## PREFACE

<b>Introduction</b> .....	<b>xi</b>
Thomas A. Adams II, Matt Bassett, Selen Cremaschi, and Monica Zanfir	
<b>Peer Review Policy</b> .....	<b>xii</b>
<b>International Scientific Committee</b> .....	<b>xiv</b>

## PART 1: PEER REVIEWED ARTICLES

### Section 1: Invited Plenary and Keynotes

<b>Thermo-Mechanical Exergy of a Substance in Cold Applications Approaching Absolute Zero</b> .....	<b>2</b>
Thomas A. Adams II	
<b>Designing Process Systems for Net-Zero Emissions and Nature- and People-Positive Decisions</b> .....	<b>10</b>
Bhavik R. Bakshi	
<b>From Then to Now and Beyond: Exploring How Machine Learning Shapes Process Design Problems</b> .....	<b>16</b>
Burcu Beykal	
<b>Artificial Intelligence and Machine Learning for Sustainable Molecular-to-Systems Engineering</b> .....	<b>22</b>
Alexander W. Dowling	
<b>Connecting the Dots: Push and Pull between Technology R&amp;D and Energy Transition Modeling</b> .....	<b>32</b>
Justin A. Federici, Dimitri J. Papageorgiou, Robert D. Nielsen	
<b>Sustainable Process Systems Engineering for Chemicals within Planetary Boundaries</b> .....	<b>39</b>
Gonzalo Guillén-Gosálbez	
<b>CO<sub>2</sub> Mitigation in Chemical Processes: Role of Process Recycle Optimization</b> .....	<b>44</b>
Diane Hildebrandt, James Fox, Neil Stacey, Baraka C. Sempuga	
<b>Towards a Sustainable and Defossilized/Decarbonized Chemical and Process Industry</b> .....	<b>52</b>
Mariano Martín	
<b>Life Cycle and Sustainability Analyses for Designing Chemical Circular Economy</b> .....	<b>60</b>
David Perez, John D. Chea, Jose D. Hernandez-Betancur, Gerardo J. Ruiz-Mercado	
<b>Towards the Development of Digital Twin for Pharmaceutical Manufacturing</b> .....	<b>67</b>
Katherine Raudenbush, Nikola Malinov, Jayanth V. Reddy, Chaoying Ding, Huayu Tian, Marianthi Ierapetritou	
<b>Towards 3-fold sustainability in biopharmaceutical process development and product distribution</b> .....	<b>75</b>
Miriam Sarkis, Steven Sachio, Nilay Shah, Cleo Kontoravdi, Maria M. Papathanasiou	
<b>Mining Chemical Process Information from Literature for Generative Process Design: A Perspective</b> .....	<b>84</b>
Artur M. Schweidtmann	
<b>From Process to Systems Design: A Perspective on the Future of Design Education</b> .....	<b>92</b>

Victor M. Zavala

## Section 2: Advances in PSE Design

<b>Development of Mass/Energy Constrained Sparse Bayesian Surrogate Models from Noisy Data.....</b>	<b>99</b>
Samuel Adeyemo, Debangsu Bhattacharyya	
<b>Guaranteed Error-bounded Surrogate Framework for Solving Process Simulation Problems.....</b>	<b>105</b>
Chinmay M. Aras, Ashfaq Iftakher, M. M. Faruque Hasan	
<b>Process Flowsheet Optimization with Surrogate and Implicit Formulations of a Gibbs Reactor .....</b>	<b>113</b>
Sergio I. Bugosen, Carl D. Laird, Robert B. Parker	
<b>A Novel Cost-Efficient Tributyl Citrate Production Process.....</b>	<b>121</b>
Andres F. Cabeza, Alvaro Orjuela, David E. Bernal Neira	
<b>Graph-Based Representations and Applications to Process Simulation.....</b>	<b>129</b>
Yoel R. Cortés-Peña, Victor M. Zavala	
<b>Improved Design of Flushing Process for Multi-Product Pipelines .....</b>	<b>137</b>
Barnabas Gao, Swapana Jerpoth, David Theuma, Sean Curtis, Steven Roth, Michael Fracchiolla, Robert Hesketh, C. Stewart Slater, Kirti M. Yenkie	
<b>Advances in Process Synthesis: New Robust Formulations.....</b>	<b>145</b>
Smitha Gopinath, Claire S. Adjiman	
<b>Integration of Design and Operation with Discretization Error Control.....</b>	<b>153</b>
Christian Hoffmann, Erik Esche, Jens-Uwe Repke	
<b>Simultaneous Optimization of Design and Operating Conditions for RPB-based CO<sub>2</sub> Capture Process.....</b>	<b>160</b>
Howoun Jung, NohJin Park, Jay H. Lee	
<b>Beyond Yield: Assessing Reaction System Performance using Economics .....</b>	<b>167</b>
Mary A. Katebah, Ma'moun Al-Rawashdeh, Patrick Linke	
<b>Adsorption-based Atmospheric Water Extraction Process: Kinetic Analysis and Stochastic Optimization .....</b>	<b>173</b>
Jinsu Kim, Shubham Jamdade, Yanhui Yuan, Matthew J. Realf	
<b>Optimal Process Synthesis Implementing Phenomena-based Building Blocks and Structural Screening .....</b>	<b>179</b>
David Krone, Erik Esche, Mirko Skiborowski, Jens-Uwe Repke	
<b>Cybersecurity, Image-Based Control, and Process Design and Instrumentation Selection.....</b>	<b>186</b>
Dominic Messina, Akkarakaran Francis Leonard, Ryan Hightower, Kip Nieman, Renee O'Neill, Paloma Beacham, Katie Tyrrell, Muhammad Adnan, Helen Durand	
<b>Design Space Identification of the Rotary Tablet Press.....</b>	<b>194</b>
Mohammad Shahab, Sunidhi Bachawala, Marcial Gonzalez, Gintaras Reklaitis, Zoltan Nagy	
<b>Recent Advances of PyROS: A Pyomo Solver for Nonconvex Two-Stage Robust Optimization in Process Systems Engineering.....</b>	<b>201</b>
Jason A. F. Sherman, Natalie M. Isenberg, John D. Sirola, Chrysanthos E. Gounaris	
<b>Optimal Design Approaches for Cost-Effective Manufacturing and Deployment of Chemical Process Families with Economies of Numbers.....</b>	<b>208</b>
Georgia Stinchfield, Sherzoy Jan, Joshua C. Morgan, Miguel Zamarripa, Carl D. Laird	
<b>A Study on Accelerated Convergence of Cyclic Steady State in Adsorption Process Simulations .....</b>	<b>215</b>
Sai Gokul Subraveti, Kian Karimi, Matteo Gazzani, Rahul Anantharaman	

<b>Optimal Design of Intensified Towers for CO<sub>2</sub> Capture with Internal, Printed Heat Exchangers .....</b>	<b>222</b>
Stephen Summits, Paul Akula, Debangsu Bhattacharyya, Grigorios Panagakos, Benjamin Omell, Michael Matuszewski	
<b>Design of Plastic Waste Chemical Recycling Process Considering Uncertainty .....</b>	<b>229</b>
Zhifei Yuliu, Yuqing Luo, Marianthi Ierapetritou	
<b>Section 3: Design and Emerging Fields</b>	
<b>A GRASP Heuristic for Solving an Acquisition Function Embedded in a Parallel Bayesian Optimization Framework .....</b>	<b>237</b>
R. Cory Allen, Youngdae Kim, Dimitri J. Papageorgiou	
<b>Learn-To-Design: Reinforcement Learning-Assisted Chemical Process Optimization .....</b>	<b>245</b>
Eslam G. Al-Sakkari, Ahmed Ragab, Mohamed Ali, Hanane Dagdougui, Daria C. Boffito, Mouloud Amazouz	
<b>Cost-optimal Selection of pH Control for Mineral Scaling Prevention in High Recovery Reverse Osmosis Desalination .....</b>	<b>253</b>
Oluwamayowa O. Amusat, Alexander V. Dudchenko, Adam A. Atia, Timothy Bartholomew	
<b>Hybrid Rule-based and Optimization-driven Decision Framework for the Rapid Synthesis of End-to-End Optimal (E2EO) and Sustainable Pharmaceutical Manufacturing Flowsheets.....</b>	<b>261</b>
Yash Barhate, Daniel Casas-Orozco, Daniel J. Laky, Gintaras V. Reklaitis, Zoltan K. Nagy	
<b>Neural Networks for Prediction of Complex Chemistry in Water Treatment Process Optimization.....</b>	<b>267</b>
Alexander V. Dudchenko, Oluwamayowa O. Amusat	
<b>Improving Mechanistic Model Accuracy with Machine Learning Informed Physics .....</b>	<b>275</b>
William Farlessyost, Shweta Singh	
<b>Optimal Design of Antibody Extraction Systems using Protein A Resin with Multicycling .....</b>	<b>283</b>
Fred Ghanem, Purnima M. Kodate, Gerard M. Capellades, Kirti M. Yenkie	
<b>Exploring Quantum Optimization for Computer-aided Molecular and Process Design .....</b>	<b>292</b>
Ashfaq Iftakher, M. M. Faruque Hasan	
<b>Learning Hybrid Extraction and Distillation using Phenomena-based String Representation.....</b>	<b>300</b>
Jianping Li	
<b>Optimizing Batch Crystallization with Model-based Design of Experiments .....</b>	<b>308</b>
Hailey G. Lynch, Aaron Bjarnason, Daniel J. Laky, Cameron J. Brown, Alexander W. Dowling	
<b>Machine Learning-Aided Process Design for Microwave-Assisted Ammonia Production.....</b>	<b>316</b>
Md Abdullah Al Masud, Alazar Araia, Yuxin Wang, Jianli Hu, Yuhe Tian	
<b>Fast, Accurate, and Robust Fault Detection and Diagnosis of Industrial Processes.....</b>	<b>322</b>
Alireza Miraliakbar, Zheyu Jiang	
<b>Development of Steady-State and Dynamic Mass-Energy Constrained Neural Networks using Noisy Transient Data .....</b>	<b>330</b>
Angan Mukherjee, Debangsu Bhattacharyya	
<b>Model Based Process Development and Operation of a Fluid Bed Granulation Unit to Manufacture Pharmaceutical Tablets. ....</b>	<b>338</b>
Salvador García Muñoz, Maitraye Sen, Shaswat Gupta, Ronald Ruff	

<b>Modeling hiPSC-to-Early Cardiomyocyte Differentiation Process using Microsimulation and Markov Chain Models .....</b>	<b>344</b>
Shenbageshwaran Rajendiran, Francisco Galdos, Carissa Anne Lee, Sidra Xu, Justin Harvell, Shireen Singh, Sean M. Wu, Elizabeth A. Lipke, Selen Cremaschi	
<b>Integrating Hybrid Modeling and Multifidelity Approaches for Data-Driven Process Model Discovery .....</b>	<b>351</b>
Suryateja Ravutla, Fani Boukouvola	
<b>Technoeconomic and Sustainability Analysis of Batch and Continuous Crystallization for Pharmaceutical Manufacturing .....</b>	<b>359</b>
Jungsoo Rhim, Zoltan Nagy	
<b>Enhancing Polymer Reaction Engineering Through the Power of Machine Learning .....</b>	<b>367</b>
Habibollah Safari, Mona Bavarian	
<b>Integrated Design, Control, and Techno-Ecological Synergy: Application to a Chloralkali Process .....</b>	<b>373</b>
Utkarsh Shah, Akshay Kudva, Kevin B. Donnelly, Wei-Ting Tang, Bhavik R. Bakshi, Joel A. Paulson	
<b>Use of Discrete Element Method to Troubleshoot Aesthetic Defects in Pharmaceutical Tablets.....</b>	<b>380</b>
Jerrin Job Sibychan, Nicola Sorace, Jason Melnick, Salvador Garcia Muñoz, David Mota-Aguilar, Eduardo Hernandez-Torres, David Boush	
<b>Reinforcement Learning-Driven Process Design: A Hydrodealkylation Example .....</b>	<b>387</b>
Yuhe Tian, Ayooluwa Akintola, Yazhou Jiang, Dewei Wang, Jie Bao, Miguel A. Zamarripa, Brandon Paul, Yunxiang Chen, Peiyuan Gao, Alexander Noring, Arun Iyengar, Andrew Liu, Olga Marina, Brian Koeppel, Zhijie Xu	
<b>Section 4: Design and Energy Transitions</b>	
<b>Equation-Oriented Modeling of Water-Gas Shift Membrane Reactor for Blue Hydrogen Production.....</b>	<b>395</b>
Damian T. Agi, Hani A. E. Hawa, Alexander W. Dowling	
<b>Modeling the Maximization of Waste Heat Use in a Liquid Solvent Direct Air Capture Plant Through Hydrogen Production.....</b>	<b>403</b>
Erick O. Arwa, Kristen R. Schell	
<b>Technoeconomic Analysis of Chemical Looping Ammonia Synthesis Reactors to Enable Green Ammonia Production .....</b>	<b>409</b>
Laron D. Burrows, George M. Bollas	
<b>Optimal Design and Control of Behind-the-Meter Resources for Retail Buildings with EV Fast Charging .....</b>	<b>417</b>
Gustavo Campos, Roberto Vercellino, Darice Guittet, Margaret Mann	
<b>Optimization of Retrofit Decarbonization in Oil Refineries .....</b>	<b>426</b>
Samprii Chattopadhyay, Rahul Gandhi, Ignacio E. Grossmann, Ana I. Torres.	
<b>Conceptual Design of Integrated Energy Systems with Market Interaction Surrogate Models .....</b>	<b>434</b>
Xinhe Chen, Radhakrishna Tumbalam-Gooty, Darice Guittet, Bernard Knueven, John D. Siirola, Alexander W. Dowling	
<b>Preliminary Examination of the Biogas-to-Hydrogen Conversion Process.....</b>	<b>442</b>
Hegwon Chung, Minseong Park, Jiyong Kim	
<b>Optimization of Solid Oxide Electrolysis Cell Systems Accounting for Long-Term Performance and Health Degradation .....</b>	<b>448</b>
Nishant V. Giridhar, Debansu Bhattacharyya, Douglas A. Allan, Stephen E. Zitney, Mingrui Li, Lorenz T. Biegler	
<b>Power System Design and Necessary Changes to Accommodate Future Energy Challenges.....</b>	<b>455</b>

Iiro Harjunkoski, Katarina Knezovic, Alexandre Oudalov

<b>Towards Energy and Material Transition Integration – A Systematic Multi-scale Modeling and Optimization Framework</b> .....	461
Rahul Kakodkar, Betsie Montano Flores, Marco De Sousa, Yilun Lin, Efstratios N. Pistikopoulos	
<b>Process and Network Design for Sustainable Hydrogen Economy</b> .....	469
Monzure-Khoda Kazi, Akhilesh Gandhi, M. M. Faruque Hasan	
<b>Integrated Temporal Planning for Design and Operation of the International Green Ammonia Supply Chain</b> .....	477
Sunwoo Kim, Joungho Park, Jay H. Lee

# Introduction

**Thomas A. Adams II, Matt Bassett, Selen Cremaschi, and Monica Zanfir**

The Foundations of Computer Aided Process Design (FOCAPD) conference is the leading conference series in the field of chemical process design. Held only once every five years, FOCAPD is not a routine research conference. It is a special time for the process design community to come together and discuss the biggest trends in the field from a big picture perspective.

FOCAPD focuses on the big picture. All speakers are selected and invited by the conference organizers, and we use a single-track approach so that attendees gather together to hear all the speakers. Speakers are asked not to focus on their own research findings and accomplishments, but rather to talk about the latest trends and forward directions in their fields more generally. We want to know what is exciting about the field, and where it is headed next. We want the whole community at each talk so we can engage in lively discussions after each one about the future of our profession.

This year's program includes 42 invited keynote and plenary speakers and 121 contributing posters, covering the most important topics to FOCAPD. The conference proceedings boasts a total of 134 peer-reviewed papers containing the latest original research from our participants in five subject areas:

- Advances in PSE Design
- Design and Emerging Fields
- Design and Energy Transitions

- Design and Sustainability
- Design Education and Future of Design

This year, FOCAPD was organized jointly between the CACHE Foundation, inc. and the American Institute for Chemical Engineers. We thank our AIChE partners for their excellent support in conference administration management.

We also thank our many sponsors. At the Conference Partners level we thank Chemstations, the Chemical Engineering department at Auburn University, and Lilly. At the Conference Supporters level, we thank the Department of Chemical and Biological Engineering at the University of Wisconsin-Madison, the Chemical and Biological Engineering department at Princeton, the Davidson School of Chemical Engineering at Purdue University, The Texas A&M Energy Institute, Linde, and Corteva Agriscience. We also thank the National Science Foundation for a grant which paid for the registration fees of 41 students, postdocs, junior faculty, and early career researchers.

This year marked a new chapter in the FOCAPD series by moving our conference proceedings to the open access Systems and Control Transactions book series, published by PSE Press, an imprint of the CACHE Foundation. We believe this will increase the impact of the conference by removing paywall barriers to our research.

We wish you an inspiring conference and a memorable stay in Breckenridge!

# Peer Review Policy

## TERMINOLOGY

We use the following terminology:

- **Conference Paper:** This is a peer-reviewed research paper describing an **original** research contribution and published in the conference proceedings.
- **Extended Abstract:** This is an optional original paper of unspecified length that is contributed by an invited speaker.

## APPLICATION

- All conference papers are subject to peer review.
- Extended abstracts are not subject to peer review.

## PUBLICATIONS

- All conference papers which have passed peer review and have been accepted by the conference chairs will be published in the conference proceedings.
- All extended abstracts which have been accepted by the conference chairs will be published in the conference proceedings.
- The conference proceedings will clearly identify which publications are conference papers and which are extended abstracts, and therefore, whether or not they were subject to peer review.

## PEER REVIEW PROCESS

### Initial Screening

The conference chairs will screen the initial submissions (one-page abstracts) of contributed papers. At their option, chairs may choose to reject these submissions for any reason, but the primary reasons for rejection at this stage are (a) subject does not match conference themes and topics; (b) in appropriate, unprofessional, unethical, or dishonest material; (c) duplicate submissions; (d) abandoned submissions; (e) multiple submissions from same presenter; (f) obvious poor quality; (g) reasonable suspicion of machine-generated text; (h) need to limit acceptances because of conference space constraints. Chairs may also transfer papers between sessions at this stage.

Conference chairs will then invite authors of the one-page abstracts that have passed the initial screening to submit a conference paper for peer review.

### Conference Paper Peer Review

Conference chairs act as editors. They will assign peer reviewers to assess the quality of the conference papers and manage the peer review process for each paper. Peer reviewers are generally selected from the International Scientific Committee who are scientists, engineers, or researchers with technical expertise in the conference topic. Peer reviewers must be considered technical experts in their field, hold a PhD, and have published peer reviewed scientific works previously. Each work must be reviewed by a minimum of two peer-reviewers.

A “single-blind” peer review system is used, in which the peer reviewers have access to the identities of the authors, but the authors are never given the identities of the peer reviewers. This is consistent with most journal peer-review procedures in our field.

Peer reviewers will be given a set of quality criteria that may include scientific and technical quality, quality of writing, originality and novelty, appropriateness for the conference topic and theme, interest to the community, and other factors of merit. Peer reviewers are expected to be rigorous and critical in their technical assessments and adhere to the highest standards in the field in order to ensure high quality. Peer reviewers are asked to comment on their assigned conference papers and issue a recommendation to the conference chairs based on this quality criteria.

Reviewers may recommend one of the following:

- **Accept Paper.** No technical changes are necessary before publication. Only typographical, spelling, grammar, or other minor changes are necessary which do not require technical review.
- **Accept Paper with Minor Revisions.** Some minor technical issues need to be addressed either through technical changes to the manuscript or through rebuttal to reviewer comments. The reviewer does not believe the issues are significant enough to require additional technical review by the reviewers. The reviewer has provided enough commentary such that the editor can decide if the minor issues have been addressed in a future revision.
- **Revise Paper with Re-Review.** Major technical issues need to be addressed either through technical changes to the manuscript or through rebuttal to reviewer comments. The reviewer believes the issues are significant enough to require that the revised manuscript receive additional review by the reviewers.
- **Reject Without Reconsideration.** The technical issues are so significant that it is unlikely that an acceptable manuscript could be produced by the deadline; or, the manuscript is out of scope, inappropriate, or computer-generated.

Peer reviewers may be asked to provide numerical scores or rankings, as well as provide written comments intended for the chairs and/or the authors. Peer reviewers are encouraged to provide specific and constructive feedback that will aid the authors in improving the work and provide advice to the chairs.

The conference chairs are responsible for making the final decision on each paper and may require several rounds of author changes if necessary to meet quality standards. Conference chairs are not required to follow the recommendations of the peer reviewers in making these decisions. It is possible that conference chairs will choose to not accept some papers that still pass through rigorous technical peer review, especially when limited by available space or when papers do not sufficiently promote conference objectives. Conference chairs may also transfer papers between sessions as desired.

## CONFLICTS OF INTEREST AND ETHICAL GUIDELINES

The chairs and peer reviewers must ensure they do not have a conflict of interest that may bias their decisions, such as ensuring that authors are at “arm’s length” and have no financial conflicts of interest. Peer reviewers and chairs must disclose if they have such a conflict of interest with a specific submission, and if so, a different chair and/or peer reviewer should be assigned to handle that submission.

To help determine conflicts of interest, and for all other ethical guidelines, we use the Systems and Control Transactions ethical guidelines described at: <https://psecommunity.org/contributor-guidelines>

# Thermo-Mechanical Exergy of a Substance in Cold Applications Approaching Absolute Zero

Thomas A. Adams II\*

Norwegian University of Science and Technology (NTNU), Department of Energy and Process Engineering, Trondheim, Norway

\* Corresponding Author: [thomas.a.adams@ntnu.no](mailto:thomas.a.adams@ntnu.no)

## ABSTRACT

In this work, we consider the thermo-mechanical exergy of a substance for cold applications, even as it approaches absolute zero. This is relevant for cold-service applications such as refrigeration, liquefied natural gas, air separation, and liquid hydrogen. We demonstrate how the optimization formulation for the determination of exergy is the most suitable way for process systems engineers to think about exergy. We provide an illustrative example by computing thermo-mechanical exergy of neon approaching absolute zero. We also discuss how this result relates with the Third Law of Thermodynamics, both how it is used to compute thermo-mechanical exergy, but also what it implies about the validity of the results and the equations used to compute them.

**Keywords:** Exergy, thermo-mechanical exergy, absolute zero, neon, low temperature

## 1. INTRODUCTION

**Exergy** is a thermodynamic property of matter and energy which describes both the quantity and the quality of an energy source by combining the First and Second Laws of Thermodynamics. It is quite useful in the design of chemical process systems, especially energy conversion systems common in chemical engineering. Exergy as a metric helps in identifying process bottlenecks, improving system efficiency, making prudent design decisions, understanding energy quality, and as an approximation for value or cost. As a result, it is increasingly popular as a systems analysis tool in scientific research, with exergy analyses considered in over 2500 journal articles published in 2022 alone (Figure 1), growing exponentially at about 14% per year.

### 1.1 General Definition

Although there are several competing definitions for exergy, the Moran *et al.* [1] definition is the most useful, the most general, and the easiest to understand for chemical engineering purposes. Our emphasis is in bold, and the definition is quoted as:

#### Definition 1. (Definition of Exergy)

Exergy is the **maximum** theoretical work obtainable from an overall system consisting of a

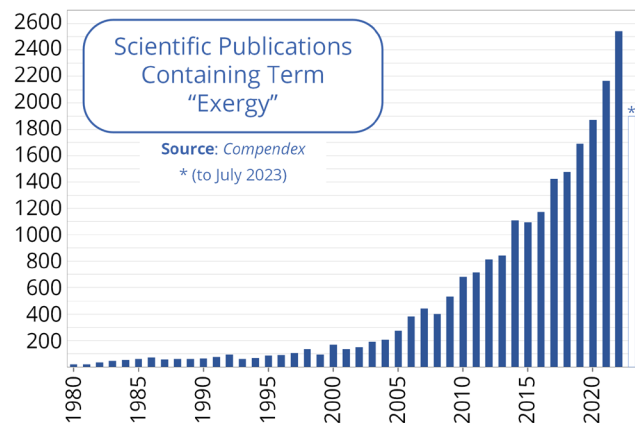

Figure 1. Scientific publications involving exergy

system and the environment as the system comes into equilibrium with the environment (passes to the dead state). [1]

This describes exergy generally, for all kinds of systems, and considering all forms of energy that contribute to the calculation of exergy. For the process systems engineer, it is convenient and useful to understand this definition in terms of an optimization problem [2]:

$$e = \max_P w \quad (1)$$

where  $e$  is the exergy of the system,  $\mathcal{P}$  is a process that brings the system into equilibrium with its environment within the set of all such processes  $\mathbb{P}$  such that  $\mathcal{P} \in \mathbb{P}$ , and  $w$  is work that is produced by  $\mathcal{P}$ . Process engineers understand optimization, and so it makes sense then to understand exergy in the form of an optimization problem. In plain language, it means that one way to compute the exergy is to find a process  $\mathcal{P}$  that produces the absolute most amount of work possible, exploiting everything possible that can be exploited, using perfect, reversible, and lossless process steps.  $\mathcal{P}$  does not have to be unique; many processes could do this in theory. This concept is general and applies to all forms of exergy.

## 1.2 Thermo-mechanical exergy

In this work, we consider only the specific thermo-mechanical exergy ( $e^{tm}$ ) of substances (noting that photons are not considered substances for this analysis), which includes the contribution of temperature, pressure, and phase of a substance. It does not consider exergy arising from chemical composition of that substance, atomic energy, motion, height, electrostatic charge, stress, strain, or other forms of energy.

As shown in [2], the following equation is one solution to the optimization problem of eq. (1) for the case of the thermo-mechanical exergy of a substance at state 1 ( $e_1^{tm}$ ) relative to environmental reference state 0:

$$e_1^{tm} = |h_1 - h_*| + (h_* - h_0) - T_0(s_1 - s_0) \quad (2)$$

where  $h$  and  $s$  are the specific enthalpy and specific entropy (on a per mass or per mole basis) of a substance at state 0, \*, or 1 [1, 2]. State 0 describes the surrounding environment, typically chosen by the person doing the analysis to be at about 1 atm and between 15–25°C for systems on the surface of the earth. State \* is an intermediate state at pressure  $p_* = p_0$  and  $s_* = s_1$ , such that the work required/produced from isentropic pressure change between state 1 and \* is  $|h_1 - h_*|$ , and the work required/produced from an isobaric reversible heat pump/reversible heat engine between state 0 and \* is  $(h_* - h_0) - T_0(s_1 - s_0)$ . Eq. (2) uses the so-called “flow exergy” form, which is exergy for systems in which mass can be exchanged with the environment. As discussed previously [3], eq. (1) differs from the classical thermo-mechanical exergy expression below ambient pressure. The classical form of thermo-mechanical exergy has historically been expressed as [4]:

$$e_1^{tm} = (h_1 - h_0) - T_0(s_1 - s_0) \quad (3)$$

Note that eq. (2) reduces to eq. (3) for  $p_1 \geq p_0$ . However, our previous work [2] showed that eq. (3) is inaccurate for  $p_1 < p_0$  because it does not solve the optimization problem in eq. (1). In short, it arises from a theoretical model that is not general enough and constrains the problem to a suboptimal solution. As a result, if eq. (3) is

used for  $p_1 < p_0$  it can result in too-low or even negative values of  $e_1^{tm}$ , which is not meaningful.

In this work, we address a much-neglected aspect of thermo-mechanical exergy of a substance, namely, its behaviour as the temperature of a substance approaches absolute zero. We discuss considerations relating to the Third Law of Thermodynamics and the Unattainability Principle regarding absolute zero. We provide a proof that  $e_1^{tm}$  is finite as  $T_1 \rightarrow 0\text{ K}$  that is general for all pressures. This work also contains enthalpy-pressure-exergy and temperature-exergy diagrams of neon, with the latter being first quantified values approaching absolute zero in the literature to the best of the author’s knowledge.

## 2. $e_1^{tm}$ AS TEMPERATURE APPROACHES ABSOLUTE ZERO

### 2.1 The Third Law of Thermodynamics

The Third Law of Thermodynamics deals with the thermodynamic properties of matter as it approaches absolute zero. A modern definition is “that any process cannot reach absolute zero temperature in a finite number of steps and within a finite time” [5]. This leads to several useful corollaries.

#### Corollary 1

The absolute entropy of a substance in thermal equilibrium, which is the total entropy of a system, tends toward zero, from above, as temperature approaches 0 K.

This is a rephrasing of the description in [6]. The exception to this rule is if the substance has a degenerate ground state at absolute zero; but nevertheless, the absolute entropy ( $s^{abs}$ ) would still be finite and zero in nearly all cases, and if not, very small [7]. This leads to a second corollary, directly quoted here:

#### Corollary 2

The heat capacity of a substance tends toward zero, from above, as temperature approaches 0 K. [7]

A simple explanation is that a substance at absolute zero cannot have any heat capacity. If it were to absorb even the slightest bit of energy, such as from a single photon collision, the temperature of the substance must increase. Otherwise, by definition, it would not have been at absolute zero in the first place. However, since it is incredibly difficult to experimentally measure heat capacity near absolute zero, models and extrapolations are needed [6].

### 2.2 $e_1^{tm}$ of a substance is finite as $T \rightarrow 0\text{ K}$

In this section, it should be noted that this proof

applies only to the thermo-mechanical exergy of substances, not matter generally, nor exergy generally.

### 2.2.1 Enthalpy

We start with eq. (3) because it is easier to follow, noting that this equation is valid for  $p_1 \geq p_0$ . We first note that  $h_0$ ,  $T_0$ , and  $s_0$  are fixed environmental reference conditions and of course finite. Therefore, to show that  $e_1^{\text{tm}}$  is finite, we need only to show that  $h_1$  and  $s_1$  are finite as  $T_1 \rightarrow 0 K$ .  $h_1$  for any pure substance is:

$$h_1 = h_{ref} + \int_{T_{ref}}^{T_1} C_p(T) dT \quad (4)$$

Where  $T_{ref}$  is some arbitrarily chosen temperature at the thermodynamic reference state such that  $h_{ref}$  is defined (usually to be 0) at  $T = T_{ref}$ . In this formulation, the heat capacity equation  $C_p(T)$  applies to the same pressure as state 1. It is important to note that the thermodynamic reference state here need not be the same as the environmental reference state. For convenience, write the equations such that the chosen reference state is at the same phase as at absolute zero (such that we do not have to consider latent heats as  $T \rightarrow 0 K$ ).

In the limit as  $T_1 \rightarrow 0 K$ , eq. (4) becomes:

$$h_{0K} = h_{ref} + \int_{T_{ref}}^{0K} C_p(T) dT \quad (5)$$

Note the integral term evaluates to a negative number for any thermodynamic reference temperature  $T_{ref} > 0 K$ .  $C_p(T)$  is finite at any  $T$  and approaches zero in the limit as  $T \rightarrow 0 K$  by Corollary 2. As a result, the integral term must be finite as well, and so must be the enthalpy.

### 2.2.2 Entropy

Corollary 1 does not imply that  $s_1 \rightarrow 0$  because  $s_1$  is not the absolute entropy, it is the thermodynamic entropy relative to the thermodynamic reference state. However, the absolute entropy  $s^{\text{abs}}$ , which is the entropy calculated on an absolute scale, and the specific entropy  $s$ , which is the entropy calculated relative to a reference condition, are easily related by a constant:

$$s_1^{\text{abs}} - s_{ref}^{\text{abs}} = s_1 - s_{ref} \quad (6)$$

The thermodynamic reference entropy  $s_{ref}$  is defined to be zero at some  $T_{ref} \geq 0 K$ , with a corresponding absolute reference entropy equal to  $s_{ref}^{\text{abs}} = s_{0K}^{\text{abs}} + \int_{0K}^{T_{ref}} \frac{C_p(T)}{T} dT$ .  $s_{0K}^{\text{abs}}$  is usually zero (but at least non-negative) and finite (corollary 1) and  $\int_{0K}^{T_{ref}} \frac{C_p(T)}{T} dT$  is non-negative and finite (corollary 2), so  $s_{ref}^{\text{abs}}$  is non-negative and finite. By eq. (6)  $s_1$  is finite and usually negative as  $T_1 \rightarrow 0K$  unless the reference condition chosen is absolute zero.

### 2.2.3 Exergy

Since  $h_1$  and  $s_1$  are finite as  $T_1 \rightarrow 0 K$ , and  $h_0$ ,  $T_0$ , and  $s_0$  are known and constant,  $e_1^{\text{tm}}$  is also finite as  $T_1 \rightarrow 0K$

(so far shown only for the  $p_1 \geq p_0$  case). Moreover, since exergy can never be negative [2],  $e_1^{\text{tm}}$  is always positive and finite, except at the environmental reference state, where it is zero. Modifications to this analysis to include enthalpy or entropy terms considering phase change or multiple species do not change the result that the exergy must be finite at absolute zero.

### 2.2.4 When $p_1 < p_0$

For sub-ambient pressures as  $T_1 \rightarrow 0 K$ ,  $h_1 \leq h_* \leq h_0$ . Since  $h_0$  and  $h_1$  are finite,  $h_*$  is always bounded between them. Therefore,  $e_1^{\text{tm}}$  in eq. (1) is always finite in the limit as  $T_1 \rightarrow 0 K$ , at any pressure.

### 2.2.5 Remarks

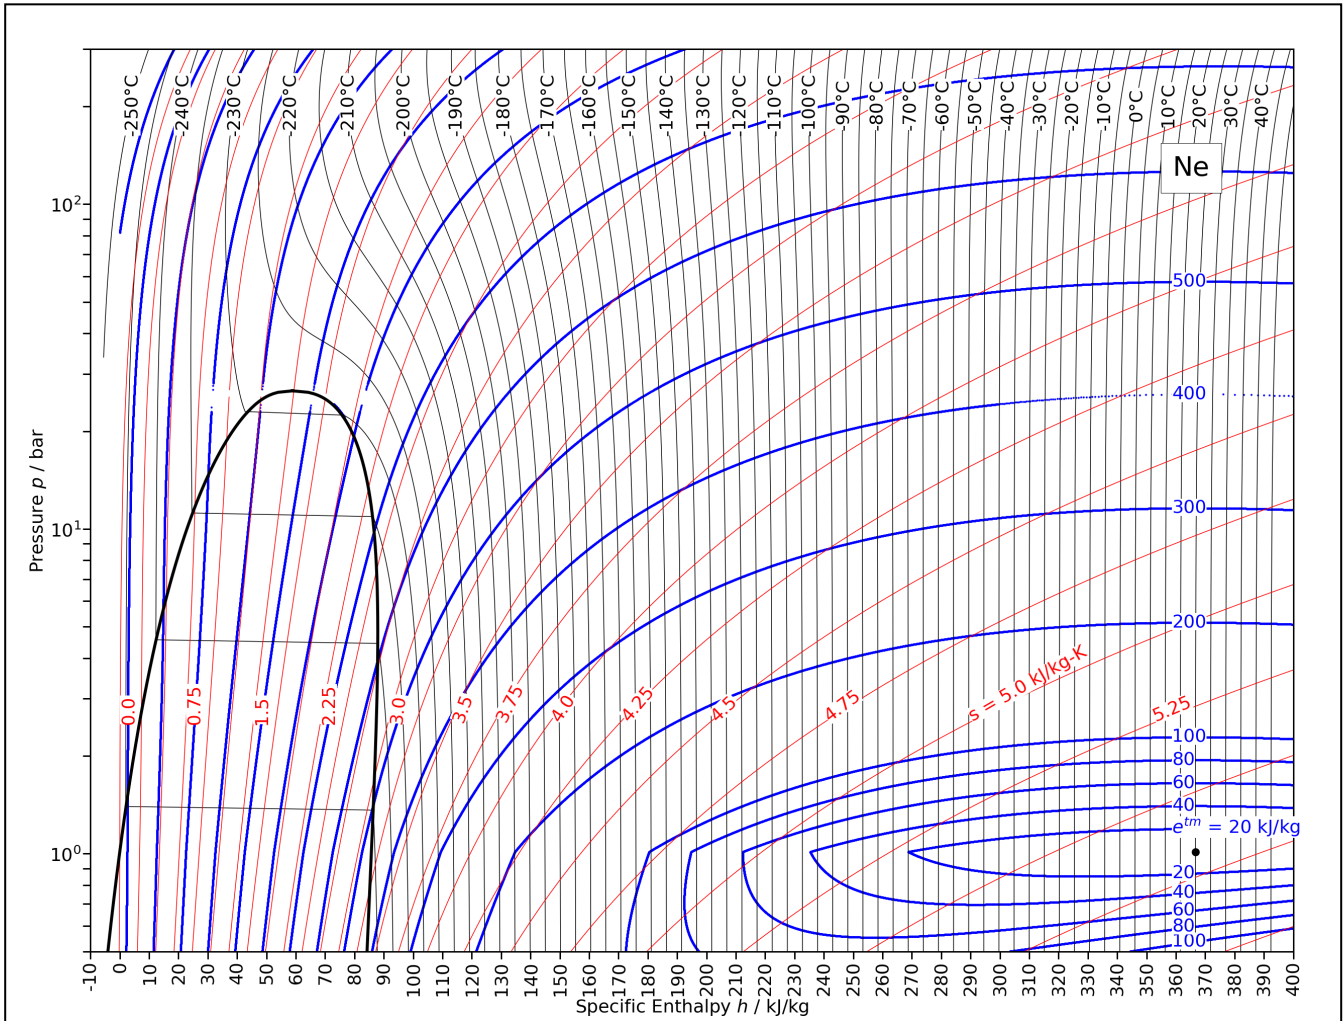

Petela [8] presented a similar proof that  $e_1^{\text{tm}}$  is finite as  $T_1 \rightarrow 0 K$ , but the proof required that the  $C_p(T)$  equation had a particular form ( $C_p(T) = mT^3$ ). It also used eq. (3) and so did not apply to pressures below  $p_0$ . In fact, the author used weak language concerning eq. 3, declaring that  $e_1^{\text{tm}}$  “**might** be expressed as [eq. (3)]” (emphasis ours) [8]. This kind of language is strangely common in the exergy literature when referring to eq. (3), and perhaps indicates a general uneasiness when using it. Therefore the above proof is stronger and applies to all pressures.

It is also interesting to note also that for a pure substance,  $\left(\frac{\partial s}{\partial p}\right)_h < 0$  and  $\left(\frac{\partial s}{\partial p}\right)_h$  tends toward zero from above as  $T_1 \rightarrow 0 K$ . This is visually apparent as nearly vertical iso-entropy lines on a pressure-enthalpy diagram below atmospheric pressure and at low temperature, as shown repeatedly in [3], and also evident on the example for neon in Figure 2, discussed in the next section. As a result,  $h_* \rightarrow h_1$  from above as  $T_1 \rightarrow 0K$ . So, eq. (2) tends toward to eq. (3) as  $T_1 \rightarrow 0 K$  at low pressures.

## 3. EXAMPLE WITH NEON

Neon is a noble gas used as a cryogenic refrigerant, especially in refrigerant blends, at temperatures potentially down to its normal boiling point near 27 K ( $-300^\circ\text{C}$ ) [9, 10]. It also forms diverse crystalline structures below its fusion point (near 24.5 K). As temperatures approach absolute zero, many different crystalline configurations have been observed or predicted using quantum mechanics-based modelling approaches. For example, as solid neon is cooled, it can in theory undergo many transitions between crystalline configurations, including core melting. This can cause the heat capacity curves to be non-monotonic in the solid region, but they still tend toward zero as temperature approaches absolute zero [11].

A pressure-enthalpy-exergy diagram of fluid-phase neon is shown in Figure 2. The enthalpy, entropy, phase, and temperature lines were computed using CoolProp [12]. The iso-exergy lines are computed using eq. (2) with

**Figure 2:** Pressure-enthalpy-exergy diagram of neon using eq. (2) for cold applications. This diagram applies to fluid phases only within model limits. Closed circle (•): Environmental reference state at  $T_0 = 25^\circ\text{C}$ ,  $p_0 = 1.01325$  bar. Blue lines (—):  $e^{tm}$  in kJ/kg. Red lines (—): specific entropy in kJ/kg-K. Black lines (—): temperature in  $^\circ\text{C}$ .

an environmental reference state of  $(T_0, p_0) = (25^\circ\text{C}, 1.01325 \text{ bar})$ .  $e_1^{tm}$  increases as neon gets colder or as the pressure deviates (above or below) the reference pressure. Due to the limits of the model used [12], the figure cannot be extended below  $-250^\circ\text{C}$ .

### 3.1 Heat Capacity Curves for Crystalline Neon

To produce a meaningful thermo-mechanical exergy curve for neon down to absolute zero, we used experimentally determined [13] heat capacity values for  $^{20}\text{Ne}$  and  $^{22}\text{Ne}$  from 3 to 23 K, which are only slightly different. Recent statistical moment method computations explain these curves well, showing that heat capacity should smoothly approach zero as temperature approaches zero [14] (see also Corollary 2).

Therefore, we used the average experimental heat capacity of the  $^{20}\text{Ne}$  and  $^{22}\text{Ne}$  isotopes to represent the solid phase neon more generally for the purposes of diagram construction. We then constructed a simple model

valid between  $0 < T < 23 \text{ K}$ :

$$C_{p,Ne}(T) = 2.3246 T^2 + 5.1511 T \quad (7)$$

where the heat capacity of bulk crystalline neon  $C_{p,Ne}$  is in J/kg-K. We note that it is an extrapolation to use this curve below 3 K but it evaluates to zero at 0 K and follows the quadratic-like trend in that region predicted by the statistical moment method models [14]. The resulting curve is shown in Figure 3.

We chose to use the as-reported experimentally determined values of  $h$  [13] as a function of temperature in the 3 K to 23 K region because of the known effect of core melting and various transitions on the heat capacity function [11] which are not reflected in eq. (7). However, eq. (7) was used to estimate the entropy from 0 K to 23 K analytically. The enthalpy of fusion at 1.01325 bar was taken to be 16.259 kJ/kg [15] which when using a melting point of 24.56 K for that pressure gives an entropy of fusion of 0.662 kJ/kg-K. All entropy and enthalpy

calculations above the melting point were performed using an equation of state for neon as computed by [12].

**Figure 3.** The heat capacity model for solid neon used in computing thermo-mechanical exergy at very low temperatures. Black lines (—): model. Circle: (○) Experimental data for <sup>22</sup>Ne. Square: (□) Experimental data for <sup>20</sup>Ne. Data from [13].

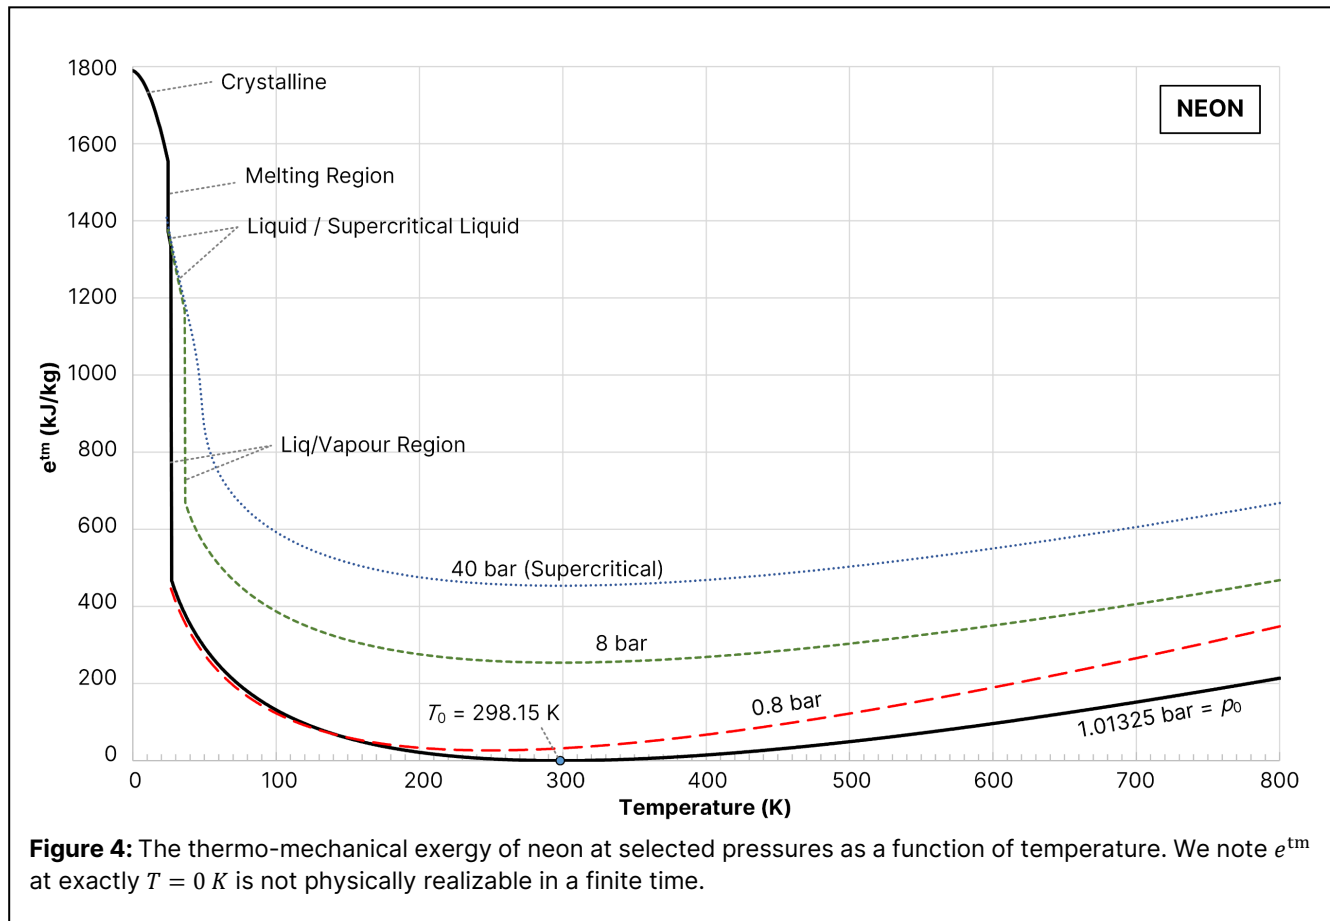

The final temperature-exergy diagram, computed using eq. (2), is shown in Figure 4. Four lines are shown for four selected pressures: one at the reference

pressure  $p_0$  (1.01325 bar), one below the reference pressure (0.8 bar), one above it (8 bar) but below the critical point of neon, and one above (40 bar) the critical point. Thermo-mechanical exergy was only computed below the melting point for the 1.01325 bar pressure case since heat of fusion data were only available at that pressure, even though it is expected to be very similar at other pressures. Thermo-mechanical exergy could only be calculated for the gas phase for the 0.8 bar state due to limitations in the equation of state model.

