK10 for the Z4.

3. Economic and environmental assessment

The economic and environmental assessment for the biorefinery is realized through the total annual cost (TAC) and the counting of released CO₂ emissions. The TAC involves two items: the capital cost, calculated by Aspen Economics, adding 18% and 61% due to contingencies, installation fees and equipment maintenance, respectively (Turton et al, 2012); and the operating cost, which includes utilities cost (heating and cooling), raw material cost (JC, CB seeds, MA, hydrogen, ethanol, methanol) and additional reagents cost (glycerol, urea, H₂SO₄, etc), excluding catalyst cost and filters. The CO₂ emissions due to the production of steam and electricity are considered, and they are calculated through the methodology presented by Gutiérrez-Antonio et al (2016). On the other hand, the gross profit is calculated with the estimated product volume from simulation results, and the market price of each product: light gases, naphtha, biojet fuel, green diesel, bio-oil, bio-char (Romero-Izquierdo, 2020). These variables allow to analyse the biorefinery with two proposed indicators: IE, energetic indicator defined as invested energy used for heating, regarding to energy delivered by the products, and IA, environmental indicator defined as CO₂ emissions regarding to total product mass obtained from the biorefinery.

4. Results

According to results, the biorefinery generates 1% of its electricity requirements, thus, 81.6% of TAC is due to external power consumption. Moreover, the microalgae cost represents 85% of total raw materials cost. The major contributor to the TAC is the operating cost, whilst the capital cost represents less than 1%. In Table 1 is presented the TAC estimated for the biorefinery scheme. On the hand, the net gross profit estimated for obtained products is presented in Table 2. As it can be seen the greater contributors to the net gross profit are biodiesel with 37.7 % and biojet fuel with 33 %, which indicates its important position as useful biofuels in the market. Regarding CO₂ emissions, 6,579.44 MTon CO₂/year and 59.56 MTon CO₂/year are due to steam and electricity requirements. Thus, 99% of total CO₂ emissions are due to heating utilities. Finally, with regard IE, per each kW of total energy delivered by the products, 5.52 kW are invested in the processing

(by heating), which means that the energy investment for this biorefinery is 5.52 times higher than delivered energy by the products. Likewise, for IA, per each kg of total product mass, 1.51 ton of CO₂ are released; thus, the CO₂ emissions by the steam and electricity requirements are high, regarding to the products obtained; but the use of turbines to produce electricity in situ is a good strategy to diminish the total CO₂ emissions released by the processing.

Table 1. TAC for biorefinery scheme.

Operating Cost (million USD/year)					
Heating	Cooling	Additional reagents	Raw material	Electricity	Total Operating Cost
\$35.188	\$121.638	\$6,360.067	\$23,816.602	\$134,682.177	\$165,015.674
Annual Capital Cost (USD/year)					
Equipment Cost		A1	A2	Total Capital Cost	
\$67.205		\$12.096	\$40.995	\$24.059	
TAC (million USD/year): \$165,039.734					

Table 2. Net gross profit from biorefinery scheme.

Products	kg/h	USD/kg	USD/h	million USD/year
Light gases	20,646.56	\$0.46	\$9,560.67	\$81.265
Naphtha	60,770.14	\$0.47	\$28,258.12	\$240.193
Green diesel	65,657.22	\$0.96	\$62,719.16	\$533.112
Biodiesel	145,322.54	\$1.06	\$153,999.83	\$1,308.998
Biojet fuel	224,737.68	\$0.60	\$134,949.04	\$1,147.066
	GJ/h	USD/GJ		
Bio-oil	1,173.17	\$13.78	\$16,161.56	\$137.373
Bio-char	382.70	\$7.38	\$2,824.34	\$24.006
Total (million USD/year)				\$3,472.018

5. Conclusions

A biorefinery scheme with multiple feedstocks has been presented in this work for the production of biojet fuel and other biofuels. In this biorefinery, the microalgae cost represents 85% of the total raw materials cost, whilst the electricity cost is the major factor affecting the TAC (81.6%). In addition, 99% of total CO₂ emissions are due to steam requirements. Regarding to net gross profit, 33% corresponds to biojet fuel, thus its price in the market occupies the second place among the biofuels obtained in this proposal. Finally, 5.52 kW are invested (by heating) per kW of energy delivered by the products, whilst 1.51 ton of CO₂ per each kg of total product mass are released; thus, it is necessary to apply strategies to minimize the energy requirements and diminishing the CO₂ emissions. Nevertheless, this biorefinery scheme is a good alternative to produce biofuels, mainly biojet fuel, from the complete use of the selected biomasses.

Abstract

The use of biomass has been associated mainly with the energy or biofuels. However, the production of high value-added products such as chemical building blocks, show a feasible alternative. However, the coordination of all the players within a market is complex because is necessary ensuring that the balance of profits generated will be greater than production and logistic cost, becoming an optimization problem. Therefore, we propose a coordination framework for managing lignocellulosic biomass from agricultural residues in a scalable manner by orchestrating biomass exchange, transportation, and transformation into value-added products, specifically: Levulinic acid and furfural. In the proposed framework, suppliers and consumers of biomass and derived products as well as transportation and technology providers bid into a coordination system that is operated by an independent system operator. All locations, prices for all biomass types and derived products are obtained by the operator by solving a dispatch problem that maximizes the social welfare and that balances supply and demand across a given geographical region. Through the coordinated framework, cleared transportation flows, locations and technologies involved are obtained to meet demand. The production of Levulinic acid was 330 Kt/year and 394 Kt/year of Furfural. Which represent 3% of global demand of raw materials for methyltetrahydrofuran. On the other hand, the benefit generated to biomass suppliers exceeds \$27 million / year, which would represent an increase in social welfare in the area, specifically to farmers. The framework allows to identify guidelines of the market behaviour considering all market players, with these guidelines is possible propose actions to be able to project a more competitive market for all products and that favors all market players.

Keywords: Coordination Framework, Agricultural Waste, Levulinic Acid, Furfural

1. Introduction

The concept of Biorefinery originated in the 1990's as a result of fossil fuel shortages and increasing trends in the use of biomass as a renewable raw material for the production of non-food products (Popa and Volf, 2018). The mismanagement and disposal of agricultural waste represents not only a danger to the environment, but also a lost economic opportunity. Specifically, there are various biomass processing technologies to generate value-added products from organic waste such as building block chemicals, fuels, and electricity. Unfortunately, the economic viability of waste processing routes depends to a large extent on the scale, transport costs and composition of agricultural waste (which vary depending on waste). Moreover, decision-makers are often unaware of the potential uses of waste streams and, therefore, of their inherent value. Another obstacle associated with waste management is the lack of cost-effective alternatives to

collect and transport large quantities over long distances. In Mexico, government regulations and incentives for the use of biomass are currently in place, however, incentives have not been able to exceed production and logistics costs. Therefore, there is no waste management network that guarantees a strong market, sustained growth for the urban and agricultural sectors. Another important aspect is that in Mexico studies on the use of biomass have focused on its use to generate energy or biofuels, for example: Quiroz-Ramirez et.al (2017) performs a optimal planning of biomass for biobutanol production and Santibañez-Aguilar et .al (2019) proposes the mathematical model for planning the use of biomass for energy production systems, both works leaving aside the potential biomass use as raw material for high added value products such as Levulinic acid and Furfural.

This work proposes a coordinated framework for the management of lignocellulosic biomass from agricultural waste (corn stover, wheat straw and sorghum stover) in a scalable way by organizing the exchange, distribution, transport and transformation of biomass into value-added bioproducts, specifically: Levulinic acid and Furfural. These high value-added products were selected because they are precursors of methyltetrahydrofuran, which is an additive that can be mixed with gasoline and that according to what was reported by Grand View Research (2015) has a demand of more than 20,000 kilo tons. The state of Guanajuato was taken as a case study, which is the second state in Mexico with the highest generation of agricultural waste that contribute 10.2 % of the national generation. Within the proposed framework, biomass suppliers, technologies involved in processing and transport suppliers participate in a coordinated system that is solved by an independent system operator (ISO). The operator solves a dispatch problem that maximizes social welfare and balances supply and demand in a specific geographical area, for this, the operator obtains all the locations, the prices of different biomass and derived products. Coordination allows the management of complex constraints and interdependencies arising from the transport and physicochemical transformations of biomass into value-added bioproducts.

2. Case of Study

Ministry of Agriculture, livestock, Rural Development, Fishing and Food (SAGARPA) shows that Guanajuato is the second state in Mexico with the highest generation of agricultural, which makes it an important sample to implement the methodology of the coordinated framework. Of the 3,830,305 tons by year of agricultural residues, corn stover represents 35 %, sorghum straw 41 %, wheat straw 17 % and barley straw 7 %. So, for this case study, only the three most abundant types of agricultural residues were considered. Production data were obtained from open data from the Agri-Food and *que* Fisheries Information Service (SIAP). To obtain the amount of biomass generated per amount of crop, we use the ratio reported by McIlveen-Wright et al. (2013) and biomass composition was taken within the ranges reported by Isikgor (2015). In addition, were used agricultural residues prices and transport cost reported by Santibañez-Aguilar et.al (2019). The optimization problem was formulated using 10-year data (2009-2018), each year was proposed as a scenario, all the scenarios were solved simultaneously. The main products are furfural, which is obtained from hemicellulose, obtaining 0.27 kg of furfural / kg of hemicellulose, and Levulinic acid, which is obtained from cellulose, with a yield of 0.49 kg of Levulinic acid / kg of cellulose. These conversions were proposed based on what was reported in previous works by Luo et. al (2019) and Reunanen et.al (2013). Biorefineries location was strategically selected, the criteria for selection were: its proximity to roads, provision of services for industries of this type and its proximity to

available biomass. In each location, the implementation of agricultural waste transformation technologies to Furfural and Levulinic acid was proposed. Levulinic acid and furfural production cost was considered based on the work of Gozan et. al (2018) and Cai et. al (2014), where the impact of the scale economy is clearly showed, considering plants between 295 tonne/day and 701 tonne/day, prices of 2159 USD and USD 1430 USD per tonne of biomass are obtained, respectively.

3. Coordination Framework

We consider a system that comprises a set of geographical locations (nodes) N , products P , suppliers S , consumers \mathcal{D} , transportation providers \mathcal{L} , and transformation (technology) providers \mathcal{T} . Products comprise different waste stream types and derived products, transportation providers offer alternatives (e.g., hauling, railway, pipelines) to move products between locations, and technology providers offer alternatives to process products to produce other higher value products.

The management system proposed is operated by an ISO that collects bidding information from all participants (costs, capacities, and transformation factors) to obtain optimal allocations of product supply, demand, transportation, and transformation services. The ISO determines these allocations by solving a dispatch problem that finds optimal transportation and transformation pathways for waste and derived products that maximize the social welfare and that balance supply and demand for all products across a geographical region. For reasons that will become apparent, this dispatch problem can be seen as a market clearing problem. The cleared transportation providers create a transportation network that connects nodes in the system that perform exchange of products. An efficient management system is expected to clear suppliers and providers that offer services at low costs and will give preference to consumers with higher bidding costs. The clearing problem also aims to find prices that are used to properly remunerate suppliers and providers to cover their service costs and to charge consumers for the service provided.

3.1. Dispatch Formulation

Given the bidding information associated with each supplier α^s , consumer α^d , transportation provider α^f , technology α^ξ and maximum capacity of biomass \bar{s} , demand \bar{d} , transportation provider \bar{f} , processing $\bar{\xi}$ the ISO solves the clearing problem Eq. (1) to find allocations. These allocations maximize the social welfare Eq. (1a) and satisfy the physical conservation laws Eq. (1b), and capacity constraints Eq. (1c)-(1f). Maximizing the social welfare function maximizes the demand served and minimizes the costs of supply, transportation, and transformation. The conservation laws are also known as the balancing constraints or market clearing constraints. The first term in parenthesis is the total input flow for product p into node n (given by supply flows and transportation flows entering the node). The second term in parenthesis is the total output flow of product p from node n (given by the demand flows and transportation flows leaving the node). The third term is the generation/consumption rate of product p in all technologies located at node n . In a work published by Apoorva et al. (2019) the complete dispatch formulation and fundamental properties of the coordination framework are described.

$$\max_{(s,d,f,\xi)} \sum_{j \in \mathcal{D}} \alpha_j^d d_j - \sum_{i \in \mathcal{S}} \alpha_i^s s_i - \sum_{\ell \in \mathcal{L}} \alpha_\ell^f f_\ell - \sum_{t \in \mathcal{T}} \alpha_t^\xi \xi_t \quad (1a)$$

$$\text{s.t.} \left(\sum_{i \in \mathcal{S}_{n,p}} s_i + \sum_{\ell \in \mathcal{L}_{n,p}^m} f_\ell \right) - \left(\sum_{j \in \mathcal{D}_{n,p}} d_j + \sum_{\ell \in \mathcal{L}_{n,p}^{out}} f_\ell \right) + \sum_{t \in \mathcal{T}_n} \gamma_{t,p} \xi_t = 0, (n,p) \in \mathcal{N} \times \mathcal{P}, (\pi_{n,p}) \quad (1b)$$

$$0 \leq s_i \leq \bar{s}_i, i \in \mathcal{S} \quad (1c)$$

$$0 \leq d_j \leq \bar{d}_j, j \in \mathcal{D} \quad (1d)$$

$$0 \leq f_\ell \leq \bar{f}_\ell, \ell \in \mathcal{L} \quad (1e)$$

$$0 \leq \xi_t \leq \bar{\xi}_t, t \in \mathcal{T} \quad (1f)$$

4. Results

Optimization problem includes: 51 nodes, 1277 biomass suppliers and 8 different products (raw materials and derived products). The 46 municipalities of the state of Guanajuato and their agricultural production for the period 2009-2018; four installation locations for conversion technologies and a single point of demand for the products resulting from the transformation was considered. To give an idea of the logistical complexity involved, the optimization problem is a linear programming problem that contains more than 24801 decision variables and 4860 restrictions.

For this case study, 60% of the biomass of the state of Guanajuato was used. This would produce around 434 Kt/year of Levulinic acid and 487 Kt/year of Furfural. However, through the implementation of the coordinated framework it shows, that having an availability of 60% biomass, the best solution found only uses 80% of this biomass, it occurs because the wheat straw processing cost is affected by the scale economy. If wheat straw were to be considered, a bigger technology for processing should be proposed. Therefore, in this work, a production of 330 Kt / year of Levulinic acid and 394 Kt / year of Furfural was obtained, which represents 3.0% of global demand of raw materials for the MTHF.

Table 1 shows the prices at which the market clears (clearing prices), these prices are calculated independently for each node present in the problem. As a result, we obtained a price range where our market still exists and all market players have benefit. In this case, the clearing prices for wheat straw are zero since they do not participate in the market. Figure 1 shows the cleared transportation flows in Guanajuato State for different biomass and derived products, in Figure 1c no flows appear because wheat straw does not participate in the market.

Table 1. Clearing prices

Product	Clearing prices		
	Theoretical Price	Minimal Price	Maximum Price
Corn stover	18.33	8.18	21.01
Sorghum straw	14.96	5.24	17.61
Wheat straw	16.66	0	0
Furfural	1700.00	1685.71	1700.00
Levulinic acid	11023	11008.71	11023

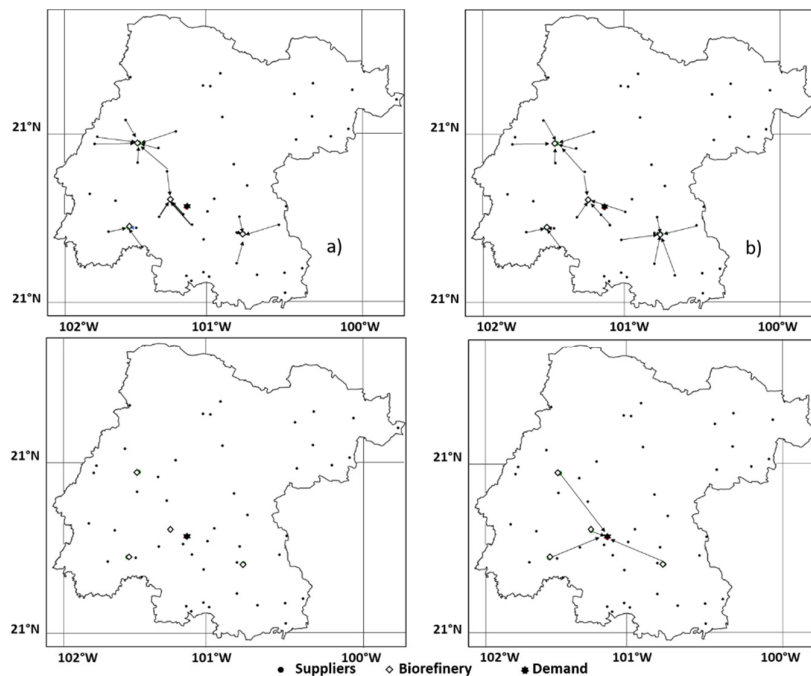

Figure 1. Cleared transportation flows in Guanajuato State for different biomass and derived products: A) Corn stover, B) Sorghum Straw, C) Wheat Straw and D) Derived products.

In Figure 1, not all suppliers are involved in the market, this due to process cost and mainly to transportation cost. The main suppliers are in municipalities near the biorefineries, in the center and south of the Guanajuato state. It may seem that there are very few suppliers involved, however it is necessary to mention that in each municipality there may be up to 10 corn stover suppliers and 10 sorghum stover suppliers. The municipalities involved in the market are: Abasolo, Acambaro, Apaseo el Alto, Celaya, Cortazar, Guanajuato, Irapuato, Jaral del Progreso, León, Penjamo, Pueblo Nuevo, Purísima del Rincon, Romita, Salamanca, Salvatierra, San Francisco del Rincon, Silao de la Victoria, Valle de Santiago and Villagran. The profit generated through the implementation of the coordinated system is $1.84E+03$ million USD/year, this profit is large due to the price of Levulinic acid. Total revenue is $4.49E+03$, this revenue is associated to sales. Although these results are encouraging, it is also important to mention that it has a direct impact on the region since the total transportation cost is 5.79 million USD/year, the total supply cost is $2.76E+01$ million USD/year.

5. Conclusions

We presented a coordinated system to facilitate the management of agricultural waste in a scalable way by coordinating the exchange, transport, and transformation of biomass into value-added products. The framework operates as a coordinated marketplace under which waste suppliers and consumers, as well as transport and technology, provide

bidding services to an independent system operator. The prices of waste and derived products in different geographical locations are obtained by solving a dispatch problem that maximizes social welfare and balances products throughout the region. Coordination enables you to handle complex interdependencies between products and locations. We demonstrate that the system offers prices and allocations that satisfy the fundamental economic and efficiency properties expected of a competitive market. We also show that the proposed system provides a systematic framework for monetizing environmental impacts, health impacts, and remediation benefits. In addition, prices reveal the true value of waste streams and capture spatiotemporal variations that help prioritize areas and reveal the need for investment in processing technologies, transportation, facility relocation, and seasonal storage. The proposed geographic framework is scalable in the sense that it can provide open access that encourages transactions between many small and large players by allowing coordination with other infrastructures. Additionally, this coordinated framework represents a valuable contribution to the visualization of the market in Mexico resulting from the use of biomass to obtain building block chemicals, such as Levulinic acid and Furfural, since to date, the efforts made have focused in the production of energy and biofuels. A coordinated framework will become increasingly necessary as the human population grows and mobilizes, and as the availability of resources becomes more uncertain.

Abstract

Currently, chemical processes must be designed and optimized considering multicriteria objectives focused on sustainable aspects. These targets can be effectively achieved via a systematic framework, capable to guide the users to take the best decision in terms of given objectives. Thus, the present work develops and implements a framework through four main steps that use multiple computer-aided tools and methods, linked to optimal indicators such as exergy loss, total annual cost and environmental factors and scores. The implementation of the methodology used a case study consisting of the ABE separation and purification scheme, using liquid-liquid extraction and conventional distillation techniques, as well as the evaluation of five extracting agents. The framework allowed to enhance the performance of all scenarios with respect the base case.

Keywords: Sustainable process design, Exergo-economic analysis, Aspen Plus-Matlab Interface, Multi-Objective Genetic Algorithms, Life Cycle Impact Assessment.

1. Introduction

Process system engineering has been successfully applied to address various product-process design problems present in the chemical and biochemical/biological industry, where the integration of computer-aided tools and systemic frameworks based on the optimization of processes in operational and design terms, it is usually a key factor for the selection of the best candidate products-processes (Gani, 2009). The current environmental challenges related to emissions, waste management and energy efficiency of the systems have motivated the search for economically feasible systems with a lower environmental impact, in this sense, the implementation of the exergo-economic analysis provides an adequate route to satisfy these targets (Akchiche et al., 2020). Additionally, exergo-environmental analysis has provided a useful approach for lower environmental impact processes design, moreover, the combination of the exergy, economic and environmental analysis approach in energy-intensive systems, has shown superior

economic and environmental benefits, compared with conventional analyses for process design (Li et al., 2019). Therefore, based on the current state of the art, the objective of this work focuses on the development and implementation of a systematic framework to determine a sustainable optimal process design based on exergetic, environmental and, economic indicators.

2. A design and optimization framework for (bio-)chemical process based on sustainability aspects

The framework for the design and optimization of (bio-)chemical processes based on sustainability aspects is presented in Figure 1. This framework includes four systematic main steps, which can be summarized as follows: 1) Problem definition, data collection, optimization techniques, available technology and, the review of methods and indicators focused on the sustainability of the product and process design. 2) Integration of thermodynamic aspects and rigorous systems designs through the use of commercial process simulator (e.g. Aspen Plus), in addition to the implementation of the model and sustainable multi-objective functions for optimization into a programming environment (e.g. Matlab), generating a simulation-optimization platform that provides a set of results that satisfy all problem constraints. 3) Selection of methods for the evaluation of the environmental impacts in process and products design, with the aim of implementing a better metric for the selection of sustainable processes. 4) Integration of graphical tools with the aim of facilitating the analysis of the results, the selection and implementation of the best scenario in the selected case study.

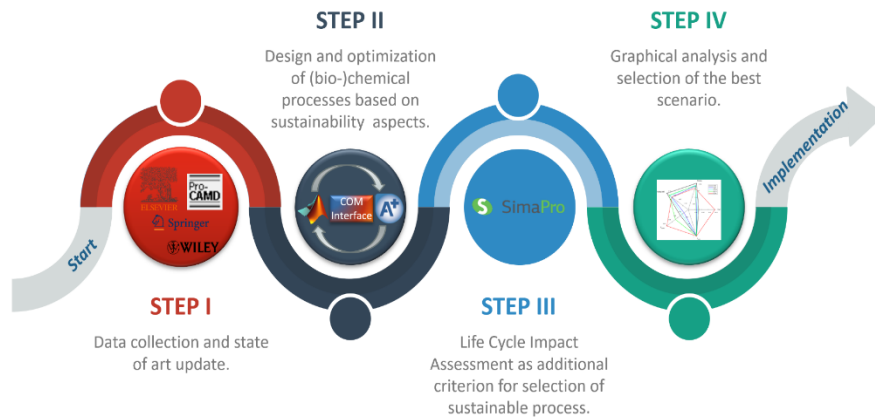

Figure 1. A design and optimization framework for (bio-)chemical process based on sustainability aspects.

3. Case study

The framework was evaluated using the separation and purification of Acetone-Butanol-Ethanol (ABE) from a fermentation broth mixture. The feed stream used in this study was 20,393.64 kg/h with a mass composition of: Acetone (0.1116), Butanol (0.2922), Ethanol (0.0784), Water (0.5138), and Carbon Dioxide (0.0040). A hybrid separation process (liquid-liquid extraction and conventional distillation) was selected, where five extracting agents (EA) were evaluated.

4. Framework description

4.1. Data collection and state of art update.

The first step was to define the case study. In a previous work some authors identified the advantages and disadvantages in the ABE broth mixture separation and purification, including general characteristics of biochemical processes as: multi-production process, diluted products, azeotropes presence, etc. These aspects were successfully addressed by implementing optimal schemes based on total annual cost (TAC) and environmental targets, including environmental, friendlier and economic extracting agents, on the separation and purification schemes (SPS) (Ponce-Rocha et al., 2018).

4.2. Design and optimization of (bio-)chemical processes based on sustainability aspects.

Nowadays, a commercial process simulator (e.g., Aspen plus) allows process design using a rigorous thermodynamic description, through the determination of suitable model and binary interaction parameters. Once the system components were established, the selection of the thermodynamic models was carried out, the NRTL and Hayden O'Connell modification were selected to describe the liquid-vapor equilibrium, respectively (Morales-Espinosa et al., 2017). The SPS were carried out based on heuristic rules, the equipment design was done using shortcut methods, rigorous methods and, sensitivity analysis to improve the design of columns. The selected extracting agents to be evaluated were hexyl acetate (HEX), heptyl acetate (HEP), a HEX-HEP mixture, 2-ethyl-1-hexanol (2-ETH-1-OL), and dichloromethane (DCM). Due to the volatilities of extracting agents, two different SPS were generated as shown in Figure 2.

Figure 2. a) DCM process configuration (ELL+3DC columns); b) HEX, HEP, HEX-HEP, and 2-ETH-1-OL process configuration (ELL+4DC columns).

An inherent characteristic in the optimization of chemical processes involves the presence of multiple objectives, unfortunately, commercial simulators lack of multi-objective optimization (MOO) modules. Thus, an alternative to tackle those issues have been done by integrating a simulation-optimization platform, using a computational interface (e.g., COM) into a programming environment. Regarding to the optimization part, the use of black-box optimization methods do not require an algebraic model for their description, only iterative evaluations of the process variables and conditions, therefore, multi-objective genetic algorithms (MOGA) are an excellent tool for making this task (Muñoz et al., 2017).

4.2.1. Optimization problem formulation

In this work the multi-objective optimization is represented as following in Equation 1:

$$\underset{x}{\text{Min}} \quad \underline{Z} = [Z_k(\underline{x})] \quad k = 1, 2, \dots, k. \quad \text{s.t.} \quad \mathbf{h}(\underline{x}) = 0; \mathbf{g}(\underline{x}) \leq 0 \quad (1)$$

where \underline{Z} represents a vector with k -objectives functions, \underline{x} is the vector of state variables (stages number, feed stages, reflux ratios, distillate or bottoms rates, and the inlet flow of the extracting agent). $\mathbf{h}(\underline{x})$ and $\mathbf{g}(\underline{x})$ are the vectors of model equality and inequality constraints associated with mass purities (P) and mass recoveries (R). (Equation 2-3 for HEX, HEP, HEP-HEX and, 2-ETH-1-OL. Equations 4-5 for DCM).

$$[P_{EA}, P_A, P_B, P_E] \geq [0.999, 0.950, 0.995, 0.900] \quad (2)$$

$$[R_{EA}, R_A, R_B, R_E] \geq [0.999, 0.995, 0.000, 0.992] \quad (3)$$

$$[P_{EA}, P_A, P_B, P_E] \geq [0.995, 0.990, 0.995, 0.990] \quad (4)$$

$$[R_{EA}, R_A, R_B, R_E] \geq [0.980, 0.990, 0.999, 0.000] \quad (5)$$

In this study, four objective functions were selected to evaluate and optimize the sustainable process configurations: the energy requirements, exergy losses, TAC and, the E factor.

The energy requirements (ER) associate the ratio between total heat requirements and the amount of product purified in each case study, as described in Equation 6.

$$ER = \frac{\text{Energy requeriments [MJ]}}{\text{Products [kg]}} \quad (6)$$

Exergy losses (σT_0) were calculated considering the total exergy losses given by the heating and cooling processes (Q), separation (Sep) and, concentration changes ($Conc$) in all the equipment (j) and streams processes (i) (see Equation 7).

$$\sigma T_0 = \Delta \dot{E}x_{In} - \Delta \dot{E}x_{Out}$$

$$\sigma T_0 = \sum_{j=1}^n \sum_{i=1}^m [\Delta \dot{E}x_{Q,j} + \Delta \dot{E}x_{Sep,i} + \Delta \dot{E}x_{Conc,i}] \quad (7)$$

Total annual cost (TAC) illustrated in Equation (8), establishes the equipment investment cost and payback period (adjusted to five years), and the sum of annualized cost of utilities, referred to extraction agent lost, cooling and heating services.

$$TAC = \frac{\text{Investment cost}}{\text{Payback period}} + \text{Utilities} \quad (8)$$

The E factor (E) determinates the waste and products ratio (see Equation 9). Further, the streams with water composition greater than 99% (mass) were not considered as waste streams.

$$E_{factor} = \frac{\text{Waste [kg]}}{\text{Products [kg]}} \quad (9)$$

3.2.1 Metaheuristic optimization strategy

The generated alternatives were evaluated and optimized using a MOGA: Gamultiobj (a variant of NSGA-II) integrated in Matlab. Each optimization considered 50 generations, 200 individuals, and a crossover fraction of 0.8.

4.3. Life Cycle Impact Assessment as an additional criterion for selection of sustainable process.

The life cycle analysis (LCA) evaluation has been considered as one of the most appropriate methodologies to estimate the environmental impacts of products and processes. This methodology is comprised of four main stages: definition of objective and scope, inventory analysis (LCI), impact evaluation or Life cycle impact assessment (LCIA), and interpretation of results. The LCIA methods (e.g. ReCiPe 2008) allow to estimate a single scores (SS) capable to describe the total environmental impact, providing an objective criterion for the comparison of systems with similar characteristics (Santos et al., 2018).

4.4. Graphical analysis and selection of the best scenario.

Finally, the previous results were compiled and selected according to the best SPS for each extracting agent using a graphical analysis to represent the four sustainable objective functions.

5. Results

The optimal results that accomplished the established constrains were selected for each extracting agent (EA), and subsequently, the total environmental impact was measured by life cycle impact assessment using ReCiPe 2008 method. Table 1 shows the most relevant indicators for base and optimal scenarios obtained for each solvent in MOO and LCIA. The best scenarios for TAC, σT_0 , ER, E and SS_{LCIA} were when using 2-ETH-1-OL, DCM, HEP, HEP and HEP, respectively.

Table 1. Summary of results of the evaluated extracting agents.

EA	Scenario	TAC [M\$/year]	σT_0 [MW]	ER [MJ/kg- ABE]	E-factor	SS_{LCIA}
HEX	Base	13.63	2.99	12.93	0.51	0.28
	Optimal	10.27	2.18	9.13	0.47	0.26
HEP	Base	11.72	3.01	10.35	0.28	0.23
	Optimal	8.09	1.95	6.99	0.25	0.21
HEP- HEX	Base (0.5-0.5)	12.49	2.93	11.14	0.35	0.24
	Optimal (0.41-0.59)	9.10	2.02	7.83	0.37	0.24
2-ETH-1- OL	Base	14.88	4.04	15.52	0.79	0.31
	Optimal	7.67	1.98	8.12	0.77	0.29
DCM	Base	26.63	1.79	7.28	1.28	0.22
	Optimal	26.14	1.77	7.00	1.28	0.22

Figure 3 shows the optimal sustainability indicators for each extracting agent given in Table 1. This graph allows a visual and clearer comparison between the optimal results

Figure 3. Optimal results using the different EA.

for each extraction agent. In this sense, the use of HEP as extracting agent provides the best scenario for separation and purification of ABE mixture under the selected sustainability targets.

Furthermore, analyzing all indicators in Table 1, it is possible to observe a major benefit in the sustainable indicators for each extraction agent optimal case (TAC, σT_0 , ER, and E-factor). In addition, these improvements minimize or alternatively keep an identical environmental impact.

6. Conclusion

The systematic steps and selected tools and methods integrated in this framework, allowed to improve most of indicators for each SPS. The results illustrated that the best SPS was found when using HEP as EA, which permitted to minimize substantially the TAC (31%), exergy losses (35%), energy requirements (32%), E-factor (11 %) and LCIA (9%) with respect to the base scenario; in addition to major sustainability benefits compared with the other indicator's values reported by each EA in Table 1. Therefore, the process design and optimization based on sustainable indicators can be applied successfully in (bio-) chemical and chemical processes with environmental and energetic problems.

Abstract

This study aims to develop a systematic methodology through the combination of process simulation and life cycle assessment (LCA) to comprehensively evaluate biodiesel production from algae biomass in terms of the minimum biodiesel selling price (MBSP) and the environmental impacts of algae biodiesel. Downstream processing stages (lipid extraction with hexane, lipid refining through esterification with glycerol, and conversion to biodiesel with an alkali-based transesterification) were designed and simulated in Aspen Plus V8.8. Then, a discounted cash flow rate of return analysis was used to obtain the MBSP. Finally, an LCA was performed to obtain the environmental impacts of algae biodiesel and identify the hot-spots in the processing stages. The MBSP was found to be 8.95 USD per gal, around 3.5 times higher than the average price of fossil diesel in 2020 for the US. The primary energy demand (PED) and climate change (CC) impacts of algae biodiesel were estimated at 1.54 MJ/MJ biodiesel and 96 g CO₂eq/MJ biodiesel, resulting 27% and 2% higher, respectively, than the reference values for fossil diesel. Lipid extraction was identified as the hotspot of downstream processing, accounting for 47% of PED and 60% of CC of the process. Hexane production and evaporation losses were also identified as major contributors to other environmental impact categories, including human toxicity, eutrophication, and photochemical ozone formation. This methodology can be used to evaluate alternative processing options for algae biodiesel, such as using bio-based solvents (terpenes) for algae lipid extraction, to contribute to more sustainable and environmentally friendly processes.

Keywords: lipid extraction, solvent selection, techno-economic analysis.

1. Introduction

Biofuels production from algae is a significant area of interest within the field of biorefining because algae offer several advantages over conventional feedstocks for biofuel production, including high productivity, high content of lipids, cultivation in saline and wastewater sources, and production of high-value coproducts. Despite these advantages, biofuel production from algae is not cost-competitive due to several challenges in the processing steps (Quinn and Davis, 2015). Among these, algae lipid extraction is a major bottleneck in biodiesel's commercial production, as it has a significant impact on the economic viability, energy consumption, and environmental performance of the process (Harris et al., 2018). Conventional processes for lipid

extraction rely on fossil-based volatile organic solvents, such as hexane, which introduce negative environmental impacts due to their hazardous, volatile, and flammable nature. Alternatives to hexane have been proposed, such as bio-based solvents (terpenes) for lipid extraction (Dejoye Tanzi et al., 2013). However, information is lacking about the process performance and sustainability of non-conventional solvents for lipid extraction.

Techno-economic analysis combined with environmental sustainability tools, such as life cycle assessment (LCA), have proven to be useful for evaluating the performance and identifying improvement opportunities of novel processes, including biodiesel production from algae (DeRose et al., 2019). The minimum selling price of algae biofuels has been estimated and reported widely in the literature (Davis et al., 2018). Most previous LCA of algae biofuels focused only on the primary energy demand and climate change impacts without considering potential impacts related to the use of hexane in the lipid extraction stage, such as human toxicity and photochemical oxidation. Besides, only a few LCA studies (Passell et al., 2013) identified hotspots in the downstream processing of algae biofuels, with the objective of improving its economic and environmental performance. In an effort to better understand the impact of the lipid extraction stage, and particularly the benchmark solvent hexane, on the economic viability and environmental sustainability of algae biodiesel production, this study presents a systematic methodology that combines process simulation and life cycle assessment to provide a robust evaluation of the economic and environmental performance of algae biodiesel on a life cycle basis.

2. Methodology

The proposed methodology, illustrated in Figure 1, consists of four iterative steps: 1) problem definition, 2) process design and simulation, 3) economic analysis, and 4) life cycle assessment. Data required and outcomes of each step are included in Figure 1. The application of this methodology allows the identification of the hotspots in algae biodiesel production, which can be modified to improve the economic and environmental performance of the product.

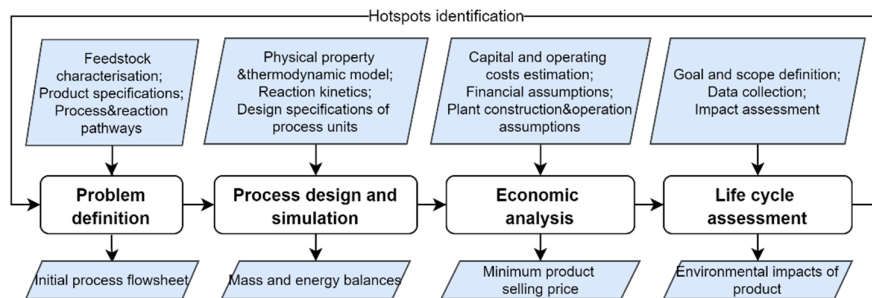

Figure 1. Proposed methodology to evaluate economics and environmental impacts of algae biodiesel

Figure 2 shows an overview of algae biodiesel's life cycle, including the processing stages and its combustion. The upstream processing stages comprise algae cultivation and harvesting/dewatering processes. *Nannochloropsis salina* was selected as the algae strain due to its demonstrated potential for biodiesel production, known composition data (Yao et al., 2015), and refining and conversion kinetics data (Silva et al., 2013). It is assumed that the algae are cultivated in an open pond system and fed with a pure stream of CO₂, which was assumed to be captured from a coal-fired power plant using monoethanolamine (MEA). Fertilisers (diammonium phosphate and ammonia) are added

to the cultivation ponds to support algae biomass growth. The biomass is then routed to the harvesting/dewatering stage, where it is concentrated from 0.5 g/L to 200 g/L with settling tanks and a centrifuge unit (Davis et al., 2016). The downstream processing stages comprise lipid extraction, refining, and conversion to biodiesel. Lipid extraction includes cell disruption (with a high-pressure homogeniser), extraction with the solvent hexane, and solvent recovery. In the lipid refining stage, the free fatty acid content of the extracted lipids decreases to < 1 wt% through an esterification reaction with glycerol (Silva et al., 2013). The refined lipids are converted to biodiesel with an alkali-based transesterification reaction with methanol in the lipid conversion stage. An anaerobic digestion/combined heat and power unit (AD/CHP) is included in the flowsheet to generate heat and power from the waste biomass (lipid-extracted algae) and waste glycerol and to recover nutrients for algae cultivation in the AD effluent stream.

Figure 2. Overview of the life cycle of algae biodiesel

The plant's objective is the continuous production of 10,000 t y⁻¹ of biodiesel that meets the quality specifications given by the ASTM D675 standard. The water content in the algae biomass is 80 wt%. The lipid content of the dry biomass is 30%, consisting of a mixture of triglycerides (85%) and free fatty acids (15%). Due to the presence of polar components and the nonideal thermodynamics of the liquid mixtures that need to be separated, the NRTL activity coefficient model is used to model phase equilibrium, and the Dortmund UNIFAC method is used to estimate missing binary interaction parameters. The lipid extraction process is modelled assuming a counter-current extraction column with five equilibrium stages, at 25°C and 1 atm. The solvent-to-dry feed mass ratio is assumed to be 5 to 1 (Davis et al., 2014). The EXTRACT block in Aspen Plus V8.8 (an equilibrium-stage model) is used to model the extraction process. In this model, the distribution coefficients are calculated with an activity coefficient model capable of representing two liquid phases (NRTL); adiabatic operation is assumed. The process design for biodiesel production from the extracted lipids proposed by Dimian and Kiss (2019) was adapted and used to guarantee that the biodiesel product meets the quality specifications. The minimum biodiesel selling price (MBSP, in USD per gal) is calculated using a discounted cash flow rate of return analysis, assuming a 10% internal rate of return (IRR) after taxes (Davis et al., 2014). Capital investment costs are estimated using the factorial method of cost estimation and Hand installation factors (Towler and Sinnott, 2020). Operating costs are calculated based on the material and energy balance of the process obtained via the simulation. The cost of the algae biomass (*Nannochloropsis salina*) that enters the lipid extraction process is taken from Davis et al. (2016).

The LCA is conducted according to ISO 14040/44 guidelines. The goal is to estimate the life cycle environmental impacts of production and combustion of biodiesel derived from algae, considering a "cradle-to-grave" scope, as illustrated in Figure 2. The functional unit is defined as "the production and combustion of one MJ of biodiesel." The inventory data

for the upstream processing stages are obtained from Davis et al. (2018), while those for the downstream processing stages are obtained from mass and energy balances resulting from process simulation. The emissions resulting from biodiesel combustion are obtained from GREET (Argonne National Laboratory, 2019). All the background data, e.g. grid electricity, provision of heat from natural gas, production of chemicals for upstream and downstream processing (MEA, fertilisers, hexane, methanol, NaOH, glycerol), and wastewater treatment, are sourced from the Ecoinvent database V3.5 (Ecoinvent, 2019). The LCA modelling is carried out in the software GaBi v9.5. The environmental impact categories are selected based on the recommendations of the International Reference Life Cycle Data System Handbook (EC-JRC, 2010) and are estimated using the ReCiPe2016 impact assessment method (Huijbregts et al., 2017).

3. Results and Discussion

The minimum biodiesel selling price was estimated at 8.95 USD per gal. This value is around 3.5 times the average price of fossil diesel in 2020 for the US (2.55 USD per gal). The cost of algae biomass and hexane accounted for 76% and 2%, respectively, of the biodiesel price. An increase in the recovery of lipids from algae biomass, e.g. using other solvents with higher extraction capacity, could reduce algae biomass's required feed rate to achieve the desired biodiesel production, thus decreasing the biodiesel selling price. Besides, many by-product opportunities for lipid-extracted algae, such as the production of bioplastics and high value-added molecules, should be explored to improve the economics of the process. Primary energy demand (PED), climate change (CC), human toxicity (HTNC), eutrophication (FE), and photochemical ozone formation (POFE) impacts of algae biodiesel are 1.54 MJ/MJ, 96 g CO₂-eq/MJ, 66 g 1,4-DCB-eq, 37.8 mg P-eq., and 0.36 g NOx-eq., respectively, with a large contribution (86% to PED, 92% to CC, 92% to HTNC, 96% to FE, and 39% to POFE) of the upstream processing stages. These stages are highly energy-intensive and involve the use of chemicals (MEA for CO₂ capture) and fertilisers (for cultivation), which explains their high contribution to the environmental impacts of algae biodiesel. In terms of downstream processing of algae biodiesel, lipid extraction is an environmental hotspot, accounting for 49% of PED, 61% of CC, 52% of HTNC, 56% of FE, and 97% of POFE. Figure 3 shows the individual contributions to the environmental impacts of the lipid extraction process. The energy required for the process (electricity and heat) is the main driver for PED, CC, and FE. Meanwhile, hexane production and evaporation losses are the main drivers for human toxicity and photochemical oxidation.

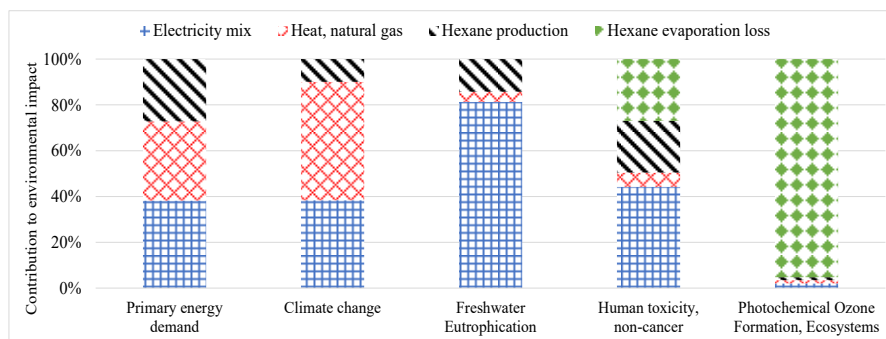

Figure 3. Individual contributions to the environmental impacts of the lipid extraction process

The replacement of hexane with more sustainable solvents could improve the environmental performance of algae biodiesel. The lipid extraction process was simulated using the same five-stage cascade referred to earlier, for four solvents: hexane and the terpenes limonene, cymene and pinene. Table 2 summarises key findings based on the simulation results.

Table 1. Performance of lipid extraction process using alternative solvents (hexane and terpenes)

Solvent	Lipid recovery (%)	Energy requirement (MJ/kg lipid)	Solvent intensity (kg solv/kg lip)	Operating costs (million USD/year)	GHG emissions (kg CO ₂ -eq)	Organic emissions (kg/h)
Hexane	99.8	7.61	0.10	22.41	635.80	19.98
Limonene	100	10.51	0.08	28.57	880.39	0.48
Cymene	99.7	10.26	0.08	30.00	854.77	0.48
Pinene	96.4	11.43	0.09	26.10	922.54	0.96

Figure 4 shows the results of the performance indicators of terpenes, normalised with respect to hexane. The health, safety and environmental (HSE) ranking of the solvents (hazardous: 1; problematic: 0.5, recommended: 0), obtained from the CHEM21 solvent selection guide (Prat et al., 2016), is also included in Figure 4. As seen, terpenes offer advantages over hexane in terms of HSE performance, organic emissions, and solvent intensity. However, terpenes have higher energy requirements, operating costs, and GHG emissions than hexane. Therefore, using terpenes may result in higher PED and CC impacts of algae biodiesel, but lower human toxicity and photochemical oxidation. In order to evaluate and understand these trade-offs, a full LCA of algae biodiesel using terpenes for lipid extraction is required.

Figure 4. Comparison of performance of lipid extraction solvents [LR: Lipid recovery; TOP: Total operating costs; EER: Equivalent energy requirement; GWP: Global warming potential; SI: Solvent intensity; OE: Organic emissions; HSE: CHEM21 ranking]

4. Conclusions

This study presents a systematic methodology combining process simulation and life cycle assessment to comprehensively evaluate biodiesel production from algae biomass in terms of economic and environmental sustainability criteria. Lipid extraction is identified as the environmental hotspot of downstream processing stages due to its high energy consumption and the use of the solvent hexane, which is an important driver for eutrophication, human toxicity, and photochemical ozone formation. The evaluation of the use of terpenes in the lipid extraction process, applying several performance indicators, showed that terpenes could offer advantages in terms of HSE performance,

organic emissions, and solvent intensity, but higher energy requirements, operating costs, and GHG emissions. Future work will carry out a complete life cycle analysis of biodiesel production from algae biomass using bio-based solvents for lipid extraction. Also, a systematic methodology to screen solvents for biorefinery processes considering techno-economic and environmental sustainability criteria on a life cycle basis will be developed.

Abstract

One of the most promising technologies for production of biogas from organic waste is anaerobic digestion (AD). As the experiments related to AD are time-consuming, labour intensive, and expensive, numerical simulations are important, because they provide a useful tool towards developing optimized and stable AD processes. This paper focuses on the optimization of the AD process in order to maximize biogas production from cattle manure by determining optimal values of process parameters. For this purpose, a modified mathematical model has been developed to simulate AD at various temperatures and pH values by considering appropriate inhibitions, detailed pH and temperature effects on microbial growth, and temperature dependencies of liquid-gas mass transfer coefficients, dissociation constants, and Henry's law coefficients. This model was applied for the simulation of AD in a batch reactor and verified with experimental data. By using this model in an optimization procedure, the optimal values of pH and temperature, both acting as design variables, were determined. By engaging a gradient-based optimizer, based on an adaptive approximation method, it was shown that a reliable AD model can be used very efficiently in gradient-based optimization. The optimization process proved to be efficient, stable, and starting-point-independent; the engagement of numerical differentiation did not cause any problems. The results show that at optimal process conditions the production of CH₄ is significantly improved in comparison to conditions often given in the literature. The results obtained confirm the usefulness of the proposed approach, which can easily be adapted or upgraded for complex substrates and other reactor types.

Keywords: anaerobic digestion, cattle manure, biogas, numerical simulation, optimization.

1. Introduction

Ever increasing energy demands, depletion of fossil fuels, and waste accumulation are the main forces for development of environmentally friendly waste-to-energy technologies. One of the most promising technologies is the production of biogas from animal manure (organic waste) by the anaerobic digestion (AD) process (Khalil et al. 2019; Rasapoor et al. 2020). As experiments related to AD are time-consuming, labor intensive, and expensive, numerical simulations are important, because they provide a

useful tool for AD process understanding and optimization (Ma et al. 2016). Till today various more or less sophisticated mathematical AD models have been developed in order to simulate biochemical, chemical, and physical processes by considering the near-actual composition of both, biogas and complex substrate (Maharaj et al. 2018; Tsapekos et al. 2018; Sun et al. 2019; Kovalovszki et al. 2020; Kegl and Kovač Kralj, 2020). These AD models are based either on ADM1, which uses the indirect Chemical Oxygen Demand (COD) for component concentrations computation, developed by the International Water Association (IWA) Task Group for Mathematical Modelling of Anaerobic Digestion Processes (Batstone et al. 2002) or on the BioModel with mass-based unit system, developed by Angelidaki et al. (1993). The objective in this study is to: (i) develop and test a modified mathematical model, based on the BioModel, to simulate AD at various temperature and pH values by considering appropriate inhibitions, detailed pH and temperature effects on microbial growth, and temperature dependencies of liquid gas mass transfer coefficients, dissociation constants, and Henry's law coefficients; (ii) attach a highly-efficient gradient-based optimizer and implement a procedure to optimize the AD process conditions by utilizing numerical differentiation; (iii) perform AD process conditions optimization from various starting points to estimate optimization process efficiency, stability and sensitivity to possible problems resulting from using derivatives obtained by numerical differentiation.

2. Mathematical model of anaerobic digestion

The proposed AD batch reactor model, which is presented in detail by Kegl and Kovač Kralj (2020), is based on biochemical reactions. It consists of a system of 21 differential equations of a microbial kinetic model and mass balance equations in the liquid, liquid-gas and gas phases. The most important equations are presented in the following, Eqs. (1)-(9). It must be pointed out that in the mass balance equations for insoluble c_{is} (gL^{-1}) and soluble c_s (gL^{-1}) organic compounds of cattle manure, volatile fatty acids (VFA) inhibition of the hydrolysis process is also considered, Eqs. (1)-(2). Furthermore, for the determination of CO_2 and CH_4 concentration in the liquid phase, $c_{\text{CO}_2,1}$ (gL^{-1}) and $c_{\text{CH}_4,1}$ (gL^{-1}), the liquid-gas transfer rate must be taken into consideration, Eqs. (7)-(8).

$$\frac{dc_{is}}{dt} = -K_0 \frac{K_{I,VFA}}{K_{I,VFA} + c_{VFA}} c_{is} \quad (1)$$

$$\frac{dc_s}{dt} = 0.55K_0 \frac{K_{I,VFA}}{K_{I,VFA} + c_{VFA}} c_{is} - Y_{s/A} \mu_A c_A \quad (2)$$

$$\frac{dc_{ac}}{dt} = Y_{ac/A} \mu_A c_A + Y_{ac/AP} \mu_{AP} c_{AP} + Y_{ac/AB} \mu_{AB} c_{AB} - Y_{ac/M} \mu_M c_M \quad (3)$$

$$\frac{dc_{pr}}{dt} = Y_{pr/A} \mu_A c_A - Y_{pr/AP} \mu_{AP} c_{AP} \quad (4)$$

$$\frac{dc_{but}}{dt} = Y_{but/A} \mu_A c_A + Y_{but/AB} \mu_{AB} c_{AB} \quad (5)$$

$$\begin{aligned} \frac{dc_{am}}{dt} = & 0.301 K_0 \frac{K_{I,VFA}}{K_{I,VFA} + c_{VFA}} c_{is} - Y_{am/A} \mu_A c_A - Y_{am/AP} \mu_{AP} c_{AP} - \\ & Y_{am/AB} \mu_{AB} c_{AB} - Y_{am/M} \mu_M c_M \end{aligned} \quad (6)$$

$$\begin{aligned} \frac{dc_{CO_2,l}}{dt} = & Y_{CO_2/A} \mu_A c_A + Y_{CO_2/AP} \mu_{AP} c_{AP} - Y_{CO_2/AB} \mu_{AB} c_{AB} + \\ & Y_{CO_2/M} \mu_M c_M - r_{l-g,CO_2} \end{aligned} \quad (7)$$

$$\frac{dc_{CH_4,l}}{dt} = Y_{CH_4/AP} \mu_{AP} c_{AP} + Y_{CH_4/AB} \mu_{AB} c_{AB} + Y_{CH_4/M} \mu_M c_M - r_{l-g,CH_4} \quad (8)$$

$$\frac{dV_{biogas}}{dt} = \frac{RTV_{liq}}{(p_{total} - p_w)} \left(\frac{r_{l-g,CO_2}}{M_{CO_2}} + \frac{r_{l-g,CH_4}}{M_{CH_4}} \right) \text{ and } \frac{dV_{CH_4}}{dt} = \frac{RTV_{liq} r_{l-g,CH_4}}{p_{total} M_{CH_4}}$$

(9)

where μ_{bac} and c_{bac} , $bac \in \{A, AP, AB, M\}$ are specific growth rates (day^{-1}) and mass concentrations (gL^{-1}) of acidogens, propionate degrading acidogenic bacteria, butyrate degrading acidogenic bacteria, and methanogenic bacteria; $Y_{i/bac}$ are yields coefficients (g of i^{th} component per g of bacteria cell); K_0 is the non-inhibited hydrolyzed rate constant (day^{-1}); $K_{I,VFA}$ is the inhibition constant of volatile fatty acids (VFA) (gL^{-1}); p_{total} and p_w are the total and saturated vapour pressures (atm); c_{ac} , c_{pr} , c_{but} , and c_{am} are concentrations of acetate, propionate, butyrate, and ammonia, respectively (gL^{-1}); V_{biogas} is the volume of produced biogas (L); V_{liq} is the liquid volume of the reactor (L); T is the temperature (K); R is the gas constant ($\text{atmLmol}^{-1}\text{K}^{-1}$); M_{CO_2} and M_{CH_4} are the molecular masses of CO_2 and CH_4 (gmol^{-1}), and r_{l-g,CO_2} and r_{l-g,CH_4} are dynamic liquid-gas transfer rates of CO_2 and CH_4 , where the liquid-gas equilibrium is reached for both gaseous components in accordance with Henry's law.