## 4. DISCUSSION

### 4.1 Qualitative Assessment

As temperature moves down from  $T_0$ , decreasing toward the melting point, all four pressure lines curve smoothly upward, forming a convex shape. For the subcritical pressure lines, this ends upon reaching the two-phase region, where it jumps sharply upward, reflecting the heat of condensation. The supercritical pressure case does not experience a jump; instead, the slope of the exergy curve transitions to something concave, with a less steep slope, closely matching the liquid curves for the 1.01325 bar and 8 bar cases in both quantity and slope. The liquid phase region is small for the atmospheric

**Figure 4:** The thermo-mechanical exergy of neon at selected pressures as a function of temperature. We note  $e^{tm}$  at exactly  $T = 0 K$  is not physically realizable in a finite time.

pressure case (only about 2.5 K). Essentially, the lines for the compressible fluids all collapse onto each other as they transition into the crystalline phases. As noted previously, this is because  $\lim_{T \rightarrow 0K} \frac{\partial s}{\partial p} \rightarrow 0$ .

In the crystalline region, exergy continues to increase as  $T \rightarrow 0K$  but with decreasing slope as the heat capacity is likewise approaching zero. The final estimate for thermo-mechanical exergy approaching absolute zero for neon at atmospheric pressure relative to 25°C and 1.01325 bar reference conditions is 1,790 kJ/kg. It should be noted that it does not make sense to speak of  $e_1^{\text{tm}}$  at 0 K exactly because it is unreachable in practice.

Finally, there is an open argument as to whether the “flow” form of thermo-mechanical exergy (eq. (2)) or the “closed” form of thermo-mechanical exergy is the more useful choice to describe the exergy of a substance for chemical process systems engineers for use as an analysis tool. The closed form is:

$$e_1^{\text{tm}} = (u_1 - u_0) + p_0(v_1 - v_0) - T_0(s_1 - s_0) \quad (8)$$

where  $u$  and  $v$  are the specific internal energy and specific volume, respectively. The closed form and flow forms differ by a term  $v_1(p_1 - p_0)$  sometimes called the “flow work” [1], which is work associated with the substance flowing into the environment and/or the boundary of the system expanding or contracting. However, for  $p_1 = p_0$ , this term is zero, making the flow and closed forms identical. Moreover, because there is very little influence of pressure on exergy in the crystalline state, the  $e_1^{\text{tm}}$  values calculated by eqs. (2), (3), and (8) converge to the same trajectory as  $T_1 \rightarrow 0K$ .

## 4.2 Comparison to Literature Predictions

Although Figure 4 is the first such quantitative diagram in the open literature that we can find, it is interesting to compare against two previous hypothetical sketches of what such a diagram would look like. Figure 5 shows two previously published curves from two previous works, for an arbitrary substance.

In Figure 5 (top),  $e_1^{\text{tm}}$  in the vacuum pressure ( $p < p_0$ ) case is sometimes negative, in contrast to Figure 4 where  $e_1^{\text{tm}} > 0$  always. This is because that work [4] assumes the form of eq. (3) to compute  $e_1^{\text{tm}}$ , which as shown previously cannot be correct precisely because it can result in negative values [2]. It is also interesting to note that the thermo-mechanical exergy of the vacuum pressure case in Figure 5 (top) has the same qualitative shape as the high-pressure case, whereas in Figure 4, the slope of the line in the vacuum pressure case increases more quickly as temperature increases, while the  $p \geq p_0$  cases have very similar slopes at all temperatures as  $T$  increases. As discussed in [2], the behaviour shown in Figure 4 is because the mechanics of mass exchange with the environment for systems above atmospheric pressure are different than those for systems below it. Also,

Figure 5 (top) does not consider phase change, nor does it account for the switch to a concave shape as  $T \rightarrow 0K$ .

**Figure 5:** Two hypothesized sketches of  $e_1^{\text{tm}}$  as a function of  $T$  and  $p$  in previous works. Top: Reprinted from Kotas [4] with digital enhancements. Bottom: Reprinted from Petela [8] with digital enhancements, noting the open circle at  $T = 0K$ . Note that  $\varepsilon_{ph}$  and  $b$  in the sketches are equivalent to our notation  $e_1^{\text{tm}}$ .

Figure 5 (bottom) [8] shows a more accurate prediction below  $T_0$ . However, in Figure 5 (bottom)  $e_1^{\text{tm}}$  increases very quickly as  $T$  increases above  $T_0$ , rapidly overtaking the maximum cold  $e_1^{\text{tm}}$  at  $T \rightarrow 0K$ . In the final result of Figure 4,  $e_1^{\text{tm}}$  for neon grows very quickly as  $T \rightarrow 0K$  and far more slowly as  $T$  increases above  $T_0$ . This prediction in Figure 5 is curious. It arises because that work assumes that heat capacity near 0 K is cubic ( $C_p(T) = kT^3$  for some constant  $k$ ), which is quite reasonable—in fact we considered a cubic version of eq. (7) and achieved almost identical results. However, in making the drawing, it assumes that  $C_p(T) = kT^3$  for all  $T$ , with no balancing factors of lower order terms, which is not reasonable. Thus in the drawing of Figure 5 (bottom),  $e_1^{\text{tm}}(T)$  is quartic ( $\sim T^4$ ) and this term dominates. This was thought to be correct because the exergy of heat radiation also grows  $\sim T^4$  above  $T_0$  and follows a very similar shape to

Figure 5 (bottom) except without the jumps due to phase change, and so it was thought to be justified by analogy. However, the real example of Figure 4 shows that this is not the case.

### 4.3 $e^{\text{tm}}$ in cryogenic applications and relationship to the Unattainability Principle

Figure 4 is useful because it shows a clear upper bound on thermo-mechanical exergy of neon as temperature approaches absolute zero. In the context of the definition of exergy, this is the thermodynamically limited maximum work that could be produced by very cold substances **from thermo-mechanical processes**. However, there are some key points for discussion.

It is well known that the processes which produce the maximum theoretical work in eq. (1) must be reversible [1] and in fact, some theorists have gone so far as to require reversibility in the very definition of exergy itself [16]. From the optimization perspective, this means the optimization problem formulation for exergy can be posed in the reverse [2]:

$$e = \min_Q w \quad (9)$$

where  $Q$  is a process that brings the system **from** equilibrium with its environment **to** the state of interest within the set of all such processes  $\mathbb{Q}$  such that  $Q \in \mathbb{Q}$ , and  $w$  is work that is required by  $Q$ . By computing a finite value for  $e^{\text{tm}}$  as a substance approaches absolute zero, this implies that this is the **minimum** amount of work that must be consumed in order to bring a substance to absolute zero, which would be finite.

However, consider the Principle of Unattainability, which Kieu [17] words as “cooling any system to absolute zero temperature in a finite number of steps and within a finite time is physically impossible by any procedure, no matter how idealized the procedure.” Razek [18] states that “it is impossible to cool, using finite resources, any finite quantum system below a certain minimal temperature  $T_{\text{min}}$ .” This is a stronger claim because it means that not only is absolute zero unattainable, but for quantum systems at least, there are temperatures above 0 K that are also unattainable. Shargut and Brodyanskii [19] reject the application of eq. (3) “in the region close to” absolute zero as being meaningless (and therefore by extension also rejecting the more general form eq. (2) or the closed form eq. (8) as noted in section 4.1) precisely because it yields something not infinite. They claim this violates the Third Law of Thermodynamics (which may not be strictly equal to the Unattainability Principle [17], discussed later).

How then can we interpret these apparent contradictions? How useful is the computed value of  $e_1^{\text{tm}}$  in cryogenic applications? First, it should be noted that the Third Law was used both in the proof of the finiteness of  $e_1^{\text{tm}}$  approaching absolute zero (namely that the absolute entropy of a substance is zero at absolute zero) and in its

computation (that the heat capacity of a substance must be zero at absolute zero), not only in this work but also through alternative approaches in [8]. So, the Third Law itself cannot imply infinite exergy.

Second, when considering the definition of exergy and its subsequent optimization formulations, there is no constraint that the theoretical process that produces the maximum work requires **finite** time. In fact, it is theoretically possible to cool a substance to absolute zero using finite energy in an infinite amount of time [18, 20]. In optimization terms, the process  $Q$  which solves eq. (9) takes infinite time but results in a finite  $w$ . In fact, some recent work provides an interesting proof that the Third Law and the Principle of Unattainability are not strictly identical, and therefore the “possibility, logically and physically speaking, of attainability of absolute zero...by non-adiabatic means” remains [17]. So perhaps the solution  $Q$  is non-adiabatic. However, we note that there is ongoing disagreement in the equivalency of the Third Law and the Principle of Unattainability.

Finally, there is a more existential issue, namely that definition 1 applies to exergy generally, not thermo-mechanical exergy specifically. This distinction is important. Most process systems engineers find it very practical to decompose exergy into various types that can be summed together to get a final exergy value, using a variety of different taxonomies to do this [3]. For example, the exergy owing to chemical potential (molecular bonds and concentration differences), height above a reference point (potential energy due to gravity), kinetic energy of motion, temperature, pressure, and phase, are conceptually decomposable in many real applications. However, it has also been shown that these different kinds of exergies are strongly interlinked, and such decompositions are not applicable in many cases. For example, the exergy associated with phase (e.g. saturated vapour vs. saturated liquid) is not isolatable because it affects both thermo-mechanical and chemical exergy [3]. Marmolejo-Correa [21, 22] also showed that even the decomposition into temperature and pressure-based contributions was not meaningful because the solutions to eq. (1) are not unique, so it is not possible to take any given thermo-mechanical exergy and uniquely describe it as the sum of a temperature and a pressure component. Therefore, the quantification of exergy at absolute zero in general outside of thermo-mechanical contributions remains an open problem. Nevertheless, the practicality of computing  $e_1^{\text{tm}}$  down to absolute zero remains because it is a good and meaningful descriptor, useful in the analysis of real cryogenic processes that considers the First, Second, **and** Third Laws of Thermodynamics.

## 5. CONCLUSIONS

Using neon as an illustrative example, we

demonstrated how the thermo-mechanical exergy of substances changes due to the impacts of pressure and phase across subcritical gas, subcritical liquid, supercritical fluid, and crystalline phases as temperature decreases toward absolute zero. Although pressure impacts exergy in the gas phase, it has almost no impact on substances in compressed phases. For example, liquid and supercritical liquid phases at the same temperature have virtually indistinguishable thermo-mechanical exergies. Furthermore, contrary to previous predictions, calculations using real data for neon shows that  $e_1^{\text{tm}}$  grows much more slowly as temperature increases away from  $T_0$  than it does as temperature decreases away from  $T_0$ .

For practicing engineers, the general form of thermo-mechanical exergy in eq. (2) can be used even for very cold situations. The most common applications in chemical process systems engineering are in assessing the quality and performance of refrigeration systems, organic Rankine cycles, and in work recovery from stored very cold substances, such as in the regasification of liquified natural gas or liquid hydrogen.

## ACKNOWLEDGMENTS

No funding was used for this work. Helpful discussions with Professors Truls Gundersen (NTNU), Bjørn Austbø (NTNU), Nadia Shardt (NTNU), and Nidret Ibric (Univ. Tuzla) are gratefully acknowledged.

## ABSTRACT

Sustainability of the chemical and materials industry (CMI) requires it to achieve net-zero emissions of greenhouse gases and other resources while making decisions that have a net-positive impact on nature and society. Many corporations, nations, and universities have pledged to meet such goals but systematic models, methods, and tools to guide this transition are missing. We present a framework to meet this need. It involves developing a comprehensive, open access model of the global CMI. In addition to existing technologies, this model includes emerging alternatives for renewable energy, circularization, and carbon capture, utilization and storage. Systematic methods help identify innovation opportunities and develop roadmaps that account for long-term changes such as technology evolution and climate change. Meeting the goal of net-zero emissions requires inclusion of life cycle impacts. Nature-positive decisions need to encourage ecological protection and restoration. This is enabled by a multiscale framework for determining the absolute environmental sustainability of products and processes by accounting for the availability of ecosystem services and their carrying capacities at multiple spatial scales. People-positive decisions need to account for the benefits to society versus harm. Issues of social justice and equity also need to be included in the decisions. More work has focused on the goal of net-zero greenhouse gas emissions but the need for better models, methods and applications remains. Nature- and people-positive decisions need to consider spatial and temporal variation of ecological and social systems. Meeting these challenges presents many novel opportunities for socially-relevant process systems engineering.

## MOTIVATION

The last few decades have witnessed a growing interest and urgency in incorporating sustainability in all aspects of human activities including process systems engineering. In process design, early efforts focused on meeting regulations expanded to waste minimization from individual processes and then the entire life cycle. From being a necessary evil, when the environment was included as a constraint in process design, environmental protection is becoming a source of competitive advantage, and is routinely included as an objective along with conventional economic goals. These efforts have resulted in methods for reducing the environmental impact

of manufacturing processes [1]. Expanding the system boundary to include the life cycle has helped in reducing the chance of unintended harm due to emissions shifting along the life cycle. However, these efforts are not enough for ensuring sustainability for the following reasons.

- Reducing emissions is necessary but not good enough. This is because for many categories, it is urgent that we reduce emissions to zero or even negative. The most important in this category is GHG emissions, but zero emissions are also needed for water, particularly in arid regions of the world, and eventually for all other emissions and

resources as well.

- Environmental sustainability requires all human activities to respect nature’s capacity, but most approaches do not include ecosystems and their capacity in system design. These approaches need to not only account for and respect nature’s limits but also encourage protection and restoration of ecosystems.
- Chemical processes have substantial positive and negative impacts on society. The positive impact includes improvement in our standard of living, employment opportunities and economic growth, while negative impacts are due to resource use, emissions, and other side effects. The net impacts on society need to be positive while preventing social inequities and injustice.

To address these shortcomings, human activities need to have net-zero emissions and resource use while resulting in nature- and people-positive decisions [2]. The goal of net-zero emissions of greenhouse gases (GHG) is currently the most active area of global effort across disciplines. It is covered by the United Nations Framework Convention on Climate Change and most corporations, university campuses, and nations have pledged to achieve net-zero GHG emissions within a few decades. Nature-positive means that decisions should result in restoration and protection of natural ecosystems and their biodiversity. This will result in the production of ecosystem goods and services, which are essential for sustaining human activities and well-being. Many nations and corporations are pledging to make nature-positive decisions so that biodiversity loss can be stopped and reversed by 2050 [3,4]. People-positive means that any negative impact of human activities should be less than the positive impacts. In addition, the impact should also be socially just, that is, the negative impact should not be a function of factors such as race or class [5]. Studies of the positive economic benefits and negative health impacts and climate change due to air pollution of sectors in the U.S. economy identify sectors with net-negative impact.

These goals are analogous to the triple bottom line [1] but take this farther by accounting for specific goals of the Paris Accord for reducing GHG emissions, respecting nature’s capacity, and doing more good than harm to people. Such pledges and efforts toward meeting them are commendable. However, achieving these goals in an economically feasible manner poses a formidable challenge since it will require transformation of industry and its supply chain in a manner and at a scale that is likely to be unprecedented. It will require innovation, and while accounting for diverse stakeholders, may result in compromise or win-win solutions. The need for such transformation is urgent since the impacts of the current

approach continues to worsen the effects of climate change, ecological degradation, and societal inequities. As conveyed in a recent emissions gap report, “the international community is falling far short of the Paris goals, with no credible pathway to 1.5°C in place. Only an urgent system-wide transformation can avoid climate disaster” [6].

Process Systems Engineering (PSE) has a unique opportunity to contribute to meeting these challenges since they require a systems view and can benefit from its methods and tools [7]. For industry, campuses, and nations to meet their pledges, they need data, models and methods to evaluate current activities, identify emerging options, and to guide the transition. This paper defines the problem and identifies the challenges in becoming net-zero, nature-positive and people-positive. We present a framework for meeting these goals, summarize current efforts and identify future needs and opportunities.

## FRAMEWORK FOR GUIDING THE TRANSITION

A general framework for guiding industry transition to a net-zero, nature-positive and people-positive future is shown in Figure 1. It relies on advanced PSE methods for modeling the current and future chemical and materials industry (CMI) pathways, evaluating trade-offs, guiding innovation and developing roadmaps to meet the specified pledges. More details about each step are provided in the rest of this section.

**Figure 1.** Framework for guiding the transition to net-zero emissions, nature- and people-positive decisions.

### Modeling the CMI

Transforming the chemicals and materials industry (CMI) to meet the goals of net-zero, nature-positive and people-positive decisions requires models of the industrial activities and their life cycles. Ideally, such a model should include details about the underlying stoichiometry, reactions, cost, and technologies of current and emerging technologies. Such models have been

developed by companies such as S&P Global and used in academic research [8,9]. However, such models do not permit widespread academic research due to their licensing constraints and high cost. A recent model of the CMI [10] overcomes these barriers due to its open access license and no cost for non-commercial use. This model can provide the superstructure of current and emerging technologies relevant to CMI. The matrix representation enables easy linking with life cycle inventory datasets from which the trade-offs between economic, environmental, social, and circularity objectives for different pathways may be identified.

**Table 1.** Ranking innovations for sustainable circular economy of grocery bags based on improvement potential (UU\*) and readiness level (RL) [11].

Rank	Innovation	RL	UU*	Ranking criterion
1	Catalytic pyrolysis of segregated LDPE	7	0.85	0.621
2	Alkaline hydrolysis of PLA to LA using ionic liquids	2	1.83	0.611
3	Linear alkyl benzenes from sorted PE	2	1.83	0.610
4	Bio-polyethylene from sugarcane based bio-ethanol harvested in Brazil	7	0.8	0.603

### Guiding Innovation

The desired transition to net-zero, nature-positive and people-positive is unlikely with currently used alternatives. Therefore, innovations in technologies, policies, and behavior are needed. Approaches such as hotspot analysis and sensitivity optimization can be used to determine where to focus future research efforts. Results from applying such an approach to alternatives relevant to develop sustainable and circular grocery bags are shown in Table 1 [11]. Here, the improvement metric, UU\* is the distance between utopia points of the Pareto surface with current alternatives and the surface after including the new alternative. The ranking criterion is the geometric mean of the readiness level and UU\*. Finding potential innovations can rely on fundamental knowledge in chemistry databases, trade and patent literature and journals [12]. Artificial Intelligence methods for text mining and large language models can also help [13].

**Figure 2.** Roadmapping results for transforming grocery bags to net-zero GHG emissions [14].

### Roadmapping

Once adequate alternatives are available for meeting a goal such as net-zero emissions, a roadmap needs to be developed to guide the transition. Given the long time horizon of the roadmap, the roadmapping approach should account for changes over this time period in aspects like technology evolution, climate change, improvement in the energy grid and changes in the economy. Such a problem has recently been formulated as a long-term planning problem which can be solved by methods such as robust optimization and multi-period stochastic programming [14]. Typical results from application of this approach to roadmapping for grocery bags with net-zero emissions is shown in Figure 2. This framework models technology evolution as continuous time Markov chains and may be linked with integrated assessment models of climate change and other large-scale changes.

### NET-ZERO EMISSIONS

Net-zero emissions are achieved when the direct and indirect emissions over the entire life cycle are zero. Some definitions consider a 90% reduction to be adequate for making claims of “net-zero”. Accounting for net-zero emissions relies on the approach of life cycle assessment and life cycle inventory databases. However, unlike the broad focus on diverse resources and impacts in LCA, most current efforts toward net-zero emissions focus only on GHG emissions. For industry to reach net-zero emissions, available alternatives belong to three broad categories: input-side technologies such as use of renewable sources of energy, circularity technologies such as mechanical and chemical recycling, and output side technologies such as carbon capture, utilization and storage (CCUS). For the hard-to-decarbonize CMI sector, circularity technologies are of critical importance since along with reducing GHG emissions, they can simultaneously reduce consumption of resources and pollution due to plastics. Reliance on CCUS may be essential for meeting goals of the Paris Accord. Reliance on renewable resources is also critical, but such technologies

are much more materials intensive than nonrenewable technologies. This may result in larger land use change and biodiversity loss due to agriculture, mining, and other land-intensive activities. Land use change can also contribute to achieving net-zero emissions by the implementation of nature-based solutions such as reforestation. For such solutions, it may be best to avoid tree plantations but rely on restoring native vegetation and biodiversity. This is likely to simultaneously contribute to all three goals of net-zero, nature-positive and people-positive solutions.

**Figure 3.** Transgression of the ecological boundary for climate change for methanol in selected nations [17]. Orange bar shows the transgression determined by direct downscaling without considering geographical variation in nature’s capacity [16].

## NATURE-POSITIVE DECISIONS

To determine whether decisions are nature-positive requires knowing the ecological impact of an activity and ensuring that ecological protection and restoration exceeds this impact. Such decisions can benefit from knowledge about the goods and services provided by nature, since that can help quantify ecological impact and restoration. A popular approach related to nature-positive decisions is based on the concept of planetary boundaries [15], which identifies the “safe operating space” for humanity. This space is based on ensuring that human activities do not exceed global ecological limits for impacts like climate change, biodiversity loss, water scarcity etc. This approach has been used to define metrics for absolute environmental sustainability, and such metrics have been calculated for various processes and products [16,17]. The result is insight into the extent to which a specific human activity transgresses planetary boundaries. Most such approaches rely on normative methods to downscale global planetary boundaries to local scales in proportion to quantities such as economic value addition, emissions, population, etc. Unfortunately, approaches based on direct downscaling of planetary

boundaries [16] need not encourage ecosystem restoration and protection because such an approach can “give away” ecosystem capacity from privately owned land to others due to their larger contribution in terms of the selected downscaling approach [17]. This approach utilizes ecological data and models to determine ecological boundaries at multiple spatial scales can provide insight into the degree of transgression of ecological boundaries and encourage.

## PEOPLE-POSITIVE DECISIONS

For a decision to be people-positive, its benefits to society should outweigh any harm. Such quantification may be done by representing the benefits and harm in monetary units. The benefits may be indicated by the economic value added by the activity while the harm can be quantified by the monetary value of lost time due to illness, disability or death. Such a study of the US economy found that for sectors such as fossil-based electricity generation, sewage treatment, and stone quarrying, the negative impact from air pollution and climate change are larger than the economic value addition from these sectors [18]. Using the framework of techno-ecological synergy for designing integrated networks of industrial and ecological systems can convert a net-negative manufacturing process into a net-positive TES system. This is by planting native and biodiverse trees in the vicinity of the manufacturing process to reduce the impact of air pollution while also obtaining other ecosystem services [19].

Another aspect of people-positive decisions involves accounting for social justice and equity. This involves at least two aspects: Industry has contributed to social inequity due to the establishment of regions where the negative impacts of industrial activity are borne disproportionately by disadvantaged communities resulting in the formation of regions such as “cancer alleys” [20]. Secondly, a minimum consumption of resources and emission of pollutants is necessary to ensure that the basic needs of a community or region are met. Thus, for decisions to be ecologically safe and socially just, they need to respect ecological limits while meeting basic needs. This operating space is referred to as the “safe and just space” (SJS) for humanity. People-positive engineering decisions require quantification of the SJS and its inclusion in process engineering methods. A recent step in this direction considers specific ecosystem services and determines the safe space or “ecological ceiling” using the TES framework described in the previous subsection. The just threshold or “social foundation” is determined as a function of the minimum food-energy-water consumption of the population in a selected region that is needed for their well-being, and the technologies used for meeting their needs. Based on this information,

the SJS has been determined for various nations in terms of the ecosystem services of carbon sequestration and water provisioning [21]. Such results are being incorporated in process and supply chain design problems and will be included in the revised version of this manuscript.

## CONCLUSIONS

Rather than just reducing emissions and environmental impact, designs for sustainability need to also meet goals of net-zero emissions particularly for greenhouse gases, respect nature's capacity while protecting and restoring ecosystems, and contribute to societal well-being and equity. Many corporations, universities and nations have pledged to meet such goals. This work describes a framework to guide industry transformation toward meeting these goals of net-zero emissions, and nature- and people-positive designs and decisions. A basic requirement for such work is the availability of a comprehensive superstructure model of the chemicals and materials industry that includes current and emerging technologies. The effect of business strategies and economic policies should also be included in such models. Developing the roadmap to meet corporate goals requires advanced optimization methods and approaches for dealing with uncertainties. Discovering innovations may be enabled by mining chemistry and engineering databases. Quantifying the metrics of net-zero emissions relies on life cycle assessment. Metrics for nature-positive decisions can use ecological models and data at multiple spatial scales, while those of people-positive decisions need to consider demographics and social equity. Meeting these goals is an urgent need that requires engineering to go beyond its traditional narrow, technocentric boundary. Companies that are successful at navigating these challenges are more likely to grow and prosper while addressing economic, environmental and social needs.

## ABSTRACT

Following the discovery of the least squares method in 1805 by Legendre and later in 1809 by Gauss, surrogate modeling and machine learning have come a long way. From identifying patterns and trends in process data to predictive modeling, optimization, fault detection, reaction network discovery, and process operations, machine learning became an integral part of all aspects of process design and process systems engineering. This is enabled, at the same time necessitated, by the vast amounts of data that are readily available from processes, increased digitalization, automation, increasing computation power, and simulation software that can model complex phenomena that span over several temporal and spatial scales. Although this paper is not a comprehensive review, it gives an overview of the recent history of machine learning models that we use every day and how they shaped process design problems from the recent advances to the exploration of their prospects.

**Keywords:** Surrogate modeling, Artificial Intelligence, Historical view, Data-driven analysis, Process synthesis

## A BRIEF HISTORY OF MACHINE LEARNING

The roots of machine learning (ML) can be traced back to the early 19<sup>th</sup> century when the method of least squares was first discovered by Legendre in 1805 and later by Gauss in 1809 [1]. However, the main concept of computers learning from experience without explicitly being programmed has roots tracing back to more recent history, the mid-20<sup>th</sup> century.

The foundational idea of neural networks emerged in the 1940s and 1950s when researchers began exploring mathematical models inspired by the structure and functioning of the human brain. Warren McCulloch and Walter Pitts' paper, "A Logical Calculus of Ideas Immanent in Nervous Activity," was published in 1943, where they proposed a mathematical model of an artificial neuron which was the first idea of using a computational model for neural networks [2]. This foundational paper laid the groundwork for subsequent developments in neural network theory. The term "neural network" itself gained prominence in the 1950s and 1960s as researchers like Frank Rosenblatt developed the perceptron, an early

form of a neural network designed for pattern recognition tasks. While the perceptron had limitations, the idea of using computational models to simulate neural processes became a cornerstone in the evolution of artificial neural networks (ANNs) and ML. Around the same timeline, response surface methodology was introduced by Box and Wilson [3], and the term "machine learning" was coined by Arthur Samuel [4].

Throughout the following decades, various modeling approaches and algorithms, including Gaussian process (GP) regression, backpropagation algorithm, support vector machines (SVMs), and Random Forest (RF), emerged in the ML landscape. Especially, the establishment of the backpropagation algorithm was a pivotal moment in the resurgence and widespread adoption of neural works starting 1980s, enabling researchers to revisit the complex problems that were not possible to address before. This ultimately led to the application of neural networks in various scientific and engineering domains, including process design and operations, and to the development of more complex algorithms. These include reinforcement learning, deep learning, natural language processing, and generative artificial intelligence (AI)

which are emerging areas of research within process systems engineering [5,6]. Although NN models have been the primary modeling strategy in process design problems due to their ability to capture nonlinearities very accurately, we will also demonstrate that SVMs and tree-based ensemble models like RF and gradient boosted trees are also studied in depth.

## PAST APPLICATIONS OF ML IN PROCESS DESIGN

With these developments underway, it was also imperative to revisit optimal design problems from the lens of ML models and process synthesis. Regression analysis and parameter estimation for kinetic or thermodynamic models were already performed for process design, dating back to the 1960s. However, with the increasing computation power and the development of process simulation software, optimal design problems recognized the need for surrogate ML models due to: (1) the “black-box” nature of the simulation software that lacks the derivative information that is imperative for optimization; (2) the computational expense associated with sample-based derivative-free optimization techniques; and (3) the high mathematical complexity of process synthesis problems (mixed-integer nonlinear program – MINLP) that become intractable with high number of variables and constraints. Hence, earlier introduction of ML techniques in process design focused on replacing highly complex and/or noisy simulations with relatively simpler representations, especially within optimization frameworks to alleviate the mathematical complexity.

For example, Caballero and Grossmann used kriging surrogate models to replace noisy unit operations in modular flowsheet optimization [7]. Likewise, Davis and Ierapetritou used kriging surrogates for tertbutyl methacrylate production design and process synthesis [8]. Henao and Maravelias used ANN surrogate models trained using the data collected from the process simulator to replace complex unit operations (*e.g.*, distillation column, expansion valves, heaters/coolers, flash vessels, absorption columns) and reformulated these ANNs to incorporate within their superstructure optimization framework [9]. Fahmi and Cremaschi also used ANNs to substitute for thermodynamics and mixing models, as well as unit operations for process synthesis of biodiesel production [10]. One of the key challenges using ANNs was also noted in this work, where these models were “data hungry” (*i.e.*, large amounts of data were required to train accurate ANN representations). The modeling complexity of the ANNs also made it challenging to incorporate them in large-scale optimization problems without any efficient reformulation strategies. Equation 1 shows the mathematical structure of a general feed-forward NN, represented by a repeated composition of functions,

$$y = \mathbf{f}(\mathbf{x}; \boldsymbol{\theta}) = f_L \circ f_{L-1} \circ \dots \circ f_2 \circ f_1(\mathbf{x}; \boldsymbol{\theta}) \quad (1)$$

where  $y$  is the output of the network,  $\mathbf{x}$  are the inputs to the network,  $f_i$  is a layer in the neural network with transformations applied by the activation functions, and  $\boldsymbol{\theta}$  are the weights and biases for the entire network. In simpler terms, this mathematical structure generates highly nonlinear expressions (except for purely linear activation functions) that create additional complexities for optimization algorithms to handle (Equation 2).

$$y = f_L(f_{L-1}(f_{L-2}(\dots f_1(\mathbf{x})))) \quad (2)$$

Especially, within a global optimization framework, this nested functional form can be intractable as well. Motivated by this, most recent progress focused on using more simplified surrogate models for process design and synthesis problems, as well as developing novel reformulation strategies that exploit the mathematical properties of activation functions. Next, we discuss these developments and other key progress in this area.

## CURRENT PROGRESS

### Reformulation of ML Models

One of the most recent key breakthroughs in using ML in any optimization framework (*e.g.*, process design, synthesis, or operations) is the ability to reformulate deep NNs with rectified linear unit (ReLU) activation functions into a mixed-integer linear program (MILP) [11-13]. By recognizing ReLU activation functions as max-affine spline operators that are piecewise linear (Equation 3), ANNs can be exactly reformulated with big-M constraints to create a MILP that can be solved to global optimality with off-the-shelf solvers.

$$y = \max\{0, z\} = \begin{cases} 0 & \text{if } z < 0 \\ z & \text{otherwise} \end{cases} \quad (3)$$

This enabled MILP-reformulated ANNs to be embedded in a variety of problems, including optimizing the extractive distillation process [14], sustainable hydrogen production using sorption enhanced steam methane reforming [15], as well as for modeling flexibility index constraints in biorefinery design by superstructure optimization [16]. This technique is also extended to other activation functions that are nonlinear [17,18], and different modeling strategies such as tree-based ML models, as they also partition the modeling space with piecewise linear models (Figure 1).

Mišić [19] and Mistry *et al.* [20] encoded trained gradient boosted regression trees, which are ensemble decision tree models, to MILP models that are later embedded into optimization problems. This technique is further extended as a black-box optimization algorithm in the ENTMOOT framework [21] and implemented as an open-source software package named OMLT [22]. The applicability of the tree-based reformulation is also

demonstrated on an optimal layout design problem of an offshore windfarm [23].

**Figure 1.** A demonstration of how decision tree models (A) partition the space with piecewise linear models; and (B) map this partitioning onto decision trees for a visual representation.

Despite reformulation strategies alleviating a portion of the nonlinearity issues in NN and tree-based ensemble models, we also observe that large-scale process synthesis problems still rely on more simplistic models. For instance, Demirhan *et al.* used linear surrogate models to model the conversion of a Haber-Bosch reactor within the renewable ammonia process synthesis problem that has 18,573 continuous, 38 binary variables, and 18,924 constraints [24]. Under such large-scale global optimization problems, reformulating MILP representations of NN or tree-based models of individual units will amplify the

number of binary variables, which will further increase the complexity of the overall optimization model. Hence, the use of ML in large-scale synthesis problems is still contingent on the overall problem complexity, even when ML models offer highly accurate predictions.

### ML Algorithms as Constraints

Nowadays, the use of ML is not limited to modeling individual unit operations or an entire flowsheet, but it can also serve as constraints to process design problems. Especially, process simulations are typically subject to black-box constraints that lack explicit analytical expressions relating the decision variables to constraint violations (*i.e.*, the constraint violations can only be obtained once the simulation run is completed). Constraint handling can be achieved in many ways, including augmented Lagrangian formulations, penalty, filter, or barrier methods [25].

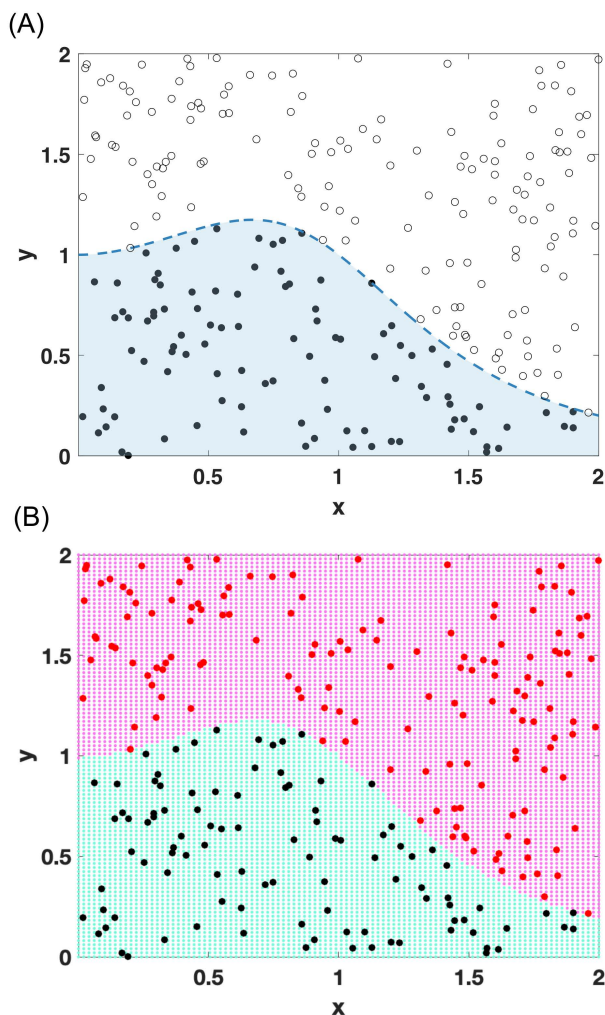

**Figure 2.** The feasible region derived by fitted surrogates using regression analysis (purple) is shown on a contour plot of the objective function. Black dots show the sampling points for the input space. The constraints are:  $x^2 + y^2 - 200 \leq 0$ ;  $x - 5y + 10 \leq 0$ ;  $25x - 2y^2 + 4y - 5 \leq 0$ ;  $-x - 2y^2 + 4y - 5 \leq 0$ .

On the other hand, ML tools can be leveraged to handle constraints individually as a regression task [26,27], where constraint violations are modeled as less than or equal to constraints with surrogate models (Figure 2), or holistically as a classification task [28-30], where a separating model between feasible and infeasible solutions are established. A conceptual demonstration of a nonlinear constraint being modeled as a classifier using SVM with Gaussian radial basis function kernel is provided in Figure 3.

This is achieved by using a dataset of simulated samples with their binary outcome (feasible/infeasible) to train one or more classification models instead of

individually modeling actual violation values as done in the regression analysis. The trained classifier can then be used with a data-driven optimizer or implemented in a superstructure model using the aforementioned reformulation strategies. In that respect, SVM classifiers are shown to effectively model the implicit constraints of numerically infeasible differential algebraic equations of a steam cracker reactor design problem [28,29]. SVM classifiers are also used for modeling feasibility constraints in the vertex formulation of modular design problems [30].

**Figure 3.** An SVM-based classifier trained to mimic the nonlinear constraint,  $y < 1/(x^3 - x^2 + 1)$ : (A) The original constraint within the bounded space; (B) The map of the feasible region captured by SVM. The predictive performance of the classifier on a blind testing set: Accuracy = 100%; Sensitivity = 100%; Specificity = 100%; F<sub>1</sub> score = 100%.

While these studies show promise for using classifiers, the offline model training is still time-consuming (*i.e.*, several thousand samples are collected from the simulator to create the model) with no efficient way to

recycle or integrate the already collected data into the decision-making process. Also, understanding the uncertainties surrounding these models as well as their misclassification rate is of utmost importance for constraint modeling, as misclassifications can lead to infeasible solutions or designs, whereas in regression-based models, such misviolations are less likely to happen.

## Large Language Models & Generative AI for Process Design

Choosing the right sequence of unit operations and connections to create a flowsheet is a fundamental practice in process design, whether it is done heuristically or through superstructure optimization. With the launch of ChatGPT, the key question becomes whether natural language processing or generative techniques can be utilized for process design and discovery. As a language model, ChatGPT is designed to understand and generate human-like text based on the input it receives. However, chemical engineering problems, such as process flowsheet generation, are based on recognizing the sequence of unit operations. This comes with the caveat of lack of suitable data to be able to train the large language models that can generate a flowsheet automatically [31]. For instance, there could be 20+ different representations for the same unit [32] or process flowsheets are most likely proprietary or unavailable to extract the information necessary for the AI model development [33].

To overcome these limitations, Vogel *et al.* developed SFILES 2.0 [33] to represent flowsheets using a graph notation, analogously similar to the text-based SMILES notation for representing chemical structures. This was primarily developed to topologically describe a flowsheet with the disadvantage of not storing any information about the sizing or the operating conditions of the units. Along the idea of ChatGPT, Vogel *et al.* also investigated the automatic completion of flowsheets using causal language modeling [34]. Their results show that the generative AI model can learn the topological patterns in flowsheet data and can automatically complete flowsheets. However, like the issues faced in ChatGPT, the generated flowsheet may not make practical sense, as the developed model does not intake contextual information about the process. Using the SFILES notation, Hirtreiter *et al.* also investigated the automatic generation of control structures for flowsheets [35]. While the predictive accuracy of the trained models was relatively high, significant limitations are also noted by the authors. Especially, concerns regarding safety indicators, understanding the process dynamics and operational objectives, and lack of information on the equipment sizing and operating conditions for the units pose major questions. These promising developments show that natural language processing and large language models can provide a “warm start” for flowsheet generation and facilitate

some of the time-consuming tasks. However, more research needs to be done in this area to be able to improve confidence in model predictions while providing a holistic view of process design beyond just the topological investigation.

## CONCLUSIONS

Artificial Intelligence and machine learning (ML) models are now an essential component of process design with efficient model integration and reformulation strategies paving the way. Constraint handling with ML models to flowsheet generation using large language models, we see new and innovative ways of how ML is used for process design problems. While the main motivation for using ML models is to alleviate the model complexities and such models have proven to be successful over the course of decades, domain knowledge and model interpretability will still play the most important role despite the promise these models hold. The ability to understand why a model makes a particular prediction and to reason if predicted results are physically sound or whether a generative model-derived process flow diagram is safe to implement becomes critically important. This judgment requires a deep fundamental understanding of the process, engineering expertise, and other relevant domain knowledge. Incorporating safety and risk measures, and combining ML models with first-principles information to create hybrid models are a few avenues that researchers are currently investigating. Nevertheless, the importance of interpretability and understanding the process relevance of the predictions will persist in this field.

## ACKNOWLEDGEMENTS

This work was supported by the National Institutes of Health [NIH P42 ES027704] and University of Connecticut. Portions of this research were conducted with the advanced computing resources provided by the University of Connecticut Storrs High Performance Computing facility. ## ABSTRACT

Sustainability encompasses many *wicked problems* involving complex interdependencies across social, natural, and engineered systems. We argue holistic multiscale modeling and decision-support frameworks are needed to address multifaceted interdisciplinary aspects of these wicked problems. This review highlights three emerging research areas for artificial intelligence (AI) and machine learning (ML) in molecular-to-systems engineering for sustainability: (1) molecular discovery and materials design, (2) automation and self-driving laboratories, (3) process and systems-of-systems optimization. Recent advances in AI and ML are highlighted in four contemporary application areas in chemical engineering design: (1) equitable energy systems, (2) decarbonizing the power sector, (3) circular economies for critical materials, and (4) next-generation heating and cooling. These examples illustrate how AI and ML enable more sophisticated interdisciplinary multiscale models, faster optimization algorithms, more accurate uncertainty quantification, smarter and faster data collection, and incorporation of diverse stakeholders into decision-making processes, improving the robustness of engineering and policy designs while focusing on the multifaceted goals and constraints in wicked problems.

**Keywords:** Artificial Intelligence, Machine Learning, Multiscale Modelling, Interdisciplinary, Optimization

## INTRODUCTION

Creating engineered solutions to help achieve UN sustainable development goals (e.g., clean water and sanitation, affordable and clean energy, responsible consumption and production),<sup>1</sup> requires managing complex trade-offs across diverse molecular, material, device, process, and infrastructure scales<sup>2</sup>. As such, breakthroughs at a single scale are often insufficient to realize global impact. Moreover, these *wicked problems*<sup>3,4</sup> require interdisciplinary teams to manage interdependencies across social, natural, and engineered complex systems.

Using four contemporary sustainability challenges in chemical engineering, this short paper argues recent advances in artificial intelligence (AI) and machine learning (ML) methods for product and process design offer new capabilities to accelerate decision-making across molecular-to-system length and timescale. For brevity, we direct the reader to several excellent review articles and editorials for technical overviews of AI<sup>5,6</sup>, ML<sup>7-11</sup>, and data

science (DS)<sup>12-14</sup> methods used in chemical engineering. This paper focuses on advances and opportunities for AI, ML, and DS for product and materials design, which we argue is inherently multiscale and interdisciplinary. Many now consider AI as an academic discipline, and ML is a field within AI<sup>15</sup>. Similarly, DS is an interdisciplinary field focused on extracting knowledge from data, which historical roots in applied statistics<sup>16</sup>. We do not dwell on the formal distinction between AI, ML, and DS.

## MOTIVATING APPLICATIONS

We start by framing four sustainability challenges, each of which presents many opportunities for innovations in designing materials, products, and processes. However, fully realizing the benefits of technology development requires holistic systems engineering approaches, which AI and ML help facilitate.

### Equitable Energy Transitions

Social, natural, and engineered systems around the

globe must adapt to climate change<sup>17</sup>. While the poorest and most marginalized have contributed minimally to global emissions, they are impacted the most by climate change<sup>18</sup>. Thus, it is critical to consider equity and environmental justice dimensions of technologies and policies to transition the global energy economy from fossil to renewable resources. Decision-making must consider many objectives and perspectives from diverse stakeholders<sup>19</sup> to manage complex interdependencies across social, natural, and engineered systems. Best practices to broaden representation in policy processes<sup>18</sup> can be integrated with systems thinking to enable participatory research on materials and chemical products focused on the authentic needs of poor and marginalized communities.

## Decarbonizing the Power Sector

A key aspect of climate adaptation is decarbonizing electricity generation through greater adoption of carbon-neutral or renewable energy sources. One key technical challenge is that non-dispatchable renewable sources, carbon capture systems, and nuclear generators are often less flexible than fossil fuel generators. New sources of dynamic flexibility are needed to continuously balance electricity generation and production and ensure resiliency to extreme events (e.g., weather). Technoeconomic analysis of grid-connect systems, including power generators, storage systems, building, and (chemical) manufacturing processes, must consider the time-varying value of electrical energy, ancillary services, and demand response incentives<sup>20-23</sup> while considering uncertainty<sup>24</sup> and trade-offs between flexible operation and emissions<sup>25</sup>. Moreover, systems modeling can help inform the value of flexibility<sup>26,27</sup> and set performance targets for materials development, e.g., degradation in energy storage systems<sup>28</sup>. However, introducing new generators, energy storage, or integrated energy systems can distort prices in energy markets<sup>29,30</sup>, which emphasizes the need for system-of-systems modeling to assess the economics of new technologies properly. Expansion planning<sup>31,32</sup> and similar decision-support tools<sup>33</sup> are needed to establish multi-decade decarbonization pathways<sup>34,35</sup> that ultimately inform materials design and technology development.

## Circular Economies for Critical Materials

Reducing society's carbon footprint requires robust supply chains of critical minerals and materials (CMMs), including rare-earth elements (REEs)<sup>36</sup>. CMMs and REEs are essential to modern technologies, including energy storage, permanent magnetism in high-efficiency motors, and wind turbines. However, primary sources of REEs (and many CMMs) are environmentally costly to extract, separate, and refine<sup>37</sup>. Moreover, global pandemics, policies, and geopolitics can complicate CMM and REE

supply chains<sup>38,39</sup>. Thus, there is a need for new materials that enable new separations and processes to recycle CMMs and REEs from distributed sources such as used batteries and consumer electronics<sup>40</sup>. In these proceedings, Dougher et al.<sup>41</sup> elaborates on opportunities for process systems engineering to accelerate membrane separations for CMMs and REEs.

## Next Generation Heating and Cooling

As part of climate adaptation, recent international agreements mandate the phaseout of hydrofluorocarbon (HFC) refrigerants due to their high global warming potential. However, recycling existing HFCs requires new materials such as membranes<sup>42,43</sup>, sorbents<sup>44</sup>, ionic liquids<sup>45-51</sup>, and deep eutectic solvents<sup>52</sup> to separate (near)-azeotropic mixtures. Beyond vapor recompression systems, new technologies such as solid-state devices may improve performance and lower carbon footprints<sup>53</sup>. Similarly, thermoelectric materials and devices can be engineered to power distributed electronics or convert waste heat into electrical energy<sup>54</sup>. These technologies require sophisticated co-optimization of materials composition<sup>55</sup>, manufacturing processes<sup>56,57</sup>, and device designs while considering performance targets from systems models.