3. Optimization

In this optimal design problem of the AD system, the objective function g_0 is defined in such a way to promote maximal production of biogas, while the constraint functions g_i

and g_2 are related to the CH_4 to biogas volume ratio, Eq. (10). The defined objective function maximizes the biogas volume, V_{biogas} , without taking any consideration of the time needed to obtain it.

$$g_0 = -V_{\text{biogas}}, \quad g_1 = \frac{V_{\text{CH}_4}}{V_{\text{biogas}}} - 0.8, \quad g_2 = 0.65 - \frac{V_{\text{CH}_4}}{V_{\text{biogas}}} \quad (10)$$

The design variables are only pH value and temperature, meanwhile there are 21 response variables. The values of pH and temperature design variables were normalized by Eq. (11).

$$x_1 = \frac{(\text{pH} - \text{pH}_{\min})}{(\text{pH}_{\max} - \text{pH}_{\min})} \quad \text{and} \quad x_2 = \frac{(T - T_{\min})}{(T_{\max} - T_{\min})} \quad (11)$$

where $\text{pH}_{\min} = 5.5$ and $\text{pH}_{\max} = 8.5$ are prescribed minimal and maximal pH values of the AD process, while $T_{\min} = 25^\circ\text{C}$ and $T_{\max} = 65^\circ\text{C}$ are prescribed minimal and maximal temperatures of the AD process.

Both the described mathematical model of the AD process and the optimization algorithm were coded in the C# language. The system of differential equations was solved by the 3th order Runge Kutta method. A gradient based approximation method optimizer, which is well described in Kegl & Oblak, (1997), was engaged to solve the NLP optimization problem. This method essentially generates an approximate NLP problem in each optimization cycle. The algorithm uses the history of provided design derivatives of the objective and constraint functions in order to enhance the quality of the approximation. To compute the design derivatives involved in the NLP functions, numerical derivation was used. The derivatives computation was parallelized in order to boost computational efficiency.

4. Numerical results and discussion

First of all, the described mathematical model was already verified (Kegl & Kovač Kralj, 2020). The needed input data for the optimization are cattle manure composition, given in Table 1, for a bioreactor with a liquid volume of 1 L.

Table 1. Feedstock characteristics

Variable	Value	Variable	Value	Variable	Value	Variable	Value
$c_{\text{is}} (\text{gL}^{-1})$	30.4	$c_{\text{pr}} (\text{gL}^{-1})$	2.3	$c_{\text{CO}_2} (\text{gL}^{-1})$	0.0	$c_{\text{AP}} (\text{gL}^{-1})$	0.01
$c_{\text{s}} (\text{gL}^{-1})$	5.4	$c_{\text{but}} (\text{gL}^{-1})$	0.2	$c_{\text{CH}_4} (\text{gL}^{-1})$	0.0	$c_{\text{AB}} (\text{gL}^{-1})$	0.01
$c_{\text{ac}} (\text{gL}^{-1})$	4.5	$c_{\text{am}} (\text{gL}^{-1})$	2.0	$c_{\text{A}} (\text{gL}^{-1})$	0.13	$c_{\text{M}} (\text{gL}^{-1})$	0.8

The design variable and objective function variation histories obtained during the optimization process are presented in Figure 1 for various initial values.

Figure 1. Optimization histories with various initial values of design variables: (a) pH, (b) temperature, and (c) objective function

Within a maximum of 14 iterations, the minimal value of the objective function was reached at the optimal values of pH 7.7 and temperature of 30 °C; all constraints were fulfilled. As can be seen from Figure 1, the optimal values of these design variables are practically the same for any initial values of pH and temperature. Moreover, the value of the objective function after optimization is the same regardless of the chosen initial values of design variables, Figure 1.

Figure 2 shows the: (a) formation and consumption of acetate, propionate, and butyrate, and (b) volumes of produced gases before and after optimization. Regarding the VFA concentrations, propionate and butyrate convert to acetate; therefore, acetate concentration is higher than the concentration of other VFA. As we can see in Figure 2, the concentration of acetate does not approach zero at initial state, while at the optimal state the whole acetate is converted to CH₄ and other components. With respect to the obtained production rate of CH₄, CO₂, and total biogas, the total volume of biogas produced at optimal conditions is higher by about 10% compared to initial conditions, Figure 2. At optimal conditions, the volume of CO₂ produced is decreased by about 23% with respect to initial conditions; meanwhile, the volume of the obtained CH₄ is more than 1.4 times higher than at initial conditions.

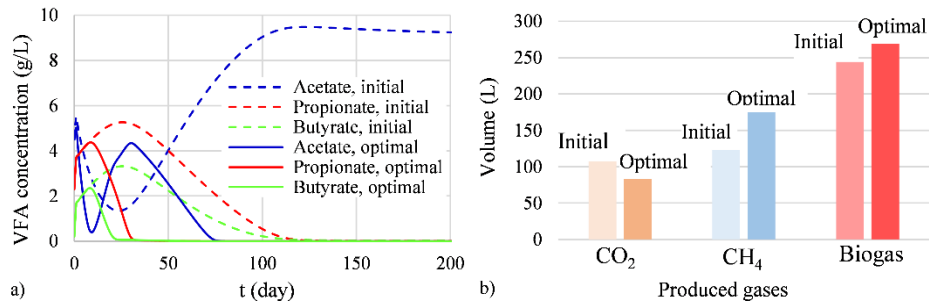

Figure 2. Acetate, propionate, and butyrate concentration (a) and gas volumes (b) before and after optimization.

5. Conclusions

Optimization of the anaerobic digestion process of cattle manure within a batch reactor was investigated. For this purpose, a modified mathematical model of the AD process was developed and the obtained results were compared with the results delivered by

existing mathematical models and with the experimental data. Both the described mathematical model of the AD process and the optimization algorithm were coded in the C# language to enable efficient numerical simulation. According to the numerical results, the following conclusions can be made:

- The model can be successfully engaged as a state equation in the optimization problem formulation and solution, where the AD conditions such as pH and temperature can be optimized in order to maximize the biogas production; the model can also be easily extended to describe certain processes more accurately, without affecting the optimization procedure layout.
- The used gradient-based approximation method optimizer is an attractive tool to solve AD process optimization problems; under the considered circumstances, it proved to deliver a stable and starting-point-independent optimization.
- The obtained optimization results show that the optimal values of design variables, 7.7 pH and 30 °C, were reached within 14 iterations for various initial values of design variables; this confirms that this optimization procedure is very efficient; since the numerical derivatives computation can be easily parallelized, the CPU times are also relatively low.

Abstract

In this work, we study PHB direct production (without a heterotrophic step) using *Synechocystis* sp PCC 6803 within a Systems Metabolic Engineering approach. We consider a GENome-scale Model (GEM) of the cyanobacteria, developed in previous work, and use it to couple growth with PHB production by finding genetic interventions (*knock-outs*) that make PHB production essential for growth. This is achieved by formulating a bilevel-programming problem, in which the *knock-outs* are represented by binary variables related to the genes of the GEM. After reformulation based on duality theory, a Mixed Integer Linear Programming (MILP) problem is obtained and solved in GAMS. A mutant that completely couples biopolymer production with growth in *Synechocystis* is obtained, and its flux distributions under exponential growth conditions are analysed by Flux Balance Analysis (FBA). Numerical results provide useful insights on sustainable photosynthetic bioplastics production with cyanobacteria.

Keywords: MILP, cyanobacteria, PHB, metabolic modelling

1. Introduction

The growing concern on climate change and environmental plastic pollution in recent years has led to the study of biodegradable and sustainable plastics based on biomass to replace conventional fossil-based plastics (García Prieto et al., 2017). Besides being produced from fossil fuels, when these polymers are incinerated, they generate carbon dioxide (CO₂) emissions that contribute to greenhouse effect, and also produce accumulation of non-biodegradable microplastics when they are built up in continental and marine environments and landfills (Kamravamanesh et al., 2018).

Polyhydroxyalcanoates (PHAs) are considered as an alternative to fossil-based plastics and are accumulated by a variety of microorganisms as a carbon and energy source (Ramos et al., 2019). Within this family, Poly(3-hydroxybutyrate) (PHB) is the most investigated bioplastic because it presents similar characteristics to polypropylene, and it is actually being commercially produced by heterotrophic bacteria, like *Cupriavidus*

necator y *Escherichia coli*. However, its production is limited due to the high production and carbon sources costs.

In this context, cyanobacteria become potential candidates for PHB production as they can grow on atmospheric CO₂, light and minimal nutrients, reducing substrate costs and contributing to lower atmospheric CO₂ concentrations. *Synechocystis* sp. PCC68003 (*Synechocystis*) is a model organism among the wide group of cyanobacteria and it has the capacity to accumulate PHB naturally under nutrient limitation conditions (Wu et al., 2001). One Systems Biology approach to study PHB production with *Synechocystis* is coupling biopolymer production with biomass production, so that it becomes essential for growth. This is achieved by identifying genetic interventions (*knock-outs*) *in silico*. We consider a bilevel programming formulation (Lasry Testa et al., 2019a), that represents these gene *knock-outs* through binary variables. In this work, we use this formulation to study the possibility of coupling PHB production with growth.

2. Methods

2.1. Genome Scale Metabolic Network

We consider a GENome-scale Model (GEM) which contains 784 reactions, divided into reversible, irreversible and exchange reactions, and 535 metabolites (Lasry Testa et al., 2019a). The model contains a detailed description of the photosynthesis, and it includes both of the reactions catalyzed by the RuBisCO enzyme: Carboxylation and photorespiration. It also contemplates the possibility of taking up carbon as CO₂ and bicarbonate (HCO₃⁻), and it allows for the interconversion of CO₂ from intracellular decarboxylation into HCO₃⁻ (Nogales et al., 2012). PHB is naturally produced by *Synechocystis* as a carbon and energy storage compound, along with glycogen, and it is accumulated as an intracellular metabolite, but to analyze its production we included a fictitious PHB excretion reaction for modelling purposes.

We consider photoautotrophic carbon limited growth conditions, to which end all organic carbon sources, like glucose, are fixed to zero. The uptake of the other inorganic nutrients (Nitrogen, Phosphorus) required is unrestricted. Inorganic carbon is limited with a maximum of 3.7 mmol gDW⁻¹ h⁻¹, which is the maximum experimental uptake identified for *Synechocystis*. The final model was turned into the GAMS Data eXchange (GDX) format to allow the use in the GAMS (GAMS Development Corporation, Washington, DC) environment.

2.2. Coupled growth-PHB production

To search for a mutant that couples PHB production to growth we formulated a bilevel programming problem which searches for the minimum set of genetic interventions needed to achieve the objective. The mathematical structure of this optimization problem is that of a MILP with the requirement that a subset of its variables is the solution to an "inner" LP. This inner LP, represented by constraints of Eq. (2) to Eq. (7), can be solved by a flux state (v) which is mass balanced (constraint XX) and fulfills a minimum growth requirement (Eq. (3)). Some reactions rates are required to be fixed at a certain value (Eq. (4)), and constant upper and lower bounds are established for each reaction (Eq. (6)). For the set K of candidate reactions, which are the reactions not

essential for growth under the photoautotrophic conditions considered, these upper and lower bounds can be set both to a value of 0, if the corresponding element in vector y is set to 1 (Eq. (4) and Eq. (5)). This vector is a variable of the outer problem, which requires these variables to be binary, therefore transforming the outer optimization problem in a MILP. The inner LP objective function minimizes the flux through the target reaction to be coupled, and a constraint on the outer problem on this value (Eq. (1)) requires it to be greater than a minimum. The amount of interventions, represented by the sum over this binary vector is minimized, as the outer MILP objective function. Therefore, the inner optimization problem guarantees that a series of interventions, represented by blocking flux through certain reactions by the outer problem, raise the minimum value of the flux through the target reaction from 0, pointing out that in the intervened flux space, the target reaction is essential to growth. For more detail in this formulation refer to (Lasry Testa et al., 2019a).

$$\min_{v,y} \sum_k y_k \quad (1)$$

$$v_{PHB} \geq v_{PHB}^{\min}$$

s.t.

$$\left. \begin{array}{l} \min v_{PHB} \\ v \\ \text{s.t.} \\ v_{biomass} \geq v_{biomass}^{\min} \end{array} \right\} \quad (2)$$

$$\left. \sum_j S_{i,j} v_j = 0 \quad \forall i \in M \right\} \quad (3)$$

$$\left. v_j = v_j^{fixed} \quad \forall j \in R^{fixed} \right\} \quad (4)$$

$$v_j \geq LB_j (1 - y_k) \quad \forall (j,k) \in K \quad (5)$$

$$v_j \leq UB_j (1 - y_k) \quad \forall (j,k) \in K \quad (6)$$

$$LB_j \leq v_j \leq UB_j \quad \forall j \in R \quad (7)$$

$$\sum_k y_k \geq 1 \quad (8)$$

$$v_j \in \mathbf{R}, y_k \in \{0,1\}$$

This bilevel problem, reformulated into a single level MILP, was solved in GAMS (GAMS Development Corporation, Washington, DC) in a PC with an Intel Core i7-4790 de 3,60 GHz processor and 8 GB RAM. To evaluate the production rates of the obtained mutants we used FBA (Savinell and Palsson, 1992).

3. Results and Discussion

We used the bilevel programming approach described to search for mutants that couple PHB production with growth in *Synechocystis*. We fixed minimal PHB production (Eq. (1)) to a value of 0.01 mmol PHB gDW⁻¹ h⁻¹ and minimal biomass production required (Eq. (2)) to 0.01 h⁻¹ to avoid a solution with zero growth rate.

With these conditions we obtained a mutant that effectively couples PHB production with growth, for which 14 genetic interventions are required. Due to the Gen-Protein-Reaction associations this *knock-outs* correspond to the deletion of 18

reactions from the GEM. The genetic interventions to obtain the mutant are presented in Table 1.

The mutant presents a growth rate of 0.0625 h^{-1} and a PHB production rate of $0.1059 \text{ mmol PHB gDW}^{-1} \text{ h}^{-1}$. The maximum growth rate of wild-type *Synechocystis* can be obtained by FBA of the GEM with biomass objective function, this value is of 0.089 h^{-1} for the photoautotrophic conditions considered (Lasry Testa et al., 2019b), and comes with no PHB production associated. We also obtained the maximum PHB production possible by running a FBA with PHB production as the objective function, resulting in a flux of $0.925 \text{ mmol PHB gDW}^{-1} \text{ h}^{-1}$ for no biomass production. Therefore, the maximum growth rate of the mutant is a 29.7% lower than the maximum growth rate of the wild type, and the PHB production rate represents and 11.5% of the maximum for no biomass production.

The PHB production pathway includes a NADPH consuming reaction, so the intervention strategy obtained is mostly related with the NADP/NADPH balance of the cell. We see in Table 1 that the *knock-outs* of genes *slr1755* and *sll1561* avoid the production of NADH to favour the use of other NADPH producing pathways. The gene *sll1342* codifies for the NADPH dependent glyceraldehyde-3-phosphate dehydrogenase, that competes with PHB production. Finally, the knock-out of gene *slr1239* avoids the possibility of the interconversion of NADPH to NADH. The knock-out of *slr0301* and *slr0783* favour flux to be directed down to the lower glycolysis, leading to an increase in Acetyl-CoA with is the precursor of PHB production. Moreover, we find the *knock-out* of the acetate membrane transporter (*gs20*) that also contributes to a rise in Acetyl-CoA production, avoiding the loss of carbon through the excretion of Acetate, whose production has to be directed completely to Acetyl-CoA production. We also find that in the mutant the TCA cycle is interrupted by the *knock-out* of gene *slr0018* which is related to the interconversion of (S)-Malate into Fumarate. As this may lead to a Fumarate overflow, the strategy also selects the Fumarate excretion reaction as another *knock-out*. The gene related to this excretion has not been identified yet, but there is experimental evidence on the capacity of *Synechocystis* to excrete this metabolite to the culture media (Du et al., 2019).

Table 1. *Knock-outs* required to obtain coupled growth-PHB mutant.

Genes	E.C. Number	Reaction
<i>slr1840</i>	2.7.1.165	$\text{ATP}(\text{cyt}) + \text{D-Glycerate}(\text{cyt}) \rightarrow \text{ADP}(\text{cyt}) + 2\text{-Phospho-D-glycerate}(\text{cyt})$

<i>g823</i>	-	$Fumarate(cyt) \rightarrow Fumarate(ext)$
<i>g820</i>	-	$Acetate(cyt) \rightarrow Acetate(ext)$

Only for comparison purposes, we simulated the described mutant in a batch bioreactor model that was implemented in gPROMS (PSEnterprise Ltd., 2020). The model included equations for biomass (Eq. (9)) and PHB production (Eq. (10)) and also an equation to account for light limitation (Eqs. (11) and (12)), a typical effect produced in photobioreactors due to the biomass shade effect (Delpino et al., 2014).

$$\frac{dX}{dt} = \mu_{max} * fI * X \quad (9)$$

$$\frac{dPHB}{dt} = v_{PHB} X \quad (10)$$

$$f(I) = \frac{I_0}{I_{opt}} \exp\left(1 - \frac{I_0}{I_{opt}}\right) \quad (11)$$

$$I_0 = 100 * \frac{1 - \exp(-K_{ext} * p * X)}{K_{ext} * p * X} \quad (12)$$

We fixed the values of μ_{max} and v_{PHB} to the values previously reported for the coupled mutant. K_{ext} , p and I_{opt} were fixed to the values $1.29 \text{ L gDW}^{-1} \text{ m}^{-1}$, 0.3 m and $125 \mu\text{E m}^{-2} \text{ h}^{-1}$, respectively (Laiglecia et al., 2013). We considered a biomass initial concentration of 0.078 gDW/L and set a simulation time of 48 hours to assure that the culture was in exponential growth phase. The model solution provides a final PHB concentration of $2.33 \text{ mmol}^{-1} \text{ L}^{-1}$ and a biomass concentration of 1.37 gDW/L . Considering the molecular weight of the PHB monomer of 84 mg/mmol , the production is equivalent to 200.38 mg PHB/L and the productivity results in a value of $100.19 \text{ mg PHB L}^{-1} \text{ day}^{-1}$.

4. Conclusions

In this work we have obtained a mutant that successfully couples PHB production to growth in *Synechocystis* by formulating a bilevel programming problem that identifies gene knockouts, which are represented by binary variables. Although the number of genetic interventions is high, CRISPR technologies (clustered regularly interspaced short palindromic repeats) are currently being developed and applied for simultaneous manipulation of multiple genes in cyanobacteria (Behler et al., 2018). Numerical results show productivity indexes of around 40% lower than the best one obtained experimentally (Wang et al., 2018) under nutrient limitation conditions. Further studies are needed to assess if coupled growth-production strategies are potentially suitable for direct large-scale PHB production through photosynthesis.

Abstract

Monoclonal antibodies (mAbs) are an example of therapeutic biomolecules which have been used for treatments of cancer, autoimmune diseases and other ailments. Numerous mAbs are currently being given market approval and the total mAb market value is predicted to increase for the foreseeable future. Traditionally, mAbs are manufactured via secretion from mammalian cell cultures such as Chinese Hamster Ovaries (CHO) or myeloma cell lines e.g. GS-NS0. Technoeconomically successful bioreactor operation is inherently dynamic and must invariably rely on limited state measurement accessibility. In all cases, culture productivity and economic incentive must be ensured simultaneously, thus implying a pressing need for model-based elucidation of optimal operation policies. Dynamic simulation is an established tool in bioprocess systems engineering which can accelerate process intensification and scale-up, for capital and operational cost reduction. The present study extends uncertainty characterization beyond recently used response envelopes by firstly presenting dynamic simulation results for a GS-NS0 culture, and then performing a parametric sensitivity analysis so as to systematically deduce the impact of model parameters on the said key output variables which govern technoeconomic appeal.

Keywords: Dynamic simulation; biotherapeutics; monoclonal antibodies/mAb; GS-NS0.

1. Introduction

Monoclonal antibodies (mAbs) encompass a wide spectrum of biotherapeutics which have gained great attention for their potential in cancer and autoimmune disease therapies. The first therapeutic mAb which received approval by the United States Food and Drug Administration (FDA) was *muromonab-CD3* in 1986; since that historic milestone, many (78) more mAbs have been approved for production and commercial use, boosting the phenomenal mAb market growth to a valuation of \$115.2 billion in 2018 (Lu et al., 2020). Traditionally, industrial manufacturing of mAbs at production scale requires the use of mammalian cell cultures in a batch or fed-batch fermentation, whose raw effluent is then fed to a sequence of downstream separation units (e.g. centrifugation, chromatography, and others) in order to isolate the active biopharmaceutical agent (Rodrigues et al., 2010). Acquiring a mechanistic understanding of how feed and culture media affect upstream metabolism is critical in order to first capture biological complexity in a tractable fashion and then identify viable, industrially valuable optimisation prospects (Chen et al., 2016). Credible modelling enables dynamic simulation and rapid technoeconomic evaluation of *in vivo* bioprocess operation policies without costly, arduous experimental campaigns, if validation is performed and relevance ensured (Shirahata et al., 2019; Diab et al., 2020).

A study published by Kiparissides et al. (2015) has employed several *in silico* techniques to quantitatively describe mAbs manufacturing from a GS-NS0 mammalian cell culture via batch and fed batch reactors. A novel, concise dynamic model and its parameterisation based on Monod kinetics has been presented but also duly validated against three batch mAb production experiments, each of which had considered a different feed composition. The purpose of the present paper is to use the same dynamic model in order to probe the industrial potential of GS-NS0 cells by means of an extensive local sensitivity analysis. Key batch reactor outputs (substrate consumption, viable cell concentration, mAb yield) and state sensitivities vs. parameter levels are obtained, indicating remarkable differences among parameters (and sometimes policies) with respect to techno-economic projections.

2. Dynamic model for mAb production from a GS-NS0 cell culture

The dynamic model for GS-NS0-based mAb production of Kiparissides et al. (2015) is summarised in Table 1, with Monod kinetics describing all metabolic reactions occurring. Eqs. (1)-(3) define volume V , viable cell concentration X_V and dead cell concentration X_D , respectively. Eqs. (4)-(9) portray metabolite and product concentrations evolution for glucose [GLC], glutamate [GLU], ammonia [AMM], lactate [LAC], glutamine [GLN], and mAb [mAb], respectively. Both glucose and glutamate are assumed to be growth-limiting substrates, hence their combined effect modelled as additive. Of the 20 model parameters, 18 are published (Kiparissides et al., 2015); the normalised total cell number and lag potential ($X_{T,NORM}$ and δ_{NORM}) have been computed on the basis of published data therein. The lag potential (δ) is a parameter describing the time required by cells for adaptation to the environment, before entering an exponential growth phase (Kiparissides et al., 2015).

Table 1: Dynamic model for mAb production (Kiparissides et al., 2015).

$$\frac{dV}{dt} = F_{in} - F_{out} \quad (1)$$

$$\frac{dX_V}{dt} = \frac{(-X_V \frac{dV}{dt} + (\mu - \mu_d)X_V V - F_{out}X_V)}{V} \quad (2)$$

$$\frac{dX_D}{dt} = \frac{(-X_D \frac{dV}{dt} + \mu_d X_V V - k_{lys} X_D V - F_{out}X_D)}{V} \quad (3)$$

$$\frac{d[GLC]}{dt} = \frac{(-[GLC] \frac{dV}{dt} - Q_{GLC} X_V V + F_{in}[GLC]_{in} - F_{out}[GLC])}{V} \quad (4)$$

$$\frac{d[GLU]}{dt} = \frac{(-[GLU] \frac{dV}{dt} - Q_{GLU} X_V V + F_{in}[GLU]_{in} - F_{out}[GLU])}{V} \quad (5)$$

$$\frac{d[AMM]}{dt} = \frac{(-[AMM] \frac{dV}{dt} + (Q_{GLN} Y_{AMM,GLN}^{ACTUAL} X_V V - F_{out}[AMM]))}{V} \quad (6)$$

$$\frac{d[LAC]}{dt} = \frac{(-[LAC] \frac{dV}{dt} + Q_{LAC} X_V V - F_{out}[LAC])}{V} \quad (7)$$

$$\frac{d[GLN]}{dt} = Q_{GLC} X_V - Q_{GLN} X_V \quad (8)$$

$$\frac{d[mAb]}{dt} = \frac{(-[mAb] \frac{dV}{dt} + (\frac{\mu_{GLU}}{Y_{X,mAb}} + m_{mAb} \frac{[GLC]}{\mu}) - F_{out}[mAb])}{V} \quad (9)$$

3. Dynamic simulation of mAb production

Dynamic simulation of mAb production has been performed on the basis of the foregoing model to validate our code vs. three published experiments (Kiparissides et al., 2016). Fig. 1 illustrates concentration and cell density trajectories for each of the three cases. The mAb maintenance term (m_{mAb}) varies among the published three experiments, being $6.244 \cdot 10^{-10}$, $9.944 \cdot 10^{-10}$ and $2.044 \cdot 10^{-10}$ mg cell⁻¹ h⁻¹ for these Expts. 1, 2, 3 respectively. Furthermore, for our dynamic model validation we assume that there is no correlation between seeding density and ammonia yield on glutamine, hence $Y_{AMM, GLN}^{ACTUAL} = Y_{AMM, GLN}$. All published dynamic simulation results and trends have been successfully reproduced. Experiments with high lag times produce mAb at the lowest concentrations (Fig. 1a, 1d), while $[mAb]$ production rate is a constant (albeit variant) derivative in all Expts. (Fig. 1d). High $[mAb]$ productivity is correlated here with high initial viable cell concentration $[X_v]$. Interestingly, the highest $[mAb]$ production occurs for a culture inoculated with the least total amount of $[GLU]+[GLC]$ substrates (Expt. 2), implying that starving the GS-NS0 culture of nutrients may prove beneficial towards boosting cellular mAb productivity. Glucose oversupply may have induced excessive $[LAC]$ (and inhibited $[mAb]$) production as by-products harm cell growth and productivity (Gagnon et al., 2011; Fan et al., 2015). Viable cell concentration $[X_v]$ clearly peaks earlier for lower lag potential (Fig. 1a), with peak magnitude increasing as a function of initial glutamate concentration. Finally, high lactate concentrations occur for high initial glucose substrate concentrations (Fig. 1b-1c).

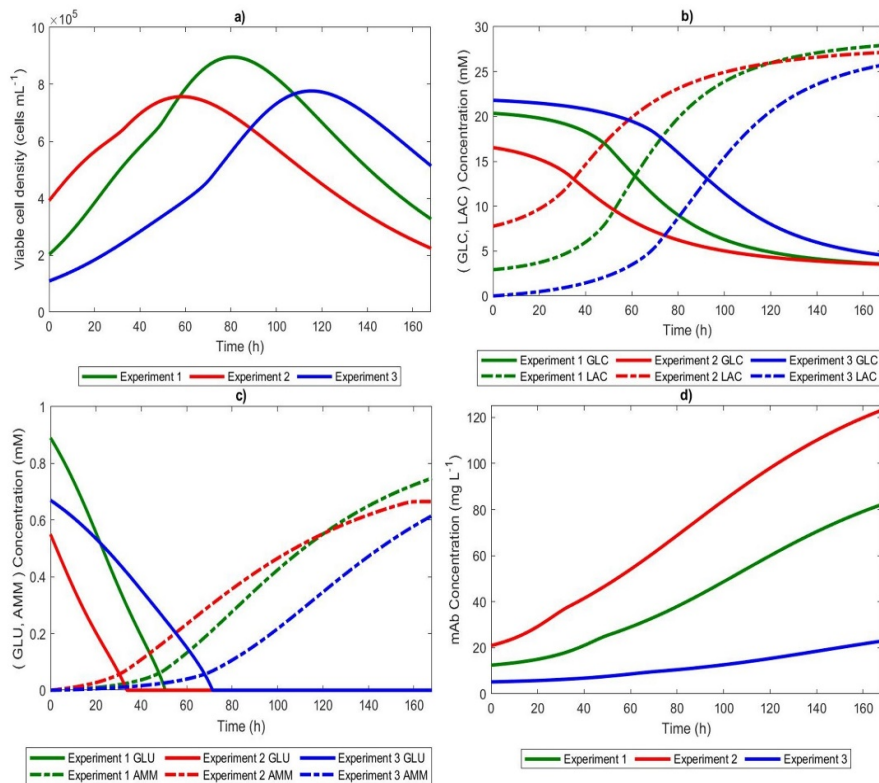

Figure 1: Dynamic simulation of key state variables for three published experiments.

4. Parametric analysis methodology

Dynamic simulation results clearly indicate that numerous factors significantly influence GS-NS0 batch culture stability and performance in regard to mAb production efficiency. Because of this intrinsic and multi-faceted variability, the purpose of this paper is to conduct a (hitherto not attempted) parametric sensitivity analysis in order to establish the influence of model parameters on process state variables at the end of each experiment. The first state variable, V (Eq. 1) remains constant in all experiments and is discounted. Our purpose is to visualise high sensitivities (e.g. > 1) which imply that a relatively small parameter change (or estimation inaccuracy) induces considerable output state variable value variation (especially $[mAb]$) at batch completion ($t = t_f$). The latter in turn signifies that small parameter estimation errors may snowball into gross model output errors, thus rendering model fidelity questionable and technoeconomic projections highly unreliable. The parametric sensitivity analysis relies on computing a sensitivity index (S) via Eq. (10) for each state (x) and parameter (P), with respective changes ∂x and ∂P (Kreyszig, 1999).

$$S = \left[\frac{\left(\frac{\partial x}{x} \right)}{\left(\frac{\partial P}{P} \right)} \right] \quad (10)$$

Four different sensitivity analysis cases have been considered and computed for as many parametric differential variation levels, $(\partial P/P) = \{-0.50, -0.05, 0.05, 0.50\}$ or $\pm 5\%, \pm 50\%$. The sensitivity outputs (S) have been normalised in every case for visual clarity, but also to comparatively appreciate the relative effect of each parameter on each state variables. The normalised sensitivity index $\bar{S}_{x,P}$ is given by the sensitivity for state variable x and parameter P , $S_{x,P}$, divided by the respective maximum observed, $S_{x,MAX}$ (Kreyszig, 1999).

$$\bar{S}_{x,P} = \frac{S_{x,P}}{S_{x,MAX}} \quad (11)$$

The initial experimental conditions remained identical to those used in section 3. Only one parameter was varied at a time, meaning the sensitivity analysis was local in nature.

5. Local parametric sensitivity analysis

Sensitivities for six states ($[mAb]$, $[X_V]$, $[X_D]$, $[GLC]$, $[AMM]$, $[LAC]$) are given in Fig. 2. A clear and remarkably consistent reversal trend emerges: for a contraction of sensitivity magnitude in case of negative parameter changes ($-5\%, -50\%$), we observe an expansion (of different magnitude) for the respective positive changes ($+5\%, +50\%$), and vice versa. All state variables are highly sensitivity to lag potential parameters (δ_{NORM} , k_{LAG} , $X_{T,NORM}$), emphasising the importance of a nutritious environment towards GS-NS0 proliferation. The state of highest technoeconomic interest $[mAb]$ is sensitive to only certain parameters ($K_{G,GLC}$, K_{LLAC} , $Y_{LAC,GLC}$, $\mu_{MAX,GLC}$, $X_{T,NORM}$) for all experiments (Fig. 2a), i.e. precisely to those affecting cell ability to consume glucose and/or produce lactate (Chen et al, 2012). Viable cell concentration $[X_V]$ is most sensitive to $Y_{LAC,GLC}$ and K_{LLAC} , in agreement with the fact that high lactate concentration adversely affects cell growth (Gagnon et al., 2011). Dead cell concentration $[X_D]$ displays much lower sensitivities to most parameters, and is relatively insensitive to cell lysis (k_{LYS}) compared to the lag potential parameters (Fig. 2c). Glucose concentration $[GLC]$ is affected by 5 parameters (>0.2) (Expts. 2-3 differ a lot). Ammonia concentration $[AMM]$ has a different sensitivity profile vs. all previous states: several (at least 8 of 20) parameters affect its final value, but also Expt. 2 seems to induce key differences vs. Expts 1+3, possibly as $[AMM]$ rises much faster in that case (Fig. 1c).

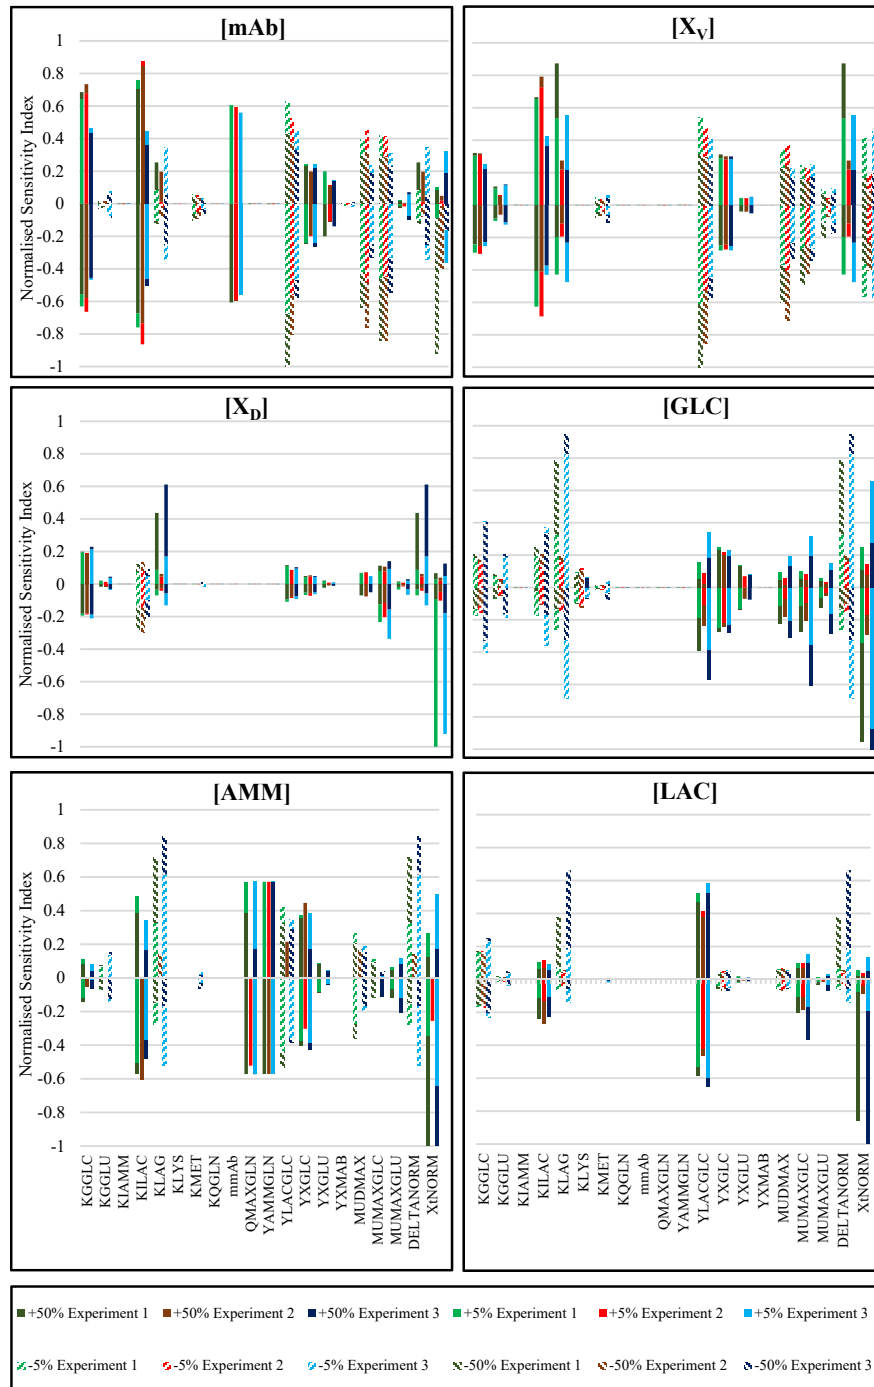

Figure 2: Local sensitivity analysis for different final state variable values.

The high $[AMM]$ sensitivity both to max. glutamine uptake rate ($Q_{MAX,GLN}$) and yield from glutamine consumption ($Y_{AMM,GLN}$) agrees with the observation that ammonia levels are correlated with glutamine and asparagine in mammalian cell cultures (Zhang et al., 2016). Lactate concentration $[LAC]$ sensitivity to its yield from glucose consumption ($Y_{LAC,GLC}$) is high, due to its key role (and inefficiency) in glucose metabolism (Gagnon et al., 2011). The said parameter ($Y_{LAC,GLC}$) influences lactate $[LAC]$ a lot more than glucose $[GLC]$ for all three Expts., illustrating that glycolysis can be more efficient towards securing energy.

6. Conclusions

Dynamic simulation and parametric sensitivity analysis of GS-NS0 culture usage for biotherapeutic mAbs manufacturing has been pursued on the basis of a published model. High target product concentration $[mAb]$ has been correlated with high viable biomass availability $[X_V]$ and low initial cumulative substrate ($[GLU]$ and $[GLC]$) concentrations. The parametric sensitivity analysis is illustrated for several key model output variables: from an operational viewpoint aimed at biopharmaceutical manufacturing improvements, GS-NS0 culture modifications decreasing $Y_{LAC,GLC}$, μ_{MAX} , $\mu_{MAX,GLC}$ and $X_{T,NORM}$ (as well as increasing $K_{G,GLC}$ and $K_{L,LAC}$) are expected to boost the final target $[mAb]$ concentration. Judicious substrate $[GLC]$ provision and suppression of lactate $[LAC]$ production over time emerge as key recommendations, beyond obvious (e.g. $X_{T,NORM}$) conditioning needs. Further to bioreactor modelling, process optimisation must also consider separation units, so that high-fidelity submodels in the latter credibly describe their output and plant yield.

Abstract

The generation of sewage sludge in the State of Qatar is increasing with the rapid growth of its population. Around 300,000 m³ of wet sludge is generated every year. Although the sludge is being treated to meet the international standards, its final disposal into landfills raises concerns associated with the limited land areas in the country, as well as the possible contamination of soil and groundwater. On the other hand, the hydrothermal liquefaction (HTL) technology is attracting more and more attention at the expense of other thermochemical waste valorisation pathways including incineration, gasification and pyrolysis. Since it can tolerate the high-water content of wet feedstocks, while the HTL biocrude has a comparable heating value to that of crude petroleum and has the potential to be co-processed in existing oil refineries. Therefore, this study investigates the technoeconomic aspects of an on-site biocrude production from sewage sludge at wastewater treatment plants in Qatar via hydrothermal liquefaction. The system is modelled using Aspen Plus, while an economic assessment is conducted with the aid of Aspen Process Economic Analyser (APEA). The results indicate a significant biocrude yield of up to 38.2 wt.% (on dry and ash-free basis). In addition, based on the economic feasibility evaluation, the produced biocrude achieved a competitive minimum selling price of 52.6 US\$/bbl, which is below the past 5-year global average price of crude petroleum. As such, the incorporation of biocrude into the oil refining process can be a promising alternative for oil-refining countries, especially at times of petroleum prices hikes.

Keywords: Qatar, Biocrude, Sewage sludge, Hydrothermal liquefaction, Treated sewage effluent.

1. Introduction

Qatar is an oil producing country and the world's second largest exporter of natural gas (Britishpetroleum, 2019). Along its prominent gas facilities, two state-owned oil refineries operate in Qatar, which are: Qatar Petroleum Refinery that mainly processes crude petroleum at a capacity of 137,000 barrels per stream day (bpsd), and Laffan Refinery that utilises field condensate obtained from natural gas facilities with a capacity of 292,000 bpsd (Qatarpetroleum, 2020).

However, the country is striving to incorporate renewables into its energy mix to mitigate carbon emissions and prolong its petroleum reserves' lifetime. For this purpose, several local feedstocks, as well as processing technologies have been investigated (Al-Ansari et al., 2020; Alnousse et al., 2018; Elkhailifa et al., 2019), which emphasised that municipal, agricultural and industrial wastes are considered as the most abundant feedstock for the production of alternative liquid and gaseous fuels. Meanwhile, the presence of refining facilities in the country and the recent ASTM certification of bio-oils' co-processing with fossil crude, these factors grant an advantage to the oil-producing biomass processing pathways such as pyrolysis and hydrothermal liquefaction (HTL) over other technologies.

Pyrolysis is a thermal decomposition of biomass in inert media to produce bio-oil and biochar at (300-700 °C). However, biomass must undergo a drying step prior to pyrolysis (Alherbawi et al., 2021a). In contrast, hydrothermal liquefaction is often utilised to decompose the high-moisture biomass using water at subcritical conditions, which mimics the crude petroleum formation underground (Alherbawi et al., 2020). The HTL process mainly produces biocrude oil which is of a better quality and with a higher net heating value as compared to pyrolysis oil (Peterson et al., 2008).

Amongst the different available wet biomass in Qatar, sewage sludge can be considered as one of the most fitting feedstocks for HTL process due to its high moisture and carbon contents. As such, no additional water is required to create a slurry feed.

With the rapidly growing population in Qatar, the quantity of generated sludge has significantly increased by 3.5 folds through 2010-2015 (MDPS, 2018), which is deemed to be a growing concern. Whereby, sludge treatment and disposal account for up to 50% of total operating costs and nearly 40% of the net GHG emissions associated to the operations of wastewater treatment plants (WWTPs) (Callegari and Capodaglio, 2018).

As such, considering alternatives to sludge disposal is becoming more urging to reduce costs and carbon footprint, as well as to valorise the sludge into value-added products.

Currently, there are 23 WWTPs in Qatar as presented in Figure 1. However, three of them account for nearly 75% of total wastewater treatment capacity, named: Doha North (30%), Doha South (22%) and Doha West (22%). Therefore, this study proposes an on-site utilisation of sewage sludge to produce biocrude via HTL in Qatar. The sludge from the three main WWTPs is to be utilised, whereby, “Doha South WWTP” is selected as the hub to establish the HTL plant for being the closest to Qatar Petroleum (QP) refinery (~45 km). While the sludge from the other two main WWTPs is transported by tanker trucks to the HTL plant. Whereas produced biocrude is assumed to be subsequently upgraded at QP refinery by co-processing with crude petroleum (not evaluated in this study). The HTL process is modelled using Aspen Plus® software, while an economic analysis is conducted to evaluate the feasibility of biocrude production with the aid of Aspen Process Economic Analyser (APEA).

Figure 1: WWTPs and oil refineries in Qatar (Data adapted from (MDPS, 2018)).

2. Methodology

2.1 Model Development

Advanced system process engineering (ASPEN PLUS V.9) is used to simulate the hydrothermal liquefaction process. All subsystems are simulated assuming to have steady-state and isothermal processes. Besides, char is assumed to comprise carbon only, while the nitrogen and sulfur contents of feedstock are released in the form of NH_3 and H_2S respectively or as nitrogen and sulfur-containing hydrocarbons (Alherbawi et al., 2021b).

Initially, the wet sludge is defined as a non-conventional component considering the proximate and elemental analysis adapted from a previous study by Shen et al. (2001). While the typical Qatari sludge's moisture content of 82% is considered (MDPS, 2018).

No water is further added to the slurry as the solid content of sludge does not exceed 18%. Sodium hydroxide is added to the slurry with a 1 wt.% load to enhance the potential of biocrude formation (Cao et al., 2017).

The stream is then pumped to 150 bars using two consecutive pumps, then passed into a counter-current heat exchanger. The initial decomposition (hydrolysis) stage is simulated using an “RYield” aspen unit, by which the biomass is broken-down into conventional components using a Fortran code (Alnousse et al., 2018).

The conventional stream is then processed into the main HTL reactor, which is simulated at 300 °C and 150 bars using an “RGibbs” unit, which functions following the principle of Gibbs free energy minimisation. The possible biocrude, gas and aqueous phase compositions are adapted from previous studies (Tekin et al., 2013).

Finally, the outflow stream is fed back into the heat exchanger to recover the heat before separating the solid phase using a solid separator. While the remaining volatile stream is fed into a three-stage flash drum, yielding three phases including gas, biocrude and an aqueous phase. The process flow diagram is presented in Figure 2.

Figure 2: Process flow diagram of HTL process.

2.2 Economic Assessment

Aspen Process Economic Analyser (APEA) is utilised to evaluate the economics of a WWTP’s on-site HTL facility in Qatar. A plant lifespan of 30 years and a start-up period of 6 months are considered. The plant’s feed capacity is fixed at 222,000 m³ of wet sludge, which roughly represents the quantity of sludge generated from the three main WWTPs of Qatar.

As for capital expenses, the main HTL reactor cost is adapted from published reports (Zhu et al., 2014), while the costs of other smaller units (i.e., heaters, pumps, etc.) are evaluated by APEA based on the defined size and operating parameters. All costs are re-evaluated for the base year of analysis (2019) using the chemical engineering plant cost index (CEPCI).

The utilities costs, sludge handling charges and wastewater discharge costs are quoted locally (Gulfimes, 2020; Kahrama, 2020). While the operating and maintenance costs are evaluated by APEA. The minimum selling price of biocrude is evaluated in (\$/bbl) based on the traditional levelised cost of energy (LCOE) formula, with a discount rate of 20%:

$$LCOE \left(\frac{U.S.\$}{bbl} \right) = \frac{\sum_1^t ((K+O\&M+R)(1+d)^{-t})}{\sum_1^t ((P(1+d)^{-t})} \quad (1)$$

Where, (K) is the annualised capital expenses, (O&M) is the operating and maintenance costs, (R) is the raw materials prices, (d) is the discount rate, (P) is the biocrude yield and (t) is the plant lifespan.

3. Results and Discussion

3.1 Process Yield

The model results indicate a considerable biocrude yield of 38.22 daf.% (on feed dry and ash-free basis), and around 14 daf.% of hydrochar as illustrated in Figure 3. In addition, a mixture of gases is obtained including CO₂, CO, H₂, CH₄ and NH₃, with carbon dioxide being the dominant gas. While the aqueous phase contains dissolved organics including alcohol, phenols, as well as carbon dioxide.

Figure 3: HTL products composition relative to dry and ash-free feed (%).

3.2 Economic Assessment

A summary of the plant's economic assessment is illustrated in Figure 4. The estimated project's capital expenses (CAPEX) is ~13.5 M\$ (million U.S. Dollars), while the annual operating expenses (OPEX) is 2.55 M\$. The breakdown of CAPEX indicates that purchased equipment contribute to the biggest portion (~41%) of the cost, followed by equipment settings (11%). As for OPEX, the catalysts and labour costs account for the highest shares of 30% and 26% respectively, followed by plant overhead (14%). Since the process is mostly operated on-site, the cost of feedstock is lowered down to only ~11% of total costs.

Figure 4: Breakdown of project's capital and operating expenses.

In addition, the achieved minimum selling price (MSP) of biocrude is at 52.6 \$/bbl, which is (3-19%) below the global crude petroleum price for the base year of analysis (2019) as presented in Figure 5. The achieved MSP of biocrude is also slightly below the past 5-year average crude price of 52.9 \$/bbl (Macrotrends, 2020). The main reason behind achieving a competitive MSP is the ‘on-site’ utilisation of sludge, which significantly reduces the collection and handling costs of feedstock.

Figure 5: Biocrude MSP (this study) as compared to global crude prices.

4. Conclusion

The on-site valorisation of sewage sludge at WWTPs proved to be a promising pathway to produce biocrude, which can be co-processed with crude petroleum at the existing conventional refineries. In this study, the HTL yielded a significant biocrude composition while the achieved biocrude’s MSP is competitive and can feasibly replace portion of crude oil, which in return helps to prolong Qatar’s oil reserves lifetime and mitigate its carbon footprint.

Abstract

The production costs of advanced biofuel options are currently higher than those of their fossil fuel equivalents. Capital Expenditures (CAPEX) for the production of liquid biofuels for road, aviation and marine transport sectors have a significant contribution to the overall production cost, together with the feedstock cost. It is, therefore, important to estimate the potential for cost reduction through R&D and experience in assembling a growing number of respective plants (i.e., from first-of-a kind (FOAK) to the Nth plant (NOAK)), which comprise a mix of established and innovative technological components. This could provide valuable information to stakeholders for the expected investment costs to meet European Commission goals in 2050.

This study adopts a methodological framework based on the “learning curve theory” to estimate cost reduction as a result from the experience of technology implementation, in terms of numbers or capacity of units implemented. This work applies the learning theory as a multicomponent analysis, which requires a systematic decomposition of the entire production process to identify established and innovative technological components that can be analysed in detail using the corresponding technoeconomic data.

The analysis showed that CAPEX reduction in the range of 10-25% could be expected to reach capacities corresponding to NOAK plants in 2050. To reach further CAPEX reduction of 40%, for example, would require higher cumulative annual growth rate to achieve two orders of magnitude increase of cumulative installed capacity. This corresponds to hundreds of GWs or equivalently some hundreds or thousands of large-scale plants to meet the goal of 20-25% transportation fuels consumption to be covered by advanced biofuels in 2050.

Keywords: biofuels deployment, CAPEX reduction, learning curve, TRL increase.

1. Introduction

The implementation of processes for advanced biofuels is a multidimensional issue affected by a wide range of technical, economic aspects and policy aspects. According to the study of IEA (2020) CAPEX values of bioprocesses based on lignocellulosic biomass have a significant contribution to the overall production cost, similar to the feedstock cost (around 40% each), while other operating and maintenance costs typically cover 15%-20% of the overall production cost.

Considering that many of these processes have reached TRL demonstration scale (e.g. gasification and 2nd generation ethanol) and/or satisfactory efficiency, the scope of CAPEX reduction due to experience gain when shifting from the first-of-a kind (FOAK) to the Nth plant (NOAK) could be a driver for long term deployment making them competitive to fossil based equivalents, and meeting the European Commission goals of

13%-24% contribution of liquid biofuels in the energy consumption for transportation in 2050 (EUROPEAN COMMISSION, 2018).

The learning curve (LC) theory is an important tool for estimating technical change related to the evolution of technologies and provides a systematic link between decreasing production costs and cumulative volume. It has found empirical support in a wide range of industrial sectors and technologies. In the energy field, the experience curve concept is so far used mostly to describe learning for modular products, such as wind turbines (Junginger M, et al., 2005), and solar photovoltaic (PV) modules (Mauleón I., 2016). Learning effects have been also investigated for bioenergy systems (Junginger et al, 2006), large-scale production of ethanol from sugarcane in Brazil (Goldemberg, 2003), the development of natural-gas-fired combined cycle power plant (Claeson Colpier and Cornland, 2002) and the case of renewable fuels (Detz et al, 2018). Most recently, an estimation of cost reduction potential of biofuels was presented by IEA (2020) using the LC theory from a top-down perspective based on data gathered from pilot and demonstration plants and interviews with experts.

The aim of this study is to develop a transparent modular framework for the application of the LC methodology for advanced biofuels from a bottom-up perspective. This is achieved by using a systematic decomposition of the advanced fuels production paths into a mix of innovative and established technologies that allows for the investigation of potential CAPEX reduction under various scenarios of installed capacity evolution. These scenarios may be influenced by policy targets and market estimates and refer to both the process as a whole and the independent evolution of some of its technological components.

2. Methodology

2.1. The learning curve framework

Technology learning is commonly modelled as a single factor approach to provide the way that production costs are reduced by a constant fraction for doubling of cumulative production). The single factor relationship is commonly expressed through a power-law function between production costs and cumulative production (Nemet 2006; Trappey et al., 2016)

$$C(Q_t) = C(Q_0) \cdot \left[\frac{Q_t}{Q_0}\right]^{-b} \quad (1)$$

where Q_t is the cumulative production, b is the positive learning parameter, related to the LR learning rate ($LR = 1 - 2^{-b}$), $C(Q_t)$ is the unit cost of production at Q_t , (i.e., operating cost and annualised investment cost, in the more general form), $C(Q_0)$ and Q_0 are respectively the cost and cumulative production at an arbitrary starting point.

The component learning approach (Ferioli et al., 2009, Upstill and Hall, 2018) extends the single factor model by not applying the methodology at the overall process level but as a sum of the costs of its individual technological components. Such an approach would be of importance when applying learning to biomass processes which consist of groups of unit operations (i.e., process components) with different maturity. In this case, the technology learning relationship may be expressed for each component individually, as follows:

$$C(Q_t) = \sum C(Q_{0i}) \cdot \left[\frac{Q_t}{Q_0}\right]^{-b(i)} = C_{01} \left[\frac{Q_{t1}}{Q_{01}}\right]^{-b(1)} + C_{02} \left[\frac{Q_{t2}}{Q_{02}}\right]^{-b(2)} + \dots + C_{0n} \left[\frac{Q_{tn}}{Q_{0n}}\right]^{-b(n)} \quad (2)$$

where $b(i)$ is positive learning parameter for technological component i , $C(Q_t)$ is the unit cost of production at cumulative production Q_t , Q_0 is the cumulative production at an arbitrary starting point, C_{0i} is the cost and Q_{0i} is the cumulative production of component

i at an arbitrary starting point, and $Q_{t,i} = (Q_{t-1,i} + CAGR_i \cdot Q_{t-1,i}) \cdot DF$. $CAGR_i$ is the cumulative annual growth rate of the corresponding technological component and DF is a decline factor as proposed by Detz, et al. (2018), equal to 0.98 for the particular calculation.

2.2. Cost reduction methodology in the case of advanced biofuels

The method is applied for the case of seven liquid biofuels (methanol, liquefied methane, jet fuels, diesel, kerosene, ethanol, butanol) produced from thermochemical and biochemical pathways. The chosen fuels and production technologies are selected as their technology readiness level (TRL) ranges from 6 to 9, (Figure 1).