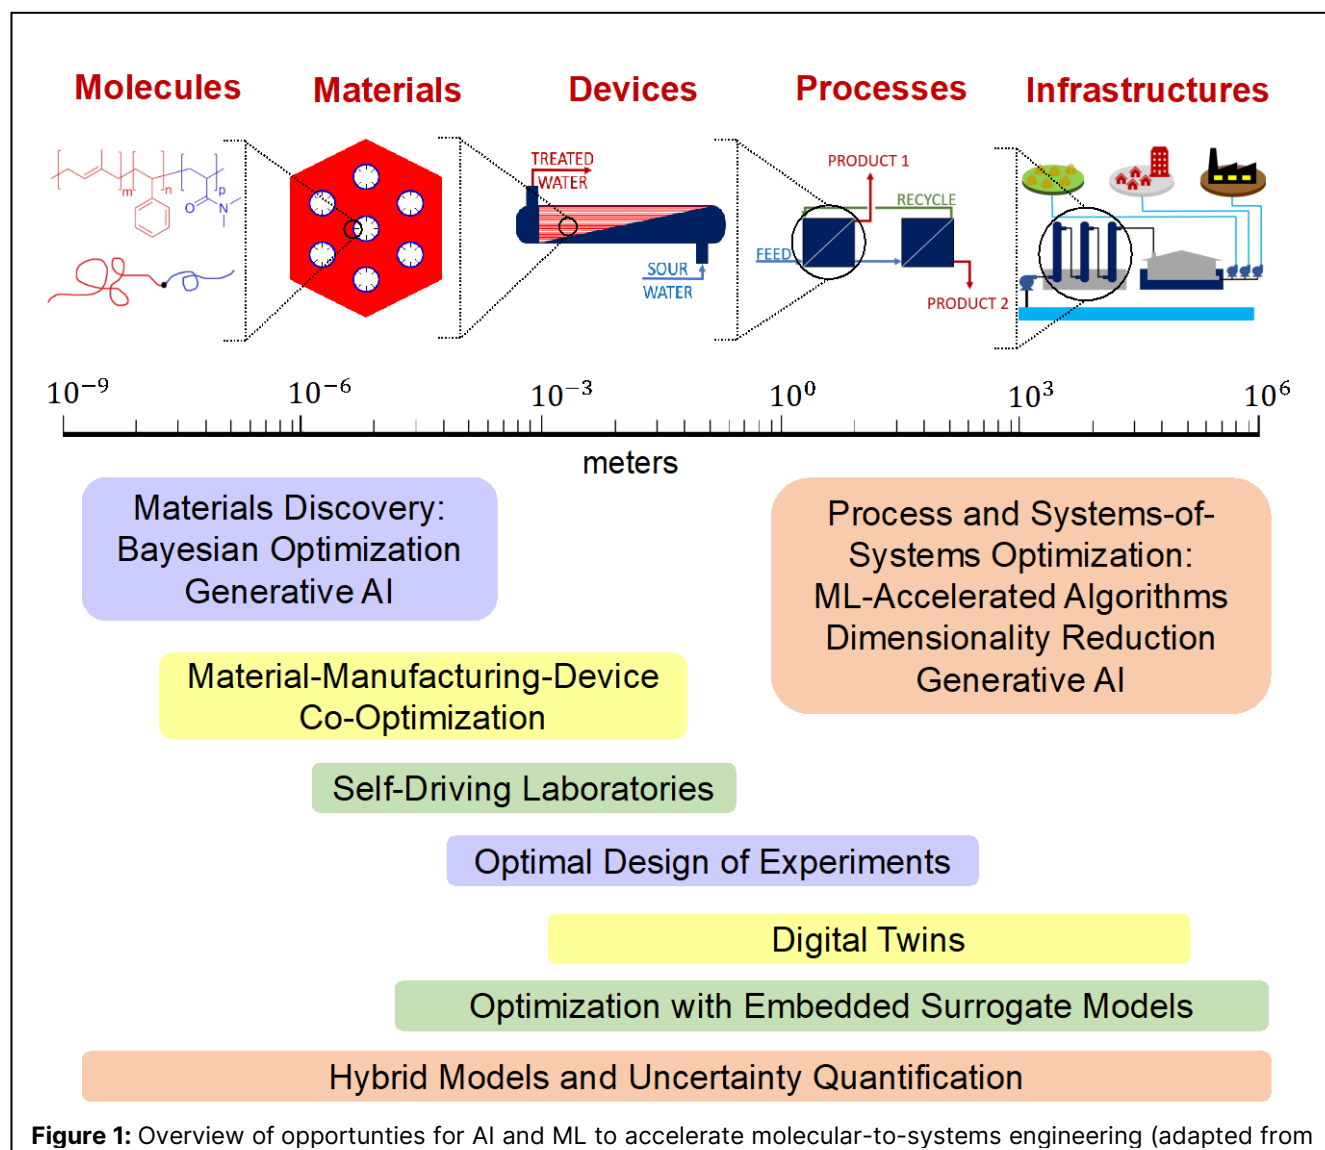

Policy-mandated phase-outs and transformations in the heating and cooling section provide another example of complex interactions between social, natural, and engineered systems<sup>58</sup>. Systems-of-system models are needed to understand the development of HFC recycling supply chains and consumer behavior, e.g., adopting new technologies to establish a circular economy, especially considering changing climates. For example, policy interventions may be needed to ensure that next-generation heating and cooling technologies remain affordable for everyone. New materials and technologies must be benchmarked using systems models that capture these complexities.

## AI & ML FOR MOLECULAR-TO-SYSTEMS

These four motivating examples emphasize the complexities of engineering new materials, chemical products, and processes to help meet sustainable development goals. This section highlights recent advances in AI and ML to address these challenges.

## Molecular Discovery and Materials Design

Computer-aided molecular design (CAMD) methods integrate predictive models to engineer novel molecules and materials, often in conjunction with processes<sup>59,60</sup>. Classic examples include co-optimizing refrigerants and refrigeration cycles, creating *designer solvents* (e.g., ionic liquids) for a wide range of separations and reactions (e.g., CO<sub>2</sub> capture, crystallization, pharmaceutical manufacturing), and engineering new materials for

**Figure 1:** Overview of opportunities for AI and ML to accelerate molecular-to-systems engineering (adapted from

energy storage (e.g., electrolytes). Advances in deep learning<sup>61</sup> combined with massive datasets enabled by new data/text mining<sup>62</sup> can provide CAMD approaches with more accurate models to predict thermophysical and mixture properties as a function of molecular/materials structure.

Molecular simulations accelerate the engineering of new molecules and materials by providing new scientific insights or predicting properties at conditions impractical to measure. AI and ML offer several opportunities to improve the speed and accuracy of molecular simulations<sup>63</sup>. For example, ML surrogate models and Bayesian Optimization (BO)<sup>64</sup> can improve the speed and accuracy of parameter estimation for force fields<sup>65,66</sup>. We proposed<sup>67</sup> and refined<sup>68</sup> an ML-assisted optimization workflow to develop new force fields for seven refrigerants. Moreover, these physically interpretable force fields accurately predict properties not considered in calibration<sup>69</sup>. An alternative approach is to replace the force field

expression with an ML model<sup>70,71</sup>. Both ML approaches are important because the lack of accurate force fields has historically hindered the use of molecular simulations to engineer some new classes of chemical products and functional materials.

Generative AI methods are emerging to engineer new molecules, materials, and synthesis pathways<sup>72,73</sup>. One popular approach uses variational autoencoders to reduce molecular descriptors into a latent space. BO<sup>64</sup> or reinforcement learning<sup>74</sup> can then optimize molecules in the latent space. ML frameworks are also emerging to co-optimize the material design, manufacturing, and end-use. For thermoelectric materials, we recently developed data science and BO methods to optimize photonic sintering<sup>57</sup> (advanced manufacturing), aerosol jet printing<sup>56</sup> (additive manufacturing), and dopant composition<sup>55</sup> (material design). These studies combined ML with expert intuition and laboratory experiments.

## Automation and Self-Driving Laboratories

Self-driving laboratories (SDLs) are revolutionizing molecular discovery and materials design by combining recent advances in robotic automation with ML<sup>75,76</sup>. Most SDLs use black-box data-driven ML models to predict experiment outcomes (e.g., material properties, synthesis yields) from input decisions. AI methods such as BO or active learning plan the next sequence or batch of experiments. SDLs have successfully optimized materials and chemical syntheses, including learning the Pareto trade-offs between competing objectives, e.g., material properties<sup>77</sup>.

Many functional materials for unit operations need to be optimized in the context of broader systems, which is likely too complex for SDLs with only data-driven ML models. For example, designing new membranes is not as simple as maximizing one property, such as selectivity or permeability, but instead, deciding how to balance material properties in the context of the broader separation system<sup>78,79</sup>. Instead, we propose combining automation and dynamic experiments for membrane characterization with science-based mathematical models<sup>80</sup>. Then model-based design of experiments methods<sup>81</sup> can be used to first distinguish between competing transport mechanisms and then optimize experiments to reduce model uncertainty. ML surrogate models can help reduce the computational burden of optimal experiment design<sup>82</sup> and model calibration<sup>83</sup>. Ultimately, this approach results in mathematical models with quantified uncertainty, i.e., digital twins<sup>84</sup>, for process and infrastructure scale optimization.

## Process and System-of-Systems Optimization

AI and ML provide new capabilities to improve the computational tractability, accuracy, and ease of implementation of integrated multiscale optimization across molecular, material, device, process, and infrastructure scales.

ML hybrid<sup>83,85</sup> or reduced-order surrogate models provide new scale-bridging approaches, especially considering the recent advances in computational optimization with embedded ML models<sup>86,87</sup>. For example, Rall et al.<sup>88</sup> used artificial neural network (ANN) surrogate models to incorporate high-fidelity ion transport membrane model performance predictions into the global superstructure optimization of a separation process. This methodology is especially powerful because it integrates rigorous models from another discipline (e.g., membrane science) with process systems engineering analyses. There is a significant opportunity for surrogate models to quantitatively establish (membrane) material property and device performance targets using process and systems models<sup>78,79</sup>.

Similarly, ML surrogate models can enhance systems-of-systems modeling. For example, Jalving et al.<sup>89</sup> trained ANN surrogate models to predict how replacing/retrofitting a generator impacts transmission network-wide outcomes in a wholesale electricity market. These ANNs were then embedded into the steady-state co-optimization of generator design and operation. This example highlights the complex interactions between individual agents (e.g., generators) in the context of a larger system (electric market). In the broader sustainability context, systems-of-systems models combine economic, societal, and environmental submodels<sup>90,91</sup>. ML surrogate models provide new opportunities to further integrate these with technology submodels (e.g., materials, processes, supply chains, infrastructure) while leveraging multi-objective computation optimization. Moreover, ML surrogate models can enable next-generation decision-support tools where diverse stakeholders interact in real time with system-of-system optimization models to facilitate negotiations. Data reduction and visualization approaches are critical to understanding and explaining trade-offs between tens or more (often correlated) objectives in sustainability problems<sup>25</sup>.

ML also provides new methods to quantify and mitigate uncertainty in decision-making. For example, Kennedy and O'Hagan hybrid models<sup>92</sup> can quantify the epistemic (model-form) uncertainty from simplifications in multiscale models<sup>93,94</sup>. We argue that Bayesian inference methods, which interpret probability as a belief, are conceptually aligned with stochastic and chance-constrained programming, which optimize over a probability distribution, i.e., the posterior from Bayesian model calibration. In contrast, frequentist statistical methods interpret probability as long-term error rates. Frequentist methods output confidence regions conceptually aligned with uncertainty sets for robust optimization. This perspective helps align the foundations of the data science and ML methods used to characterize uncertainty with the choice of optimization under uncertainty paradigm. Computational tractability remains a significant challenge to incorporating uncertainty in multiscale simulation and optimization problems. ML facilitates improved decomposition methods<sup>95</sup>, aggregation and clustering<sup>96</sup>, and branching strategies<sup>97</sup>. New generative AI methods are emerging to either accelerate or replace classical mixed integer optimization algorithms, e.g., fast sensitivity analysis<sup>98</sup>.

Finally, generative AI can accelerate the problem formulation and time to solution. For example, generative AI for flowsheet synthesis<sup>99</sup> can dramatically reduce the time to screen novel materials (e.g., new catalyst) in the context of a chemical manufacturing process. Likewise, generative AI can propose model reformulations, variable and constraint scaling, and initialization to improve model diagnostics<sup>100,101</sup> to reduce the barriers to nonlinear

optimization. These advances would make sophisticated optimization paradigms more accessible to general chemical engineering practitioners instead of highly specialized experts.

## CONCLUDING REMARKS

AI and ML improve the tractability of multiscale optimization, use data more effectively to quantify and mitigate uncertainty, and facilitate automation and faster time to solutions. These new capabilities complement recent trends in modeling software<sup>102</sup> that enable process systems engineers to guide the development of novel molecules, materials, devices, processes, and systems to address global grand challenges such as sustainable development. AI and ML provide methods that help facilitate bidirectional feedback across diverse scales and disciplines<sup>2</sup>. The described themes and opportunities are broadly relevant to sustainability challenges beyond the four motivating examples, such as recycling plastics, remediating legacy pollutants (e.g., perfluoroalkyl and polyfluoroalkyl substances (PFAS), lead), and decarbonizing chemical production (e.g., H<sub>2</sub>, ammonia, biofuels).

## ABSTRACT

This paper discusses the symbiotic relationship between technology research and development (R&D) and energy transition modeling. On the one hand, energy system modeling has a noteworthy history of providing macroscopic views and critical insights concerning the role that myriad technologies may play in the future energy system. On the other hand, R&D can lead to both incremental and disruptive technological advances that can shape energy transition planning. In this work, we focus on the bidirectional flow of information between the two with a particular focus on highlighting the potential role of carbon capture, storage, and sequestration technology.

**Keywords:** Energy, Multiscale Modelling, Carbon Capture, Carbon Dioxide Sequestration

## INTRODUCTION

As nations, communities, and organizations continue to determine their role in the energy transition, energy system modeling offers a means for these entities to understand and appreciate the intricacies of today's massive energy system. This is particularly relevant as there has been increasing interest in understanding how the world will address the so-called "energy trilemma," which involves providing low-emissions energy, at low cost, while ensuring energy security from geopolitical risk and economic hardship. Thanks to their macroscopic purview, energy system models can help policymakers understand the trade-offs associated with different energy transition pathways so that they can strike a balance amongst different objectives. At the corporate level, they can inform the direction of a company's technology R&D portfolio as certain technologies may play to the organizations strengths and capabilities and appear more profitable under a wide range of energy transition scenarios while others may only appear profitable under a narrow range of scenarios or may differ widely from the corporate focus. Meanwhile, technology R&D plays a significant role in shaping the assumptions and parameters that populate an energy system model. Improvements in cost and efficiency may allow for certain technologies to become more favorable under a range of societal energy transition goals.

**Figure 1.** 2022 Global CO<sub>2</sub> emissions [Gt] and corresponding percentage. Source: (Liu et al., 2023)

In 2022, global greenhouse gas emissions totalled roughly 36.1 Gt (Liu et al., 2023); see Figure 1. While there exist competitive, low- to zero-carbon technologies to highly decarbonize sectors such as power generation and light-duty vehicle transportation, there remain "difficult-to-eliminate emissions related to aviation, long-distance transportation, and shipping; structural materials; and highly reliable electricity total[ing] ... 27% of global CO<sub>2</sub> emissions from all fossil fuel and industrial sources" (Davis et al., 2018). Zero-carbon technologies may exist for these sectors, but their competitiveness and availability are far less established relative to the incumbent

technologies and infrastructures (Fankhauser et al., 2022). Meanwhile, as shown in Figure 2, global commercial (i.e., non-light-duty) transportation, industrial, and power demand are projected to increase significantly by 2050, particularly in China, India, and other non-OECD countries.

**Figure 2.** Global energy demand (past, present, and projected) by sector and country. Source: (ExxonMobil Global Outlook, 2023)

Numerous organizations indicate that society should pursue a multitude of technologies to decarbonize the energy sector. For example, the United Nations Intergovernmental Panel on Climate Change reports that “global modelled mitigation pathways reaching net zero CO<sub>2</sub> and GHG emissions include transitioning from fossil fuels without carbon capture and storage (CCS) to very low- or zero-carbon energy sources, such as renewables or fossil fuels with CCS, demand-side measures and improving efficiency” (IPCC, 2023, B.6.3). Individual corporations must decide which options within this portfolio they will pursue based on their insights and analysis.

In what follows, we discuss the interplay between energy system modeling and process modeling as they relate to the energy transition and technology R&D. We first discuss current trends in energy system modeling and then offer potential directions for future research. We then link this discussion with the role of process modeling for technology R&D for a specific CCS application. We conclude by discussing opportunities and challenges associated with the bidirectional flow of information between energy system and process models.

## ENERGY SYSTEM MODELING

For decades, energy system models have assisted planners, policymakers, and stakeholders gain insights related to short- and long-term policy decisions. Surveying over 30 energy system models, Lopion et al. (2018), Groissböck (2019), Prina et al. (2020), and Fodstad et al. (2022) review a diverse set of reputable decision support tools based on attributes including data requirements, foresight, methodology (e.g., simulation, optimization), operational/process granularity, sectoral coverage, spatial and temporal resolution, transparency, uncertainty, and more.

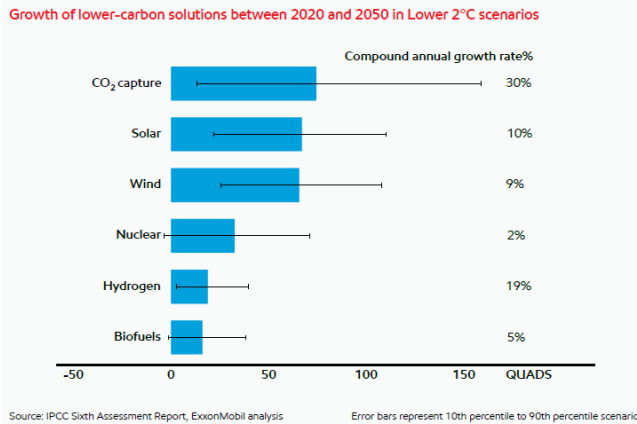

Energy system models are often partitioned into top-down and bottom-up models. Top-down models emphasize connections between the energy system and the larger economy. Due to their simplified energy system representation, they are not always appropriate to analyze sector-specific policies (Prina et al., 2020). In contrast, bottom-up models seek to integrate highly resolved components and interconnections between energy sub-sectors. “These detailed models from a techno-economic point of view allow the user to compare the impact of different technologies on the energy system and to evaluate the best future alternatives to lower GHG emissions for the achievements of the energy targets. However, the bottom-up approach does not take into account the connections between the energy system and the macro-economic sectors, thus neglecting the impacts on these sectors” (Prina et al., 2020). Hybrid models have therefore become popular in recent years to strike a balance between the two approaches.

State-of-the-art energy system models operate at multiple scales (Kakodkar et al., 2023) capturing global detail (as found in integrated assessment), national detail to investigate domestic trends and impacts, and sectoral detail to explore technological transitions in fundamental end-use sectors. Optimization- and simulation-based models are the most common tools, each with their own idiosyncrasies to handle behavioral assumptions of individual actors (i.e., energy sector supply and demand participants). Model outputs typically provide strategic insights to policymakers concerning equity and cost-effective outcomes of alternative energy transitions. We discuss how individual corporations may consume model outputs below.

## Influence of Energy System Models on Technology R&D

In 2022, the IPCC published the Working Group III contribution to the Sixth Assessment Report on Mitigation of Climate Change (IPCC AR6, 2022) and utilized more than 1,200 potential pathways with underlying socioeconomic development assumptions, energy system transformations, and land use change until the end of the century. The IPCC report identified 311 scenarios as “Lower 2°C,” which are defined as pathways with a 67% likelihood of limiting peak warming to below 2°C throughout the 21st century. These scenarios imply a range of lower-emission growth opportunities as highlighted in Figure 3, which looks across the IPCC Lower 2°C scenarios and illustrates the average (blue bars) growth potential of various lower-emission solutions. While all these solutions are needed, the black bars represent the wide range of growth potential across the IPCC Lower 2°C scenarios. To support further deployment of these technologies at scale, additional policies and technology advancements are needed to incentivize investments and

influence consumer behavior. Striking the right balance in investments at a pace consistent with policy support and technology advancements is crucial (P.26 & 28, ExxonMobil ACS 2023).

**Figure 3.** Growth of lower-carbon solutions between 2020 and 2050 in IPCC “Lower” 2°C scenarios. Source: (ExxonMobil ACS, 2023)

Figure 3 offers a concrete example of how energy system models and integrated assessment models can influence technology R&D decisions. The figure summarizes outcomes from models in the open literature from diverse groups with different technology performance and cost assumptions bases. These outcomes give rise to a wide range of potential technology adoption, with certain technologies that are commonly called on at scale, such as CCS. Corporations may use this macroscopic analysis to guide the resources that they allocate towards certain decarbonization technologies that they believe will be most competitive in a low-carbon future.

Technology R&D can also benefit from more microscopic energy system model output, that includes sector and sub-sector modeling. While large scale modeling identifies key technology types, it does not assess the performance at a resolution necessary to evaluate important process trade offs. Resilience and robustness of a technology mix may depend on geographic or temporal factors arising from demand variation and fuel supply. Examples include electricity grid power system modeling that includes weather and seasonal demand inputs. Industrial end-use planning that places a premium on continuity of operation may contemplate exposure to fuel price variation favoring diversity or flexibility of fuel type.

### Open Research Questions on Energy System Models

We conclude this section on energy system modeling with future research opportunities and directions. Prina et al. 2020 highlight four “engineering” challenges for the community: resolution in time, space, techno-economic detail, and sectoral coupling. While these points

are valid, numerous “economic” and “policy” challenges exist and are ripe for future research. Therefore, in contrast to Prina et al. 2020, we highlight orthogonal dimensions including behavioral economics (including endogenous demand modeling), policy uncertainty, technology “spillover” effects, applications of artificial intelligence/machine learning, and sustainability objectives.

While a rich literature exists on how to model and algorithmically handle high-resolution spatio-temporal representations of supply (Kakodkar et al., 2023), Nikas et al. (2020) assert that demand-side modeling is far less mature. “Values, choices, cohesion, culture, and lifestyle shifts in society are indirectly narrated as assumptions,” but not interwoven into the model with the same granularity as given to the supply side (O’Neill et al., 2017). Rebound effects, whereby improvements in technology efficiency lead to an overall increase in energy consumption, are well documented, but rarely modeled. Individuals do not always behave rationally or make decisions based solely on cost optimization. Li (2017) and the references therein highlight “the energy efficiency gap” as a prime example of how energy efficiency measures, which could offer a “cost-effective contribution to GHG mitigation, fuel poverty reduction, and energy security objectives,” have historically witnessed non-cost barriers prevent or diminish their widespread adoption. In short, greater attention to endogenous demand modeling is needed.

Rarely does a policy get implemented without unintended consequences. Well-intentioned policies may fail to deliver desired results. In Europe, inexpensive Asian palm oil is being passed off as used cooking oil because it receives additional credits as the latter; meanwhile, palm oil extraction may be causing deforestation abroad (Reuters 2023). Following a cautionary introduction entitled “The EV transition is harder than anyone thinks,” Charette (2023) highlights recent examples of unintended policy consequences in the EV transition and other sectors. While vehicle-to-grid (V2G) capabilities have the potential to offer energy and reserves to the power grid, modeling V2G policies and vehicle owners’ V2G willingness and behavior remains a challenge.

Technology “spillover” effects may also have a manifest impact on energy system model output. Nemet (2012) presents examples and evidence of inter-technology spillovers for energy technologies in which seemingly unrelated innovations and improvements in one technology impact those of another. “For example, the very commonly used General Electric LM6000 50 MW gas turbine is directly descended from the TF39 high-bypass turbo-fan engine developed for military aircraft, such as the C5 Galaxy, in the 1960s” (Nemet 2012). Meanwhile, spatial spillover effects, in which innovations and cost reductions in one region influence those of another, are well documented (Stephan et al., 2019).

Although some research has been done to address endogenous experience curves and spillover in energy system modeling domain, e.g., (Louwen et al., 2020) and (Straus et al., 2021), more research is warranted.

AI is emerging as a potential tool to assist key steps in energy system modeling. At the front end, applications include capturing information and synthesizing data sets to improve input to energy system models. Improvements can be expected in terms of the fidelity and geographic uniformity of data sets for existing energy generators and infrastructure, as well as sharpening estimates of future demand inputs. Examples include matching separate cost and production data sets where asset identifiers differ; combining satellite and areal data to identify capacity in regions where information is incomplete, e.g., powerlines or residential solar use in emerging countries; demand prediction that combines smart meter, satellite and survey information. Downscaling of highly-resolved data sets and data imputation for incomplete data sets are other possibilities. AI tools may find application in terms of efficient algorithm and constraint development. Examples include efficient approximation to expensive non-linear non-convex problems; formulating constraints that involve multi-objective input, e.g., estimating the total available land resource for renewables based on resource quality and societal or stakeholder goals. Ultimately, AI tools may lead to the synthesis of disparate data to provide system-level case sets that reflect a wholistic picture of energy system supply and demand.

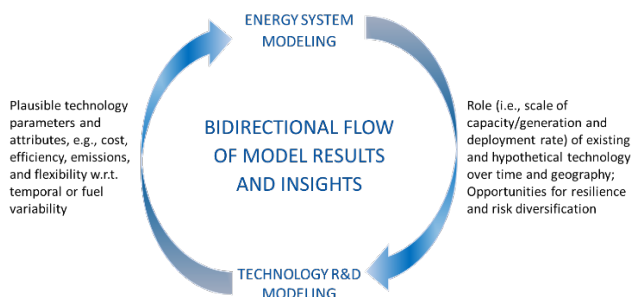

In certain settings, energy system models should attempt to incorporate multiple objectives. Current energy systems are typically constructed with an emphasis on total cost minimization and bounds on greenhouse gas emissions (Algunaibet et al., 2019). Thakker and Bakshi (2022) present a multi-scale multi-objective optimization framework capable of designing chemical reaction pathways, life-cycle value-chains, and economic cash flows in an integrated manner from a superstructure network containing alternative solutions. Sustainability, poverty, affordability, education, and other metrics should be considered. How do we model, or at least incorporate, sustainable development goals (SDGs) (IPCC AR6, 2022)? We need new approaches to include SDG-based metrics in quantitative assessments in energy system modeling.

## TECHNOLOGY R&D

As shown in Figure 4, energy system models and technology R&D have a symbiotic relationship. Energy modeling informs R&D possibilities by helping to identify what role a technology type could play in terms of deployment scale and rate, given an assessment of performance and cost attributes; in other words what technologies are robustly important. Conversely, energy

modeling can illustrate how targeted R&D improvements in technology performance and cost could lead to a wider or more rapid adoption; in other words what it would take for a technology to play a larger role.

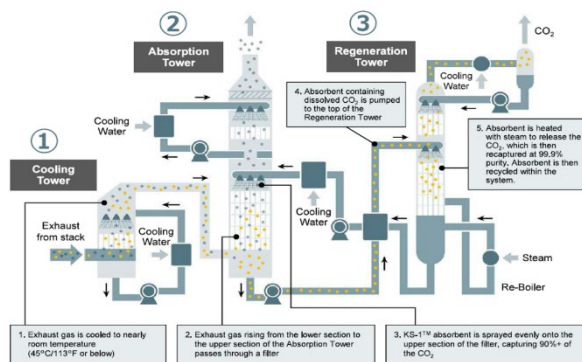

Figure 3 illustrates that CCS technology is expected to play a major role in IPCC “Lower” 2°C energy transition scenarios. More granular modeling could help differentiate specific forms of CCS technology in terms of potential impact. Applications include point source capture as well as distributed opportunities, requiring different modeling approaches. In the case of CCS there is a common underlying technology that could be used for a wide range of applications: amine-based capture. Process modeling bridges to the final step of how to implement a specific technology.

**Figure 4.** Bidirectional flow of information between energy system models and technology R&D models.

## Amine Based Carbon Capture Process

Based on the need to decarbonize various sectors of the global economy, a great deal of R&D has focused on point source post-combustion carbon capture. While there are many different avenues to take CO<sub>2</sub> out of a flue gas stream, to date aqueous amine-based process technology has been proven to be the simplest and most cost-effective method (Herzog 2018). One of these amine-based technologies can be seen in Figure 5.

**Figure 5.** KM CDR Process™ for Postcombustion CO<sub>2</sub> Capture. Courtesy of MHI.

As seen in Figure 5, the process is quite simple. Flue

gas is cooled via direct contact cooling with water (1). It is then sent to an absorption tower (2) where it is contacted with a proprietary, industry performance leading amine-based solvent (KS21) (Kamijo 2023). The flue gas is decarbonized via an intrinsic chemical reaction between the CO<sub>2</sub> acid gas and the basic amine solution. Depending on the design, the percentage CO<sub>2</sub> removal can be anywhere from 90% to 99% removal. Based on recent IEA reports, higher capture rates should be investigated based on the need to reduce CO<sub>2</sub> avoided (still CO<sub>2</sub> leaving the top of the tower) (Thambimuthu 2023). In addition to the amine treating, there are additional clean up steps that occur at the top of the tower (wash sections). The CO<sub>2</sub> that was captured in the aqueous amine solvent moves with the liquid through heat exchangers and is sent to the regeneration tower (3). It is here that steam is used to heat and strip off the CO<sub>2</sub> as a product gas where it can either be compressed/stored or utilized. The regenerated amine is then sent back through the other side of the heat exchanger and the cycle starts again in the absorption tower (2). While a relatively simple process, substantial effort is required to model and predict the process performance accurately.

### Process Modeling Methodologies

When it comes to process modeling, it is always important to understand the model objective. Depending on these objectives, multiple modeling platforms and strategies can be used. Generation of heat and material balances are very useful for understanding steady state energy consumption and steam balance of a CCS plant. These flowrates are also important when designing detailed equipment lists. By combining the two, OPEX and CAPEX can be estimated, financial models developed, and the famous “\$/tonne CO<sub>2</sub>” capture metric can be calculated. It is vital that the underlying assumptions and approximations employed are understood when reporting out such values.

For example, for scoping level estimation of process performance, one may use equilibrium based models for the three towers in Figure 5. This requires an understanding of how to translate a theoretical stage into a specific packing height. Another more accurate method would be to explicitly solve for the packing height via rate based tower models. Software platforms such as ProMax, ProTreat, and AspenPlus all have these features. The Rochelle research group and CCSI are two excellent examples on how to develop these models. Surrogate models can also be developed for detailed process models. Platforms such as Aspen and IDAES are very good for building such reduced order models.

### Linking Process with Plant Economics

While developing models that capture the fundamentals is important for optimization of technical

parameters, it is not enough. Economics must also be understood to make CCS technology investment decisions. This can be a challenge as the skillsets of a research or process engineer may lack project or capital cost estimation. Thus, there has been development on the linkage between process simulators and economic evaluation. For example, the IDAES equation-oriented modeling platform (Miller et al., 2018) has the capability to integrate with cost estimation tools from the Department of Energy (DOE) and the National Energy Technology Laboratory (NETL) as seen in Figure 6.

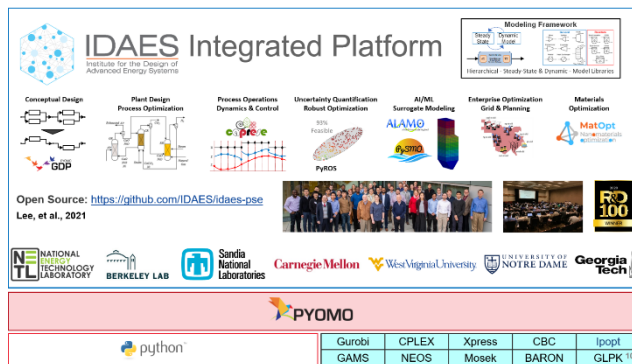

Figure 6. Multiscale IDAES Modeling Platform.

Another example for linking process flowsheet simulation with capital estimation is from AspenTech. Through the concurrent engineering concept of digital thread, a single modeling platform can integrate multidisciplinary teams all working on the same platform.

Through the use of phenomenological, process scale up models, researchers are able to evaluate novel improvement concepts for active materials (amine solvents) at the molecular level. For process engineers, optimal contactor/tower design can be evaluated for these new solvents and integrated into a process design. Various trade offs can be explored on either technical (steam balance) or economic (\$/tonne CO<sub>2</sub> captured) metrics. The end result is a tailored design based on a firm set of model assumptions. This is critical when utilizing these models for energy system modeling.

## BIDIRECTIONAL FLOW AND FUTURE DIRECTIONS

Although there has been extensive work done in the post carbon capture technology space, there is still more work to do. To have an advantaged amine technology, a multiscale, model-centric approach can be used to look at materials (amines), contactors (traditional or intensified), and process configurations to best integrate with current and future power generation and manufacturing plants. As stated before, there is also a need to look at the energy systems scale of states, countries, or even

globally. However, computational intensity becomes an issue based on the shear difference in magnitudes of these systems (molecules to global energy economy). Thus, more academic, government lab, and industrial work should focus on the development of fit for purpose models. These can include: 1) transient models to understand load following and 2) reduced order models for integration in more complex modeling systems (such as IDAES).

A few examples of bidirectional flow of information from post-combustion capture with aqueous amines and energy systems modeling include: 1) reduced-order models (ROMs) as surrogates; 2) transient response of power plants (non-steady operation); and 3) degradation of amine solvent solutions in the presence of flue gas impurities. It is in these three areas that the authors feel like future work should be directed. One great example of this type of work is the FOCUSS (Flexibility Operated Capture Using Solvent Storage) project with SSE Thermal, AECOM, and the University of Sheffield.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge David Tremblay and Mark Lauritsen from AspenTech as well as David Miller from NETL for their help in many technical discussions.

## ABSTRACT

The planetary boundaries (PBs) define ecological limits that are critical to preserve the stability of the Earth. Six of them have already been exceeded, which calls for urgent action to optimize industrial systems capable of operating within the safe operating space that they define for humanity. Here we discuss the challenges and opportunities of including PBs in a range of application domains in Process Systems Engineering, focusing on chemicals and fuels production and the use of mathematical programming coupled with life cycle assessment to support sustainable decision-making.

**Keywords:** Environment, Renewable and Sustainable Energy

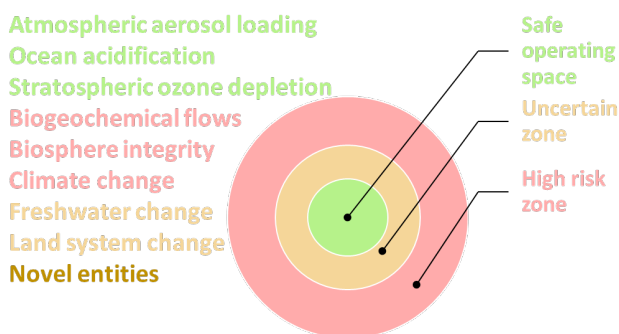

## INTRODUCTION

### The role of the planetary boundaries in the transition to sustainable chemicals

The chemical sector currently faces the challenge of curbing its carbon emissions to meet the climate goals. This will require replacing fossil carbon with renewable carbon as main feedstock, either in the form of captured CO<sub>2</sub> from the air, waste (e.g., polymer waste) or biomass. Unfortunately, emerging renewable-carbon based technologies often lead to inherent trade-offs when compared to the fossil business-as-usual counterpart, not only in terms of cost vs. environmental impacts, but also between environmental categories. For example, chemicals produced *via* carbon capture and utilization (CCU) are often expensive due to the high cost of electrolytic hydrogen, while at the same time could worsen human toxicity impacts owing to the large amounts of renewable power required to activate the CO<sub>2</sub> molecule [1].

This occurrence of burden-shifting (one impact, e.g., global warming, improves at the expense of worsening others) should be carefully investigated to ensure a truly sustainable transition to a defossilized chemical sector. However, while the environmental assessment methods that exist today are useful for comparing alternative technologies, they provide very limited insights into their impact in absolute terms. Because of this, the

broad implications of the large-scale deployment of technologies, specifically concerning their potential global environmental collateral damage, remain unclear, which can lead to spurious conclusions and wrong advice.

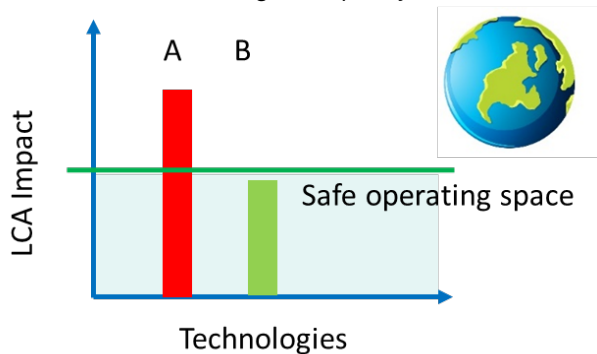

**Figure 1.** Planetary boundaries defined on nine Earth-system processes. Earth-system processes are coloured according to the current transgression level (note that the upper end of the zone of increasing risk has not yet been quantitatively defined for the novel entities PB [3]).

The planetary boundaries (PBs) provide an excellent framework to evaluate the global damage on the planet of emerging routes and the severity of burden-shifting when attempting to combat climate change. The PBs, originally proposed by Rockström et al. [2], define limits on nine Earth-system processes (Fig. 1), all key for

regulating the stability of the planet. For each Earth-system process, thresholds were proposed that define a safe operating space (SOS) for humanity for many centuries to come. Exceeding such limits could trigger critical events that could challenge the resilience of the planet and shift its equilibrium state to a new one with unknown consequences. According to the latest update, six PBs (out of nine) have been already transgressed [3], which calls for urgent action to design and operate chemical systems within the ecological limits of the Earth.

The PBs were not originally intended to be directly applied to industrial systems, yet recent work linking emissions data to impacts on the PBs control variables enabled their application to chemical processes. Standard life cycle assessments (LCAs), the current prevalent approach to evaluate chemical technologies environmentally, lack absolute thresholds to interpret impact values. This shortcoming limits their application to relative comparisons, as already said. Specifically, given two alternative technologies, we could conclude with a standard LCA that one is less environmentally impactful than the other in a given category, but whether they are truly sustainable in absolute terms would remain unclear. The PBs explicitly address this specific question by comparing impact values with a given threshold derived from the carrying capacity of the planet Earth (Fig. 2). If the threshold is exceeded, the system is deemed unsustainable, and would be considered sustainable otherwise. Hence, coupling LCA with PBs allows to explicitly evaluate whether industrial systems operate sustainably within the Earth's ecological capacity.

**Figure 2.** Application of PBs to the assessment of industrial systems. A threshold based on the PBs is established to interpret the impact values quantified *via* LCA.

## PLANETARY BOUNDARIES IN PROCESS SYSTEMS ENGINEERING (PSE)

### Planetary boundaries application to industrial systems

The PBs assessment of technologies comprises two steps (Fig. 3). First, a share of the SOS is assigned to the

system studied following some downscaling (sharing) principles. The SOS should be shared among all economic activities jointly, so shares of the total budget need to be defined and allocated to the specific system investigated prior to the assessment. This is a controversial step on which there is no consensus yet and that can result in different environmental budgets depending on the principle applied. Once the threshold is established for a given chemical system, a standard LCA is conducted. However, in the impact phase, impacts on the control variables of the PBs (rather than standard LCIA metrics) are determined using recently developed planetary damage models [4-5]. In the last LCA step, the results are interpreted, and conclusions and recommendations are provided considering the planet-wide impact of the studied industrial system.

The added value of performing an absolute LCA based on the PBs is that it allows classifying systems as sustainable or unsustainable in each Earth-system process. This, in turn, allows interpreting environmental trade-offs by quantifying the extent to which processes contribute to trespassing global boundaries, not only those linked to climate change.

Step 1: Calculate shares of the safe operating space ( $SoSOS_p$ ).

Step 2: Calculate the transgression levels.

$$\text{Transgression}_p = \frac{\text{IMP}_p}{\text{SoSOS}_p} \forall p$$

$$\left\{ \begin{array}{l} < 1 \rightarrow \text{Sustainable} \\ > 1 \rightarrow \text{Unsustainable} \end{array} \right\}$$

**Figure 3.** Application of PBs to the assessment of industrial systems. First, a share of the SOS is determined. Then, the transgression level is calculated by comparing the impact values with such a share.

PBs were originally defined to monitor the environmental state of the planet Earth. Here I argue that they could also be incorporated into the design and operation of sustainable industrial systems as additional constraints/criteria, to enforce that they ultimately comply with global environmental guardrails that are essential for ensuring sustainable development. This paradigm shift towards PBs-based decision-making opens the door for a myriad of applications, within the chemical sector and beyond, for which computer-aided tools quantifying explicitly the PBs impact of engineering decisions across scales could be developed. While, in principle, any industrial process could be evaluated using the PBs, PBs studies are (arguably) better suited to large-scale systems

with large potential impacts that could destabilize Earth-system processes. For example, PBs assessments of bulk chemicals, such as ammonia, might be more relevant as their current fossil production routes emit large amounts of CO<sub>2</sub> contributing strongly to the transgression of the climate change boundary, regarded as a core planetary boundary. On the other hand, PBs assessments of chemicals produced at smaller scales might be less appealing, as the implications for the planet's stability will likely be less critical. Note, however, that the control variable for the novel entities PB is, in principle, independent of the quantities produced (i.e., percentage of synthetics released into the Earth system) [3], so the above might not hold fully true for this case.

Overall, the PBs framework provides valuable insights out of reach for standard LCAs, and here I suggest that they are adopted in sustainability problems to complement other environmental metrics, ultimately guiding research and policymaking more sensibly.

### Application domains in Process Systems Engineering

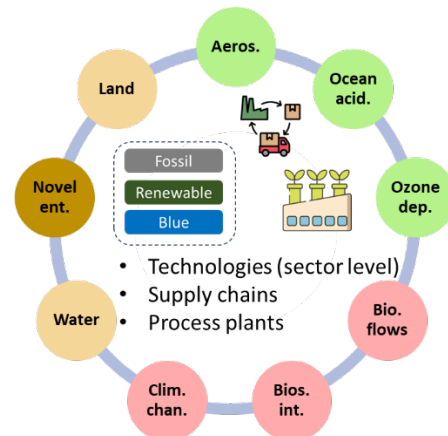

The PBs offer a comprehensive framework to design sustainable chemical systems operating within the SOS. In essence, this could be accomplished by leveraging the existing life cycle optimization framework [6], widely applied in PSE [1, 7-8], in conjunction with the recently proposed PBs characterization factors [4-5]. Following the life cycle PBs-based optimization approach, an optimization model shall be formulated where life cycle assessment principles are explicitly included *via* linear constraints linking mass and energy flows with emissions data and their PBs impact, as shown in the general compact formulation below.

$$\begin{aligned}
 \min \quad & f(x, y) \\
 \text{s. t.} \quad & h(x, y) = 0 \\
 & g(x, y) \leq 0 \\
 & \sum_i CF_{ip} LCI_i \leq SoSOS_p \quad \forall p \\
 & x \in \mathbb{R}^n, y \in \{0,1\}^m
 \end{aligned}$$

Here,  $f(x, y)$  represents the objective function to be optimized, often related to economic performance, whose value is determined from the continuous variables  $x$  (e.g., temperatures, pressures, capacities of supply chain (SC) nodes, etc.), and binary variables  $y$  (e.g., selection of unit operations in a process flowsheet or SC entities in a network problem). Equality and inequality constraints describe the system studied and may include, in addition to the formulas required to compute the objective function value, equations linked to mass and energy balances and thermodynamic constraints in process synthesis problems, or capacity limitations and mass balances in supply chain problems. An inequality constraint

can be added to the model to impose a maximum impact on the PBs. To this end, we link the life cycle inventories entries  $i$  (i.e., life cycle feedstock requirements, emissions and waste calculated for the functional unit taken as a basis in the LCA calculations) to the impact on the control variables of the PBs using tailored characterization factors  $CF_{ip}$  defined for each Earth-system process  $p$ ; moreover, we enforce that the resulting impact should not surpass the share of the SOS allocated to that particular system. Such a PBs constraint might be relaxed, allowing the system to transgress the PBs share, while penalizing such transgression in the objective function using slack variables and penalty coefficients.

The optimization model can take distinct forms depending on the scope of the analysis, e.g., MILP/LP in sectoral and supply chain problems or an MINLP in process synthesis or molecular design problems. We can then capitalize on the rich optimization theory and existing software tools to identify solutions with minimum PBs impact (for further details on mathematical programming applied to sustainable process systems engineering, see [9-12]) Moreover, standard LCAs, extensively employed in the environmental assessments of a wide range of chemical technologies, can be easily enlarged in scope to evaluate the PBs impact, thereby providing additional insights. These conventional LCAs have become very popular in chemical engineering, with increasing applications in the evaluation of low TRL chemical technologies [13].

**Figure 4.** Examples of application domains across scales, including network models optimization (at the sector level), supply chain optimization, and process design.

Focusing on PSE application domains (Fig. 4), the areas of sectoral analysis (network modeling), supply chain optimization and process synthesis seem to offer the largest potential for applying the PBs framework. In network models, a superstructure of technologies is postulated to find the best portfolio to cover the demand of given products, often at minimum cost. Superstructures were for example defined for biomass routes to chemicals and fuels [14], CCU technologies [1] and chemical

recycling pathways [15]. Here the problem is often formulated as an LP, using simplified equations based on linear yields to model technologies. Such simplified network models are typically employed to generate insights into the best routes to meet some demand (top-down) or the best technologies to transform given feedstock into valuable products (bottom-up). The spatial scope can be quite broad, particularly when considering global demands and capacity limitations based on the global availability of resources. Network models are very well suited to identify technologies that are truly sustainable in absolute terms. Here, a share of the global SOS can be allocated to the demanded products to define environmental constraints that should not be violated, as we did in recent work where we studied how to produce plastics sustainably within the PBs [16].

At a higher level of detail, supply chain (SC) models optimize the network topology and associated operations, including the location and capacities of nodes (e.g., plants, warehouses, distribution centers) and the production rates and transport flows between the SC entities. The inclusion of PBs in standard SC formulations is of particular relevance when considering technological decisions, which often lead to critical trade-offs. For example, we recently included PBs in the optimal design of hydrogen supply chains, finding solutions that decrease substantially the pressure exerted on the Earth-system processes by replacing grey with green H<sub>2</sub> [17].

PBs could also be considered in process design problems to find the optimal topology and operating conditions to optimize economic performance while respecting global environmental limits. One option here is to formulate the design problem in global terms, focusing on finding the optimal design of a plant of standard size that could be installed across the world to cover the global demand of given chemicals. Because the technology (chemical pathway) is already fixed here, the potential for environmental gains is typically more modest. This is because once a chemical route is selected, processes implementing such a pathway often operate near the stoichiometric amounts of the required reactants, which often constitute the main environmental hotspot contributing the most to total impacts. Notably, although heat integration can still play a role, impacts (particularly in bulk chemicals) are still mostly dictated by the raw materials' environmental footprint. Consequently, implementing alternative unit operations and optimized operating conditions is unlikely to reduce the impact sharply unless the provenance of the reactants is modified (e.g., grey vs. green H<sub>2</sub> in carbon capture and utilization routes). However, given the large production volumes of some chemicals, particularly bulk chemicals, even marginal improvements are worthy to pursue. Recently, we introduced PBs in the design of a methanol flowsheet, letting the model select the hydrogen source depending on the

objective function optimized. We found that substantial reductions in global impacts can be attained by resorting to renewable carbon feedstock [18].

Lastly, PBs can also be easily incorporated into standard LCAs. For example, using absolute sustainability LCAs based on the PBs, we showed that almost all widespread fossil chemicals transgress at least one PB due to their large CO<sub>2</sub> emissions [19]. We also demonstrated with LCAs based on PBs that current fossil platform chemicals require around one quarter of a planet to operate, also owing to their large carbon footprint, and investigated ways to defossilize chemicals production sustainably by shifting to renewable carbon sources [5].