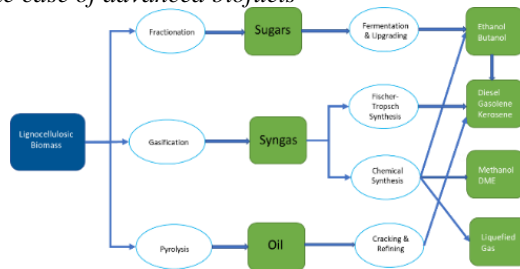

Figure 1. Production pathways for the liquid biofuels of the current study

To apply the multicomponent learning approach for the case of advanced biofuels, their production is modelled by a pathway consisting of a sequence of unit processes which produce the desired processes and replace equivalent fossil-based products. Each pathway of biofuels may consist both of purely biobased processes which convert biomass into intermediate products and conventional parts for upgrading purposes.

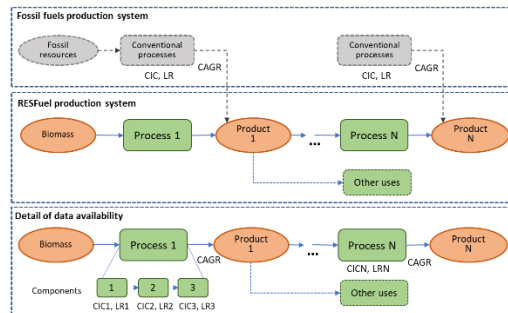

Figure 2. Decomposition of biobased pathway into unit processes for subsequent division into technological components (see Step 2).

Thus, the application of the learning curve theory to assess cost reduction potential through learning by doing is composed of three steps.

Step 1: The technology pathway is divided into process steps (first decomposition level represented by the intermediate box of Figure 2) resulting in a specific intermediate product (syngas, pyrolysis oil, etc.). Then, each process step is divided into components representing elementary technological steps (second decomposition level represented by the lower box of Figure 2). These components are those presented in Eq. 2. For example, in the case of methanol two process steps are identified in the first decomposition level (i.e., biomass gasification and methanol synthesis), while the decomposition of each process steps into technological components is presented in Table 1. This two-level process decomposition facilitates an efficient use of available data with respect to LR and CAGR values, while considering the technological maturity of the various components and maintaining the bottom-up nature of the proposed application of the technological learning framework. This is further explained in Step 2.

Step 2: For each time point t , defined as one year starting from 2020, the specific investment of each technological component i , $C(Q_t,i)$, is calculated from the analysis of cost reduction based on the learning curve theory (Eq. 2). Regarding the selection of LR values, the ideal case would be that a process step contains a combination of identifiable

mature and less mature technological components and the LR of all component are known but this is not the case.

For this reason, the next two rules are followed. In case of missing LR values for these technological components, mature technologies (e.g., conventional steps) are assigned by default a low LR value of 0.05 and less mature steps a higher value of 0.15 (e.g. in the cases of LR₁, LR₂, LR₃ of Process 1 in lower box of Figure 2).

Table 1. Input values to LC method for methanol for baseline scenario (Zhu, et al., 2011)

Process steps	Technological components	CAPEX (Euro 2018)	Learning rate (LR)	Cumulative installed capacity (CIC), (MW)	Cumulative annual growth rate (CAGR)
Gasification step	Air separation unit	0.0	0.05	200	11%
	Feed prep and drying	33.0	0.05		
	Gasification with tar reforming, heat recovery, scrubbing	44.9	0.15		
	Syngas cleanup & compression	84.7	0.15		
Methanol synthesis	Methanol synthesis & purification	37.2	0.05	57040	7%
	Steam system and power generation	27.7	0.05		
	Remainder off-site battery limits	6.5	0.05		
	Total CAPEX	234.0			

If, however, LR values for the entire process are available (e.g., Detz et al., (2019)) and LR values for mature and less mature technologies in this process step are not available, then the LR value for the entire process step is used and not the default LR values mentioned above. For example, for the case of biomass to methanol, the first rule of addressing LR values to mature and less mature components was applied as shown in Table 1; the gasifier operation in the gasification process step was considered as less mature and all the other components as mature technologies in conventional systems. Cumulative installed capacities (CIC) are defined by considering information for demo or pilot plants in operation in Europe or globally or values mentioned in simulation reports as representative for FOAK plants. For example, CIC of 200 MW is assumed for the gasification step, while for the methanol synthesis step the global production capacity for methanol in the year 2018 is used regardless of its production as fossil or renewable (M. Alvarado, IHS Chem. Week, 2016, 10–11). CAGR values are generally lacking due to very limited and relatively very recent commercial plants in operation. CAGR values are defined based on scenarios depending on policy targets and estimations of the market evolution of the corresponding conventional fuels. The growth rate of advanced biofuels is subject to many uncertainties depending on current conditions for growth rates of fossil-based demand and their future role in the transportation mix. In this work, three scenarios are formulated:

The *Baseline Scenario* which assumes CAGR values equal to the growth rate of the corresponding market of the fuel, which is a conservative scenario not leading to “greening” of the transportation mix. *Scenario A* assumes marginally higher CAGR values than the growth rate of the corresponding market of the fuel. Thus, it does not lead to a significant share of the market in short- to mid-term and the corresponding “greening” achieved is not enough to satisfy environmental targets for the time horizon (i.e., 2030-2050). *Scenario B* assumes an annual growth that is considerably bigger than the growth rate of the corresponding market of the fuel to an extent that it can satisfy targeted shares of the market in the considered time horizon. *Scenario B* estimates the CAGR of the biobased fuel to achieve 20% of the production of the respective fossil-based fuel. This is in agreement with the scenarios of European Commission 2018 that refer to 13%-24% contribution of liquid biofuels in the energy consumption for transportation in 2050 (EUROPEAN COMMISSION, 2018).

Step 3: By adding the values of all process components, the total specific investment cost of the process step is calculated and consecutively of the whole technological pathway ($CAPEX(t)$) at the time point t and therefore also at $CIC_i(t)$ (or Qt_i according to Eq.2).

3. Results

CAPEX reduction for the biomass to methanol pathway through indirect gasification, according to the *Baseline Scenario* is presented in Figure 3, showing the extent to which the components with the greater LR values present higher cost reduction rate. With respect to all advanced fuels analysed in this study based on Scenario A, Figure 4 shows that CAPEX reductions from 10-25% can be expected assuming only a handful of plants installed.

Figure 3. CAPEX reduction for methanol synthesis

If higher cumulative installed capacities are reached in 2050 (Scenario B, Figure 5), meeting the goal of 20-25% of transportation fuels consumption (to be covered by advanced biofuels), CAPEX reduction up to 40-50% can be expected for the new plants that will be built then. In this regard, it is important to remember that not all pathways reach similar CIC values in 2050, and thus the results should not be interpreted as a difference arising from the “potential to learn” or the status of the current maturity of the pathway. As an example, methanol and methane production via biomass gasification are both of similar technical maturity, the gasifier technology being the process component with higher technical learning potential. The reason that, in Figure 5, CAPEX of liquefied methane production appears to decrease faster than the methanol one is the very different CAGR values leading to CICs of 390 GW for liquefied gas to 53 GW of methanol. On the other hand, in Scenario A (Figure 4), where the CAGR values of methanol are higher than those of biogas, the opposite trend appears with respect to CAPEX decrease potential.

Figure 4 Scope of CAPEX reduction (2020-2050) of advanced biofuels from lignocellulosic biomass for a scenario of capacity annual growth rate marginally higher than the current fuel demands.

Figure 5 Scope of CAPEX reduction (2020-2050) of advanced biofuels from lignocellulosic biomass for a scenario of capacity annual growth rate meeting the goal of 20-25% transportation fuels consumption to be covered by advanced biofuels in 2050.

4. Conclusions

Notwithstanding the large uncertainties in the cost data, the learning curve theory can be useful to structure cost data, as a basis for estimating reductions as a function of installed

capacity. In the case of advanced biofuels, most of the technical learning is allocated in assembling the plants which consist, to a large extent, from mature technological components. It is, however, clear that substantial investment in large-scale plants is required in order to achieve CAPEX reduction of 40-50%, which together with favourable policies (e.g., access to capital, public/private partnerships, etc.) and feedstock cost factors, may increase the competitiveness of advanced biofuels. Two important methodological aspects refer to the degree of available information allowing or not a detailed decomposition of the pathway to process components, as well as the technical learning potential of these components and especially after which time point (or installed capacity) this can be assumed to attain near zero values. Disruptions (e.g. unforeseeable external events that may affect market conditions) have not been included in the modelling procedure. The method can become even more sophisticated by considering gradual or step changes in the learning parameters when a status of NOAK plant is reached to impose asymptotic behaviour faster and by incorporating sensitivity analysis for parameters of high uncertainty (e.g. LR and CAGR). It should be noted that technologies of advanced biofuels are only available in limited numbers. As a result, learning curve theory estimations cannot be based on a sufficient sample of similar systems. Secondly, there are very few full-scale plants available for advanced biofuel production on a commercial basis. This introduces significant uncertainties both in short- and long-term cost estimations of such plants. Additionally, if large facilities for fuel production are implemented, they will most likely affect the price of biomass leading to higher operating costs (or other market factors related with the role of biomass in the future energy system).

Abstract

The primary management of the organic fraction of municipal solid waste (OFMSW) was commonly composting, landfill or incineration, while now the anaerobic digestion of OFMSW offers the possibility of a clean and renewable energy source. This work presents the modelling and simulation of an OFMSW biorefinery to produce biogas, fertiliser and bioethanol. The conceptual design of the biorefinery begins with an anaerobic digestion to degrade OFMSW and produce biogas. The resulting solid fibres and the effluent are sent to the subsequent stages to produce fertiliser from the solid waste and anhydrous bioethanol from the fermentation broth. The process simulations are based on an anaerobic biorefinery capable to treat 1,000 tonnes per day of OFMSW generated in CDMX. The main results show the yields are 73 kg ethanol, 54 kg biogas and 59 kg fertiliser per tonne of dry waste.

Keywords: biorefinery, biofuel production, process simulation, municipal solid waste.

1. Introduction

The production and management of municipal solid waste (MSW) is a critical global problem. In general, the organic fraction of municipal solid waste (OFMSW) is a common name for heterogeneous waste mixtures from residential, commercial, partly industrial and urban areas. It is made up of different organic and inorganic fractions such as food, vegetables, paper and wood. Despite the variability in its composition, the OFMSW constitutes the highest percentage of the solid waste which can be broken down into simpler compounds by anaerobic microorganism (Bilgili et al., 2009). In the past decades, OFMSW's primary management was generally composting, landfill or incineration. Recently, OFMSW has become a promising candidate for energy recovery through the production of biofuels, such as biogas, bioethanol, biohydrogen, biodiesel, etc. (Campuzano and Gonzalez-Martinez, 2016). Despite the fact that several reviews have been published both to determine the composition (Campuzano and Gonzalez-Martinez, 2016) as well as the challenges and opportunities of biorefineries (i.e., Sawatdeenarunat et al., 2016; Dahiya et al., 2018), very few studies report aspects of modelling, simulation and design of these biorefineries.

Treatment processes for an integral OFMSW harnessing can be classified into three groups (Nizami et al, 2017): (1) thermochemical (e.g. pyrolysis or gasification), (2) physicochemical (e.g. hydrolysis or transesterification), and (3) biochemical (e.g. anaerobic digestion or fermentation). Each treatment can generate different products of added value and has advantages or disadvantages depending on the raw material and conditions of the place or country (Tsakalova et al., 2014). In particular, anaerobic digestion is considered the most technologically feasible method due to its many advantages, as it not only serves to efficiently manage and treat a huge amount of OFMSW, but also acts as a convenient source of unconventional energy (Wang et al., 2017).

Currently Mexico City has several transfer stations, classification plants, compactor plants, composting plants and landfills for the management of OFMSW. Thus, in this work an alternative to the management of OFMSW is proposed, through the design of a biorefinery to process 1,000 tons of OFMSW per day generated in Mexico City. The products generated from the OFMSW-biorefinery are biogas, fertiliser and bioethanol. Modelling and simulation tools are used for the design of the plant. The biorefinery begins with an anaerobic digestion where biogas is produced, and then several processing stages are followed to produce anhydrous ethanol as the main product and fertiliser as a fermentation by-product.

2. Methodology

2.1. Biorefinery conceptual design

The conceptual design of the biorefinery consists on seven stages, as shown in Figure 1. The biorefinery begins with an anaerobic digestion to degrade OFMSW and produce biogas. The resulting solid fibres and the effluent are sent to the subsequent stages of pretreatment by acid hydrolysis, saccharification by enzymatic hydrolysis, co-fermentation of sugars (pentoses and hexoses) to ethanol, evaporation and distillation to concentrate the ethanol solution, and finally ethanol dehydration by adsorption with molecular sieves. Fertiliser is obtained as a by-product of the sugar fermentation.

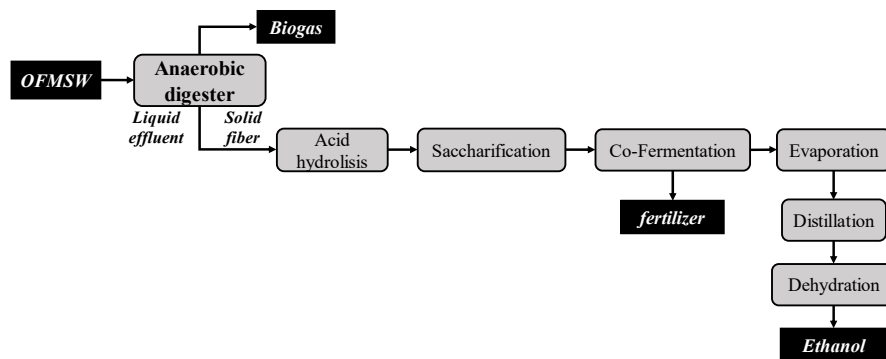

Figure 1. Conceptual design of the *OFMSW*-biorefinery

2.2. Implementation of the simulation models

The process flow diagram of the biorefinery was implemented in Aspen Plus® V.10 (see Figure 2), considering rigorous kinetics for the anaerobic reactor (Rajendran et al., 2014) and stoichiometric reactions for the hydrolysis, saccharification and fermentation reactors

(Aden et al., 2002). The thermodynamic properties of pure components and mixtures were estimated using the database and included methods, and the NRTL (Non-Random Two Liquid) model was employed as thermodynamic method.

Anaerobic digestion process of OFMSW was simulated using a model previously developed by Rajendran et al. (2014), which is based on the Anaerobic Digestion Model 1 (ADM1) and was validated against a variety of lab and industrial data. A total of 46 reactions were used in this model including inhibitions, kinetic rates, ammonia production, reactor volume, loading rate, and retention time. The biodigester was modelled in Aspen Plus as an RSTOIC block model (D-0), where hydrolysis occurs at 55 °C and 1 atm; together with a CSTR block model (D-1), where acidogenic, acetogenic and methanogenic reactions are carried out at 55 °C and 1 atm.

The pretreatment stage was simulated using two stoichiometric reactors (HIDROLI1, HIDROLI2), both operated at the same pressure and temperature conditions (190°C and no vapour fraction). The first reactor converts most of the hemicellulose into shorter chain polysaccharides through hydrolysis reactions (with 20% conversion), while the second reactor converts these polysaccharides into soluble sugars, mainly xylose, mannose, glucose, galactose and arabinose (with 92.5% conversion). Hydrolysis reactions also produce soluble lignin, acetic acid, and degradation products (mainly furfural and hydroxymethylfurfural).

The saccharification process was simulated in a stoichiometric reactor (SACHAR), where enzymatic hydrolysis reactions are carried out at 1 atm and 65 °C. The main reaction corresponds to the conversion of cellulose to glucose (with 90% conversion). And the co-fermentation process was simulated in a stoichiometric reactor adding *Zymomonas mobilis* as strain for the cultivation, where the conversion of both pentoses and hexoses are converted into ethanol (with 97% conversion), at 1 atm and 41 °C.

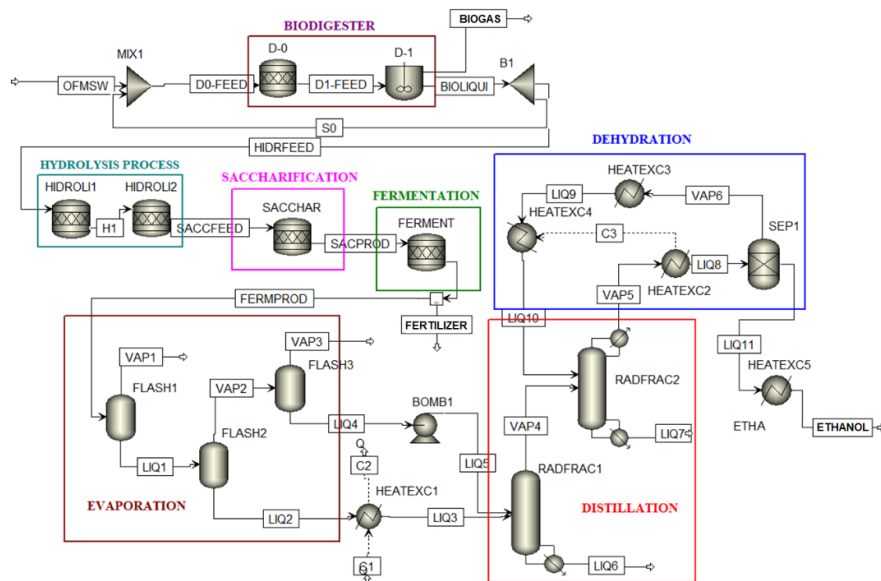

Figure 2. Process flow diagram for OFMSW-biorefinery

The outlet stream from the fermenter was treated by an evaporation section to remove considerable amounts of components such as CO₂, NH₃, H₂S, O₂ and H₂O, among others. Subsequently, two distillation columns (RADFRAC1, RADFRAC2) were simulated to concentrate the alcoholic broth near the azeotropic point. The theoretical number of equilibrium stages for the first column was 9, without condenser and with a molar reflux ratio in the reboiler of 0.23, the pressures of stages 1 and 9 were 1.53 and 1.67 atm, respectively. The theoretical equilibrium stages for the second rectifying column were 18, with molar reflux ratios of 2.3 and 0.23 for condenser and reboiler, respectively; the pressures of stages 1 and 18 were 1.36 and 1.63 atm, respectively. And finally, the distillate stream was sent to the dehydration process by adsorption with molecular sieves. This dehydration technology uses a zeolite bed in which the water molecules are strongly retained within the pores, while the ethanol molecules pass through the bed. The process consists of combined cycles of dehydration of ethanol and regeneration of the molecular sieve. The main stream reaches an ethanol purity of 99.5%, which is cooled and stored

3. Simulation results

For simulation purposes, the biorefinery was designed to process 1,000 t/d of wet waste, assuming an average OFMSW composition of Mexico City presented in Table 1, which was adapted from Campuzano and González-Martínez (2016). The composition and properties of OFMSW were implemented in Aspen Plus® using its extensive database of components and property estimation.

Table 1. Components and mass fraction of OFMSW.

Component	Molecule	Chemical formula	Mass fraction
Carbohydrates	Cellulose	C ₆ H ₁₀ O ₅	0.0471
	Hemicellulose	C ₅ H ₈ O ₄	0.0114
	Dextrose	C ₆ H ₁₂ O ₆	0.0234
	Starch	C ₆ H ₁₂ O ₆	0.0381
Protein	Protein	C _{4.13} H ₂₅ O ₇ N ₃ S	0.0212
	Keratin	C _{4.39} H ₈ O _{2.1} N	0.0127
Lipids	Triolein	C ₅₇ H ₁₀₄ O ₆	0.0098
	Tripalmitate	C ₅₁ H ₉₈ O ₆	0.0098
	SN-1-Palmito-2-Olein	C ₃₇ H ₇₀ O ₅	0.0098
	SN-1-Palmito-2-Linolein	C ₃₇ H ₆₈ O ₅	0.0098
Lignin	Lignin	Inert	0.0300
Ashes	Ashes	Inert	0.0739
Humidity	Water	H ₂ O	0.7030

Table 2 shows the results for the main streams of each stage of the process, where it can be seen how OFMSW is degrading as it passes through each stage of the process. The biogas yield was 0.538 kg/kg of dry waste. Being the most common use of biogas for heat

and electricity generation. While the fertiliser yield was 0.059 kg/kg of dry waste. The use of biofertilisers improves the fertilization of crops compared to chemical fertilisers and does not compromise the yield or quality of the crops (Dahiya et al., 2018). And finally, the ethanol produced was 0.073 kg/kg of dry waste. This is low compared to the reported values of 1.15-1.5 kg ethanol/kg dry waste (Sawatdeenarunat et al., 2016). The main reason is due to the low carbohydrate composition of the OFMSW obtained for Mexico City (Table 1). It is worth mentioning that the anhydrous ethanol is a product with high added value, which can be used mixed with gasoline as a fuel for transportation. Although the product yields obtained in this work are still low compared to those obtained with other lignocellulosic substrates, the complex nature of this substrate must be taken into account. Up to now, the simulation was focused on the conceptual design, but the next step will be to improve the operating conditions of each stage.

Table 2. Main streams for the OFMSW-biorefinery.

Stream	Stream Name	Flow (t/d)	Composition
Biodigester feed	DO-FEED	1,000	Given in Table 1
Hydrolysis feed	HIDRFEED	836.81	42.4% CH ₄ , 43.6% CO ₂ , 12.4% H ₂ O, 0.8 % Ethanol, 0.7 % H ₂ S, 0.1% others
Saccharification feed	SACCFEED	836.82	78.1% H ₂ O, 12.4% inert, 2% C ₅ H ₇ NO ₂ , 1.4% Ethanol, 1.1% Cellulose, 0.9% Xylose, 0.9 % Starch, 0.5% CH ₃ COOH, 2.6% others
Fermentation feed	SACPROD	830.35	78.5% H ₂ O, 12.5% inert, 2% C ₅ H ₇ NO ₂ , 2.0% Ethanol, 1.3% Glucose, 1.0% Xylose, 0.5 % CH ₃ COOH, 2.8% others
Evaporation feed	FERMPROD	830.78	78.5% H ₂ O, 12.5% inert, 2.7% Ethanol, 2% C ₅ H ₇ NO ₂ , 1.2% CO ₂ , 0.6% CH ₃ COOH, 2.6% others
Distillation feed	LIQ3	816.87	79.3% H ₂ O, 12.7% inert, 2.7% Ethanol, 2% C ₅ H ₇ NO ₂ , 0.6% CH ₃ COOH, 2.7% others
Distillation feed	LIQ5	0.30	90.9% H ₂ O, 8.5% Ethanol, 0.3% CH ₃ COOH, 0.3% others
Dehydration feed	LIQ8	102.98	69.2% H ₂ O, 29.3% Ethanol, 0.4% CH ₃ COOH, 1.1% others
Biogas	BIOGAS	159.77	42.4% CH ₄ , 43.6% CO ₂ , 12.4% H ₂ O, 0.8 % Ethanol, 0.7 % H ₂ S, 0.1% others
Fertiliser	FERTILIZER	17.59	93.5% <i>Z. mobilis</i> , 5.0% H ₂ O, 1.5% others
Ethanol	ETHANOL	21.55	99.95% H ₂ O, 0.05% Ethanol

4. Conclusions

The conceptual design and simulation of a biorefinery to convert OFMSW into value-added products have been presented as decision support for the management of OFMSW in Mexico City. The results show that its reuse is feasible for the production of biogas, bioethanol and fertiliser. An important problem for obtaining OFMSW bioproducts is their heterogeneity and variability in chemical composition, such that they could modify the results obtained. For example, when food waste is the major compound, biogas production would increase; while when lignocellulosic compounds predominate, the production of bioethanol and biofertilisers would increase.

We are currently working on the economic evaluation, as well as on the extension of this conceptual design proposal to produce other value-added products, such as the production of biodiesel using the liquid effluent from anaerobic digestion (with algae that can also reduce CO₂), lignin, recovery of solid waste generated in fermentation, and possible production of electricity by combustion of solid waste.

Abstract

In this work, two different bioprocess plants are economically compared using Aspen Plus process simulations based on information from literature. Olive tree pruning (OTP) wastes are used as the raw material in the processes which are valorised through two different processing plants. One biorefinery scheme consists of an initial steam explosion pre-treatment to further obtain three final products: ethanol, xylitol and antioxidants (steam explosion plant = SEP). The other one consists of an organosolv (ethanol and water) pre-treatment operation to finally ferment glucose to ethanol, co-producing catechol from lignin depolymerization (organosolv plant = OP). Both plants show similar equipment costs (43-47 M€). However, the first plant (SEP) manufacture three marketable products with lower ethanol production (6364.35 m³/yr) than OP (8118 m³/yr). In comparison, the production of xylitol (999.36 tonne/yr) and antioxidants (1214.46 tonne/yr) as co-products in the SEP are much higher than the catechol production (124.05 tonne/year) in the OP. As a result, much of the organosolv resulting lignin is burned to produce energy. Considering all costs and incomes in both plants, the SEP would attain a profitability of 20%, while the OP would be -7%.

Keywords: Lignocellulosic biorefinery, Organosolv, Steam explosion, Technoeconomic analysis.

1. Introduction

Currently most of the fuels obtained from biomass sources in a commercial scale come from corn, sugarcane, wheat and other cereals, which means that most of the biofuels are obtained in first generation plants. On the contrary, second generation bio-products obtained from lignocellulosic biomass do not compete in the human food market, being one of the reasons why they have attracted many attention in the last decade (Haghighi et al., 2013).

In Spain, many works at different scales are being developed using olive tree pruning (OTP) wastes to obtain marketable products. That biomass is highly available (around 4.5 Mtonnes of OTP are generated each year), being burned in most of the cases to obtain thermal energy (Manzanares et al., 2017). However, different high-value products can be also synthesized from OTP wastes. For instance, antioxidants from olives are highly

demanding bio-products by society in food and cosmetic applications. They have been successfully extracted (Conde et al., 2009) from OTP wastes, as well as xylose which can be used as raw material for the production of both xylitol (Rivas et al., 2006) and ethanol. Obtaining these products usually requires an initial steam explosion or organosolv pre-treatments to separate lignin from fermentable compounds.

On the other hand, lignin is usually burned to obtain energy. Some authors (Toledano et al., 2012) showed that depolymerization of OTP lignin is feasible and some valuable compounds can be produced (p.e. catechol). Organosolv pre-treatment has shown the best performance to obtain exploitable lignin.

In this work, two biorefineries schemes are compared, both using OTP waste as raw material. One of the considered processes uses steam explosion as the pre-treatment operation, producing antioxidants, ethanol and xylitol, (lignin along with the rest of the organic waste will be burned to obtain thermal energy). The other plant uses organosolv in the pre-treatment step, producing ethanol and lignin which is further depolymerized to produce catechol. Aspen Plus software is used to model and simulate both plants and a techno-economic evaluation is carried out as shown in section 3.

2. Materials and Methods.

2.1. Feedstock

The input in both plants are 96.96 tonnes of OTP wastes per day. The composition (% dw) is the same described by Ballesteros et al. (2011): 28.0 cellulose (as cellulose); 20.6 hemicellulose (as xylan); 25.2 lignin; 2.1 acetic groups; 5.9 Ash (as CaO); and extractives with is a mixture of: 7.9 glucose, 0.1 arabinose, 0.1 mannose, 0.9 galactose, 4 mannitol and 3.8 antioxidant (hydroxytyrosol as the reference compound) (Conde et al. 2009).

2.2. Process description of plant A

In plant A, the pre-treatment has two steps; firstly, the OTP is sent to a solid-liquid extraction using water at 393.15 K and 5 bar. The water stream extracts 90% of extractives (Ballesteros et al., 2011). The remaining solid fraction is sent to a steam explosion process at 468.29 K and 14 bar with phosphoric acid (1%) as catalyst (Negro et al., 2014). Then a water insoluble solid fraction (WIS) and a liquid fraction with xylose and the degradation compounds as principal components (LiX), are obtained.

The liquid fraction with the extractives is cooled down to 308.15 K and streamed to a liquid-liquid extraction column with ethyl acetate (EtA) at 303 K, where 90% of the antioxidants are extracted by EtA. Antioxidants are then separated from EtA by a non-ionic adsorption process (Romero-García et al (2016)). All EtA is separated from water and other organic components by distillation and recirculated to the process, recovering 98% of EtA. The LiX is cooled down at 323 K and mixed with $\text{Ca}(\text{OH})_2$ to remove furans and phenolic compounds. Then, it is neutralized with H_2SO_4 . The detoxified LiX is then fermented at 303 K (75% of xylose is fermented to xylitol). The product is filtered to remove the yeast and other solids and evaporated to concentrate the xylitol at 313 K (this temperature avoids xylitol degradation). Xylitol is mixed with ethanol to reduce xylitol solubility and then purified by crystallization at 268 K (yield of 47 % with a purity of 99% (Rivas et al., 2006). The WIS stream is sent to a pre-saccharification and simultaneous saccharification and fermentation process (PSSF) for the production of bio-ethanol. Pre-saccharification is carried out at 323 K. Then the resulting stream is further cooled to 308 K and fermented to ethanol (70% of theoretical yield is obtained) (Ballesteros et al., 2011). The resulting ethanol stream is firstly purified in a beer column which

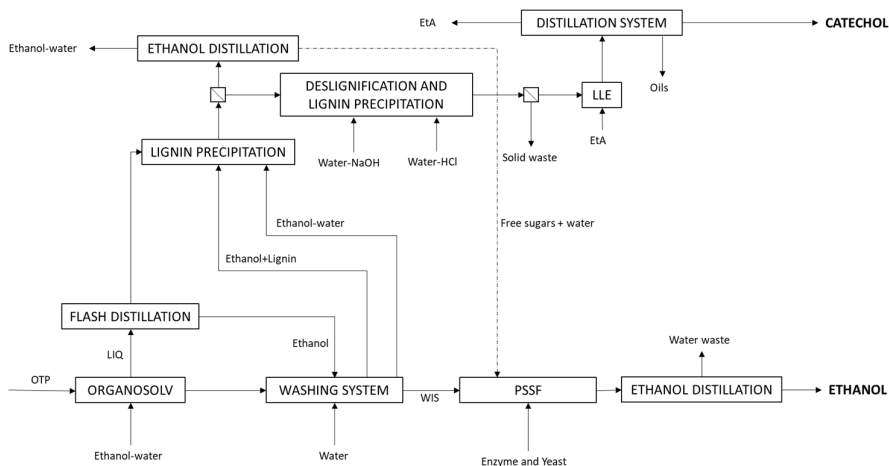

Figure 2. Block diagram of the modeled plant B

2.4. Process modelling and economic evaluation.

Both processes are simulated in Aspen Plus V11 software (Aspen Technology Inc, USA). Physical property data of cellulose, hemicelluloses, lignin and enzymes was taken from literature (Wooley, 1996). The non-random two liquid (NRTL) thermodynamic model was used in the process. Antioxidant are modelled as hydroxytyrosol, whose properties are calculated using the built-in property estimation models (group contribution approach from molecular structure). Missing binary interaction parameter are estimated using UNIFAC. To economically compare both plants, the Discounted Cash Flow Rate of Return (DCFRROR) and Net Present Value (NPV) are calculated for a 15-y period with a cost of capital of 15%. These parameters provide a useful way of comparing the performance of capital for different projects. Aspen Economic Analyzer V11 (Aspen Technologies Inc, USA) is used to calculate equipment cost of both plants. Raw materials and products prices are obtained from literature (Susmozas et al. 2019) and utilities consumptions are calculated following the methodology available in (Sinnot & Towler 2008).

3. Results and Discussion.

Table 1 shows the distribution of equipment cost, revenues and the major contributions of the operating costs. Plant B revenues do not compensate the estimated investment so the NPV is negative. In this plant, the depolymerization process accounts for the 18% of the equipment cost, not compensating by the revenues obtained from the production of catechol. The yield of catechol is quite low, just representing 0.31% of all products obtained on the delignification process, so most of the products obtained from delignification are burned to obtain thermal energy. Even more, organosolv is more expensive than steam explosion, because it requires more equipment to recover as much ethanol as possible.

On the other hand, Plant A is estimated to be profitable, with a calculated DCFRROR of 20% and NPV at year 15 of 11.54 M€. In both plants cooling water represents the highest utility consumption. That makes sense considering that both plants pre-treats OTP wastes at high temperature and the subsequent enzymatic hydrolysis takes place below 323 K.

Furthermore, the biological reactors operate at constant temperature so cooling water is also needed.

Table 1. Equipment cost, revenues, variable cost distribution and DCFROR

4. Conclusion

In this work, we have compared two different OTP waste biorefinery schemes in terms of capital and operating costs, and potential revenues. Our results show that delignification is not yet a competitive route in comparison with the obtention of antioxidants and xylitol from OTP wastes. Current yields to catechol limit the potential of the delignification route (efficiency of the depolymerisation around 5%). Other high-value products are being developed from the organosolv resulting lignin, which would expand the range of marketable compounds, thus increasing the competitiveness of this route. On the other hand, high revenues have been estimated for the case of the steam explosion-based plant. In that biorefinery scheme, xylitol, ethanol and antioxidants are

simultaneously produced. Our results show that the most economically promising route is the production of antioxidants from OTP through a liquid-liquid extraction process with ethyl acetate.

The Use of GVL for Holistic Utilization of Biomass

Antreas Pateromichelakis, Melina Psycha, K. Pyrgakis, A. Kokossis*

National Technical University of Athens, Iroon Polytechniou 9, GR-15780, Greece

Abstract

This work presents solutions for the holistic utilization of lignocellulosic biomass based on the “lignin-first” concept. Biomass is fractionated by means of γ -Valerolactone (GVL) and Formaldehyde solvents to effectively extract and protect lignin and xylose ingredients. The process flowsheet and simulation of a large scale biomass fractionation technology – recently validated in laboratory scale by Shuai et al. (2016) – are developed to test and build performance in use of energy, water and materials. The biorefinery value chain additionally integrates chemistries for the production of platform chemicals and biofuels (furfural, levulinic acid and lignin-aromatics), while the C6 sugars fraction is partially converted into GVL to offset solvent losses. Finally, energy integration and techno-economic analysis resulted in up to 6% steam savings, 1.8 MW power cogeneration and 37 M€/yr net revenues for the overall biorefinery.

Keywords: γ -Valerolactone (GVL), Lignin-first, Biorefineries.

1. Introduction

Biomass fractionation is challenged by the effective recovery of cellulose, hemi-cellulose and lignin components. While organosolv technologies have been credited to extract xylan and glucan, processing and depolymerization of lignin structures are mostly inhibited by degradation of ether bonds and spontaneous repolymerization of C-C bonds resulting in random structural recombination of the polymer matrix. The limited recovery of functional lignin intermediates usually leads to misconceptions that the lignin-rich pulp is a process-waste or low value fuel. The technology proposed by Shuai et al. (2016) takes advantage of the “lignin-first” concept to stabilize and protect lignin from repolymerization during processing and extraction. The aim of this work is to face underutilization of the lignin content and test performance of large scale lignin-first biorefineries for the production of platform chemicals and high value biofuels.

2. Bottlenecks in lignin processing and extraction

Lignin-rich feedstocks and lignin aromatic content are underutilized due to processing bottlenecks during biomass fractionation stages, whose goal is to separate and transform lignin into functional units by cleavage of biopolymer bonds in between lignin polymer chains and intramolecular bonds within polymer chains. Biomass pre-treatment commonly takes place at relatively high temperature (>120 °C) and in strong acid or alkaline environments (>1% wt). Under these conditions, there is a featured effect related with cleavage of ether bonds (β -O-4, 4-O-5 etc.) in between monolignols and repolymerization by the formation of C-C bonds due to interactions between positively charged and electron-rich sites. This effect results in irreversible condensation of lignin and significantly reduced yields of aromatic monomers during subsequent processing.

The yield of desired lignin-aromatics is correlated with the ether bond content and is enabled by the use of catalysts. The use of unprotected lignin is responsible for the reduction of aromatic yields and the inhibition of catalytic activity due to the existence of C-C bonds in lignin structure.

The above processing bottlenecks have an apparent negative impact on the utilization of biomass lignin content and, thus, on process economics. This work exploits the “lignin-first” concept – recently validated in laboratory scale by Shuai et al. (2016) – as a practice to protect lignin and build high performance industrial scale biorefineries.

3. The “Lignin-first” concept

The implementation of lignin-first biomass fractionation aims to successfully extract lignin by inhibiting the formation of C-C bonds during pre-treatment and to protect lignin through the reaction system of Figure 1.a. The fractionation process utilizes a γ -Valerolactone (GVL)-water mixture as solvent, which (a) favors selectivities towards sugars, lignin and platform chemicals; (b) limits sugars and lignin degradation; (c) features limited solvent degradation in the selected process conditions; and (d) facilitates downstream separations due to properties (n.b.p. 219 °C) (Alonso et al., 2017; Questell-Santiago et al., 2018). In addition, this work examines the use of formaldehyde in biomass fractionation to further inhibit the formation of C-C bonds between monolignols by reacting with newly cleaved sites.

An additional effect of formaldehyde is the protection of xylose. Another major reaction that occurs during fractionation is the depolymerization of hemicellulose into xylose and its degradation into furfural and humins. The formation of furfural at this stage complicates downstream separations due to the formation of furfural-water azeotrope. Formaldehyde protects the xylose content by the formation of diformyl-xylose (reaction system of Figure 1.b), which is next converted into xylose by introducing an additional intermediate reaction stage before finally upgrading xylose into furfural end-product.

The protected (by GVL and formaldehyde) lignin is next hydrogenated in presence of Pd-Ru supported catalysts resulting in near theoretical lignin-aromatic yields of 50%, whereas corresponding yields based on unprotected lignin are typically expected in the range of 5-20%. Moreover, the use of GVL favors the formation of hydroxymethyls, which in turn yield in blends suitable for biojet and biodiesel use.

GVL has been selected as the primary solvent for the depolymerization of sugars due to its ability to deter degradation of biomass components; to effectively depolymerize hemicellulose into xylan; to inhibit humins formation; and to dissolve solid lignin. The latter, can be tuned by simple addition of water. The chemistry takes advantage of a GVL-water (80-20 wt%) mixture to dissolve biomass components, while lignin precipitation starts at higher water/GVL mass ratios (>1.5). The zeotropic GVL-water mixture also facilitates downstream processing and separations. Considerable improvements on the yields and quality of extracted lignin are attributed to the use of formaldehyde (3% w/w) as co-solvent to prevent lignin condensation, to hinder the formation of C-C linkages and to produce soluble lignin (Shuai et al., 2016). Based on the laboratory scale efficiencies of Shuai et al. (2016), process systems engineering methods are used to test and build performance of large scale lignin-first biorefineries.

Figure 1. Lignin protection from GVL (a), xylose protection from formaldehyde (b)

4. Methodological steps

In this work, two alternative biorefinery scenarios have been developed for the production of xylose-based furfural, glucose-based levulinic acid and lignin-aromatics. The next objective is the evaluation of the effects of lignin exploitation on process economics with a purpose to identify most profitable solutions and set the basis of an expanded value chain. Both biorefinery cases (A & B) use GVL in biomass fractionation, while the second case (B) additionally uses formaldehyde as co-solvent.

The biorefinery plant (Figure 2) includes 5 Units: (U200) Biomass fractionation unit; (U300) Glucose-to-Levulinic acid unit; (U400) Xylose-to-Furfural unit; (U500) Lignin-to-aromatics unit; and (U600) Waste Water Treatment (WWT) unit. Energy integration and techno-economic analysis are next implemented both in contexts of each Unit and the overall biorefinery to estimate steam savings and extract conclusions regarding capital and operating expenses and profitability margins of each biorefinery case.

Mass and energy balances are calculated in the basis of 10 tn/h of white birch as feedstock, which features high lignin (18-25%) and ether (46-75%) bond contents. In Case A, each part of biomass requires 3.2-0.8-0.04 parts of GVL-water- H_2SO_4 in fractionation stage, while in Case B, 0.18 parts of formaldehyde are additionally used per part of biomass in feed. The process flowsheets (Figure 3) and mass and energy balances for each case (A/B) have been developed and calculated in Aspen plus (v8.6).

5. Results

5.1. Process flowsheeting and simulation

Figure 3 presents the process flowsheets of all biorefinery units (U200-U600 for Case A & B), which are interconnected according to the process diagram of Figure 2 and simulated as a single biorefinery plant in Aspen plus (v8.6). The simulation results are presented in Table 1 including key input/output mass balances for each unit and case.

The process flowsheets of biomass fractionation (U200) and Xylose upgrade (U400) are different for each Case A & B due to additional requirements in Case B, for the recovery of formaldehyde in U200B and the conversion of diformyl-xylose into xylose in U400B. The Units U300, U500 and U600 are the same for both Cases A and B.

Biomass fractionation (U200) is operated in a monophasic (liquid) reactor at 120 °C and 2 bar. GVL hydrolyses 81% of hemicellulose into xylose and dissolves 95% of lignin content; 93% of cellulose is recovered as solid pulp through a two-stage centrifugation system. The extracted lignin is next precipitated with the addition of water using a 6:1 water-GVL mixture. In Case B of U200, formaldehyde additionally reacts with the hydroxyl content of lignin driving the stabilization of dissolved lignin, while, next, formaldehyde is recovered through the distillation of U200B. The downstream units are developed for the conversion of intermediate sugars and lignin into platform chemicals.

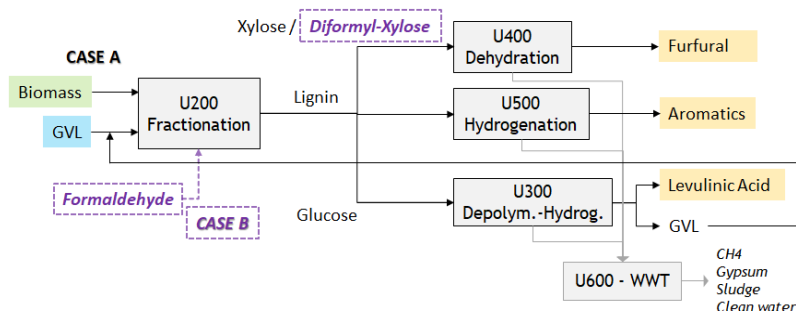

Figure 2. Lignin-first biorefinery diagram for Cases A and B.

In U400A, the extracted xylose-GVL mixture is concentrated through evaporation, while GVL is next recovered by means of distillation; in Case B (U400B), an intermediate reactor is introduced to transform diformyl-xylose into xylose, which is finally dehydrated into furfural by 90%. In U300, the cellulose-rich pulp is mixed with pure GVL, hydrochloric acid (HCl 37 wt%) and water forming an 80:20 wt% GVL-water mixture. Depolymerization of cellulose occurs at 150 °C and 3 bar, where cellulose depolymerizes into glucose, glucose isomerizes into fructose and fructose is hydrolyzed into 5-Hydroxymethylfurfural; the latter decomposes into levulinic acid and formic acid. The overall glucose to levulinic acid yield is 55%. The levulinic-formic acid mixture exiting the reactor is partially driven to a hydrogenation reactor for the conversion of levulinic acid into GVL, while the rest is separated by distillation resulting pure levulinic acid. U500 is responsible for the hydrogenation of lignin into aromatics in presence of THF solvent. In U500B, the treatment of protected lignin (by formaldehyde) yields in 10 parts of aromatics for each 100 parts of biomass – while in absence of formaldehyde (Case A), the yield in U500A is only 3 parts of aromatics – resulting in a significant impact on biorefinery economics. WWT is implemented for the recovery of contaminated process water and anaerobic digestion (AD) of organic residual content. U600 respectively achieves 97% and 90% water recovery in Case A & B, while methane production by AD is respectively estimated at 193 and 247 kg/hr.

5.2. Energy and economic analysis results

Total Site integration (Pyrgakis and Kokossis, 2019) is implemented to estimate utilities, steam savings and cogeneration targets for the overall lignin-first biorefinery. The Grand Composite Curves of all units are developed and combined resulting in the Site Sources and Sinks Profiles of Figure 4 for each Case A & B. The energy results of Total Site integration analysis are summarized in Table 2.

Figure 5 presents the breakdown of materials expenses for each case highlighting the need for less expensive biomass types. Concerning Case A, cheaper solvent alternatives

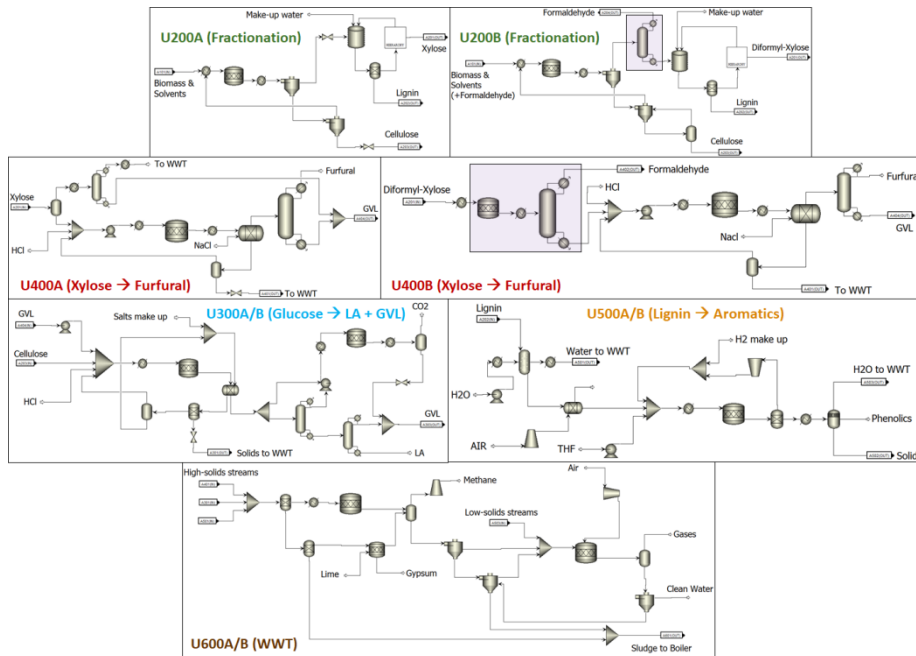

Figure 3. Process flowsheets of biorefinery units (Cases A and B) in Aspen plus v8.6.

Table 1: Inlet and outlet mass balances [tn/hr] for each Unit and each Case A & B.

	IN	OUT	IN	OUT	IN	OUT	IN	OUT	IN	OUT
Units in Case A	U200A		U300A		U400A		U500A		U600A

THF					0.2					
Others			0.2		0.3				0.6	5.4

should be considered instead of THF for lignin upgrade, highlighting the option for partial conversion of furfural output into THF solvent. In Case B, upgrading of lignin attributes to 34% of material costs (including formaldehyde), while the high cost for mineral salts results in the need for cost effective salt recovery systems. Table 2 summarizes the net revenues per product in each case. In the case of aromatics, catalytic hydrogenation of unprotected lignin in Case A should be reconsidered due to its negative economic impact. To the contrary, the exploitation of protected lignin in Case B favors profits from lignin-aromatics. Levulinic acid production appears similar economics in both cases. Finally, furfural production in Case A appears superior economics compared to Case B; however, the milder pre-treatment with formaldehyde in Case B preserves a higher cellulose fraction than that of Case A, which in turn yields in larger amounts of levulinic acid. Overall, the use of formaldehyde in Case B results in better process economics and higher net revenues than those of Case A by 34%.

6. Conclusions

The exploitation of unprotected lignin in Case A for the production of aromatics features a large relative difference in net revenue compared with Case B. In both cases, biomass cost is nearly half of total material expenses, thus cheaper biomass feedstocks should be considered, while the high cost of THF solvent justifies the need for partial conversion of furfural end-product into THF. In conclusion, the implementation of “Lignin-first” concept in presence of formaldehyde (Case B) for the fractionation of biomass is considered as the most profitable option.

Abstract

This work has performed Life Cycle Assessment (LCA) and Techno-Economic Analysis (TEA) to assess the sustainability of a novel process to convert sugarcane bagasse to lactic acid. Experimental results are combined with downstream process simulation using Aspen Plus[®] to generate process data. The LCA model is developed in OpenLCA, with a cradle-to-gate scope and 1 kg of LA as a functional unit. Ecoinvent[®] database is used for inventory, and ReCiPe Midpoint (H) methodology is chosen for impact assessment. Process economic approach is used to perform TEA, and the payback period and product costs are calculated. LCA results showed that climate change impact was 4.62 kg CO₂ eq. per kg LA, with the pretreatment stage identified as a hotspot. TEA results showed that LA product cost was \$3.27/kg, which reduced to \$2.9/kg if bagasse was free. Recycling of NaOH used in pretreatment can result in environmental and economic benefits of the bagasse based LA process.

Keywords: Life cycle assessment (LCA), sugarcane bagasse, lactic acid, techno-economic assessment, waste valorization

1. Introduction

Sustainable valorization of industrial and agricultural wastes is of utmost importance for a thriving circular bioeconomy (Stegmann et al., 2020). In this context, sugarcane bagasse, a lignocellulosic fibrous waste generated by the sugar industry, has gained significance. Increasing research trends in bagasse valorization can be attributed to its wide availability, affordability, and vast potential to produce a multitude of products such as biofuels, biochar, and biochemicals (Meghana and Shastri, 2020). In India, a leading country in sugarcane cultivation, bagasse is burned in the boiler to meet a sugar mill's energy demands. Large mills use to produce surplus electricity and sold to the grid. However, the valorization potential of lignocellulose resource like bagasse is not completely exploited in these current practices. Additionally, current handling practices of bagasse are not environmentally benign due to added emissions resulting from bagasse burning (Meghana and Shastri, 2020). Therefore, developing sustainable production routes that enable and utilize the lignocellulose nature of bagasse to produce value-added chemicals and biofuels is important.

Utilization of bagasse to produce lactic acid (LA), one of the platform chemicals with diverse applications in the food, pharmaceutical, cosmetic, and polymer industry (Alves de Oliveira et al., 2018), has garnered significant interest. Integrating environmental assessment and techno-economic assessment is a way forward for the successful development of bagasse-based routes to produce value-added chemicals like lactic acid in a sustainable manner.

In this study, detailed environmental and techno-economic assessment is performed for an upstream technology developed at Vasantdada Sugar Institute (VSI) to produce LA from bagasse in the Indian context. Reactive distillation is employed for separation and purification of LA and is simulated using Aspen Plus[®]. The life cycle assessment (LCA) framework is employed to identify the environmental hotspots, and techno-economic evaluation has been performed to assess the economic viability.

2. Process Development

The methodology followed for developing the LA production route from bagasse is described in the following section. Upstream stages developed by VSI and downstream simulated using Aspen Plus[®] software are briefly discussed.

2.1. Process description

Detailed process technology developed by VSI is reported elsewhere (Nalawade et al., 2020). Upstream stages involve size reduction followed by alkali pretreatment with NaOH. In hydrolysis, cellulose and xylan present in the pretreated solid fraction are hydrolysed to fermentable sugars by Cellic CTec2 enzyme. The saccharified broth is filtered to remove the solid fraction, and the hydrolysate proceeds to fermentation. In fermentation, excess calcium carbonate (CaCO₃) is added to the hydrolysate to maintain the desired pH, along with yeast extract and inoculum. Glucose present in the broth is metabolized by *Bacillus coagulans* NCIM 5648 to produce L (+) lactic acid.

As shown in Eq. (1), LA present in the broth reacts with CaCO₃ to form calcium lactate. Acidification with sulfuric acid (H₂SO₄) liberates calcium lactate to form lactic acid, as shown in Eq. (2). The broth is then filtered to obtain a stream containing water and dilute concentrations of LA.

2.2. Downstream separation

In the downstream stage, the stream obtained after filtration is subjected to multi-effect evaporation to concentrate the LA to 40 %, followed by reactive distillation with ethanol in esterification column. In this column, LA reacts with ethanol to produce ethyl lactate and water, as shown in Eq. 3. Ethyl lactate, water, and unreacted ethanol obtained in the top stream are then fed to the hydrolysis column to undergo hydrolysis, as shown in Eq.

(3), to give 99.9 % pure lactic acid. The ethanol removed from the top is fed to the next column, where ethanol is separated by distillation and recycled.

The downstream separation of LA is simulated using process simulation software Aspen Plus[®]. Reaction kinetics and catalyst assumption data are taken from the literature (Su et al., 2013). UNIQUAC method is chosen as the property method, and evaporators are simulated using the flash model. RADFRAC is used to model the reactive distillation columns and DSTWU block for modeling the ethanol-water separation column.

3. Methodology

The LCA and TEA assessment has been performed for a LA facility with 104 tonnes per day production capacity, annexed with an existing sugar mill. The bagasse is assumed to be transported to the LA facility by trucks at a round trip distance of 100 km. Size reduction data is obtained from the literature (Shastri et al., 2012)(Moiceanu et al., 2019). Upstream stages are adjusted accordingly in a sequential batch process, so that downstream takes place in a continuous mode.

3.1. LCA Methodology

The methodology followed for LCA analysis is per ISO 14040. The goal of the LCA is to quantify the environmental impacts of bagasse based LA production facility annexed with an Indian sugar mill. The LCA model has cradle to gate scope, including stages of sugarcane farming, transportation, pretreatment, hydrolysis, fermentation, and downstream. The system boundary of the LCA analysis can be seen from Figure 1. 1 kg of LA is chosen as a functional unit.

Inventory data for farming (Mandade et al., 2016) and transportation (Murali and Shastri, 2019) specific to India are taken from literature. Economic allocation method is used to allocate these impacts for bagasse. Carbon sequestration of biomass and avoided impacts due to bagasse valorization are not included in the study. Experimental data provided inputs to the upstream stages, and process simulations are used for downstream data. Emissions data for producing the enzyme, an input to the hydrolysis stage, are adapted from literature (Sreekumar et al., 2020). The LCA model is developed in OpenLCA, and Ecoinvent[®] database is used for inventory. Recipe (H) mid-point indicators methodology is used for impact assessment.