## CONCLUDING REMARKS

The chemical sector should transition to defossilized technologies to close the carbon loop and operate sustainably within the Earth's ecological capacity. This will require assessing and minimizing the unintended detrimental effects of emerging routes on environmental categories beyond climate change. In this context, the planetary boundaries offer an excellent framework to perform holistic assessments and identify solutions operating within the safe operating space for humanity. Here I argue that due to its systems thinking and powerful computer-aided tools, Process Systems Engineering is in a unique position to embrace this new methodology in current assessments and optimizations of sustainable industrial systems, from molecules, through process to supply chains, sectors and the planet level.

By incorporating the impact on the PBs explicitly in decision-support tools, the broad environmental implications of chemical systems will become clearer. This will allow us to identify the most promising technologies consistent with the planet's ecological capacity early on, guiding experimental research and policy-making more effectively.

## ABSTRACT

In designing low-carbon processes, the unintended emission of CO<sub>2</sub> remains a significant concern due to its global environmental impact. This paper explores carbon management within chemical processes, specifically examining the correlation between the process material balance (PMB) and CO<sub>2</sub> emissions to understand and identify the potential for reducing these emissions. We interrogate the foundational issue of carbon discharge by analyzing the interplay among mass, energy, and entropy balances, which collectively influence the PMB. We introduce the concept of the Target Material Balance (TMB), which represents the material balance of a process corresponding to minimum CO<sub>2</sub> emissions within the given constraints. We could ask what decisions in the design and operation of processes result in higher CO<sub>2</sub> emissions than the TMB. We will focus on the interaction between reactions and recycles and how the arrangement of recycles in processes can inadvertently change the PMB, thereby increasing CO<sub>2</sub> emissions substantially above that of the TMB. We will demonstrate how recycle streams can be introduced to modify the PMB to approximate the TMB more closely. We will finally illustrate these concepts using simple examples, which demonstrate that a carbon-emitting process, such as reforming, can have the TMBs adjusted to create a design that not only reduces carbon emissions but eliminates them entirely.

## INTRODUCTION

Process Systems Engineering (PSE) is a connecting force in chemical engineering, providing both a scientific foundation and computational resources to tackle current and future challenges in areas like energy, environmental science, the 'industry of tomorrow,' and sustainability [1]. The methodologies developed within PSE can be classified into heuristic, insight-based, and mathematical optimization approaches [2]. Heuristic methods leverage the designer's experience and intuition, while insight-based approaches depend on deep understanding and analytical insights.

Heat exchanger network synthesis, commonly referred to as "pinch analysis," is a heuristic method developed by Linnhoff and team in the late 1970s [3][4]. The

approach offers a systematic method for reducing energy consumption in industrial processes by optimizing heat recovery systems.

Mathematical optimization techniques systematically enumerate various potential unit operations, alternate system configurations, process integration structures, operating modes, and other crucial aspects within a superstructure representation. Sorin et al. [5] use a reducible superstructure to minimize a system's exergy. However, the effectiveness of a superstructure-based solution is contingent on the comprehensiveness and richness of the proposed superstructure and process units, with no assurance of identifying the global optimum of the system.

The second law of thermodynamics, or entropy, is seldom explicitly employed in process design [6]. Instead, entropy's application is primarily implicit, such as

in determining phase and reaction equilibria, rather than being directly utilized in the process design or synthesis. Echoing this sentiment, Leites et al. (2003) [7] identify a "lack of understanding" of how second law methodologies can enhance process reversibility as a principal factor behind suboptimal designs, which in turn leads to elevated energy consumption. A review of the methodologies for conducting exergy and energy analyses of thermal power plants notes that most approaches either adopt a superstructure methodology or focus on the analysis and optimization of a specific proposed flowsheet [8]. This highlights a gap in leveraging thermodynamic principles, specifically entropy, more effectively and explicitly in pursuing energy-efficient process designs.

The second law of thermodynamics is implicitly used in process design, for example, by minimizing Gibbs Free Energy to predict chemical and phase equilibrium [9] [10], analyze the temperature dependence of reactions in novel chemistries [11], or predict the effect of feed composition on unwanted side reactions [12].

These methods fall short in offering guidance on the explicit application of second-law analysis for ascertaining the performance limits of a reversible process. The scope of the pinch approach has been extended to encompass targeting for both work and heat exchangers [13]. A superstructure methodology is utilized in order to identify the optimal network configuration.

Process Targeting refers to any methodical procedure for determining the fundamental performance limits of a proposed process pathway based on its inputs and outputs. It enables designers to compare process pathways purely based on thermodynamics, unconstrained by the specifics of design and equipment. This conceptual phase offers the broadest optimization space of any stage of design; the optimization spaces of all subsequent stages of design are just subsets of the optimization space defined during Process Targeting.

By omitting this phase of design, the chosen superstructure or flowsheet may operate within a constrained optimization space that may not contain the global optimal performance and, hence, may impose unnecessary performance limits. The majority of a process's economic and environmental impacts are determined during the conceptual stage of design [14], so it is crucial that the superstructure or flowsheet chosen contains sufficient richness and appropriate interconnections so that its performance is contained in full optimization space.

There is also an argument to be made for Process Targeting based on the scientific principle of Falsificationism – a hypothesis regarding process performance cannot be falsified by a plant design failing to meet the stipulations of the hypothesis because that failure could be attributable to specific design decisions or equipment limitations. Conversely, if the fundamental performance

limits defined by Process Targeting do not meet the stipulations of a hypothesis, then that hypothesis is sufficiently falsified.

Hence, initiating the design procedure with Process Targeting is important for two main reasons – it is more compatible with the defined scientific method than other design approaches that start with equipment and/or a pre-defined flowsheet, and it allows for consideration of a broader optimization space for finding the best-performing processes.

This manuscript seeks to demonstrate this design approach by applying it to a straightforward chemical system in the earliest stages of design, by defining a Target Material Balance (TMB) which serves as a performance target against which subsequent Process Material Balances (PMBs) can be compared at each stage of design. At each stage of design, the available optimization space narrows down to a selected subset of the space defined by previous design decisions and, correspondingly, the limits of the PMB gradually become more constrained with each subsequent design decision.

The TMB serves as a goal, indicating an optimum point in terms of a selected objective function [15], and decisions made at each stage of design can be evaluated in terms of how the new constraints it imposes impacts the PMB, that is moves it further from the TMB.

This approach is intended to adhere to the knowledge-generation standards defined by the Falsificationist scientific method and to thereby circumvent design decisions that impose unnecessary constraints during the early design stages.

The proposed approach [15] [16] [17] uses the deceptively simple concepts of material, energy and entropy balances during the conceptual phase of design, as the first and second laws of thermodynamics dictates the outer limits of the optimization space and therefore, the bounds of the PMB.

Heuristics to improve the reversibility of a process have been suggested, including reducing driving forces and the design of the reactor among others [7]. However, the nuanced impact of choices related to recycles on the PMB tends to be overlooked in the initial design phases. These decisions may inadvertently set the bounds of process efficiency and CO<sub>2</sub> emissions, their impact being locked into subsequent design stages, ultimately influencing the profitability and performance of the operating plant. Recognizing this intricate interplay underscores the need for a more comprehensive integration of mass, energy and entropy/work considerations in the early design stages.

## THEORY

A process can be defined by the set of material balances and associated extents [18]. Consider a set of N

species, where a species  $j$  is denoted by  $A_j$  and  $1 \leq j \leq N$ . We specify that  $j$  must either be a feed to or a product (final or intermediate) of the process. We can represent the set of species as vector  $\underline{\mathbf{A}}^T = \{A_1, A_2, \dots, A_N\}$  where  $\underline{\mathbf{A}}^T$  represents the transpose of vector  $\underline{\mathbf{A}}$ . Let  $n_j$  be the number of moles of species  $A_j$ . We can represent the composition of a process stream as vector  $\underline{\mathbf{n}}^T = \{n_1, n_2, \dots, n_N\}$ .

We denote the number of independent material balances (IMBs) that describe the relationship between the elements of  $\underline{\mathbf{A}}$  as  $S$ . IMBs have also been called independent chemical reactions, but in this paper, we will refer to IMBs, as the IMBs may not reflect or coincide to the actual individual reactions occurring in the process. Different procedures to determine the IMBs have been reported by Yin, (1989) [6].

The stoichiometric matrix  $\mathbf{v}$ , with elements  $v_{ij}$  where  $1 \leq i \leq N$  and  $1 \leq j \leq S$ , is defined such that the  $S$  IMBs can be written as  $\mathbf{v}\underline{\mathbf{A}} = \underline{\mathbf{0}}$ . We define the extent vector  $\underline{\boldsymbol{\varepsilon}}$  of the  $S$  IMBs as  $\underline{\boldsymbol{\varepsilon}}^T = \{\varepsilon_1, \varepsilon_2, \dots, \varepsilon_S\}$ . The relationship between the molar composition of the reaction mixture  $\underline{\mathbf{n}}_{out}$ , the initial or feed composition  $\underline{\mathbf{n}}_{in}$  and the stoichiometric matrix  $\mathbf{v}$  is given by:

$$\underline{\mathbf{n}}_{out} = \underline{\mathbf{n}}_{in} + \mathbf{v}^T \underline{\boldsymbol{\varepsilon}} \quad (1)$$

where the range of  $\underline{\boldsymbol{\varepsilon}}$  is such that all  $n_i \geq 0$

We begin by defining properties that will be used to analyze heat and work flows in a process. The molar enthalpy of component  $A_i$  in a mixture at temperature  $T$  and pressure  $P$  is denoted  $\hat{H}_i(T, P)$ . The molar enthalpies of formation of  $\underline{\mathbf{A}}$  can be combined into vector  $\underline{\hat{H}}(T, P)^T = \{\hat{H}_1(T, P), \hat{H}_2(T, P), \dots, \hat{H}_N(T, P)\}$ . Similarly, the molar Gibbs Free energy of formation vector of  $\underline{\mathbf{A}}$  in a mixture at  $T$  and  $P$  is defined as  $\underline{\hat{G}}(T, P)^T = \{\hat{G}_1(T, P), \hat{G}_2(T, P), \dots, \hat{G}_N(T, P)\}$ , where  $\hat{G}_i(T, P)$  is the molar Gibbs Free energy of formation component  $A_i$  at  $T$  and  $P$ .

The enthalpy of a stream of composition  $\underline{\mathbf{n}}$  at temperature  $T$  and pressure  $P$  is defined by:  $H(T, P) = \underline{\mathbf{n}}^T \cdot \underline{\hat{H}}(T, P)$ . The Gibbs Free Energy of a stream at temperature  $T$  and pressure  $P$  is similarly defined by:  $G(T, P) = \underline{\mathbf{n}}^T \cdot \underline{\hat{G}}(T, P)$ . Consider a process, as shown in Fig. 1, where the inlet and outlet stream are at ambient temperature  $T^\circ$  and ambient pressure  $P^\circ$ , and where a quantity  $Q$  of heat at  $T^\circ$  and work  $W$  are added to the process, as shown in Fig. 1.

An energy balance across the process gives:

$$\Delta H = H_{out}(T^\circ, P^\circ) - H_{in}(T^\circ, P^\circ) = Q(T^\circ) + W \quad (2)$$

Similarly, an entropy balance, combined with eq. (2), assuming reversibility gives, work or Gibbs Free Energy balance:

**Figure 1.** Schematic diagram of mass, heat, and work flows in a generalized process. Note the process is not assumed to be either isothermal or isobaric

$$\Delta G = G_{out}(T^\circ, P^\circ) - G_{in}(T^\circ, P^\circ) = W_{rev} \quad (3)$$

For irreversible processes, the actual work added to the process,  $W$ , is such that  $W > W_{rev} = \Delta G$ . (When  $\Delta G < 0$ ,  $|W| < \Delta G$ ) Thus, more work than the reversible limit (target) is added to processes where  $\Delta G < 0$ , and less work is produced than the reversible limit when  $\Delta G > 0$ .

For the overall process, including utility streams,  $\Delta G \leq 0$  and typically  $\Delta H \leq 0$  in that the process must be designed so as to supply heat and work requirements. Thus, processes need to satisfy the following constraints.

$$\underline{\boldsymbol{\varepsilon}} = (\mathbf{v}^T)^{-1}(\underline{\mathbf{n}}_{out} - \underline{\mathbf{n}}_{in}) \quad (4)$$

$$\Delta H = \mathbf{v}^T \underline{\boldsymbol{\varepsilon}} \cdot \underline{\hat{H}}(T, P) \leq 0 \quad (5)$$

$$\Delta G = \mathbf{v}^T \underline{\boldsymbol{\varepsilon}} \cdot \underline{\hat{G}}(T, P) \leq 0 \quad (6)$$

The PMB is given by  $\mathbf{v}\underline{\mathbf{A}} \cdot \underline{\boldsymbol{\varepsilon}} = 0$  and is thus set by the choice of extents of the IMBs. Furthermore, the PMB also sets  $\Delta H$  and  $\Delta G$  for the process and ensures that eq.(5) and (6) are satisfied. We define the TMB as  $\mathbf{v}\underline{\mathbf{A}} \cdot \underline{\boldsymbol{\varepsilon}}^* = 0$ , where the equality holds for either equation (5) and (6), ie  $\Delta H=0$  and  $\Delta G < 0$  in a heat-limited process or  $\Delta H < 0$  and  $\Delta G=0$  in a work-limited process. The TMB describes the limit or target for the PMB.

We will explore the relationship between the TMB, PMB and flowsheet by using the concept of the process target on a simple, well studied and industrially important process, namely production of methanol from natural gas

### Example: Analyzing the overall process for conversion of methane to methanol

Consider reforming methane to produce 1mol/s of methanol. We define  $\underline{\mathbf{A}}^T = \{\text{CH}_4, \text{O}_2, \text{CH}_3\text{OH}, \text{H}_2\text{O}, \text{CO}_2\}$ . There are only two IMBs in this case, and the set of independent equations will be defined as:

$$\Delta H_I = -164.3 \text{ kJ/mol}; \Delta G_I = -115.6 \text{ kJ/mol}$$

$$\Delta H_{II} = -890.3 \text{ kJ/mol}; \Delta G_{II} = -817.8 \text{ kJ/mol}$$

Defining the extent of the reactions as  $\varepsilon_I$  and  $\varepsilon_{II}$ , respectively, we see that the requirement of a production rate of 1 mol/s of methanol, sets the value of  $\varepsilon_I=1$ . Thus,

we require:

$$\text{From eq(4) : } \varepsilon_I \Delta H_I + \varepsilon_{II} \Delta H_{II} = -164.3 - 890.3 * \varepsilon_{II} \leq 0$$

$$\text{From eq(5): } \varepsilon_I \Delta G_I + \varepsilon_{II} \Delta G_{II} = -115.6 - 817.8 * \varepsilon_{II} \leq 0$$

We see that the above equations are satisfied for  $\varepsilon_I=1$  and  $\varepsilon_{II}=0$ . As  $\Delta H$  and  $\Delta G$  are negative for IMB (I), the process would be exothermic and would be irreversible if work was not recovered from the process. Combusting more  $\text{CH}_4$  via IMB (II) will make  $\Delta H$  and  $\Delta G$  even more negative, consequently increasing  $\text{CO}_2$  emissions.

The PMB for  $\varepsilon_I=1$  and  $\varepsilon_{II}=0$  is:

with  $\Delta H=-164.3$  kJ/mol and  $\Delta G=-115.6$  kJ/mol.

Thus, in principle, 1 mole of methane is converted to 1 mole of methanol and no  $\text{CO}_2$  or water is produced as a waste product. The process will also reject heat, and if no work recovery is in place, it will lose 115.6 kJ/mol of work potential.

According to Monjur et al. (2021) [20], the PMB for a conventional natural gas to methanol process is:

with  $\Delta H=-225.7$  kJ/mol and  $\Delta G=-172.0$  kJ/mol

PMB2 corresponds to extent  $\varepsilon_I=1$  and  $\varepsilon_{II}=0.069$ . Notice that a conventional process produces both  $\text{CO}_2$  and water as waste products and simultaneously rejects more heat and work than PMB1.

Monjur et al. optimizes the natural gas to methanol flow sheet and finds PMB3 with  $\varepsilon_I=1$  and  $\varepsilon_{II}=0.055$  giving:

with  $\Delta H=-213.2$  kJ/mol and  $\Delta G=-160.5$  kJ/mol

We see that this improved design reduces the amount of  $\text{CO}_2$  produced and that both  $\Delta H$  and  $\Delta G$  across the process are also less negative compared to PMB2. Thus, the improved process described by PMB3 would be less exothermic and have less lost work than PMB2. This process still, however, does not match the performance of the original PMB 1, where no  $\text{CO}_2$  was emitted.

We could then ask how we might improve PMB3 even further? Without having a process target, one cannot decide if design decisions were made that impose unnecessary constraints on the process described by PMB 3. One could, for example, falsify the proposition that PMB 3 is optimal by proposing that the  $\text{CO}_2$  and  $\text{H}_2\text{O}$  in the product be recycled back into the process. If this were done, then PMB 3 would be transformed to PMB 1. Notice that introducing the recycles would result in reduced flowrates of  $\text{CH}_4$  to the process and simultaneously reduce the heat and work losses. This seems to be a win-win for increasing plant profitability and reducing

environmental impact.

PMB1 is better than PMB2 or PMB3 in terms of feed utilization, less lost work, and lower  $\text{CO}_2$  emissions. However, is PMB1 the "best" PMB? The "best" PMB is the TMB which requires that either  $\Delta H$  or  $\Delta G$  be zero, and PMB1 does not satisfy this. The process target for this system is work-limited and the TMB for  $\Delta G=0$  corresponds to  $\varepsilon_I^*=1$  and  $\varepsilon_{II}^*=-0.141$ ; giving:

with  $\Delta H=-35.5$  kJ/mol and  $\Delta G=0$  kJ/mol

The TMB corresponds to the process target – no process based on IMB's (i) and (ii) can perform better than this. Furthermore, the TMB can be used to compare processes via the PMB to identify if there are opportunities for improvement in process performance. Any improvements will result in improved  $\text{CH}_4$  utilizing, and simultaneously reduce heat and work losses.

Examining the TMB, we see that both  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  are consumed and, by doing so, the reversible process would convert 0.859 moles of methane to 1 mole of methanol. It might appear, because of the negative value of  $\varepsilon_{II}^*$ , that the TMB requires a unit operation where methane is "un-combusted" or equivalently where  $\text{CO}_2$  and  $\text{H}_2$  are converted to  $\text{CH}_4$ . However, (I) and (II) are IMBs and may not correspond to actual reactions occurring in the process. Although PMB1 was better than either PMB2 or PMB3, it is still very far from the TMB.

In summary, the TMB describes the PMB for a reversible process, and so we would not expect a real process to match the TMB. However, the TMB gives information about how much room there is for improvement in the PMB. It can be used as a guide against which design decisions are made, so that as we take irreversibilities in the process into account by modifying the process and thus the PMB, we can benchmark the impact of the decision on the PMB by comparing it to the TMB.

This approach can also be used on sections of a plant to define the TMB across sections of the plant is and, thus, gives insights on how to integrate the mass, heat, and workflows between sections so as to approach the TMB of the overall process.

### Example: Analyzing the process subsections in the conversion of methane to methanol

Methane to methanol plants typically consist of two subsections, namely a section which generates the synthesis gas, a mixture of  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{H}_2$ , which we will call the reformer section followed by a methanol synthesis section where the syngas is converted to methanol as shown in Fig. 2.

We will again use a production rate 1mol/s of methanol as a basis. Looking further into the process details,

we need to include the components of syngas in the definition of  $\underline{A}$ . Furthermore, water will exist in both the liquid and vapor phases (and thus have different G and H), and so we will include these as two separate species.

**Figure 2.** The methane to methanol process broken in a reformer and methanol synthesis section. Molar flowrates (mol/s) corresponding to the TMB are indicated in black, heat flows in red and workflows in blue

We therefore define  $\underline{A}^T = \{CH_4, O_2, CH_3OH(l), H_2O(l), H_2O(v), CO_2, CO, H_2\}$ .

There are 5 IMBs in this case, and we will define the IMBs in terms of reactions or unit operations that may be occurring in the process, namely:

We can calculate the extent of these IMBs that correspond to the overall TMB. In order to achieve the TMB we require  $\underline{\epsilon}^{*T} = \{\epsilon_{III}^*, \epsilon_{IV}^*, \epsilon_V^*, \epsilon_{VI}^*, \epsilon_{VII}^*\} = \{0.75, 0.109, 0.25, 0.283, 1\}$ . For illustrative purposes, we will specify the composition of the syngas, leaving the reformer section as having ratio  $CO:H_2 = 1:2$ . We will further assume that the liquid feed water is evaporated in the reformer section. Thus, IMBs III, IV, V, and VI will occur in the reformer section, while only IMB VII will occur in the methanol section because of the specified composition of the intermediate syngas is in the stoichiometric ratio defined by IMB (VII). This allows us to determine the TMB of the individual sections of the plant that will be consistent with the overall TMB. Conditions (5) and (6) can be lifted for process subsections, with the understanding that a plant subsection with  $\Delta H > 0$  implies that heat integration needs to be done between this plant subsection and the other, which will be exothermic, namely with  $\Delta H < 0$ . Similarly, a plant subsection with  $\Delta G > 0$  implies that work integration

needs to be done between this plant subsection and another with  $\Delta G > 0$ .

The TMB for the reformer section,  $TMB_{Ref}$ , can be calculated using  $\underline{\epsilon}^{*T} = \{\epsilon_{III}^*, \epsilon_{IV}^*, \epsilon_V^*, \epsilon_{VI}^*, \epsilon_{VII}^*\} = \{0.75, 0.109, 0.25, 0.283, 0\}$  giving:

with  $\Delta H = 90.14 \text{ kJ/mol}$  and  $\Delta G = 29.23 \text{ kJ/mol}$

Similarly, the TMB for the methanol synthesis section,  $TMB_{Meth}$ , can be calculated using  $\underline{\epsilon}^{*T} = \{\epsilon_{III}, \epsilon_{IV}, \epsilon_V, \epsilon_{VI}, \epsilon_{VII}\} = (0, 0, 0, 0, 1)$ , giving:

with  $\Delta H = -128.1 \text{ kJ/mol}$  and  $\Delta G = -29.23 \text{ kJ/mol}$

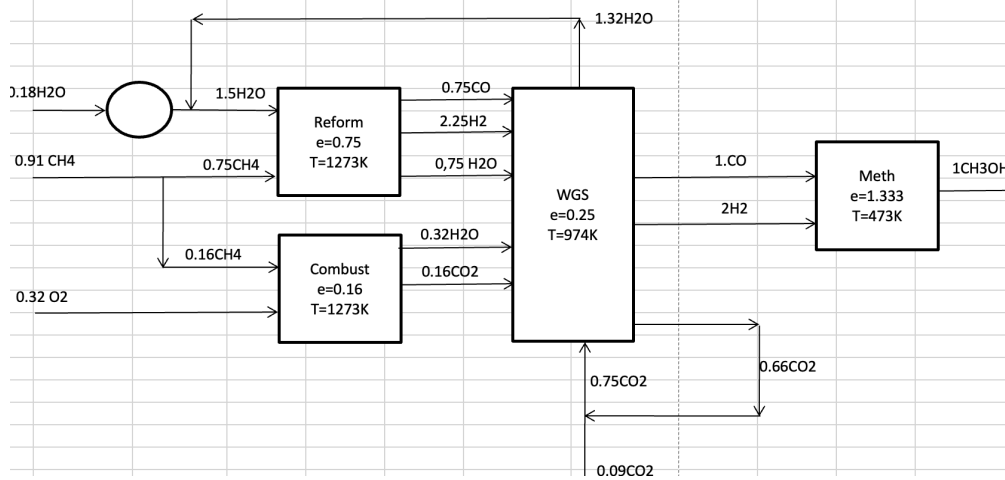

We see that both work and heat will need to be transferred from the methanol synthesis to the reformer section, as indicated in Fig. 2. We will consider the reformer section further to show how we can use the  $TMB_{Ref}$  to develop a flowsheet and related PMB.

### Example: Development of the Reformer Flowsheet using the $TMB_{Ref}$

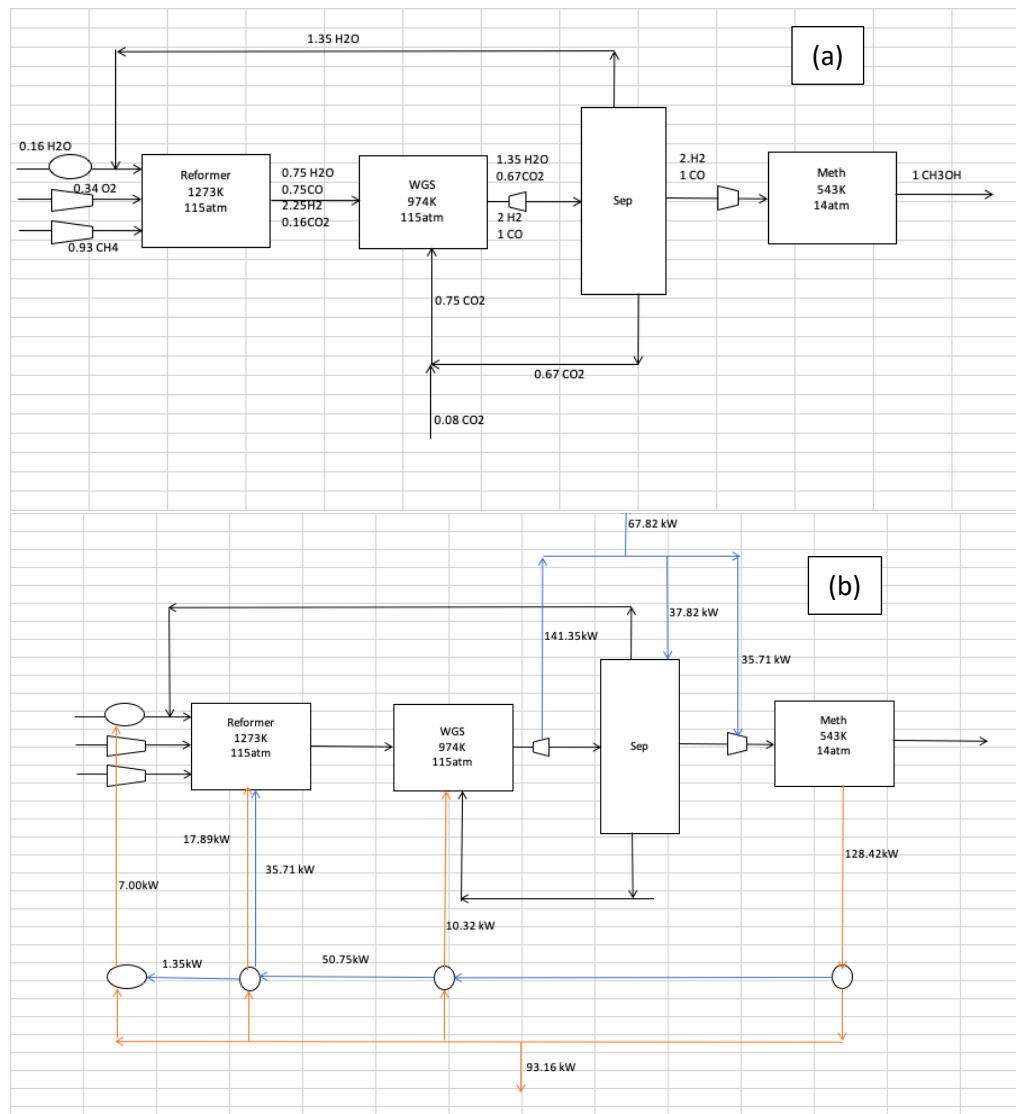

The development of the reformer flowsheet is iterative in terms of setting up the flows and recycles and the heat and work integration. This paper will focus on setting up the mass flows (Fig. 3) and will show an example where heat and mass integration has been incorporated (Fig. 4).

The reformer section consists of a combustion process where  $CH_4$  is combusted to provide the work to drive the reforming reaction, a steam reforming reaction and a water gas shift (WGS) reaction to shift the gas to the correct  $CO:H_2$  ratio of 1:2. The extents of reforming, WGS and combustion are initially set by the  $TMB_{Ref}$ .

There are two exothermic, work producing reactions, namely combustion and methanol synthesis. The amount of work that can be recovered from a process is given by  $\Delta H(1 - T^0/T)$  [16], where  $T$  is the temperature of the heat ( $\Delta H$ ) added or rejected by the reaction. The combustion process is particularly irreversible, as the Carnot temperature for combustion of methane is very large ( $\sim 147000K$ ). Thus, the amount of  $O_2$  fed to the process for combustion must be increased so that the recovered work from both the combustion and the methanol synthesis subprocess is sufficient to supply the overall process work. This is done by increasing the extent of combustion ( $\epsilon_{IV} > \epsilon_{IV}^*$ ) and, consequently, increasing the amount of oxygen and methane fed to the combustion reaction. This design decision introduces process irreversibility which results in the PMB moving away from the target TMB. We describe how the new PMB is calculated below.

**Figure 3:** Example of the molar flows around the reformer section (mol/s) corresponding to PMB 4.

**Figure 4:** (a) Mass flows and (b) heat flows in red and work flows in blue for a process producing 1 mol/s methanol which has been heat and work integrated.

Further design constraints can be specified; for example, we set the reforming temperature at 1273K and specify the ratio of H<sub>2</sub>O:CH<sub>4</sub>=2:1 entering the reformer in order to suppress carbon depositing; as we know the flow rate of methane entering the reformer ( $\varepsilon_{III}$ ) this then sets the water flowrate entering the reformer ( $2\varepsilon_{III}$ ), and consequently the flowrate of water in the stream leaving the reformer as well as the water recycle flowrate. Setting the reforming temperature sets  $\varepsilon_{IV}$  as we require that the work rejected by the combustion when the heat is rejected at 1274K, and methanol synthesis reactions must supply the work for the reforming process, i.e.:

$$\varepsilon_{III}^* \Delta G_{III} = \varepsilon_{VII}^* \Delta G_{VII} + \varepsilon_{IV} \Delta H_{IV} \left(1 - T^0 / 1274\right) \quad (7)$$

Solving eq.(7) gives that  $\varepsilon_{IV} = 0.16$ , thus setting the flowrate of O<sub>2</sub> to 0.32 mol/s, and the flowrate of methanol entering the combustion process as 0.16 mol/s, which ensures that sufficient work is supplied to the process once the irreversibility of work transfer from combustion is taken into account, as shown in Fig. 3.

In order for the WGS reaction to operate at its Carnot Temperature  $T_c$ , we require that the WGS equilibrium constant,  $K_{WGS}$ , be 1 (i.e.  $\Delta G(T_c, p) = 0$ ), which corresponds to an operating temperature of  $T_c = 974$  K. As we know the flow rate of CO, H<sub>2</sub> and H<sub>2</sub>O leaving the WGS reactor, we can then determine the amount of CO<sub>2</sub> in the product stream of the WGS reactor so as to meet the requirement that ( $K_{WGS} = 1$ ); this then allows us to subsequently calculate the CO<sub>2</sub> recycle flowrate. The resulting flowsheet is shown in Figure 3. The PMB for the overall process in Fig. 3 is given by:

with  $\Delta H = -83.65$  kJ/mol and  $\Delta G = -42.38$  kJ/mol

The PMB for the reformer section is described by:

with  $\Delta H = 44.4$  kJ/mol and  $\Delta G = -12.8$  kJ/mol

The PMB<sub>IV</sub> consumes less CO<sub>2</sub> than the TMB; however, it is considerably better than the PMB's 1, 2 or 3 given earlier. This is mainly due to the use of recycles to ensure that we approach the TMB more closely than in the previous processes. The process flowsheet can be iteratively developed to ensure that the workflows to each section are such that  $\Delta G \leq 0$  for each reaction system. Work can, for example, be *added* to a process by operating at high pressure when there is a decrease in moles of gas across the process. The exact operating pressure can be calculated to ensure that the correct amount of work is added via this route. The flow sheet can be developed, taking temperature constraints and

work flows to ensure that  $\Delta G \leq 0$  in each reactor, and an example of the flow sheet that is mass, heat and work integrated is given in Figure 4 [8]. This process not only consumes CO<sub>2</sub>, but also produces 67 kW of work (based on a production rate of 1 mol/s methanol).

## CONCLUSION

The TMB represents the overall process material balance for either a reversible process (in the case of a G-limited process) or an adiabatic process (in the case of an H-limited process). The TMB also sets the limiting process heat and work flows. The TMB represents the limit of performance of the process; thus the overall material balance across a process, which we refer to as the PMB, may at best, in the limit approach the TMB. The further the PMB is from the TMB, the more room for improvement there may be. Any design decision that results in a sizable departure of the new PMB from the TMB therefore represents the introduction of irreversibility which constrains the performance limits for subsequent design steps.

The TMB can be calculated using only the Gibbs Free Energy and Enthalpies of formation of the feed and product species. The TMB in the case of a G-limited process corresponds to the situation where the chemical potential of the feed (s) is conserved in the product. It also represents the limiting amount of CO<sub>2</sub> that is emitted from a process.

A design procedure can, therefore, reliably and falsifiably search for optimal processes by first defining the TMB and comparing the subsequent PMBs resulting from subsequent design decisions against that benchmark. In this way, the TMB can be used as a tool for iterative design, which conserves as much of the feasible optimization space as possible through each stage of design.

The TMB can also be modified by the inclusion of specific constraints that may reduce the optimization space, such as heat transfer occurring at temperatures other than the process or reaction Carnot temperature. Thereafter, in the case of reversible reactions, recycles can be introduced to ensure that the desired extent of reaction is achieved. In this way one can work toward the desired TMB rather than accepting the PMB given by a simulation.

While the TMB represents a performance benchmark that might not be achievable in real processes, it is useful as a means of identifying, and hopefully avoiding, design decisions that prematurely constrain the optimization space for design which can in some case result in both carbon release and inefficient utilization of the feed. It is also a useful basis of comparison between processes of differing levels of technological maturity, where it can identify which processes have the most inherent potential regardless of current levels of optimization and equipment design, making them a useful tool for long-range

planning and R&D investment decisions.

## ABSTRACT

This work presents an overview of the path towards the use of renewable and nonconventional resources for a sustainable chemical and process industry. The aim is not only to lead the way to meet the sustainable development goals but also to maintain the style and quality of life achieved by the technologies and products developed within this sector. Alternative raw materials are to be used and processed differently while a new paradigm for utilities is to be established. The development of technologies and their deployment faces several barriers that we as process engineers can help overcome by providing insight into the alternatives, the thresholds to achieve to become competitive, and strategic analyses.

**Keywords:** Process Design, Renewable and Sustainable Energy, Modelling, Process Synthesis, Energy Storage

## INTRODUCTION

The current chemical and process industry stands at a crossroads. Over the last decades its products have provided a lifestyle and wellbeing to society non precedented. Even though there are thousands of chemicals, most of them can be directly related to eight building blocks (ammonia, methanol, ethylene, propylene, benzene, toluene, and mixed xylenes) that are typically produced from fossil resources. Energy intensive chemical production processes consumed 14% of global oil and 9% of global gas and released 13% of global industrial direct CO<sub>2</sub> emissions in 2020,<sup>1,2</sup> it represents the largest energy consumer and the third largest direct CO<sub>2</sub> emitter.<sup>3</sup> Adding to production the use of the product, the chemical industry accounts for 45% of global greenhouse gas (GHG) emissions. Therefore, reducing the use of resources this sector, it is possible to cut the global emissions by 39% (22.8 Bt).<sup>4</sup> These processes can be divided into different business such as chemicals (including consumer products and pharma), food and beverage, petroleum refining, iron and steel, cement, among others that required utilities of different grades.<sup>5</sup> Thus, the transition towards a new process industry starts from the raw materials but it also must include the utilities required to process them into the final products, such as thermal and electrical energy or water, see Figure 1.<sup>6</sup>

**Figure 1.** More sustainable production system

In the path to meet the sustainable development goals both aspects are to be addressed simultaneously. However, the problem has been addressed by pieces by different research groups. The efforts have been placed either on evaluating alternative sources for the chemicals or the production of utilities. A wider and more systematic view<sup>7</sup> is required for the integration of resources and

technologies, and the selection of the best use of the natural resources towards sustainability.

In this perspective, we present the different efforts and challenges at process scale and at strategic level as well as the barriers<sup>8</sup> new technologies face that include the social perspective.<sup>9</sup> Once the information is on the table, the opportunities that process system engineering has to offer to help overcome those barriers and contribute to the sustainable transformation of the chemical industry are presented. Chemical engineering has contributed to the past industrial transitions, there is no reason to think why it is not possible to do that again.

## STATE OF THE ART ON THE TRANSFORMATION TECHNOLOGIES

In the path towards a sustainable chemical and process industry there have been several efforts in parallel, raw materials, utilities and the process design itself, but that are intrinsically related. Over the last years there has been a trend to evaluate the possibility of substituting the production of basic chemicals from biomass and waste, specifically the major building blocks, see Figure 2.

**Figure 2.** Use of CO<sub>2</sub> as raw material

### Renewable Raw Materials

It is expected that by 2050 the chemical system will reduce the use of fossil feedstock down to 10–42%.<sup>1</sup> While the early works focused on the use of biomass and wastes to produce biofuels such as ethanol or biodiesel<sup>1</sup>, the extension of the application to substitute fossil fuels has been limited so far. Beyond ethanol and glycerol, as biodiesel major byproduct,<sup>10</sup> that can be used as a source of other chemicals including monomers, (i.e. ethylene, butadiene), the production of platform chemicals from biomass (i.e. Dimethyl furfural, xylitol)<sup>11</sup>, as well as specialty chemicals, (i.e. limonene, phenols)<sup>12,13</sup> has been the follow-up effort. So far two main barriers have been identified, their economics, the higher production cost<sup>1</sup> and the tight margins of the bulk chemicals<sup>14</sup> together with the fact that the petrochemical industry and the related

business are well established. The additional processing steps required in waste processing add cost to the final product, even if the raw material is cheap or even free,<sup>15,16</sup> so that the use of residues is first and foremost a waste management strategy before a true starting point for a circular economy. Only in the case of high added value products it is interesting to use biomass as a resource and biorefineries that produced them as principal product, together with others including biofuels and/or utilities are the most interesting processes.<sup>12,13</sup> The similarities between the crude oil refineries and thermochemical biorefineries have provided the opportunity to retrofit conventional facilities into biobased ones.<sup>17</sup>

The discussion extends and holds true for CO<sub>2</sub> as raw material.<sup>18,19</sup> The increase in the CO<sub>2</sub> concentration in the atmosphere is one of the major concerns because of its effect on global warming. While it is possible to capture it from point sources such as industries (cement, steel) and power plants, direct air capture (DAC) has become an interesting technology to reduce the CO<sub>2</sub> already in the atmosphere. However, recent works show that the energy consumption to capture and further use of the CO<sub>2</sub> can represent a high share leading to a high level of related emissions due to the capture step unless less carbon intense technologies and resources are used to produce PV panels and wind turbines.<sup>20</sup> Utilization of CO<sub>2</sub> rather than just sequestration<sup>21</sup> can provide a way to create a circular economy around it, once the levels in the atmosphere are back into acceptable ones. The use of renewable energy to process CO<sub>2</sub> is one of the first cases of integrating alternative energy sources as utilities within major chemical processes. As a result, CO<sub>2</sub> has been the base for e-fuels including methane, methanol, Dimethyl ether (DME), Fischer Tropsch-fuels among others. The reduction of CO<sub>2</sub> via hydrogenation<sup>14</sup> or electroreduction<sup>22,23</sup> are possible technologies that have been evaluated towards the production of methanol or ethylene and all the way to polymers. However, some are still at low TRL. In addition, most of them can be produced also from biomass, several studies compare both alternatives.<sup>14</sup> Comparing CO<sub>2</sub> and biomass as raw material for the same product, biomass-based processes require more processing stages to prepare the syngas, but in general they are more mature technologies while the need for renewable based electricity results in higher investment costs in Solar panels and wind turbines. In addition, the need to overdesign of the units to operate over a year or the storage of hydrogen represents an additional burden. Biomass based products show lower production costs<sup>14,24</sup> but biomass availability is limited, and it has a wider spectrum of final products represents a decision on the best use is yet to be taken. But it has to be made not at process level, but a more strategic one which calls for a multiscale approach.

### Sustainable Process Design

Process design towards efficiency in the use of energy and raw materials is and has been the first step towards sustainability. Selection of processing paths and technologies is an important synthesis problem to be solved. The catch is that novel technologies present a lack of information on their operation and/or the uncertainty in their performance. Modelling and simulation are key for process synthesis and represent a challenge when dealing with novel technologies, but first principles can help and provide the first approach while artificial intelligence (AI) is becoming a powerful tool also. Apart from the economic feasibility, the distributed availability of the resources also jeopardizes the facilities using alternative resources. No longer scale-up and economies of scale play an important role but scale down and the effect that it has on the selection of technologies to build a process.<sup>25</sup> Distributed production and modularization are part of the new design approaches for the exploitation of biomass, solar and wind energy.<sup>26</sup> This is also true for the case of small nuclear reactors<sup>27</sup>, see Figure 3, which also adds the social acceptance as a variable to the deployment of non CO<sub>2</sub> based technologies. To help in the path, circular process design, such as the effort in plastic recycling,<sup>30,31</sup> creating a circular economy around CO<sub>2</sub>, process integration to avoid the use of external chemicals<sup>2</sup> and intensification<sup>32</sup> are additional tools to be developed and implemented.

## Renewable Utilities

It is also important to highlight another line of work that typically progresses in parallel with the production of chemicals. The transformation processes require energy and cooling. Even if the raw material is a residue or a renewable resource, the utilities required must also be provided avoiding fossil-based CO<sub>2</sub> emissions. This has been a common weakness in the analysis of the process. Either the utilities are decarbonized and/or new technologies are to be implemented. However, even new processes using unconventional raw materials have been built based on the same principles, so that the same utilities are used.<sup>28,29</sup>

Utilities refer to electricity and heat representing 20 % and 80% respectively of the total energy consumption in the production of chemicals.<sup>29</sup> Therefore, utilities decarbonization means heat decarbonization,<sup>28,35,36</sup> all the way from steam decarbonization,<sup>37</sup> either using biofuels<sup>20</sup> or hydrogen for high temperature requirements<sup>38</sup>, to the electrification of the units, refrigeration cycles<sup>39</sup> including heat pumps cycle lay out and fluid selection,<sup>40</sup> or the use of Solar based ones such as gasification or reforming or to provide energy for endothermic reactions in general.<sup>41</sup> In addition, recovering heat from waste streams to produce power<sup>33</sup>, and water network<sup>34</sup> design require additional analysis but is proven to reduce the need for external resources.

**Figure 3.** Scale down of technologies. effect on the facility and on the surroundings<sup>27</sup>

As in the case presented for the transformation stages, the use of nonconventional utilities requires unit and process design. In addition, novel process approaches such as intensification, plasma technology, ultrasound microwaves and others have reduced the costs and the generation of wastes.<sup>29</sup> Some of them are related to the use of utilities differently. The design of such novel units is still in their infancy and involves the concept of process and product design and requires considering additional principles beyond traditional chemical engineering since solar and electrical heating are involved. Transport phenomena, unit operations and reactor engineering need to team up with electrical engineering and electro chemistry and can play an important role for the new technology to become competitive. The role of minerals and their availability to build these units can represent another limitation on the extent of the expansion of the penetration of renewable energy.<sup>42</sup> So far only pilot plant scale studies are available. The MeOH is among the first examples of defossilization considering both the raw materials and the utilities involved.<sup>24</sup>

CO<sub>2</sub> utilization as well as utilities decarbonization is linked to the use of renewable energy and electricity and green hydrogen. Carbon capture and utilization (CCUS) involves the production of chemicals out of it, including methane, DME, methanol or urea creating a circular economy for CO<sub>2</sub>. But it is also possible to fully avoid the use of carbon-based chemicals developing non-carbon-based power plants<sup>44,45</sup> via the temporal storage of hydrogen ammonia, MgH<sub>2</sub><sup>44</sup> or Liquid organic hydrogen Carriers (LOCHs). In all these cases, the integration of solar and wind within the chemical transformation is key and affects process design.

## Challenges of Process Operation Integrating Variable Resources

Management of highly volatile resources such as wind and the Sun calls for process and resource integration<sup>46</sup> as well as smart storage, where chemicals can play an important role<sup>47</sup> to reduce the need to build batteries beyond the minerals availability.<sup>48</sup> The operation of

processes that rely on variable resources, variable because of their composition, i.e. biomass, or availability, solar and wind, results in demand site management problems that have been addressed at small scale<sup>45</sup> due to their complexity. In addition, most of the work in heat integration of power to heat for process industries integration has used the pinch technology, but the use of mathematical optimization has proven a powerful tool that has been used traditionally in the petrochemical industry and for the penetration of renewables but the full electrification results in problems that are mathematically really complex due to the variability of the resources and novel tools are being developed<sup>49,50</sup>

### Assessment of Process Sustainability

One question arises here, when a new process is more sustainable than the one is trying to substitute. Recent studies have posed that question and presented interesting results for several examples.<sup>51,52</sup> Further analysis is required to cover the entire spectrum. One on the current limitations is the tools to quantify the environmental impacts. LCA analysis present limitations when novel technologies are evaluated due to the lack data to characterize them. Similarly, the technoeconomic analysis of processes involving novel biomass pretreatments, energy collection technologies as well as new units that substitute the current state of the art to provide utilities<sup>53</sup> to the process represent an additional challenge.

## DEPLOYMENT OF TECHNOLOGIES

Process level provides the feasibility analysis of the technology and the economic and environmental evaluation that can establish the need for improvements until it can become competitive. But for the production of really high added value products, i.e. polymers or active ingredients for food or the pharma industry,<sup>12,13</sup> additional incentives are needed to substitute/modify production processes that require several years amortization. By enforcing emission levels and providing incentives<sup>54</sup> is how Europe,<sup>55</sup> or the US have been moving towards net zero emissions. However, the transition, the deployment of a decarbonized chemical industry, is to be carried out at a larger scale, at strategic scale. It is at this scale that the incentives need to be designed.

Multiscale approaches have been typically presented within the process community to be able to present strategic decisions to the decision makers, either stakeholders or the governments, see Figure 4.<sup>17</sup> These models require real data, that sometimes are not easy to find, the proper scale-up of the process so that the comparison among alternatives is consistent,<sup>56</sup> an issue that is sometimes overlooked, and the problem, if formulated, is highly complex to solve. Several cases of study are available for biofuels, power at country and continental

level<sup>57,58,59</sup> showing certain limitations as how far we can get. European size examples for electricity and fuels alone are the work of many groups and special solution techniques, variable aggregation, reduced area and time discretization are to be implemented.<sup>57</sup>

However, these studies use the resources towards a particular target. The actual issue is when the raw materials are to be shared to meet the current demand of all products, how far is it possible to get using waste biomass, residues, and renewable resources in general<sup>1</sup>. The ultimate question is what is the best use of the limited resource? what to produce out of it? Therefore, the decision boils down to the availability of natural resources required<sup>60</sup>, including water<sup>61</sup>, area, or mineral among others and the social, environmental, and economic advantages of producing it via that path. Area, water, and nutrients are needed to grow biomass, area is required to install PV panels and wind turbines as well as heliostat fields. To build these units as well as others such as electrolyzers, or bateries<sup>62</sup> we need minerals. Preliminary studies show that it is not possible to cover the first generation of electrified systems, the one that will allow start recycling.<sup>60</sup> On the one hand the actual availability of area, harvesting sites and soil properties have lately been analyzed via GIS, originally for food production<sup>63</sup> but also as a potential for energy crops<sup>64</sup>. To reduce the use of area several strategies arise such as the use of the residues from food production, beyond the needed for animal feed, as well as novel developments in PV panels that are transparent and allow for biomass growing in the same field<sup>65</sup>. On the other hand, planetary boundaries have been presented as a way to evaluate how far it is possible to go with the natural resources,<sup>60,66</sup> but show several issues on how we allocate the possible growth. Such a problem is basically the combination of some of the ones presented for the different cases but has not been addressed so far.