3.2. TEA Methodology

An economic evaluation of the LA facility annexed to an existing sugar mill is performed to determine the product cost as reported in Table. 1. Equipment cost for pretreatment is calculated by designing the reactor using engineering design principles. Whereas the equipment cost for other upstream stages is adapted from the literature by scaling the cost

using the six-tenth rule and downstream from Aspen Plus® process economic analyzer. The facility is assumed to operate for 330 days. Bagasse is priced at \$54/tonne and costs of cooling water, natural gas, and boiler water are taken as \$0.54/m³, \$1.22/m³ and \$1.86/MMBTU, respectively. Electricity required for the LA facility is assumed to be supplied by the cogeneration plant in the sugar mill. The cooling tower assumed to be part of the sugar mill's infrastructure is not included in the costing.

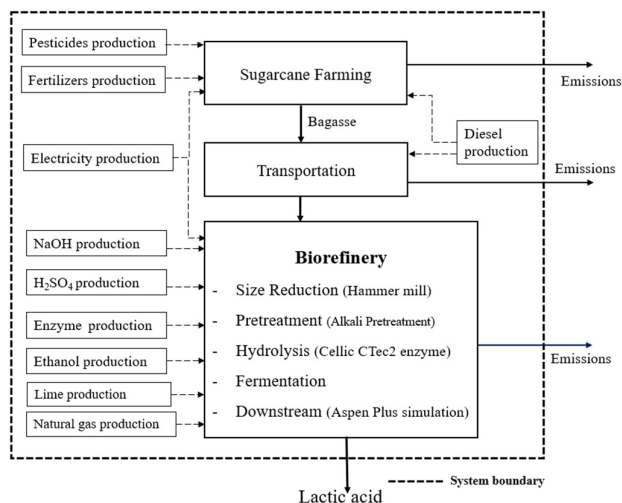

Figure 1: System boundary considered for LCA analysis of bagasse based LA production

Table.1: Economic assessment methodology followed for the LA facility

Economic Estimation Summary

Procurement Cost = 1.15 * Equipment Cost

Fixed Capital Cost (FCC) = Procurement Cost / 0.4

Working Capital = 0.15 * FCC

Total Capital Investment = Fixed Capital + Working Capital

Fixed Operating Cost (FOC): Maintenance = 0.05 * FCC; Operating labour (OL) = (0.5-0.15) * TOC; Laboratory Cost = 0.2 * OL; Supervision = 0.2 * OL; Plant Overheads = 0.5 * OL; Insurance = 0.01 * FCC; Capital Charges = (FCC * economic life of plant) /100; Local taxes = 0.02 * FCC; Royalties = 0.01 * FCC

Variable Operating Cost (VOC) = Raw material Cost + Utilities

Total Operating Cost (TOC) = Fixed Operating + Variable Operating Cost

General Overhead (GO) = 0.25 * TOC

Annual Production Cost = TOC + GO

4. Results and discussion

Environmental assessment results revealed that the life cycle climate change impact for the bagasse-based LA process was 4.62 kg CO₂ eq. per kg LA. Figure 2 shows the

pretreatment stage as a major environmental hotspot for GHG emissions. Adverse impacts associated with NaOH manufacturing, an input to the pretreatment stage, alone resulted in 2.66 kg CO₂ eq. emissions. Whereas, enzyme production and sugarcane farming resulted in 0.78 and 0.42 kg CO₂ eq. emissions respectively. Recently published LCA studies on corn-based LA (Ögmundarson et al., 2020) and vine based LA (Pachón et al., 2020) reported life cycle GHG emissions as 7.9 kg CO₂ eq. and 3.26 kg CO₂ eq., respectively. They also reported that the usage of chemicals such as lime, triethanolamine majorly contributed to GHG emissions. However, Nature works reported relatively lower emissions for corn-based LA production at 1.53 kg CO₂ eq. per kg of polylactic acid produced (Vink et al., 2010). This lower value can be attributed to the improved fermentation technology that required less CaCO₃ and absence of pretreatment stage.

Figure 2: Stage-wise distribution of GHG emissions for bagasse based LA production

LCA analysis revealed water depletion and agricultural land occupation of the LA process as 18.89 m³ and 1.02 m²a, respectively.

From economic evaluation, the total capital investment and total annual operating cost of the LA facility were estimated at 69.86 Million \$ and 86.50 Million \$, respectively. The product cost for LA was \$3.27/kg (Rs.242/kg) when bagasse was not free, with hydrolysis and pretreatment stage contributing to 38 % and 36 % of this product cost. Higher costs associated with hydrolysis and pretreatment stage was due to enzyme and NaOH requirement. For a 10.32% internal rate of return and 6 years payback period, the LA price was found to be \$3.58/kg (Rs. 265/kg). The total capital investment value presented in this work agrees with a study based on an economic evaluation of LA biorefinery (Manandhar and Shah, 2020) upon scaling to the same production capacity.

If bagasse was available for free, LA production cost and LA price to achieve 6 years payback time with 10.32% internal rate of return were \$2.9/kg (Rs.215/kg) and \$3.21/kg (Rs.237/kg), respectively. Sensitivity analysis was also performed for key parameters to identify opportunities to reduce the life cycle impacts and production cost.

5. Conclusions

The production of LA from bagasse was found to be economically viable based on the proposed process, with the market price of commercially produced LA at \$ 3/kg. Solid loading in pretreatment, the amount of NaOH used for pretreatment, and enzyme quantity used in the hydrolysis stage were three significant factors affecting the production cost and the life cycle GHG emissions of the LA process. Recycling of NaOH used in the pretreatment process can result in environmental and economic benefits of the bagasse based LA process.

Abstract

Compared to conventional petroleum-based polymers, biopolymers like polyhydroxyalkanoates are a promising alternative as raw material for manufacturing of plastics. One way to reduce the microbial PHA production costs is to use organic wastes from agriculture and food industries, which contain a wide range of carbon sources. Two organic waste carbon sources are fructose, present in fruit juice waste and acetate, present in waste from wine or biogas production. Simulations using kinetic models can help to reduce the range of optimal substrate combinations and thus prevent time-consuming and costly experimental investigations. This contribution outlines an extended hybrid cybernetic model for the polyhydroxybutyrate production in *Cupriavidus necator* growing on fructose, acetate, and nitrogen. Data from bioreactor experiments are used for the adjustment of the kinetic parameters and for the validation of the hybrid cybernetic model. The new model is able to precisely predict the dynamic behavior of hydroxybutyrate while co-feeding with fructose and acetate. Finally, our model is used in a computational study to analyze different initial carbon/ammonium ratios and oxygen partial pressures with respect to the maximum hydroxybutyrate concentration.

Keywords: Polyhydroxyalkanoates, Hybrid Cybernetic Modeling, *Cupriavidus necator*, carbon/ammonium ratio, oxygen partial pressure

1. Introduction

In recent decades, plastic pollution has come more and more into focus. Besides large plastic carpets, there is also a huge amount of microplastic beneath the ocean's surface. Due to the ingestion of these particles by aquatic animal species, our garbage ultimately ends up on our plate. In addition to personal rethinking towards reusable packaging materials and optimizing the recycling stream, investigations of less durable alternatives to conventional plastic raw materials are necessary. Polyhydroxybutyrate (PHB) from the group of polyhydroxyalkanoates (PHA) is one example of a suitable raw material that can be used to replace conventional plastic (Sabapathy *et al.*, 2020). PHA is biodegradable in the environment, non-toxic and bio-based since PHA can be produced using a wide variety of microorganisms. The best examined representative is *Cupriavidus necator* (*C. necator*), which was also used in this work. Compared to the production of conventional plastic raw material, PHA production is very expensive. The costs of the

process can be reduced by using inexpensive substrates (Riedel *et al.*, 2015), intelligent control strategies (Morabito *et al.*, 2019) or adapting production process conditions (Lopar *et al.*, 2013). Mathematical models can help to avoid costly experimental investigations by simulating a large number of possible process conditions and investigating the product yield.

This contribution presents a hybrid cybernetic model (HCM) with two carbon sources as inputs, which typically occur in waste from juice, wine or biogas production. The model is based on our previous approach in (Duvigneau *et al.*, 2020). In contrast to this, additional experimental data for a mixture of fructose and acetate as carbon sources and additional elementary modes (EMs) were considered. It is shown that the extended model is able to reproduce the experimental data significantly better. Further, the growth rate expression is extended to account explicitly for different oxygen partial pressures in the culture broth which has a major influence on the maximum concentration of hydroxybutyrate (HB). Finally, the HCM is used to correlate different carbon/ammonium (C/N) ratios and oxygen partial pressures (pO_2) and to evaluate them with regard to the maximum concentration of HB. The preliminary analysis with our mathematical model makes it possible to identify suitable initial substrate concentrations for precise experimental screening studies.

2. Experimental Methods

The strain *Cupriavidus necator* (H16, DSM 428) obtained from DSMZ GmbH Braunschweig was used in the presented experiments. The experimental data set with acetate as single carbon source was obtained as described in (Duvigneau *et al.*, 2020). For the other two data sets, the strain was cultivated in a DASGIP parallel bioreactor system (Eppendorf, Jülich) with 1 L working volume. The initial and cultivation conditions are summarized in Table 1. Ammonium concentrations were determined from supernatants of the samples using an enzymatic test kit (R-Biopharm AG, Darmstadt, Germany) and following the manufacturer's instructions.

Acetate, HB and cell dry weight (total biomass) concentrations were determined as described in (Duvigneau *et al.*, 2020). Fructose concentrations were determined with high performance liquid chromatography (HPLC, Agilent Infinity II 1290, Agilent, Waldbronn, Germany). For this, 10 μ L of the filtered supernatant was loaded on an RHM-Monosaccharide ion exchange column (Phenomenex, Torrance, USA) and eluted isocratically with 0.6 $mL \cdot min^{-1}$ DI-water at 80 $^{\circ}C$. The fructose peaks were detected with a refractive index detector (G7162A, Agilent, Waldbronn, Germany) at 40 $^{\circ}C$.

Table 1: Cultivation conditions

data set	[FRU(0), ACE(0), $NH_4Cl(0)$] in g/L	media	T in $^{\circ}C$	pO_2 in %
I	[22, 0, 1.7]	M81 ¹	30	70
II	[26, 4.4, 1.4]	M81 ¹	30	5

¹ Recipes for the Medium 81 can be found in (Franz *et al.*, 2011) or on the web page of the DSMZ.

3. Mathematical Model

Differential equations for the substrates (fructose, acetate, ammonium), HB content and the total cellular biomass are defined as follows:

$$\frac{d}{dt} \begin{bmatrix} x_{fru} \\ x_{ace} \\ x_N \end{bmatrix} = \mathbf{S}_S \mathbf{Z} \mathbf{r}_M \mathbf{c}, \quad \frac{dm_{HB}}{dt} = \mathbf{S}_{HB} \mathbf{Z} \mathbf{r}_M, \quad \frac{dc}{dt} = \mu c \quad (1)$$

The EM matrix in yield space for the substrates $\mathbf{S}_S\mathbf{Z}$ consists of the stoichiometric information of the metabolic network. The metabolic model was derived in (Duvigneau *et al.*, 2020) from models published in (Franz *et al.*, 2011) and (Yu and Si, 2004). The Monod-type kinetic in $r_{M,i}$ (see Equation (5)) expresses influence of substrate concentrations for each selected EM. Internal metabolites, except for internal storage material such as PHB, are assumed to have fast dynamics compared to the external substrates and do not need a model equation. The EM matrix in yield space for HB $\mathbf{S}_{HB}\mathbf{Z}$ describes normalized consumption and production of HB in yield space.

The growth rate μ consists of a rate vector \mathbf{r}_M , the EM matrix for the normalized biomass production $\mathbf{S}_c\mathbf{Z}$ and a proportional factor K_μ :

$$\mu = \mathbf{S}_c\mathbf{Z}\mathbf{r}_M K_\mu \quad (2)$$

The proportional factor K_μ can be calculated for each experimental setup with respect to the pO_2 in the culture broth by using the following correlation:

$$K_\mu = \frac{\mu(pO_2)}{\mu(70\%)} \quad \text{with} \quad \mu(pO_2) = -0.151pO_2 + 0.256 \quad (3)$$

Further, the use of enzymes for each chosen EM is characteristic for the hybrid cybernetic approach:

$$\frac{de}{dt} = \alpha + \mathbf{r}_{EM}b - \beta\mathbf{e}, \quad \text{where } e_i^{\text{rel}} = \frac{e_i}{e_i^{\text{max}}} \quad \text{with } e_i^{\text{max}} = \frac{\alpha_i + k_{e,i}}{\beta_i + k_{r,i}(\mathbf{S}_c\mathbf{Z})_i} \quad (4)$$

The increase of the enzyme level occurs via the constitutive enzyme synthesis rate α and the catalytically active part of the total biomass b . Monod-type kinetics \mathbf{r}_{EM} (Equation (5)) control the catalytically active biomass fraction. The term $-\beta\mathbf{e}$ represents the enzyme degradation by a protein turnover (β). Compared to the previous model description, the dilution terms $-\mu m_{HB}$ and $-\mu \mathbf{e}$ were excluded in Equation (1) and (4), respectively.

A general description of rates r_M and r_{EM} of the i^{th} EM is

$$r_{M,i} = v_i k_{r,i} e_i^{\text{rel}} r_{\text{core},i} \quad r_{EM,i} = u_i k_{e,i} r_{\text{core},i} \quad (5)$$

The rate r_{core} of the i^{th} EM is a multiplied Monod-type kinetic:

$$r_{\text{core},i} = \frac{X_1}{K_{X_1} + X_1} \cdots \frac{X_n}{K_{X_n} + X_n} \quad (6)$$

The number of negative yield coefficients (consumption terms) in each EM defines the number of factors given in Equation (6). For the regulation of enzyme synthesis and activity, cybernetic control variables u and v are introduced and calculated by cybernetic control laws as described in the publication of (Young and Ramkrishna, 2007).

The matrix of all normalized EMs $\mathbf{SZ} = [\mathbf{S}_S\mathbf{Z}, \mathbf{S}_{HB}\mathbf{Z}, \mathbf{S}_c\mathbf{Z}]$ was obtained in (Duvigneau *et al.*, 2020). The selection of EMs describing the co-feeding with fructose and acetate was done during parameter estimation of the kinetic parameters \mathbf{k}_r for those modes. For this, the set of 38 generating modes from yield analysis of the underlying metabolic model was used to find a sufficient EM candidate (Song and Ramkrishna, 2009; Duvigneau *et al.*, 2020).

The model was implemented and solved numerically in *MATLAB2019b*. Parameter adjustment of rates \mathbf{k}_r was performed using the *MATLAB* routine *fmincon* with a lower boundary zero and a multi-start approach with $n=1000$ by minimizing the following objective function

$$\text{ESS} = \sum_{i=1}^n \left(\frac{\mathbf{x}_{\text{exp}}(t_i) - \mathbf{x}_{\text{sim}}(t_i)}{\max(\mathbf{x}_{\text{exp}})} \right)^2. \quad (7)$$

Kinetic parameters \mathbf{k}_r are shown in Table 2. All other 49 parameters of the model were kept as described in (Duvigneau *et al.*, 2020).

4. Results

Figure 1 (dashed lines) shows the dynamics for the substrates and products after simulation of the model in (Duvigneau *et al.*, 2020) applying the initial condition of data set II (acetate and fructose as carbon sources).

The model already delivers a qualitatively good result without the inclusion of EMs with both substrates as input.

After inclusion of these EMs and the kinetic parameters \mathbf{k}_r of these EMs (set A) the model simulation shows the consumption of both carbon sources at the same time (diauxic growth), but underestimates the final biomass by approx. 20 %. The simulation result with set A can be seen as solid lines in Figure 1.

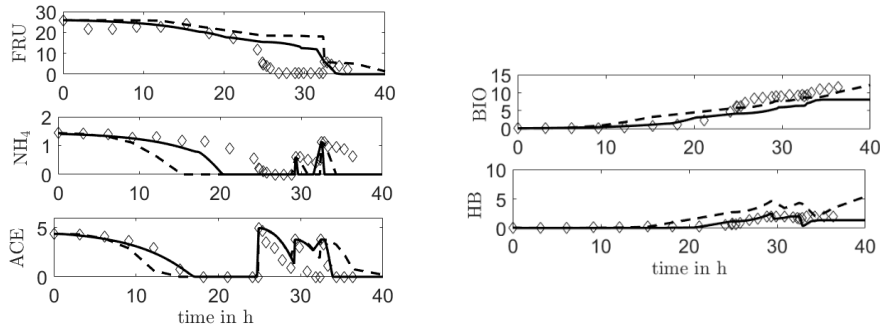

Figure 1: Model simulation and experimental data set II (fructose and acetate co-feeding, diamonds) using the model of (Duvigneau *et al.*, 2020) (dashed lines) and the adapted version with respect to the kinetic parameters \mathbf{k}_r of the EMs with acetate and fructose as co-substrates (solid lines, set A). Legend: FRU, fructose; NH_4 , ammonium; ACE, acetate; BIO, total biomass; HB, hydroxybutyrate. All concentrations are given in g/L.

In general, precise data sets with controlled and constant process conditions are required for adapting kinetic models (Carius and Findeisen, 2016). The data sets from (Duvigneau *et al.*, 2020) and data set II were obtained from different cultivation systems and hence, differ in their dynamic behavior. For this reason, data sets I and II as well as the data set with acetate as the single carbon source from our previous publication were selected for a new adjustment of the kinetic parameters \mathbf{k}_r . The data sets only differ in the available carbon source and $p\text{O}_2$ (see Table 1). A proportionality factor K_{μ} can be determined with Equation (3). This leads to an increased growth at lower $p\text{O}_2$. Furthermore, dilution terms in the differential equations for the HB content and the hybrid cybernetic enzymes have been eliminated (Equations (1) and (4)). The result of adapting the new model to the above-mentioned data sets can be seen in Figure 2. Now, the concentrations of HB and

biomass can be simulated more precisely. All model simulations show an overestimation for fructose between 25 and 30 h. This discrepancy between simulation and experimental data could be compensated by considering maintenance, energy generation or CO₂ due to the activity of the central metabolism.

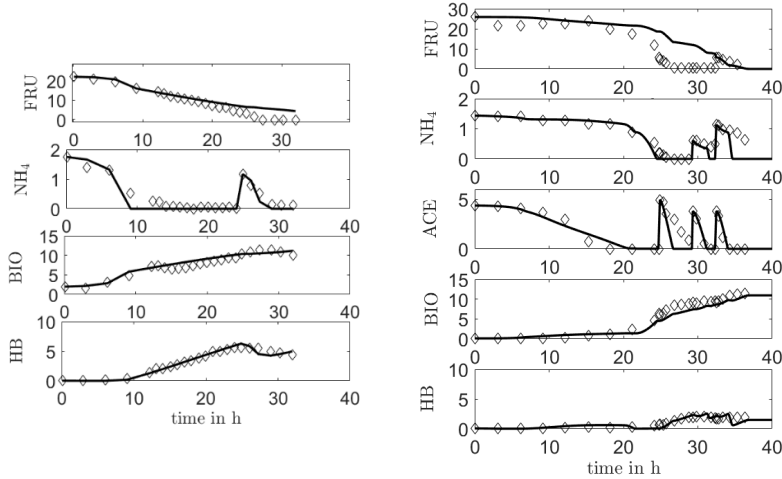

Figure 2: Model simulation and experimental data set I (left) and data set II (right) using the restructured and adapted model. Legend: FRU, fructose; NH₄, ammonium; ACE, acetate; BIO, total biomass; HB, hydroxybutyrate. All concentrations are given in g/L.

The new model can be used to analyze different initial conditions with respect to the maximum product concentration. Besides a well-chosen ration of fructose and acetate (FRU/ACE ratio), ammonium in the culture broth promotes the growth of non-PHB biomass. Thus, the C/N ratio can also be decisive. Figure 3 shows a simulation study using different C/N ratios and pO₂ while keeping the initial concentrations for the carbon sources as in data set II. The model study delivers one very interesting result: with decreasing pO₂, a higher C/N ratio can be selected, so that a higher maximum HB concentration is reached.

Figure 3: Model study with different carbon to ammonium ratios (C/N) and oxygen partial pressures (pO₂). Selected pO₂ levels are shown in the legend.

5. Conclusion

In the presented work an HCM was adapted to experimental data with fructose and acetate as carbon sources. Diauxic growth is one of the effects that can be described very well with a hybrid cybernetic approach (Song, Morgan and Ramkrishna, 2009). By changing the kinetic parameters, it is also possible to describe diauxic growth in the presence of fructose and acetate with the model presented in this manuscript. By including the pO_2 in the model structure further improvement of the model can be achieved.

Finally, we investigate different C/N ratios and pO_2 levels with respect to the maximum product yield. Therein, lower pO_2 values lead to higher HB concentrations. In addition, a different C/N ratio should be selected for each pO_2 level in order to achieve an optimal production yield. Future work will focus on an extension of the model study using different initial carbon concentrations, experimental validation of the results shown here and a comparison of the pO_2 effect with other factors e.g. temperature variations.

Abstract

Compared to crude oil-based polymers, biopolymers like polyhydroxyalkanoates represent a promising raw material to produce plastics as they feature eco-friendly desirable properties such as biodegradability and non-toxicity. Moreover, polyhydroxyalkanoates can be produced by a wide range of microorganisms from organic material under phosphorus, nitrogen, or oxygen limitation. This motivates application of microbial production processes for valorization of organic wastes from agriculture and food industries, containing a wide range of carbon sources. Mathematical modeling of cellular metabolism as well as polymer formation is necessary for sophisticated process control and intensification. In this contribution, a multi-scale model for PHB production in *Cupriavidus necator* under limiting conditions is presented, which accounts for the dynamics of the chain length distribution and also the intracellular regulation of the cellular metabolism. While the dynamics of chain length distribution is described by a population balance model, cellular metabolism is characterized by a hybrid cybernetic model.

Keywords: Polyhydroxyalkanoates, Polymerization, Population Balance Modeling, Multiscale Modeling

1. Introduction

Due to the existing global waste problem, the demand for alternatives to conventional plastic is continuously increasing. Polyhydroxybutyrate (PHB) from the group of polyhydroxyalkanoates (PHAs) is bio-based and, above all, biodegradable and therefore represents a suitable alternative. In addition, PHAs can be produced by a large variety of microorganisms (Jendrossek and Pfeiffer, 2014; Singh et al., 2018). One common PHA producer is *Cupriavidus necator* (*C. necator*), which was also used in this work. In addition to precise measurements and predictions of overall PHA concentrations, the specific structure of the polymer chains in terms of chain length and composition, is an important property which is related to physical properties, like melting point and brittleness (Laycock et al., 2014). Thus, there is an increasing interest for production of PHAs of specific structure to meet certain product requirements.

In this context, multi-scale mathematical modeling of the cellular metabolism and polymer chain formation supports experimental investigations. Early modeling approaches used only little structural information from metabolic networks to explain the general dynamics of the polymer production (Heinzle and Lafferty, 1980). Starting in the

1990s, first structural information on reaction kinetics and metabolic regulation was added (Leaf and Srien, 1998). Further models used small metabolic reaction networks to describe PHB production more precisely for mixed microbial cultivations (Dias et al., 2005). Coupling of the thereby described dynamics on the reactor scale to chain formation models have been presented employing a population balance modeling framework to describe the dynamics of chain length distribution (CLD) (Penloglou et al., 2010, 2012a,b, 2017; Mantzaris et al., 2002). Those are derived from similar models characterizing chemical polymer formation in bulk solution or emulsion (Butté et al., 2002; Kiparissides, 2006; Vale and McKenna, 2005) and can be solved with established numerical techniques (Kumar and Ramkrishna, 1996; Krallis et al., 2008). Further extensions include modeling of block-copolymer chains (Krallis et al., 2008; McChalicher and Srien, 2007). Those models have been used for the development of control concepts (Penloglou et al., 2017; Mantzaris et al., 2001; Iadevaia and Mantzaris, 2006) for the design of polymers with desired properties.

A shortcoming of the previous approaches is that they lack detailed information on the cellular metabolism, in particular intracellular regulation. As an alternative to dynamic flux balance analysis, the hybrid cybernetic modeling (HCM) approach developed by Ramkrishna and coworkers (see (Ramkrishna and Song, 2018) and the references therein) can be used to take into account optimal and detailed metabolic regulation (resource allocation) with respect to existing substrates. This is achieved by introducing hybrid cybernetic control variables.

In this contribution, we will present a multi-scale model for PHB formation in *C. necator* which combines an HCM and a dynamic model for CLD dynamics. Therein, two different carbon sources, namely fructose and acetate, are considered (Duvigneau et al., 2020).

2. Model Formulation

The proposed multi-scale model consists of a state-of-the-art HCM (Duvigneau et al., 2020) characterizing the cellular metabolism and intracellular regulation which is complemented by a population balance model describing dynamics of the PHB chain length distribution Penloglou et al. (2017).

The HCM in (Duvigneau et al., 2020) represents a set of ordinary differential equations that describes the temporal evolution of concentrations of substrates fructose, acetate and ammonium but also total biomass concentration and intracellular PHB content

$$\begin{aligned} \frac{d}{dt}(x_{fru} \ x_{ace} \ x_N) &= S_S \cdot Z \cdot r_M \cdot c, \\ \frac{d}{dt}(c \ m_{PHB}) &= (S_c \cdot Z \cdot r_M \cdot c \ S_{HB} \cdot Z \cdot r_M - \mu \ m_{PHB}) \end{aligned} \quad (1)$$

with the Monod-type kinetics r_M and selected active modes (AMs) for substrates, biomass and biopolymer $S_S \cdot Z$, $S_c \cdot Z$, $S_{HB} \cdot Z$, which are determined by metabolic yield analysis (Song and Ramkrishna, 2009). The kinetic rates r_M are controlled by so-called cybernetic control variables which represent intra-cellular regulation of enzyme activity. Further, the HCM includes by the enzyme dynamics for each AM

$$\frac{de}{dt} = \alpha + r_{EM} \cdot b - \beta \cdot e - \mu \cdot e. \quad (2)$$

To account for the dynamics of the chain length distribution, the HCM is complemented

by a population balance model (Vale and McKenna, 2005). Here, polymers from HB-monomers are distinguished into active (living) and inactive (dead) polymer species, $[LP]_i$ and $[DP]_i$. The dynamics of their CLDs are described by

$$\begin{aligned}\frac{d[LP]_i}{dt} &= \delta(i-1)k_{ini}[MonSyn] + k_{m2}[Mon]([LP]_{i-1} - [LP]_i) - k_{term}[LP]_i \\ \frac{d[DP]_i}{dt} &= k_{term}[LP]_i - k_{dep}([DP]_i - [DP]_{i-1})\end{aligned}\quad (3)$$

where $[e]_i$ denotes the number density distribution of chains with distinct chain length i .

In contrast to Penloglou et al. (2017), the species of intermediate polymers is neglected in our formulation. The dynamics of the monomer concentration and the monomer-synthase complex are given by

$$\begin{aligned}\frac{d[Mon]}{dt} &= -k_1[Mon][Syn] - k_{m2}[Mon]\sum_{i=1}^{\infty}[LP]_i + [Mon]^+ \\ \frac{d[MonSyn]}{dt} &= k_1[Mon][Syn] - k_{ini}[MonSyn]\end{aligned}\quad (4)$$

Under the assumption, that both are not accumulated, i.e., monomers are directly polymerized and constant synthase concentration $k_{m1} = k_1[Syn] = const.$, steady states for both are derived as

$$[Mon]^* = \frac{[Mon]^+}{k_{m1} + k_{m2}\sum_{i=1}^{\infty}[LP]_i}, \quad [MonSyn]^* = \frac{k_{m1}[Mon]^+}{k_{ini}}\quad (5)$$

The total amount of PHB is now given by

$$\begin{aligned}\frac{1}{MW_{HB}}\frac{dc_{m_{HB}}}{dt} &= \frac{d}{dt}\left\{\sum_{i=1}^{\infty}i([LP]_i + [DP]_i)\right\} \\ &= k_{ini}[MonSyn]^* + k_{m2}[Mon]^*\sum_{i=1}^{\infty}[LP]_i - k_{dep}\sum_{i=1}^{\infty}[DP]_i \\ &\quad r_{PHB}^+ MW_{HB}^{-1} \quad r_{PHB}^- MW_{HB}^{-1}\end{aligned}\quad (6)$$

with the molecular mass of a HB-monomer MW_{HB} . The PHB-production and depletion rates r_{PHB}^+ and r_{PHB}^- can be derived from the HCM. Taking all above considerations into account the production rate of monomers $[Mon]^*$ and the depolymerization rate k_{dep} are given as

$$[Mon]^+ = \frac{r_{PHB}^+}{MW_{PHB}}, \quad k_{dep} = \frac{r_{PHB}^-}{MW_{PHB}\sum_{i=1}^{\infty}[DP]_i}\quad (7)$$

3. Numerical Solution

The overall model (1)-(6) consists of a large-scale system of ordinary differential equations. As the average chain length is in the order of 10^6 , simulation of each single chain length class is unfeasible. To scale the computational effort to an approachable scale the Fixed-Pivot-Method (Kumar and Ramkrishna, 1996; Saliakas et al., 2007) was

applied to divide the chain length scale into 100 different pivots. The resulting system of 220 ODEs was solved numerically in MATLAB using ode15s and the parameters reported in Duvigneau et al. (2020) for the HCM-model. Due to lack of experimental data of PHB CLDs, parameters of the polymerization model were chosen such that the obtained CLDs are in ranges reported for microbial PHB production (Kawaguchi and Doi, 1992).

4. Results

The simulation scenarios followed in this contribution have been presented first in Duvigneau et al. (2020) and are based on two different experimental runs with either acetate or fructose as carbon supplying substrate. In Fig. 1 the simulation results for substrates and overall biomass and PHB are shown along the experimental records. It is seen that the amount of PHB of the macroscopic HCM and the microscale polymerization model are the same. It can thereby be inferred that the applied numerical scheme provides an accurate solution for the latter. In Fig. 2, characteristics of the overall CLD (active +

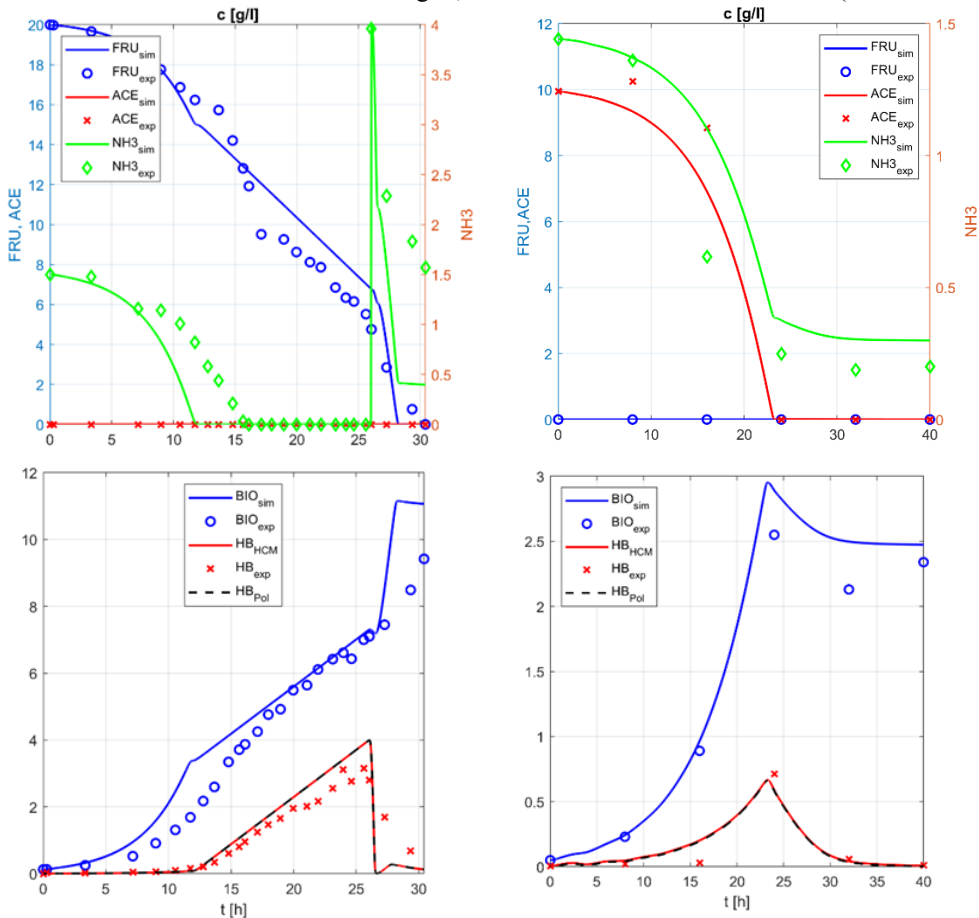

Figure 1: Macroscopic dynamics for scenario I (left, fructose) and scenario II (right, acetate)

inactive polymer chains) are depicted. It is seen that the addition of ammonium in the first scenario (fructose as the single carbon source) results in general PHB consumption, represented by a flattening CLD. However, for $t > 27h$ the kinetic model predicts a small increase of PHB for a short time range. This is also seen from the increased CLD in Figure 2. The model also indicates that for $t > 28.5h$ the CLD flattens out as PHB is metabolized and the chain depolymerize. For the second scenario (acetate as single carbon source), a similar effect is visible after acetate is depleted for $t > 24h$. The intracellular PHB is metabolized as ammonium is still present in the medium resulting in a flattening CLD. For both cases, the number average molecular mass is in the order of 10^6 while the polydispersity index is around 2 and thereby within ranges reported by Kawaguchi and Doi (1992).

5. Conclusion

In this contribution a multi-scale model for PHB formation was presented, which links a state-of-the-art HCM with a detailed description of the chain length distribution dynamics. To the best of our knowledge, this is the first multi-scale model which is able to describe PHB formation on two different carbon sources combining a medium scale metabolic model, optimal intracellular regulation and polymerization kinetics at the same time. The simulation delivers reasonable average chain lengths in the right order of magnitude and will be a valuable tool for future investigations.

Figure 2: Overall chain length dynamics for scenario I (left, fructose) and scenario II (right, acetate)

Future work will be concerned with model calibration using own data from experiments with *C. necator*. Afterwards, the multi-scale model shall be used for optimization of substrate feeding strategies to obtain high PHB molecular weights. Furthermore, the model could be extended to include additional carbon sources and account for co-polymer formation.

Abstract

Systems biology is a field where Process System Engineering has an immense potential for contribution. The first step in applying Systems Biology to a given problem is to characterize potential microorganisms to be used for a transformation of interest. One basic characterization is to estimate what are the extents of the reactions that take place inside the cell, which is called flux analysis. In this contribution, we present an application of identifiability analysis to ¹³C-Metabolic Flux Ratio Analysis (¹³C-MFA), which is essentially a parameter estimation problem. A simple and precise way to assess if an experiment would give a unique solution for all flux ratio estimates is important for the successful use of ¹³C-MFA. In this work, the principal components (PC) of the Hessian matrix were evaluated to assess the identifiability of metabolic fluxes on labeling experiments. A recently proposed sparse PC calculation was used for that end and compared with classic PC. This approach was applied to the estimation of metabolic flux ratios of the central metabolism of *Pseudomonas aeruginosa* producing polyhydroxyalkanoates (PHA). The results indicated that sparse PC make it straightforward to interpret dependencies among fluxes, and that the substrate [6-¹³C]glucose is the best option for labeling experiments with *Pseudomonas aeruginosa*. The identifiability analysis also showed that the exchange rates of the PP pathway cannot be estimated uniquely, just some combinations of a reduced set of them are identifiable. In contrast, the flux through the Entner-Doudoroff Pathway can be estimated with high accuracy. The results presented here indicate that applying identifiability analysis to ¹³C-MFA can reduce experimental costs and increase estimation precision.

Keywords: Identifiability, ¹³C-MFA, Metabolism, Systems Biology, Metabolic Engineering

1. Introduction

Metabolic Engineering is a field that aims to assist in the development of new strains for sustainable production of valuable bioproducts. In essence, it consists of applying mathematical models to guide genetic modification in cells in order to obtain higher yields and productivity (Sauer, 2006). Among the tools that have been developed in the field, ^{13}C -Metabolic Flux Ratio Analysis (^{13}C -MFA) emerged as a powerful tool to describe the metabolism of a cell (Sauer, 2006) by estimating the flux distribution of metabolites. Figure 1 illustrates how this method works; first a carbon 13 labeled substrate is used in the culture medium (e.g. $[6-^{13}\text{C}]$ glucose), then the labeling goes through the internal metabolites until it reaches a bioproduct. The labeling pattern in the bioproduct is a function of the pathway that was used by the cell, and each pathway shuffles the labeling differently. Finally, the labeling in the bioproduct is measured by techniques such as Gas Chromatography-Mass Spectrometry (CG-MS) and Nuclear magnetic resonance (NMR). Using a metabolic network model, an estimation problem is formulated and solved and the flux distribution inside the cell estimated. Determining precisely what fluxes can be estimated from a given experiment architecture (i.e. labeling substrate and bioproducts measurements) is crucial due to the high experimental cost associated with carbon labeling experiments.

The Process System Engineering community has given important contributions to the identifiability of nonlinear model parameters, and identifiability studies on ^{13}C -MFA have also been conducted (van Winden et al., 2001; Kappelmann et al., 2016). However, most of them focus on structural identifiability and not on practical identifiability. Here, the well-known Principal Component Analysis (PCA) is applied to identify nonlinear relations between metabolic fluxes in ^{13}C -MFA. Also, a recently developed methodology to obtain sparse PC is applied (Nakama et al., 2020). As a case study, the identifiability of metabolic flux ratios of the central metabolism of *Pseudomonas aeruginosa* producing polyhydroxyalkanoates (PHA) is evaluated. PHA is a group of natural biodegradable polyesters and, to make its production economically feasible, their yield must be increased.

Figure 1: ^{13}C -MFA method flow diagram. The labeling substrate is metabolized by the cell that will shuffle the labeling pattern depending on the flux distribution. The labeling pattern of specific metabolites is measured by analytical techniques and using a metabolic network model the flux distribution can be estimated.

2. Methodology

The ^{13}C -MFA metabolic model consists of metabolite and carbon labeling (x) balances. The metabolic fluxes (v) were parameterized using the metabolite balances and

calculated in terms of the so-called free fluxes (v_{free}). The approach for parametrization of fluxes variables presented by Wiechert et al. (1999), where a bidirectional reaction has a net flux (v_{net}) and an exchange flux (v_{xch}), was also applied. The fluxes are then represented by

$$v = g(v_{free}), \quad v_{net} = v^{\rightarrow} - v^{\leftarrow}, \quad v_{xch} = \min(v^{\rightarrow}, v^{\leftarrow}) \quad (1)$$

The labeling balance (2) is a system of bilinear equations. By performing a linear transformation of the variables (Wiechert et al., 1999), it is possible to compute the sensitivities of the labeling of measured components with respect to the free fluxes in an explicit form (3).

$$f(x, x_{inp}, v_{free}) = 0, \quad y = h(x) \quad (2)$$

$$\frac{\partial y(x, v_{free})}{\partial v_{free}} = \frac{\partial y(x)}{\partial x} \cdot \frac{\partial x(v_{free})}{\partial v_{free}} \quad (3)$$

where x_{inp} is the labeling of the substrate and y the labeling of the measurements. PCA was applied to assess the identifiability of the parameters of the nonlinear model and select a subset of parameters that can be estimated with high accuracy (Vajda et al., 1989). The method consists in computing the Hessian matrix (H) obtained by the Gauss-Newton approximation, using normalized sensitivities. Then, its PCs are obtained with the Singular Value Decomposition (SVD) as follows:

where V is the matrix of PCs (eigenvectors of H) and Σ the matrix with the eigenvalues of H. The PCs of H represent linear combinations of the original parameters, which may indicate dependencies between parameters. However, because these matrices are normally dense, finding combinations with a reduced number of relevant parameters can be challenging. Recently, Nakama et al. (2020) developed a method to compute sparse PC that are orthogonal to the components associated with small eigenvalues, which can be particularly blamed for the large variance in the parameters. In this work, both PC and sparse PC were computed to evaluate the identifiability of metabolic fluxes. The ^{13}C -MFA metabolic model was implemented in MATLAB_{v2015a} and the sparse eigenvector decomposition was calculated in Julia.

3. Case study

To evaluate the efficiency of this new methodology, a small but challenging estimation problem of ^{13}C -MFA was selected. This case study is based on the work of Riascos et al. (2013), which consists of the estimation of metabolic flux ratios of the central metabolism of *P. aeruginosa* producing PHA with only few measurements available. Usually, the ^{13}C -MFA method is applied under growth conditions and the labeling measurements of amino acids are available (Sauer, 2006). However, PHA production by *P. aeruginosa* mainly occurs under non-growth conditions and, in this case, only the measurements of PHA mass isotopomer are available (Riascos et al., 2013). The metabolic network of *P. aeruginosa* used in this work is presented in Figure 2. It uses glucose as the sole carbon source and PHA is the only bioproduct. There are two

options to metabolize glucose into PHA, either by the Pentose Phosphate (PP) pathway, or by the Entner-Doudoroff (ED) pathway, which can also operate in a cyclic mode. Riascos et al.(2013) estimated the metabolic fluxes ratios on *P. aeruginosa* using data from an experiment with 80% of [U-¹³C]glucose and made the hypotheses that the ED pathway operates only in linear mode and the PP pathway without reversible reactions. However, those hypotheses are not necessarily valid and, in this case, these pathways would shuffle the labeling of PHA mass isotopomers (Kohlstedt and Wittmann, 2019).

Figure 2: *Pseudomonas aeruginosa* metabolic network.

In this work, the effect of considering the aforementioned pathways in the fluxes ratio estimation problem is evaluated by an identifiability analysis. The network has 15 reactions (including three reversible reactions from the PP pathway), 9 internal metabolites, and glucose uptake is fixed at the unity. Consequently, the system has five degrees of freedom, that is, five free fluxes. The chosen free fluxes are: the net flux of the oxidative PP pathway (PP_{oxi}); the net flux of the cyclic mode of the ED pathway (ED_{cyc}); and the exchange fluxes of the PP pathway ($PP_{xch.1}$, $PP_{xch.2}$, and $PP_{xch.3}$).

4. Results

The results presented in this section are based on a flux distribution similar to the one used by Riascos et al. (2013), in which part of the flux through the ED pathway was directed to its cyclic mode (Figure 2). PCs associated with small eigenvalues implies in a large variance of the estimates. Based on the standard deviations of measurements presented by Riascos et al. (2013), eigenvalues lower than 10^{-4} are considered small (Vajda et al., 1989). The eigenvectors (v) and eigenvalues (σ) of the Hessian matrix for the [U-¹³C]glucose experiment are presented in Table 1. Only one of the eigenvalues is above the threshold, indicating that the problem has identifiability issues with dependencies between parameters. The only component that can be estimated with a certain confidence is the flux through the cyclic mode of the ED. After analyzing a few commercially available labeled glucose, substrate [6-¹³C]glucose presented the best results regarding parameter identification. As it can be seen in Table 1, only two components are below the threshold. Although the problem still presents identifiability

issues, more parameters can be estimated with higher confidence with this experiment. Obtaining a more precise and physically meaningful combination of the parameters from data is not always a simple task (Vajda et al., 1989). For this reason, the sparse eigenvectors of the hessian matrix were calculated.

Table 1: Eigenvectors (PC) and corresponding eigenvalues of the Hessian matrix.

[U- ¹³ C]Glucose					
	V ₁	V ₂	V ₃	V ₄	V ₅
PP _{oxi}	-0.19	-0.06	0.08	-0.97	-0.14
ED _{cyc}	-0.92	0.36	0.04	0.16	0.01
PP _{xch1}	-0.08	-0.33	0.83	0.04	0.44
PP _{xch2}	-0.08	-0.29	0.33	0.19	-0.87
PP _{xch3}	-0.33	-0.82	-0.45	0.06	0.15
σ^2	0.17	8e-18	9e-19	5e-19	2e-20
[6- ¹³ C]Glucose					
	V ₁	V ₂	V ₃	V ₄	V ₅
PP _{oxi}	-0.07	0.35	0.29	-0.69	0.56
ED _{cyc}	0.37	-0.86	0.16	-0.24	0.20
PP _{xch1}	0.59	0.21	-0.32	0.39	0.59
PP _{xch2}	0.59	0.21	-0.32	-0.50	-0.50
PP _{xch3}	0.41	0.22	0.82	0.25	-0.20
σ^2	60.7	0.69	0.004	9e-16	1e-16

Sparse PCs were obtained using the methodology proposed by Nakama et al. (2020). Components v_4 and v_5 were removed and the other components were sparsified, keeping the orthogonality to v_4 and v_5 . Sparse PCs for the [6-¹³C]glucose experiment using the complete network are presented in Table 2. Now some combinations of parameters can be easily identified; by analyzing component one, it is clear that the objective function only depends on the PP_{xch1}/PP_{xch2} combination, not on these fluxes separately. Component v_2 indicates that flux ED_{cyc} can be estimated individually. A similar analysis can be applied to component v_3 , and PP_{xch3}, and flux PP_{oxi} cannot be individually estimated from this experiment.

The metabolic network for *P. aeruginosa* can differ among strains, hence two other typical networks were also considered, the Δ ED_{cyc} and the Δ PP_{oxi} strains. For the former, in which the ED pathway cannot operate in cyclic mode (Table 2), PP_{oxi} could be

estimated separately, which was the original goal of Riascos et al. (2013). The relation among the exchange fluxes of the PP pathways practically remains unchanged; however, component v_1 now has no influence from PP_{xch3} . The other common variation of the *P. aeruginosa* network considered is the absence of the oxidative branch of the PP pathway (Table 2). In this case, the situation is similar to the complete network without the PP_{oxi} influence on the components.

Table 2: Sparse PC of the Hessian matrix for the [6- ^{13}C]glucose experiment.

	complete network			ΔED_{cyc}			ΔPP_{oxi}		
	v_1	v_2	v_3	v_1	v_2	v_3	v_1	v_2	v_3
PP_{oxi}	0.00	-0.33	0.34	0.00	1.00	0.00	x	x	x
ED_{cyc}	0.00	0.94	0.00	x	x	x	0.00	1.00	0.00
PP_{xch1}	-0.67	0.00	0.00	-0.71	0.00	0.00	-0.71	0.00	0.00
PP_{xch2}	-0.67	0.00	0.00	-0.71	0.00	0.00	-0.71	0.00	0.00
PP_{xch3}	-0.29	0.00	0.94	0.00	0.00	1.00	0.00	0.00	1.00

5. Conclusion

Identifiability analysis is an essential tool for research in which ^{13}C -MFA is applied. This analysis can reduce experimental costs and increase the precision of the estimated metabolic fluxes. Here, it was demonstrated that the application of a sparse PC decomposition can improve the identification of dependencies among parameters and the determination of estimable fluxes from available data. In the case study of *P. aeruginosa* producing PHA, the identifiability analysis indicated that the substrate [6- ^{13}C]Glucose allows for the estimation of the fluxes through the ED pathway in cyclic mode and the oxidative branch of the PP pathway for some networks. The method presented in this work enables the identification of parameter combinations that can be estimated from labeling experiments. This represents an advantage when compared to the methods presented in literature that only verifies whether a subset of parameters is identifiable, leading to a combinatorial problem (van Winden et al., 2001; Kappelmann et al., 2016).

Abstract

The Numerical Matrices Methods (NMM) are assessed regarding their potential for reconstructing the topology and kinetics of biochemical reaction networks featuring increasing complexity, from a single-enzyme system to a three-enzyme cyclic network. The eventual goal is to use this analysis framework for synthetic *in vitro* enzymatic networks for which kinetic data are available. The NMM use time-dependent concentration data of the chemical species to reconstruct the network and determine its kinetic parameters. Preliminary results indicate that the methods are able to identify the correct network structure and kinetics, but have problems dealing with rate constants deviating from each other by several orders of magnitude. This finding is particularly relevant for biochemical systems with highly variable kinetics. Future addressing of the problem will enable the NMM to accommodate fast reaction kinetics and aid the establishment of a more robust model-based design and optimization framework.

Keywords: metabolic engineering, enzymes, Numerical Matrices Methods, network reconstruction, biochemical kinetics

1. Introduction

There is an increasing interest in *in vitro* metabolic engineering due to the advantages of using cell-free ensembles of purified enzymes or cell lysates for the production of compounds of biotechnological interest (Dudley et al. 2015). Synthetic *in vitro* metabolic networks (*SivMeNs*) operating in cell-free systems are easier to manipulate and optimize due to the reduced complexity compared to living cells – the interconnectivity and cell-wide regulations of the latter are yet to be properly understood, even for model organisms such as *Escherichia coli*. The complete decoupling of the enzymatic pathway of interest from other cellular processes allows cell-free systems to redirect all the input biomass towards product formation, with consequent increase in product yields (Erb 2019, Bowie et al. 2020).

An example of such a *SivMeN* is the CETCH cycle, designed for biochemical carbon fixation. This cycle can convert two molecules of CO₂ to one molecule of either glyoxylate or malate, both of which are two-carbon metabolites (Schwander et al. 2016). The introduction of engineered enzymes was among the many improvements carried out during the course of its development. Addition of methylsuccinyl-CoA oxidase (Mco) in the CETCH cycle allowed oxidation of methylsuccinyl-CoA by molecular oxygen instead of relying on artificial electron acceptors such as ferrocenium, while the engineered

proofreading enzyme propionyl-CoA oxidase (Pco) prevented metabolite loss due to the build-up of dead-end metabolites such as malyl-CoA.

As reaction kinetics govern the behaviour of *Siv*MeNs, kinetic modelling is essential for pathway design and further optimization. Metabolic network reconstruction and kinetic parameter identification from experimental data may prove useful for gaining additional insights into pathway performance improvement. For example, nodes engaged in unwanted and previously unknown side reactivities can be pinpointed through network structure identification.

Several methods have been developed to deduce the connectivity of chemical species participating in a reaction network from time-series concentration data. For example, in the correlation metric construction (CMC) method, a map of connections is determined through analysis of time-lagged concentration correlation functions of two chemical species at a time (Arkin et al. 1995, Arkin et al. 1997). In comparison, the Numerical Matrices Methods (NMM) are based on the analysis of correlations between kinetic complexes to determine not only the network structure, but also the kinetic parameters using linear algebra and statistical methods. The present work aims at evaluating the capabilities and drawbacks of NMM for analysis of cyclic *Siv*MeNs such as the CETCH cycle.

2. Numerical Matrices Methods (NMM)

NMM was developed for network structure identification as well as for the determination of the respective rate constants through least squares parameter estimation (Karnaukhov et al. 2007). The NMM use the formalisms of kinetic complexes, a key aspect of the chemical reaction network theory according to which linear, bilinear and quadratic rate expressions are applied to identify all possible uni- and bimolecular interactions among chemical species, that may occur in a given reaction network. A short survey of the tools included in the NMM is illustrated in Figure 1.

The first tool, called the Kinetic Matrix Method (KMM), expresses the rate of change of the concentrations $X_j(t_i)$ of the chemical species as a product between a kinetic matrix \tilde{A} and a vector of kinetic complexes \tilde{F} , as shown in Figure 1b. The vector \tilde{F} is calculated from the exponentiation of the species vector $\tilde{X}(t_i)$ with the matrix \tilde{Y} formed from the set of complex vectors \hat{y}_k , as stated in equation (1). The species vector $\tilde{X}(t_i)$ has a number of ns rows, equal to the number of chemical species involved, where its elements represent the concentration X_j of the chemical species j at time point t_i .

$$\tilde{F}(t_i) = [\tilde{X}(t_i)]^{\tilde{Y}} = \prod_{j=1}^{ns} [X_j(t_i)]^{y_{jk}} \quad (1)$$

The KMM initially reconstructs a primary kinetic matrix with null columns, each of which contains elements with values below a certain threshold ε_k . Such columns represent complexes that do not contribute to the network dynamics. A second KMM with more accurate values of the matrix \tilde{A} can be executed through the removal of the non-relevant complexes from the initial matrix \tilde{Y} of complex vectors. Afterwards, the Representation Matrix Method (RMM) is used to decompose the kinetic matrix \tilde{A} into a set of representation matrices \tilde{G}_p and a vector of nonzero parameters $\hat{k} = k_p$ that contains

np nonzero elements of \tilde{A} with absolute values above a certain threshold ε_k , as shown in Figure 1c.

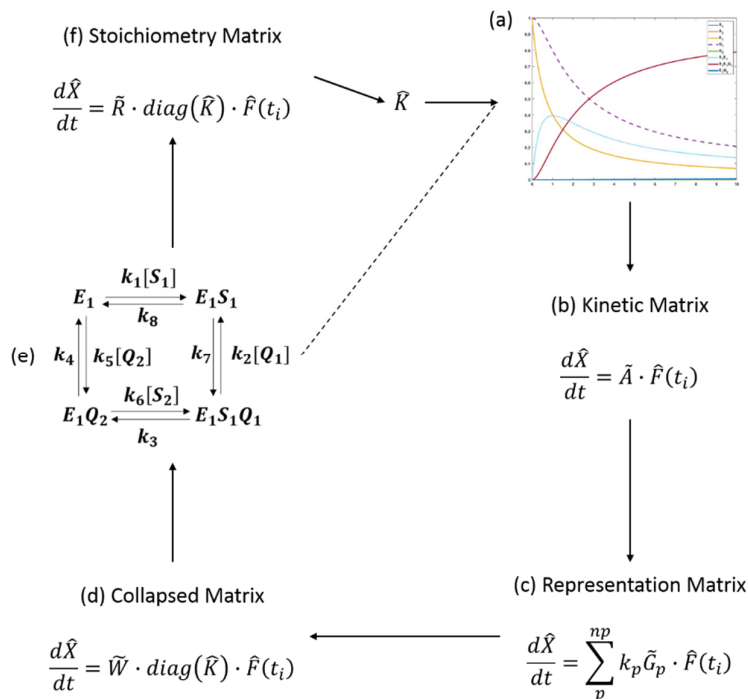

Figure 1. Overview of the tools of the Numerical Matrices Methods. Starting from time series of concentration data for all the chemical species participating in a given reaction network (a), a sequence of matrix-based numerical steps (b-f) is executed that finally leads to the reconstruction of both the network stoichiometric matrix \tilde{R} and the vector of rate constants \tilde{K} .

Then the stoichiometric matrix \tilde{R} is reconstructed from the set of representation matrices \tilde{G}_p through an intermediate “collapsed” kinetic matrix \tilde{W} (see Figure 1d). The columns of \tilde{W} corresponding to multivariant reactions (or reactions that share the same reactant complex, but with different product complexes) are then decomposed into reaction vectors of the stoichiometric matrix \tilde{R} . In the complete absence of multivariant reactions in the chemical reaction network of interest, \tilde{W} will be equal to \tilde{R} .

Once the stoichiometric matrix \tilde{R} is fully known (see Figure 1e), the last method called the Stoichiometric Matrix Method (SMM) is used to calculate the vector \tilde{K} of rate constants. The SMM mathematically expresses the rate of change of $X_j(t_i)$ as a function of the matrix \tilde{R} and the vector \tilde{K} as shown in Figure 1f.

3. Numerical Experiments

MATLAB-based numerical experiments were conducted to test the capabilities of NMM in reconstructing the kinetic mechanisms governing enzyme-catalyzed reaction networks.

In particular, the NMM were tested for its ability to reconstruct the reaction network structure and determine the values of the rate constants starting from time series of concentration data. To achieve this goal, *in silico* data sets describing the concentration profiles over time of three models of enzyme-catalyzed reactions were generated and used as input information for the NMM-based reconstruction approach. The first model represents a single-enzyme mechanism, the second model represents a two-enzyme cascade, and the third model represents a three-enzyme cycle that resembles a strongly simplified CETCH cycle. In all of these cases, the enzymes were modeled to follow the compulsory-ordered ternary complex mechanism. Figure 2 shows the schematic representation of the three enzymes that participate in the designed models.

The aforementioned *in silico* data sets were generated through numerical integration of the differential equations representing the mass balances of the chemical species participating in the three enzymatic networks. Due to the nature of these equations, the generated datasets also contained complete information about the concentration dynamics of the transitional enzyme-substrate complexes. Such information is usually not present in concentration profiles gathered under laboratory conditions. During numerical integration, the maximum chosen duration was $t_{max}=10$, with concentration values known at a resolution of 0.01 mol/l.

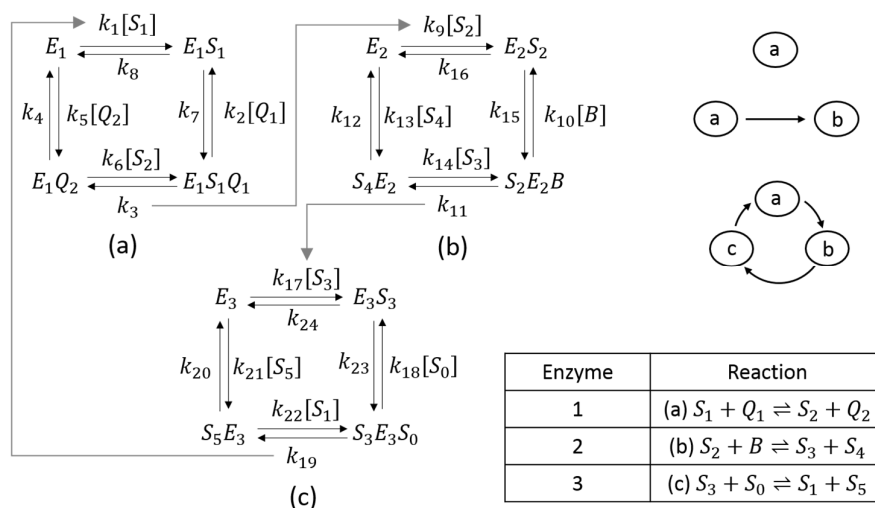

Figure 2. Diagrams that represent the compulsory-ordered ternary complex mechanism that governs the kinetics of the enzymes considered in the network models. The single-enzyme model contains the rate expressions of (a). The two-enzyme model contains the rate expressions of both (a) and (b). The cyclic three-enzyme model contains the rate expressions of (a), (b) and (c).

The values of the rate constants used during synthetic data set generation were chosen to ensure that the enzyme-substrate complex formation steps are fast reactions, while the product formation steps were considered as the rate-determining steps. The difference between the rate constant values of the slowest and the fastest steps of both forward and reverse reactions are chosen to reach up to three or more orders of magnitude. Such a range of values mimics biological reality, as similarly huge differences between rate constants have been observed in enzymes such as the yeast hexokinase (Noat et al. 1968)

and bovine heart mitochondrial malate dehydrogenase (Heyde et al. 1968). The chosen values for each of the rate constants are given in Table 1 and were later varied, as explained in section 4.

To enable faster and more accurate determination of the kinetic matrix \tilde{A} during the execution of the KMM, a preliminary elimination of the complex vectors was carried out. Thereby, we excluded species' interactions that usually do not occur in enzyme catalysis. Examples of such kinetic complexes include the ones that correspond to interactions between small molecules that are not bound to their respective enzymes or enzyme-substrate complexes, interactions between unbound enzymes, interactions between enzyme-substrate intermediates, and interactions between free and bound enzymes. It was also assumed that no dimer formation occurs during the operation of the three network models. For this reason, the complex vectors representing such interactions were eliminated beforehand. We noted that these complex interactions may need to be reconsidered in the future, in order to better reflect the biological reality, for instance with respect to signaling pathways in which interactions between different enzymes are present.

In enzymatic reactions and networks, the linear dependencies among the chemical species due to the conservation of mass in the system of reactions lead to singularities of the kinetic matrix \tilde{A} . To break these *holonomic conditions* intrinsic to stoichiometric matrices of reaction networks, a sufficient number of time-dependent concentration profiles with different initial concentration conditions were collected. The number of time-series of concentration data nm , and the initial concentration values used, were chosen according to a fractional factorial design. Two-level designs were chosen, with the normalized lower level assigned with the value of 0.05 and the normalized higher level with the value of 0.5. These values are given only to the concentrations of the unbound enzymes, substrates, cofactors and products, while to the rest of the chemical species we assigned the initial concentration values of zero during dataset generation. For the single-enzyme kinetic model, a 2^{3-1} design was chosen. For the two-enzyme kinetic model, a 2^{9-4} design was sufficient to break the holonomic constraints. For the three-enzyme kinetic model, a 2^{11-4} design is sufficient, as long as a twelfth factor has non-zero initial concentration values (either 0.05 or 0.5 in any of the 32 numerical experiments).

4. Results

Karnaikhov et al. (2007) tested the NMM by using a network model representing a hypothetical assembly mechanism of a quaternary complex between ribosomal RNA and three RNA-binding proteins. The used rate constant values were in the range of 0.001–1.3. Using the same range of rate constant values for our three network models during numerical dataset generation and setting the threshold $\epsilon_K = 0.0005$, the NMM managed to properly reconstruct the stoichiometric matrices and the values of all rate constants.

But in the case of the three-enzyme network, the SMM gave incorrect stoichiometric matrices when the rate constant values of the first step of the reverse reactions catalyzed by the three enzymes (i.e. $k_{5,13,21}$) were one order of magnitude smaller than the values of the next step involving the binding of substrate. If at least one of these rate constants had a value that was in the same order of magnitude as that of the next step, then the NMM properly determined the correct entries of the stoichiometric matrix. If the rate constant values were changed to get a difference of more than three orders of magnitude between the slowest and fastest steps (e.g. setting either $k_1 \geq 10$ or $k_3 < 10^{-3}$), the SMM

calculations became very slow, as the kinetic matrix \tilde{A} at this point assumed a very high rank and condition number. A similar issue occurred in the cases of the simpler single-enzyme and two-enzyme cascade models, where differences of more than three orders of magnitude between the slowest and fastest steps resulted in incorrect dimensions and incorrect entries of the reconstructed stoichiometric matrix.

Table 1. The non-dimensional rate constants chosen during numerical dataset generation.

Rate constants	Values used	Rate constants	Values used
k_1	1.3	$k_{8,16,24}$	0.011
k_2	0.75	k_9	1.03
k_3	0.001	k_{10}	0.6
$k_{4,12,20}$	0.009	k_{11}	0.006
$k_{5,13,21}$	0.5	k_{17}	1.1
$k_{6,14,22}$	0.85	k_{18}	0.95
$k_{7,15,23}$	0.009	k_{19}	0.005

5. Conclusion

The Numerical Matrices Methods (NMM) are useful tools for kinetic network reconstruction from time-dependent concentration data. However, problems arise when the rate constants in a given network differ by more than three orders of magnitude between fast and slow steps (i.e. the rate-determining steps). The findings suggest treating the network reconstruction task better as a dynamic optimization problem, constrained by a differential-algebraic equation (DAE) system, where the fastest steps are modelled as chemical equilibrium constraints. As rate constants are often not known *a priori*, one should create a family of kinetic network alternatives, from which the best network could be identified by systematic model discrimination. In this way, the model-based design and optimization of synthetic *in vitro* metabolic networks (SivMeNs) can be addressed.

Abstract

Chimeric Antigen Receptor (CAR)-T cell therapies are a type of patient-specific cell immunotherapy demonstrating promising results in the treatment of aggressive blood cancer types. CAR-T cells follow a 1:1 business model, translating into manufacturing lines and distribution nodes being exclusive to the production of a single therapy, hindering volumetric scale up. In this work, we address manufacturing capacity bottlenecks via a Mixed Integer Linear Programming (MILP) model. The proposed formulation focuses on the design of candidate supply chain network configurations under different demand scenarios. We investigate the effect of an intermediate storage option upstream of the network as means of: (a) debottlenecking manufacturing lines and (b) increasing facility utilisation. In this setting, we assess cost-effectiveness and flexibility of a decentralised supply chain and we evaluate network performance with respect to two key performance indicators (KPIs): (a) average production cost and (b) average response treatment time. The trade-off between cost-efficiency and responsiveness is examined and discussed.

Keywords: personalised medicine, supply chain, optimisation.

1. Introduction

Chimeric antigen receptor T cell (CAR-T cells) therapy is a type of adoptive cell immunotherapy (Zhang *et al.* 2017; Guthrie, 2018). T cells are a sub-type of white blood cells that assist cell-mediated immunity. In the case of CAR-T cell manufacturing, T cells are genetically modified and enabled to recognise and kill target cancer cells. Their manufacturing process starts with the extraction of T cells from the donor's (allogeneic) or patient's (autologous) blood stream through a specialised procedure (leukapheresis). The leukapheresis sample is then transferred to the manufacturing facility for further processing that involves cell expansion, genetic modification and Quality Control (QC). The approved therapy is then sent to the hospital and administered to the patient (Levine, 2015). Autologous CAR-T cell therapies have received landmark approvals by the U.S. Food and Drug Administration (FDA) (2017) and the European Medicines Agency (EMA) (2018) and are currently offered for the treatment of recurring, aggressive B-cell lymphoma, under a controlled scheme (EMA, 2018; Novartis, 2018; FDA, 2017). At the moment, autologous CAR-T cells seem to be leading the race in personalised cell therapies, while the allogeneic counterpart is also gaining attention.

A unique feature of autologous CAR-T therapies is that the patient's cells are used as raw material and therefore the therapy manufacturing and distribution that follow are exclusively dedicated to the production and delivery of a single therapy. In such cases, volumetric scale-up is not applicable and is replaced by scale-out solutions, where parallel manufacturing lines are available. In addition, CAR-T cell life cycle involves the

distribution and handling of sensitive materials with short shelf lives. This is translated into tight time constraints that challenge the supply chain network even more. Given the autologous and sensible nature of CAR-T therapies, novel decentralized manufacturing models are considered promising alternatives to a traditional centralized approach, since small scale local manufacturing facilities offer greater flexibility and can significantly reduce transportation costs (Harrison *et al.*, 2018). On the other hand, intermediate storage of the therapies might be necessary to serve as buffer when the demand temporarily exceeds the manufacturing facilities' capacity or to optimise the facility utilisation and is crucial to efficiently coordinate manufacturing and distribution tasks.

In this work, we present a Mixed Integer Linear Programming (MILP) formulation that provides candidate solutions with respect to the location, number and capacity of manufacturing sites, storage duration, and the most suitable mode of transport. In particular, the MILP model is used to assess the supply chain network performance under three different time constraint scenarios (19, 22 and 25 days) total return time. The latter refers to the total duration of the therapy life cycle, starting from the leukapheresis procedure and ending with the delivery of the therapy at the hospital. All the scenarios are assuming a demand of 500 patients per year.

2. Materials and methods

The general supply chain network considered in this work is represented in Figure 1. It consists of 5 nodes in total, namely: leukapheresis site, storage site, manufacturing site, Quality Control and hospital. It should be noted that storage in this case is optional, thus the model is allowed to by-pass it and proceed directly into the manufacturing. The location of both storage and QC facilities is assumed to be co-located with the manufacturing facilities in this work. Nevertheless, the model formulation has the capability of evaluating outsourced storage and QC, whereby the decision becomes a design variable of the supply chain network.

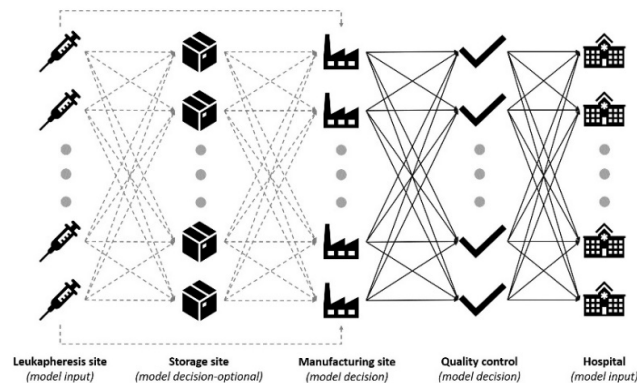

Figure 1: Supply chain network considering 5 nodes: (a) leukapheresis site, (b) storage site, (c) manufacturing site, (d) Quality Control and (e) hospital. Storage of leukapheresis samples is optional allowing the model to by-pass this node and move directly into manufacturing.

Manufacturing facilities of three different capacities are considered. These include facilities of 4, 10 and 31 parallel production lines, corresponding to a maximum capacity of approximately 200, 500 and 1500 therapies per year respectively. Manufacturing costs are based on the information available from Spink and Steinsapir (2018), while QC costs

are proprietary to Trakcel Ltd. The unit transport costs across the various locations are estimated costs from a white glove courier with cell therapy processes. Storage costs consider preservation of samples at -150°C.

Based on economies-of-scale, the variable manufacturing cost per therapy is assumed to be a decreasing function of the percentage at which the respective facility is utilised. This is represented by an originally non-linear formulation that is then linearized using a McCormick envelope (McCormick, 1976). Constraints representing the minimum flow of samples are adapted from Tsiakis *et al.* (2001).

The model considers that manufacturing facilities are placed close to transport hubs, such as airports, ports and train stations to facilitate distribution. In addition, the locations align with existing cell and gene therapy facilities in Europe, US and the UK. In this case, we assume that QC is co-located with the manufacturing facility. We consider that QC facilities are of 20-fold higher capacity when compared to the manufacturing facilities, relaxing therefore QC capacity constraints. Following standard European and UK practices of public and public and/or semi-public healthcare systems, we assume that the choice of collaborating hospitals and specialist centres is not under the manufacturer’s sole control. Therefore, these two nodes are considered as model inputs and not as decision variables. For the leukapheresis sites we consider a capacity of 8 patients per day, while we assume that capacity is not a bottleneck for the administration of the therapy at the hospital site and thus no upper limit is provided. Following the Advanced Therapy Treatment Centre (ATTC) model as discussed in Papathanasiou *et al.* (2020), we assume that leukapheresis sites and hospitals are different facilities, located in the same region. We assume that transportation can happen either within 24 or 48 hours, irrespective of the mode of transport (i.e. car, rail etc). This is to align the model assumptions with standard practice in the cell therapy space where courier contracts are costed based on the estimated time of delivery. An overview of the model formulation is presented in Table 1.

Table 1: Overview of model formulation.

	Index	Mathematical formulation	Description
Obj function	(1)	$C_{tot} = C_m + C_{tr} + C_{QC} + C_{st}$	Total cost
Constraints	(2)	$TRT_p = t_{delivery} - t_{start} \leq U^t$	Total return time of therapy
	(3)	$FCAP_m \cdot E_m - \sum_p INM_{p,m,t} \geq 0$	Manufacturing capacity constraint
	(4)	$\sum_m E_m \leq U^M$	Total number of manufacturing sites
	(5)	$INC_{p,c,t} = OUTC_{p,c,t+TLS}$ $INS_{p,m,t} = OUTS_{p,m,t+Tsd}$ $INM_{p,m,t} = OUTM_{p,m,t+TME}$ $INQ_{p,q,t} = OUTQ_{p,q,t+TQC}$	Sample balance at each node (leukapheresis site, storage, manufacturing and quality control)

We consider a base case where the samples are processed immediately after they reach the manufacturing facility (Scenario A), and four alternative scenarios where the samples can be stored at the manufacturing facility site for up to six days and different time constraints are enforced. Table 2 summarizes the constraints in each scenario. The assumed duration of the manufacturing is 7 days, representing a forward-looking scenario of technology developments that can lead to decreased culture times with respect to current industrial average (~19 days).

Table 2: Summary of the five scenarios considered in this paper.

	Storage	# of manufacturing facilities	U^t
Scenario A	No storage	2	19 days
Scenario B	✓ (up to 6 days)	2	19 days
Scenario C	✓ (up to 6 days)	2	22 days
Scenario D	✓ (up to 6 days)	2	25 days
Scenario E	✓ (up to 6 days)	2	No constraint

3. Results and discussion

The model described above is used for the design and assessment of a supply chain network to deliver 500 therapies per year. The demand distribution is assumed to be homogeneous among each year quarter, for which results are demonstrated here. In all examined scenarios the model is allowed to invest into maximum two manufacturing facilities to be built.

The model has 10,338,522 variables and 2,502,554 discrete variables and all the scenarios have been executed in a 24-Core Xeon E5-2697 machine with 96GB Ram. The scenario with the highest CPU time is Scenario E and it required a CPU time of ~98 hours to reach an optimality gap lower than 3%.

Figure 2a illustrates the results of all five scenarios in terms of average cost and return time of a therapy, Figure 2b focus on Scenarios A, B and C, and Figure 3 reports the utilisation of the manufacturing facilities in Scenario A and C.

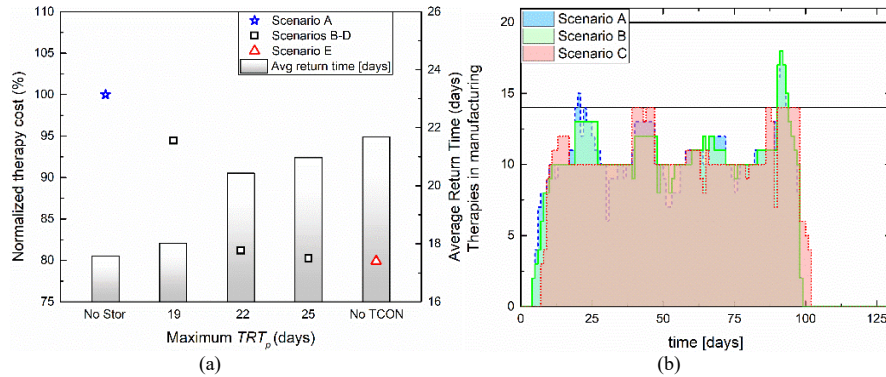

Figure 2: (a) Average therapy cost in Scenario A (blue star), B-D (black squares) and E (red triangle). The bars represent the average return time of a therapy in each scenario. (b) Number of therapies in manufacturing in Scenario A and C. The black horizontal lines represent the thresholds of 14 and 20 therapies.

We can observe that the average therapy cost decreases when storage is chosen as an option, as it allows for improved manufacturing planning. This is achieved by scheduling to manufacture more therapies in parallel, therefore decreasing the operating cost. When the same upper bound for the total return time of a single therapy is considered then a 5% decrease of the cost is achieved with an incremental increase in the average return time (~1%). A sharper decrease of 20% of the average therapy cost can be achieved by increasing the upper bound for the total return time of a therapy to 22 days. Relaxing further this constraint leads to negligible improvements in the cost.

The reason of the decrease of the average therapy cost is explained by the choice and utilisation of the manufacturing facilities. Given the sizes of the manufacturing facilities considered in this work, a different combination of small (4 parallel manufacturing lines) and medium-sized (10 parallel manufacturing lines) is required for scenarios A and C. As we can observe in Figure 2b, in Scenario A the threshold of 14 therapies in manufacturing, which can be satisfied by a small and a medium facility, is temporarily exceeded in a small subset of days. On the other hand, in Scenario C the same total demand can be satisfied by one medium and one small facility, as the threshold of 14 therapies in manufacturing is never exceeded. It is important to note that in Scenario B two medium-sized facilities are still needed in order to satisfy the demand.

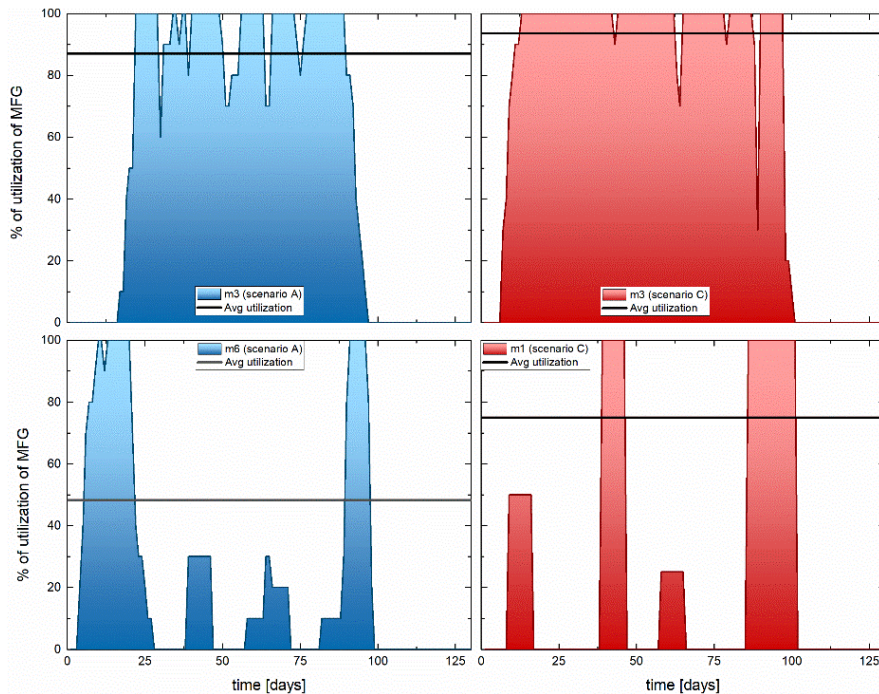

Figure 3: The graphs on the left represents the utilisation of the manufacturing facilities $m3$ (top) and $m6$ (bottom) in Scenario A, the graphs on the right represents the utilisation of manufacturing facilities $m3$ (top) and $m1$ (bottom) in Scenario C. The black horizontal line in each plot represents the average utilisation.

From Figure 3 we can observe that the facility $m6$ in Scenario A is significantly underutilized, resulting into a higher operating cost per therapy. In Scenario C the main facility $m3$ is almost always operating at maximum capacity, while the smaller facility $m1$ is used only when the demand cannot be satisfied by $m3$ and on average the utilisation is higher than the utilisation of $m6$ in Scenario A, due to its smaller size. It should be mentioned that the average utilisation is calculated excluding the days when the facilities are not in operation.

4. Conclusions

In this work we present a Mixed Integer Linear Programming (MILP) formulation for the design and optimisation of supply chain networks in personalised therapies. The latter present the unique characteristic of a 1:1 business model, where manufacturing and distribution lines are occupied for the production and delivery of a single therapy. This is translated into increased per-therapy costs, as well as manufacturing bottlenecks, considering that volumetric scale up is not applicable in such cases. The MILP model investigates the potential of decentralised manufacturing as well as storage in an attempt to create a flexible, cost-efficient network that remains responsive to the patient schedule. We consider different life cycle duration scenarios and an annual demand of 500 patients throughout. Overall, the model indicates that cost decreases as a function of the return time, while the use of multiple facilities may lead to lower operating costs. The latter is related to the variable cost being calculated as an inverse function of the facility utilisation. Lastly, results from this work demonstrate that storing leukapheresis samples upstream of the supply chain can allow for improved manufacturing planning, as well as debottlenecking. This can be attributed to the flexibility added in the overall network that allows samples to be stored until a critical mass is ready to be manufactured in parallel, leading therefore to a higher utilisation percentage of the facility and lower operating cost.

Abstract

The optimisation of heat treatment processes in the dairy industry is of high practical interest. Models are key to understanding and optimising equipment design, operating conditions, energy and water utilization, heating and cleaning cycles and economics. Decades of research have led to the development of many models, however, there is still a lack of understanding about the role and mechanism of denaturation and deposition of proteins from whey solutions. Extensive validation of the more recent thermal and fouling models against experimental data is also incomplete.

Here, five sets of detailed data from dynamic experiments in typical Plate Heat Exchangers (PHEs) are used to validate a 2D-distributed, dynamic model under fouling. The model accounts for the exchanger geometry, operating conditions and prevailing local conditions. Three reaction mechanisms for β -lactoglobulin (β -LG) protein unfolding, aggregation and deposition are considered, one of which is novel.

First, a validation was carried out of the thermal PHE model alone (i.e. under clean conditions, with no fouling) against a water-water dynamic experiment, with excellent results. The exit temperatures predictions match the experimental observations within $<1^\circ\text{C}$ on average. The fouling model was then validated against four dynamic water-whey protein solutions (WPS) experiments (hot water heating a cold WPS stream) covering different conditions. Some of the model deposition constants were obtained through parameter estimation. Comparison of predicted and measured quantities (exit temperatures and amount of deposit in each channel at the end of the experiments) show that neither the aggregate protein deposition model nor the unfolded deposition model on their own can describe the observations. It is shown that a new modification that combines both mechanisms results in an improved fitting of the data in all experiments. The combined deposition scheme results indicate that both mechanisms are important in different parts of the exchanger, and even along individual plates.

Keywords: food thermal treatment process, pasteurisation, fouling, experimental model validation, unfolded and aggregate proteins, dynamic simulation, parameter estimation.

1. INTRODUCTION

Thermal treatments such as pasteurisation and ultra-high-temperature (UHT) processes, widely used in the dairy and food industries to insure product hygienic safety and long

shelf life. They typically use plate heat exchangers (PHEs). Fouling reduces PHEs thermal efficiency, requires frequent cleaning that generates large volumes of wastewater and increases costs. The optimisation of such processes is therefore of high practical interest. Reliable, predictive models of heat transfer and fouling are key to optimise equipment design, operating conditions, energy and water utilization, heating and cleaning cycles, productivity and economics. Decades of experimental and modelling research have led to the development of many models to characterise, in particular, the role and mechanism of denaturation and deposition of whey proteins (for example, but not limited to, β -lactoglobulin, β -LG) in dairy derivatives (Loveday, 2016, Blanpain-Avet, et al., 2016, Khaldi, 2016, Sharma and Macchietto, 2019). However, there is still uncertainty about the denaturation/deposition mechanisms, and an extensive validation of the most recent models against experimental data is still missing. Here, the objective is to assess a recently developed dynamic model of PHEs subject to fouling, developed at Imperial College London, against some high quality experimental data collected at UMET/INRAE, France. The work is part of a collaboration aimed at the development and validation of improved fouling and cleaning technology.

1.1. Fouling reaction model

Above a certain temperature β -LG undergoes denaturation whereby the native protein (N) changes to an unfolded form (U) with highly reactive thiol groups exposed. The unfolded proteins irreversibly react to form insoluble aggregates (A). All the reactions are assumed to begin at 70°C, and the unfolding and aggregation reactions to occur in both bulk fluid and boundary layers with the same kinetic parameters. The unfolding reaction is reported to be limiting below 80°C and the aggregation reaction limiting above 80°C. Controversy still exist in literature concerning the denaturated protein species (unfolded and/or aggregated) which are supposed to form the deposit (Bansal and Chen, 2006; Sadeghinezhad et al., 2013, Blanpain-Avet et al., 2016). Consequently, in addition to deposition arising from Aggregates (Type A model) and Unfolded (Type B model) proteins alone, a new model that combines them (Type C model) is proposed (Figure 1). The kinetics parameters of the denaturation reactions are taken from (Khaldi, 2016) and those of the deposition reactions from (De Jong, 1996). The deposition proportionality parameters, β_U and/or β_A , were estimated from the channel mass deposit data. Full details and parameters values are given in Darko, 2020.

1.2. Plate Heat Exchanger model

The PHE dynamic model considers a whey protein fouling fluid being heated as flowing in a channel delimited by two hot plates (Guan and Macchietto 2018). The model is distributed in 2 directions, longitudinally (coordinate x) and across (coordinate y), considering five domains (Figure 2, from left to right): Ω_W^L : Left plate wall domain; Ω_L^L : Left plate deposit layer domain; Ω_F : Channel fluid flow domain; Ω_L^R : Right plate deposit layer domain; Ω_W^R : Right plate wall domain. A uniform distribution is assumed along the plate width, W . Differential mass and energy balances in the 5 domains plus the above reaction models define 2D-distributed temperature profiles, heat fluxes, and deposition rates at each location of each plate, according to the local thermal and hydraulic conditions. A similar model describes the hot fluid channel (for a non-fouling fluid, the fouling reactions are omitted). The models of all channels are then integrated into an overall model (Figure 3, left) through appropriate boundary conditions, according to the PHE design and flow configuration. The resulting partial differential and algebraic equation (PDAE) system was implemented in a commercial simulator (gPROMS, 2018).

The full dynamic model is used both in simulation mode (to calculate all outputs given all parameters and inputs) and in parameter estimation mode (to estimate the best parameters given all inputs and selected output measurements). Details of model and solution method are given in Sharma and Macchietto, 2019 for a single PHE and in Zhu et al., 2020 for application to a complete heat treatment process.

Figure 1: Protein denaturation and deposition mechanisms and reactions (adapted from Georgiadis and Macchietto, 2000)

1.3. Experimental setup and data

The PHE apparatus in Figure 3 was used in five experiments at different operating conditions (Table 1) (Khaldi, 2016). Flowrates, inlet and outlet temperatures of both hot and cold streams were measured every 15 seconds. Experiment No. 0 used water in both streams (no fouling). This corresponds to a preheat phase, where the PHE is brought to a desired steady state temperature. Fouling experiments 1-4 involved a specially prepared whey protein solution (WPS), heated by a hot water stream. After an initial preheat phase as in Exp. 0, the cold stream is switched from water to the fouling fluid. Initial conditions at this point are given in Table 1. In these fouling runs, the outlet WPS temperature was manually maintained constant by manipulating the inlet hot water temperature (and in some cases, its flowrate). At the end of each experiment the deposit in each channel was collected and weighed (Table 1). Measurement variances are 0.1 g for mass deposition and 0.1°C (at calibration, rising gradually to 0.3°C) for temperature.

4	6.58	60	74	5.05	81	64	5.18	0.2	0.9	1.2	1.3	3.4	6692

2. Model Validation

The measured inlet temperature and mass flowrate profiles of both streams were reproduced using linear and quadratic polynomial splines. As an example for Exp. No. 0,

Figure 4 (left) shows that the inputs to the simulations are very well captured. Experiment No. 0 (with no fouling), allows validating the PHE thermal model. Excellent agreement is observed between experimental and predicted exit temperatures of both cold and hot water streams (Figure 4, right), with average absolute deviations of $0.5 \pm 0.6^\circ\text{C}$ and $0.8 \pm 0.5^\circ\text{C}$, respectively. The model has the structural adequacy and predictive ability to describe heat transfer dynamics for the clean PHE. Then, for each fouling experiment 1-4, the channel mass deposit data at the end of the run (Table 1) were used to estimate the remaining constants (β_A and/or β_U) in the three deposition models (A to C) described in Figure 1. Results (e.g. Exp. No. 1 in Figure 5) show that the Type C model (which combines aggregated and unfolded deposition) gives a better fit in all experiments. Post treatments of the numerical data obtained by Type C model seems to indicate that the ratio of aggregated and unfolded proteins in the deposit varies both along the length of the channels, and between channels (Figure 6). Hence both reaction schemes are important in different locations and temperature conditions.

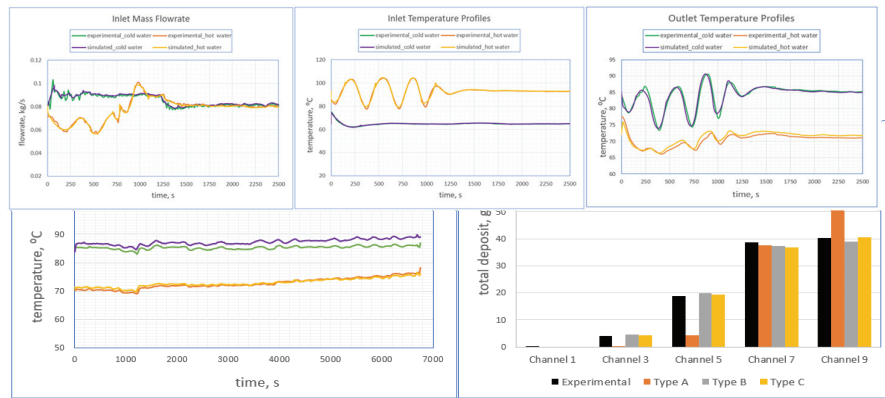

Figure 5 Experiment No. 1: Exit temperature profiles with model Type C (left); Experimental and simulated deposit mass in the fouling channels with all deposition models (right)

Figure 6 Experiment No. 1: Distribution of aggregate and unfolded proteins in the deposit layer along the length of a plate (left); total protein deposited in the fouling channels, C1-C9 (right)

3. Discussion and Conclusions

The dynamic, 2D distributed PHE model was tested on experimental data from five well documented experiments with three protein reaction/deposition models. Validation of the

PHE thermal model with a highly dynamic water-water run showed an excellent agreement between data and model, without parameter adjustments. The fouling runs (here and Darko, 2020) show that the aggregate proteins (Type A) fouling scheme does not adequately describe the final channel mass deposit data. The unfolded proteins (Type B) scheme performs better, however, neither scheme alone is adequate in all experiments. A linear combination of the two (Type C) gives a better agreement under all conditions. The predicted spatial distribution in the channels of unfolded and aggregate proteins in the deposit shows that both mechanisms are locally important and must be considered together. Protein ratios in the deposit were not measured, so remain to be validated. The combination of thermal and fouling models with quality experimental data enabled a systematic assessment of two traditional protein deposition models and a proposed new one, for dairy heat treatment in PHEs. Additional results and a sensitivity analysis will be reported elsewhere. This work could be extended to whey protein solutions containing calcium, which has a significant influence on denaturation and is known to promote binding of unfolded protein (hence aggregation and fouling). The approach, models and results presented will improve the optimal monitoring, operations and design of heat treatment in dairy and related food processes.

Abstract

Energy is one of the essential inputs for socio-economic, and geo-political strategies in nation building. Among potential interests, lignocellulosic biomasses constitute a prime source of biofuel and other value-added products. The thermochemical approach resolve to the degradation of cellulosic biomass into fragments of lignin, hemicellulose and cellulose. From the fragmented components, extraction of fermentable and hydrolysable sugars could be obtained through various combined process steps and finally converted into desired products (alcohols, alkanes, CO, H₂). In this research, an average of wet bagasse (C₃₀H_{120.11}O_{53.84}) with 49.28% moisture content; dry bagasse (C₃₀H_{46.65}O_{17.11}); dry molasses (C₃₀H₅₆O₂₈) and dry filter cake (C₃₀H_{51.14}O_{22.7}), were taken for the conversion analysis, with sulphur and nitrogen remained neglected. Adopting gasification as a proposed approach on all of the incoming wet bagasse (16.53 kg/s), mobilizes 6907 kg of water or 5.03% of total water in it. Since, the factory is characterized by low energy efficiency, using a large fraction of the bagasse produced as fuel in the cogeneration system to supply the process energy requirements. The possibility of selling surplus electricity to the grid and utilizing surplus byproducts as an input for the other processes has motivated to enhance more efficient cogeneration systems and process thermal integration.

Keywords: Energy, Lignocellulose, Bagasse, Hydrolysis, Biorefinery.

1. Introduction

1.1. Background

Energy is one of the essential inputs for the socio-economic development (Brew-Hammond, 2010), and geo-political strategies in nation building. Nations set the ball rolling by putting forward their strategic development vision with clear objectives to meet the energy demands. Among the potential interests to extending alternatives bioenergy resources, lignocellulosic biomass has been identified as the prime source of biofuels and other value-added products (International Finance Corporation, 2017), and geared towards the production of cost-effective biofuel (Boateng & Lee, 2013), from inputs which are not food competitive by nature (Viikari et al., 2012). A new scenario, with the possibility of biomass conversion technologies to the production of alkanes (C_nH_{2n+2}O) from hydrolyzed bagasse with dodecane (C₁₂H₂₆) as the longest carbon chain produced, the conversion of bagasse and molasses into alcohols (C_nH_{2n+2}O). Eventually, conversion of biomass into hydrogen(H₂) and carbon monoxide (CO) are considered through conversion mechanisms at a higher level to sustainable economy.

In Ethiopia, the Wonji-Shoa sugar factory crushes about 906,089 tons of cane per year and produces about 111,014 tons of sugar. Its energy demand depends on the cogeneration plant designed to produce 31 MW power of electricity from surplus bagasse and consumes 11 MW power of electricity to self-sufficiency. However, the factory has been historically characterized by low energy efficiency due to the lack of process energy integration in the sugar mills.

2. Biofuel processing routes from biomass

2.1. Biofuel processing routes from sugarcane bagasse

Essentially, there are two different approaches (i.e., thermochemical and biochemical) for the bioethanol production from biomass(bagasse) (Cesaro & Belgiorno, 2015). Both approaches resolve to the degradation of cellulosic biomass into fragments of lignin, hemicellulose and cellulose. The biochemical pathway includes physical and biological pretreatments of the lignocellulosic biomass. The physical pretreatment is commonly used methods subject to high pressure saturated steam at temperatures of 160–260°C and pressure of 0.7 to

4.8MPa (Kucharska et al., 2018). Biological pretreatment (enzymatic hydrolysis) is an ideal approach for degrading cellulosic biomass (bagasse) into fermentable sugars and generally it can be accomplished by the role of at least three major class of enzyme synergetic action such as endoglucanases, exoglucanases, and β -glucosidase to extract fermentable sugar. later on, the sugars are converted into bioethanol *via* fermentation and anhydrous ethanol is produced *via* distillation. Thermochemical biomass conversion includes a number of possible routes to produce useful fuels and chemicals from the initial biomass feedstock. Biomass can be used as a solid fuel, or converted into liquid or gaseous forms for the production of electric power, heat, chemicals, or gaseous and liquid fuels (Kundu et al., 2018). The thermochemical approach under process consideration includes incineration, combustion, sophisticated oxidation such as HydroThermal oxidation (SHTO) and Wet Air Oxidation (WAO) (Goffè & Ferrasse, 2019). This technology requires high level of heat and results in syngas (synthesis gas) such as CO, H₂, and CO₂. These gases are chemically converted into a mixture of alcohol using metal catalysts. The process can occur through direct combustion, pyrolysis, gasification, torrefaction and liquefaction. The process to biomass conversion use three ways. It can be burned to produce heat and electricity, changed to gaseous fuels such as methane, hydrogen, and carbon monoxide or changed to liquid fuels (Cesaro & Belgiorno, 2015).

2.2. Pretreatment

This process has an essential effect on the overall process of biofuel from lignocellulose, which makes the cellulose accessible to hydrolysis for conversion to biofuel. Lignocellulosic biomass is pretreated by diverse methods including physical, chemical, physicochemical, biological pretreatment or combined pretreatment (Asgar et al., 2020). In this step, it is applied to modify the macroscopic as well as the microscopic size and structure of lignocellulosic feedstock (Kazemi Shariat Panahi et al., 2020). Steam explosion taken as the sole pretreatment method for sugar yield improvement is been considered for the biofuel production (Boateng & Lee, 2013). One of the most important evidences of implementing pretreatment methods for the alcohol and alkanes production is the removal of lignin and hemicellulose, through cost-effective processes.

2.3. Hydrolysis

The goal of this process is to generate fermentable monomeric sugars from hemicellulose (C₅) and cellulose (C₆) content of lignocellulosic biomass in conversion scheme. Its performance is highly associated with the selected pretreatment process (Achinas & Euverink, 2016). This step can be accomplished by two different processes steps, namely, acid hydrolysis and enzymatic hydrolysis. In acid hydrolysis either sulphuric acid or hydrochloric acid-based hydrolysis process is operated under two different conditions; (i) a process that uses concentrated acids operates at a lower temperature and, (ii) a process that uses dilute acid concentration and operates at a higher temperature. On the other hand enzymatic hydrolysis, which is an ideal approach for degrading cellulosic biomass into reducing sugars, generally can be accomplished by the role of at least three major classes of enzyme synergetic action (section 2.1). However, enzymatic hydrolysis depends on certain critical optimal conditions for maximal efficiency such as sample moisture content can cause an irreversible collapse of the pore cellulosic structure, decreasing the hydrolyzability (Taherzadeh & Karimi, 2007) and the cellulose access to the enzymatic reaction and limit the number of hydrolyzed carbon atom within the reaction stoichiometry (Da Silva & Chandel., 2014). The hydrolysis reactions of biomass specifically cellulose and hemicellulose components under go monomeric generation shown in reaction equation (1 & 2) respectively. The lignin component resistant to hydrolysis could be a source of heat and electricity in cogeneration plant during gasification.

Where, n is the stoichiometric coefficients of reactants consumed and products generated from the utilized biomass for reaction (1 & 2). Taking into account reaction (1) each glucose unit in the long chain combines with a water molecule, and 180 mass units of glucose are released from 162 mass units of glucan and 18 mass units of water, an 11.1% substantial mass gain and from hemicellulose hydrolysis over 13.6% mass gain is reported from the theoretical weight percent ratio. For this research the mass of cellulose and hemicellulose from 141285.7334 ton/year of moisture free bagasse calculated accordingly to the weight percent value reported on table (1).

Table 1A: biochemical composition of bagasse

Biochemical composition	Weight %
Cellulose	44
Hemicellulose	27
Lignin	25
Sucrose loss	4

Table 1B: biochemical composition of bagasse

Elemental composition	Weight %

3. Materials and methods

The methodology of the considered system includes the conversion reaction and combustion reaction that provides energy to the system for reactants and products in their standard states and the results presented from the MATLAB code in which coded by **J.-H. Ferrasse**. In the case of material selection with respect to the desired products (alcohol, alkane, carbon monoxide, hydrogen), thermochemical path way is chosen for this research sugarcane bagasse whose characteristics have been extracted from the database for biomass and waste of the energy research center of the Netherlands (**Goffé & Ferrasse, 2019**). An average of wet bagasse ($C_{30}H_{120.11}O_{53.84}$) with 49.28% moisture content (factory records); dry bagasse ($C_{30}H_{46.65}O_{17.11}$); dry molasses ($C_{30}H_{56}O_{28}$); dry filter cake ($C_{30}H_{51.14}O_{22.7}$); taken for conversion analysis, where sulphur and nitrogen were neglected. The formula values used for the study assumed on a carbon basis number of 30, sulphur and nitrogen are neglected. To construct comparability among results one kilogram per second of biomass is considered as an input of the designed reaction system. Biomass to which shall put the subject of biomass conversion in the proper energy perspective to variables in the conversion process (reaction stoichiometry), technology, and the desired end product (**Detroy & St Julian, 1982**). **Table (2)** list the values used for the study on a carbon basis number of 30, sulphur and nitrogen are neglected.

Table (2)Biomass composition used for the study, ash and moisture-free basis.

Biomass	Formula	C (%)	H (%)	O (%)	H/C	O/C
Sugarcane bagasse	$C_{30}H_{46.65}O_{17.11}$	52.90	6.86	40.24	1.56	0.57
Molasses	$C_{30}H_{56}O_{28}$	41.56	6.50	51.94	1.87	0.93
Filter cake	$C_{30}H_{51.14}O_{22.7}$	46.50	6.6	46.90	1.70	0.76

3.1. Conversion products

The first biomass conversion is the production of alkanes ($C_nH_{2n+2}O$) from hydrolized bagasse with dodecane ($C_{12}H_{26}$) as the longest carbon chain produced, to conventional corresponding products found in liquid hydrocarbons. The second product with the longest carbon chain family dodecanol ($C_{12}H_{26}O$), is the conversion of biomass into alcohols ($C_nH_{2n+2}O$). The third product with the stright carbon chain family n-nonane ($C_9H_{20}O$), is the convesion of biomass (molasses) into alcohols (C_nH_{2n+2}). Eventually, conversion of biomass into hydrogen(H_2) and carbon monoxide (CO) are considered through conversion mechanisms. The biomass and product (s) considered in this research paper by taking into account inputs bagasse, molasses and filter cake mixed together to simultaneous fermentation after individual components pretreatment and hydrolysis, if biochemical pathway is favoured. Since input components differ from each other in their sugar content and number of atoms in their chemical formula resulting to differ their lower heating value (LHV) defined in the Boie equation (Eq. (3)) as thermochemical biomass conversion is the sole process prototype.

$$LHV_{Boie} = 348.35C + 938.7H - 1080 + 62.8N + 104.65S \quad Eq. (3)$$

Each capital letter (eq. 3 and 4) is the mass percent (wt%) of corresponding atoms in the element and the LHV is expressed in kJ/kg. The LHV of input components is subject to its moisture content. In the case of additional drying, the energy (if we wanted to dry) represents 2%, assuming that the sun brings us to a dryness of 85% (which remains to be verified). Therefore, the LHV of inputs can be specified as wet and dry to remark the impact of moisture content on biomass to energy conversion scenario. For wet bagasse with its expression ($C_{30}H_{120.11}O_{53.84}$) the LHV is: $LHV_{wet, bagasse} = 10.816$ MJ/kg and for dry bagasse with its expression ($C_{30}H_{46.65}O_{17.11}$) the LHV is: $LHV_{dry, bagasse} = 20.519$ MJ/kg. For wet molasses with its expression ($C_{30}H_{94}O_{47}$) the LHV is: $LHV_{wet, molasses} = 10.997$ MJ/kg and for dry molasses with its expression ($C_{30}H_{56}O_{28}$) the LHV is: $LHV_{dry, molasses} = 14.964$ MJ/kg. For wet filter cake with its expression ($C_{30}H_{51.14}O_{22.7}$) the LHV is: $LHV_{wet, filter\ cake} = 4.906$ MJ/kg and for dry filter cake with its expression ($C_{30}H_{51.14}O_{22.7}$) the LHV is: $LHV_{dry, filter\ cake} = 17.331$ MJ/kg. In the case of alkanes and alcohol, the modified version of Boie equation is used to liquid and gaseous fuel (Eq. 4).

$$LHV_{modified} = 349.1C + 958.3H - 103.4O - 15.1N - 100.5S \quad Eq. (4)$$

Biomass and products representation helps to structured elements depend on the two atomic ratio on the basis of carbon atom, H/C and O/C. By increasing H/C and decreasing O/C it is possible to visualize the conversion impact. The biomass conversion performance can be seen from material and energy ratio indicators in which inputs calculated from the biomass and energies comes from biomass and their products. Depend on the energy supply to the system either biomass or products become a role play to material ratio indicator calculation. Here, if only biomass is involved, equation (5) used to calculate material ratio.

$$\eta_{\text{material}} = \frac{n_{\text{product obtained}} * M_{\text{product}}}{(n_{\text{biomass conversion}} + n_{\text{biomass burned}}) * M_{\text{biomass}}} \quad \text{Eq. (5)}$$

on the other hand , if the combustion of products become an energy supply source to the system equation (6) is used to determine kilogram of bomass converted.

$$\eta_{\text{material}} = \frac{(n_{\text{product obtained}} - n_{\text{product burned}}) * M_{\text{product}}}{n_{\text{biomass conversion}} * M_{\text{biomass}}} \quad \text{Eq. (6)}$$

where, n_i and M_i are refer to the mole number and molar mass of component “i” respectively. The energy ratio indicator considered as a measure of energy value contained by the biomass or the product(s) from its lower heating value (LHV) and the source of energy supply to the system. If the biomass is used to supply energy to the system, it will follow equation (7) to determine biomass conversion.

$$\eta_{\text{energy}} = \frac{n_{\text{product obtained}} * LHV_{\text{product}}}{(n_{\text{biomass conversion}} + n_{\text{biomass burned}}) * LHV_{\text{biomass}}} \quad \text{Eq. (7)}$$

when the energy supply to the system is originated from the product conversion, equation (8) is used to determine energy efficiency of the system.

$$\eta_{\text{energy}} = \frac{(n_{\text{product obtained}} - n_{\text{product burned}}) * LHV_{\text{product}}}{n_{\text{biomass conversion}} * LHV_{\text{biomass}}} \quad \text{Eq. (8)}$$

Parameters for the system can be considered as conversion and thermo-chemical for biomass conversion and energy analysis. In thermo-chemical parameters the energy analysis viewed from the first law of thermodynamics in which the calculation of reagents and products done in their standard states ($T = 298 \text{ K}$ and $P = 1.01325 * 10^5 \text{ Pa}$) and the LHV described in equation (3 and 4) from simulis[®] thermodynamics database. In this stance the amount of energy necessary to supply to the system can be calculated by the standard enthalpy of reaction described in equation (9). In conversion parameters the biomass could be a limiting reagent or reaction rate determining agent by taking into account some assumptions according to biomass elemental composition. Upon the behavior of limiting reagents and converted products biomass perceived carbon and hydrogen rules that marked the conversion ratio of carbon and hydrogen atoms in biomass conversion.

$$\Delta_r H_{298}^{\circ} = \sum_i v_i \Delta_f H_{298}^{\circ} \quad \text{Eq. (9)}$$

3.1.1 Carbon as limiting reagent

Carbon rule details about the amount of atomic carbon conversion present in the biomass (numbered as carbon 30) into valuable products such as alkanes, alcohol, or carbon monoxide with range of conversion from 0 to 100% in proportion to the production of carbon dioxide from the reaction. The proportional carbon conversion ration given by equation (10).

$$C\% = \frac{n_{\text{product}} * \xi_{\text{Cproduct}}}{n_{\text{biomass}} * \xi_{\text{Cbiomass}}} \quad \text{Eq. (10)}$$

Where, n_{biomass} , n_{product} refers to stoichiometric number of moles of biomass and products in equilibrium reaction respectively. The formation of carbon dioxide in the reaction measures the carbon conversion ratio and

the supply of oxygen into the reaction. As well the formation of carbon monoxide basically appreciated by the partial oxidation of biomass described by equation (14) . The general conversion reaction of the biomass equation (11 - 13) considered sulphur and nitrogen are negligible. The reactions were conducted with providing only oxygen and only hydrogen equation (12 and 13), and with simultaneous provision of oxygen and hydrogen, equation (13).

where, the parameter (β) used to adjust the CO_2 production and carbon conversion ratio (C%).

Eq. (14)

Hence, the general biomass conversion, $C_x H_y O_z$ into alkanes can be described as equation (14 - 16) with provided only oxygen, only hydrogen, and with simultaneous provision of both oxygen and hydrogen in the conversion reaction.

3.1.2 Hydrogen as limiting reagent

In this perspective the atomic hydrogen in biomass taking a role play career as a limiting reagent in the biomass conversion reaction. The amount of hydrogen contain in the biomass converted into useful products such as alkanes, alcohol, or hydrogen. on the same analogy of carbon the hydrogen atom in the biomass conversion performance described by hydrogen conversion ratio equation (18).

$$H\% = \frac{n_{product} \cdot \xi_{Hproduct}}{n_{biomass} \cdot \xi_{Hbiomass}} \quad (18)$$

Like the carbon conversion ration (C%), hydrogen conversion ratio (H%) used a defined adjustable parameter (α) for hydrogen conversion and water production. The potential of hydrogen conversion differ accordingly with the biomass composition and H/O ratio. Based on the unified generalized molecular formula of dry bagasse ($C_{30} H_{46.65} O_{17.11}$), dry molasses ($C_{30} H_{56} O_{28}$), and dry filter cake ($C_{30} H_{51.14} O_{22.7}$), the H/O ratio accounts 2.73, 2, and 2.25 respectively considered to the capture or supply of carbon and oxygen for possible reactions. The possible reactions to decide the product either alkanes or alcohols shown equation (19 - 23).

$$n_{biomass} \cdot C_{\xi_C} H_{\xi_H} O_{\xi_O} \rightarrow n_{product} \cdot Product + \alpha H_2O + n_{CO_2} \cdot CO_2 + n_{O_2} \cdot O_2 \quad (23)$$

The production of water and hydrogen conversion appreciated by exothermic reaction of biomass without the supply of external heat described by equation (24).

$$C_x H_y O_z + \frac{1}{2}(2x - z + \alpha) \cdot O_2 \rightarrow \frac{1}{2}(y - 2\alpha) \cdot H_2 + \alpha H_2O + x \cdot CO_2 \quad (24)$$

Similarly considering hydrogen as a limiting reagent to the biomass conversion to the product formation of alkanes given equation (25 - 28).

$$C_x H_y O_z \rightarrow \frac{y-2\alpha}{2n+2} \cdot C_n H_{2n+2} + \alpha H_2O + \left[x - \frac{n(y-2\alpha)}{2n+2} \right] \cdot C + \frac{z-\alpha}{2} \cdot CO_2 \quad (25)$$

$$C_x H_y O_z \rightarrow \frac{y-2\alpha}{2n+2} \cdot C_n H_{2n+2} + \alpha H_2O + \left[x - \frac{n(y-2\alpha)}{2n+2} - \frac{z-\alpha}{2} \right] \cdot C + \frac{z-\alpha}{2} \cdot C \quad (26)$$

$$C_x H_y O_z + \left[x - \frac{n(y-2\alpha)}{2n+2} - \frac{z-\alpha}{2} \right] \cdot O_2 \rightarrow \frac{y-2\alpha}{2n+2} \cdot C_n H_{2n+2} + \alpha H_2O + \left[x - \frac{n(y-2\alpha)}{2n+2} \right] \cdot CO_2 \quad (27)$$

$$C_x H_y O_z \rightarrow \frac{y-2\alpha}{2n+2} \cdot C_n H_{2n+2} + \alpha H_2O + \left[x - \frac{n(y-2\alpha)}{2n+2} \right] \cdot CO_2 + \left[\frac{z-\alpha}{2} - x + \frac{n(y-2\alpha)}{2n+2} \right] \quad (28)$$

In the case of alcohol the $C_n H_{2n+2}$ terms of equation (25 - 28) replaced by $C_n H_{2n+2}O$. The parameter β varies accordingly with the amount of carbon, ξ_C . The variation can be between $\beta = 0$, and $\beta = 30$. When $\beta = 0$, the carbon conversion is the same as the amount of carbon contained in the biomass. When $\beta = 30$, all the carbon atom in the biomass converted to CO_2 . Similarly, the parameter α varies with the conversion of hydrogen in the biomass into water and hydrogen.