Strategic studies also allow evaluating the social issues that the deployment of the new system can bring to regions that host the new facilities<sup>44</sup>. How to measure circularity and the social impact of the transformation of industry require further analysis and metrics beyond the ones available such as job based<sup>5</sup> indexes and marginalization.<sup>67</sup> The challenge may not be to decarbonize industry but to get to zero net emissions and to create an economy that makes the best use to the resources substituting those that are harmful for the system creating circular economies for those wastes to avoid accumulation in the system.

**Figure 4.** Deployment of technologies

## OVERCOMING THE BARRIERS: INCENTIVES AND SOCIAL IMPACT

The transition to a new system presents opportunities in terms of generation of wealth and jobs due to the installation of transformation facilities. But at the same time, the transition is closing down business, i.e. coal mining and thermal power plants.<sup>44</sup> As such, the decision on where to install them poses a number of social impacts. The first barrier to address is *the social or behavioral one*. Acceptance of a technology has been related to the psychology in product selection, that has been a field of study over the last decades. There is a high activation energy to change. This is similar to customer loyalty to a brand. To address these issues, international agencies campaign to present the need and benefits, such as the United Nations with the SDGs<sup>68</sup> and the effort to convince the population that another production and consumption system is possible. These organizations require systematic studies to provide with reliable data to be able to come to those advertisements. Acceptance of a technology may have an additional positive outcome. On the one hand, society can push their governments to change if the people are convinced. On the other hand, it can be a barrier. One example is nuclear power. Recent efforts focus on small reactors to avoid the society concerns on large facilities close to the cities, see Figure 3.<sup>27</sup> Psychological factors also affect the investors since they need to envision benefits.<sup>54</sup> Apart from this barrier, technical barriers are in place.<sup>69</sup> The *technical barriers* are the ones presented along the first sections of the paper. It is something we as engineers are directly involved in. The third barrier is the so-called *Organizational barrier*. It depends on the companies that are running the business. It is somehow related to the first one in the sense that there is a psychological aspect behind. They need to see the advantage of the new technology. It can also be linked to the incentives that they are going to get.<sup>54,70</sup> Being the first operating a technology provides expertise, at a cost. Technology lock-in only appears when it is widely used<sup>71</sup>. Governments, agencies and other associations, (i.e. EU, UN) play a role in that. The creation of incentives, to

reduce taxes or impose ones to certain technologies, help in the development of the technologies and reduce bureaucracy,<sup>54,72</sup> and present targets such as the ones in emissions or temperature increase, has been the usual one. From the systematic studies of the entire system, it is possible to design and define such incentives since they identify the bottlenecks of the technologies themselves as well as their deployment. The competitors also represent a barrier. New technologies come to take a piece of the cake and represent a threat to a running business. However, some of the companies are already diversifying their portfolios to embrace alternative resources.<sup>54</sup> Finally, *political barriers* are somehow linked to the ideology that not all the times is linked to scientific facts and have an effect on the organizational and the social but also on the development of the technologies due to the incentives Governments can assign and the campaign in favor or against it.

We as process system engineers can play a role in most of them by providing tools, and results that can support the selection of new technologies, the breakeven points (the threshold effect) for one technology to be deployed as well as scenario based analysis for the decision makers to be aware of economical, environmental and social issues as well as defining the incentives<sup>73</sup> required for a particular transition to occur or for a technology to enter the market

## CONCLUSIONS

In this perspective we aimed at presenting the current trends to pave the way towards a more sustainable production system, but in particular, to transform the chemical and process industry into a more sustainable operation. The barriers new technologies are to face come from society itself as well as the stakeholders. Process system engineering, with its systematic analysis of technologies and multi scale studies, are in a pivotal role to provide insights for the decision makers to select the best use of resources considering not only economics and environmental metrics, but also the social impact that the deployment of the new technologies can have.

## ABSTRACT

Sustainability and circular economy enclose initiatives to achieve economic systems and industrial value chains by improving resource use, productivity, reuse, recycling, pollution prevention, and minimizing disposed material. However, shifting from the traditional linear economic production system to a circular economy is challenging. One of the most significant hurdles is the absence of sustainable end-of-life (EoL)/manufacturing loops for recycling and recovering material while minimizing negative impacts on human health and the environment. Overcoming these challenges is critical in returning materials to upstream life cycle stage facilities such as manufacturing. Chemical flow analysis (CFA), sustainability evaluation, and process systems engineering (PSE) can supply chemical products and processes performances from environmental, economic, material efficiency, energy footprint, and technology perspectives. These holistic evaluation techniques can improve productivity, source material reduction, reuse, recycling, and prevent and minimize releases and disposal rates. Therefore, this contribution offers a computational framework that covers CFA, sustainability assessment, and risk evaluation for quantifying the benefits and challenges of chemical circular economy routes versus conventional linear systems. Finally, this contribution shows promising techniques and challenges for employing CFA, sustainability evaluation, and PSE as multicriteria decision-making tools for designing a closed-loop chemical management infrastructure and transforming the US chemical industry sector from linear to circular.

**Keywords:** Supply Chain, Life Cycle Analysis, Modelling, Machine Learning, Wastewater

## INTRODUCTION

### Tracking Chemicals and Releases at Industrial End-of-Life Activities

The Frank R. Lautenberg Chemical Safety for the 21st Century Act amended Toxic Substances Control Act (TSCA) instructs the US Environmental Protection Agency (USEPA) to conduct risk evaluations of existing high-priority chemicals to find whether a chemical substance in the US market may pose an unreasonable risk of harming the environment or human health across its life cycle stages (manufacturing, use, end-of-life (EoL))

[1]. Therefore, chemical risk evaluation supports alternative assessments of selecting chemicals and materials with safer profiles and ensures sustainable circular economy paths (recycling, reusing, and recovering processes). However, the list of registered chemicals used in US commerce continuously grows. Also, data gathering, reconciliation, and management for performing life cycle risk evaluation are time-consuming and challenging. Notably, evaluating the chemical risk and safety at its EoL stage is more difficult due to high uncertainty, less data availability, variability, material blends, and the absence of directing requirements for proper reporting and traceability.

Several efforts aim to create a data engineering framework for building an EoL database and tracking chemicals at their EoL stage. This framework performs a data engineering procedure to gather, clean, wrangle, and integrate information from publicly available USEPA databases such as the Toxics Release Inventory (TRI), the Facility Registry Service (FRS), and the Substance Registry Services (SRS). Furthermore, the framework supports data cleaning, filtering, filling data gaps, and transformation into machine-readable queries to address and enhance chemical risk evaluation of chemicals of concern.

As described in **Figure 1**, the first module of the EoL framework addresses EoL flows generated by industrial facilities (manufacturing and industrial use life-cycle stages) and transferred for further EoL management at recycling, energy recovery, treatment, and disposal facilities (RETDFs). Also, a case study of methylene chloride (dichloromethane) showed the practicality of the developed framework for tracking and analyzing EoL chemical flows from the generator industry sector of a chemical (e.g., inorganic chemical manufacturing), conditions of use (e.g., reactant, formulation component, products), the EoL facility industry sector (e.g., cement manufacturing), EoL activity (e.g., recycling, incineration, landfill), and the environmental compartment (e.g., net recycling, onsite soil releases, etc.), and estimating potential releases at EoL activities [1].

Moreover, Hernandez-Betancur et al. (2021b)

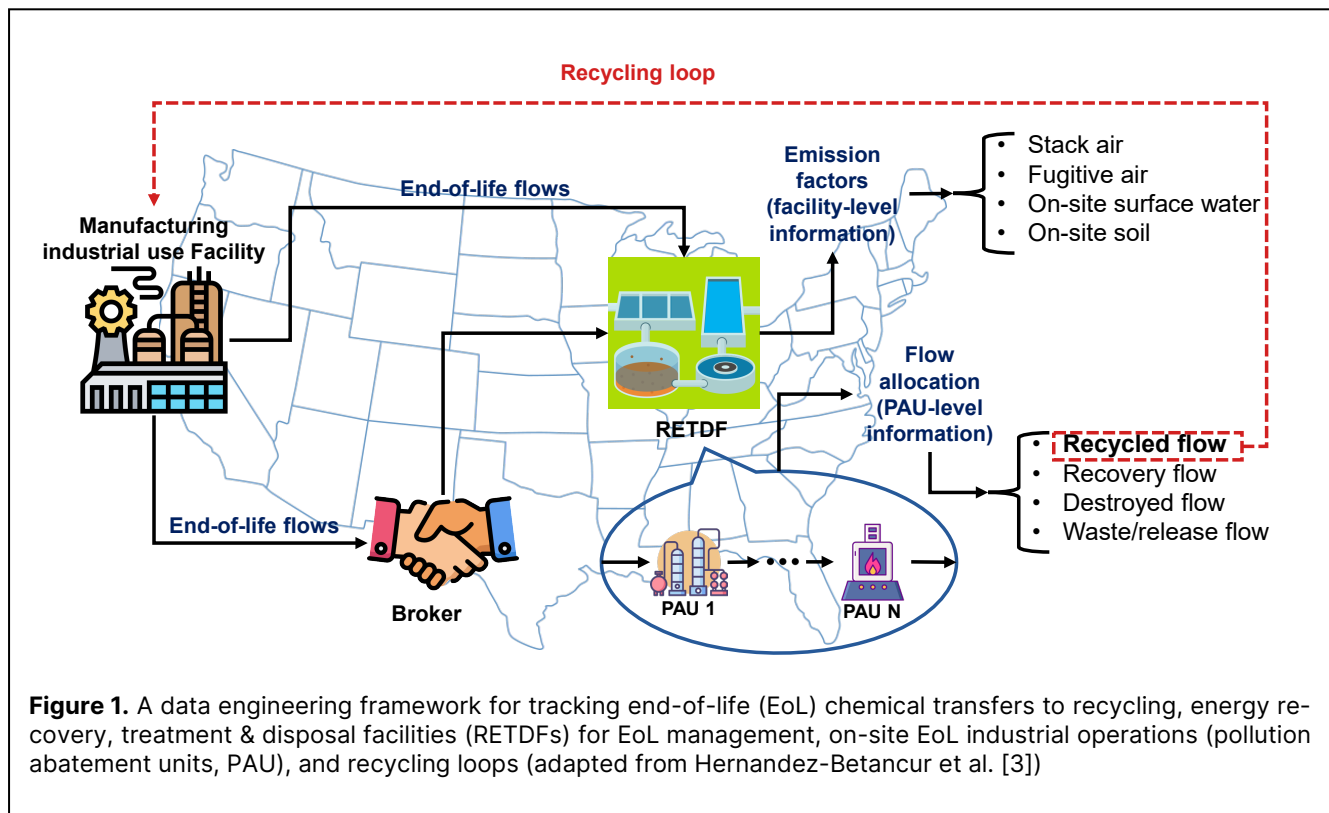

enhanced the data engineering framework by using EoL pollution abatement units (PAU)-level information, chemical process design, and equipment performance data for calculating emission factors and distributing releases [2]. On-site EoL activities consist of PAUs like distillation, aerobic treatment, neutralization, incinerator, etc. The enhanced framework also offers structure design alternatives, efficiencies, chemical releases, exposure media, operating expenses, and capital expenditures for the PAU operations.

Although the developed data engineering framework estimates EoL industrial releases and distribution, it must supply potential circular economy paths and destination of recycled/recovered chemical flows transferred to upstream chemical life cycle stage facilities (e.g., manufacturing).

## METHODOLOGY

### Data Analytics Techniques Supporting Safer Circular Economy Paths

The presence of chemicals causing significant adverse human health and environmental effects during EoL stages is a challenge for implementing sustainable materials management efforts towards a circular life-cycle path of chemicals. Therefore, conducting chemical risk evaluation and exposure assessment of potential EoL scenarios can aid the understanding of the chemical EoL management chain for its safer use in a circular life-cycle

environment.

Thus, we enhanced the data engineering framework by implementing probabilistic graphical models like Markov random field to mimic the relationship between the chemical EoL management components like the EoL flow generators, RETDFs, and manufacturing facilities [3]. The updated framework finds potential safer circular economy scenarios for recycled chemicals. These circular economy scenarios consider whether the recycled chemical might end up in industrial, commercial, consumer uses, and processing operations. Additionally, the framework can find if the recycling activities target the chemical under analysis instead of managing other chemical substances, such as the EoL multicomponent material flow transfers. The novel approach also considers regulatory constraints on closing the recycling loop operations and supplies an estimation of environmental releases related to occupational exposure.

## RESULTS AND DISCUSSION

Completing life cycle and sustainability analyses requires adapting different strategies based on the varying levels of information available. In this computational framework, data-driven model systems may be used to accurately track and predict material pathways throughout the life cycle when process, chemical, and material exchange information are available in larger quantities. Conversely, chemical flow analysis (CFA) may be used to qualitatively map the allocation of chemicals and quantify the relative mass flow distribution across EoL pathways and technologies. The output of these material tracking methods can establish a basis for sustainability analysis because the process efficiency and material releases can be calculated. With sufficient process-level information, PSE models can enhance the granularity of the chemical release approximation, such as releases from individual process units. Subsequently, the operation details can be acquired and used to identify the potential occupational exposure scenarios and areas of improvement throughout a chemical life cycle analysis to achieve a circular economy.

### Data-Driven Model Systems to Estimate Releases from Novel Chemical End-of-Life Scenarios

Hernandez-Betancur et al. (2023a) enhanced the EoL database by integrating cross-year and country data and considering the change of the regulatory foundations across different geographical locations and reporting years [4]. Thus, the data engineering framework is scalable and adaptable to develop machine learning (ML) models for predicting potential EoL activities, chemical

flow allocation, environmental releases, and exposure routes for chemicals outside the comprehensive EoL database.

Hernandez-Betancur et al. (2023b) utilized the EoL database created by Hernandez-Betancur et al. (2023a) to investigate tree-based ML algorithms to construct an EoL release modeling approach influenced by Quantitative Structure-Activity Relationship (QSAR) models often used in cheminformatics and toxicology research [5]. In addition, the developed ML models use chemical descriptors, EoL chemical transfer quantities, industry sectors, environmental policies, industry-sector value-added, chemical structure, and chemical prices to predict potential EoL activities and the chemical transfer distribution among the EoL activities. Therefore, these ML models aid early stage chemical process/product designers in deciding if chemical substances at their potential EoL stage meet environmental regulations or need redesign before entering the market.

Although these data-driven developments based on top-down facility information aid the tracking and estimation of EoL chemical releases and finding potential occupational exposure routes, decision-makers would need to incorporate PSE methods and tools to design and evaluate chemical processes and implement enhancements to minimize or end negative environmental and economic impacts at process equipment level toward a more holistic sustainable performance (bottom-up approach).

### Process Systems Engineering to Estimate Releases and Evaluate Sustainability from Chemical End-of-Life Scenarios

Chemical process synthesis, design, modeling, and simulation developments aid stakeholders in performing CFA, occupational exposure, energy footprint, release estimation, and life cycle inventory generation during EoL chemical stages. For example, Chea et al. (2023) performed a qualitative and quantitative tracking of plastic chemical additives to estimate their potential environmental releases, life cycle inventories, occupational exposure, greenhouse gas emissions, energy footprint, and environmental impacts within the plastic EoL stage and activities [6]. Also, this work shows a sensitivity analysis of future chemical additive release scenarios involving chemical recycling, increasing recycling rates, and chemical additive extraction. To complement these PSE applications, Agbleze et al. (2023) showed recent efforts to estimate chemical releases and evaluate sustainability indicators at the chemical manufacturing stage of existing chemicals, new manufacturing processes, and dynamic operating conditions [7]. Also, this contribution describes how to apply the Gauging Reaction Effectiveness for the ENvironmental Sustainability of Chemistries with a multi-Objective Process Evaluator (GREENSCOPE) sustainability assessment tool to evaluate the sustainability

of chemicals synthesized from a laboratory-scale reaction or manufactured in a plant-scale reaction [8], [9]. GREENSCOPE quantifies and assesses the sustainability of a given process or supply from a multi-stakeholder perspective, including material efficiency, environmental impacts, energy requirements, and cost through mathematical indicators.

Finally, after describing recent PSE applications on EoL material flow analysis for supporting chemical risk assessment, sustainability evaluation, and safer circular economy paths, the subsequent sections describe crucial PSE applications for managing the EoL stage of novel product manufacturing techniques like additive manufacturing (AM) and quantifying and tracking chemical releases in unconventional EoL paths like publicly owned treatment works (POTWs). These efforts aid decision-makers in finding new potential chemical exposure routes and updating regulatory requirements due to ineffective EoL chemical management methods.

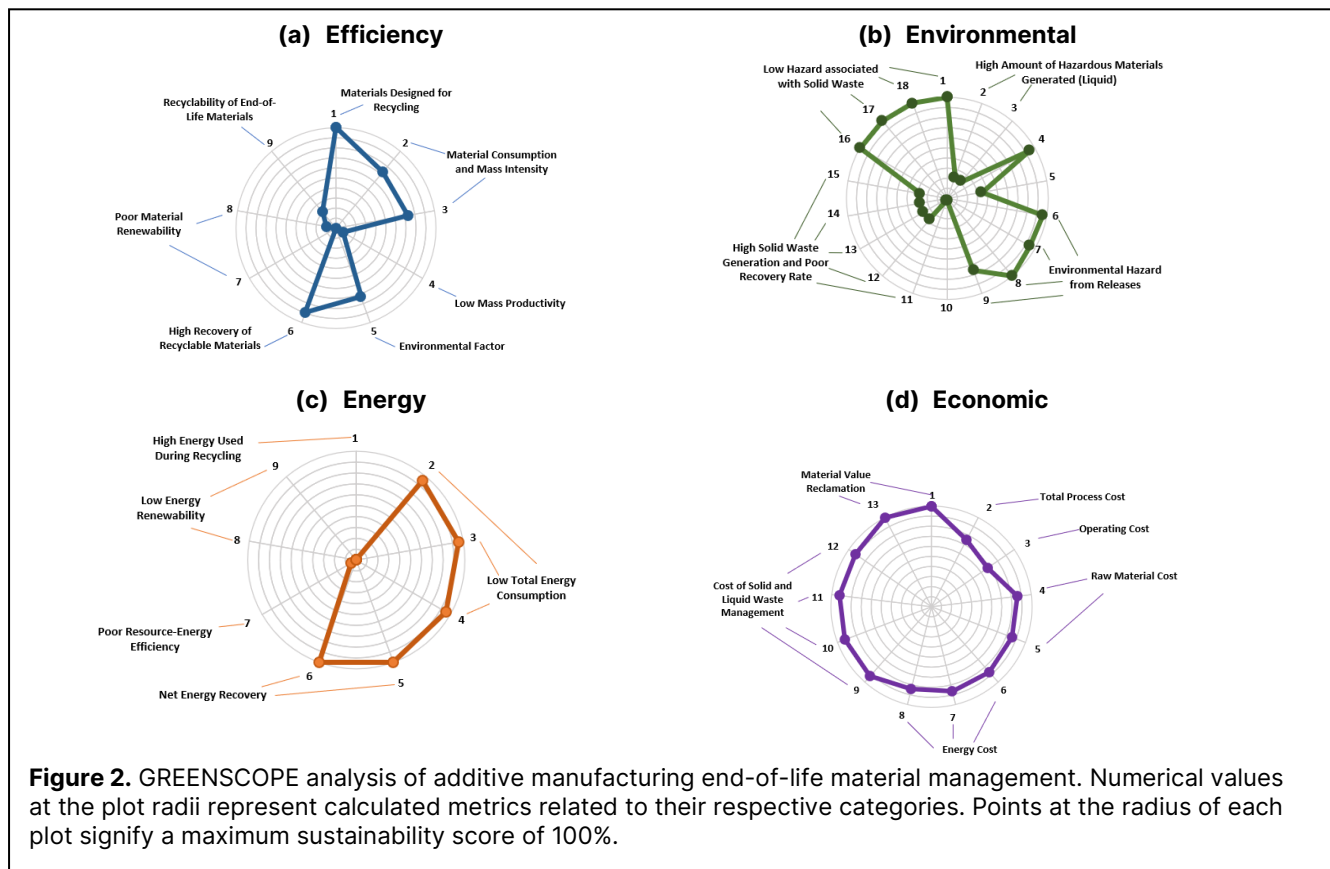

### Shifting Additive Manufacturing End-of-Life Management Toward a Circular Economy

AM techniques have been widely used to create customized products and parts from a multitude of raw material types with high efficiency [10], [11]. However, most attention toward AM challenges is centered on the manufacturing stage of the material life cycle, emphasizing releases and occupational hazards [12]–[14].

Achieving sustainability and the state of a circular economy within a given supply chain requires that the fate of all materials used is accounted for throughout the life cycle.

Presently, AM practices can result in potential releases to the environmental compartments, namely land, water, and air, and creating new exposure pathways in the EoL stage if unmitigated. The variety of materials used during the manufacturing stage creates high uncertainties on the fate of the materials. Solid materials for EoL management ultimately combine with conventional municipal solid waste (MSW) management infrastructure at the forefront of AM material management, while liquid EoL materials are treated as hazardous waste. Releases from the manufacturing stage can go unreported because improper EoL chemical management methods or cleaning practices were used or the total releases at individual operation sites are lower than the reporting thresholds.

The GREENSCOPE tool was used to find specific challenges and process modification opportunities within the EoL stage of the AM life cycle. The calculated indicators were compared against best- and worst-case scenario values to compute a sustainability percent score ranging from 0 to 100%, in which a 100% score signifies the best sustainability scenario. **Figure 2** illustrates the sustainability analysis, summarizing concerns on the low recycling rate of AM EoL materials and the inherently low

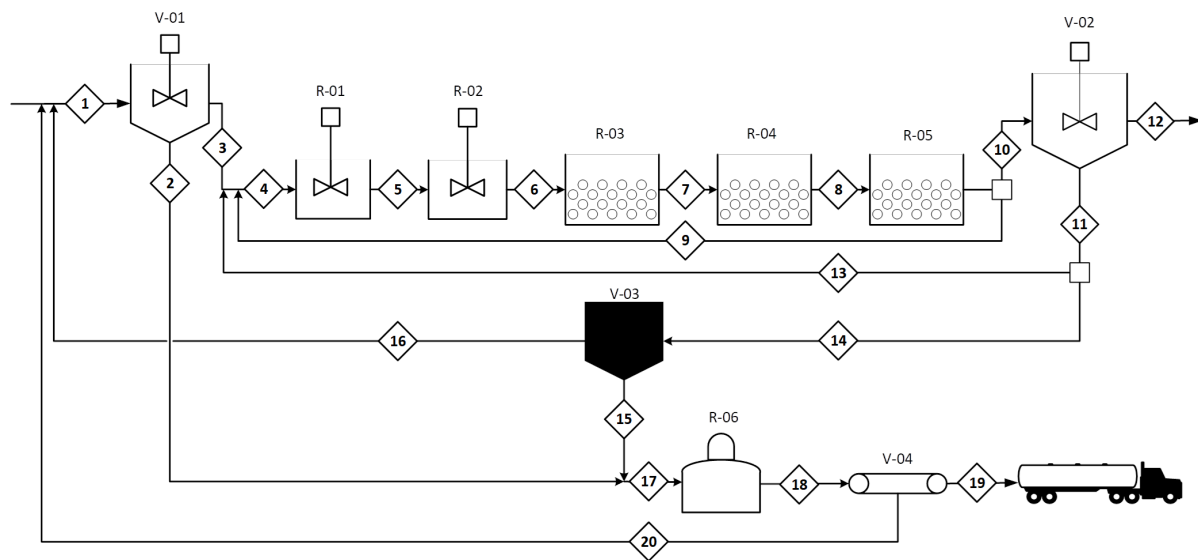

renewability. The overall AM life cycle also generates a high amount of hazardous EoL materials and their releases to the environment. The total energy consumption is relatively low, but the renewability of the energy source requires improvement. Alternatively, the various cost aspects of AM EoL management processes are close to optimality. However, variation can be expected because the management infrastructure varies between regions, in addition to the variety in material types expected from releases and the manufacturing stage.

### Tracking and Estimating Industrial Wastewater Transfers to Publicly Owned Treatment Works

The influx of industrial wastewater with conventional and emerging chemical contaminants to POTWs poses potential exposure risks, leading to environmental impacts and human health risks caused by polluted water discharges, land depositions, and air releases. Quantifying and tracking industrial chemical releases to POTWs are necessary to find unaddressed potential exposure routes. Therefore, this research effort proposes PSE approaches to tracking and estimating chemicals of concern across POTWs that foster bottom-up process modeling and chemical allocation to simulate fate and transport comprehensively.

The work introduces a POTW design, modeling, and simulation model that integrates detailed representation

**Figure 3.** A process flow diagram of a generic publicly owned treatment works (POTWs) vessels(V-0X) and reactors(R-0X). Process units include a primary clarifier (V-01), a secondary clarification unit (V-02), a sludge thickening unit (V-03), a dewatering unit (V-04), aerated and un-aerated activated sludge unit (R-01;R-05), and anaerobic digestion equipment (R-06)

of individual process units from primary clarification to advanced biological treatment, delineating settling characteristics, biological transformations, nutrient removal, and sludge management. Process units include a primary clarifier, a secondary clarification unit, an aerated and un-aerated activated sludge unit, an anaerobic digestion equipment, and an influent generator model that creates influent profiles mimicking POTW influent variations as illustrated in **Figure 3**. The model captures interactions between chemicals of concern and wastewater treatment operations, allowing for the estimation of chemical partitioning across unit operations such as sedimentation, biological treatment, adsorption, volatilization, and transport mechanisms. The selection of volatile organic compounds (VOC) as the first chemical class for model integration stems from their distinct behavior within the proposed treatment processes, characterized by their volatility, sorption, and biological uptake tendencies.

**Table 1** shows the mass flow changes and notable reductions to solid and liquid phase methylene chloride ( $\text{CH}_2\text{Cl}_2$ ) from influent to effluent, showcasing removal rates at each process unit. The substantial reduction in  $\text{CH}_2\text{Cl}_2$  concentrations, primarily attributed to biological degradation mechanisms within secondary treatment (stream # 4-10), along with the lack of adsorption capacity seen throughout the plant, aligns with real-world scenarios [15].

Our proposed PSE-based approach, employing bottom-up methodologies, offers a valuable tool for assessing the efficiency of different treatment strategies and showing potential areas for improvement in EoL chemical management. The usability and value of this model extend to its potential applications in environmental risk assessment, regulatory compliance, and the development of more effective treatment methodologies.

## CONCLUSIONS

This work describes a computational framework based on data engineering, data-driven modeling and PSE models to predict EoL chemical releases and potential occupational exposure scenarios. This contribution also shows a comprehensive EoL database created from publicly accessible domestic and international regulatory systems. Moreover, this contribution describes the application of GREENSCOPE to inform the development of more sustainable chemicals by reducing their environmental and human health impacts, implementing pollution prevention, and source reduction while increasing economic and social benefits. This multi-stakeholder analysis can be extended toward potential trade-off analysis, such as trading costs, the highest-performing category, investing in recovery processes, better waste treatment and management procedures, and selecting renewable materials sources for manufacturing. The gradual adoption of material management and selection guidelines and process improvement opportunities can allow EoL

chemical generators to take on a more active role in aiding the shift of linear economy practices toward the state of a circular economy.

Future steps are to understand the near-field exposure associated with circular economy paths and compare the composition and functionality between recycled and brand-new products to avoid unintended recycling of toxic substances at post-recycling/recovery activities, including chemicals not currently subject to USEPA regulatory programs. To resolve this problem, we can use data engineering and data-driven approaches to effectively combine facility, PAU, and equipment level data. This integration would enable the detection of potential EoL exposure scenarios, calculation of releases, and monitoring of upstream recycling scenarios for chemicals of concern. The CFA will utilize PAU/equipment-level data to estimate releases inside chemical facilities and allocate chemicals into environmental compartments. Facility-level data will provide insights on regulatory affairs, as well as the behavior of the supply chain and interconnectivity of chemicals in the EoL stage of the industry. Future research should concentrate on integrating isolated environmental regulatory data and developing modeling pipelines and architecture. These can range from graph representation learning for supply chain simulation to hybrid modeling for combining top-down (chemical facility data and models) and bottom-up (operating units, equipment) approaches.

## ABSTRACT

Pharma 4.0 has continued to advance as the industry develops advances in process analytical technologies, automation, and digit-ization. Digital twins which transform on-line process measurements into meaningful outputs in real-time are being developed to seize the opportunity made possible with this shift. Digital twins can be used for improved process optimization on a range of scales, from determining optimal metabolite concentrations in upstream bioreactors to considering economic and environmental impacts of process decisions. In this paper, we explore the current uses of digital twins in solid-based pharmaceutical space and the bio-pharmaceutical manufacturing. Applications cover scale up of upstream processes, product quality control, and consideration of continuous systems. We also describe the intersection of digital twins in flow sheet modeling, sensitivity analysis and optimization, and design space evaluation. Finally, areas requiring further improvement for industry adoption are addressed.

---

**Keywords:** Digital twin, Process Modeling, Pharmaceutical manufacturing, Biopharmaceutical manufacturing

## INTRODUCTION

The pharmaceutical industry has been on the rise in the U.S., dominating the global market with roughly 50% of the sales revenue being generated in the U.S. Roughly 20% of the total revenue generated is directed to research and development (R&D), to bring new drugs to market and improve the current manufacturing processes. In the last two decades, research efforts have focused on improving the predictive ability of the current manufacturing practices to increase production rates, reduce resource losses and improve the overall effectiveness of manufacturing. With advances in digitization, Internet of Things (IoT), and automation, the pharmaceutical industry is transitioning towards Industry 4.0 [1]. Known as Pharma 4.0 in the pharmaceutical industry, this transition aims to improve efficiency, productivity, responsiveness and flexibility, with varying market demands of drug products and biologics [2]. A crucial component of this transition involves the development of a digital twin framework (a digital replica of the physical manufacturing system), which has been shown to be quite effective in risk assessment and regulation-

compliant manufacturing [1].

Process systems engineering tools have been used in the development of digital twins to ensure regulation-compliant manufacturing of drug products [3]. Predictive models developed for digital replicas prove valuable in correlating equipment, process, and material parameters with the critical quality attributes (CQAs) of pharmaceutical products. This ensures that the drug products meet quality standards set by regulations, making production more efficient and flexible. Additionally, these models assist in identifying and addressing potential risks [4].

The US FDA approved the 100<sup>th</sup> mAb in 2021 with 870 more in clinical development as of 2021 [5]. Process development of these therapeutics involves several stages including cell line development, media formulation, scale up, and screening product quality [6]. These therapeutics are produced to treat various types of diseases, some of which are chronic and affect a large patient population. This leads to a drastic increase in demand for therapeutics which require large scale, robust, economically feasible manufacturing processes to produce [7]. A large number of novel, blockbuster biotherapeutics are falling off patent in this decade. This is

leading to the rise of a biosimilar market. The number of biosimilars approved has been increasing every year [8]. Biosimilar products can lead to significantly lower costs compared with the novel therapeutic [9]. Hence, the market is shifting to the most affordable biosimilar. Efficient process development enables affordability of biosimilars. The US FDA has set guidelines for Quality by Design to improve the understanding between process conditions and product quality [10]. Understanding these relationships could require large amounts of experimental data by using statistical design of experiments. Application of process models can improve process understanding, cheaply evaluate large numbers of process conditions which help to reduce the design space, improve process control, and simulate the effect of process perturbations and critical material attributes on critical quality attributes. Robust process models can help monitor the process without the need for a large number of expensive analytical measurements required in traditional process analytical techniques [11]. Hence, the development of reliable process models used within digital twins is crucial for effective process monitoring and for guiding key experiments to reduce the overall experimental expenditure. Reducing the time required to perform expensive experiments can speed up process development timelines which is crucial for the staying on the cutting edge in the fast-paced biopharma industry and succeeding in the biosimilars boom that is to come.

## MODELING COMPONENTS OF A DIGITAL TWIN

A digital twin is a digital informational construct of a physical system, created as an entity on its own and linked with the physical system [12]. It consists of a physical component, a virtual component, and automated data communications between the physical and virtual components [13]. The following sections highlight the modeling components of a digital twin for solid-based pharmaceutical and biopharmaceutical manufacturing processes [14].

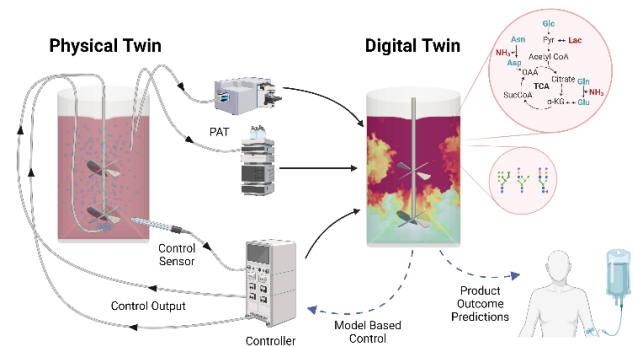

### Solid-based pharmaceutical manufacturing

In solid-based pharmaceutical manufacturing, various models have been developed to better understand the different steps involved [15]. This is not a comprehensive list but is offered as examples of such models. Loss-in-weight (LIW) feeders are used to feed ingredients in the continuous manufacturing processes. Data-driven models [16], first-order delay differential equation [17], semi-empirical models [18] and Discrete Element Models (DEM) [19] have been developed for this step. Continuous blenders blend various powdered materials to create a consistent powder mixture. DEM [20], Population Balance Model (PBM) [21], hybrid PBM-DEM [22],

compartment models [23] and residence time distribution models [24] have been utilized to simulate the blender unit. Roller compactors produce compacted ribbon products from powder materials under high pressure exerted by rotating rolls. These modeling effort includes steady state models [25] and dynamic models [26]. Data driven models, PBM and DEM are widely used for wet granulation [27, 28], which is used to achieve particle enlargement with the addition of liquid binders. For the tablet press unit, Kawakita equation, Heckel equation and their variations have been widely used [15].

### Biopharmaceutical manufacturing

In the biopharmaceutical space, digital twins have been developed to model many unit-based operations. These include bioreactor scale-up using computational fluid dynamics (CFD), product quality modeling, metabolic modeling, modeling of bioreactor physical parameters, and modeling of perfusion systems. The models of each operation may be combined to provide a digital twin of the upstream manufacturing process, illustrated in Figure 1. On-line measurements are taken continuously thanks to the advancements in process analytical technologies (PAT). The digital twin can be run alongside the physical twin, informed by continuous PAT measurements, which can inform model-based control of the bioreactor. For off-line investigations, the upstream digital twin can be integrated into flow sheet modeling, sensitivity analysis, design space identification, and process optimization, with an overarching goal of improving patient outcomes.

**Figure 1.** Upstream bioreactor cell culture performance is modeled in a digital twin representation through computational fluid dynamics, metabolic modeling, and glycosylation modelling.

### Bioreactor scale-up

A well-designed digital twin can simplify the expansion of initial processes and improve the chances of successful production runs in large-scale bioreactors from the first attempt. The inherent challenges associated with the prohibitively expensive and often impractical nature of experimental testing at large scales underscore

the critical role played by small-scale experiments and scale-up tools. These tools aid in establishing scale specific operational parameters and provide baseline expectations for yield and quality in large-scale bioreactors.

Digital twins enhance our ability to anticipate the impacts of scaling up, especially those that go beyond the capabilities of experimental measurements, such as local  $kLa$  distributions. They also provide a means to test and correct for unexpected variations observed upon process scale up.

A major concern during bioreactor scale up is the formation of heterogeneities: nutrient concentration gradients and gradients in important physical parameters, such as dissolved oxygen and carbon dioxide, temperature, pressure, and pH. Control of these parameters is key for consistent production and product quality [11]. Incorporating CFD modeling into a digital twin of the upstream process allows us to examine the behavior of throughout bioreactors at small and large scales. CFD can predict gradients across the volume of the bioreactor by capturing fluid flow, bubble dynamics, and heat and mass transfer. The prediction of gradients ahead of scale up proves invaluable for the assessment of the severity of scale up formed gradients [29]. Moreover, the predicted dynamics of cells flowing in and out of the gradients can inform scale up simulator experiments which mimic oscillations and measure impacts [30].

Creating effective digital twins for upstream biopharmaceutical manufacturing relies heavily on accurate models of metabolism and critical product quality attributes like glycosylation. There are several methods to couple CFD with metabolic modeling, though this remains a non-trivial task due to the wide range of time scales involved [31–34]. These models can be used to explore scenarios and ‘what if’ analyses, identify optimal operating conditions, and develop response plans to unexpected variations in bioreactor performance at the large scale [14]. Integration into flow sheet modeling of entire production systems can enable predictions of scale up effects on downstream processes and final product quality [35, 36]. Finally, comprehensive upstream digital twins provide a tool to better understand biological systems, an invaluable asset to biopharmaceutical research and process development.

### Product quality

N-linked glycosylation is an important Critical Quality Attribute (CQA) in the manufacturing of biotherapeutics. Changes to upstream process conditions can result in changes to the glycan fractions of the glycoprotein. This subsequently affects important properties of the product such as half-life, efficacy, immunogenicity, and aggregation [37]. Hence, it is especially important to study the upstream design space and monitor the N-linked glycosylation of the products. Measurement of this

CQA requires expensive and laborious analytics. Implementing industry 4.0 will involve development of a digital twin capable of predicting the N-linked glycosylation profiles of biologics as a function of the state (temperature, pH, media, etc.) of the bioreactor. Mechanistic models for N-linked glycosylation can be used to incorporate the effects of process parameters on N-linked glycosylation to develop a framework that improves process understanding and can simulate different operating conditions [11]. Models of N-linked glycosylation approximate the Golgi of CHO cells as continuously stirred tank reactors (CSTRs) [38] or plug flow reactors (PFRs) [39] have been developed which can provide mechanistic insights into glycosylation changes upon changes in critical process parameters (CPPs) such as bioreactor pH, temperature, and galactose addition on the N-linked glycosylation of monoclonal antibodies (mAbs). Site specific N-linked glycosylation is another layer of complexity in quality modeling. Our research has indicated that changes to bioreactor pH leads to changes in the fucosylation, galactosylation and sialylation on the mAb. Upon assessing site specific analysis, it was determined that fucosylation was only affected in the Fab region and not the Fc region. Previously developed glycosylation models are being used to explain the observed differences [38, 40]. Integrating mechanistic models of N-linked glycosylation into digital twins will expand the capabilities of digital twin predictions and enhance process simulation and decision-making capabilities.

### Cell Metabolism and Continuous Upstream Manufacturing

As the biopharmaceutical industry increases its rate of transition to continuous manufacturing, the resulting efforts to develop comprehensive digital twins will increase in parallel to the increased complexity and operational demands of continuous systems. Regarding upstream production of biologics, perfusion bioreactors and the associated cell retention modules constitute the most important unit operations, for which the required components of a digital twin as defined by Grieves and Vickers [12], are being individually developed in the literature.

Dynamic mechanistic models of host cell platform metabolism pose as strong candidates for the virtual component of a digital twin. Dynamic Metabolic Flux Analysis (DMFA) and Dynamic Flux Balance Analysis (DFBA) models are two such frameworks, which combine kinetic and stoichiometric constituents to predict intracellular metabolism as a function of bioreactor conditions with a minimal set of inputs [41–43]. These frameworks can explicitly link several of the key CPPs of perfusion related to bulk mass transfer, such as the perfusion rate, bleed rate, and media composition, to cell performance. Their mechanistic basis ensures physiologic constraints guaranteeing meaningful and interpretable predictions.

However, their curation takes time, sufficient process understanding, and requires high-quality process data. Their success is dependent on the availability of the required data, such as cell density, titer, and nutrient availability, which in turn are dependent on the existence of robust PAT for those measurements [14].

Extensive modelling work of the associated cell retention module, as either Alternating Tangential Flow Filtration (ATF) or Tangential Flow Filtration (TFF), has also been done [44-46]. The complexity of these models spans from straightforward mass-balanced based approaches, which assess product retention as a function of filter performance, to computationally expensive models leveraging CFD to interrogate mechanisms of filter fouling and the effect of flow patterns on cell viability. A critical step towards the development of robust digital twins for perfusion operation will require integration of bioreactor and cell retention modelling frameworks with tolerable computational costs.

## FLWSHEET MODELING

By integrating unit operation models with relevant information transfer, it becomes possible to construct flowsheet models for early-stage design, assessment, and decision-making processes.

In solid-based pharmaceutical manufacturing processes, flowsheet models have been developed for different production routes, including direct compaction route, dry granulation route, and wet granulation route [15] enabling systematic process analysis, including sensitivity analysis, design space identification, and optimization [47].

Flowsheet modelling has also been applied in the field of biomanufacturing. For example, Yang et al. [48] and Ding et al. [36] have developed process flowsheet to represent monoclonal antibody (mAb) production and conducted thorough analyses to compare batch and continuous operations. The primary objective was to assess the feasibility of transitioning from batch to continuous manufacturing from the economic and environmental perspective. Yang et al. [49] extended the application of flowsheet modeling to gene therapy, demonstrating the economic advantages of continuous operation in the production of recombinant adeno-associated virus (rAAV). Additionally, within the realm of plasma separation, the implementation of flowsheet modeling has enabled process scheduling and debottlenecking strategies to address potential bottlenecks, which could help enhance batch throughput and overall efficiency, and thus improve the overall process performance.

## SENSITIVITY ANALYSIS AND OPTIMIZATION

Sensitivity analysis enables the investigation of process risk based on the variability in outputs that may be caused by particular CPPs. Popular methods include Morris method and variance-based method, which have been investigated and applied to various solid based pharmaceutical manufacturing processes; CPPs that influence tablet properties have been identified such as dryer air temperature, drying time, and liquid to solid ratio [50, 51].

Utilizing a mechanistic model directly for optimizing pharmaceutical and biopharmaceutical manufacturing processes could be inefficient due to the inherent complexity, nonlinearity, and nonconvex nature of the optimization problem created by the model. A machine-learning enhanced optimization framework, specifically a surrogate-based feasibility-driven optimization algorithm, has been developed and explored to improve modelling efficiency without sacrificing model fidelity. This investigation considered various options for surrogate models, adaptive sampling acquisition functions, and strategies for distributing the sampling budget among feasibility characterization, objective function optimization, and global exploration [52-54]. This framework can be used for general deterministic or stochastic simulation-based optimization problems with black-box constraints, and it is exemplified in applications in both solid based and biopharmaceutical manufacturing [52-55]. Machine learning based optimization and surrogate modelling have the advantage of reduced computational time but also hold the potential to yield superior solutions compared to traditional optimization approaches.

## DESIGN SPACE EVALUATION

A design space is essential for defining a process's operational ranges to guarantee production rates and sufficient product quality and aid in understanding the impacts of process variables on these attributes as well. It can be interpreted as the region of the input domain where the corresponding predicted model response satisfies all the required constraints [56]. Surrogate-based feasibility analysis approaches have been proposed to solve problems with computationally expensive process models. Different surrogate models with corresponding infill criteria have been developed and tested on different example problems, including Gaussian process model [16, 57, 58], radial basis functions [59], artificial neural networks [60], support vector machines [54], and stochastic kriging [61]. The framework was applied and demonstrated to characterize the design space of direct compaction [47], roller compaction [57-59, 61], and wet granulation [60] processes in solid-based pharmaceutical manufacturing.

Models for N-linked glycosylation can be very computationally intensive as they involve solving NLPs or

PDEs [11] making it challenging to run these models for operations that require a large number of function evaluations. Surrogate-based feasibility analyses have been developed to determine design space boundaries for efficient bioreactor operations. Dynamic kriging was used to develop a surrogate model of N-linked glycosylation. This surrogate model was used to evaluate the design space of pH and temperature in an upstream bioreactor process to achieve a certain range of N-linked glycan quality attributes [62]. In the context of biopharma downstream processes, the design space was identified for a twin-column continuous Protein A chromatography column, and the impact of process variations on this design space was examined. Rather than relying on a detailed mechanistic model, this work utilized a framework of surrogate-based feasibility with adaptive sampling, aiming at striking a balance between accuracy and computational complexity [63].

## FUTURE DIRECTIONS - CHALLENGES

While the application of digital twins in the burgeoning pharmaceutical and biopharmaceutical industry has shown clear promise, there remain notable challenges. In pharmaceutical industry, one of the current challenges is enabling high accuracy of prediction (using tools such as discrete element modeling) with continuous data-transfer and model updates between predictive and physical plant. DEM being time-intensive necessitates the development of reduced order modeling tools that can retain the accuracy of the DEM models with reduced simulation times. Another challenge is integrating the impact of material properties in the digital twin. To this end, an accurate methodology for representation of material properties within the process models is imperative. This is quite challenging with the bulk material calibration efforts to obtain a unique representation of the powder material. Development of more detailed models are also needed, for example better describing the effects of electrostatics on powder processes and the subsequent impact on product quality.

Within the biopharmaceutical industry, as more sophisticated process unit operation models are developed in isolation, their integration into comprehensive flowsheet structures to enable a holistic understanding of bioprocesses presents a critical advancement. Balancing higher fidelity flowsheet models with tolerable computational costs and time will require continued innovative approaches. Successful refinement, validation, and application of flowsheet models towards sensitivity analyses and optimization will rely on the availability of the required PAT, such as recent spectroscopic-based methods, for in-line measurements of process parameters and CQAs to provide real-time analysis and corrective action.

## ABSTRACT

The (bio-)pharmaceutical industry is facing crossroads in an effort to ramp up its global capacity, while working to meet net-zero targets and to ensure continuous drug supply. Beyond geopolitical challenges faced worldwide, (bio-)pharmaceutical processes have been historically very complex to design, optimise and integrate in a global distribution network that is resilient and adaptable to changes. In this paper we offer a perspective of how Process Systems Engineering (PSE) tools can support and advance (bio-)pharma practices with an outlook towards 3-fold sustainability. The latter is considering three main pillars, namely social (drug supply), economical and environmental sustainability. We discuss PSE contributions that have revolutionised process design in this space, as well as the optimisation of distributions networks in pharmaceuticals. We do this by means of example cases: one on model-based unit operation design and a second one on sustainable supply chain networks in the space of advanced therapeutics. As such, this contribution offers a perspective on how PSE methodologies can offer a systematic way to integrate social, environmental, and economical sustainability throughout process design and product distribution.

**Keywords:** Process Design, Biosystems, Supply Chain, Machine Learning, Dynamic Modelling, Industry 4.0, Sustainability

## INTRODUCTION

As the world moves towards truly sustainable development, the process industries are re-evaluating their operations and consider the wider environmental impacts of their products. While the biopharmaceutical and life sciences sector is at the forefront of the economy (UK turnover of £81B and USA turnover of US\$285B) [1], its growth is linked to an increase in biohazardous waste, including disposable plasticware, media waste, and high volumes of purification buffers and resins. To establish profitable and resilient operations, (bio-) pharmaceutical manufacturers will need to revolutionise the current state-of-the-art. Radical changes are necessary to tackle challenges related to material-intensive research and development (R&D) and wasteful manufacturing operations. This goal has been embraced by (bio-) pharmaceutical companies, many of which have committed to ambitious net-zero targets that require a step-change to their

current modus operandi [2–6].

## (bio-) pharmaceutical challenges and future directions

Achieving resource-efficient R&D and manufacturing requires in-depth understanding of this industry that is governed by stringent regulatory constraints. Product quality and production rate are typically conflicting Key Performance Indicators (KPIs) with the former prioritized over the latter. The current, often purely experimental, approach to the identification of suitable operating conditions that satisfy quality KPIs is resource- and time-intensive and typically leads to suboptimal, inflexible processes. Within the biopharmaceutical sector, the adoption of platform processes means that upstream process operation follows fixed protocols that often overestimate nutrient requirements. The lack of end-to-end process design further exacerbates the above challenges. As the industry tends to work in silos, upstream and downstream

operations for the same manufacturing process are developed by different teams. Successes in increasing upstream product titres achieved over the past 3 decades have generally shifted the majority of operating costs downstream [7, 8]. Despite the Quality by Design initiative, development of quantitative process understanding often relies on statistical approaches, which are not generalizable and transferable across production processes. At the same time, the sparsity of available datasets or even unavailability of measurements, particularly in the case of cell-based biopharmaceuticals production, points to the need for mechanistic mathematical representations or hybrid approaches.

Against this background, the (bio-)pharmaceutical industry is currently transitioning to personalised therapeutics, which are manufactured for individuals or small cohorts of patients. An example of these are viral vectors for gene therapies [9]. Personalised therapeutics pose new challenges because they require on-demand manufacture and delivery to the clinic within constrained timeframes [10–12]. To meet patient needs, the industry needs to now consider drug product delivery to the patient within its operations envelope. In other words, manufacturing and supply chain design must be considered in tandem, with both economic and, primarily, patient-centric KPIs in mind.

### The concept of 3-fold sustainability in (bio-)pharma and the role of Process Systems Engineering (PSE)

The positive health impact of Life Sciences on the society has been, so far, outweighing the environmental footprint of the sector. This has been leading decisions around process and product development, ensuring that therapeutics meet the purity constraints and manufacturers demonstrate control over their process operation. Nonetheless, and despite scientific advances in this space, regulators report drug shortages due to batch failures as one of the most pressing challenges. At the same time, COVID-19 demonstrated that the resilience of the global (bio-)pharma network is susceptible to unforeseen events, raw material shortages, as well as rapid increase in the demand for advanced therapeutics. This is now jeopardising the overarching goal of the industry to always meet drug demand.

Drawing all objectives into the picture, one could summarise those as: (a) meeting the demand (social objective), (b) being economically efficient (economic objective) and (c) reducing the environmental footprint (environmental objective). The identification of the sweet spot that meets these three objectives requires holistic approaches that orchestrate R&D, manufacturing, and distribution decisions. In this new context, knowledge-transfer and wet-lab experimentation are no longer sufficient to advance the sector alone. The systematic use of

computational approaches to guide R&D and end-to-end process design all the way to the clinic has the potential to yield a step increase in efficiency addressing both economic and environmental sustainability targets. Specifically, the use of generalizable, first-principles mathematical models of cell metabolism [13], cell culture operation [14] and chromatographic separation [15] can complement experimental investigations to accelerate process development for the purpose of flexibility analysis, and [16] process optimisation [17]. Similarly, model-based tools that can integrate manufacturing uncertainties in the supply chain network can revolutionise the decision-making process when it comes to investment and capacity planning across the product lifecycle.

### PSE in (bio-)pharmaceutical process design and product distribution

The PSE community has a long-standing track record in developing cutting-edge methods and tools that can advance the way process and distribution networks are designed, optimised and operated. Specifically, in (bio-)pharmaceuticals, there have been contributions that investigate and propose methodologies for unit operation design, as well as end-to-end process flowsheet and optimisation, the fundamentals for many of which lie in seminal contributions in PSE [18, 19]. Indicatively, groups have proposed surrogate modelling [20–24], (adaptive) sampling [16, 22, 25, 26] and probabilistic approaches [27, 28] to map and identify a process design space. Other approaches consider variance-based methodologies to investigate the impact of design variables on the process performance and thereafter constrain the feasible space [29–31].

Similarly in operations, computer-aided tools can help assess trade-offs between KPIs during scale-up and supply chain development. Capacity planning under clinical trial and demand uncertainty pressures decision-makers to quantify cost benefits of early-stage scale up approaches, which are tied to higher initial capital investments and risk. In this space, stochastic programming and rolling horizon approaches are well-established tools in investment optimisation under uncertainty [32–35]. Network optimisation with respect to cost and environmental metrics has been explored by several contributions focusing on process industries and the pharmaceutical sectors [36–38]. These works integrate life cycle assessment (LCA) in the optimisation problem formulation, thereby quantifying environmental impacts of candidate solutions and constructing Pareto frontiers to explore cost-environmental trade-offs. In the specific context of biopharmaceuticals, pioneering work has studied the impact of single-use equipment in manufacturing of mAbs via LCA [39, 40]. There remain open questions regarding the identification of main sources of impact for emerging biopharmaceuticals and manufacturing platforms.

Optimisation-based PSE tools have an inherent potential to help assess trade-offs between cost and footprints and ensure therapy availability.

## EXAMPLE CASES

### Case study 1: Computer-aided design of chromatography

#### The system

Monoclonal antibodies have been the major growth driving force of the biopharmaceutical industry [41]. Their purification relies on a series of chromatographic separation steps and results in large requirements for buffers and chromatographic resins. When developing the downstream process for a new product, several commercially available resins are usually screened experimentally. Here, we demonstrate how computer-aided design space analysis can support resource-efficient resin screening as well as identifying suitable operating conditions that meet productivity and quality KPIs. Specifically, we consider the protein A affinity chromatography step (Fig. 1). The feed contains the product (mAb), as well as impurities that result from the upstream bioreactor that act as disturbances. The model describing this system is a Partial Differential and Algebraic Equation (PDAE) model and uses a general rate mass balance to describe the mass transport across the column length and radial axes [42]. The experimental validation of the model has been carried out for five different commercially available resins.

**Figure 1.** Illustrative schematic of the protein A column.

The performance of chromatographic units in bio-processing is typically assessed via two KPIs; namely yield ( $K_{YD}$  in %) (Eq.1) and productivity ( $K_{PD}$  in mg/ml/min) (Eq.2). Although the yield is constrained, productivity is usually monitored and aimed to be maximised. In this example, we introduce resin utilisation ( $K_{RU}$  in %) (Eq.3) as a third KPI. This is in an effort to design innovative separation processes that not only meet the product specifications, but also make better use of the materials towards more sustainable operation.

$$K_{YD} = 100 \frac{m_{fed} - m_{lost}}{m_{fed}} \quad (1)$$

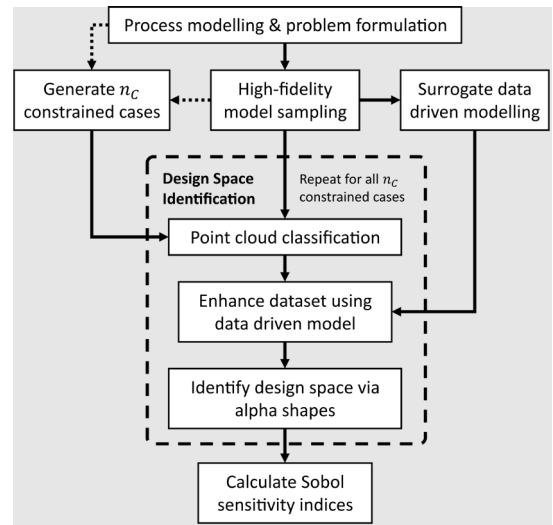

$$K_{PD} = \frac{m_{fed} - m_{lost}}{60V(1-\varepsilon_c)t} \quad (2)$$

$$K_{RU} = 100 \frac{m_{fed} - m_{lost}}{1000q_{max}V(1-\varepsilon_c)(1-\varepsilon_p)M} \quad (3)$$

where  $m_{fed}$  is the amount of mAb fed into the column,  $m_{lost}$  is the amount of mAb that leaves in the breakthrough,  $V$  volume of the column,  $\varepsilon_c$  and  $\varepsilon_b$  porosity of the column and the bed, respectively,  $t$  time,  $q_{max}$  maximum binding capacity, and  $M$  molar mass of the mAb. The productivity calculated is per volume of resin packed inside of the column, which enables comparison among the resins. For the purposes of this paper, the methodology and results are presented and discussed on the industrially relevant resin, MabSelect SuRe™.

#### Design Space Identification

To identify a feasible design space for this operation, we follow the framework in Fig. 2 presented by Satchio et al. [16].

**Figure 2.** Framework for model-based design space identification via machine learning.

#### Problem formulation

For any given process, the design space is identified as a set of points that satisfy user-defined constraints of the KPIs. For this, first, a design problem is formulated (Eq.4-6).

$$y = f(\theta) \quad (4)$$

$$\theta_L \leq \theta \leq \theta_U \quad (5)$$

$$g(y) \leq 0 \quad (6)$$

where  $y$  is the vector of monitored KPIs,  $f$  is the process model,  $\theta$  vector of the design decisions,  $\theta_L$  and  $\theta_U$  are the vector of lower and upper bound of the design decisions, respectively. While  $g$  represents the target KPI constraints that need to be satisfied. These can be upper and/or lower bound constraints on the monitored KPIs.

#### Data generation

Next, the design decisions are identified, and the high-fidelity model is sampled for the generation of a

point cloud that captures the process performance. Varying the design decisions within the bounds in Table 1, 4096 computational experiments are generated via Sobol sampling. Each combination of those decisions results into a different set of the process KPIs. Real-world processes are often highly nonlinear, therefore challenging computationally quasi-random sampling methods. For this, we integrate in the workflow, the development of an Artificial Neural Network (ANN) surrogate to be used as data interpolator. The objective of this is to increase the resolution of the search space, bypassing the computational complexity of sampling the high-fidelity model. This facilitates the identification of smooth boundaries and decreases the risk of void areas to be included in the design space.

**Table 1:** Design decisions considered and their respective bounds.

Design Decision	Lower bound	Upper bound
$c_{in}$ (mg/ml)	1.65	4.95
$Q_{in}$ (ml/min)	0.50	2.50
$T_{load}$ (min)	10	60

### Condition screening against the KPI constraints and design space identification

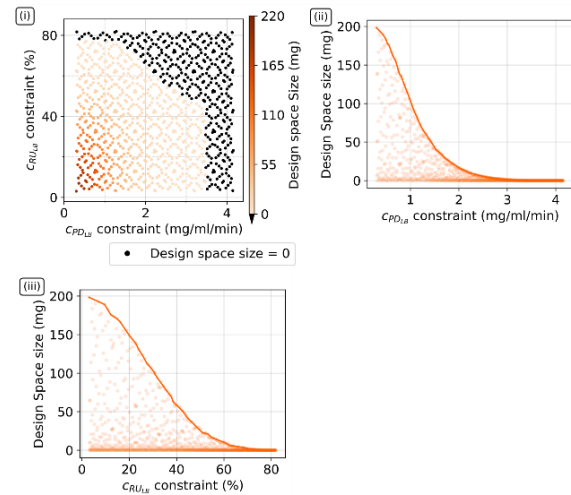

In this step, the point cloud is screened via the application of constraint combinations of the KPIs. For this problem case, process yield is strictly constrained ( $K_{YD} \geq 99\%$ ), while productivity and resin utilisation can vary between a lower and an upper bound ( $0.3 \leq K_{PD} \leq 4.2, 3 \leq K_{RU} \leq 82$ ). We generate 1024 combinations of constraints which are used to classify the original 4096 points for their feasibility to meet the constraints. Based on the density of the cloud in each case, the ANN may need to be employed for the generation of additional points such that the design space boundaries can be smoothly identified. For the design spaces generated in this case, an ANN has been used in most of the cases, generating 1-927 additional points, based on the density of each given space. The boundaries of the design spaces are then defined using alpha shapes [16].

### Resin performance and experimental validation

The 1024 identified design spaces are mapped against the two flexible constraints: productivity and resin utilisation (Fig. 3i). All the identified design spaces satisfy  $K_{YD} \geq 99\%$  yield constraint. The presented approach further allows quantification of the generated design space, whereby 0 mg is translated into absence of a feasible operating space under the given constraints. To display the density of each identified space, a colour-code is applied (Fig. 3i). On this occasion, black dots correspond to the absence of points that satisfy the given combination of constraints (0 mg space), while dark orange dots correspond to large design spaces (> 160 mg).

The size of the design space can be correlated to the operational flexibility of the process under the chosen constraints. The larger the design space (in mg), the greater the ability of the process to satisfy KPI constraints within the given bounds.

The presented approach enables manufacturers to gain insights on the process and material performance during the process development stages. For example, a trade-off between productivity and resin utilisation is observed (Fig. 3i), with the best achievable performance lying at  $K_{PD} \approx 2.8 \text{ mg/mlmin}$  and  $K_{RU} \approx 58\%$ . It is observed that the flexibility of the unit operation is inversely correlated to both productivity and resin utilisation (Fig. 3ii and 3iii). Amongst the two constraints, productivity results the most stringent one for the size of the design space.

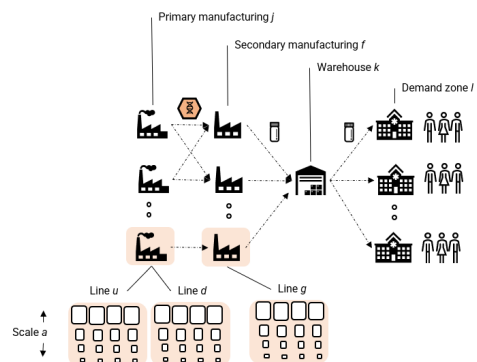

**Figure 3.** (i) 1024 design spaces generated as a function of the productivity and resin utilisation, (ii) design space-productivity constraint trade-off and (iii) design space-resin utilisation trade-off.

The generated design spaces have been validated using experimental data [42]. For the purposes of this paper, only the worst-performing scenario is displayed (Fig. 4). For this, the inlet product concentration ( $c_{in}$ ) is fixed at  $3.33 \text{ mg/mL}$  and the validation plot is presented in 2-D, where the design space is a function of the remaining two design decisions ( $Q_{in}$  and  $T_{load}$ ). It is observed that the identified design space is in good agreement with the experimental runs. RT6 is of particular interest and criticality, as the high-fidelity model and all the model-based analysis thereafter were blind to this experiment. Even in this case, the identified design space captures accurately the process performance and does not include any false positive points. This is of high importance as any consideration of false positive points within the design space boundaries can jeopardise the process performance and therefore the product specifications.

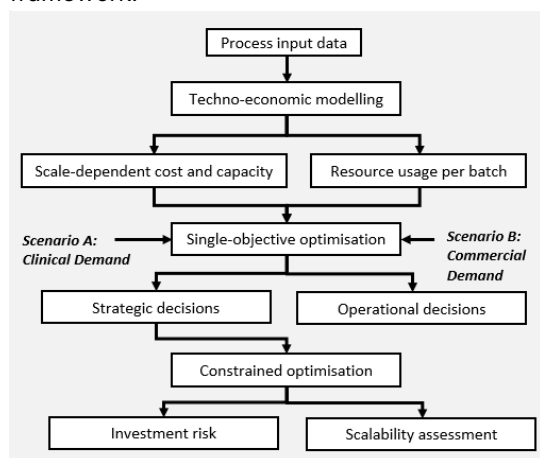

**Figure 4.** Experimental validation of the design space identified for the MabSelect SuRe™ resin.

**Figure 5.** Superstructure of supply chain optimisation framework.

**Figure 6.** Techno-economic modelling and optimisation framework.

### Remarks

The presented methodology harnesses the computational efficiency of model-based approaches to screen operating conditions and materials for their performance in an economically efficient manner. This also translates in overall better use of resources and more sustainable manufacturing platforms. The methodology can be used as an accompanying tool to accelerate process development in (bio-) pharmaceutical manufacturing and beyond. Importantly, the presented framework is adaptable and can be tailored to incorporate design decisions and KPIs of interest to the manufacturer. Critically, computational results of the example case compare favourably with wet-lab experimental data. This validation provides an

additional level of certainty that the design spaces generated with this approach can be trusted and do not run the risk of false positive operating points to be included in the design. Case study 1 is a demonstration of a PSE tool for flexible process design. This effectively assists manufacturers in the development of continuous and robust manufacturing platforms operating in a more resource efficient fashion.

## Case study 2: A sustainability assessment of advanced therapeutic supply chains

### The system

The second case study focuses on the integration of sustainability considerations in biopharmaceutical supply chains. We consider a multi-site capacity and distribution optimisation for viral vector supply chains, where nodes include upstream (USP), downstream (DSP) and fill-and-finish (F&F) (Fig.5).

### Data collection

The model [43] considers a generalized viral vector process that has been previously modeled in SuperPro Designer (Intelligen) for the calculation of batch sizes for each scale  $a$ , process times for USP, DSP, F&F, process bottleneck times and scale-dependent capital and operating costs. The techno-economic model also computes the resources ( $w$ ) consumed and emissions per batch. In this case we focus on consumption of water and electricity and CO<sub>2</sub> emissions for each process section and scale  $a$ . The analysis is conducted on different scales of primary and secondary manufacturing (50, 200, 1,000L and 2,000L bioreactor working volumes). Storage costs, capacity and electricity usage for 2 fridge types was recorded, namely MATOS PLUS Cloud 300 UF (Cloud) and MATOS PLUS Eco 300 UF (Eco) freezers. Data on distances between supply chain nodes, logistics costs, and CO<sub>2</sub> emissions per km traveled was also collected.

### The optimisation framework

The optimisation is formulated as a mixed-integer linear problem (MILP). Given the above set of scale-dependent manufacturing and logistics and a target demand, the optimisation determines network structures, selects manufacturing scale, production targets and computes associated costs and environmental footprint. The environmental footprint for each candidate design and scale assessed via the optimisation are calculated via formal LCA metrics, incorporating midpoint and endpoint categories. The environmental footprint is computed as the sum of the normalised mid-point impacts from water usage, energy usage and CO<sub>2</sub> emissions, leveraging on the normalisation factors presented in the Environmental Footprint (EF) 3.0 framework [44] (Table 2).

The problem can be solved as a single-objective optimisation with respect to each of these indicators. In this

case, we illustrate an optimisation for cost minimisation and monitor environmental footprint and production targets as output variables of the supply chain model. We generate candidate supply chain structures by considering a set of scenarios. Specifically, we illustrate how *risk-averse* decision-making leads to an optimisation for a lower demand target (Scenario A), where *risk-taking* approaches consider a larger demand target (Scenario B). The former staged-approach minimises capital investment in early stages of development under clinical trials uncertainty, whereas the latter case represents an early-scale up strategy.

**Table 2:** Impact categories and normalisation factors (NF).

Impact category	Units	NF
Climate change	kgCO <sub>2</sub> eq	$5.79 \times 10^{13}$
Water use	m <sup>3</sup> water eq	$7.91 \times 10^{13}$
Resource use, fossil-based	MJ	$4.5 \times 10^{14}$

### Scalability analysis & investment planning

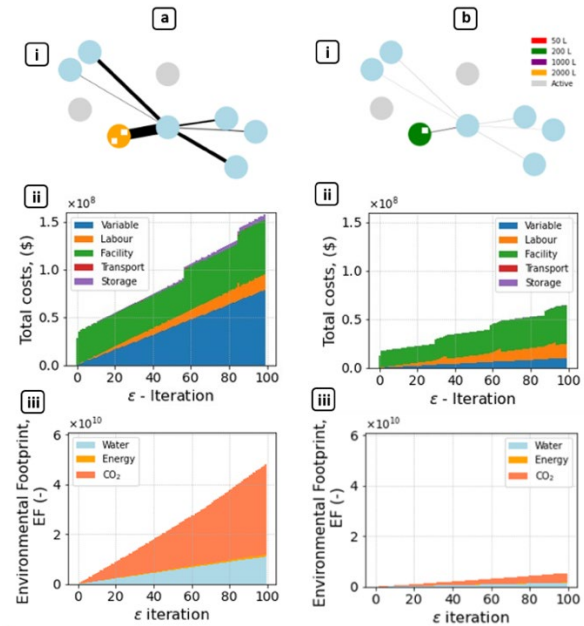

The performance of candidate network structures for Scenario A and B respectively can be assessed by constrained optimisation. Specifically, the network configuration and scales obtained via the solution of the single-objective cost minimisation can be fixed and tested for a range of demand realisations. This approach enables the assessment of the worst-case cost and emissions in the case of a demand decrease (i.e. clinical trial fails.), as a first attempt to integrate environmental sustainability in the pharmaceutical workflow. This information can also be used to identify the scalability of the candidate investment plan. The total environmental footprint and mid-point impacts of the supply chain operations are recorded.

### Cost-optimisation

The adoption of a risk-taking approach results in a centralised network consisting of 2 USP production lines, 1 DSP line and 1 F&F line. The scale selected is 2,000L, which is the largest available thereby maximising benefits from economies of scale given the target demand. At this cost-optimal point, total supply chain operating costs are computed as ~70M\$/y, with variable costs of manufacturing (~30%) and equipment expenses (~60%) being the main contributors.

Notably, storage costs from installing cheaper storage (Cloud) are minimal. This is the case for the range of demand realisations (Fig. 7a, ii). The total environmental footprint is mainly due to CO<sub>2</sub> (58-66%) emissions and water utilised during manufacturing (41-33%), whereas electricity usage in manufacturing and storage is

negligible (Fig. 7a, iii). A risk-averse approach results in a 200L scale being installed in USP, DSP and F&F, in a centralised manufacturing facility. The cost-optimisation results and scalability analysis highlight lower total costs and total footprint overall, with main cost drivers and environmental impacts remaining variable and facility-dependent expenses and water and CO<sub>2</sub> emissions for the range of demand realisations (Fig. 7b, iii).

**Figure 7.** Performance of candidate networks. Risk-taking (a): (i) nominal network structure, (ii) total costs, (iii) total emissions computed through scalability analysis. Risk-averse (b): (i) nominal network structure, (ii) total costs, (iii) total emissions computed through scalability analysis.  $\epsilon$  iterations correspond to the range of demand realisations from worst-case to best-case demand.

### Trade-off analysis

The *social* sustainability of the biopharmaceutical supply chain can be understood as the amount of therapy delivered. Quantifying the supply chain performance under demand uncertainty helps quantify the scalability of each investment decision. In this fashion, candidate investments can be compared with respect to cost and emissions per dose delivered and their respective scalability. The risk-averse investment results in larger emissions per dose compared to the risk-taking investment. Resource used in manufacturing are better used at larger scales in a similar fashion to economies of scale. In addition, risk-taking strategies and investing in a larger scale allows covering for up to 60,000 doses (Fig. 8). This is 10-fold larger than the risk-averse case which uses 200L manufacturing platforms.

**Figure 8.** Trade-off between financial risk and 3-fold sustainability.

The presented *what-if* analysis offers a first insight into a key trade-off between financial risk of investment and the 3-fold sustainability of the supply chain. As the therapy availability is maximised, the cost and environmental sustainability of supply chain operations is improved. This is seen by comparing Scenario A to B which result in 2 different operating scales, as well as maximising throughput of the facility once the asset is fixed. These trends highlight that a risk-taking approach in early stages of scale up can minimise emissions throughout clinical trials, although entail larger initial capital investments and risk if the clinical trial fails.

### Remarks

The proposed case study highlights that cost and environmental footprints for stainless steel facilities are not conflicting objectives. This may not be the case for other therapeutics and/or alternative equipment choices in manufacturing. We foresee more complex trade-offs by introducing in the framework the selection of equipment type for USP, DSP and F&F steps, comparing candidate manufacturing platforms relying on single-use and/or stainless-steel equipment. Each design decision would result in a range of environmental impacts from plastics disposal to water depletion and use of solvents for cleaning. In addition, the presented analysis focuses on 3 midpoint impacts within the LCA framework. The environmental footprint quantification can be augmented for a larger midpoint impact set as well as end-point aggregation. In this context, case study 2 illustrates a methodology to generate datasets for different candidate equipment technology and assess the sustainability of alternative manufacturing and network setups and its correlation to cost and service levels.

### CONCLUSIONS

As the (bio)pharmaceutical industry commits to net-zero targets, ramping up the global capacity in an economically and environmentally sustainable fashion amid a background of regulatory concerns related to drug shortages will push manufacturers to take bold decisions on

revolutionising their day-to-day operation. Adding the complex process dynamics of production systems results in a multifactorial, non-trivial problem that the sector is asked to solve in a timely manner.

In this setting, the legacy of the Process Systems Engineering (PSE) community in the development of cutting-edge methodologies, algorithms and tools becomes a vital enabler. PSE approaches are an excellent vehicle for the integration of social, economic, and environmental objectives when designing and optimising the next generation of (bio-) pharmaceutical processes and supply chains. Model-based approaches enable manufacturers to tackle challenges related to data unavailability, scale-up bottlenecks, raw material scarcity and uncertain demand profiles. Embedding such approaches in industrial workflows can shed light to novel process designs through better utilisation of the present assets or even by considering novel materials that offer improved performance. Another key advantage of PSE decision tools is the guidance towards better use of resources to reduce cost and impact per therapy/drug delivered.

To fully respond to today's needs, however, one needs to consider pathways whereby all available tools of the broad PSE portfolio are combined and used in a customised fashion. In that respect, high-fidelity process models remain a great resource that offers process insights and can help tackle challenges related to limited or complete lack of measurements. At the same time such models are highly transferrable across different products and modalities, following a suitable degree of re-parameterisation. On the other hand, Artificial Intelligence (AI) offers opportunities towards the reduction of the computational complexity of large-scale, nonlinear models, often encountered in this setting towards online deployment. Lastly, modelling manufacturing nodes dynamically and accounting for underlying uncertainties can enable the design of agile and responsive supply chain networks that meet regulatory, economic and patient related KPIs.

### ACKNOWLEDGEMENTS

The authors would like to acknowledge funding from: the UK Engineering & Physical Sciences Research Council (EPSRC) for the i-PREDICT: Integrated adaPtive pRocEss Deslgn and ConTrol (Grant reference: EP/W035006/1) and the Future Targeted Healthcare Manufacturing Hub hosted at University College London with UK university partners Grant Reference: EP/P006485/1). The authors would like to thank Prof. Blaž Likozar and Dr. Martin Grom (Department of Catalysis and Chemical Reaction Engineering, National Institute of Chemistry, Ljubljana) for expert input and data used in the design space example case. Input from Mr Alasdair Fyfe in the supply chain example case is also gratefully acknowledged.

## ABSTRACT

Artificial intelligence (AI) and particularly generative AI led to recent breakthroughs, e.g., in generating text and images. There is also a potential of these technologies in chemical engineering, but the lack of structured big domain-relevant data hinders advancements. I envision an open Chemical Engineering Knowledge Graph (ChemEngKG) that provides big open and linked chemical process information. In this article, I present the concept of “flowsheet mining” as the first step towards the ChemEngKG. Flowsheet mining extracts process information from flowsheets and process descriptions found in scientific literature and patents. The proposed technology requires the integration of data mining, computer vision, natural language processing, and semantic web technologies. I present the concept of flowsheet mining, discuss previous literature, and show future potentials. I believe the availability of big data will enable breakthroughs in process design through artificial intelligence.

**Keywords:** Artificial Intelligence, knowledge graph, data mining, computer vision, natural language processing

---

## INTRODUCTION

The transformation of the chemical process industry to renewable energy and feedstock supply requires the design of highly integrated, flexible, and efficient plants [1]. In the current setting, the development of chemical processes is a challenging task, which is mostly performed by manual simulation or optimization approaches that rely on hierarchical decomposition proposed in the 1980s [2]. There is a need for a paradigm shift that accelerates the development of chemical processes.

Machine learning (ML) and, more generally, artificial intelligence (AI) have great potential for chemical process design but usually require big data [3, 4]. Recent breakthroughs in ML led to success in games, computer vision, healthcare, finance, etc., even surpassing human performance in numerous tasks [5]. This great surge of AI applications often stems from the accessibility of big data, i.e., big in volume, variety, and velocity (cf., discussion on definitions of big data [6]) [7].

While engineers use a variety of data and knowledge to design chemical processes, most ML approaches that are used in the context of chemical process design currently do not rely on big data [8]. Instead,

most ML approaches used for process synthesis rely on regression models that are trained on manually collected datasets for specific applications [4]. For example, there exist numerous works that train surrogate models on process simulations and subsequently optimize the process design using superstructure formulations (e.g., [9–14]). Although these works frequently deal with a large number of data points (i.e., big in volume), there is a lack of variability in the data. In particular, most previous approaches do not consider a variety of process topology data from different processes but rather keep the considered topology fixed. Since ML models cannot extrapolate, these isolated approaches are limited to their specific process applications and validity domains [15].

ML methods have the potential to learn from process typologies and assist the process design in the future. Interestingly, a few pioneering works presented methods that have the potential to learn from multiple processes. Gani and coworkers extended a group contribution method to flowsheet graphs to estimate the process performance and guide decision-making [16, 17]. Also, Sahinidis and co-workers identified common patterns in flowsheet graphs [18, 19]. Recently, we also proposed new generative AI algorithms for the

autocompletion of flowsheets [20], autocorrection of flowsheets [21], and automatic prediction of control structures [22]. However, these methods have not yet unfolded their full potential because they have only been applied to datasets with few instances of flowsheet graphs and lack physical knowledge. In this article, I will focus on the methods to make more information accessible to the ML algorithms through data mining.

Scientific literature and patents provide much information about chemical engineering processes (cf. big scholarly data [23]). Flowsheets are the most important building blocks to define and communicate the structure of chemical processes [24]. As shown in **Figure 1**, they are schematic drawings describing overall process design, i.e., interconnection and type of unit operations. Depending on the development phase of a process, there exist different flowsheets with varying levels of detail (i.e., ranging from block flow diagrams (BFDs) to process flow diagrams (PFDs) and piping and instrumentation diagrams (P&IDs)) [24]. There is at least one flowsheet for every chemical process ever developed or built. These flowsheets are commonly available in PDF format in scientific publications, simulation files, patents, and company reports. Most information about industrial processes is confidential and unavailable for public research. However, in this article, I focus on flowsheet information extraction from publicly available patents and scientific publications. In the future, the proposed methods can also be used on industry data. In addition to flowsheet images, process descriptions and stream tables usually provide additional information about flow compositions, operating conditions, and sizing of the unit operations (see **Figure 1**).

**Figure 1.** Illustration of the potential for information extraction from flowsheets, process descriptions, and stream tables. Note that NLP is the abbreviation for natural language processing.

The document-centric workflow in chemical process development is inadequate. Since the existing data is unstructured, necessitating the need for chemical engineers to manually review the literature to learn about existing process designs for their specific application. Manually reviewing, verifying, and utilizing this vast amount of unstructured data is not only cumbersome but also can be inaccurate. Given the sheer number of

existing flowsheets, no human can comprehend all information that has been incorporated into flowsheets. Understanding how to store, structure, and link this vast amount of chemical flowsheet data and knowledge is key to further progress.

Semantic Web (SW) technologies offer functionality to connect previously isolated pieces of data and knowledge, associate meaning to them, and represent knowledge extracted from them. In particular, SW addresses data variety, by proposing graphs as a unifying data model, to which a data source can be mapped [25]. Such graphs not only contain data, but also metadata and domain knowledge (ontologies containing axioms or rules), all in the same uniform structure, and are then called knowledge graphs (KGs) (i.e., ontology + data = knowledge graph) [26, 27].

I envision that document-centric process information will be transformed into a findable, publicly accessible, interoperable, and reusable (FAIR) [28] knowledge base by representing information through a KG (cf. efforts to structure scholarly information [29]). The first step towards my vision involves the automatic extraction of information from flowsheets and process descriptions in scientific literature and patents. As illustrated in **Figure 1**, the automated extraction of information necessitates a combination of natural language processing (NLP) and computer vision techniques. In this contribution, I propose and concept of “flowsheet mining”. Moreover, I review relevant interdisciplinary literature and outline perspectives for future research.

## FLWSHEET MINING

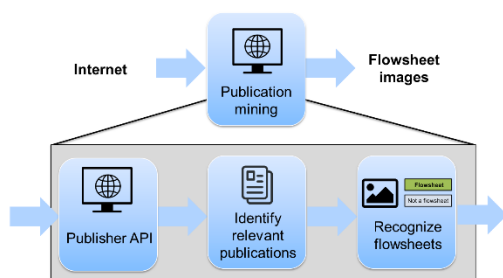

As illustrated in **Figure 2**, I propose a four-step approach for flowsheet mining. In Step 1, publications are automatically downloaded, relevant publications are identified, and flowsheet figures are extracted. In Step 2, flowsheet figures are digitized and saved in a graph format. In Step 3, information is extracted from process descriptions and stream tables. In Step 4, the extracted information is semantically enriched and saved in a knowledge graph.

**Figure 2.** Proposed four-step approach for flowsheet mining.

### Publication mining

The goal of the publication mining step is to identify relevant publications that describe a chemical process and extract flowsheet images (see **Figure 3**).

**Figure 3.** Illustration of Step 1 of the overall flowsheet mining approach: The publication mining.

The automated download of scientific publications and patents is possible through application programming interfaces (APIs). For example, CrossRef provides metadata of scientific publications through a Representational State Transfer (REST) API given a digital object identifier (DOI) [30]. This metadata includes titles, authors, license information, and links to the documents (e.g., publications in PDF or XML format), which are hosted by the corresponding publishers.

Given the large number of scientific publications, the automated identification of relevant publications is crucial. For example, crossref currently stores metadata for over 120 million records (January 2021). To identify chemical engineering publications, I propose to generate a list of all chemical engineering journals.

Only a small fraction of chemical engineering publications describe processes. Thus, the goal is to further identify chemical engineering publications that most likely contain a process flowsheet. I propose to train a topic model on the abstracts, title, and keywords of chemical engineering publications. Topic models are unsupervised ML models that can predict the topics of publications. The common latent Dirichlet allocation (LDA) for instance is a probabilistic topic model that relies on a bag-of-words approach, which means that the model considers the (tokenized) words of the passed documents disregarding their initial order [31]. To predict if an unseen publication contains a flowsheet, a classification model can be trained on the predicted topic distribution (cf. [32]).

After identifying and downloading relevant publications, the flowsheet images need to be identified. This step necessitates the extraction of all images from a PDF document (e.g., using Python package PyMuPDF or PDF-Figures 2.0 [33]). Afterward, I propose to train a classification algorithm that recognizes flowsheet images. The flowsheet image recognition is a fairly simple classification problem as flowsheets are usually black-white technical drawings that follow conventions (e.g., ISO 10628). Given the success of deep convolutional neural networks (CNNs) and transfer learning in computer vision [34–36], I propose to use pre-trained state-of-the-art CNN architectures (e.g., VGG16 [37]). The results of the whole

publication mining step are the extracted images of flowsheets from scientific publications.

In our recent work, we demonstrate that flowsheet images can be recognized from literature [38]. We trained a CNN on a training set including about 1,000 PFDs and about 13,000 other images. The model showed a good overall performance with a precision of 80.7% and a recall of 94.4%. In a preliminary study, we identified about 2,500 PFDs in the journal *Computers & Chemical Engineering* which corresponds to approximately 4.5% of all images in the journal. Moreover, we identified about 2,300 PFDs in the journal *Chemical Engineering Science* and about 560 PFDs in the book *Ullmann's Encyclopedia of Industrial Chemistry*.

## Flowsheet digitization

The goal of the flowsheet digitization step is to extract the flowsheet topologies from the flowsheet images and save them in a graph format (see **Figure 4**). The digitization of chemical process flowsheets involves an object detection step [39] and a pathway exploration step. In the object detection step, a model identifies the position and type of unit operation on the flowsheet. In the pathway exploration step, the connectivity of the unit operations is explored.

**Figure 4.** Illustration of Step 2 of the overall flowsheet mining approach: The flowsheet digitization.

Digitization of various types of engineering diagrams has been a focus of research in the computer vision domain since the 1980s, but most developed methods relied on classic computer vision methods (e.g., [40–46]). For example, Okazaki et al. [42] combined template matching and feature extraction in a hybrid model for symbol identification in circuit drawings. However, template matching can only be utilized when all drawings are identical in shape. With the emergence of deep CNNs, the field of computer vision has seen great advancements [47].

Recent literature distinguishes one stage from two-stage object detection algorithms [39]. One stage CNNs solve the tasks of (1) localizing and (2) classifying objects within a single network. Common frameworks of this network type are YOLO [48], its successors [49–51] as well as RetinaNet [52]. Single-stage networks have been

employed in the context of P&ID digitization [53–55]. However, single-stage networks do not perform as well as two-stage networks on common benchmark datasets and they often lack accuracy for the detection of small objects [50, 56].

**Figure 5.** Illustration of our preliminary object detection algorithm for the digitization of PFDs.

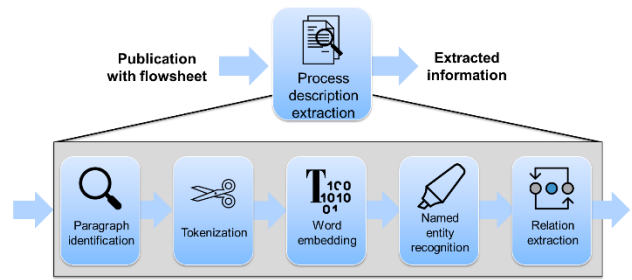

Two-stage detectors extract a feature map from the original image using a backbone network in the first stage, which is then used to find regions of interest and classify them. The most common two-stage detector is Faster R-CNN [57]. Recently, the potential of two-stage object detection for process symbols and piping detection has been demonstrated [58–60]. While there exist established algorithms for object detection, the automated exploration of the connectivity is still limited and relies on rule-based approaches [61]. The final result of the flowsheet digitization should be saved in a standardized data exchange format to enable interoperability (cf. DEXPI initiative for data exchange in the process industry [62, 63]).

In our recent work, we demonstrate that convolutional neural networks can digitize P&IDs and PFDs to a high accuracy. **Figure 5** shows the prediction of our object detection algorithm for the digitization of PFDs [60]. The figure shows the identified bounding boxes and associated object class abbreviations (e.g., hex for heat exchanger).

### Process description extraction

The goal of the process description extraction step is to extract relevant process information from process descriptions in text format.

In the NLP community, the process of automatically extracting structured information from unstructured and/or semi-structured machine-readable documents is called Information extraction (IE) [64, 65]. As illustrated in Figure 6, this includes several sub-steps that are described in the following.

**Figure 6.** Illustration of Step 3 of the overall flowsheet mining approach: The process description extraction.

The process description is usually only a small part of scientific publications. Thus, the relevant paragraphs including the process description need to be identified. This task is closely related to the identification of relevant publications (see Section Publication mining). Consequently, I propose to use topic models to identify relevant paragraphs.

Tokenization splits text into smaller tokens for further processing [66]. The simplest (rule-based) tokenizers split sentences into tokens based on white spaces, punctuations, or grammatical and syntactical rules. Tokenization is well-established in NLP and there exists a broad variety of implementations and comparisons (e.g., [67]).

In the word-embedding step of the document processing pipeline, each token is represented by a real-valued vector that can be processed by subsequent ML models. The goal is to design a mapping that represents the token's meaning as a vector. For example, the word vectors of the words “king” and “queen” should be close to each other because they have a similar meaning. Thus, this step is also referred to as representation learning.

Named entity recognition performs classification on tokens. This is necessary to identify the type of information that is provided. For example, **Figure 7** shows an illustrative example where a named entity algorithm identifies the token “heat exchanger” as a type [UNIT]. In the relation extraction step, possible relationships between entities are identified (i.e., green arrows in **Figure 7**).

**Figure 7.** Illustration of tokenization, named entity recognition and relation extraction.

Relation extraction can also involve relation classification, which is typically formulated as a classification problem to classify the relationship between the entities identified in the text [68]. A classifier takes the contextualized representation of two or more entities (e.g., words) as inputs and predicts possible relations between the entities as output. Feature- or kernel-based methods such as the conditional random field are earlier

approaches used for named entity recognition and relation extraction in a pipeline setting [68]. However, the performance of traditional approaches heavily depends on manual feature engineering, which requires domain-specific knowledge and a deep understanding of linguistics [68]. Also, several deep learning architectures have been proposed for entity recognition and relation extraction, which are mostly recurrent types of neural networks based on Bidirectional Long Short Term Memory (BiLSTM) or Gated Recurrent Unit cells [69, 70]. These models are often available in NLP tools (e.g., spaCy, Stanford CoreNLP, AllenNLP, and IBM Watson Natural Language Understanding).

Recently, transformer language models [71] have become the de-facto standard for representation learning in NLP allowing for domain-specific transfer learning. Compared to transformer models that benefit from abundant knowledge from pre-training and strong feature extraction capability, approaches based on BiLSTM have shown a lower generalization performance [68] and are less efficient in capturing long-distance context (due to vanishing gradients in the training process) [65]. Specifically, Bidirectional Encoder Representations from Transformers (BERT) [72] is a common language model that utilizes bidirectional attention mechanism and large-scale unsupervised corpora to obtain effective context-sensitive representations of each word in a sentence [68]. Moreover, various improved variants of BERT have been proposed for various downstream NLP tasks. For example, BERT-based approaches have been applied to scientific texts (e.g., SciBERT [73]) and have even been adapted for molecular property prediction (e.g., ChemBERTa [74]). Recently, large language models (LLMs) such as ChatGPT have also solved various IE tasks through prompting.

The majority of traditional IE approaches are focused on informal text (e.g., social media texts), or biomedical text (e.g., PubMedInfo Crawler [75]), while only a little literature on chemical engineering-related text exists (e.g., chemical patents [76]). In particular, very little attention is paid to IE for chemical process design. Xu et al. [77] showed that bio-entity extraction based on BioBERT [78] can significantly outperform other methods. Thus, a great potential for transformer-based language models on chemical engineering entity extraction tasks can be expected. However, relation extraction is highly domain-specific, due to the variety of underlying ontologies and relation types. To overcome this issue, approaches that combine LLMs, information retrieval, and SW technologies are promising (cf. [79]).

### Semantic database synthesis

The goal of the semantic database synthesis step is to build a knowledge graph by integration of the extracted information (see **Figure 8**).

**Figure 8.** Illustration of Step 4 of the overall flowsheet mining approach: The semantic database synthesis.

A KG is an effective means for capturing and structuring a large amount of multi-relational data from various disciplines [26]. KGs are typically represented in the standardized Resource Description Framework (RDF) data model and queried using the SPARQL Protocol and RDF Query Language. It can be formally defined as  $G = \{E, R, T\}$ , where  $G$  is a labeled and directed multi-graph, and  $E, R, T$  are the sets of entities, relations, and triples, respectively. Each triple is formalized as  $(u, e, v) \in T$ , where  $u \in E$  is the head node,  $v \in E$  is the tail node, and  $e \in R$  is the edge connecting  $u$  and  $v$  [27]. KGs are usually stored in a graph database system (e.g., Neo4j or virtuoso).

Ontologies are semantic data models that define the types of things that exist in a domain and the properties that can be used to describe them, including the relationships between them [27]. The main components of an ontology are individuals (instances or objects) of classes (distinct types of concepts that exist in the data), relationships (ways to relate classes and individuals), and attributes (aspects, properties, features, characteristics that objects and classes can have). RDF Schema (RDFS) and OWL (Web Ontology Language) are two different language models that enable the construction of quantified statements in the form of RDF graphs. Currently, a few ontologies have been developed for process systems [80, 81], process safety [82, 83], process operation [84–86], and kinetic reactions [87, 88]. However, these ontologies are mostly generalized data models that have not yet been used in conjunction with big data to form a KG. Currently, there exists only one publicly available chemical engineering KG, which creates a digital twin of the eco-industrial park on Jurong Island, Singapore [89]. To build the process flowsheet KG, I recommend extending the ONTOCAPE ontology [80, 81]. Furthermore, I recommend linking or integrating flowsheet information into existing open scholarly KGs, e.g., the open research knowledge graph (ORKG) [90].

## CONCLUSIONS

In the current setting, information about chemical

processes is often not easily findable, accessible, interoperable, and reusable (FAIR). In particular, process design information is depicted in flowsheets and described in text format (e.g., in scientific literature, patents, or company reports). This lack of structured data is a major hurdle for the development of processes. Also, the lack of structured data is a bottleneck for process design through AI algorithms.

This article describes the steps of a larger ongoing research agenda that aims to build an open Chemical Engineering Knowledge Graph (ChemEngKG). I envision that all (publicly available) chemical processes will be accessible in the ChemEngKG. To achieve this goal, I proposed the concept of “flowsheet mining” that will enable the autonomous extraction of chemical process information from scientific literature. The proposed concept mines scientific literature and patents, identifies and digitizes flowsheet images, extracts information from process descriptions, and saves all information in a semantic database. Thus, flowsheet mining requires the integration and further development of algorithms from several domains. I review relevant interdisciplinary literature in data mining, computer vision, natural language processing, and semantic web technologies. Moreover, I highlighted the potentials for the development of algorithms that are relevant for flowsheet mining.

Finally, I envision that the ChemEngKG will be an enabler technology for innovative generative AI algorithms facilitating chemical process design. There exist a multitude of powerful ML algorithms that have already demonstrated breakthrough results in other domains such as molecular design. I believe that these methods have also a great potential for AI-assisted process design. First methods already show the potential of AI for the auto-completion, autocorrection, and auto-generation of flowsheets. In the future, further development is needed to integrate engineering knowledge, big data, and AI for process design.

## ABSTRACT

Chemical engineers are natural “systems-thinkers”; this is a skill that allows us to analyze highly complex processes that involve heterogeneous components, phenomena, and scales. Systems-thinking skills are fostered in the chemical engineering curriculum via integrative and project-based courses, such as process/product design and laboratories. However, existing curricula tends to focus scope to product/process boundaries, offering limited opportunities to capture connections to behavior occurring at small scales (e.g., atomistic and molecular) and at large scales (e.g., supply chains, policy, markets, and infrastructures). This limit in scope can hinder our ability to appreciate how products/processes that we develop impact society, markets, and the environment (e.g., the opioid addiction crisis, environmental impacts of forever chemicals and chemical fertilizers, and electricity markets). This limit in scope can also hinder our ability to appreciate how emerging tools from the molecular sciences can help us design better products/processes. Expanding the boundaries of our thinking is essential in overcoming these limitations. In this perspective, I discuss how emerging concepts and technologies from machine learning, data science, environmental sciences, molecular simulations, and mathematics provide powerful tools to help foster systems-thinking over a broad set of scales and to help establish connections with non-traditional disciplines (e.g., social sciences). In addition, I discuss the need to create new conceptual frameworks, case studies, and software that can help foster systems-thinking.