4. Results and Discussion

4.1. Hydrolysis of bagasse

To achieve the conversion of bagasse to biofuel, since it is unrealistic to convert water (moisture content), the assumption is that water can hydrolyze cellulose and hemicellulose to sugar. The sugar obtained will have for molar composition the same composition as that already contained (presented) in the bagasse. Thus, the hydrolyzed biomass has a composition of $C_{30} H_{50.34} O_{18.18.96}$ and a LHV of 19.60 MJ / kg if it is considered to be dry. Virtually this consists of using 4.66% wet biomass (kg water / kg bagasse). In this specific case all, the water is consumed. If this operation is done on all of the incoming bagasse (16.53 kg/s), it will mobilize 6907 kg of water or 5.03% of the total water that constitutes the moisture in the bagasse. Hence, wet biomass: $C_{30} H_{120.11} O_{53.84}$ (LHV = 10.81MJ/kg) flow rate of 16.53 kg / s; dry biomass: $C_{30} H_{46.65} O_{17.11}$ (LHV = 20.51 MJ/kg) flow rate of 8.38 kg / s and hydrolyzed biomass: $C_{30} H_{50.34} O_{18.18.19}$ (LHV of 19.60 MJ / kg) flow rate of 8.79 kg / s. There is a slight drop in LHV, but a change in composition and a slight increase in throughput. The two offset each other. The gain is therefore not energy, but it gives a "realistic upper limit to the water that can be taken into account". In this stance 100% dry bagasse amount come into effect hydrolysis and of which 1 mole of cellulose gain 1 mole of water to release simple sugar. Since cellulose is a polymer and to define exact number of moles of hydrolyzed product assumed that $1 \cdot 10^6$ as a constant factor. Therefore, the number of moles of cellulose generated from the given mass can be calculated as equation (29).

$$n_{cellulose} = \frac{1E6 \cdot \dot{m}_{cellulose}}{M_{cellulose}} \quad (29)$$

Thus, from 62,165.7227 ton/year cellulose, $n_{cellulose}$ accounts 383739029.1 moles. The gain of water which is the same molar value assumption with the hydrolyzed cellulose and can be calculated as equation (30).

$$\dot{m}_{H_2O} = n_{cellulose} \cdot \frac{M_{H_2O}}{1E6} \quad (30)$$

The mass of water gained during hydrolysis goes to 6907.302524 ton/year, which is only 5.032% of the water contained in the original bagasse it accounts 49.28% moisture content from the total 278560.20 ton/year of bagasse production. Consider that the calculated dryness of 50.7% moisture free bagasse. In the case of additional drying, the energy (if necessary to dry) represents 2%, assuming that the sun brings us to a dryness of 85% (which remains to be verified). This question of drying will be central if design to make a biorefinery scheme, less important if this is satisfied with a theoretical analysis and relying on the sun. The amount of water evaporated is considered as the difference of amount of water in the original biomass and the amount of water required for hydrolysis process equation (31), which is about 130367.164 ton/year.

$$\dot{m}_{H_2O, \text{ evaporated}} = \dot{m}_{H_2O, \text{ biomass}} - \dot{m}_{H_2O, \text{ hydrolysis}} \quad (31)$$

To reach to complete dryness of bagasse it requires energy for evaporation depend on the latent heat of evaporation and the amount of water evaporated as described in equation (32).

$$E_v = \dot{m}_{H_2O} * L_v \quad (32)$$

Where, E_v , and L_v are heat energy required for evaporation and specific latent heat of vaporization (2250 kJ/kg) of water respectively. Therefore, energy required to evaporated the specified amount of water is $2.93326 * 10^{11}$ kJ/year. The amount of energy contained in hydrolyzed biomass according to its lower heating value equation (3) from the molecular formula ($C_{30}H_{50.34}O_{18.96}$) is calculated as equion (33).

$$E_{\text{hydrolyzed biomass}} = \dot{m}_{\text{hydrolyzed biomass}} * LHV_{\text{hydrolyzed biomass}} \quad (33)$$

Therefore, the hydrolyzed bagasse energy content refers to $2.90482 * 10^{12}$ kJ/year. Taking into account the percent ratio of energy required to evaporation to the energy contained in the hydrolyzed biomass ($E_v/E_{\text{hydrolyzed biomass}}$) about 10. Thus to evaporate the water gained for hydrolysis, in order to obtain a dry product, one can consider a complete or partial thermal action in addition to solar drying. In the case of complete drying, without the integration of heat, the energy required to represents 10% of the energy contained in the hydrolyzed bagasse.

4.2. Site power requirements

The power requirement to sugar production assumed be the unit's overall needs are covered by bagasse. The calculations presented (Table 1), are for dry bagasse. But the same is found for the other two forms of biomass (molasses and filter cake). The designed power requirement of the factory is 11 MW of electricity generated from its back pressure turbine with an average steam to cane ratio of 0.56 from 906089.5 ton/year crushed cane. The annual steam production could reach 507410.12 ton/year at 180°C. Therefore, the steam power can be calculated as given equation (34).

$$P_{st} = \frac{\dot{m}_{\text{steam}} * H_{v, H_2O}}{t_{\text{operation}}} \quad (34)$$

Where, P_{st} and $t_{\text{operation}}$ are steam power potential and annual operation time (4680 hr/year) of the case factory. Hence, the steam power calculated is 83.785313 MW for bagasse 49.28% moisture. The heat requirement for electricity generation can be determined from the electricity consumption to bagasse feed ratio ($\frac{P_{\text{consumption}}}{\dot{m}_{\text{bagasse}}}$) or (11 MW/16.5337251 kg/s), of which 0.6653 MW/kg bagasse. On the same way the heat requirement for steam production follow steam to bagasse ratio ($\frac{\dot{m}_{\text{steam}}}{\dot{m}_{\text{bagasse}}}$), about 1.821546 with enthalpy of the steam at specified temperature (180°C). Table (3) describes the heat requirement values for electricity generation and steam production for a flowrate of 1 kg/s of bagasse.

Table (3) heat requirement values for electricity generation and steam production for 1 kg/s biomass.

Heat for electricity generation	1.869661953 MW/kg bagasse	$(\frac{P_{consumption}}{m_{bagasse}}) / (1 - (\sqrt{\frac{T_{cold}}{T_{hot}}}))$, $T_{cold} = 300k$ and $T_{hot} = 723k$
Heat for steam production	5.067539993 MW	$(\frac{m_{steam}}{m_{bagasse}}) * \Delta H_{steam, T=180^{\circ}C}$

Therefore, it becomes 1.31 MW/kg of total dry bagasse. Electricity is produced from steam at 300 °C and it consider an efficiency to be closer to finite time production $(1 - (\sqrt{\frac{T_{cold}}{T_{hot}}}))$, with $T_{cold} = 300K$, $T_{hot} = 573 K$.

Table 4. Biomass to energy conversion result on moisture free feedstocks and hydrolysed bagasse

Feedstock	Alcohol			Alkane			CO+H ₂		Flow (kg/s)	LHV (MJ/kg)
	Energy [kJ]	Mass [kg]	C	Energy [kJ]	Mass [kg]	C	Energy [kJ]	Mass [kg]		
Hydrolyzed bagasse	93.30	56.20	12	93.30	41.40	12	94.00	123	2.37 (3.30*)	19.60
Dry bagasse	93.30	54.60	12	93.30	43.40	12	93.40	129	2.36 (3.17*)	20.51
Dry molasses	93.30	46.70	9	93.20	31.00	10	94.60	1	1.20	14.96
Dry filter cake	93.30	52.60	10-12	93.10	36.50	12	94.30	1,12	1.97	17.33

(C refers to carbon atom number), (* refers to hydrolysed biomass flowrate)

For steam, the power found is 83 MW. The ratio of 0.56 (steam to cane ratio), for steam becomes in MW/kg dry bagasse is 3.59. To fix ideas it is necessary to articulate the energy equivalent of 1kg/s of wet bagasse is the production of 4.74 MW electricity and 9.99 MW steam. However, with a dry bagasse flow rate of 8.38 Kg/s and a LHV 20.51 MJ/kg to cover the plant's needs, it will therefore be necessary to burn 1.93 kg/s for electricity and 4.08 kg/s for steam generation.

In this case Steam/electricity production is not optimized in the sense of cogeneration. But, in view of the ratio of vapor taken, this is a point to be discussed and it leaves a flow rate of 2.36 kg/s of dry biomass. This calculation done for the wet biomass, results 2.59 kg/s and 2.37 kg/s for the hydrolyzed biomass. It's preferred to retain the two values of 2.36 kg/s and 2.37 kg/s to conversion for LHV of wet biomass. Hence, the power requirement can be seen with cogeneration and extraction, and without cogeneration schemes. The cogeneration and extraction scheme considered that the steam cycle at a hot temperature of 450°C to 180°C withdrawn the turbinéd horse power (HP) with no stretch to 27°C. This is substantial gain of 3.1 kg/s (Table 4) of dry biomass which is almost 107 theoretical MW power and 98,000 tons of biofuel. Where as, without cogeneration integration scheme the production of biofuel (alcohol and alkanes), goes to 93 MW of power from 5.1 kg/s biomass and 86,000 tons of possible biofuel during the whole operation time in a year.

5. Conclusion

Biomass is a versatile and abundant resource, which can be used to produce energy via different routes. Several kinds of biomass can be used either to produce bioethanol or alkanes, CO and H₂. To this end, some boundary conditions, including the area of application and the presence of existing infrastructure to process integration, have to be identified. It is suspected that from the complete balance sheet of the biomass composition, water has significant role in the final energy content (LHV). Although biochemical pathway is reliable techniques, already common at full-scale, the integrated thermochemical process feasibility for industrial application should be more deeply investigated. Nevertheless, the strongest integration is the water treatment unit. Water is three times more important than biofuel. This treated water (and separated in fact if it is concentrate the material in sugar + biofuel) also has a significant value. Since, 92% of Ethiopia's policy is based on the biomass resource; biorefinery integration into the sugar factories is of prime importance.

Abstract

With the emergence of new pathogens, e.g., methicillin-resistant *Staphylococcus aureus* (MRSA), and the recent novel coronavirus pandemic, there has been an ever-increasing need for novel antimicrobial therapeutics. In this work, we have developed support vector machine (SVM) models to predict antiviral peptide sequences. Oscillations in physicochemical properties in protein sequences have been shown to be predictive of protein structure and function, and in the presented work we have taken advantage of these known periodicities to develop models that predict antiviral peptide sequences. In developing the presented models, we first generated property factors by applying principal component analysis (PCA) to the AAindex dataset of 544 amino acid properties. We next converted peptide sequences into physicochemical vectors using 18 property factors resulting from the PCA. Fourier transforms were applied to the property factor vectors to measure the amplitude of the physicochemical oscillations, which served as the features to train our SVM models. To train and test the developed models we have used a publicly available database of antiviral peptides (<http://crdd.osdd.net/servers/avppred/>), and we have used cross-validation to train and tune models based on multiple training and testing sets. To further understand the physicochemical properties of antiviral peptides we have also applied a previously developed feature selection algorithm. Future work will be aimed at computationally designing novel antiviral therapeutics based on the developed machine learning models.

Keywords: Computational biology, Machine learning, Support vector machines, Feature selection, Antiviral peptides

1. Introduction

With the increasing threat of viruses on human populations around the world, as evidenced by the recent COVID-19 pandemic, there is significant need for approaches for rapid development of treatments for novel viral outbreaks. If and when a new viral outbreak poses an eminent threat, the availability of tools for therapeutic design could enable the fast and efficient development of novel antiviral treatments. One promising class of antiviral treatments are anti-viral peptides (AVPs), which can act in a variety of ways, such as inhibiting replication, preventing binding to host cells, and interrupting virus-induced host signalling. Rational approaches have been previously used to successfully design AVPs, and more recent efforts have been aimed at using computational methods to predict their function based on the peptide sequence. One challenging aspect of developing machine learning models is identifying how to best encode or represent a peptide's sequence or properties. Most datasets of peptide function include peptides of varied length and to train a machine learning model one

must ensure that every peptide is represented by the same number of features. Past efforts for predicting AVPs have used peptide features that include the number of positively/negatively-charged amino acids, the charge of the peptide, the frequency of each amino acid in the sequence, the amount of possible H-bonds, molecular weight, and average hydrophobicity. One major limitation of these features is they do not maintain information regarding the ordering of amino acids or properties along the peptide structure, which is known to be crucial to protein structure and function. An alternative approach for developing physicochemical descriptors of protein sequences has been previously proposed that takes advantage of underlying periodicities in protein/peptide physicochemical properties (Eisenberg et al. 1984; Rackovsky 1998). Rackovsky (1998) has shown that periodicities of physicochemical properties along the sequence of a protein can be used to categorize families of protein structure/function. By using Fourier transforms and numerical tricks, it is possible to encode peptide sequences of varying lengths in terms of the same number of features based on the oscillation of amino acid properties.

In this work, we have used data analysis (i.e., PCA) and machine learning (i.e., support vector machines) to develop accurate models for predicting AVP sequences based on periodicities of amino acid properties. Additionally, by ranking the importance of the developed Fourier-based features, we were able to train SVM models with improved accuracy and generalizability, while also beginning to gain some insights into the importance of oscillations in physicochemical properties for AVP function.

2. Methods

In this work, we have used the R statistical language to perform all steps of our analysis including the generation of amino acid property factors using PCA, Fourier-based feature extraction, training/validating support vector machines, and feature selection. Below are more detailed descriptions of how these elements of our approach were implemented.

2.1. AVP Dataset

To develop data-driven classification models we need to have access to sufficiently large datasets, which contain both amino acid sequences and function labels. At present, there are multiple publicly available databases that hold the identities of some known antiviral peptides, including AVPpred (Thakur et al. 2012), APD3 (Wang et al. 2016), and CAMPR3 (Waghu et al. 2016). In the current study, we have focused on the AVPpred dataset, which contains 544 experimentally validated antiviral peptide sequences along with two sets of negative AVP: i) 407 experimentally validated nonactive peptides; and ii) 544 randomly selected non-secretory peptides. To eliminate the possibility of potential bias, we filtered the AVPpred dataset to eliminate any sequences with greater than 40% sequence identity. This was performed by first using the Clustal Omega webserver (<https://www.ebi.ac.uk/Tools/msa/clustalo/>) to align all sequences of the AVPpred dataset, and then applying hierarchical clustering in R to identify clusters of sequences sharing more than 40% sequence identity. The medoid of each cluster was selected as the representative sequence, resulting in 195 AVP sequences, 259 nonactive AVP sequences, and 492 randomly selected non-secretory peptides. The filtered dataset is what was used for all of the model training and validation in presented work.

2.2. Principal component analysis

To generate physicochemical Fourier-based features, we first need to convert amino acid sequences into numerical vectors based on amino acid properties. The AAindex dataset, found in the *protr* R package, is a collection of 544 amino acid properties from the literature that include various physicochemical descriptors. All of the 544 amino acid properties could be used to convert the amino acid sequences into property vectors; however, this would result in thousands of potential features once the property vectors were converted into Fourier coefficients. Alternatively, we can perform dimensionality reduction to reduce the number of amino acid property vectors prior to conversion to Fourier coefficients. In the current work, we have applied principal component analysis to generate amino acid property factors, as has been proposed previously. We used the *prcomp* function in R to extract principal components and to select a subset of the principal components based on contributions to the overall variance in the data (Figure 1).

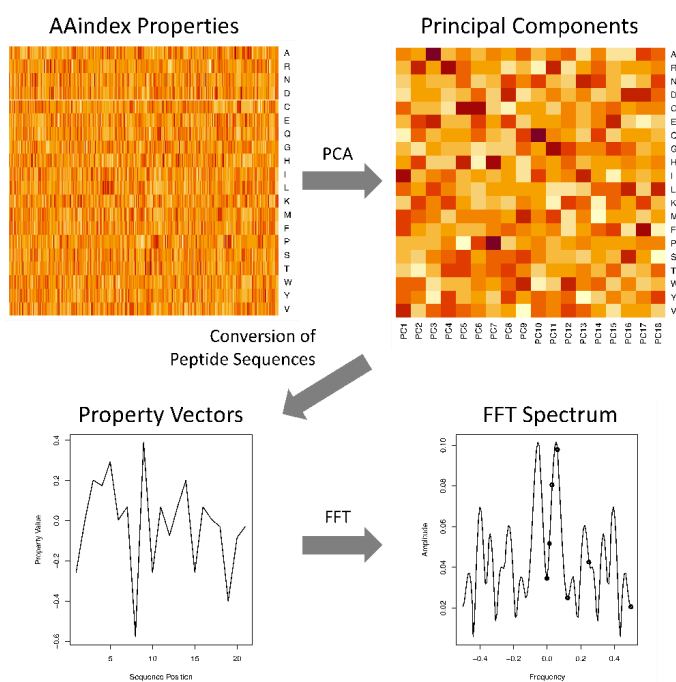

Figure 1. Schematic of feature extraction procedure based on amino acid property periodicities.

2.3. Feature extraction

Based on the generated amino acid property factors, we then converted the amino acid sequence of each peptide into physicochemical vectors (Figure 1). Fourier transforms, using the *fft* function in R, were then applied to each of the property factor vectors. To ensure that the same number of frequency (Fourier) components were generated for each property vector we used zero padding and an assumed maximum sequence length of 128 amino acids (maximum AVP sequence length in the dataset is 107 amino acids). The moduli of the complex Fourier coefficients for frequency values of 0, 0.015625, 0.03125, 0.0625, 0.125, 0.25, and 0.5 were selected as the features for training models (Figure 1). The frequency components (features) corresponding to periods that are

longer than a given peptide were set to zero. We eliminated features (columns) from the full set of features if more than 70% of peptides had a value of zero.

2.4. Support vector machines

All support vector machines were trained using the *svm* function of *e1071* R package based on the radial basis function nonlinear kernel. The cost and gamma hyperparameters of the SVM models were tuned using a grid-search with cost and gamma values based on powers of two, $2^n \forall n \in \{-9, \dots, 8\}$, where n is an integer. Five-fold cross-validation, based on balanced training sets containing 435 AVP and 435 non-AVP sequences, was used to tune and validate the models based on first sorting the peptide sequences according to length and then select five training and testing sets with an equal number of samples for each peptide class. Model performance was measured based on classification accuracy and is reported as the fraction of classes (AVP or non-AVP) that was predicted correctly in the testing sets (Figure 3). The reported cross validation accuracies are the average of the classification accuracies for the five training and testing sets.

Figure 2. Variance explained by the 20 principal components from the PCA of the 544 AAindex amino acid properties.

2.5. Feature selection

Feature selection is a crucial aspect of data science as it can enable the identification of an essential set of predictive descriptors (features), as well as it can increase the robustness of models to prevent overfitting. Previously, we have developed a feature selection algorithm based on non-linear SVMs, which is general in nature and has been applied to predicting fault detection in chemical plants (Onel et al. 2018; Onel et al. 2019) and HIV-1 viral entry (Kieslich et al. 2016). The algorithm is model-based and requires first training a SVM model prior to computing a criterion that quantifies the contribution of each feature to the SVM objective function to determine which features to remove. The criterion (Eq. 1) is derived based on sensitivity analysis of the dual formulation of SVM models.

$$crit_k = - \frac{1}{2} \sum_i \sum_j \alpha_i^* \alpha_j^* y_i y_j \frac{\partial K(x_i^{\circ z}, x_j^{\circ z})}{\partial z_k} \Big|_{z=1} \quad (1)$$

The algorithm uses a greedy approach to rank the features, where we start with a training model based on all of the features, compute the criteria for all features, and remove a fraction of the features with the largest criteria values. In the presented work,

we removed 25% of the remaining features after each iteration of the algorithm and returned the hyperparameters after each iteration of the algorithm. The feature ranking procedure was applied to each of the five training sets and a consensus ranking was generated based on the average rank of each feature across the five training sets.

Figure 3. Feature contributions to model accuracy based on feature selection ranking. A) Feature selection results for classifying AVPs vs. random peptides; B) Feature selection results for classifying AVPs vs. non-AVPs.

3. Results

The principal component analysis of the amino acid properties from AAindex dataset was based on a data matrix consisting of 20 instances (amino acids) of 544 variables (properties). The PCA analysis generated 20 principal components that describe the more than 500 amino acid properties, and the contribution of each principal component is visualized in Figure 2. In choosing which principal components to use as amino acid property factors, we selected the principal components which contribute more than 1% of overall variance in the data. The first 18 principal components met our criteria (>1% variance) (Figure 2), and together describe over 99% of the total variance. The analysis resulted in 18 amino acid property factors that were used to generate 18 property vectors for each of the peptide sequences. For each peptide, the FFT spectrum of each property vector was computed and the frequency components corresponding to the sequence average and the oscillations with periods of 2, 4, 8, 16, 32, or 64 amino acids were extracted. This resulted in 126 features based on 7 frequency components from 18 property vectors for each sequence, which was filtered to 90 features by removing features with at least 70% of the values being zero.

Based on the generated features, we developed two SVM models, one to distinguish the AVP peptides from each of the types of non-AVP peptides (nonactive and random non-secretory peptides). For both classification tasks, we performed feature selection to rank the physicochemical features. To measure the contribution of each feature to model accuracy we performed five-fold cross validation after adding each feature one at a time starting with the highest ranked feature. As can be seen in Figure 3, distinguishing AVPs from random non-secretory peptides is an easier classification task

than distinguishing AVPs from nonactive AVPs, since the maximum accuracy when using random peptides is 0.912 and only 0.752 for the nonactive peptides. Only 5 of the 90 features are necessary to achieve the majority of the accuracy of the AVP-vs-random model, while about 4 times as many features are necessary to achieve the maximum accuracy of the AVP-vs-nonactive model, which is further evidence of the difficulty distinguishing between active and nonactive AVPs.

4. Conclusions

In this study, we have developed support vector machine models that distinguish between antiviral peptide sequences and two classes of nonAVP sequences. To develop these models, we first generated amino acid property factors by applying principal component analysis to a dataset on amino acid properties from the literature. We then used the property factors to convert AVP sequences into property vectors that served as the input for Fourier analysis to extract the features used in training our models. The proposed approach for feature extraction and model development, including the incorporation of the feature selection algorithm, have potentially applications in prediction of peptide properties and function. Future work will be aimed at improving the Fourier-based encoding of peptide sequences and applying the approach to predicting various peptide functions/properties, as well as further development of approaches for SVM-based feature selection. The models developed in this study could have potential use in designing novel antiviral peptides but given the remaining challenges in distinguishing between active and nonactive AVPs further investigation is necessary, which may need to include both computational and experimental studies.

Abstract

Mammalian circadian clocks are composed of transcriptional-translational feedback loops. Transcriptional activators (BMAL1/CLOCK) form positive arm and transcriptional repressors (CRYPTOCHROMEs (CRYs) and PERIODs (PERs)) form the negative arm of the clock mechanism in mammals. CRYs have conserved primary (FAD binding) and secondary pockets critical to interact with different proteins. Despite high structural similarities between CRY1 and CRY2, studies suggest each CRY plays a different role in the circadian clock. For example, the binding of the CRY1 to CLOCK is regulated by a dynamic serine-rich loop (Ser-loop) around the secondary pocket. A recent report showed that a distant residue Arg-293 allosterically regulates the Ser-loop in CRY1. Here, using molecular dynamics simulations, we showed that Arg-311 to His mutation in CRY2 (homolog of Arg-293 of CRY1) had a minor effect on the allosteric path to Ser-loop.

Keywords: Circadian Clock, Cryptochromes, Allosterism, Molecular dynamics simulation

1. Introduction

The circadian clock regulates several behavioral and physiological processes such as alertness, memory, heart rate, blood pressure, and immune responses through rhythmic transcriptional regulation (Cermakian *et al*, 2013). Several diseases e.g. diabetes, obesity and some sleep disorders are associated with circadian rhythm abnormalities (Sahar & Sassone-Corsi, 2009).

At a molecular level, BMAL1 and CLOCK form heterodimer and bind to E-box (CACGTG) in the promoter region of clock-controlled genes (CCG) including *Period* (*Per*) and *Cryptochrome* (*Cry*) to initiate their transcription in mammals (Aryal *et al*, 2017). After accumulation and translocation of PER and CRY along with casein kinase I ϵ (CKI ϵ) into the nucleus, they bind BMAL1/CLOCK dimer and inhibit transcription (Aryal *et al.*, 2017; Kavakli *et al*, 2017; Kavakli & Sancar, 2002). The degradation of

CRY and PER proteins relieves the repression of BMAL1/CLOCK, restarting the cycle (Takahashi, 2016).

There are two *Cry* genes in mammals and studies suggested that CRYs have different roles in the circadian clock as discussed in (Cal-Kayitmazbatir *et al.*, 2021; Fribourgh *et al.*, 2020; Gul *et al.*, 2020). CRYs contain a photolyase homology region (PHR) comprising primary (FAD binding) and secondary pockets and an extended C-terminal region (Kavakli *et al.*, 2017; Ozber *et al.*, 2010; Partch *et al.*, 2005). PHR and C-terminal regions of the CRYs are necessary to maintain rhythmicity and amplitude of circadian rhythm, respectively (Gao *et al.*, 2013; Khan *et al.*, 2012). CRY1 interacts directly with CLOCK and BMAL1 through two distinct regions in the PHR domain (Michael *et al.*, 2017). C-terminal regions of CRYs interact with the transactivation domain (TAD) of BMAL1 (Czarna *et al.*, 2011; Xu *et al.*, 2015). Mutational analysis of CRYs showed that residues around the secondary pocket of CRY1 and CRY2 are critical for the CLOCK binding and their repression activity (Rosensweig *et al.*, 2018). A human gain-of-function CRY1 variant (exon 11 skipping mutation in C-tail of CRY1), exhibiting high affinity to BMAL1/CLOCK, and another CRY1 mutant (exon 6 skipping mutation in PHR of CRY1), causing an arrhythmic phenotype in a cell line, were found in people suffering from familial delayed sleep phase disorder and attention deficit/hyperactivity disorder (Onat *et al.*, 2020; Patke *et al.*, 2017).

Our recent study revealed that the Arg-293 of CRY1, within the FAD binding pocket is important for the allosteric regulation of Ser-loop and has affected the molecular clock (Gul *et al.*, 2020). Sequence alignment showed that the Arg-293 is a conserved amino acid residue in both CRY1 and CRY2. Thus, in this study, we performed the molecular dynamics simulation to understand the role of Arg-311 in CRY2 (the homolog of Arg-293 in CRY1) in the allosteric regulation of the Ser-loop.

2. Materials and Methods

Complete photolyase homology region of mouse CRY2 with accession number of NP_034093.1 was obtained from NCBI database. Sequence was submitted to the RaptorX web-server to get complete PHR structures for CRY2 (Kallberg *et al.*, 2012). CRY2-Arg-311His (homolog of Arg-293 of CRY1) mutant protein structure was generated using VMD psfgen plugin. Protonation states of ionizable residues of all four models calculated using PDB2PQR webserver that uses PROBKA. The CHARMM36m forcefield and NAMD software were used for parametrization and to run simulations respectively. Systems were solvated in a rectangular box that extends 10 Å from the closest protein surface by TIP3P water. Periodic boundary conditions and Particle Mesh Ewald (PME) used for full electrostatic interactions with a 12 Å cutoff. All covalent hydrogen bond lengths were constrained with SHAKE algorithm with a time step of 2 fs. Systems were, then, neutralized with the appropriate amount of sodium and chloride ions. Energy minimization was performed for 100,000 steps. After, systems were heated and equilibrated for 140ps. The temperature increased gradually, 5K per step, until 310K using a Langevin thermostat. NPT equilibration performed at 310K and under 1 atm, pressure using Langevin barostat. During equilibration, harmonic restraints of 3 kcal·mol⁻¹·Å⁻² on Ca atoms were gradually removed. Production simulations were run for CRY2, and CRY2-Arg-293His for 300ns and 150ns, respectively. Temperature and pressure were maintained by the Langevin thermostat and the Langevin barostat, respectively. NAMD software and CHARMM force fields were used to run all MD simulations (Phillips *et al.*, 2005).

For analysis of simulations, all trajectories were aligned to the initial structure, and we discarded first 10 ns of all simulations. RMSD, H-bonds and RMSF calculations were performed by using VMD. Each of the refined trajectories was saved as two multi-frame pdb files with 1 ns and 100 ps intervals for analysis to be used in POVME and WISP, respectively. Secondary pocket volume was calculated using POVME 3.0 software (Wagner *et al.*, 2017), with a 1 ns intervals. The Wilcoxon rank-sum test was used to determine the significance of the difference between the pocket volumes implemented in R (Wickham, 2009). WISP 1.1 software was used to analyze the allosteric pathways (Van Wart *et al.*, 2014).

3. Results

Our previous work showed that p.Arg293His CRY1 variant exhibits CRY2-like *in vitro* properties (Gul *et al.*, 2020). Our further molecular dynamic simulation revealed that the Arg-293 is responsible for allosteric regulation of the Ser-loop, which plays an important role in CLOCK-CRY1 binding. The multiple sequence alignment with other CRYs from different organisms showed the conservation of this residue, including mammalian CRY2. To understand the role of Arg-311 (homolog of Arg-293 of CRY1) in allosteric regulation of CRY2 we employed molecular dynamics (MD) simulations using CRY2 and CRY2-R311H structures. For comparison, previously reported simulation data of CRY1 and p.Arg293His CRY1 were used (Gul *et al.*, 2020). Root-mean-square deviation (RMSD) values for each structure was calculated to show that simulations reached equilibrium (**Figure 1A**). Next, the dynamics of CRY1 and CRY2 were compared by plotting root-mean-square fluctuation (RMSF) of each amino acid residue in CRYs. Overall, the dynamicity of both CRYs is different, especially in α/β domains including Ser-loop and P-loop (**Figure 1B**). Ser-loop in CRY1 was found to be highly dynamic compared to Ser-loop of CRY2. We then compared RMSF plot of CRY2-R311H with CRY2 to evaluate change in the dynamicity of both structures. Results demonstrated that Ser-loop dynamicity are very similar in both structures. However, the P-loop behavior was greatly affected by the mutation in CRY2 (**Figure 1B, C, D**). The same mutation increased the dynamicity of C-lid that is critical for CRY-PER2 and CRY-FBXL3 interactions (Czarna *et al.*, 2013), in both CRYs (**Figure 1C, D**). Collectively, our data suggested that the highly conserved Arg amino acid residue in CRY1 and CRY2 has differential effects on the CRYs.

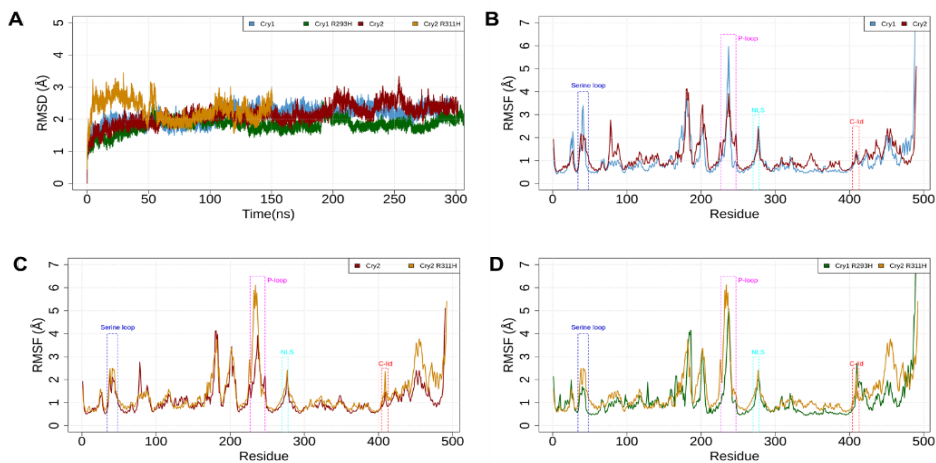

Figure 1: **A)** Root mean square deviation (RMSD) of all simulations (CRY1, CRY1-R293H, CRY2, CRY2-R311H). Root mean square fluctuation (RMSF) of **B)** CRY1 and CRY2; **C)** CRY2 and CRY2-R311H; **D)** CRY1-R293H and CRY2-R311H. For the sake of figure clarity, residue numbering in CRY1 was followed. The critical and functional parts of CRYs were shown between dashed lines. NLS: Nuclear localization signal.

We then calculated the secondary pocket volumes (SPV) of CRY2 and CRY2-R311H and compared them previously reported CRY1 and CRY1-R293H results (Gul *et al.*, 2020) to analyze the effect of mutations, where CLOCK binds. The SPV of the CRY2-R311H was quite larger than both CRY1 and CRY1-R293H and comparable to that of CRY2 (**Figure 2A**). Unlike Arg-293 mutation to His in CRY1, Arg-311 to His mutation in CRY2 did not affect the SPV. The distance between the Ser-loop and secondary pocket was not affected in CRY2-R311H, however, the same distance was affected in CRY1-R293H (**Figure 2B**). Finally, the number of H-bonds was calculated between the Ser-loop and the rest of the protein. The decreased distance between Ser-loop and secondary pocket in CRY1-R293H can be explained by more hydrogen bond formation throughout the simulation compared to CRY1. Amount of hydrogen bond per frame was similar in CRY2 and CRY2-R311H. H-bond analysis suggests that the effect of Arg-311 mutation in CRY2 has a different effect on CRY2 than that of its homolog mutation in CRY1 (**Figure 2C**). To address the effect of R311H mutation on the allosteric regulation of Ser-loop in CRY2 we investigated the allosteric paths between Ser-loop and Arg-311 using WISP. The shortest lengths of the allosteric paths (between Ser-loop and residue 311) in CRY2 and CRY2-R311H were 3.4 Å and 2.2 Å, respectively. Other suboptimal paths to Ser-loop were quite different in CRYs (**Figure 2D**). WISP analysis for CRY2 structures in this study and our previous CRY1 results (Gul *et al.*, 2020) showed that: 1) CRY1 and CRY2 path lengths are changing in different magnitudes, implying that allosteric regulations between the Arg293 and the Arg-311 and Ser-loop in CRY1 and CRY2 are different, respectively; 2) while Arg293His mutation changed the shortest path length dramatically in CRY1, Arg-311 to His mutation in CRY2 had less effect on the path length. To note, SPV mainly affected by the position of highly dynamic unstructured Ser-loop in CRY1, however, Ser-loop in CRY2 has a turn of an alpha helix that increases its rigidity. Because of the rigidity of

Ser-loop in CRY2, the effect of mutation might not alter its dynamics as drastically as in the CRY1.

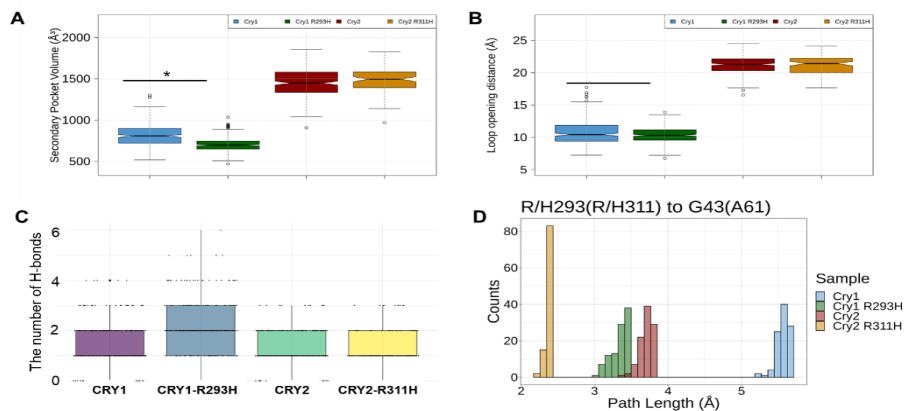

Figure 2: Box-plot representation of the **A**) secondary pocket volume (Wilcoxon rank sum test *: $p < 0.0001$); **B**) loop distance between Ser-loop (Gly43/Ala61) and Phe 105/123 (first residue number is for CRY1, second for CRY2), **C**) number of H-bonds between Ser-loop and rest of the protein per frame. The same number of pdb files were used for each calculation. **D**) Histogram representation of pathways' length calculated by using WISP.

Conclusions

Despite high primary sequence and tertiary structure similarities between CRY1 and CRY2, their different functions in the mammalian circadian clock remained elusive. One of the most notable differences between CRY1 and CRY2 is their differential affinity to CLOCK. Recent reports shed light on the critical amino acids and loop dynamics for the CRY-CLOCK binding (Fribourgh *et al.*, 2020; Rosensweig *et al.*, 2018). Our recent paper identified unique allosteric regulation between the Arg-293 in the primary pocket and Ser-loop in CRY1 (Gul *et al.*, 2020). In this report, we analyzed the role of homolog Arg residue (Arg-311) of CRY2 in allosteric regulation using MD simulations. Full-length PHR domains of CRY2 and CRY2-R311H were modeled and simulated and compared with previously reported CRY1 simulations. RMSF analysis showed that CRY1 and CRY2 have different dynamics. Mutations on CRY1 and CRY2 differentially affected the overall dynamicity. While dynamics of Ser-loop were significantly reduced in CRY1-R293H mutant, it didn't get affected in CRY2-R311H mutant. H-bond analysis suggested that the reduced Ser-loop dynamicity may stem from an increase in H-bond interaction between the loop and the rest of the protein in CRY1-R293H. Unlike CRY1-R293H, the secondary pocket volume of the CRY2-R311H remained unchanged. The dynamics of CRY1 and CRY2 were drastically different in primarily two regions, Ser-loop and P-loop. While CRY1-R293H had reduced the dynamics of both regions, CRY2-R311H had a subtle effect on the dynamics of Ser-loop but increased the dynamics of the P loop. Consistently both mutations increased the dynamicity of C-lid. Experimental studies need to be carried out to show the physiological significance of such dynamical changes in the CRY2.

Reflections on the development of scenario and problem-based chemical engineering projects

A. Tsatse, E. Sorensen*

Department of Chemical Engineering, University College London, Torrington Place, WC1E 7JE London, UK

e.sorensen@ucl.ac.uk

Abstract

This work reflects on the use of scenario- and problem-based learning as a way of conveying not only fundamental knowledge, but also to provide training in the use of computational Process Systems Engineering (PSE) tools applied to open-ended real world problems. The teaching framework also has a strong emphasis on the development of professional skills and to evaluate the recommended design solutions considering multiple perspectives such as economics, safety, environment and societal context. The framework is implemented through week-long group projects called Scenarios, taking place mainly in the first two years of study, and examples are given of different variations of Scenarios. This teaching approach has multiple benefits, including but not limited to, students' understanding of PSE tools and the development of their critical engineering thinking.

Keywords: problem-based learning, Scenarios, Process Systems Engineering

1. Introduction

University College London (UCL) has long been considered a global leader in engineering education, and has also recently been identified amongst one of the strongest emerging trailblazers delivering cutting edge engineering education (Graham, 2018). The latter is partly due to the introduction of UCL's Integrated Engineering Programme (IEP) which was introduced in 2014/15. The IEP is a teaching framework that allows both specialist and interdisciplinary engineering education to be delivered across different engineering disciplines and in programmes that teach fundamental technical knowledge through interdisciplinary, research-based projects and professional skills. The programme aims to produce independent and self-directed engineers based on innovative teaching practices which includes the use of scenario- and problem-based learning using real world examples (Sorensen, 2016).

One of the main aspects of the IEP is a strong emphasis on modelling and design, starting with two compulsory modules dedicated to mathematical modelling & analysis for all engineering students in Years 1 and 2 (Molaei Chalchooghi and Sorensen, 2018), which for chemical engineering is supplemented by a third module on computational modelling and analysis. The use of computational tools is embedded within the curriculum and within most individual modules, and the students become proficient in the use of Matlab, GAMS, gPROMS and Aspen Plus. More importantly, they are taught

how to critically evaluate the results based on the assumptions made in the definition of the problem.

Most of the curriculum is still dedicated to core engineering disciplinary content, mainly for accreditation reasons, which is delivered through lectures, tutorials and labs, however, the IEP also introduced a series of project-based learning opportunities, in particular, during the first two years of studies. Students in their very first term take on two five-week engineering design challenges, where traditional lectures are replaced by smaller design workshops. During these workshops, they participate in modelling, testing and prototype-making of their engineering solutions for global challenges such as sustainability and global health (Sorensen, 2016). Similarly, within each department, including UCL's Department of Chemical Engineering, core modules have been re-configured into four-week blocks such that they offer a theoretical context for a one-week team-based project, within the IEP called Scenarios, following the block. Scenarios are one week-long projects where students working in groups are asked to tackle an open-ended real world problem that is related to the modules considered in that teaching term. The undergraduate curriculum currently delivers six such Scenarios across Years 1 and 2, all of which have a strong element of modelling and design (Molaei Chalchooghi and Sorensen, 2018), as well as of safety (Pollock and Sorensen, 2018), the latter not considered in this work but is also an integral part of each Scenario. In the following, the structure of the Scenarios will be presented, and examples of Scenario problems will be provided with particular emphasis on Process Systems Engineering (PSE), followed by a discussion of the benefits of this innovative approach on students' learning.

2. Problem-based learning through Scenarios

The Scenarios are research-based projects, firmly embedding the six dimensions of UCL's Connected Curriculum which aims to ensure that all UCL students are able to learn through participating in research and enquiry at all levels of their programme of study (Fung, 2017). The Scenarios teach fundamental engineering knowledge, but also have a strong focus on professional skills, ethics and safety. Of particular focus is the Statement of Ethical Principles set out by UK's Engineering Council and the Royal Academy of Engineering (Royal Academy of Engineering, 2017), an engineering concern that is not normally addressed in technical modules but is highly relevant to the discipline.

Each of the six Scenarios focuses on a different problem, the subject of which is of relevance to the topics that have been covered during the teaching term in the core modules, for instance, transport phenomena, thermodynamics or mass transfer. The Scenarios are usually related to the chemical industries, thus giving the students some insight into the types of problems they will face as practicing engineers during their career. The students are given five days to come up with a solution to the problem, attending progress meetings and facilitation sessions throughout the week, before submitting and presenting their results in a report and through a poster, presentation or video. Whilst the technical topics of the Scenarios are linked to core technical modules, the marks contribute to IEP modules on Design and Professional Skills, covering general learning outcomes related to these themes rather than technical aspects.

The department has used gPROMS ModelBuilder (Process Systems Enterprise, 2020) in undergraduate teaching for over 15 years, within the IEP introduced in the second term of Year 1. Process flowsheeting is introduced at the start of Year 2, with particular emphasis on Aspen Plus (Aspentech, 2017), which together with gPROMS are the main simulation tools used across the curriculum. Both tools are used within the Scenarios, which therefore also serve to introduce students to the importance of PSE and to how they can use their theoretical knowledge and modelling skills in order to model a chemical process, interpret its behaviour and think critically about how the process could be further improved from a design and/or operational perspective.

Team working is a key aspect of the IEP and for each Scenario teams are allocated on a different basis, for instance, based on accumulated average mark or even allocated randomly. A discussion of the rationale behind the different team allocations methods is unfortunately beyond the scope of this paper, so it will therefore suffice to say that, at the end of the sixth and last Scenario, and before the students start their capstone design project in Year 3, students are generally very confident that they can perform in various teams towards a common goal, ensuring that all team members have an equal workload and are respecting each other.

The Scenarios are normally launched on a Monday morning during a plenary introductory session where the Scenario topic and deliverables are presented by the teaching team and the expectations are stated to make sure the students understand the goals for this Scenario. Next, students are informed about the two client (progress) meetings during the week, the helpdesk sessions for any questions they might have and for software support, the deadlines they need to meet, as well as suggested literature. In this way, the teaching team ensures that the students are sufficiently guided, but at the same time have freedom to organize their work within their groups of five to six students (Wankat and Oreovicz, 1993). The teaching team usually consists of four members of teaching/academic staff and two Postgraduate Teaching Assistants (PGTAs) supporting a cohort of around 120 students. Staff members participate in the progress meetings and in the final presentations, whilst PGTAs mainly support students in the helpdesk sessions.

3. Scenario examples

In the following, three different Scenarios will be discussed. The focus will be on a Scenario normally delivered as the fourth Scenario, taking place at the end of the first term in Year 2, to illustrate different ways of delivering the same learning outcomes. The Scenario considered is linked to an introductory module on Separation Processes which covers fundamental aspects of distillation, absorption and extraction as well as basic column design.

Different Scenarios problems are considered each year. This is quite challenging for the teaching staff but ensures that students are not able to plagiarise a previous problem, or even seek assistance from older students. As the module lecturer is always one of the Scenario staff members, they can focus the delivery of the module around the Scenario problem to ensure that all the learning outcomes for the module are met regardless, hence the variation in the Scenario topic is not a concern.

a) Reactive distillation for the production of MTBE

The design of a reactive distillation process was considered in the 2017/2018 academic year. As reactive distillation is not exhaustively covered in the module curriculum, students were introduced to the concept of process intensification in depth for the first time in this Scenario. The first deliverables were therefore focused around reviewing the process; understanding its working principle and why it is considered a prime process intensification example; discussing the advantages and potential limitations of the industrially relevant case study, i.e. the production of MTBE, etc. Then, students were asked to simulate the case study using Aspen Plus (Aspentech, 2017), but were given a template input file from which to start. After the fundamental process modelling step, the next deliverable included suggestions from each team with regards to potential process improvements, demonstrating the benefits of their suggested design revisions on process performance and economics, and grounded in the simulation work.

b) Carbon Capture and Sequestration

Another example includes consideration of Carbon Capture and Sequestration (CCS), introduced in 2019/2020, where students were asked to design a carbon capture absorption unit based on a post-combustion method. The deliverables included reviewing the social context of the method based on recent European greenhouse gases regulations. In addition, teams were required to evaluate alternative process development options, and to design the absorption column for post-combustion using Aspen Plus (Aspentech, 2017) whilst evaluating the associated process safety aspects by conducting a Failure Mode and Effect Analysis (FMEA). The final deliverable also focused on suggestion of process alternatives to encourage students to think about how their process can be further improved, and to justify their choices based on the current (and future?) regulations, process design limitations and simulation results. The students were also asked to consider the concept of sequestration, and to recommend whether or not this should be considered by future engineers. A number of student teams reported concerns with sequestration and suggested other ways of combating climate change should instead be considered.

c) Fermentation bio-butanol process

In a slightly different case study, introduced in 2018/2019, student teams were asked to design a simple batch biofuel separation process for the production of biofuel for use by anthropologists studying indigenous Indian tribes in the Amazon delta. Students first explored current bio-butanol processes, in particular, identify design limitations of the process such as potential azeotropes based on VLE diagrams generated using simulation tools. The next deliverable was to provide suggestions for process developments related to raw materials, resources, biological aspects etc. and to demonstrate the associated benefits based on their simulations. Finally, each team discussed the impact of their suggested process design with regards to local land use, water contamination etc., concluding on whether their solution is acceptable or not, from a sustainability and social perspective, for use in a vulnerable area such as the Amazon. In this particular Scenario, the tutors therefore encouraged the teams to make their decisions not only in terms of process feasibility and performance, but also in terms of its social and environmental impact. The majority of student teams recommended that their design should *not* be implemented due to concerns for the impact on the indigenous tribes, thus clearly demonstrating that the IEP focus on professional skills and social responsibility is taken very seriously by the students.

All the Scenarios mentioned above make use of simulation tools as an integrated part of the Scenario. The aim is very much to make the students proficient in the use of computational tools but for them to see them precisely just as tools to achieve the engineering calculations they require rather than a means to an end.

Prior to the helpdesk sessions, a short video is issued which explains how the process considered works, and how it can be simulated using the appropriate software to ensure that the students have understood the fundamental concepts and how they could proceed with setting up their simulation. During the helpdesk sessions, the students can ask questions, addressing them not only to the tutors (staff and PGTAs) but also to the rest of the class as peer discussion has been found to be particularly effective as a teaching and learning practice (U.S. Department of Education, 1986).

In all Scenarios, progress meetings are held twice during the Scenario week. During these meetings, each student team is given limited time to critically present their findings so far, demonstrating that they are able to meet all deliverables. In cases when teams have difficulty addressing some of the deliverables, the tutors can direct them without directly providing the answer. With regards to the design of the processes considered, all teams are encouraged to properly justify their design decisions based on their simulations, and using proper model analysis tools such as sensitivity analysis.

In the final presentations, each team presents their findings and all team members are expected to participate, including answering questions from the tutoring team. From a teaching perspective, presenting their work in teams is beneficial for students' learning as they learn how to cooperate and obtain knowledge both within the group and individually, and to defend a team decision. For their presentations, time is deliberately very limited, forcing the students to think critically about which findings to present and how to justify their final decisions, leaving the rest for their written report.

4. Discussion

The example Scenarios presented above have hopefully illustrated how different engineering concepts can be considered using project-based learning with a strong focus on team working and professional skills. Each Scenario considers a different real world problem, for which students must make use of computation tools and to use their critical engineering thinking in order to reach a solution. For all the Scenarios presented, the concepts considered have been carefully selected in terms of the knowledge and professional skills students should ultimately obtain. Firstly, students learn how to apply fundamental engineering knowledge (mathematic equations, process principles etc.) in order to tackle an open-ended real world problem. Secondly, understanding how computational tools can be used in order to investigate a process, as well as learning how to take into consideration the impact of their design decisions on a number of aspects (e.g. economic, environmental, societal etc.) is another key aim of these Scenarios. Through scenario-based learning students learn how to convert their theoretical knowledge into not only modelling equations, but also how to investigate the process using sensitivity analyses and optimisation making therefore, design choices which can be properly justified.

It is truly impressive to see how much students achieve during a Scenario given that they were first introduced to the problem at the beginning of the week, having therefore very limited, if any previous, background on the topic. The use of project-based learning undoubtedly has a significant impact on student learning, as has the use of simulation tools required to meet the deliverables. From a teacher perspective, it is highly satisfying to see how the students develop from one Scenario to the next; in particular, how they feel more confident about their suggested solutions and how their confidence in arguing their decisions increases. This is, in our opinion, in part due to the fact that their decisions are based on proper investigations within a computer-aided process engineering framework.

5. Conclusions

This work has presented the rationale behind the use of project-based learning in an integrated engineering programme, implemented through six week-long Scenarios, including the use of computational tools in considering open-ended real world problems. Several example Scenarios have been presented and discussed, highlighting how this teaching approach has multiple benefits, including but not limited to, students' understanding of PSE tools and the development of their critical engineering thinking in their use.

Abstract

Industry 4.0 is moving towards the digitalization of traditional manufacturing processes, and thus, the educational system must adapt and meet the demand of engineers able to work in this digital paradigm. In this context, students, and engineers, are now more than ever required to possess programming skills. Therefore, in this work, we collected and evaluated the students' perceptions about the need of acquiring programming skills in (bio)chemical engineering education. The data has been collected through a quantitative survey distributed to undergraduate and graduate students in the chemical and biochemical engineering study programs at the Technical University of Denmark. In general, the students pointed towards an insufficient presence of programming content in their study plan, and they favor Python as the preferred programming language. Moreover, the students selected actions to improve the integration of programming in their curriculum, focusing on increasing the content of programming applied to the (bio)chemical engineering field and using only one programming language. In addition, the students pointed out modeling and optimization as the most useful topics for their future career. Finally, a learning design has been developed to fulfill these needs and it has been implemented in an educational computer-aided tool, called BioVL (**Bioprocess Virtual Laboratory** - www.biovl.com).

Keywords: Computer-aided tool, Education, Programming, (Bio)chemical engineering.

1. Introduction

Industry 4.0 is a current trend in the bio-manufacturing industry, with the focus to introduce and use digital solutions inside traditional manufacturing. In this context, the digital realm has an important part to play, with examples such as the Internet of Things (IoT) or Digital twins (DT). Accordingly, educational systems must become active agents for this ongoing transformation (Gargalo *et al.*, 2020; Narayanan *et al.*, 2020); universities are engaged in integrating the current and future needs of the digital transition into their curriculum. This digital dimension relies on computational tools and methods to implement the interactions among the operation units, share information between different processes and systems, and adopt decisions without human intervention. Therefore, although there is an increasing need for engineers with programming skills, there is no data on the students' perception and opinion about the

programming content in their education. Meanwhile, students' perception of an activity's value is strongly linked to performance and success in the task. This corresponds to the Expectancy-Value Theory (Wigfield and Eccles, 2000), which is the educational theoretical framework used in this study. In this context, we have collected and evaluated the students' interests and opinions regarding the programming content and implementation level in their curriculum. Moreover, these insights are then used to design a topic-related pedagogical description, which is then implemented in an educational computer-aided tool; called BioVL (**Bi**oprocess **V**irtual **L**aboratory).

2. Methods

A quantitative assessment of the students' perceptions about the need of programming skills in the curriculum was performed. The data was obtained by using a multiple-choice questionnaire. This survey was distributed to students through a link in the following courses: 1) Chemical reaction engineering (the third and final year of their BEng education) (DTU, 2020a); and 2) Process adaptation in Fermentation Based Biomanufacturing (first year of their MSc) (DTU, 2020b). Both courses belong to the chemical and biochemical engineering study programs at the Technical University of Denmark.

3. Results and Discussion

In 2020, 52 students completed the survey: 39% were BEng students, while 61% were MSc students. The questions asked were related to previous knowledge about programming and how they perceived programming to be implemented in their education. This assessment aims to provide a complete view of the students' education gaps and requests; and deliver a road map to better integrate, if necessary, programming in their studies. Therefore, the main aim of this work is to propose a learning design to bridge the identified gaps as well as include, as much as possible, wishes brought up by the students.

3.1. Students' perception: a quantitative approach

Initially, the students were asked if they perceived their programming education as sufficient. The collected data is presented in Figure 1.

Figure 1. Survey responses to: do my studies include enough programming?

As it can be observed in Figure 1, 66.7% of the participants are convinced that their studies do not include enough programming, and none of the participants strongly agrees on the extent of their current programming education. Hence, this data clearly

identifies that the students feel that the extent of programming in their curriculum is not enough.

The second line of research has to do with gathering the students' views on including the teaching and practical implementation of programming skills into their curriculum.

Therefore, as presented in Figure 2, we have started by identifying the students' preferred programming language. It shows that most of the students have previous knowledge on MATLAB or/and Python. Notably, approximately 30% of students declared that they do not have knowledge or experience in any programming language. Considering that the students are in the last year of their BEng or the first year of their MSc, we believe this to be a concerning reality.

On the other hand, Figure 2-b) shows that students prefer Python (79%) and MATLAB (73%) over other programming languages, such as R. However, when asked to select only one programming language, 60% of the participants choose Python, while 30% voted for MATLAB. The remaining students selected R (5%) or were indecisive (5%). The data showed a difference between the programming language that the students had previous knowledge about and the language that they see as most useful for their future careers. To understand the inbuilt motivations behind the students' choices, they were questioned about the characteristics of the different languages that impacted their decision (see Table 1).

Table 1. The most important characteristics identified by the students for the selection of a programming language.

Statement	Percentage
Easy to read and easy to code	66.7%
Open source / Free license	52.9%
Can be used for artificial intelligence and machine learning	11.8%
Several available packages	17.6%
A great online community and support	68.8%
Multidisciplinary	29.4%
Availability of models in chemical and biochemical engineering	39.2%

Table 1 shows a strong agreement in three characteristics: 1) great online community; 2) easy to read and to code; and 3) open source. By selecting these attributes, the students are again supporting their choice for Python, a very popular and well-documented open-source language, built on a philosophy emphasizing code readability. Moreover, the students used the 'extra comments' section in the survey to highlight their interest in favoring the programming languages currently being used in the industry.

Once the students have evaluated their programming skills, they had the opportunity to assess ways to improve them in their education. The survey statements and the collected data are presented in Table 2. Here, a high number of the students advocated for more practice on programming through an applied programming course in the latest part of their studies (65.4%) as well as more applied exercises (59.6%). Besides, most students also agree on their interest in using only one programming language (57.5%). These strategies have already been implemented in universities, such as Lund University that systematically uses MATLAB in their engineering education, or (dos Santos, Vianna and Le Roux, 2018) who implemented a programming course in Fortran in the final year of chemical engineering education with positive but inconclusive results at the University of São Paulo.

Table 2. Students' perspectives on how to improve the teaching of programming in their education.

Statement	Percentage
Only one programming language for all subjects in my studies (e.g. MATLAB, Python)	57.5%
More exercises on programming related to a specific topic	59.6%
Introductory sessions on the programming language before using it in the classroom	55.8%
A teacher assistant for programming in the classroom	36.5%
Hands-on programming course for chemical and biochemical engineering in the latest part of my study plan	65.4%
None of the above	0%

Furthermore, the students added suggestions in the comments section, coming up with proposals such as inviting experts from the industry.

Finally, the students were asked about the expected purpose of the use of their programming skills in their future careers; the collected data is presented in Figure 3.

Figure 3. Survey responses related to the expected use of programming in the students' future careers.

These results show that almost all students (94%) selected "modelling" as the main application of programming in their future, closely followed by "optimization" (85%). On the other hand, only 17% have chosen "artificial intelligence and machine learning", even though it currently is a hot topic in (bio)chemical engineering.

To sum up, students were critical about the content of programming in their studies, highlighting a gap in their educational curriculum.

3.2. Learning Design

A specific learning design should be developed to overcome the identified pedagogical need, and later on implemented and validated. This work will mainly focus on the definition of a learning design and its implementation. The developed learning design aims to establish a pedagogical frame to teach applied modelling in Python for chemical and biochemical engineers in the final years of their education mostly through programming exercises.

In general, a learning design consists of the specification of the following points: 1) prerequisites of learning; 2) settings; 3) learning goals; 4) content; 5) learning process; and 6) assessment. This didactic frame was first proposed by (Hiim and Hippe, 1997) and later expanded by (Weitze, 2016).

Table 3 shows the defined characteristics of the developed and implemented learning design in this study. It is important to highlight that the learning goals in Table 3 intent to include and integrate the higher levels of the Bloom taxonomy (Abdulwahed and Nagy, 2009) associated with meta-cognitive knowledge.

To conclude, this learning design has been implemented into a computer-aided tool - BioVL. A prototype of BioVL is available at www.biovl.com. This software focuses on explaining, solving, and enabling the modification of conditions and parameters in mechanistic models for bioprocesses focused on undergraduate education. Currently, BioVL has been designed as a complementary material for the students' education to provide more programming exercises. It includes among its functionalities, a Python library with the models, questionnaires, mini-games, a chatbot, and the possibility to confront realistic operational problems (de Las Heras *et al.*, 2019).

Table 3. Learning design for the teaching of programming to (bio)engineering students.

Element	Definition
Pre-requisite of learning	Students with previous knowledge on process design and a basic knowledge of modelling and programming.
Setting	A computer-aided tool, called BioVL.
Learning goals	It aims to: 1) apply Python to solve (bio)chemical engineering problems; and 2) create (and implement) process models in Python.
Content	It covers: (i) theoretical and practical knowledge of Python and object-oriented modelling; (ii) theoretical knowledge on how to create a model.
Learning process	Collaborative learning between students, a chatbot and the Kolb's experiential cycle.
Assessment	Use of variable feedback and self-evaluation as the students test their hypothesis and develop and test abstract conceptualization (Hattie and Timperley, 2007).

4. Conclusions

Industry 4.0 has the potential to greatly improve (bio)chemical processing. However, to shift paradigms and bring traditional manufacturing to the digital era, engineering students need to be able to communicate and connect the physical and digital world. This is done through programming, and therefore, programming skills must be seen as an essential tool and integrated into the university's curriculum. In addition, the students' involvement in the development of a learning design for the teaching of programming can have significant benefits, such as increased motivation and performance. Therefore, in this work, we quantitatively assessed the students' perceptions about their knowledge of programming, as well as their main interests. After the students have indicated that their curriculum's programming content was insufficient, the survey asked how to improve this based on the students' perception. Furthermore, the students indicated their preferred programming language as being Python, to be applied for modelling and optimization. These needs identified by the students were used as guidelines to define a learning design. Finally, the appropriate learning design is integrated into a computer-aided tool. This computer-aided tool is called BioVL (www.biovl.com), and it is currently in its prototype stage, focusing on modelling of bioprocesses.

Engineering Social Responsibility: Rising to the Challenge of Sustainable Development

Iain Duncan Stalker^a, Rinkal K. Desai^b

^a*Institute of Management, University of Bolton, Bolton BS1 1SW, United Kingdom*

^b*WMG, University of Warwick, Coventry CV4 7AL, United Kingdom*

Abstract

To successfully rise to the challenges of contemporary physical and social contexts, and thus secure a more sustainable world, (process) engineering (under)graduates must learn to engage effectively with other professionals. This demands that we structure learning opportunities that make explicit with whom engineers need to engage and promote softer skills that form an essential foundation of effective professional engineering practice. As a step towards this, we present a workspace that provides a holistic perspective on the intersections of the various value chains that obtain in manufacturing and process industries; this framework helps to identify key partners from professions and stakeholder groups. We also show how this framework informs the discussion around employability and professional competence.

Keywords: Engineering Education, Ethical Practice, Sustainable Development, Employability, Circular Economy.

1. Background

Engineers shape the world around us, changing both physical and social contexts. Ingenious materials and innovative industrial processes yield technologies and business models that improve standards of living. Yet, this increased quality of life is not universally enjoyed and in the longer-term the procurement of profits threatens to exact a heavy price on people and the planet; cf. Elkington (1997) and Savitz and Weber (2006). Growing awareness of the cumulative environmental impact of extraction, synthesis, manufacturing, and transport provokes increasing demands for accountability and corporate responsibility (Horrigan 2010). A groundswell of opinion challenges industries to be more transparent in their practices and proactive in replacing the traditional “take-make-waste” model with a so-called “Circular Economy” (MacArthur Foundation 2019).

Engineers are precisely the professionals to take a lead in rectifying such imbalances; indeed, resolving contradictions is a fundamental aspect of an engineer’s mindset; recall for example, TRIZ (Altshuller 2006). Moreover, responsibility in processing, manufacturing, distribution, and use has long been a key imperative in Engineering, cf. Life-Cycle Assessment (e.g., Ashby 2005) and initiatives for sustainable industrial systems (Pozo et al, 2020). Redress demands the “creative destruction” of established processes (Schumpeter 1934) and the innovation of new, more sustainable practices; and this cannot be done in isolation. Engineering systems must be recognised as systems within larger systems; thus, practitioners must work together with stakeholders and

other professionals to accommodate the needs of all those directly or indirectly affected by the outputs—concepts, systems, products, etc.—of their industries; see Freeman (1994).

We must ensure that engineering graduates know with whom to speak, how to engage, why and about what. We must equip them with appropriate skills to debate; and we must ensure that they are familiar with ethical perspectives to promote appreciation of different viewpoints in the pursuit of rapport. As a step towards this, we present a ‘workspace’ that provides a holistic perspective on the intersections of the various value chains that obtain in process engineering, manufacturing and product development; this makes explicit the many paths through which products and services are created and developed (“innovation trajectories”) and the (artificial and natural) contexts from which these draw; this in turn helps to identify key partners from professions and stakeholder groups. Knowing with whom one must engage, how and why directly supports softer skills that are an essential foundation of an effective professional engineering practice. Our key contribution here is a framework to structure appropriate learning opportunities, ensuring that engineering education fulfils these essentials. We also consider this framework a useful mechanism to inform the discussion around employability and professional competence; cf. Dacre Pool and Sewell (2007).

The structure of the article is as follows: in Section 2, we clarify sustainable development; in Section 3, we present our workspace, outlining its construction and briefly illustrating its application; we close in Section 4 with an indication of its relevance to employability

2. Sustainable Development

There are many uses of the terms ‘sustainability’ and ‘sustainable development’; perhaps the most oft-cited definition of sustainable development is that of the Brundtland report (WCED 1987): “development which meets today’s needs without compromising the ability of future generations to meet theirs” (p. 41).

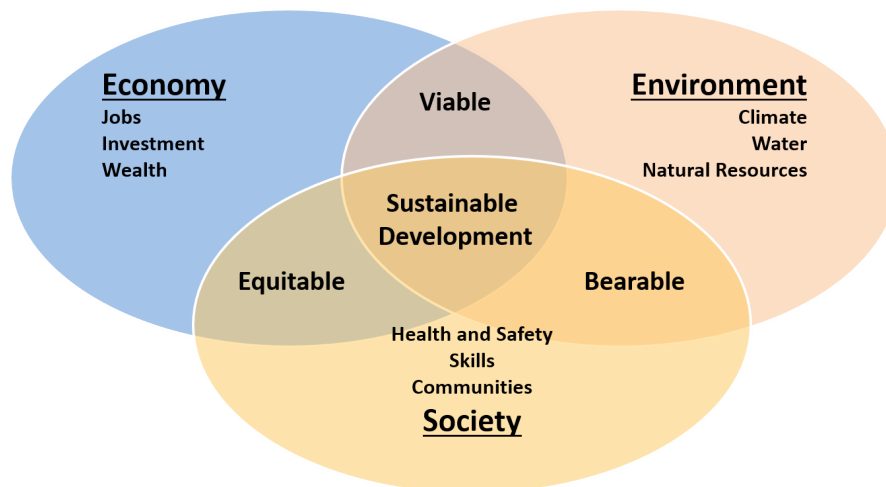

Figure 1: Sustainable Development

We prefer a more wholistic conceptualisation that recognises the three pillars of Elkington (1997), see Figure 1: unless there is explicit consideration of the needs of people (society) and economic viability in conjunction with responsible curation of the environment, we will not have a truly sustainable approach; cf. the observations of *inter alia* Savitz and Weber (2006) that sustainable development arises where “business interests and the interests of the environment and society intersect”.

3. The SAMITE Workspace

3.1. Framework and Trajectories

The SAMITE workspace of Figure 2 (Stalker *et al* 2011) comprises: a framework that coordinates elements essential to a full characterisation and understanding of a product-service bundle, its composition and interaction with users and markets; and ‘innovation trajectories’ that elucidate routes through the framework

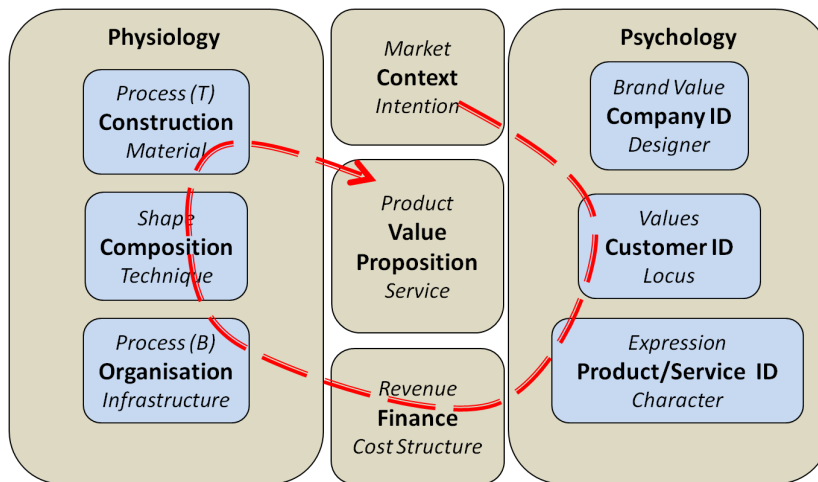

Figure 2: SAMITE Workspace with a Market-Driven Innovation Trajectory

Value proposition denotes a bundle of products and services offered to a specific customer. It acts as the focal point of the framework.

Physiology denotes the structural aspects of the value proposition and comprises

- **Construction** which treats the physical form, material(s), and the technical process(es) employed.
- **Composition** which addresses design approach(es), specific shape(s) and technique(s) applied.
- **Organisation** which addresses the means through which the value proposition is brought to market; it also addresses the intangible analogue(s) of physical form for services; it consists in business processes and the organisational infrastructure or ecosystem.

Market captures the commercial context, identifying target customer(s), i.e. market(s), and design intention.

Finance captures the revenue stream(s) through which the value created will be appropriated and makes explicit the cost structure(s) involved in creating and delivering the value proposition.

Psychology denotes the intangible aspects of the value proposition; it follows the product expression model of Gotzsch (2006) and comprises Company ID, User ID¹ and Product/Service ID.

An ‘(innovation) trajectory’ is a path through the framework; it begins at an ‘epicentre’ and visits each main area; it is descriptive rather than prescriptive. Tracing possible trajectories clarifies how to bring products, services, or bundles to market, e.g. what to consider and whom to consult. This reveals the fundamental nature of the framework as a clarifying structure: it elucidates aspects to be evaluated and considered; it identifies potential roles where teams coordinate their efforts; and it gives suggestions of whom, i.e. what categories of stakeholders, to approach to realise products, services or bundles. Figure 2 illustrates a trajectory with an epicentre in ‘context’: we refer to this as a ‘market-driven innovation trajectory’. The driver for the innovation is a new market opportunity. From this, a profile of the target customer is developed and used to define a product-service bundle to meet the demand. If the market opportunity can be clarified in terms of price, then the product-service bundle definition is augmented with strategic pricing and an appropriate (target) cost structure. This cost structure is likely to influence the choice of business processes, composition techniques and the physical construction of the final offering. To refine the choices and decisions that will ultimately lead to the value proposition, the trajectory will be traced a number of times; each tracing provides opportunities to explore the economic viability of the value proposition, the social contribution and costs of developing the value proposition and the environmental/ecological impact of delivering it.

Naturally, other epicentres are possible and give rise to complementary trajectories; for example, an epicentre in ‘physiology’ deriving from (say) the development of a new (technical) process that is more environmentally friendly would be referred to as a ‘process driven innovation trajectory’ (Stalker *et al* 2011). Often, an innovation will unite and unify a number of developments; for example, a new market opportunity may coincide with the development of a new process, e.g., the more ethically minded consumer demands more sustainable fabrics that can be realised through the use of ‘newer’ fibres such as bamboo. In this case, we consider multiple trajectories from multiple epicentres and refer to the coordination of the individual trajectories into a single trajectory as ‘(innovation) trajectory alignment’ (Stalker *et al* 2011). These invite the coordination of efforts from different disciplines and motivate the education of engineers and other graduates of the future in the context of product-service developments.

3.2. *Summary Case Study: Synthetic Biology*

Synthetic biology is an exciting subfield of bioengineering that promises disruptive innovation in the development and production of drugs and vaccines and therapeutics (Freemont 2019). It comprises *in silico* design informed by real biological data and was identified by the European Parliament as an emerging technology with the potential to combat the COVID-19 pandemic (Kritikos 2020). By its very nature, being

¹ Here, we use ‘locus’ to signify expressions of time, place, status, and culture.

laboratory-informed and computation-based, it promises sustainable approaches to product design and process development. We believe that it makes an interesting and topical case study for the use of the SAMITE workspace in the education of (process) engineers to foster sustainable development and stakeholder engagement: what we refer to as “Engineering Corporate Responsibility”. For example, Bruynseels (2020) examines responsible innovation through synthetic biology and data positionality, exploring several ethical issues on the way. We can view this as a market-driven approach to vaccine development that, when scaled up to production, would trace an innovation trajectory like that of Figure 2. The trajectory makes clear the stakeholders whose engagement is essential to the realisation of commercially viable sustainable process (for the final vaccine) at industrial scale. Moreover, that the preliminary product design is computational—as indeed could be the process synthesis, e.g., cf. Fraga *et al* (2000)—means that the translation of the designs into physical and business processes affords ample opportunity to convene implementation groups of specific stakeholders and professionals that not only have necessary expertise, but would have a vested interest working to ensure the most sustainable process is delivered owing to their engagement.

4. Conclusion

Sustainable development and practices cannot be realised in isolation. To ensure that the challenges of physical and social contexts are confidently met and surmounted, and thus a sustainable world secured, future (process) engineers must convene effective teams of appropriate professionals and relevant stakeholders. They must be educated in what such teams look like. We believe that SAMITE is a constructive step towards this. The notions of epicentre and trajectory foster systematic engagement: making explicit the many paths through which products and services are created and developed and the (artificial and natural) contexts from which these draw helps to identify key partners from professions and stakeholder groups. Moreover, this provides a fundamental platform for communication: it offers an explicit recognition of the interfaces at which the vocabularies of disparate areas must be aligned.

The SAMITE workspace is also a useful mechanism to inform the broader discussions around employability, contributing directly to development of a fuller understanding of the context of ones subject, confidence in knowing how to assemble an appropriate team to address challenges, and reflection on the need to engage with stakeholders; cf. Understanding, Efficacy and Metacognition in the USEM model of Knight and Yorke (2004). Knowing with whom one must coordinate and why directly supports softer skills that are an essential foundation of an effective professional engineering practice; for example, it explicitly supports the ‘personal and professional skills’ components of the CDIO framework (www.cdio.org); the structures can be used to structure interdisciplinary project teams, which supports the ‘interpersonal skills’ component of the CDIO Framework; and of course other professional frameworks.

Virtualization of Pressure Control Demonstration

Unit – A Step Towards Virtual Laboratory

Miloš Bogataj^{a,*}, Nejc Arh^a, Zdravko Kravanja^a

^a*Faculty of Chemistry and Chemical Engineering, University of Maribor, Smetanova ulica 17, SI-2000 Maribor, Slovenia*

milos.bogataj@um.si

Abstract

In this paper, we present virtualization of the pressure control demonstration unit. The two main objectives were: to determine a dynamic mathematical model of the unit, and to use the mathematical model to virtualize the process that enables open and closed loop simulations. The dynamic model of the unit, which was developed based on experimental input-output data, shows Fit to Working Data greater than 95 %. Finally, the unit was virtualized in a form of a graphical user interface that hides all the modeling components from the user. The virtual unit is thus designed to enable students with limited or no prior knowledge of control theory and modeling of dynamic systems to study and analyze the dynamics of the system and to observe the effects of feedback control mechanisms.

Keywords: Education, Modeling, Process Dynamics, Process Control, Virtual Laboratory.

1. Introduction

The pandemic of 2020 has changed the way knowledge is passed on from teachers to students. Classroom lectures have been replaced by online lectures practically overnight. Due to restrictions, some laboratory exercises, which are essential for undergraduate chemical engineering students to acquire practical competences and skills, had to be modified, condensed, recorded by technical staff and presented online to students (Pintarič and Kravanja, 2020), leaving them with no or only limited practical experience. Process control is regarded as one of core topics of most undergraduate chemical engineering curricula. The course not only exposes students to the rigors of process dynamics and control, but also teaches them how to tackle complex problems and apply good engineering judgment to obtain results of engineering usefulness (Byrne, 2006). Putting theory in practice is crucial in this respect. In a recent study, Zender and Greiner (2020) conclude that learning by computer simulation performs similarly to learning by experimental method. However, to achieve the best learning outcome, the two methods should be considered complementary.

If laboratory or demonstration equipment is not available, there are many simulation environments that can provide virtual learning experience. Some of them are commercial (e.g. *Matlab & Smulink* (www.mathworks.com), *SimulationX* (www.simulationx.com), *PiDISTILL*, *PITOPS-TFI*, *SIMCET* (www.picontrolsolutions.com)) and some are opensource (e.g. *OpenModelica* (www.openmodelica.org), *Scilab & Xcos* (www.scilab.org)).

In the remainder of the manuscript, we present a study on virtualization of the pressure control demonstration unit RT-634 (GUNT GmbH, Hamburg) – a step towards making the laboratory equipment virtual so that it can be made available to students to enhance their learning experience.

2. Case Study and Methods

The pressure control demonstration unit RT-634 is shown in Fig. 1. Its main components are hardware controller (a), control valve (b), pressure tanks (c, d), pressure sensor (e), and needle valve for air tapping (f). The air pressure at the inlet of the controller valve (p^{in}) is assumed constant at 4.5 bar. The actuator driving the control valve is connected to a standard modulated signal (0 V – 10 V). At 0 V the valve is fully closed and at 10 V the valve is fully open. The needle valve can be adjusted to allow for a specific maximal pressure (p^{max}) to be attained in the system. The equipment can be operated either by the hardware controller or by a software controller within the provided instrumentation and control software. In addition to the control functionality, the software also enables data logging.

Figure 1: Pressure control demonstration unit RT-634 (Source: GUNT GmbH).

2.1 Experimental

Experiments were conducted on unit RT-634 to obtain three sets of input-output data needed for data-driven model development at three different values of maximal pressure ($p^{\text{max}} = 3.3$ bar, 3.6 bar, and 4.0 bar). An identical set of input data (i.e. modulated voltage applied to the actuator) was used in all experiments. The input data set was designed by a random number generator (Fig. 2). In this way, most of the important dynamics of the system were excited. The system output (pressure (p)) was recorded in 0.5 s intervals over the duration of the experiments.

2.2 Model identification

The identification of the RT-634 demonstration unit model was performed in Matlab (Matlab, R2019a) using experimental input-output data and System Identification Toolbox.

2.3 Modeling and virtualization

Virtualization of the RT-634 unit was performed in Simulink (Matlab, R2019a) using the identified dynamic input-output model and graphical modeling, simulation, and visualization capabilities of Simulink.

Figure 2: Piecewise-constant input data set (modulated voltage) with variable time step.

3. Results

In this section we present the results of the model identification, and modeling and virtualization of the RT-634 unit.

3.1 Model identification results

Among the many models available in the System Identification Toolbox, the nonlinear Hammerstein-Wiener (NLHW) model was found to produce the best agreement between experimental and simulated data. The NLHW model was set up with a 10-segment piecewise linear function as input nonlinearity, and a 4th order one-dimensional polynomial as output nonlinearity. The metrics related to the quality of the identified models – Fit to Working Data (FWD), Final Prediction Error (FPE) and Loss Function (LS) – are listed in Table 1.

Table 1: Model quality metrics.

Mode	p^{\max} (bar)	FWD (%)	FPE (/)	LF (/)
l				
M3.3	3.3	96.74	0.001	0.001
M3.6	3.6	95.51	0.002	0.002
M4.0	4.0	95.02	0.004	0.004

The results given in Table 1 show that the models provide a good fit to the experimental data. This is indicated by FWD values (normalized root mean squared error as %), which are greater than 95 %. In addition, the values of complementary metrics (FPE and LF), are less than 0.004 in all the cases. The plot representing simulated response to changes in voltage applied to the actuator versus the experimental response to those changes for model M4.0 is presented in Fig. 3. The plot shows that even at FWD = 95 %, the simulated

response is in good agreement with the experimental data over the entire range of tested input voltage values.

Figure 3: Experimental and simulated response to modulated voltage input (Model: M4.0).

3.2 Modeling open and closed loop response

Fig. 4 shows the Simulink model of the demonstration unit RT-634. The model can be used to simulate open and closed loop response. The developed dynamic models (M3.3–M4.0) are embedded in subsystem NLHWs and can be switched on and off during simulation as required. To avoid unnecessary discontinuities in the model, switching between open and closed loop operation is accomplished through gain K , which can take a value of 1 or 0. The model operates in an open loop mode if $K = 1$, on the other hand, if $K = 0$, the model operates in closed loop mode. For consistent and realistic simulation results and to prevent numerical difficulties, a saturation block is put downstream of the NLHWs subsystem, with the lower saturation limit set to 10^{-5} and the upper saturation limit to 4.5. In addition, the PID output is limited between the values 0 and 10.

Figure 4: Simulink model.

The model shown in Fig. 4 is fully functional in terms of simulation capabilities, but a novice unfamiliar with the Simulink environment might find the user experience overwhelming. A graphical user interface that hides the model and presents it in a more familiar look, revealing only the necessary features, can be built using elements from Simulink block libraries such as subsystems, dashboard switches, sliders, gauges, scopes etc.

3.3 Graphical virtualization

The virtual RT-634 graphical user interface is shown in Fig. 5. The block model (Fig. 4) is embedded in a subsystem and masked by the image of the demonstration unit. The control panel is equipped with a rotary switch to select the maximal attainable pressure (p^{\max}). A toggle switch enables the user to switch between open and closed loop mode. In open loop mode, the voltage applied to the actuator can be set using the slider. On the other hand, in closed loop mode, the user can adjust the set-point value and set the values of PID controller constants. All the inputs available on the control panel can be adjusted during the simulation run.

The simulation results are shown in two plots. In open loop simulation, the results shown in the plots are the value of the process variable (p) and the voltage applied to the actuator. In loop simulation, the results shown are the value of process variable (p) and the set-point value.

Using Simulink Simulation Pacing, the simulation time can be synchronized with the wall clock time, making the learning experience more realistic. All data generated during the simulation is saved to Matlab Workspace and can be used for additional analyses (e.g. system identification, model linearization, controller tuning).

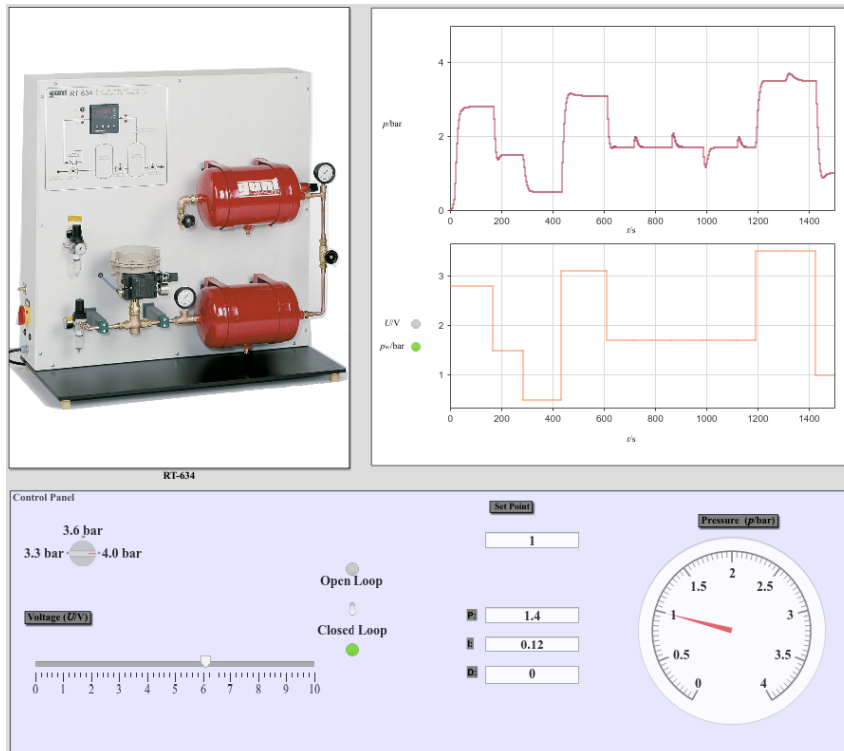

Figure 5: Virtual pressure control demonstration unit – graphical user interface.

4. Conclusions

A dynamic model of the RT-634 unit was developed based on experimental input-output data using MATLAB's System Identification Toolbox. The Hammerstein-Wiener model

with piecewise linear input nonlinearity and polynomial output nonlinearity provided the best fit among the tested models. Fit to Working Data was greater than 95 % indicating that the model captures the experimental behavior of the unit. The RT-634 was virtualized in Simulink in a form of graphical user interface.

The virtual unit is designed as to enable students with limited or even without previous knowledge of control theory and modelling of dynamic systems to study and analyze system dynamics and to observe the effects of P, PI and PID feedback control mechanisms in the context of servo and process control problems in real time.

Although, practical training with real demonstration unit and control hardware, even if computer-controlled, allows for more realistic and memorable experiences, the virtual counterpart is a valuable alternative. One of the main advantages is its continuous availability. Finally, future work will focus on virtualization of flow, level, pH, and temperature control demonstration units, so that the students will have virtual laboratory at their disposal.

Abstract

Academia is an arena where practitioners from industry are integrated to theoreticians. Such alliance has been intensified by the industry 4.0 (I4) age from which these counterparts are seeking to merge efforts towards society 5.0 (S5), enabling next generations to easily accept novelties and changes in well-established operations, process-of-work, behaviours, etc. In educational centres, such a pace into the I4-S5 state pushes new ways of adopting (or adapting current) sharing of work among peers since this may potentially become a tool for an efficient process-of-research. Thus, we particularly cover postgraduate centres with part-time (PT) and full-time (FT) students in the fields of process system engineering (PSE) and we are widely relying on computer aided process engineering (CAPE) tools, algorithms, software, packages, etc. A collaborative research and development of PSE-CAPE systems may a) involve PT and FT postgraduates in multi-disciplinary fields of science and engineering and b) go across physics, math, and technologies to include social sciences, public policies, and beyond. The proposition is to analyse PT-FT synergies considering their experiences, accessibility of data to validate models, viability to handle CAPE tools, etc. An example of collaboration between PT and FT students, involving a university, a research center, a consulting company, and a medical corporation, is highlighted to optimise healthcare treatment systems for social progress and sustainable development amid COVID-19.

Keywords: Education in PSE, part-time postgraduates, shared working, teamwork.

1. Introduction

The increasing number of part-time students in postgraduate centres worldwide has brought concerns about their evolution as researchers and developers of technology and related impacts in communities. How supervision tasks should adapt to this and which mechanisms must be adopted to address such situations are the points to be answered in this paper. This study particularly focuses on postgraduates from the fields of process system engineering (PSE) or widely counting on computer aided process engineering (CAPE) tools, algorithms, software, packages, etc. In the argumentation, complementarities of part-time (PT) and full-time (FT) postgraduates of PSE/CAPE are analysed from the point of view of the industry (organisations, companies, ministries, etc.) aiming to identify gaps and drawbacks of PT postgraduates that work in parallel with the FT postgraduates. Considering companies' investments in employees, release time and PT's extreme efforts given their job workloads and academic duties, challenges to facilitate such a scenario need to be discussed to improve the synergies in the relationship between industry and academia.

Lacking data on postgraduation numbers in terms of distribution and effectiveness of PT and FT students, an analogy with postsecondary education in the United States is introduced. Data from the Integrated Postsecondary Education Data System (IPEDS) published for the first time in 2017 shows the alarming results on postsecondary part-time students' efficiency, which demonstrates the need to improve the path of their academic endeavour. According to IPEDS (2017), among the postsecondary students, which represents 37% of the PT students, only 17% received a degree or certificate within six years (considering five years as the effective time of graduation as a bachelor). In comparison, around 56% of FT postsecondary students graduated within six years of enrolment. The poll covered about 1.2 million PT students from 2008 to 2017. Several other details on the distribution of PT per sector and data differentiating private and public and profit and non-profit institutes are given in the IPEDS survey.

For several years, sharing of information among students, despite being PT or FT, postsecondary or postgraduates, has been established as a framework to equalise the quality of the knowledge given that bridges are built to allow students with weaknesses to succeed towards standards of learning. Nevertheless, as we sustain in this work, a certain level of intrusive management on behalf of the PT and FT learning success must emerge in supervision activities. It is clearer when PT students are allowed in PSE education centres and it gets stronger when most of the students are PT. By doing a postgraduation in parallel while working in public and private sectors, the available time of PT students to research and to develop a PSE postgraduate study is reduced. It is intensified when CAPE tools are involved in the research and development of a product to be deployed further in industrial, ministerial, etc., sectors that have followed the evolution of their employees and allowed the investment in their released time as PT students in academia (Kelly and Menezes, 2020).

From such study, complementarities of PT and FT students are evaluated by comparing pros and cons in terms of practitioners' and theoreticians' capabilities and efforts to be conjugated or combined into a teamwork process of making research and development for a complete deployment of the postgraduate topic. The coordination of such cooperation among PT and FT students resembles the hierarchical decomposition heuristic (Kelly and Zyngier, 2008) that focuses on solving the overall problem when managing a decentralized and distributed system integration of competing targets and

directions of multiple sub-systems. These must be defined systematically every semester and re-tuned whenever needed. As potential assistants of supervisors, FT students have more time to spend in the postgraduation studies covering theories, configuration and codification of algorithms in mathematical and computing languages, extra paper writing (e.g., review papers), etc. However, challenges exist such as a) tools to allow sharing of work without compromise learning; b) exposition of weaknesses of students who are underperforming; c) balances of number of PT and FT students for teamwork supervision; and d) extra work for advisory coordination and control of effectiveness of the PT learning and FT assistance.

2. Previous literature on PSE/CAPE tools for teamwork applications

Into the applicability of process system engineering in industry to facilitate PT and FT students in a staged fashion within an easy pathway, Menezes and Kelly (2018a) presented open-use and community-based tools for education in PSE with several examples in industrial applications from decision automation (or decision-making or prescriptive analytics) to data analytics (or predictive analytics). Menezes and Kelly (2018b) extended their previous work describing prescriptive and predictive analytics examples found in batch and continuous processes in industry by using the mathematical modeling platform IMPL (Industrial Modeling and Programming Language) that embeds the unit-operation-port-state superstructure (UOPSS) and the quantity-logic-quality phenomena (QLQP) from Kelly (2005). In their work, the so-called industrial modeling frameworks (IMF) are given as an initial phase for the development of PSE applications by using the built-in UOPSS flowsheet network. Within this stage of the learning process, equations are not coded, instead, the problems are configured using the input data in specific meaningful frameworks with respect to keywords or semantics to be learned as in any modeling and programming language. This type of modeling platform is known as structure-based (as opposed to the set-based such as GAMS and scalar-based such as MATLAB), whereby the equations are constructed automatically by the configuration of the problems using the UOPSS constructs and QLQP concepts (Kelly and Menezes, 2019).

Kelly and Menezes (2020) presented a path to evolve towards advanced modeling and programming skills by using a blend of IMPL's IML (Industrial Modeling Language), IPL (Industrial Programming Language), and IMPC (Industrial Modeling and Programming Code). This hybrid modeling allows sharing work between PT and FT students (configuration in IML and codification in IPL and IMPC). In such a way, the PT students can drive the achievements of the project by using the IML configuration considering the vast number of parameters, variables, and constraints and the UOPSS-QLQP elements without coding. For more advanced steps to programmatically model the problems integrated with other systems connecting graphical user interface and database, the use of an application program interface (API) may be accomplished by FT students using IMPL's IPL codifications via computing languages as Python, Julia, R, C, C++, C#, Java, Visual Basic, etc. The development of ad hoc libraries for PSE packages (thermodynamics, kinetics, etc.) can be developed in IMPL's IMPC using Intel-Fortran. IML, IPL, and IMPC can coexist simultaneously in a model in a hybrid PT-FT work. More recently, IMPL-DATA has been released which has always been a part of IMPL to pre- and post-process problem data, but is exposed to support the user in the creation of simpler and smaller analytics, estimation and optimization deployments. Therefore, the PT students can progress from a low-skilled modeler or

mere user of off-the-shelf tools to a high-skilled developer that drives the design and implementation of solutions to be deployed in the postgraduation and their companies.

3. Postgraduates from industry and academia

For those postgraduation centres with part-time students for research and development in process system engineering topics, some particularities must be addressed. In analysing potential synergies and trade-offs or pros and cons in the combination of PT and FT experiences, time spent for researching, accessibility of data to validate models, viability to handle CAPE tools, supervisors learn from such study everywhere this applies.

In this way, we initialise the argumentation with a digression. In such comparative analyses, the uniqueness aspects of industry and academia aim to be merged in favour of the researching, development, and deployment (RD&D) in the engineering management and decision sciences on the process of making decisions to be managed the executions. In the digressive example, both the trial-and-error procedures based on previous experiences and the automated decision-making via exact methods of mathematical programming are found. One would be inclined to say that the latter would be more efficient than the former. This may be true if the automated engine based on decision sciences is representative enough to be accepted as the result to be followed in the execution of the decisions. However, industrial practitioners may act as validators of the theoretical decisions. Joly et al. (2017) discussed lessons learned from developing and implementing refinery production scheduling technologies pointing out the weaknesses and strengths of both development and implementation or deployment part of the whole, when involving researchers and developers in research centres and end-users (the validators) in industrial production sites.

3.1. Part-time (PT) students from industry, organisations, companies, ministries, etc.

Campbell and Bombardieri (2017) address postsecondary learning and fulfilment steps of PT and FT students. In the postsecondary environment, the majority of PT are older and financially support themselves and their families. Approximately 75% of them are currently working and 40% of them work 40 hours per week. Obviously, this situation is even worse in postgraduation since the students are within a further stage of their career than in the postsecondary stage. As an extrapolation, the complicated state for PT postgraduates of PSE centres must be considered by the advisers in the coordination of their challenges to succeed.

Despite the barriers of PT students, their strengths related to previous experiences on the topics of the postgraduation's researching and development may allow them to act as validators of the theories and proofs from the academic environment. Furthermore, the PT student's access to data must be considered as a powerful attribute, however such data mostly needs to be sanitized to hide confidential information. These PT qualities are shown in the example of the healthcare treatment system to be seen.

3.2. Full-time (FT) students: the additional arms of PT supervision

Postgraduate FT students need some essential core skills if they are going to assist their supervisors in advising PT students. Some core skills are required for a better supervision, such as leadership, time management, technical expertise, communication

skills, and ability to judge. One of the pillars of growth in both business and academia is to have good leadership and supervision skills over team members. Therefore, improving the FT student expertise in leadership and supervision is required to interact with other peers, which also supports the faculty supervision process through the enrolment period. The core skills are following. First, being a good leader is critical for FT, it is the first step towards managing tasks delegated by faculty supervisors and collaborate with team members (FT or PT students) as they would rely on their leader for guidance and mentorship. Second, time management skill is considered the seed to thriving in any task or activity as it is implemented in every workplace and for any position. Third, strong technical skills are required when a peer asks for technical support and knowledge that FT should be able to deliver as close as their supervisor. Fourth, communication skills are needed since the FT should be prepared as it helps to professionally transfer the message or tasks to others. Fifth, judgmental skills are required in certain situations to overcome unexpected outcomes, although it will improve based on previous advising experiences.

4. Example of a merge of industry and academia

The problem in Figure 1 is addressed by a collaboration between PT and FT students within a coalition of a university, a research center, a consulting company, and a medical corporation to develop predictive and prescriptive analytics based on machine learning and optimisation for the optimal healthcare systems in the planning, scheduling, and coordination of the treatment networks amid the COVID-19 pandemic.

This study aims to better predict the spread of the disease in order to prepare for the avalanche of the number of patients in the healthcare treatment systems. In measuring or simulating the selected inputs (social distance, lockdown policies, out-of-stock of personal protective equipment (PPE), climate, etc.), the spread of the new number of cases per day (epidemiology curve) can be modeled through a data analytics machine learning approach. In a second step, using epidemiology curve predictions, an optimal design, operation, and control of the healthcare treatment systems can be determined. Then, the sensitivity analysis for an assessment on social progress and sustainable economy can be performed. In the first and second steps of the project, FT students with machine learning and optimisation skills develop the configuration, codification, interfaces, etc., needed to predict the epidemiology curves of COVID-19 positive patients in the near future and this will be an input of the optimisation and control of the healthcare treatment systems. The data, modeling and results of such complex problems are validated by the PT students that work in the medical corporation.

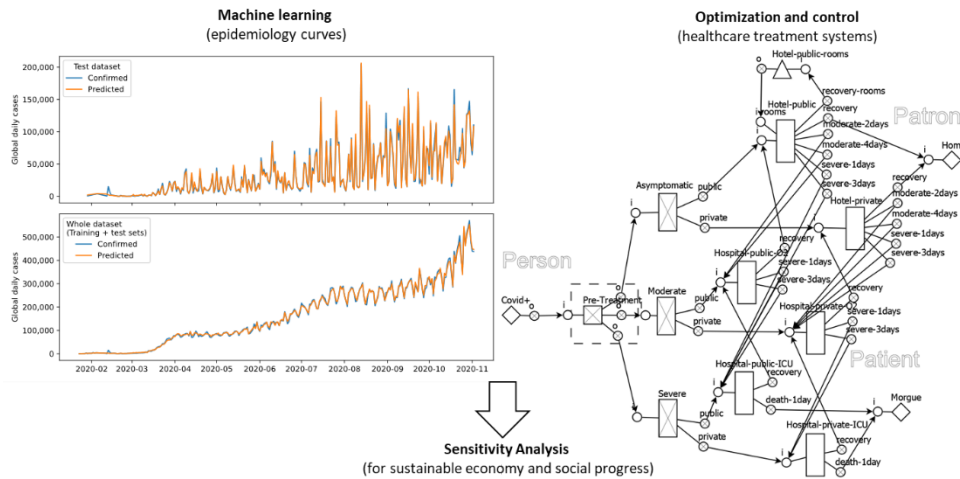

Figure 1. Advanced analytics for healthcare systems: merge of industry and academia.

For a medical resource supply chain resilience against the COVID-19 pandemic, a generalised performance model can be developed considering minimisation of deviations from targets, standards, policies, etc., to be gathered by the PT student. A target can be defined as the safety level of PPE stocks in the location for use and in the warehouse for distribution. However, one of the biggest challenges is to determine the forthcoming number of patients, considering models of the contagious curve and how this can be used in a performance model in agreement with a) standards (soft bounds or targets); b) limits in the treatment capacities; and c) correlated processes by using lower and upper bounds of variables. Under certain circumstances, the use of penalties can be considered to avoid infeasible problems (out of stock on the PPE as an example).

5. Conclusions

The complementarities of part-time and full-time postgraduates in process system engineering centres are a topic to be addressed by policymakers, institutional leaders, and researchers to improve part-time student efficiency. Education in PSE/CAPE tools highlights the importance of merging industry and academia to validate case studies, find synergies, coordinate the cooperation of postgraduates, etc. It also participates in building a future society that balances economic development, addresses social issues and incorporate technology to solve sustainably real-world problems. The example of optimisation and control of healthcare systems illustrates how industry, represented by the medical corporation, must be in consonance with the knowledge provided by academia. The case was developed based on a synergy between a part-time student exposed to the needed tools from academia and real data gathered from the industry.

Abstract

The Quantum industry is currently at an embryonic stage. If it is to grow, it will require new markets, and, a workforce with the requisite skills and knowledge to support it. Anticipating this potential growth, this paper will explore capacity building within engineering education on the subject of Quantum Computing (QC). This work has two aims. On the one hand, it seeks to illustrate the need for developing education on the subject, inferred by trends in open literature. On the other hand, it seeks to suggest a starting point for quantum computing education in higher education. Since 2018, a sharp incline can be observed in the number of publications on topics related to QC. These publications are arising within several fields related to engineering including, but not limited to, material science, chemistry and computer science. In response to this trend, this paper will evaluate several third party educational approaches to teaching emergent technologies with a view to developing a model for teaching QC. Due to a lack of precedent in a wide range of industry applications and the current limitations in the state-of-the-art of this technology, the educational model proposed will be one that exploits imagination, as opposed to knowledge acquisition, in the pursuit of new knowledge building.

Keywords: Education, Emergent Technologies, Quantum Computing, Engineering.

1. Introduction

This paper highlights the current progress of a project for which the objective is to build capacity within engineering education at the Department of Chemical and Biochemical Engineering at the Technical University of Denmark and at the Lassonde School of Engineering at York University in Canada. The goal is that when Quantum Computing technology is ready for widespread adoption, we will be ready to support its growth.

1.1. Quantum Computing

Quantum Computing (QC) can be described as an emergent technology. Whilst its scientific principles (e.g. superposition and entanglement) are well understood, it currently possesses several limitations in relation to its useful application in the real

world. Despite these limitations, several early use cases have been shown to be competitive compared to classical systems whilst many areas have been identified as having great potential for quantum advantage in the future. For example, in the field of Process Systems Engineering (PSE), Ajagekar and You (2020) published experimental results where a proposed QC-based fault diagnosis model outperformed both state-of-the-art data-driven approaches and deep neural network based models in almost all cases. Activities such as process optimization and process data analytics (Pistikopoulos et al., 2021), and, areas such as drug discovery (Hassanzadeh, 2020), and, energy systems and supply chains (Ajagekar, You, 2019), are projected to benefit from QC.

1.2. Quantum Computing Education

Despite the potential for the future application of quantum computing in engineering, no unified curriculum exists to bring these approaches to engineering education across its various disciplines. This may be because teaching and learning an emergent technology presents many unique challenges. More precisely and unlike an established technology, it may not be possible to present a full body of science. Further, adequate tools and techniques may not be developed, and real-world examples will be sparse. Day and Shoemaker (2000) proposed several unique characteristics that can be ascribed to emergent technologies that result in significant challenges in the sphere of teaching and learning. These characteristics include ‘uncertainty, an evolving understanding of functional benefits, formative regulatory standards, speculative use patterns, incomplete market knowledge, embryonic industry structure, new market players and emergent and fast changing rules of the game’. Quantum computing can be qualified as possessing many of these characteristics and therefore, we will approach the challenge of designing education on this subject in the broader context of designing education for an emergent technology. Whilst adopting this broader approach will make it easier to conceptualise the problem, it does not make it easy to solve. Due to the breadth of characteristics that apply to emerging technologies, and the variation that may be inherent within each, a bespoke design is often required.

2. The Growing Interest in Quantum Computing

To explore the growing investment in quantum computing within academia, a quantitative analysis was undertaken with a view to identifying trends across time. ‘Count of publications’ was selected as the quantifying parameter whilst a list of keywords served as the qualifying parameter. The keywords were as follows: (i) Quantum Computing, (ii) Quantum Computation and (iii) Quantum Computer.

The keywords were applied to journal ‘Titles’ in the first instance and journal ‘Topics’ in the second, resulting in the production of a list of journal entries for each search respectively. ‘Title counts’ were intended to illustrate the growth in focus on the subject of quantum computing whilst ‘Topic counts’ were intended to illustrate a more general growth in interest. The results of the analysis are illustrated in Figure 1.

As Figure 1 demonstrates, the annual count of ‘Titles’ containing a keyword was reasonably uniform between 2001 and 2017. A significant upturn occurred in 2018, which continued into 2019 where an increase in excess of 100 % is illustrated in the number of ‘Titles’ containing a keyword compared to just two years previous.

Turning to the count of ‘Topics’ containing a keyword, a more gradual increase in interest can be observed in quantum computing over the same period. In agreement with the trend in ‘Title’ counts, ‘Topic’ counts also illustrate a sharp upturn in growth in both 2018 and 2019 offering further support that a transition is on the horizon. With a view to

Figure 1: Count of ‘Titles’ and ‘Topics’ containing the search keywords

developing a more granular overview of the growing interest in QC, the topics were then broken down by ‘field’, as illustrated in Figure 2.

Figure 2 illustrates that physics and mathematics are the fields that are producing the greatest output in terms of the number of publications. Relatively speaking, mechanics, computing, optics, and chemistry are also making a respectable number of contributions, whilst material science is close behind. Whilst the trend line for mechanics, and to a lesser extent optics and chemistry, appears to be well correlated with that of physics and mathematics, the computing trend line is not. Between 2009 and 2015, computing appears to have experienced a trough in interest for reasons we are unable to identify here.

Figure 2: Count of ‘Topics’ containing the search keywords, broken down by Field

However, what is apparent is that several fields are experiencing accelerated growth in interest in the area of quantum computing, and with this, one can expect an emerging demand for a growing talent pool with appropriate knowledge, skills and creativity. And, whilst the education field has also experienced a relative increase in the number of publications on quantum computing over the last couple of years (at 22 and 30 publications for 2018 and 2019 respectively) we might have reasons to be concerned that the level of interest expressed here is simply not enough to match demand elsewhere. Validation for this concern is supported by a recent Black and White report commissioned by D-Wave where 59% of the survey respondents who are not using or considering using quantum computing in the near future are not doing so because of skills issues (451 Research, 2020).

3. State-of-the-Art: Teaching Emerging Technologies

Consulting literature on the topic of Education for emergent technologies, several methodologies have been proposed and/or implemented. Three methods will be outlined below.

Nilsen & Puroo (2005) outline how a trio of pedagogical traditions, objectivist, constructivist and social-cultural could be mapped to a trio of learning objectives, namely the learning of tools, the understanding of principles and the application of these tools and principles in problem solving respectively. Employing a case study research methodology, they were able to identify several challenges to teaching emergent technologies within their own field (Information Systems) and hence, proposed some recommendations to overcome same. These recommendations included the use of flexibility in structuring courses, the use of practical elements in content building, and, a need to engineer roles that can evolve over time, thus permitting the use of multiple pedagogies in the delivery of a single course.

The Pritzker School of Molecular Engineering (PME) at the University of Chicago (IL, USA) created an elective titled 'Introduction to Emerging Technologies' with a view to attracting new students to diversify their student body. In their recent paper, Fowler, et al., propose how systems thinking can be integrated into their current course by adding a number of systems thinking techniques to a series of case studies (Fowler et al., 2019). The subject of the case studies range from tissue engineering to quantum information technologies whilst the proposed systems thinking techniques, many of which can equally be applied to a range of other pedagogies, include think-pair-share, relationship identification between actors within a system, and, questioning (carefully selected in advance). Fowler, et al., correctly identify that systems thinking has applications beyond the sphere of technology in assessing and addressing problems in the wider societal landscape.

A few years earlier, Bishop (2009) opted to use a socio-technological development model for the design of an elective course involving the study and analysis of emerging technologies for the systems engineering department at the United States Naval Academy. The foundation of the course is to address three fundamental questions: 1) What is possible? 2) What is achievable? 3) What is valuable? A number of models including the McKenzie certainty trough and the Disruptive Innovation model are woven into a series of case studies that allow the course participants to expand their skills in recognising *the factors that affect and effect technological change* (Bishop, 2009).

Figure 3: Visual Illustration of Bishop's three fundamental questions

4. Analysis

Nilsen & Purao's (2005) course attempted to address the full range of knowledge and skills required to be competent in a technology. The year was 2004 and their emergent technology was XML. XML and Quantum Computing are not comparable technologies, hence, the challenges they encountered were quite different from the challenges we are encountering with quantum computing today. Using their trio of pedagogies and corresponding learning outcomes, it was the principles and the potential use cases of XML where the ambiguity was most prominent, and hence most challenging for education. Whilst Quantum Computing also suffers from ambiguity in the region of potential use cases, it differs significantly from XML in that it is the lack of tools, and not principles, that pose the greater challenge. To cut through the ambiguity residing with XML technologies in 2004, explanations, guidelines and standards were required. To cut through the ambiguity residing in quantum computing today, a technological leap is required.