**Keywords:** Education, Chemical Engineering, Design, Systems Engineering

## INTRODUCTION

A “system” is defined as a collection of interconnected components; these components can be *heterogeneous* (have different functionalities) and can interact in a *hierarchical* manner (over multiple spatial and temporal scales). A chemical process is a *complex system*; chemical processes involve unit operations that carry out distinct functionalities (e.g., mixing, reaction, separation) and that are tightly interconnected. A unit operation (e.g., a reactor) is also a complex system that integrates components (e.g., reactants, inerts, catalyst, cooling/heating system) to form diverse products/byproducts. A catalyst is also a complex system that integrates components (e.g., promoter, support, and active materials) at a molecular level to facilitate reactions. A chemical process can be seen as a component of a larger system (e.g., a refinery), which is in turn a component of an even larger

system (e.g., a supply chain). This supply chain interacts with other complex systems (e.g., the environment, the power grid, and energy markets). This highlights how systems exhibit hierarchical structure that links behavior over multiple scales, see **Figure 1**. For instance, the disruption of a chemical process (e.g., due to weather) can collapse an entire supply chain; similarly, the design of a catalyst can impact the performance of a chemical process (e.g., energy use due to more difficult separation of products/byproducts).

The definition of a system is powerful in that it is *abstract* and thus general: *everything* is technically a system (e.g., the cell, the human body, human society). Having an abstract way of thinking is critical, as this facilitates transferring of knowledge across disciplines. For instance, chemical engineers leverage systems-thinking skills when applying principles of thermodynamics for analyzing systems that are outside our “traditional” domain

of expertise. This is one of the reasons why chemical engineers have been impactful in a broad range of domains (e.g., biomedical, electrochemical, materials, environmental, pharmaceutical).

**Figure 1.** Hierarchical graph representation of a complex system involving multiple scales.

I would argue that “systems-thinking” has been at the core of chemical engineering since our profession was created (it is in our DNA). Let’s recall that chemical engineering was created as a branch of mechanical engineering (an already established profession), with the goal of designing manufacturing processes for chemicals. This required, *from the get-go*, a type of engineer that could fuse concepts from diverse disciplines. Modern chemical engineers combine concepts of transport, thermodynamics, conservation, chemistry, chemical kinetics, mathematics, and so on for analyzing and designing products and processes for manufacturing such products. Modern chemical engineers actively collaborate with scientists and engineers from a broad range of disciplines; this collaborative nature is also the result of systems-thinking, which helps establish connections/bridges with other domains.

The need to navigate the complexity of chemical processes has required chemical engineers to develop *conceptual abstractions*. I would argue that the first of such abstractions was the notion of a “*unit operation*,” which is an abstraction that compartmentalizes chemical processes to understand functionality and connectivity/interactions of different components. The unit operation is a powerful *unifying abstraction* because it can be applied to a broad range of systems beyond chemical processes (e.g., the kidneys and the lungs can be seen as unit operations of the human body). The concept of the unit operation is so *ingrained* in our chemical engineering psyche that it is difficult for us to think in other ways (we naturally compartmentalize systems); this way of thinking has been challenged by our need to intensify

processes via tight integration of phenomena (e.g., reactive separations).

Chemical engineers have developed powerful conceptual abstractions by leveraging mathematical modeling techniques (e.g., transport models, thermodynamic models, optimization models, dynamics/control models). The use of mathematical modeling marked the origin of our research field of process systems engineering and marked the origin of other related fields such as computational fluid dynamics, computational chemistry, multi-scale modeling, and molecular simulations.

*Society is becoming increasingly complex*, linking humans, technology, policy, economy, and the environment in a complex manner. This coupling is giving rise to a broad range of problems that need to be addressed (e.g., air/water pollution, addiction, mental health, resource scarcity, climate change). It is important to recognize and acknowledge the role that chemical engineers have played in creating such problems (e.g., design of highly addictive drugs and foods, design of fuels and chemicals that rely on fossil sources, design of plastics that are difficult to recycle, socio-political conflicts due to oil exploitation). I would argue that many of the problems that we have created are, in part, the result of a *lack of “holistic” thinking*. For instance, in some cases, we have failed to anticipate connections of the products/processes that we create with other systems (we have taken a myopic view of problems). This failure has not always been intentional; in some cases, connections remained hidden from us due to limits in technology and scientific understanding; for instance, heroin was found to be addictive *years* after commercial manufacturing and PFAS contaminants are present in the environment at concentrations of *parts-per-trillion* (there are limited technologies that can detect this).

Chemical engineers have played and will play a critical role in providing solutions that benefit society; but, in doing so, *we need to think holistically*. This will require us to expand the domain of our thinking and to anticipate the impact of our products/processes with the environment and with society at large scales (e.g., economics and policy) and at molecular scales (e.g., toxicology). Expanding our domain of thinking can also help us identify innovative solutions to pressing problems. For instance, fostering molecular-level understanding can help us develop more effective drugs and can help us design better catalysts, but it is important to understand the impact of such drugs and catalysts on overarching systems (e.g., healthcare costs, materials availability, and carbon emissions). Moreover, fostering infrastructure-level understanding can help us develop more effective energy and manufacturing systems (e.g., electrochemical processes that interact with the power grid and technologies that valorize plastic waste). To enable more holistic thinking, it is necessary to adapt chemical engineering education

by expanding the current focus on product/process design to discover non-obvious interconnections with other systems and across diverse scales. This is not a straightforward task, as it requires *thinking deeply* about how to contextualize and link topics covered in the curriculum and outside of the curriculum.

In this short perspective, I argue that emerging technologies from machine learning, environmental sciences, molecular simulations, and mathematics can help us develop *new and powerful conceptual abstractions* that can help chemical engineers reinforce systems-thinking skills and solve problems of increasing complexity. Specifically, I discuss how *graph theory* provides a powerful unifying abstraction to represent complex systems and their connectivity across scales. Moreover, I discuss how *machine learning* tools can help develop models that link behavior across scales and how *lifecycle assessment tools* can help define and navigate domain boundaries that span multiple scales. My discussion will be inspired by problems that I have encountered in my own research and based on recent experiences in teaching topics of supply chains, machine learning, markets, and life-cycle assessment in my courses. I will also emphasize why I think that we need a new generation of modeling and simulation tools that help students visualize and navigate *hierarchical arrangement* and *multi-scale interactions*.

## UNIFYING ABSTRACTIONS

The notion of a unit operation provides a unifying abstraction that helps navigate complexity of diverse systems (e.g., by separating functionalities). The notion, importance, and use of the unit operation can be understood from the perspective of *graph theory*; specifically, we can think of a chemical process as a graph/network in which unit operations represent nodes and their connectivity is expressed as edges. The graph-theoretic view of a chemical process provides a powerful unifying abstraction that allows us to capture multi-scale interactions, see **Figure 1** [1]. For instance, going in the “up” direction, one can think of a chemical process as a node that forms part of a bigger graph/network that represents an entire chemical complex (a chemical complex involves processes that generate different types of products and that are exchanged with other processes). A chemical complex can also be seen as a node that forms part of a bigger graph that represents a local supply chain, the local supply chain is a node of a regional supply chain, and the regional supply chain is a node of a global supply chain (all these supply chains are linked and form a chemical supply chain). A chemical supply chain can also be seen as a node that forms part of a bigger graph that represents an *infrastructure network* (e.g., power grid and natural gas network); this reveals how a supply chain is connected to energy markets and can be affected by

disruptions of infrastructure. A supply chain can also be seen as a node that forms part of a bigger graph that represents society or the environment; this reveals how a supply chain is connected to consumer demands, resource availability, and weather disruptions. This also reveals that a supply chain can impact the environment and human health; for instance, a pandemic can suddenly increase demands for chemical products from the supply chain (sounds familiar?). Now, going in the “down” direction, one can think about molecules as graphs in which nodes represent atoms and edges represent bonds. One can represent environments that molecules form as graphs in which nodes represent an entire molecule and edges represent intermolecular forces (e.g., hydrogen bonds). One can also represent a molecular environment as a node that affects mesoscale behavior observed in a unit operation (e.g., a chemical reactor).

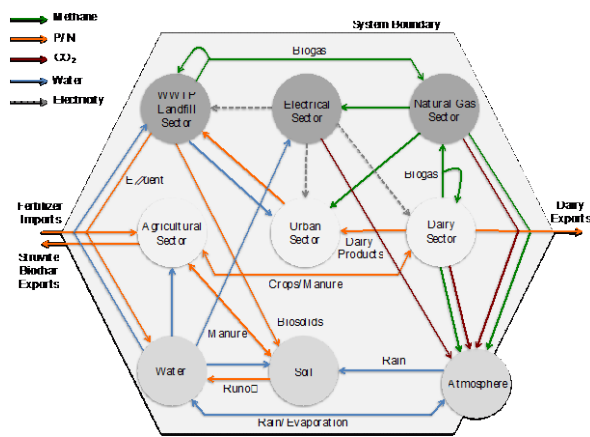

The previous discussion highlights how a graph is a conceptual abstraction that helps us think about how systems and phenomena are linked across scales. Computational and algorithmic tools from graph theory can be used to visualize/analyze such links and gain interesting insights. For instance, one can aim to identify nodes that are more tightly connected to others (and are thus more critical). Graph representations for molecules can also be used by machine learning (ML) models to predict emergent properties such as thermodynamic and toxicity properties. These machine learning models thus establish a link between molecular-scale behavior (non-observable) to meso-scale behavior (observable); in other words, ML models can be used to create bridges/edges across scales. ML can also be used to create graph representations of different resolution; for instance, one can create an ML model for a unit operation or an ML model an entire chemical process. ML thus allows us to aggregate nodes of a graph and thus to construct system representations of different levels of resolution (which can be critical in navigating and handling complexity). For example, when aiming to understand the behavior a supply chain, it might be sufficient to have a simple “input-output” model of a chemical process (there is no need to capture all the internal complexity of the process). Similarly, when aiming to understand the interdependencies of the power grid with the manufacturing sector, one can capture the sector using a simple input-output model.

Graph abstractions can also be used to capture connectivity of chemical processes with other systems (e.g., environment and policy). Capturing this connectivity is important, as this can help understand the impact that these externalities can have on the economic viability of the process or can help us understand how the process impacts markets and the environment. For instance, we can capture how a carbon tax impacts the selling price of a chemical, how carbon emissions impact the environment, and how the environment inherently restricts the

functionality/viability of a process (e.g., availability of resources such as water). Graph abstractions can also help engineers to *imagine or anticipate* what types of impacts their products and processes can have on humans and the environment (e.g., anticipate cascading effects). Uncovering non-obvious connections between systems can also be used to identify new markets and needs for products (e.g., one can make chemicals from cow manure via pyrolysis).

## ILLUSTRATIVE EXAMPLES

I now proceed to draw examples on how systems-thinking is necessary to tackle emerging societal challenges. In doing so, I will draw examples from my own research and teaching experiences.

**Figure 2.** Interconnections of the dairy sector with other industrial sectors.

### Example I. Fertilizer Pollution

The U.S. dairy industry is a multibillion-dollar industry that provides essential food products (e.g., milk, cheese, yogurt) [2]. This industry operates a massive manufacturing and supply chain infrastructure that manages millions of cows that produce milk; cows are fed corn stover and grass, thus demanding substantial amounts of agricultural land and crops. Supplying feed for cows demands large amounts of nutrients, which are provided in the form of chemical fertilizer and cow manure. Cow manure is a natural fertilizer, and its use enables a certain degree of circularity for nutrients; however, loss of nutrients (e.g., fertilizer run-off) requires the use of synthetic chemical fertilizers such as ammonia and diammonium phosphate. Overapplication of fertilizer creates nutrient accumulation in soil, and uncontrolled run-off pollutes waterbodies (e.g., triggers algae blooms). Nutrients in waterbodies can be transported over long distances by following hydrological networks. For instance, nutrient pollution in Pennsylvania can propagate

all the way to the Mississippi river; this indicates that communities can be affected by pollution that is generated outside their jurisdiction (this is known as *environmental injustice*). In addition to water pollution, application of manure and synthetic fertilizer leads to significant emissions/leaks of methane and ammonia to the environment; for instance, organic matter in manure is degraded by bacteria to generate methane and ammonia injected in the soil (a gas) cannot be fully absorbed by the soil. The dairy industry is a sector that is tightly connected to other sectors (chemical industry and agricultural industry) and with the environment in complex ways, see **Figure 2**. The chemical industry can help address environmental impacts of the dairy sector by designing new fertilizer products that minimize run-off/emissions or by designing new crops that require less fertilizer. Nutrient run-off can also be mitigated by identifying technologies that can separate nutrients from manure streams in a scalable and economic manner.

**Figure 3.** Interdependence between the power grid and the chemical sector.

### Example II. Exploiting Electricity Markets

Decarbonization of the chemical industry requires *electrification*, as this pathway can help leverage the use of renewable power [3]. At the same time, decarbonization of the power grid via adoption of renewable power requires that power demands/loads *are more flexible*, as such flexibility is key for mitigating intermittency of renewable power. Electrochemical technologies such as electrolysis will play a crucial role in decarbonizing both the chemical and power sectors, as these technologies help bridge/connect these sectors, see **Figure 3**. For instance, one can produce clean (carbon-free) hydrogen via water splitting systems to be used as feedstock for other chemical processes such as methanol synthesis, which currently uses large amounts of (carbon-intensive)

hydrogen generated via steam reforming and natural gas. Electrolyzers can exploit *dynamics of electricity markets*, which currently exhibit high fluctuations and, in some regions, high frequency of negative prices (consumers get paid to use power). It has recently been shown that hydrogen produced via electrolysis (and via exploitation of electricity market dynamics) can be cheaper than hydrogen produced via steam reforming. Moreover, because electrolysis is modular, one can envision creating hybrid systems that produce hydrogen on-demand and in locations where building natural gas delivery infrastructure is difficult. Identifying these types of opportunities requires that chemical engineers think about how their *processes connect with infrastructure* (power grid and natural gas networks) and associated markets. At the same time, chemical engineers should work with electrical engineers to identify how to *leverage electrolysis flexibility* in power grid operations. Electrochemical technologies also offer an opportunity to shift power demands over multiple temporal scales (e.g., from hours to days to seasons); visualizing how to schedule these shifts is challenging.

**Figure 4.** Design of a multi-layer plastic film for food packaging.

### Example III. Food Packaging Design

*Food packaging* is one of the main uses of plastic materials around the world. These packaging systems consist of *multi-layer plastic films*, which comprise different types of plastics that conduct different functionalities (e.g., oxygen barrier, moisture barrier, heat isolation, and mechanical strength), see **Figure 4** [4]. The engineering of these packaging materials helps minimize food spoilage and helps maximize access to food supply (better packaging leads to more flexible transportation and inventory management). Unfortunately, multi-layer plastic films cannot be recycled using mechanical recycling technologies. *Solvent-based separation technologies* offer a promising pathway to enable recovery of plastic materials from multi-layer films; in such processes, solvents are carefully selected to separate specific plastic films in a selective manner. The selection of the solvent plays a critical role in the efficiency of the separation process, in resource use (e.g., energy), and ultimately in recycling cost. Moreover, the selection of the solvent separation sequence is dictated by the nature of the multi-layer film

to be separated (and waste streams tend to have high variability). As such, when designing this recycling processes, it is important to think about how to design the food packaging materials, the solvent, and the process *simultaneously*. The selection of the solvent can be accelerated by leveraging molecular simulations tools such as *COSMO-RS*. Chemical engineers can leverage these types of tools to inform product/process design. Moreover, chemical engineers should use *lifecycle analysis tools* to quantify the environmental impact of recycling processes and to compare this with virgin plastic production; for instance, designing an ineffective recycling process can do more harm than good to the environment (e.g., can lead to a high carbon footprint or to higher ecotoxicity). Lifecycle analysis is a technique that fosters multi-scale, systems-thinking, as this requires the careful selection of domain boundaries, careful definition of pathways and steps followed to obtain products, and careful identification of interdependencies of these pathways and external systems (e.g., sources of energy and associated carbon footprints). Notions of graph theory can be valuable here, as they can help visualize interdependencies between products, technologies, and impacts. For instance, graphs can be used to identify all steps needed to arrive to plastic materials from oil and to identify all environmental impacts generated along the way.

## FUTURE OUTLOOK AND NEEDS

As society becomes more complex and it becomes increasingly difficult to assess how chemical products and processes interact with other systems, it will be necessary to identify better conceptual frameworks to capture connectivity of complex systems across multiple spatial and temporal scales. Graphs can be used to represent shifts of power in space and time, a principle that is being used to manage the power loads of power-intensive data centers. In addition to new conceptual frameworks, it is also necessary to develop modeling and simulation tools that can help engineers visualize multi-scale interdependencies arising in complex systems. This is critical in navigating complexity and in fostering understanding of impacts of products and processes at a large scale. It is also necessary to develop modeling tools that can link process simulators to molecular scale phenomena (e.g., microkinetic models and molecular simulations), to understand inherent physical limitations that processes might have. In enabling this couple, it is needed to develop tools that can seamlessly replace complex simulation models with machine learning models, which can be much easier to manage and manipulate.

## ABSTRACT

This paper presents an algorithm for developing sparse surrogate models that satisfy mass/energy conservation even when the training data are noisy and violate the conservation laws. In the first step, we employ the Bayesian Identification of Dynamic Sparse Algebraic Model (BIDSAM) algorithm proposed in our previous work to obtain a set of hierarchically ranked sparse models which approximate system behaviors with linear combinations of a set of well-defined basis functions. Although the model building algorithm was shown to be robust to noisy data, conservation laws may not be satisfied by the surrogate models. In this work we propose an algorithm that augments a data reconciliation step with the BIDSAM model for satisfaction of conservation laws. This method relies only on known boundary conditions and hence is generic for any chemical system. Two case studies are considered—one focused on mass conservation and another on energy conservation. Results show that models with minimum bias are built by using the developed algorithm while exactly satisfying the conservation laws for all data.

**Keywords:** System Identification, Machine Learning, Algorithms, Design Under Uncertainty, Optimization

## 1.0 INTRODUCTION

Surrogate models are of great use for many process systems when developing the first-principles model is complex and/or time-consuming or the repeated simulation of the first-principles model for optimization/control is computationally expensive and/or difficult to converge reliably [1-3]. In recent years, greater access to numerous sensors, ease of collection and storage of large amount of data for many process systems and increased computational power with the emergence of supercomputers incentivized the development of data-driven models.

In the area of data-driven models, there are significant works on artificial neural network (ANN) models, with many powerful tools being readily available in the public domain. However, due to the black box nature, ANN models suffer from the lack of model interpretability which is a desired property of surrogate modeling. In addition, ANN models often require large amount of data for training while the developed models are often characterised with limited extrapolation capabilities. One approach to address these limitations is to develop data-driven

interpretable models by using well-defined basis functions such as those employed in Sparse Identification of Nonlinear Dynamics (SINDy) [4], Automatic Learning of Algebraic Models (ALAMO) [5] and Algebraic learning via elastic net (ALVEN)[6]. However, these existing approaches can perform poorly when trained with the noisy data especially for the case of correlated noise which is common for the industrial data. For the SINDy algorithm in particular, several methods including ensemble modeling [7] and implicit SINDy [8] have been proposed to enhance the robustness of the algorithm to the noisy data. Still, the level of noise that is acceptable for satisfactory model building can be highly limited. In addition, these approaches often result in more complicated models leading to some loss of desired model interpretability and sparsity. In our previous work [9], we proposed the Bayesian identification of Dynamic Sparse Algebraic Models (BIDSAM) algorithm that addresses the challenges of sparsity, model interpretability and robustness to noisy data. The developed algorithm employs Bayesian inferencing implemented in the expectation maximization (EM) framework for simultaneous model parameter estimation and uncertainty quantification that

explicitly accounts for correlation in the measurement noise, if exists. In that algorithm, system nonlinearities are approximated by linear combinations of linear and nonlinear basis functions that are transformations of input variables and their interactive effects among themselves and the output variables. The optimal sparsest subset of the resulting large family of basis functions is selected using the branch and bound algorithm which returns a set of hierarchically ranked sparse models by minimizing an information criterion that not only incentivizes model fitness but also accounts for parameter estimability.

It is desired that models of chemical systems satisfy mass/energy constraints. Else the predicted results by a surrogate model can be meaningless. To this end, there exists several works in which physics-informed machine learning algorithms are developed for satisfying some physics constraints [10-12]. Most of these are not for satisfying mass or energy constraints, but for satisfying other physical constraints such as thermodynamic constraints. In addition, these approaches are highly specific requiring detailed knowledge of the system, which may not be available for a system where data-driven models are being developed.

In this work, we propose an approach that extends the capabilities of the BIDSAM algorithm for identification of robust sparse models that satisfy mass/energy conservation laws exactly both for the forward and inverse problems without loss of sparsity and model interpretability. The proposed approach guarantees the satisfaction of the conservation laws for all predictions while relying only on the knowledge of boundary conditions.

## 2.0 THEORY

### 2.1 Sparse Model Selection and Parameter Estimation

Consider a general nonlinear system with states  $x$ , inputs  $u$ , measured outputs  $y$ , and model parameters  $\theta$  represented by the following set of differential and algebraic equations:

$$\dot{x} = f(x, u, \theta) \quad (1)$$

$$y = g(x) \quad (2)$$

The BIDSAM algorithm proposed in our previous work [9] approximates the system nonlinearities with a linear combination of linear and nonlinear transformations of input variables and their interactive effects among themselves and the measurements. The resulting model takes the following form:

$$y_k = \mathbf{A}y_{k-1} + \mathbf{C}U_{k-1}^* + \omega_k \quad (3)$$

where  $U_{k-1}^*$  represents the set of basis functions,  $\omega_k$  stands for additive noise and  $\mathbf{A}, \mathbf{C}$  are the model

parameters. Using Bayesian inferencing implemented in the Expectation-Maximization (EM) framework, uncertainty quantification is undertaken while estimating model parameters. A branch and bound algorithm is developed to search for the sparsest subset of basis functions that best approximates the system behavior given the available data. The BIDSAM algorithm returns desired numbers of hierarchically ranked models based on a modified Akaike information criteria that is used as the model fitness criterion.

### 2.1 Model Update for Satisfaction of Conservation Laws

The models resulting from the BIDSAM algorithm show superior performance compared to existing algorithms especially when training data is corrupted with correlated noise. But the BIDSAM models are not guaranteed to satisfy conservation laws. This becomes very important especially when the training data are significantly noisy and violate the conservation laws. In this work, the BIDSAM model is augmented with a dynamic data reconciliation (DDR) step and an algorithm for updating model parameters so that final model results satisfy the mass/energy conservation laws. The overall model structure is given in Figure 1. The approach includes a linear transformation of the output from the BIDSAM model,  $x$ , by introducing a transformation that brings in more degrees of freedom for the optimization.

Figure 1: Mass/energy constrained model

#### 2.2.1 Inverse problem

The inverse problem involves updating the BIDSAM model parameters in an iterative manner while solving the following optimization problem.

$$\min_{\Omega, y_{ddr}} \sum_i (\Omega x^k - y_{ddr})^T W_1^{-1} (\Omega x^k - y_{ddr}) + \sum_i (y_{data} - y_{ddr})^T W_2^{-1} (y_{data} - y_{ddr}) \quad (4)$$

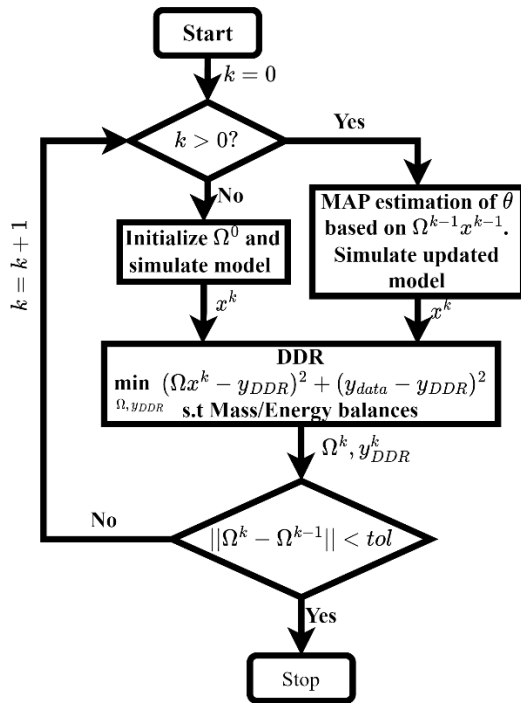

s. t. Mass/Energy balances

In Equation 4,  $W_i$ 's represent the weighting matrices,  $y_{data}$  denote the measured data and  $y_{ddr}$  denote the final model output that are desired to satisfy mass/energy balances. For the case of mass conservation, atom balance can take the following general form:

$$\sum n_{j,p_i}(u_p(k)) = \sum n_{j,q_o}(y_{q,adr}(k)) \quad (5)$$

where  $n_{j,p_i}$  is the number of atoms of element  $j$  with respect to input variable  $p$ , and  $n_{j,q_o}$  are the number of atoms of element  $j$  with respect to output variable  $q$ . For energy conservation, a similar approach is followed by considering enthalpy in and out for the system as discussed later in section 3.2 for the second case study. Although equation 5 has been written for a general case of multiple component situation, the same conditions apply to scenarios in which only total mass flow is known at the inlet or outlet of the system. The situation in which only total flows in and out of the system are known is considered trivial and mass is assumed to be generally conserved conditioned on the known mass flow rate into the system as shown in the second case study.

The overall algorithm for solving the inverse problem is shown in Figure 2.

**Figure 2.** Sequential algorithm for inverse problem.

In the first iteration, initial values are assumed for the hyperparameters  $\Omega$ , then we solve the optimization problem in Equation 4 using the Interior point (IPOPT) algorithm [13]. In subsequent iterations, model parameters are updated based on the optimal values obtained for  $\Omega$  in the previous iteration. This is done by undertaking a maximum a posteriori (MAP) estimates of these parameters using Bayesian inferencing and the EM algorithm as detailed in our previous work [9]. The iteration continues till

convergence.

### 2.2.2 Forward problem

The overall structure in Figure 1 remains the same for the forward problem. However, in this case, the parameters  $\Omega$  and  $\theta$  assume the optimal values obtained from the inverse problem and remain unchanged while DDR is undertaken just one time for each set of desired prediction. The following objective function replaces that in Equation 4 for the forward problem:

$$\min_{\Omega, y_{adr}} \sum_i (\Omega x^k - y_{adr})^T W_1^{-1} (\Omega x^k - y_{adr}) \quad (6)$$

The constraints for this optimization remain the same as for the inverse problem.

## 3.0 CASE STUDIES

The efficiency of the developed algorithm is tested on two case studies: an isothermal CSTR and a lumped parameter superheater system.

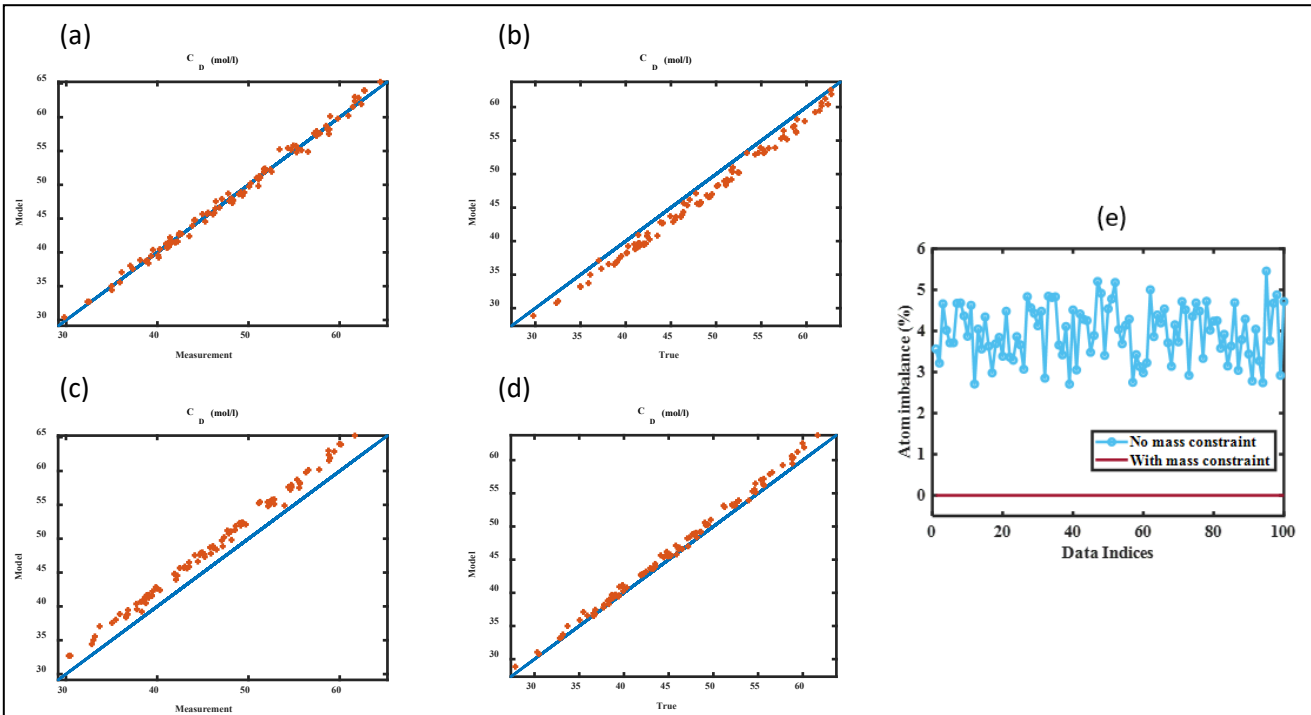

### 3.1 Isothermal CSTR

For this case study, the performance of the developed algorithm is examined for the satisfaction of mass conservation. A schematic of the CSTR is shown in Figure 3. Chemical reactions for this system are as follows:

**Figure 3.** Schematic diagram of isothermal CSTR.

For this modeling purpose, the input variables considered are the reactor feed rate ( $F$ ) and species concentrations at the inlet ( $C_{Af}$ ,  $C_{Bf}$ ,  $C_{Cf}$  and  $C_{Df}$ ). We seek to predict the concentration of each species ( $C_A$ ,  $C_B$ ,  $C_C$  and  $C_D$ ) at the reactor outlet based on changes in the input variables. Training data are simulated by solving the differential equations used to model the system from first-principles. Simulated correlated noise and constant bias

**Figure 4.** Validation plots for isothermal CSTR model: (a)-(b) BIDSAM, (c)-(d) BIDSAM with mass constraint.

**Table 1.** Performance measures of the models of the isothermal CSTR.

Mass constrained?	No. of parameters	% RMSE			
		$C_A$	$C_B$	$C_C$	$C_D$
<b>Trained using True Data</b>					
No	24	1.32	0.64	1.47	1.59
Yes		1.44	0.75	1.41	1.02
<b>Trained using Noisy Data with Bias</b>					
No	24	4.36	4.04	4.45	4.25
Yes		2.05	1.81	2.00	2.12

are added to this data which is then used for model training. Validation plots for a model obtained when training is done by using noisy data with bias are shown in Figure 4.

Figures 4(a-b) show that while the results from the BIDSAM model without constraints match the training data quite well but there is bias with respect to the truth. Figures 4(c-d) show that the results from the model built by using the algorithm with mass constraint exhibit bias with respect to the biased noisy data, but are closer to the truth. Figure 4(e) shows that while the model built without considering mass conservation constraints violates the mass balance, the algorithm with mass constraint included results in exact satisfaction of the conservation law. For training with noisy data with bias, the maximum %RMSE for the unconstrained algorithm is 4.45% while for the constrained algorithm we have

2.05%.

### 3.2 Adiabatic superheater system

This case study evaluates the performance of the BIDSAM model with energy constraints included. A superheater from a power plant, shown in Figure 5, where steam is superheated by using the hot flue gas is considered. The system has a cross-flow configuration. The input variables considered are the steam and flue gas mass flowrates ( $\dot{m}_{st}$ ,  $\dot{m}_{fg}$ ), temperatures ( $T_{st,in}$ ,  $T_{fg,in}$ ) and pressures ( $P_{st,in}$ ,  $P_{fg,in}$ ). The output variables are the steam and flue gas outlet temperatures ( $T_{st,out}$ ,  $T_{fg,out}$ ).

The energy balance constraints to be included as equality constraints in the optimization problem given by Equation 4 are as follows:

**Figure 5.** Schematic of lumped superheater system.

$$\begin{aligned} & \dot{m}_{fg}(k) C_{p_{fg}}(k) (T_{fg,in}(k) - T_{fg,out}(k)) \\ & = \dot{m}_{st}(k) (h_{st,out}(P_{st}, T_{st,out}, k) - h_{st,in}(P_{st}, T_{st,in}, k)) \quad (8) \end{aligned}$$

Here, it is assumed that the flue gas is treated as an ideal gas with constant specific heat capacity while specific enthalpies for steam are computed by using the IAPWS R7-97 correlations. Similar to the first case study, model training is done by using the noisy data with constant bias. Plots comparing results from the models built with and without energy constraints are shown in Figure 6.

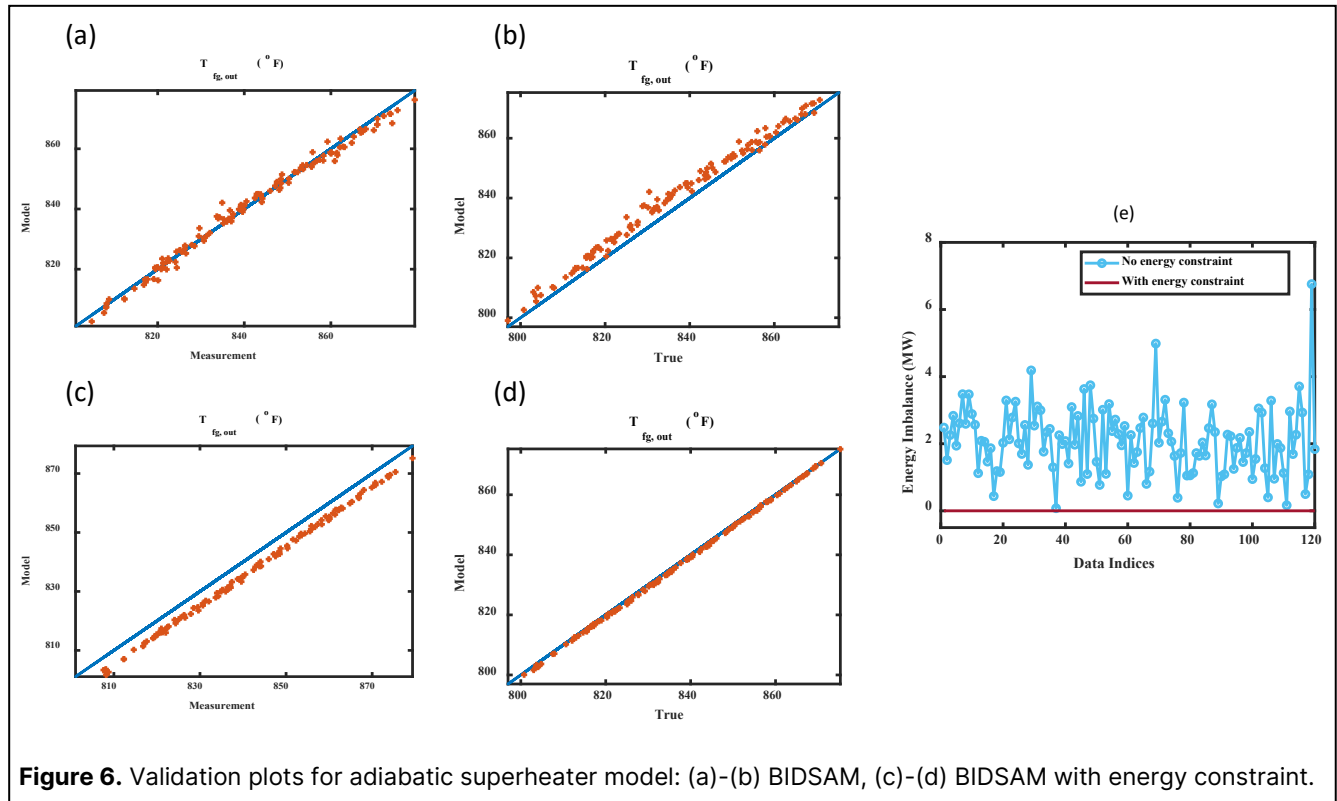

Figures 6(a-b) show the results from the model built by using the algorithm without energy constraints while

Figures 6(c-d) compare the results from the model built by using the algorithm with energy constraints. Figure 6(c-e) show that although the algorithm with energy constraints included leads to biased estimate with respect to the data, it has practically negligible bias with respect to the truth and also satisfies the energy conservation constraints. This is reverse for the model built by using the algorithm without energy constraints.

The key performance measures are shown in Table 2. It is observed that while the RMSE for both output variables have increased when trained using the data with bias for both the models built with or without considering energy constraints, the relative increase is higher for the model built without considering energy constraints. Particularly for the flue gas temperature ( $T_{fg,out}$ ) there is considerable difference in the results obtained by using the algorithm with energy constraints.

**Table 2.** Performance measures of the models for the adiabatic superheater system.

Mass constrained?	No. of parameters	% RMSE	
		$T_{st,out}$	$T_{fg,out}$
<b>Trained Using True Data</b>			
No	10	1.35	1.98
Yes		0.99	0.23
<b>Trained Using Noisy Data with Bias</b>			
No	8	4.10	4.31
Yes		2.61	0.75

**Figure 6.** Validation plots for adiabatic superheater model: (a)-(b) BIDSAM, (c)-(d) BIDSAM with energy constraint.

## CONCLUSIONS

An algorithm has been developed that guarantees the satisfaction of conservation laws by sparse models obtained by using the enhanced BIDSAM algorithm. The results for the case studies show that the sparse models built by using the algorithm guarantee the satisfaction of mass/energy balance even when trained by using data that are noisy with constant bias with respect to the truth. For the isothermal CSTR case study, %RMSE of the models built with and without mass constraints remains similar when the training is done by using the true data but there was considerable difference in results from the models when training is done by using the noisy data with bias. Similar observations are made for the adiabatic superheater case study as well, there was reduction in the model error with the constraints where energy constraints are satisfied by the enhanced BIDSAM algorithm. One limitation of the proposed algorithm is in the relatively larger training time for the selection of appropriate basis function using the BIDSAM approach. Detailed analysis of this can be found in our previous work [9]. In the future, the algorithm will be extended to application for dynamic model building and for simultaneous conservation of mass and energy while also improving on the computational efficiency for model selection.

## ACKNOWLEDGEMENTS

The work was funded by the U.S DOE through the project titled "Boiler Health Monitoring Using a Hybrid First Principles-Artificial Intelligence Model" (Grant # DE-FE0031768). The DOE financial support is gratefully acknowledged by the authors of this paper.

## ABSTRACT

Process simulation problems often involve systems of nonlinear and nonconvex equations and may run into convergence issues due to the existence of recycle loops within such models. To that end, surrogate models have gained significant attention as an alternative to high-fidelity models as they significantly reduce the computational burden. However, these models do not always provide a guarantee on the prediction accuracy over the domain of interest. To address this issue, we strike a balance between computational complexity by developing a data-driven branch and prune-based framework that progressively leads to a guaranteed solution to the original system of equations. Specifically, we utilize interval arithmetic techniques to exploit Hessian information about the model of interest. Along with checking whether a solution can exist in the domain under consideration, we generate error-bounded convex hull surrogates using the sampled data and Hessian information. When integrated in a branch and prune framework, the branching leads to the domain under consideration becoming smaller, thereby reducing the quantified prediction error of the surrogate, ultimately yielding a solution to the system of equations. In this manner, we overcome the convergence issues that are faced by many simulation packages. We demonstrate the applicability of our framework through several case studies. We first utilize a set of test problems from literature. For each of these test systems, we can find a valid solution. We then demonstrate the efficacy of our framework on real-world process simulation problems.

## INTRODUCTION

Systems of equations arise in many fields of practical interest such as engineering, economics, physics, and chemistry. A system of equations in  $N$  -dimensions is represented as:

$$\mathbf{F}(\mathbf{x}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_N(\mathbf{x}))^T$$

Simulation of chemical processes involve numerically solving such systems of equations. Solving such a system means finding a vector  $\mathbf{x}$  such that  $\mathbf{F}(\mathbf{x}) = 0$  where  $\mathbf{x} = (x_1, x_2, x_3, \dots, x_n)$ , which is not trivial, but there are many existing methods that have been developed to solve such systems traditionally. These methods can be categorized under three general classes: i) Homotopy continuation methods; ii) Interval-Newton methods; iii) Newton-type methods.

Homotopy continuation methods involve starting with a system of equations  $\mathbf{G}(\mathbf{x})$ , whose solution is known, embedded in a homotopy function  $\mathbf{H}(\mathbf{x}, t)$  along with the original system of equations  $\mathbf{F}(\mathbf{x})$  where  $t$  is the homotopy parameter. The idea here is to solve a series of problems as  $t$  increases from 0 to 1 to obtain the solutions of  $\mathbf{F}(\mathbf{x})$  by following the solution paths starting from  $\mathbf{G}(\mathbf{x})$  [1,2]. Interval-Newton methods involve finding intervals of the solution space where solutions can exist with mathematical guarantee [2,3].

Newton's methods [4] or Newton-type methods are iterative techniques that generate increasingly improved approximations of the root with each iteration. These methods have a faster rate of convergence but there are a few issues associated with Newton-type methods [5], e.g., i) Newton-type methods require computation of the Jacobian while some require the inverse of the Jacobian

as well which may be computationally expensive to obtain for large systems of equations at every iteration; ii) This may also lead to numerical instabilities with convergence if the Jacobian is very close to zero; iii) The convergence of such methods also depends upon the initialization. It is difficult to know apriori if a particular initialization converges to a root within a desired neighborhood. If initialized at a point which is far away from a root, convergence to that desired root may not be obtained.

Several other algorithms have been developed which do not exactly fall under any one of these categories but are nevertheless intelligent algorithms to find solutions to systems of equations. Grosan and Abraham [6] developed an evolutionary algorithm where they convert the system of equations into a multi-objective optimization problem and use pareto dominance relationships to find solutions. Ramos and Vigo-Aguiar [5] developed an approach which involves replacing a non-linear equation with 2 associated equations with the idea being that the system of associated equations is easier to solve than the original equation using Newton's methods. Ramos and Monteiro [7] further developed this approach to solve systems to non-linear equations.

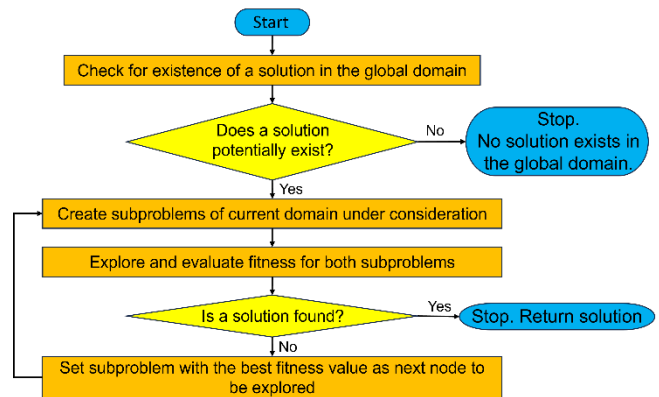

This work aims to propose and study the GEMS framework which we have developed to solve systems of equations. GEMS stands for Guaranteed Error-bounded Modeling of Surrogates which involves replacing each of the original  $C^2$ -continuous equations by surrogates. The maximum error between these equations and their respective surrogates is bounded by an error metric,  $\epsilon_{max}$ , which can be derived through the theory of guaranteed estimators and using interval arithmetic methods [8]. One of the key features of the GEMS framework is that it does not depend on the Jacobian of the system of equations but does require a bound on the diagonal elements of the Hessian. Another key feature is that it allows the user to define domain bounds to selectively search the space for solutions. Lastly, it defines a convergence criterion which ensures that a solution is found.

The contents of this work are organized as follows: the methodology section introduces the overall flow of the framework along with the theoretical requisites. In the next section, we present case studies to demonstrate the applicability of the framework. The computational results are reported in the next section, finally followed by the conclusions.

## METHODOLOGY

We propose the GEMS framework to solve systems of equations with one of its key ideas being that it can check whether a solution exists in a search space using sampled data, the error metric  $\epsilon_{max}$ , and interval arithmetic. From the point of view of the user, GEMS takes in input data in the form of the systems of equations  $F(x)$

and the global domain bounds and returns a solution to  $F(x)$ . When provided with a system of equations and the global domain bounds, the framework first checks for the existence of a solution in the global search space. If a solution can exist, the search space (domain) is then divided into two subproblems which are explored. Exploration of a subproblem involves checking for the existence of a solution which, if exists, necessitates the evaluation of the fitness for the subproblem. The domain of the subproblem with the best fitness is then set as the domain to be explored next. This is done iteratively until a solution is found. A high-level flow of the GEMS framework is shown in Figure 1.

**Figure 1:** Overall flow of the GEMS framework.

The subsequent subsections explain the theories and subroutines that are utilized in the GEMS framework.

## Data Sampling and Generation of Convex Hull Surrogates

GEMS replaces the original system of equations with convex hull surrogates. Given a search space i.e., a bounded domain, the functions are evaluated (sampled) at the domain bounds so that the set of points used to generate the convex hull can cover even the extremities of the search space. An  $N$ -dimensional space has  $2^N$  vertices. The number of vertices increases drastically as  $N$  increases thereby making it impractical to have a function evaluation at every vertex for higher dimensional problems. Caratheodory's theorem states that given an  $N$ -dimensional space, if any point  $x$  lies within a convex hull defined by a set of points, then it is possible to express  $x$  as a convex combination of at most  $N + 1$  points in that set of points [9]. In other words,  $N + 1$  points are sufficient to generate a convex hull surrogate in any domain. When obtaining  $F(x)$  is expensive, this theorem can be used to reduce the number of required function evaluations. We consider both cases where  $2^N$  and  $N + 1$  points are used to generate the convex hull surrogates. To illustrate, the 2-D functions  $f_1(x, y) = x^2 + y^2 - 25$  and  $f_2(x, y) = (x - 6)^2 + y^2 - 9$  with their convex hull

surrogates  $c_1(x, y)$  and  $c_2(x, y)$  which are constructed using the vertex evaluations are shown in Figure 2.

**Figure 2:**  $f_1(x, y)$  (blue) and  $f_2(x, y)$  (orange) shown in a given domain (left). Their respective convex hulls  $c_1(x, y)$  (blue) and  $c_2(x, y)$  (orange) shown over the same domain (right). The red and green curves represent the zeros of  $f_1(x, y)$  and  $f_2(x, y)$  respectively.