Working independently, both Fowler et al. (2019) and Bishop (2009) approached the topic of emerging technologies from a non-technical angle. Unlike Nilsen & Purao (2005), they focused their programs on the socio-cultural aspect of the technology, relieving themselves of the need to employ multiple pedagogies within a single course. Whilst it is essential to understand something about the scientific principles and state-of-the-art that underpin, or occasion, the technologies that they present, there is no requirement for the participants to be expertly versed or skilled in them.

At the same time, there are a few departures between these two socio-technological approaches. As stated above, Fowler, et al., are proposing a systems thinking methodology whilst Bishop is leveraging a system of probing. Systems thinking champions joined up thinking, which is a valuable way to assess the viability of a new technology, however, seeing beyond what already exists is not a core function of this pedagogical style. Put another way, it may be that systems thinking is better at telling us what is likely or unlikely to succeed as opposed to assisting us in developing new ideas. Alternatively, Bishop's more open-ended approach of questioning draws us closer to the human cognitive capacity for imagination.

5. Proposed Model

The educational model that this paper proposes to develop is one that separates the teaching of the core technology from that of exploring its socio-cultural applications. Tailoring a single course for engineering students where the objective of the course is to design new use cases, participants will be encouraged to investigate how quantum computing can be harnessed where other methods are currently utilized across industry. Excluding the more practical implementations of quantum computing, and according to McKenzie's certainty trough, we anticipate that the participants of the course will be more optimistic about the possibilities that the technology presents, given their distance from the technology itself. This course will also lean towards Bishop's system of probing.

6. Conclusion

Designing education for emergent technologies presents unique challenges as knowledge, skills and use cases pertaining to the technologies are not well established and subject to change. Quantum computing is one such technology and whilst this paper does not predict when this technology will become established, our quantitative analysis of published papers on the subject indicates that we are drawing closer. To build capacity within engineering education we must confront these educational challenges. Otherwise, we may not be ready to support the market for quantum computing as the technology becomes more frequent and accessible. We have proposed to implement a learning design that will exercise the cognitive muscle for imagination as well as joined up thinking. Ultimately, we hope that our pedagogical approach will permit more freedom of the imagination, thus widening the circle of what is deemed possible within several engineering industries, and, in quantum computing more generally.

Teaching PSE Mastery During, and After, the COVID-19 Pandemic

Daniel R. Lewin

Department of Chemical Engineering, Technion. I. I. T., Haifa 32000, Israel

Email for correspondence: dlewin@technion.ac.il

Abstract

The author has been teaching process systems engineering (PSE) courses to undergraduates at the Technion for more than 30 years, evolving his teaching to active learning methods, and in the last five years, to the “flipped class” model. In the spring of 2020, teaching became particularly challenging, since it was taught on-line for the first time, with students having to collaborate remotely with each other also for the detailed design work. This contribution presents the experiences and conclusions resulting from the first COVID-19 semester (spring 2020). At the time of writing, the recommendations are being implemented on two flipped courses, on process design and process control, which are being taught completely on-line in winter 2020 to the same class of 53 students. The presentation will thus summarize the lessons learned over a complete year of practice

Keywords: Process design instruction, process control instruction, project-based learning, active learning, flipped classroom, on-line learning.

1. Introduction – typical instructional objectives for PSE mastery

All of us in the PSE community will agree about the importance of taking a systems approach in chemical engineering design and analysis instruction (Silverstein et al, 2013). Within the framework of PSE, this instruction would include at least courses in the central expertise areas of numerical methods, process control and process design, composed of curricula like those listed below. A helpful way of teaching these materials is by making use of concept maps, which facilitate explaining the connection between the course components. An example of a concept map for a course on numerical methods is presented in Figure 1. Representative learning outcomes for these three key courses are outlined next.

1.1 Numerical Methods: This course ideally instructs the students in the understanding of the basic building blocks of numerical methods, before continuing to providing tools for their practical application. On the completion of such a course, students are expected to select the appropriate numerical method for a given problem, implement it, and interpret the obtained result. Typical course outcomes are as follows:

Building blocks:

- Efficient solution of linear systems
- Finite difference approximations (derivatives, interpolation, integration)
- Efficient solution of nonlinear systems
- Mastery in unconstrained and constrained minimization (Linear Programming)

Applications:

- Linear and nonlinear regression capabilities
- Efficient solution of ODEs, IVPDEs and BVPs
- Integrated problem-solving capabilities

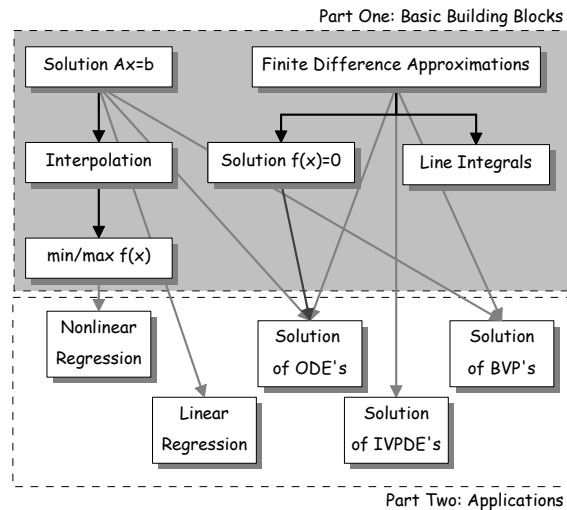

Figure 1. Concept map for a typical course on numerical methods.

1.2 Process Control: This course provides the tools to develop first principles and empirical process models, and then using the derived models, to design simple control systems to meet desired closed-loop performance. Typical course outcomes (Seborg et al, 2004) are as follows:

Process modelling:

- First-principles modelling capability
- Ability to generate state-space and transfer function models
- Block diagram manipulation capability
- Ability to analyse the transient response of linear systems

Process control synthesis:

- Frequency domain analysis capabilities
- Stability analysis capability
- Capability to synthesize control systems to meet response specifications using the root locus method
- Knowing how to tune PID controllers effectively
- Capability to design cascade and feedforward control systems

1.3 Process Design: The capstone design course represents the acid test of a student's ability to apply the engineering tools he/she has acquired, with typical desired outcomes (Seider et al, 2017) being as follows:

- Capability to carry out plant costing and profitability analysis
- Separation sequence synthesis capability for both zeotropic and azeotropic systems
- Capability to perform MER targeting and heat exchanger network synthesis
- Plant-wide control system configuration capability
- Capability to perform a HAZOP and to carry out a HAZAN
- Proven cooperative design project capability, demonstrating both team and individual skills

2. Student-centered vs Teacher-centered teaching

As postulated by Bloom (1968), the degree to which students achieve mastery depends on four conditions: (1) Clear definition of what constitutes mastery; (2) Systematic, well-organized instruction, focused on student needs; (3) Assistance for students when and where they experience difficulties; (4) Provision of sufficient time for students to achieve mastery. Bloom reports the modes of learning that improve outcomes, with the most significant obtained by personal tutoring, which increases the degree of mastery as exhibited by exam grades up to two standard deviations higher than for students taught conventionally by a lecture-based approach.

In a course that is taught in a teacher-centred approach, the contact time between the teacher and the students is mostly utilized for lectures by the teacher, often with modest involvement of the students. In recitations, the assistant will often take the same approach. This means that in a teacher-centred approach, students are largely passive in most of the contact time available, with the students expected to take an active role mostly when tackling homework sets on their own. These deficiencies reduce the degree to which students acquire mastery in higher-level design and evaluation capabilities.

In contrast, in a student-centred approach, the contact time is focused on giving opportunities for students to become involved in class activities, with the teaching staff acting as mentors. Amongst the activities are class quizzes leading to discussions, brainstorming, cooperative problem-solving, and student presentations. By nurturing student involvement, the teacher will be able to better assess the degree of mastery being built up by the students. Student involvement is even more critical in the recitations, where the focus should be on giving students time to work problems for themselves. For students to learn, they need to be given opportunities to make mistakes, understand the reasons for the mistakes, and correct them. This takes time, and the more recitation time taken up by the TA explaining his/her problem-solving strategies, the less time the students will have for their own efforts. Mentoring students' work, should fill most of the recitation time, enabling staff to mentor and assess student capabilities.

This formative assessment can only be ascertained if the teachers and assistants reduce the amount of time that they are lecturing in favour of providing time for active learning by the students (Velegol et al, 2015). One of the best ways to make this happen is to transition to flipped classes, which move a large part of the information transfer to on-line, pre-recorded lectures, which the students need to complete as their homework in advance of class activities. The *flipped classroom*, involves the following sequence of activities, repeated in every week of each course:

- a. *On-line Materials* – Produced by converting lectures to pre-prepared, on-line lessons composed of 5-15 min video clips interspersed by on-line quizzes. Students are expected to cover these materials on their own as homework in advance of each week of activity and are given course credit for it. **Benefits:** Students learn the basic materials covered in each week at their own pace, and their learning is reinforced by addressing the on-line activities as they follow the materials. The on-line activities can be tailored to achieve specific objectives in each stage of the course. These can be: (a) Regular quizzes: Quiz questions posed as multiple-choice, matching, or numerical computations; (b) “Your turn” extended calculations and small-scale designs: A problem for the student to tackle independently is defined at the end of a video clip, which is followed by a movie in which a possible solution to the problem solved is presented, which students can compare to their solutions; (c) Preparing for brainstorming: A video clip can present a problem that requires group effort to address, for which students are requested to collect information, write down ideas,

and bring their results to class for groups discussion. Note that all these activities increase the students' stake in their learning and will prepare them to make better use of the next resource – the Class Meeting.

- b. *Class Meetings* – Moving from *teacher-cantered lecturing* to *student-cantered meetings in the classroom*. A typical class meeting combines quizzes, class discussions and open-ended problem solving, with the focus being to keep the students active. **Benefits:** Giving students the opportunity to prepare ahead increases their effective participation in class and impacts positively on the degree to which they learn and master the application of what they have learned. The specific benefits of each type of activity that could be utilized are as follows: (a) Quizzes for comprehension: These could be clicker questions, to test comprehension of concepts learned at home, or to reinforce previous, related materials. The lecturer can check the level of understanding exhibited by all of the students, instantly; (b) Quizzes to generate discussion: When the questions raised may have more than one solution, it pays dividends to use them to generate class discussion. Learning from incorrect answers is often more valuable than focusing only on correct ones; (c) Open-ended problem solving: This is one of the main reasons for having class meetings. The focus should be on getting students to participate in the development of solutions. For particularly complex problems, dividing the class in separate workgroups may have benefit.
- c. *Active Tutorials* – For students to master course content, they need to apply themselves to independently work problem sets covering the curriculum. The job of the teaching assistant in this setting is to be the enabler for student efforts rather than a demonstrator of solutions. **Benefits:** In active tutorials, students working in teams solve the classwork (previously referred to as homework) in class time. This ensures that: (a) All students who participate in the sessions are actively involved in working problems; (b) Assistance can be provided by staff and from students, helping each other; (c) Students, assistants and the lecturer all receive feedback in a timely fashion (in real time).

3. On-line challenges and how to address them

The spring of 2020, with the resulting COVID-19 lockdowns, introduced additional challenges to effective teaching. Several problems surfaced, associated with a need for social distancing and on-line lessons. Here is an itemized list of problems together with the ways that have been found helpful in overcoming them:

- a. Undesirable on-line behaviour of students, such as students turning off cameras and microphones or passive and/or low student attendance. **Fixes:** (a) Request that students turn on cameras with microphones on mute, turning on microphones to participate. A bright and positive attitude by the lecturer will go far in securing cooperation of the students. (b) What worked outstandingly well was to invite all of the students to an on-line “BYOB Party” before the start of classes, to get to know them and to use the informal meeting as a chance to share expectations. After that, the ice was broken and most of the students were cooperative in the on-line Zoom sessions. Attendance was high (usually over 80% of the students), with many students participating in class discussion.
- b. Undesirable on-line behaviour of teachers, such as the teacher talking most of the class time, or teachers demonstrating solutions of problems, with little involvement of students, or allowing a few students to dominate the in-class discussions. **Fixes:** (a) Pause in presentation to give students a chance to ask questions. Respond to the

- questions and check that the response fully-addresses them; (b) In-class problem solving should involve the students. Do not provide full solutions up-front but get students to contribute suggestions and partial solution steps by brainstorming with student involvement; (c) Use on-line quizzes to promote class discussion, with all students participating. Use polling software to involve the whole class in this, and use the class answers, especially the wrong ones, to generate discussion in the class.
- c. Too many students (typically 15-25%) not preparing for the synchronous meetings by studying the on-line lessons in advance. **Fix: You cannot afford to lose 15-25% of the class!** Not taking steps to bring these non-performers back into the fold can mean a large proportion of underperformers who do not even pass a course. Efforts need to be made to track the non-collaborators, reaching out to them from Week 1 of the course, and bring them back in, and it is surprising how easy this is to do. Many of them will take kindly to your outreach, especially if your communication is positive and focused on how much you care about their success. If the percentage of students truly on-board is maintained high during the entire course, the whole class will benefit, and the outcomes at the end of the course will reflect this.
- Most of these suggested fixes will work in a regular, face-to-face (F2F) setting also.

4. A flipped roadmap for the future

The author has had a long and successful experience with the effective implementation of the flipped classroom to the teaching of both process control and process design, now for seven consecutive years. There is evidence for improved outcomes in process design instruction resulting from the implementation of active methods (Lewin and Barzilai, 2020a). In the year of the pandemic, and the consequently imposed lockdowns, the flipped classroom was relatively easily adapted to on-line learning (Lewin, 2020b). The experiences gained in the second semester of the pandemic to a relatively large group of students who simultaneously participated in courses in process design and process control have led to a clear conclusion that a correctly implemented flipped paradigm is highly effective. This implementation involves the following eight key components:

1. *Have a game plan.* Balance expectations of the lecturers, teaching assistants and students, as all three stakeholder groups need to be on board. It is recommended that a lecturer with no previous experience in flipping try the paradigm first on a single week of class, selecting the week that is the most challenging to fully-cover using a conventional approach. In addition to preparing the on-line lesson as homework, the class meeting and the active tutorial should be included in this trial.
2. *Preparation of on-line lessons.* Define instructional objectives for each lesson. Divide the lecture into video segments of between 5–15-minute duration, ensuring that the content is complete (e.g., cover all steps in a mathematical development). Write and use a script when recording the video segments and practice the delivery before recording. Audio quality is more critical than video quality.
3. *Preparation of effective quiz questions.* Follow each video segment with a quiz question/cluster/activity to test students' understanding. Write useful explanations of all answers (especially important for the wrong ones) and allow students to retry the questions that they get wrong. This is not a test – it is part of their learning!
4. *Lesson assembly and testing.* Upload questions and videos and generate a Moodle Lesson (or similar). The teacher should test the flow and system response first, and have an assistant perform an independent check.

5. *Require students to complete the lessons before Class Meetings.* Students should be given credit for this crucial preparatory step. Continuously follow up on students who do not do this, starting from the first week of the semester.
6. *Plan for a useful Class Meeting.* Prepare additional materials and do not repeat what the students have already learned on-line. The following is a partial list of activities that have been found to be useful: (a) Short quiz questions – to be used to foster class-discussion; (b) Open-ended exam-style questions to be solved with class participation; (c) Project/design work, executed in “break out rooms”; (d) Short student presentations.
7. *Schedule an Active Tutorial.* Schedule sufficient time as this activity largely replaces what used to be “homework.” Allow time to discuss solution strategies in class. Divide the class into small work groups, using breakout rooms if on-line, or by ensuring appropriate seating arrangements if F2F. Make sure question levels in each week’s problem set span from easy to difficult (exam level), and make solutions available on-line. It is unreasonable to expect students to handle exam-level questions well in the final exam without giving them the opportunity to practice solving similar questions for themselves in the Active Tutorials during the semester.
8. *Follow up on every component.* All three steps of the flipping paradigm are critical to success and all of them can be continuously improved. For the On-line Lesson, were there any problematic video segments, and were there any problematic or particularly useful quiz questions, and should more questions be added? For the Class Meeting, were there enough students active, and how many attended? Were the planned activities suitable? For the Active Tutorial, how many students attended, and how many of them were actively engaged and completed the assignments?

5. Conclusions

Experience with the flipped-class approach indicates that engagement with the materials throughout the semester improved the students’ level of confidence in their mastery of the subjects. These observations could explain the improved performance in the final exams in both the process design and the process control courses since adopting active learning and flipping in both. The encouraging outcomes obtained in both courses suggest that this format can be taught to good effect in more than one course at a time, and equally well both on-line and in F2F teaching. Hopefully, these findings and recommendations will encourage others in the PSE community to move to active learning methods.

Real-Time Chemical Process Monitoring with UMAP

Zachary Webb^a and José Romagnoli^{a,*}

^a*Louisiana State University, 3307 Patrick F. Taylor Hall, Baton Rouge, LA 70803, USA*
jose@lsu.edu

Abstract

In the modern chemical world, engineers have access to millions of data points at their fingertips. Using this data properly can help us to recognize vast improvements in the way plants are run, especially in process monitoring. In this paper three aspects of process monitoring are considered: visualization, fault identification, and fault diagnosis. For each aspect, the use of modern machine learning techniques for addressing these issues is discussed, and improvements over outdated methods are illustrated. This proposed approach is tested using the Tennessee Eastman Process (TEP) for several types of faults.

Keywords: Process Monitoring, Dimensionality Reduction, Clustering, Fault Detection, Fault Diagnosis

1. Introduction

The chemical industry has always had a need for a system to monitor the process and ensure the quality of chemical product. Such a monitoring system has four goals: fault detection, fault identification, fault diagnosis, and process recovery. In the past, these goals could be achieved to a degree for any individual process with a model developed carefully with specific process knowledge, using tools like univariate error charts and alarms. Methods have been developed to bring about more sophisticated process monitoring that takes advantage of multivariate data information. Common methods like Principal Components Analysis (PCA) and recursive PCA (RPCA) are useful in some cases, but are deficient in dealing with data containing nonlinearities, which is especially problematic in the chemical industry. The other drawback is that a PCA model is unable to trace such normal process drifting, while most of the industrial processes are time-varying due to catalyst deactivation, equipment aging, and tube coking.

Recent breakthroughs in dimension reduction (DR) techniques and topology have popularized the Uniform Manifold Approximation and Projection (UMAP) algorithm for projecting high dimensional data into 2 or 3 dimensions. With UMAP, we can reduce the dimensionality of process data and apply modern clustering algorithms to quickly and effectively categorize it. Once a model has been created using the historical information, incoming data points can be passed through the same UMAP model and a fault detection program (FDP). The FDP uses an adaptive k-Nearest Neighbor (AkNN) method to determine the belongingness of each incoming data point to the clusters of data in the historical model. Data which correspond to known clusters are added to a repository of historical information, and data which do not are classified as “faulty”. We can diagnose

the cause of faulty points using a subspace greedy algorithm (SGS), which determines the variables that contribute to their differences from known clusters. After diagnosis is accomplished, the route to process recovery will be much clearer for the responsible engineer. This proposed method is tested using the Tennessee Eastman Process (TEP) for several types of faults. The proposed method of process monitoring outperforms traditional methods. The online monitoring tool provides fast and useful information to engineers or operators in the case of a fault, leading to speedy recovery of the process.

2. Methods

2.1. Uniform Manifold Approximation and Projection (UMAP)

UMAP is a dimension reduction technique developed by McInnes et al. in 2018. It is a manifold learning technique based on Riemannian geometry and algebraic topology. UMAP works by first discovering the relationships of the input data in the high-dimensional space, using fuzzy simplicial complexes, which are a topological representation of a local neighborhood graph. Once a graph has been constructed, UMAP uses stochastic gradient descent optimization to find a low-dimensional representation that is most similar to the high-dimensional input. UMAP improves upon the previous state-of-the-art DR algorithm, t-SNE, by better preserving the global structure of the input data in the low-dimensional space. For low-dimensional t-SNE representations, the within-cluster distances were meaningful for determining similarity of data, but the between-cluster distances were not guaranteed to be important. Because the real-time process monitoring workflow hinges on the separation of faulty data in the low-dimensional space, this improvement is critical.

2.2. K-Nearest Neighbors Fault Detection

The k-Nearest Neighbor (kNN) algorithm is a popular classification method for unknown data. By using the Euclidean distance, we can classify a data point based on information known about its k-nearest neighbors. If we set $k=1$, then each point will be classified just by its single nearest neighbor, and if we set k to a large integer value, it will be classified by a vote of the aggregate classes of its k nearest neighbors. Using the output distances from the kNN, we can determine the likelihood that a single point belongs to a known group of points. In a plant setting, we can use kNN to scan incoming data points in real-time, compare them to a historical database of pre-classified points, and determine if the incoming point characterizes an abnormal event based on a threshold distance.

2.3. Adaptive kNN

In order to run a kNN fault detection program for any amount of time, the trained kNN graph must have the ability to adapt over time. The behavior of a chemical plant is subject to time-varying behavior and process drift. Because the pairwise kNN graph construction is computationally expensive, we can reduce the workload of the computation engine by maintaining a database of only data which are prototypical for each class we are interested in. For a data point x , the number of its neighbors, in data set D laying within the k th threshold distance d_a , denoted as N_x , is defined:

$$N_x = |\{q \in D | \text{dist}(x, q) \leq d_a\}| \quad (1)$$

Thus, we can define a prototype by naïve criteria. A point x is considered a prototype if the N_x is equal to k . This definition is too strict, so we can expand the scope of the prototype by using an updating factor, p , where $p \in (0,1)$. Now we can define the extended prototype:

$$k(1 - p) < N_x < k(1 + p) \quad (2)$$

We can now also define a fault:

$$N_x \leq k(1 + p) \quad (3)$$

Using these definitions, we now have an adaptive kNN algorithm that can determine if incoming data points would be redundant in the model or if they otherwise provide new useful information. We can also define a “valley” point within the sorted k-dist graph:

$$x = \min \{x \in [a, b] | \frac{f(x + \frac{s}{2}) - f(x - \frac{s}{2})}{s} \geq \frac{f(b) - f(0)}{b}\} \quad (4)$$

Where $f(x)$ is the sorted k-dist curve, and the searching step is defined as s where $s > 1$.

2.4. Variable Contribution using Subspace Greedy Search Algorithm

Now that the monitoring framework can use AkNN to detect faulty data, the next stage is to diagnose those faults as soon as they occur. If we can determine which of the real input variables contribute to the differences in a faulty data point, recovering from the abnormal event will be much easier. The goal of fault identification is to find the combination of the most contributing group of variables (subspace) which causes the discriminant between normal and faulty data. A naïve approach which tests all possible subspaces for a difference in disparity between normal and faulty data will fail for two reasons. First, the curse of dimensionality will dull this effect on the score as the data grows in dimension. Second, with a number of possible subspaces given by 2^d , where d is the number of input variables, it is impractical to calculate the score for each subspace due to computational complexity. In order to address these problems, subspace greedy search (SGS) is implemented. The testing score is calculated by comparing the k-distance between the normal and faulty data for each target subspace. Use of a greedy algorithm beginning in low-dimensional subspaces allows the search to terminate in a reasonable number of step and return a list of input variables ranked by their contribution. This addition will allow users to react appropriately to data found to be faulty.

3. Results

3.1. The Tennessee Eastman Process

The Tennessee Eastman Process (TEP) is a simulation developed by Downs and Vogel, which is used as a benchmark for studying process control and monitoring. It consists of

two liquid products along with an unwanted byproduct, which are generated by four gaseous reactants and one inert. The simulation offers 20 process faults among 53 measurements. We studied TEP0 (normal data), TEP2 (step change in the inert composition), and TEP10 (random variation in the feed temperature). For each of these faulty conditions, the goal is to create a good visualization in 2D space using UMAP, identify the faults using AkNN, and to diagnose the root cause of the event using SGS.

3.2. Projection into 2D space

For the step change introduced in TEP2, all three methods of visualization accomplish the goal of separating the TEP0 data from the TEP2 data in 2D space. For this task, UMAP was run with $k=50$ neighbors and $\text{min_dist}=0.5$. These projections are depicted in Figure 1.

For the random variation introduced in TEP10, the three methods give us drastically different results. PCA struggles to separate the TEP0 data from the TEP10 data, so in 2D space, all of the data points fall into one group. The t-SNE results are much better, separating out two groups of TEP10 data from the larger group of TEP0 data at the top left. UMAP is able to separate the two groups of TEP10 and show the separation clearly in 2D space, outperforming the other two DR algorithms. For this task, UMAP was run with $k=10$ neighbors and $\text{min_dist}=0.05$. These projections are depicted in Figure 2.

3.3. Error Testing

The AkNN fault detection system was able to characterize the faulty data at over 99% accuracy for both faults TEP2 and TEP10 compared to the normal data TEP0 (shown in Figures 3 and 4). With faulty data showing a knn-dist measurement above the given threshold, AkNN can identify faults and alert personnel quickly when faults occur.

Figure 5: TEP0 (Normal) and TEP2 (step change) contribution chart

Figure 6: TEP0 (Normal) and TEP10 (random variations) contribution chart

3.4. Variable Contribution

The subspace greedy search algorithm was able to identify the primary source of the fault TEP2 (step change in the inert composition) and TEP10 (random variation in the feed temperature). When compared to the variable contributions given by the explained variance of PCA, this SGS algorithm is clearly preferable. SGS often returns only one or two contributing input variables, which speeds up the recovery process by pointing to the most responsible contributors, while PCA can give a long list of partially contributing variables, leaving personnel with not much assistance.

4. Conclusions

In this paper, we propose three tools: dimension reduction for improved process visualization with UMAP, real-time process monitoring including fault identification based on AkNN, and variable contribution fault diagnosis with SGS to form a full process monitoring environment for detecting and recovering from abnormal events, especially in the chemical processing world. We have shown that these modern tools are competitive with traditional techniques and in many cases improve upon them. An environment which uses all of these methods in conjunction with a user-friendly interface will be the introduction of many in the chemical industry to the world of machine learning and computer science. These advanced methods improve the popularity real-time process monitoring, which would improve the quality of chemical products and better the safety of those nearby.

Abstract

In this paper we show that for a zeotropic mixture the simultaneous implementation of different heat integration alternatives like direct reboiler-condenser heat exchange, Direct or reverse vapor recompression cycles, multi-effect distillation, partially or totally breaking of thermal couples and substitution of thermal couples by the equivalent only liquid transfer alternative, when possible, considerably increase the thermal efficiency of a sequence of distillation columns and its total cost. We illustrate the procedure with the separation of a four-component mixture. Results show that we can get impressive reductions in total annual cost.

Keywords: Thermally Coupled Distillation, Heat Integration, Process Integration, Vapor Recompression Cycle.

1. Introduction

In the chemical industry engineers have a large number of unit operations to separate components (e.g. adsorption, extraction, membranes, absorption, etc.). However, distillation accounts around 90-95% of all the liquid separations and purifications in industry, and this situation is not likely to change in the near future (Humphrey and Keller, 1997). In spite of the predominance of distillation, it is not uncommon the claim that distillation is an inefficient separation technology. However, Agrawal and Tumbalam Gooty, (2020) have shown that this belief is a misconception likely based on the fact that distillation involves vaporization of one or more components and therefore is more energy intensive than other alternatives that do not require phase change. However, the energy required in distillation is not necessarily proportional to the reboiler duty and distillation can be much more efficient than intuition seems to suggest. Conversely, for many applications, the high efficiency of distillation makes it challenging for alternatives to even achieve the same energy as that of distillation (Agrawal and Tumbalam Gooty, 2020). In this work we will show how the systematic implementation of heat integration alternatives can substantially increase the energy efficiency in distillation.

The characteristics of the search space for the sharp split of M components in N fractions, were established by different authors around 10-15 years ago by Caballero and Grossmann, (2006) and following a different approach by Giridhar and Agrawal, (2010). Shah and Agrawal, (2010) defined a regular configuration as a sequence of distillation columns formed by exactly $N-1$ columns (where N is the number of key components to be separated). If each one of the columns of the sequence has a reboiler and a condenser, then the sequence is a basic sequence. Basic sequences can be generated only by relations

between separation tasks and therefore it is possible to separate the structural considerations associated with the separations from the heat requirements of each distillation sequence. Alternatively, Caballero and Grossmann, (2006) used the concept of «structurally different configurations» to refer to a given sequence with a specific separation task without specifying any particular assignment of heat exchangers. The extension from structural different separations (or Basic) to the regular ones only requires to assign a heat exchanger or a thermal couple to each one of the streams connecting two columns in the sequence. Those authors showed that if we do not consider further integration or intensification, the optimal sequence is a regular sequence.

While there have been important advances in theory and algorithms for the generation of distillation-based separation sequences, and a good number of alternatives have been proposed for improving the energy efficiency (i.e. heat integration, vapor recompression, multi-effect distillation, partially thermally coupled columns, heat pumps, etc.) there are no a systematic framework for combining all those possibilities (and of course the new ones that could eventually appear) to generate efficient distillation sequences. In this work we present a systematic approach for designing separation sequences of zeotropic mixtures that simultaneously consider thermally coupled distillation (TCD) sequences, together with different alternatives for heat integration.

2. Algorithm for the efficient energy integration in thermally coupled distillation.

A good number of alternatives have been proposed to increase the energy efficiency in distillation. Direct heat integration between condensers and reboilers. Multi-effect distillation. Thermally coupled distillation, VRCs (or RVRC) are also a common approach to save energy when the temperature difference is not too large (typically no more than 30°C) and it is usually implemented between the condenser (or the rectifying section) and the reboiler (or the stripping section) of a column. Navarro-Amorós et al. (2013) showed that in thermally coupled distillation is possible to take advantage of the inherent inefficiency of TCD systems, by withdrawing the excess vapor (liquid) inside certain column sections and using it in a VRC (RVRC). The benefit is twofold; on one hand, the optimal operating conditions of the TCD system are recovered and therefore the diameter of some column sections and the utilities consumption are reduced. On the other, the VR or RVR allow further reductions in utilities consumption. Other alternatives, like partially thermally coupling; or the only liquid transfer alternative (Jiang and Agrawal, 2019; Skiborowski, 2020), are structural modifications that can be used to improve the heat integration.

The simultaneous design of the distillation sequence and all previous heat integration alternatives (and others that could eventually appear) is likely to produce very large and complex models that could be, at least, very hard to solve. Instead, we propose a sequential approach:

1. Select the best sequence of distillation columns in the space of regular configurations. In this work we use the disjunctive approach proposed by Caballero and Grossmann, (2006). This model, that relies on the Underwood-Fenske-Gilliland shortcut model, was validated using the commercial process simulator Aspen-Hysys. The next steps are developed using rigorous simulations.
2. For the selected configuration, identify:

- 2.1. Inefficiencies in the connection points between separation tasks that belong to the same column. The excess of vapor/liquid can be removed by heat exchanger. Those heat exchangers use utilities at intermediate temperatures, which in some cases allows the use of cheaper utilities. Besides, the internal flows decrease in some of the decoupled sections and therefore also the column diameter.
If the unbalance of flows in the connection points is large then consider to implement a VRC or RVRC to further reduce the energy costs.
- 2.2. Identify the possibility of heat integration between reboilers and condensers. Consider also the possibility of changing the pressure of some columns, breaking totally or partially some thermal couples if needed to get direct reboiler-condenser heat integration or indirect through a VRC/RVRC cycles.
- 2.3. For difficult separation task, consider the possibility of a multi-effect column integration. If that separation task is thermally coupled with other separation task, there are different alternatives: a) consider the possibility of partially (or totally) breaking the thermal couple introducing a new heat exchanger. b) Use the 'liquid transfer only' proposed by Agrawal. This last approach requires adding a new column section and a heat exchanger. With this approach, at least one of the columns that form the multi-effect arrangement can be maintained thermally coupled with the rest.
3. Repeat step 2 until no further improvement be possible.
4. Consider the possibility of intensification. This last point is not included in this work, but a review of different alternatives can be found in (Jiang and Agrawal, 2019)

3. Example

We illustrate the algorithm by designing the separation of a equimolar mixture of propane (A), isobutane (B), n-butane (C) and pentane (D). The objective is to obtain each component with a purity of at least 0.99 mol fraction. The best distillation sequence is shown in Figure 1a. The result, including the sizing of the columns was validated using ASPEN-HYSYS. Table 1 shows the data for the example.

Table 1. Data for the example.

Components	Composition (mol fraction)		
A: Propane	0.25	Feed Flow	200 kmol/h
B: i-Butane	0.25	Nominal Pressure	1000 kPa
C: n-Butane	0.25		
D: Pentane	0.25	Thermodynamics:	Peng Robinson
Cold Utilities	Cost (\$/kW·y)	Hot Utilities	Cost (\$/kW·y)
Refrigerated water (5-15 °C)	127.6	LP Steam (5 bar 160 °C)	404.67
Cold Water (20 – 35°C)	10.2	HP Steam (10 bar 180 °C)	427.14
Electricity 0.06 \$/kWh equivalent to 480\$/kW·y based on 8000 h/y of operation			
Annualization factor = 0.162 (interest = 10% in 10 years)			
Cost estimation based on correlations by (Turton et al., 2013)			

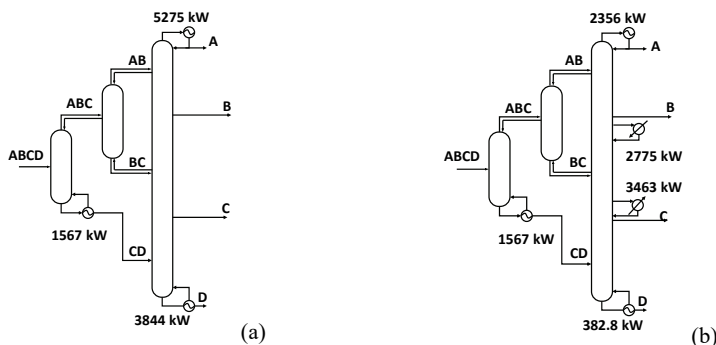

Figure 1. a) Optimal thermally coupled initial configuration, b) configuration after adding intermediate heat exchangers.

The temperature difference between the component B (i-C4) and C(n-C4) at the operational pressure is around 13-14 °C, so the integration of a VRC could eventually be of interest (Figure 2.a). On the other side, it would be possible to increase the pressure in the first column to try a heat integration with the reboiler C (Figure 2.b). However, to that end we need to remove the thermal couple in the top of the first column and substitute it by a condenser. Of course, this change is not for free, (remember that the optimal solution does not include this heat exchanger): it affects the rest of the system, adds a new heat exchanger, and the increase in pressure increases the hot utilities. With only the VRC we can reduce the TAC up to 3255 k\$/y, and with only the direct heat integration up to 3144 k\$/y, around a 29 and 31% compared to the base case. In both cases, there is still an important duty that is not satisfied in reboiler C. But with the simultaneous heat integration and the VRC we completely remove the duties in the reboiler C (See Figure 2.c), and the TAC is reduced in a 36.5% (2924.4 k\$/y).

Going back to the initial configuration it is possible to implement a different strategy for heat integration. Due to the fact that separation of butanes (B/C) is much more difficult than the rest, we can consider the possibility of a multi-effect integration. To that end, it is necessary to brake, at least partially, the thermal couple associated to the stream 'BC'. There are at least two possibilities: one is to add an extra column section and a new reboiler to convert the thermal couple BC in an equivalent 'only liquid transfer stream.'

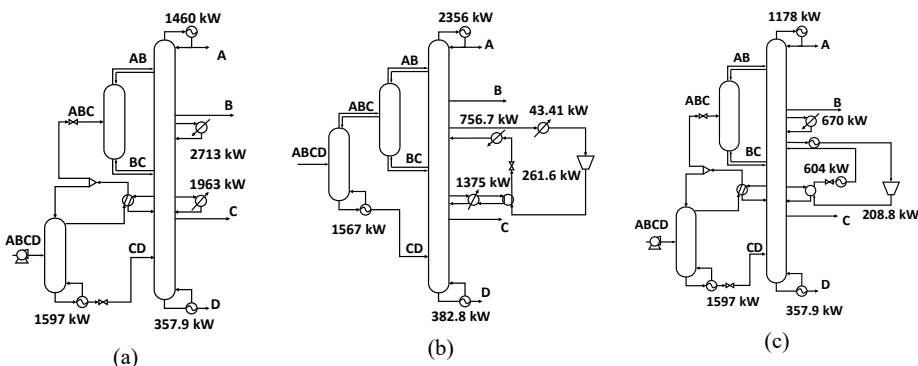

Figure 2. a) Direct heat integration between condenser of the first column and reboiler in C, b) Vapor recompression cycle between states B and C, c) Direct heat integration + VRC.

Another consists of adding a reboiler in stream BC, but at the same time partially maintain the thermal couple BC. With the second approach we avoid adding an extra column section, and therefore, it is the selected approach. The flows in the thermal couple and the liquid stream that form the new set of streams BC are adjusted to allow the heat integration between the two columns that form the thermal couple. Note that in this case, we can reduce the pressure of one of the columns that separate B from C to around 550 kPa, and maintain the thermal couple in the other separator B/C, and at the same time the integration of this last column B/C with C/D in the same column. In this way, we have halved the reboiler duty associated to stream C, but at the prize of adding two small reboilers (one in the stream BC and another in stream B) and a condenser (in stream B of the low-pressure B/C separator). Even though with this configuration the TAC is 3152.6 k\$/y a 31.6 % lower than the base case -Figure 3.1-.

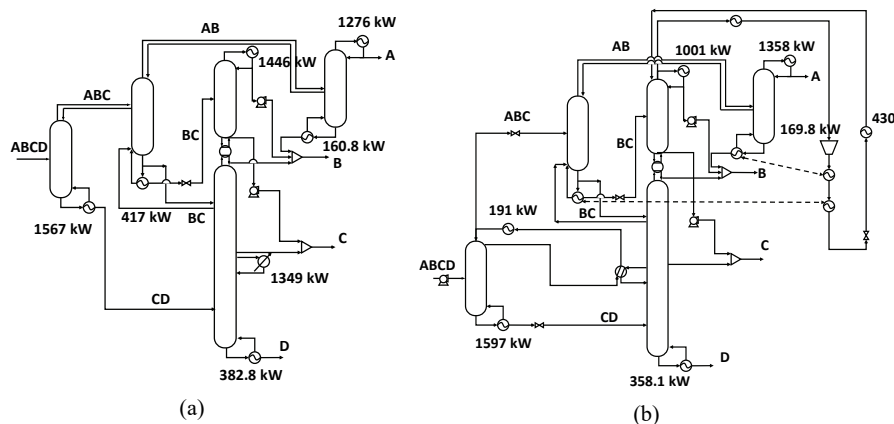

Figure 3. a) Partial thermal couple in state BC, and multi-effect integration by dividing the separation B/C in two columns at different pressure. b) Same that in (a) adding direct heat integration with first column and a VRC.

Following the same reasoning that in first configuration, we can break the thermal couple in ABC, and increase the pressure in the first column to integrate the condenser of this column with the reboiler associated to stream C. Adding this direct heat integration the total cost reduces up to 2349.6 k\$/y a 49% lower than the base case. Finally, the temperature in the condenser of the low-pressure B/C separator is around 44°C and the temperatures in the reboilers of separators A/B and AB/BC are around 66 and 72 °C respectively. Then, a VRC from the upper of low-pressure B/C separation can provide duty enough to satisfy those two heat exchangers. The cost of this last configuration is reduced to 2163 k\$/y a 53% lower than the base case -Figure 3.b.

4. Conclusions

In this paper we have shown that starting from the best thermally coupled sequence of distillation columns obtained from the set of regular configurations it is possible to increase the efficiency of distillation columns by sequentially and iteratively adding different alternatives of heat integration. While no one of those alternatives is new, the

simultaneous consideration of all/some of them can produce an impressive increase in energy efficiency that is reflected in considerable reduction in total costs.

We have illustrated the procedure with the separation of a four-component mixture that includes a difficult separation. The identification of points of inefficiency and the systematic inclusion of intermediate heat exchangers, vapor recompression cycles, breaking totally or partially some thermal couples to implement direct heat integration of multi-effect heat integration have produced two configurations one with a reduction of 36% in TAC and the second one over a 50%

Enhancing operability during early stage of process synthesis considering flexibility and inherent safety simultaneously

Andreja Nemet*, Klavdija Zirngast, Zdravko Kravanja, Zorka Novak Pintarič

Faculty of Chemistry and Chemical Engineering, Smetanova ulica 17, 2000 Maribor Slovenia

andreja.nemet@um.si

Abstract

Obtaining optimal solutions in process synthesis has great potential to improve the future profitability and sustainability of the process. Nowadays, most processes are either over- or undersized, resulting in suboptimal designs or designs with low operability performance. The latter means processes that in most cases do not meet production requirements or do not operate optimally under varying process parameters. There are several aspects of operability, all of which should be considered to achieve process designs that operate successfully in the real world. Moreover, the operability analysis should be included in the early stages of the process design. Once the process design is selected, there are limited opportunities for improvement and in most cases no substantial enhancement can be achieved. In this study, process synthesis is upgraded to include an operability view, that simultaneously considers flexibility and inherent safety to achieve economically optimal, flexible and safe process designs. The results of the case study show that an increase in flexibility of 3417 % and reduction in risk of 43 % can be achieved with a negligible loss in economic viability of 0.85 %.

Keywords: MINLP process synthesis, operability, flexibility, inherent safety, simultaneous approach

1. Introduction

Heat Integration remains to be a core task in the process synthesis due to its high potential for energy and emission reduction. The methods for obtaining Heat Exchanger Network (HEN) are getting increasingly developed resulting in highly integrated networks. Although at nominal data these network designs seem to represent an optimal solution, the operability of such networks might be highly uncertain. One should be aware that the more the systems are integrated the lower is the degree of freedom, which narrows the operating window (Tian et al., 2018). Therefore, when obtaining HEN designs the operability should not be neglected, since HENs are inevitably highly integrated in process systems, connecting different parts of processes. The traditional hierarchical approach considers the operability of the energy systems at the third stage of the development, after synthesizing network and obtaining utility system. This approach has its disadvantages as the system configuration is already selected, which can lead to “topological trap”, when the operability of the energy system cannot be substantially

improved (Andiappan et al., 2017). In previous work Escobar et al. (2013) considered the flexibility and controllability of HEN design using two-step approach.

In this work two aspects of operability have been considered, flexibility and inherent safety. Flexibility is enhanced, when heat exchangers are optimally oversized, allowing larger number of degrees of freedom (Novak Pintarič and Kravanja, 2004). On the other hand, decreased risk (increased safety) is obtained when smaller and more compact heat exchangers are used (Nemet et al., 2017). Considering both, flexibility and inherent safety simultaneously, leads to trade-off solutions among different aspects of operability. Objective of this study is to simultaneously achieve flexible and inherently safer HEN designs.

2. Methodology

A multi-scenario mixed-integer nonlinear programming (MINLP) model was developed to simultaneously consider the inherent safety and flexibility in process synthesis. The initial HEN synthesis model by Yee and Grossmann (1990) was extended by i) considering different types of heat exchangers (Soršak and Kravanja, 2004), ii) calculations of the inherent safety index (Nemet et al., 2017), and iii) strategies for achieving flexible HEN under varying input parameters (Zirngast et al., 2019).

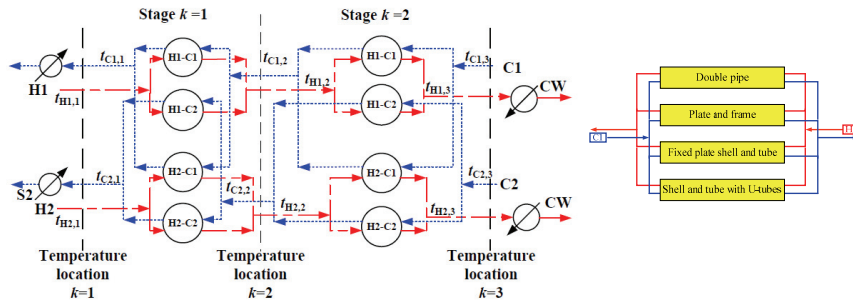

Figure 1: HEN superstructure.

Both sequential and simultaneous approaches were performed. With the sequential approach, a Pareto solutions of flexible HEN designs at various risk limits were obtained. The economic objective was the expected net present value (NPV) of the savings NPV^{savings} . Savings were defined as the difference between the solution where no Heat Integration was considered, $NPV^{\text{no_HI}}$, and the case with Heat Integration, NPV^{HI} (Eq. 1). The NPV consisted of investment (I), discounted annual cash flow (F_c) terms considering the discount rate r^{disc} and the lifetime t_{LT} of HEN.

$$NPV^{\text{savings}} = NPV^{\text{no_HI}} - NPV^{\text{HI}} = -\Delta I + F_c \cdot \frac{(1 + r^{\text{disc}})^{t_{\text{LT}}} - 1}{r^{\text{disc}} \cdot (1 + r^{\text{disc}})^{t_{\text{LT}}}} \quad (1)$$

Eq. 2 presents the discounted annual cash flow (F_c), which takes into account the tax rate (t), revenue (R), expenses (E) and depreciation (D).

$$F_c = (1 - t) \cdot (R - E) + t \cdot D \quad (2)$$

In the simultaneous approach, the safety/risk was also considered in the objective function. The flexible HEN with no safety consideration was taken as a reference case.

The objective function Z was defined as a difference between NPV of savings normalized with NPV obtained at flexible design $NPV_{flexible}^{savings}$ and risk index RI normalized with risk index determined at flexible design $RI_{flexible}$ (Eq.3). The aim was to maximize Z . In this way, the economic performance tends to be as high as possible and the risk as low as possible.

$$Z = \frac{NPV_{flexible}^{savings}}{NPV_{flexible}^{savings}} - \frac{RI}{RI_{flexible}} \quad (3)$$

The RI (Eq. 4) is determined for each substance on the hot hp and cold cp side (process) separately, for matches in each temperature stage k , for each type of heat exchanger hx . The risk index depends on the failure rate of the heat exchanger f_{hx}^{fail} , density of the substance in heat exchanger ρ , heat exchanger area $A_{hp,cp,k,hx}$, and area density of the heat exchanger β_{hx} . Additionally, the risk index depends on risk factors accounting for i) process installation versus storage f_{1hx} , ii) indoor/outdoor positioning f_{2hx} and and iii) process conditions f_{hp}/f_{cp}^3 divided by limiting value G . The limiting value G for toxic substances depends on lethal concentration LC50 (rat, inhalation, 1 h) at 298 K and phase of the substance as presented in Nemet et al (2017).

$$RI_{hp,cp,k,hx} = \sum_{hx \in HX} \left(f_{hx}^{fail} \cdot \frac{\rho \cdot A_{hp,cp,k,hx}}{\beta_{hx}} \cdot \frac{f_{hx}^1 \cdot f_{hx}^2 \cdot f_{hp}^3}{G_{hp}^h} \right) + \sum_{hx \in HX} \left(f_{hx}^{fail} \cdot \frac{\rho \cdot A_{hp,cp,k,hx}}{\beta_{hx}} \cdot \frac{f_{hx}^1 \cdot f_{hx}^2 \cdot f_{hp}^3}{G_{cp}^c} \right) \quad (4)$$

$\forall hp \in HP, cp \in CP, hx \in HX, k \in K$

The overall risk RI^{tot} is determined (Eq. 5) by summation of individual risk $RI_{hp,cp,k,hx}$ over substances in hot and cold process streams and all types of heat exchangers in each stage.

$$RI^{tot} = \sum_{hp} \sum_{cp} \sum_k \sum_{hx} RI_{hp,cp,k,hx} \quad (5)$$

3. Case study

The synthesis of a HEN was carried out as an illustrative example to test the operability (Table 1). The uncertain parameters were the heat capacity flowrates (CF) of the streams H1 and C1 as presented in Table 1. In this example, flexibility is understood as the minimum oversizing of the HEN required to cope with disturbances in the heat capacity flowrates. This type of variations corresponds to exogenous uncertainty as it does not depend on the decisions made. A lifetime of 15 years, a discount rate of 7 % and a tax rate of 20 % were assumed.

Table 1: Input data for process streams and utilities

Stream	T_s /K	T_t /K	CF /kW K ⁻¹	h / kW m ⁻² K ⁻¹	LC ₅₀ (rat,1h, inh) mg ⁻¹
H1	500	400	150±30	0.6	100
H2	450	390	390	1	600
C1	330	390	240±24	0.7	10
C2	380	380	50	1	500
Hot utility	510	510		5	-
Cold utility	300	321		1	-

Figure 2 shows the solution obtained at nominal values. As can be seen, the types of heat exchangers selected were the less compact ones, shell and tube, U-tube, and double pipe.

Figure 2: Solution at nominal input values

Figure 3: Design considering flexibility

Figure 3 shows the HEN design obtained using the strategy for flexible designs. Note that the total heat exchanger area installed was now higher by almost 60 % 3,434 m², compared to design obtained at nominal input data (3,434 m² vs. 2,157 m²); however, in both cases mostly the less compact shell and tube heat exchangers were selected ($\beta = 720$ m²/m³). Using a sequential approach, a bi-criteria optimization of NPV vs. risk index was performed. The optimization was performed firstly at nominal conditions and secondly by the strategy to obtain flexible designs. Figure 4a presents both Pareto curves for nominal and the flexible cases.

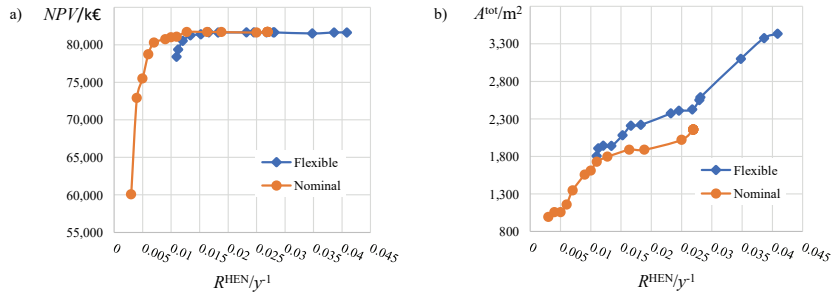

Figure 4: Pareto curve of a) NPV and b) total area versus risk index for nominal and flexible HENs

Figure 5: The solution at nominal input values and risk index at 0.011

The NPV curves remain relatively flat until a certain point while still decreasing the risk. In general, flexible designs have a higher risk compared to the solutions obtained at nominal input data. Improving safety in flexible HEN designs is more limited as the lowest risk index achieved was 0.010952, while at nominal values it was 0.003. Figure 4b presents the Pareto curve of total HEN area installed versus the risk index. One can see that flexible design does require more extensive areas. A probable space of optimal solutions would be in the range of risk index 0.01-0.015 and the NPV of savings around 80,000 k€, looking at the Pareto solution obtained for flexible designs. Figure 5 presents the safest HEN design obtained at nominal value having NPV 81,062 k€. All the selected heat exchangers are of compact plate and frame type ($\beta = 1300 \text{ m}^2/\text{m}^3$). More compact heat exchangers result in a lower mass of substances in the heat exchangers, which pose a lower risk. The total installed area was 1729 m². Figure 6 illustrates the safest flexible HEN design. The total area of the safest flexible HEN design was 1,806 m² and the NPV obtained was 78,401 k€. The safety was enhanced at the expense of the economic performance while keeping the flexibility of the HEN design.

Figure 6: Flexible solution with decreased risk having risk index value 0.0109

Using the sequential approach, the possible space of optimal design could be determined around kink of Pareto curves; however, not in the unique way. For this purpose, the simultaneous approach, considering the economic viability and the risk in the objective function simultaneously was applied.

Figure 7: Design obtained with multi-objective optimization considering normalized NPV and risk index

The result obtained with the simultaneous approach was within the optimal region determined with the sequential approach. The objective function of the simultaneous solution was $Z = 0.9548$, NPV 81,013 k€ and the risk index 0.015. Comparison between this solution and the most economically efficient solution reveals that the NPV decreased from 81,642 k€, by 629 k€ (0.7 %) and the risk index decreased from 0.04086 by 0.02586 (63.3 % decrease). The obtained solution design is presented in Figure 7, showing that four of six heat exchangers are the compact plate and frame type. Compared to the most

economically viable flexible HEN design (Figure 3), there is an additional cooler for stream H2. The HEN's total area was 1,996 m², which is a significant decrease from 3,434 m² (Figure 3).

Comparison between the simultaneous solution and the nominal solution leads to a very similar conclusion. The NPV of the solution at nominal input data was 81 713 k€, while for the simultaneous solution, it was 81,013 k€, which is a 700 k€ (0.85 %) decrease. This decrease is negligible when considering the operability performance. The flexibility increased from 0.029 to 1.02 representing 0.991 (3,417 %) increase, while the risk index decreased from 0.0269 to 0.0153 representing a 0.0116 (43.1 %) decrease.

4. Conclusions

A mixed-integer nonlinear programming (MINLP) model for HEN synthesis considering simultaneously two aspects of operability, flexibility and inherent safety, was developed. The results show that enhancing flexibility leads to an increase in the total area of HEN to cope with variations in the uncertain parameters. On the contrary, inherent safety is enhanced by selecting smaller heat exchangers with fewer potentially harmful substances. By considering flexibility and inherent safety simultaneously, appropriate trade-offs between these effects are established, leading to optimal compromise solutions. Sequential and simultaneous approaches were used to obtain results. The sequential approach showed that significant improvement in safety and, hence, risk, can be obtained, while the economics of HEN designs were not significantly reduced. It also revealed that flexible designs are associated with higher risks. The result obtained with the simultaneous approach shows that the NPV decreased by less than 1 % compared to the value obtained at the nominal conditions. At the same time, the flexibility was more than 30 times higher and the safety almost twice as high. Therefore, even with a negligible reduction in economic performance, the operability of the HEN design was enormously improved.