## Interval Arithmetic

We use our in-house subroutine to compute Hessian bounds for a  $C^2$ -continuous function in a closed form involving the standard arithmetic, trigonometric, logarithmic, and exponential operators. We first generate the computational graph for a given function, and then implement interval arithmetic rules in all nodes of the graph to efficiently compute bounds on the output. An automatic differentiation type scheme is then used to compute bounds on the gradients. The computational graph that corresponds to the gradient is dynamically created to store all dependencies. Using these graphs, we then automatically compute bounds on the Hessian. A key advantage of this approach is the guaranteed estimation of Hessian bounds that can not be achieved using point-wise evaluation techniques. In some cases, we also use interval arithmetic on the computational graph to compute a lower bound,  $lbmin$  and upper bound,  $ubmax$  for each function in the case where enough samples aren't available.

## Guaranteed Estimators

Now that Hessian bounds can be obtained, the concept of guaranteed estimators is utilized which is used to compute the error metric  $\epsilon_{max}$ . Namely, we use the guaranteed edge-concave underestimator [10],  $L(x)$  defined as:

$$L(x) = f(x) - \sum_{i=1}^N \theta_i^L (x_i - x_i^G)^2 \quad (1)$$

where  $\theta_i^L = \max\left\{0, \left[\frac{d^2 f}{dx^2}\right]^U\right\}$

The edge-concave definition for a function  $f$  is equivalent to:

$$\frac{d^2 f}{dx^2} \leq 0 \quad \forall i = 1, \dots, N \quad (2)$$

For an edge concave function,  $\theta_i^L = 0 \forall i = 1, \dots, N$

Similarly, we use the edge-convex overestimator,  $U(x)$  defined as [11]:

$$U(x) = f(x) + \sum_{i=1}^N \theta_i^U (x_i - x_i^G)^2 \quad (3)$$

where  $\theta_i^U = \min\left\{0, -\left[\frac{d^2 f}{dx^2}\right]^L\right\}$

The edge-convex definition for a function  $f$  is equivalent to:

$$\frac{d^2 f}{dx^2} \geq 0 \quad \forall i = 1, \dots, N \quad (4)$$

For an edge convex function,  $\theta_i^U = 0 \forall i = 1, \dots, N$

$x_i^G$  is the point from which the estimator is generated. The estimators are illustrated in Figure 3.

**Figure 3:** The function  $f(x)$  shown along with its guaranteed underestimator  $L(x)$  (shown in orange) and its guaranteed overestimator  $U(x)$  (shown in green) generated from the sample point (shown in red).

## Error-boundedness

$\epsilon_{max}$  is the maximum possible error between the equations and their respective surrogates and therefore it is desired to have the smallest  $\epsilon_{max}$  as possible. If the closed form of the equations is convoluted in the sense that it contains nested terms, interval arithmetic may result in extremely large (loose) values of  $\epsilon_{max}$ .

Based on the nature of the function i.e., based on its  $\theta_i^L$  and  $\theta_i^U$  values, each of the functions in the original system can be classified into one of three categories:

- i) Category 1 - The function is neither edge-convex nor edge-concave in all dimensions,
- ii) Category 2 - The function is both edge-concave and edge-convex in all dimensions,
- iii) Category 3 - The function is edge-convex or

edge-concave in some but not all dimensions.

The value for  $\epsilon_{max}$  for each of these categories when we consider the set of all  $2^N$  vertices and then a subset of  $N + 1$  of those  $2^N$  are shown in Tables 1 and 2 respectively.

**Table 1:**  $\epsilon_{max}$  values when all  $2^N$  vertices are evaluated.

Category 1	$\epsilon_{max} = \sum_{i=1}^N (\theta_i^l + \theta_i^u) (x_U^i + x_M^i)$
Category 2	$\epsilon_{max} = \max\{f_{eval}\} - \min\{f_{eval}\}$
Category 3	$\epsilon_{max} = f_{IAmax} - f_{IAmin}$

**Table 2:**  $\epsilon_{max}$  values when  $N + 1$  vertices are evaluated.

Category 1	$\epsilon_{max} = \sum_{i=1}^N (\theta_i^l + \theta_i^u) (x_U^i + x_M^i)$
Category 2	$\epsilon_{max} = f_{IAmax} - f_{IAmin}$
Category 3	$\epsilon_{max} = f_{IAmax} - f_{IAmin}$

Here,  $\max\{f_{eval}\}$  is the maximum of the vertex function evaluations,  $\min\{f_{eval}\}$  is the minimum of the vertex function evaluations,  $f_{IAmax}$  is the upper bound on the function obtained through interval arithmetic and  $f_{IAmin}$  is the lower bound on the function obtained through interval arithmetic.

### Solving the system of surrogates

Now that we have our system of error-bounded convex hull surrogates, we wish to find a point  $x^*$  in the search space such that the distance  $\tau$  between furthest the convex hull surrogate and the zero "plane" is minimized. The following linear programming (LP) model CH enables us to do that:

$$\begin{aligned} & \min \tau \\ \text{s. t.} \quad & x_n = \sum_{v \in cv} \lambda_{j,v} \hat{x}_{v,n} \quad \forall n \in N, j \in J \end{aligned} \quad (5)$$

$$CH_j = \sum_{v \in cv} \lambda_{j,v} f_j(\hat{x}_{v,n}) \quad \forall j \in J \quad (6)$$

$$\sum_{v \in cv} \lambda_{j,v} = 1 \quad \forall j \in J \quad (7)$$

$$CH_j \leq \tau \quad \forall j \in J \quad (8)$$

$$-CH_j \leq \tau \quad \forall j \in J \quad (9)$$

$$0 \leq \lambda_{j,v} \leq 1 \quad \forall j \in J, v \in V \quad (10)$$

In this formulation, Equations 5, 6 and 7 are referred to as the convex combination constraints. Equations 7 and 10 ensure that the point lies inside the domain under consideration. Here,  $J$  is the set of functions and  $V$  is the set of vertices.

Note that,  $\hat{x}_{v,n}$  is the known co-ordinates of vertex  $v$  in dimension  $n$  and  $f_j(\hat{x}_{v,n})$  is the value of the function

evaluation for a function  $j$  at the point  $\hat{x}_{v,n}$ .  $\lambda_{j,v}$  is the weight assigned to vertex  $v$  for the function  $j$ .

Solving this formulation, we obtain a point ( $x^*$ ) at which we evaluate fitness defined as follows:

$$Fitness = \sum_{j=1}^N f_j^2(x^*)$$

This fitness allows us to define a metric for quantifying the "closeness to zero" or quality of the obtained solution. It is desirable to have a fitness function value close to zero.

### Branch and Prune

With the theoretical requisites established, GEMS involves a branch and prune subroutine (which is inspired by the classical branch and bound) where, given an initial search space, the idea is to repeat the following steps iteratively:

- 1) Prune regions of the search space based of the existence of a solution in that space.
- 2) Branching to generate two subproblems if a solution could exist.
- 3) Choose subproblem with the best (smallest) fitness value to be explored next.

Each subproblem in the branch and prune tree is also called a node. The current node is branched at the midpoint of the domain of the variable having the longest edge. For systems of equations where the domain bound ranges are unequal, we scale the domain bounds relative to the global domain bounds and branch at the midpoint of the domain of the variable having the scaled longest edge. To check whether a solution exists in each search space (each node), the GEMS framework does the following: for each function, we perform a loose pruning check which involves computing a lower bound,  $lbmin$  and an upper bound,  $ubmax$  based solely using interval arithmetic. For any function, if its lower and upper bounds have the same sign, it is not possible for that function to have a solution in that space. Each function has a distinct lower and upper bound. If any of the functions have  $lbmin$  and  $ubmax$  of the same sign, it is impossible for the entire system of equations to have a solution in that space, thereby allowing us to discard that node from further consideration. Note that, we are using the  $lbmin$  and  $ubmax$  based solely on IA which are loose. However, this check helps eliminate unnecessary computation. We move to the next step of node exploration if a solution can exist in the node i.e., if it cannot be pruned based on the loose pruning condition. We then perform function evaluations and Hessian bound estimations to obtain tighter  $lbmin$  and  $ubmax$  values for another tighter pruning check. Figure 4 shows the node exploration subroutine. The  $lbmin$  and  $ubmax$  for each of the categories when we consider the set of all  $2^N$  vertices are

shown in table 3. Similarly, the values of  $lbmin$  and  $ubmax$  when we consider a subset of  $N + 1$  vertices are shown in table 4. Note that for functions which are both edge-concave and edge-convex in all dimensions (Category 2), when we have function evaluations at all  $2^N$  vertices, Tardella's theorem [12,13] enables us to obtain tightest  $lbmin$  and  $ubmax$ .

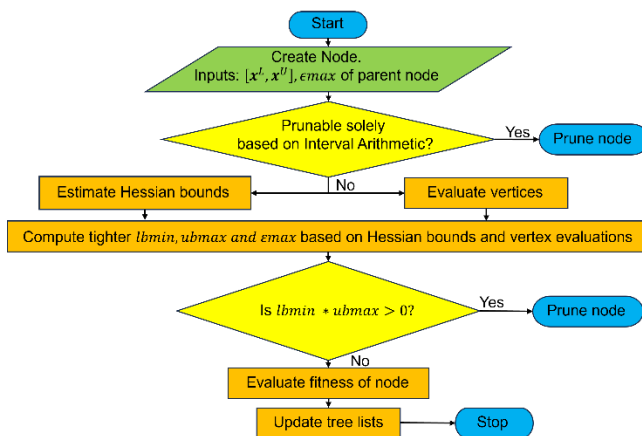

**Table 3:**  $lbmin$  and  $ubmax$  values when all  $2^N$  vertices are considered.

Category 1	$lbmin = \min\{f_{eval}\} - \epsilon_{max}$ $ubmax = \max\{f_{eval}\} + \epsilon_{max}$
Category 2	$lbmin = \min\{f_{eval}\}$ $ubmax = \max\{f_{eval}\}$
Category 3	$lbmin = f_{IAmin}$ $ubmax = f_{IAmax}$

**Table 4:**  $lbmin$  and  $ubmax$  values when all  $N + 1$  vertices are considered.

Category 1	$lbmin = \min\{f_{eval}\} - \epsilon_{max}$ $ubmax = \max\{f_{eval}\} + \epsilon_{max}$
Category 2	$lbmin = f_{IAmin}$ $ubmax = f_{IAmax}$
Category 3	$lbmin = f_{IAmin}$ $ubmax = f_{IAmax}$

If  $lbmin$  and  $ubmax$  have different signs, a solution may possibly exist, and we move to the next step of node fitness evaluation. The node fitness evaluation involves generation of the convex hull surrogates and using the LP formulation to find the point at which we evaluate fitness. If the fitness of a node falls below a certain threshold ( $<1e-4$ ) we have found a point for which the value of each function in  $F(x)$  is extremely close to zero which basically means we have found a solution to the original system of equations.

**Figure 4:** The node exploration subroutine.

## Convergence

As  $\epsilon_{max}$  reduces, the error between the function and its convex hull surrogate reduces. The error metric  $\epsilon_{max}$  is dependent on the Hessian bounds and domain sizes which means the  $\epsilon_{max}$  of a child node can never be greater than the  $\epsilon_{max}$  of its parent. In other words, the error-bound for any subproblem is less than or equal to its parent problem. The sum of all  $\epsilon_{max}$ s for the child node will always be greater than the sum of  $\epsilon_{max}$ s of the parent node. It can be considered an equivalent to the gap in the classical branch and bound technique used in optimization. Also, having a small enough value of  $\epsilon_{max}$  can lead to efficient pruning of sub-regions.

This concludes the overall flow of the GEMS framework.

## CASE STUDIES

We consider some test problems having a single solution as well as a few benchmark problems from literature along with examples of systems of equations arising from test problems in chemical engineering literature.

### Test problems

- 1) Hypersphere systems – The following system of equations can be scaled to N-dimensions while still maintaining the characteristic of having a single solution. We consider the 10, 50 and 100-dimensional systems for our studies. Here, R is the radius of the hyperspheres.

$$F_{HSN}(x) = \begin{cases} \sum_{i=1}^N x_i^2 - R = 0 \\ (x_1^2 - 2R)^2 + \sum_{i=2}^N x_i^2 - R = 0 \\ \sum_{i=1}^N x_i^2 + (x_j - R)^2 - R = 0, \forall j = (3, \dots, N) \end{cases}$$

### Benchmark systems in literature

- 1) Interval Arithmetic [14] – The following system has been considered as one of the benchmark problems from interval arithmetic:

$$F_{IA}(x) = \begin{cases} x_1 - 0.25428722 - 0.18324757x_4x_3x_9 = 0 \\ x_2 - 0.37842197 - 0.16275449x_1x_{10}x_6 = 0 \\ x_3 - 0.27162577 - 0.16955071x_1x_2x_{10} = 0 \\ x_4 - 0.19807914 - 0.15585316x_7x_1x_6 = 0 \\ x_5 - 0.44166728 - 0.19950920x_7x_6x_3 = 0 \\ x_6 - 0.14654113 - 0.18922793x_8x_5x_{10} = 0 \\ x_7 - 0.42937161 - 0.21180486x_2x_5x_8 = 0 \\ x_8 - 0.07056438 - 0.17081208x_1x_7x_6 = 0 \\ x_9 - 0.34504906 - 0.19612740x_{10}x_6x_8 = 0 \\ x_{10} - 0.42651102 - 0.21466544x_4x_8x_1 = 0 \end{cases}$$

- 2) Neurophysiology Application [15] – The

following system arises from an application in neurophysiology:

$$F_N(x) = \begin{bmatrix} x_1^2 + x_3^2 = 1 \\ x_2^2 + x_4^2 = 1 \\ x_5x_3^2 + x_6x_4^3 = c_1 \\ x_5x_1^3 + x_6x_2^3 = c_2 \\ x_5x_1x_3^2 + x_6x_2x_4^2 = c_3 \\ x_5x_3x_1^2 + x_6x_4x_2^2 = c_4 \end{bmatrix}$$

where the constants  $c_i$  can be arbitrarily chosen. We consider all  $c_i = 0$ .

## Systems arising from process engineering models

- 1) Combustion Application [16] – The following system arises from the combustion of propane in air. The stoichiometric equation is:

where R is the relative amounts of air to fuel. Combustion Application – The following system arises from the combustion of propane in air. The variables  $x_i$  for  $i = 1$  to 10 are the number of moles of product  $i$  formed per every mole of propane combusted.

$$F_{CA}(x) = \begin{bmatrix} x_1 + x_4 = 3 \\ 2x_2 + 2x_5x_6x_7 = 8 \\ 2x_3 + x_9 = 40 \\ 2x_1 + x_2 + x_4 + x_7 + x_8 + x_9 + 2x_{10} = 10 \\ x_1x_5 = K_5x_2x_4 \\ \sqrt{40}x_6x_1^{0.5} = K_6\sqrt{x_2x_4N_{Tot}} \\ \sqrt{40}x_7x_4^{0.5} = K_7\sqrt{x_1x_2N_{Tot}} \\ 40x_8x_4 = K_8x_1N_{Tot} \\ \sqrt{40}x_9x_4 = K_9x_1\sqrt{x_3N_{Tot}} \\ 40n_{10}n_4^2 = K_{10}n_1^2N_{Tot} \end{bmatrix}$$

where,

$$N_{Tot} = \sum_{i=1}^{10} x_i$$

The first four equations in the system arise from the mole balances while the rest arise from the equilibrium relations.  $K_i$  for  $i = 5$  to 10 are the equilibrium constants.

- 2) Chemical Equilibrium [17] – The mathematical structure of the combustion application system is analysed and reformulated by using the notion of ‘element variables’ (surrogates for atomic combinations). The first four equations arise from the reformulation of the mole balances in the combustion application system whereas the equilibrium relations reduce to a single equation because of the element variable substitutions

which leads to the following system:

$$F_{CEQ}(x) = \begin{bmatrix} x_1x_2 + x_1 - 3x_5 = 0 \\ 2x_1x_2 + x_1 + x_2x_3^2 + R_8x_2 - Rx_5 \\ + 2R_{10}x_2^2 + R_7x_2x_3 + R_9x_2x_4 = 0 \\ 2x_2x_3^2 + 2R_5x_3^2 - 8x_5 \\ + R_6x_3x_4 + R_7x_2x_3 = 0 \\ 2x_4^2 - 4Rx_5 + R_9x_2x_4 = 0 \\ x_1(x_2 + 1) + R_{10}x_2^2 + x_2x_3^2 + R_8x_2 \\ + R_5x_3^2 + x_4^2 - 1 + R_6x_3 + R_7x_2x_3 \\ + R_9x_2x_4 = 0 \end{bmatrix}$$

Note that the variables  $x_i$  for  $i = 1$  to 5 have been redefined along with the constant R for  $i = 5$  to 10 to account for the element variable substitutions.

- 3) Recycle and Purge in the Synthesis of Ammonia – The ammonia synthesis process involving a recycle and a purge stream is considered. Given the feed stream specifications and the reactor conversion, it is desired to calculate the overall conversion of nitrogen and the ratio of moles of gas purged to the moles of gas leaving the condenser.

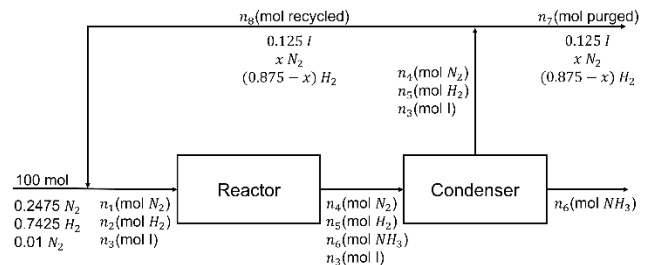

Figure 4: Flowsheet for the ammonia synthesis process.

The following system of equations arises from the overall mole balances, stoichiometric relations, and material balances at the mixing and split points.

$$F_{AS}(x) = \begin{bmatrix} 1 - 0.125n_6 = 0 \\ 148.5 - 3n_5 - 1.75n_6 + 2n_6x = 0 \\ 49.5 - 2n_6x - n_5 = 0 \\ n_6 - 0.75n_1 = 0 \\ 0.5n_1 - n_5 = 0 \\ n_6 - xn_7 - n_4x = 0 \\ 74.25 + 0.875n_7 - xn_7 - n_2 = 0 \\ 1 + 0.125n_7 - n_3 = 0 \end{bmatrix}$$

The domain ranges considered for each of these problems are shown in Table 5.

Table 5: Domain bounds for the test problems

Problem Instance	Domain Ranges
10D-hyperspheres	$x_i \in [-5,5] \forall i = 1, \dots, 10$

50D-hyperspheres	$x_i \in [-5,5] \forall i = 1, \dots, 50$
100D-hyperspheres	$x_i \in [-5,5] \forall i = 1, \dots, 100$
Interval Arithmetic	$x_i \in [-4,4] \forall i = 1, \dots, 10$
Neurophysiology Application	$x_1 \in [-10,5]$ $x_2 \in [-10,6]$ $x_3 \in [-10,7]$ $x_4 \in [-10,8]$ $x_5 \in [-10,9]$ $x_6 \in [-10,9]$
Combustion Application	$x_i \in [-5,5] \forall i = 1, \dots, 10$
Chemical Equilibrium	$x_i \in [-5,5] \forall i = 1, \dots, 5$
Ammonia Synthesis	$n_i \in [0,500] \forall i = 1, \dots, 7$ $x \in [0,1]$

## COMPUTATIONAL EXPERIMENTS AND RESULTS

All runs were performed on an Intel Xeon Gold 6248R 3GHz processor running on Linux (CentOS 7). The algorithm was developed in Python v3.6.8 and used CPLEXv20.1.0.1 in GAMSv35.1 to solve the LP model CH for the system of surrogates.

**Table 6:** Fitness of solution obtained, number of nodes explored and number of function evaluations for the test problems.

Instance	Fitness of Solution	Nodes Explored	Function Evaluations
10-D hyperspheres	7e-5	228	1487
50-D hyperspheres	1e-4	1278	35827
100-D hyperspheres	4e-5	813	51713
Interval Arithmetic	1e-5	64.48	1823
Neurophysiology Application	6e-5	307	1301
Combustion Application	1e-4	21650	97856
Chemical Equilibrium	8e-5	837	3149
Ammonia Synthesis	1e-8	383	54483

We have reported the solutions for each of the test problems using a sampled data set of  $N + 1$  vertices except for the system of equations arising from the ammonia synthesis model where we have used  $2^N$  vertices. The solution of the LP (to minimize the distance to the furthest convex hull surrogate) highly depends on choice of the  $N + 1$  sampled vertices. In other words, the choice of the set of the sampled data affects the path of the branch

and prune search.

## CONCLUSIONS

In this work, we report a data-driven branch and prune approach that has the potential to unlock new avenues for finding solutions to systems of equations without the requirement of an initial guess. Furthermore, the user can specify the domain bounds if solutions within a desired search space are required. Multiple potential sampling strategies need to be investigated which may aid in faster convergence. Further work is needed to reduce the number of required function evaluations.

## ABSTRACT

Alternative formulations for the optimization of chemical process flowsheets are presented that leverage surrogate models and implicit functions to replace and remove, respectively, the algebraic equations that describe a difficult-to-converge Gibbs reactor unit operation. Convergence reliability, solve time, and solution quality of an optimization problem are compared among full-space, ALAMO surrogate, neural network surrogate, and implicit function formulations. Both surrogate and implicit formulations lead to better convergence reliability, with low sensitivity to process parameters. The surrogate formulations are faster at the cost of minor solution error, while the implicit formulation provides exact solutions with similar solve time. In a parameter sweep on the autothermal reformer flowsheet optimization problem, the full-space formulation solves 33 out of 64 instances, while the implicit function formulation solves 52 out of 64 instances, the ALAMO polynomial formulation solves 64 out of 64 instances, and the neural network formulation solves 48 out of 64 instances. This work demonstrates the trade-off between accuracy and solve time that exists in current methods for improving convergence reliability of chemical process flowsheet optimization problems.

## INTRODUCTION

The selection of optimal operating conditions is a fundamental task in chemical process design. This requires the minimization or maximization of an objective function subject to nonlinear and nonconvex constraints. While local solvers such as CONOPT [1] and IPOPT [2] can handle these problems, their convergence can be very sensitive to model formulation, initial guess, and scaling factors. In addition, flowsheet design equations usually contain complex nonlinear expressions, including logarithms, high-degree polynomials and bilinear terms. At certain variable values, these equations can be undefined, and their Jacobian can become singular, hindering convergence.

Some methods to improve convergence of a full space flowsheet optimization problem and address sensitivity to initial parameters include using (1) sophisticated initialization routines and (2) model reformulation

strategies, such as surrogate models and implicit functions.

In the case of (1), it is well known that an effective initialization strategy determines how easily the optimization algorithm converges to a solution [3]. However, finding a good initialization is a cumbersome task because some unit operations do not easily converge for a set of specifications, and there is no systematic way to determine good initial values [4]. In addition, there is a significant computational cost associated with trying multiple initialization methods for each problem instance one attempts to solve.

Regarding (2), surrogate models aim to be simple models that approximate the input and output behaviour of complex systems (in our case study, a Gibbs reactor) over a specific input domain. A surrogate model typically relaxes accuracy in exchange for lower dimensionality and more reliable convergence [5]. Even if the development of these models requires computationally

expensive simulations over a range of input values, they are computationally cheaper to evaluate once they are embedded into a larger interconnected system of equations, such as a chemical process flowsheet. Two surrogates that have been recently used in chemical engineering are neural networks and ALAMO polynomials [6]. Neural networks have been widely used in process control, modeling, and optimization. For instance, Henao and Maravelias use neural networks to model the production of maleic anhydride in a superstructure optimization problem [7]. The ALAMO framework [8] is a recently developed tool used to build simple and accurate polynomial surrogates from a minimal set of training data. It makes use of an integer programming technique to choose basis functions of the input variables and compute the output variables as a linear combination thereof [6,9]. Surrogate optimization using the ALAMO framework has been used in superstructure optimizations for carbon capture systems [10], in global optimization of poly-generation systems [11], and distillation sequences [9].

Reformulating a model with the implicit function theorem, as proposed by [12], aims to exploit the fact that the difficulty of converging a large-scale nonlinear program (NLP) may be due to the effort required to converge the system of nonlinear equality constraints corresponding to specific unit operations in the flowsheet. Solving these units separately from the original formulation can significantly improve convergence reliability. In this work, we take advantage of non-singularity of the Gibbs reactor equations. Given that the Jacobian of these equations with respect to the Gibbs reactor's output variables is non-singular, solving the Gibbs reactor equations yields a unique solution for these output variables. This implies that there exists a function mapping state and input variables to the outputs of the Gibbs reactor. The utility of this property is that complicated algebraic equations from a unit operation can be removed from the NLP using implicit functions. This leaves a smaller set of equations to be seen by the solver and fewer variables to initialize and scale [12].

The surrogate and implicit reformulation strategies are similar in that they both remove complicating equations that describe a difficult-to-converge unit model. In this work, we design an autothermal reformer flowsheet (ATR) in the IDAES process modeling framework [13] and we formulate a full space optimization problem, as shown in Section 3. We then compare convergence reliability, solution quality, and solve time among full-space, implicit function, and surrogate formulations of this problem, and study the trade-offs among these formulations.

## BACKGROUND

### Full Space Formulation

Vector  $x$  is a vector of state variables corresponding to each unit model in the flowsheet, while  $u$  is a vector of manipulated inputs. Function  $G$  describes operational constraints, function  $H$  describes the equality constraints corresponding to each unit model in the flowsheet not including the unit model we intend to replace, and function  $R$  describes the equality constraints only for this unit model. Vector  $y$  is a vector containing the outlet variables corresponding to this unit and any additional intermediate variables used only by this unit. Eq. (1d) will be replaced by either a surrogate model or an implicit function.

$$\max f(x, u) \quad (1a)$$

$$\text{s. t. } G(x, u) \leq 0 \quad (1b)$$

$$H(x, y, u) = 0 \quad (1c)$$

$$R(x, y, u) = 0 \quad (1d)$$

### Surrogate Formulation

This formulation is identical to the one shown in Eq. (1) except for Eq. (2d), which instead of representing first-principles design equations for the unit model of interest, contains a surrogate model  $\bar{R}(x, y, u)$  that approximates this unit's behavior. While this surrogate can be obtained using a variety of methods, as described in [6], in this paper we use neural network and polynomial surrogates.

$$\max f(x, u) \quad (2a)$$

$$\text{s. t. } G(x, u) \leq 0 \quad (2b)$$

$$H(x, y, u) = 0 \quad (2c)$$

$$\bar{R}(x, y, u) = 0 \quad (2d)$$

### Implicit Formulation

The implicit function theorem states that Eq. (1d) can be reformulated as  $y = R_y(x, u)$  if  $\nabla_y R$  is non-singular for all values of state and input variables. Under this condition, Eq. (3) is an exact reformulation of Eq. (1). We solve for  $y$  externally as a square system of equations in a separate interface and the resulting values and derivatives are communicated back to the optimization solver, specifically to Eq. (3c), which links the outlet variable  $y$  calculated by the implicit function to the inner optimization problem. Since this formulation keeps Eq. (1d) feasible and the unit model equations are not seen by the NLP solver, we expect it to lead to better convergence reliability.

$$\max f(x, u) \quad (3a)$$

$$\text{s. t. } G(x, u) \leq 0 \quad (3b)$$

$$H(x, R_y(x, u), u) = 0 \quad (3c)$$

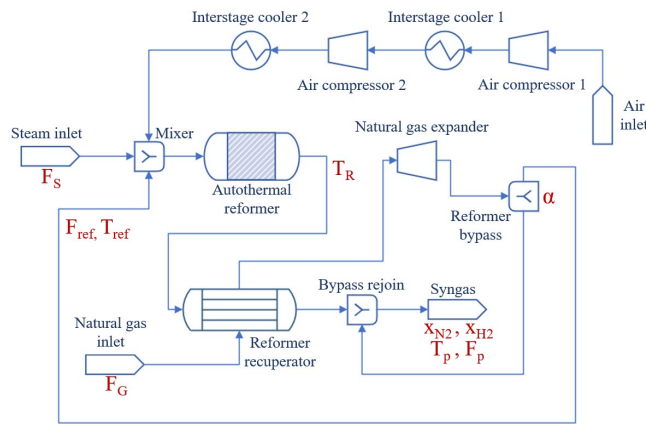

To solve this formulation with a second-order optimization method (e.g., IPOPT), the routines implemented

in [12] are used to calculate the constraint Jacobian, objective gradient, and Hessian of the Lagrangian. As an example, Eq. (4) shows the Jacobian of  $y$  as a function of  $x$  and  $u$ , which is used to calculate the former derivative matrices.

$$\nabla_{x,u}y = -\nabla_y R^{-1} \nabla_{x,u} R \quad (4)$$

## PROBLEM STATEMENT

An autothermal reforming flowsheet is used as an example in the Optimization & Machine Learning Toolkit (OMLT) [14]. The main objective of the autothermal reformer (ATR) is to produce syngas, mainly composed of  $H_2$ ,  $CO$ ,  $CH_4$  and  $CO_2$ . The process is shown in Figure 1. First, a mixture of natural gas, steam, and air is fed into the ATR (modeled as a Gibbs reactor). The hot syngas is then circulated through a shell and tube heat exchanger, also called the reformer recuperator, to heat the natural gas feed. This natural gas feed is then expanded to generate electrical power and is finally fed into the reactor, closing the loop.

**Figure 1.** Process Flow Diagram of the ATR process.

In this study, the objective of all optimization problems is to maximize the hydrogen concentration in the syngas stream, as shown in Eq. (5),

$$\max x_{H_2} \quad (5)$$

The operational constraints are specified in Eq. (6).

$$T_R \leq 1200 [K] \quad (6a)$$

$$T_p \leq 650 [K] \quad (6b)$$

$$F_p \geq 3500 \left[\frac{mol}{s}\right] \quad (6c)$$

$$x_{N_2} \leq 0.3 \quad (6d)$$

$$1120 \leq F_G \leq 1250 \left[\frac{mol}{s}\right] \quad (6e)$$

$$0 \leq \alpha \leq 1 \quad (6f)$$

$$200 \leq F_s \leq 350 \left[\frac{mol}{s}\right] \quad (6g)$$

Where  $T_R$  is the autothermal reformer outlet temperature and  $T_p$ ,  $F_p$  and  $x_{N_2}$  correspond to product's temperature, molar flow rate and nitrogen concentration respectively. The manipulated variables are  $F_G$ ,  $F_s$  and  $\alpha$ , corresponding to inlet molar flow rate of natural gas, inlet molar flow rate of steam, and bypass fraction respectively. The full space optimization problem is composed of 898 variables and 895 equality constraints describing material, energy, and momentum balances for each unit model, where 55 of these correspond to algebraic equations describing the Gibbs reactor, such as Gibbs energy minimization, and enthalpy, element, pressure, total flow, and component flow balances. As an example, the Gibbs minimization equation is shown in Eq. (7a).

$$g_{partial,j} + \sum_e (L_e \times \beta_{j,e}) = 0, \quad \forall j \in J \quad (7a)$$

$$J = \{H_2, CO, H_2O, CO_2, CH_4, C_2H_6, C_3H_8, C_4H_{10}, O_2\} \quad (7b)$$

$$J_{inert} = \{N_2, Ar\} \quad (7c)$$

Here,  $g_{partial,j}$  is the partial molar Gibbs energy of component  $j$ ,  $L_e$  is the Lagrange multiplier of element  $e$  and  $\beta_{j,e}$  is the number of moles of element  $e$  in one mole of component  $j$  [13].

In this work, we implement full-space, surrogate, and implicit function formulations for solving this optimization problem. The Gibbs reactor, Eq. (1d), will be replaced by a surrogate and an implicit function.

## IMPLEMENTATION

We used Pyomo 6.7.1 [15], an open-source optimization modeling language, and IDAES 2.4.0 [13], a process modeling framework, to design the ATR flowsheets in Python 3.9.6. The optimization problems were solved with IPOPT 3.14.11 [2] using linear solver MA27, called via the Cylpopt interface. The surrogates were obtained using the ALAMO machine learning framework [8] and TensorFlow 2.15. The neural network was embedded into the optimization problem using OMLT 1.1 [14]. Derivative computations are performed via the AMPL solver library (ASL) [16] via the PyNumero interface [17]. Results were produced on a machine with an Apple M1 Max processor and 32 GB of RAM running macOS Ventura 13.6.6.

### Dataset Generation

A dataset describing the Gibbs reactor was generated to train the ALAMO polynomials and the neural network. This data was generated from 625 samples of the four-dimensional input space: five samples in each input arranged in a regular grid. The ranges of sampled inputs are shown in Table 1. The outputs (13 in total) correspond to reactor's outlet temperature ( $T_{out}$ ), outlet molar flow rate ( $F_{out}$ ), and outlet compositions for the eleven

components. Time to acquire this data was 400 seconds.

**Table 1:** Inputs and ranges of the ALAMO and neural network surrogates.

Input Variable	Unit	Range
Steam molar flow rate ( $F_s$ )	[mol/s]	200 – 350
Natural gas temperature ( $T_{ref}$ )	[K]	600 – 900
Natural gas flow rate ( $F_{ref}$ )	[mol/s]	600 – 900
CH <sub>4</sub> Conversion in ATR ( $X$ )	[%]	80 – 95

This data set was partitioned into 80% training and 20% validation data to train the ALAMO and neural network surrogates and then gauge their accuracy. We consider that a surrogate is accurate if the coefficient of determination ( $R^2$ ) is greater than 0.8 for each of the 13 parity plots obtained from the validation dataset.

### ALAMO surrogate

The Gibbs reactor was replaced by a surrogate block containing simple algebraic equations determined by the ALAMO machine learning framework. To balance the bias-variance trade-off and calculate a model with low nonlinear complexity, the four basis models we consider are a quadratic, a cubic, a linear variable and a constant. We have the option to include bilinear terms and higher degree polynomials to achieve a higher surrogate accuracy. However, for the purpose of this research, convergence could be hindered with the inclusion of those terms, particularly if we observe that a linear combination of simple basis functions can effectively approximate the reformer's behavior. The surrogate model is composed of 13 equations and 3 variables, in contrast to the 55 equations and variables that model this first-principles Gibbs reactor. A subset of these 13 equations is displayed in Eq. (8). Training time to acquire this surrogate model was 1.6 s.

$$T_{out} = 8.2 \times 10^{-4} F_s + 0.41 F_{ref}^3 + 897.4 X \quad (8a)$$

$$F_{out} = 3.9 F_{ref} + 1.1 F_s - 7.9 \times 10^{-7} F_{ref}^2 + 685.0 X^2 \quad (8b)$$

$$x_{H_2} = 5.3 \times 10^{-4} F_{ref} - 1.5 \times 10^{-10} F_{ref}^3 + 0.14 X^3 \quad (8c)$$

$$x_{CO} = -6.2 \times 10^{-10} F_s^3 + 8.1 \times 10^{-4} F_{ref} - 4.1 \times 10^{-7} F_{ref}^2 + 0.2 X - 0.35 \quad (8d)$$

$$x_{CH_4} = 1.5 \times 10^{-5} F_{ref} - 6.0 \times 10^{-6} F_s - 0.33 X^2 + 0.16 X^3 + 0.16 \quad (8e)$$

### Neural network surrogate

The autothermal reformer was also replaced by a surrogate block containing a neural network. Hyperparameter tuning was performed to obtain the neural network with the lowest validation loss, quantified with the mean squared error. Hyperparameter ranges are shown in Table 2. The sigmoid and tanh activations were chosen because they are smooth functions, matching our setting

of nonlinear continuous optimization. The Adam optimizer was used for training.

**Table 2:** Hyperparameter ranges used to train the neural network.

Hyperparameter	Range/value
Activation function	Sigmoid & tanh
Number of layers	2 – 5
Number of neurons	20 – 35
Epochs	500

The training time to run every hyperparameter combination in Table 2 was 550 s. Ultimately, the neural network that best approximates the Gibbs reactor uses the tanh activation function and has 4 hidden layers with 32 neurons each. The time to train this neural network in isolation was 9.5 s. The optimization formulation uses the full space option provided by OMLT, as it was found to converge more reliably than the reduced space formulation. In the full-space formulation, variables and constraints corresponding to interior nodes in the neural network are explicitly included in the optimization problem. While only a single neural network surrogate is considered in this work, a comparison of optimization problems with many different architectures (and equation-based formulations) of embedded neural networks would be an interesting future study.

### Implicit function

The theoretical formulation given in Eq. (3) can be implemented as shown in Eq. (9).

$$\max f(x, u) \quad (9a)$$

$$\text{s.t. } G(x, u) \leq 0 \quad (9b)$$

$$H_{internal}(x, u) = 0 \quad (9c)$$

$$H_{linking}(x, y, u) = 0 \quad (9d)$$

$$R(x, y, u) = 0 \quad (9e)$$

Here, Eq. (9e) solves for  $y$  externally as an implicit function  $y = R_y(x, u)$  using the PyNumero interface and the resulting values are communicated back to Eq. (9d), which is exposed to the NLP solver. In this case, Eq. (9d) is referred to as a set of linking equality constraints that link the externally obtained outlet variables  $y$  to the inlet variables of the reformer recuperator, which is downstream of the Gibbs reactor (See Figure 1). The dimension of  $y$  equals the dimension of  $R$  and  $\nabla_y R$  is non-singular.

The Gibbs reactor is replaced by an implicit function  $y = R_y(x, u)$  that solves the reactor equations as a parameterized system of equations. The PyNumero interface solves this system at every iteration of the nonlinear optimization solver with a decomposition that partitions variables and equations into block-lower triangular form

before solving the resulting blocks independently. The block triangular partition is computed by the approach of Duff and Reid [18] using the Incidence Analysis Pyomo extension [19]. The PyNumero interface also computes the derivatives required by IPOPT.

The system of equations for  $R_y(x,u)$  decomposes into 55 diagonal blocks, where 18 have dimension  $1 \times 1$  and one has dimension  $37 \times 37$ . The block triangular form of this system's incidence matrix is shown in Figure 2.

**Figure 2.** Incidence matrix of the square system corresponding to the Gibbs reactor.

Each independent system of equations is solved with SciPy's `fsolve`, a wrapper around MINPACK's implementation of Powell's hybrid trust region method [20].

## RESULTS

To compare convergence reliability, solve time and solution quality between the full space, implicit function, and surrogate-based formulations, we perform a parameter sweep varying the inlet natural gas absolute pressure and its conversion in the Gibbs reactor. We attempt to solve the optimization problem using IPOPT [2] for every combination of these two parameters for a total of 64 problem instances. These have identical initialization methods and solver options, where the maximum number of iterations are 300 and each must converge to a tolerance of  $10^{-7}$ . The code used to implement these formulations and reproduce the results can be found at <https://github.com/Robbybp/surrogate-vs-implicit>.

The convergence status for each formulation is shown in Figure 3. An unsuccessful run is due to the optimization solver reaching the iteration limit, converging to an infeasible point, or a failure due to repeated function evaluation errors. Here, a function evaluation error may be an error in a scalar-valued function, such as attempting to evaluate the logarithm of a negative number, or a more complicated error such as a failure to solve the square system that defines the implicit function  $R_y(x,u)$ .

A successful run indicates not only that the optimization problem converged, but also that the calculated input variables yield no constraint violations when used to simulate the full-space model.

In this experiment, the full space formulation was able to successfully converge 33 out of 64 instances, the implicit function formulation solved 52, the surrogate-based formulation using ALAMO converged 64 instances, and the surrogate-based formulation using a neural network converged 48. Regarding the full space formulation, many of these failed instances are due to large residuals in calculating energy balances in the autothermal reformer and the reformer recuperator.

The implicit function formulation obtains the same objective and values for the manipulated inputs as the full space formulation but converged 58% more instances. The unsuccessful instances at higher conversion are due to function evaluation errors.

In the failing instances, the implicit function formulation experiences evaluation errors in the Gibbs minimization equations. Given the high conversion, the optimization algorithm calculates a value near zero for the outlet molar composition of propane in the reactor, which is used to calculate the entropy of the ideal gas. Here, one of the terms attempts to calculate the natural logarithm of this composition, causing numerical stability issues, as shown in Eq. (10). In consequence, the Newton solver fails to calculate  $g_{partial,C_3H_8}$ , see Eq. (7), and the outer optimization does not converge. The entropy of the ideal gas is used to calculate the ideal partial Gibbs energy of propane, which is then corrected with a departure function.

$$S_{C_3H_8}^0 = \int_{298.15}^T \frac{A+BT+CT^2+DT^3}{T} dT + \Delta S_{form}^{298.15} - R \ln \frac{P}{P_{ref}} - R \ln x_{C_3H_8} \quad (10)$$

The ALAMO and neural network formulations introduce only a minor increase in solution error. To evaluate solution quality, we solved a square system for the original flowsheet, where the fixed inlet natural gas, steam molar flow rate, and bypass fraction correspond to the values calculated by the ALAMO and the neural network formulations, separately. Then, we compared the objective value given by these simulations with the objective value calculated by the full space optimization problem. This comparison was done for the 25 instances for which full space, ALAMO, neural network, and implicit formulations all converged successfully. The average relative objective function difference for the ALAMO formulation was 1.9%, with a maximum difference of 2.1%. For the neural network formulation, the average relative objective function difference was 0.96%, with a maximum difference of 2.4%.

It is important to note that even though the ALAMO models were trained in the range of conversion of 80 to

**Figure 3:** Convergence status for each formulation. “Untrained region” indicates conversions above 0.95, the upper bound used for surrogate training data. The results indicate that while all three alternative formulations are more reliable than the full-space formulation, the ALAMO surrogate is the most reliable.

**Table 3:** Problem statistics for each formulation.

Formulation	N. Iterations	Avg. solve time (s)	Max. solve time (s)	Std. dev. (s)
Full Space	95	1.7	5.1	0.9
Implicit	46	1.5	3.2	0.4
ALAMO	30	0.5	0.6	0.03
Neural Network	51	0.8	0.9	0.05

**Table 4:** Qualitative results for each formulation applied to the autothermal reformer optimization problem.

Formulation	Solution accuracy	Solve time	Training time	Reliability
Full Space	High	Moderate	N/A	Low
Implicit	High	Moderate	N/A	Moderate
ALAMO	Moderate	Low	Moderate	High
Neural Network	Moderate	Low	High	Moderate

95%, they were able to find accurate solutions with conversions of up to at least 97%. We note that there is no increase in error when conversions above 95% are tested. However, this situation may not be replicated when modeling another process. The neural network surrogate formulation provides virtually the same solution quality as the embedded ALAMO polynomials. Nonetheless, in contrast to those surrogates, it fails to converge when the conversion is 96% or higher, that is, outside training bounds. One interpretation of these convergence failures is that the neural network surrogate has been over-trained to accurately represent the reactor model in the training region, while the comparatively simple and sparse surrogate generated by ALAMO has resisted this over-training. Additionally, hyperparameter tuning is required to obtain an accurate neural network, which is a computationally costly task.

A breakdown of problem statistics is shown in Table 3, where “N. Iterations” refers to the *average* number of iterations it takes for the optimization solver to converge and “Std. dev (s)” refers to the standard deviation of the average solve time from the successful instances. As before, these statistics were computed for the intersection of successful instances among the four formulations.

Despite relatively expensive function evaluations

that solve a square system at every iteration, the implicit function formulation converges slightly faster than the full-space formulation. This is because the implicit function formulation requires fewer IPOPT iterations to converge the optimization problem.

The standard deviation of solve time for the full space formulation shows that different flowsheet parameters have a significant impact on the optimization solver’s ability to converge. Conversely, the implicit and especially surrogate formulations exhibit more uniform solve times and converge for a higher percentage of instances, supporting the idea that they are robust and less sensitive to process parameter values.

Finally, a summary of qualitative results for the four formulations is shown in Table 4. Our qualitative assessment of training time includes time required for data generation and hyperparameter tuning. We note that surrogate training time could be further reduced by using more efficient sampling techniques, such as Latin Hypercube Sampling [21], which would potentially generate a smaller and more representative dataset of the entire experimental region, which might also lead to higher solution accuracies.

## CONCLUSIONS

We have presented four different formulations for optimization of a chemical process flowsheet using the IDAES modeling framework. The implicit function approach demonstrates an improved convergence reliability in contrast to the full space approach. The ALAMO surrogate formulation is the fastest and most reliable optimization alternative in this study that results in low solution errors for the objective value and the manipulated inputs. Nonetheless, the implicit function formulation may be preferred in cases where the design specifications of a process are not able to tolerate the introduction of errors into the calculations, or where producing enough simulation data to train an accurate surrogate model is computationally prohibitive. For instance, large chemical process flowsheets involving wastewater treatment units or gas scrubber systems, where environmental regulations specify a strict threshold for pollutant compositions in water or gas being released into the atmosphere, may not be appropriate for a surrogate formulation.

In this case study, the ALAMO surrogates were able to effectively approximate the behavior of a Gibbs Reactor. Nevertheless, more complex unit models with polar components, such as multi-component distillation columns, or stripping and absorbing columns, might require neural networks to provide a good approximation of the associated differential-algebraic systems. Finally, the implicit function and surrogate formulations presented in this paper constitute important approaches to optimize a chemical process flowsheet when the classical method fails, and their advantages would be more prominent in the design phase of complex, large scale chemical processes where superstructure optimization (MINLP) might be involved.

## ACKNOWLEDGEMENTS

We gratefully acknowledge the support of the U.S. Department of Energy through the Los Alamos National Laboratory (LANL) LDRD program and the Center for Nonlinear Studies (CNLS) for this work.

Los Alamos National Laboratory is operated by Triad National Security, LLC, for the National Nuclear Security Administration of U.S. Department of Energy (Contract No. 89233218CNA000001). This work is approved for unlimited release under LA-UR-23-31036.

## ABSTRACT

Phthalates are the most widely used plasticizers in the polymers industry; however, their toxicity and environmental impacts have led to their ban in various applications. This has driven the search for more sustainable alternatives, including biobased citrate esters, especially tributyl citrate (TBC) and its acetylated form. TBC is typically produced by refined citric acid (CA) esterification with 1-butanol (BuOH). However, the high energy and materials-intensive downstream purification of fermentation-derived CA involves high production costs, thus limiting the widespread adoption of TBC as a plasticizer. This work presents an innovative approach for TBC production using calcium citrate as feedstock instead of pure CA. The process involves a simultaneous acidification-esterification stage and further hydration of calcium sulfate, thus reducing costs by avoiding multiple CA refining steps. The approach proceeds via a solid-solid-liquid reaction of calcium citrate with sulfuric acid in butanol, releasing CA, which is simultaneously esterified to form TBC. The resultant calcium sulfate aids in water removal to enhance esterification conversion. Based upon experimentally validated models and rigorous simulations, the proposed approach was evaluated, and it exhibited significant reductions in processing times and operating costs, with savings of at least 46% in utilities compared to traditional TBC production. The novel approach was found suitable and promising for industrial deployment.

## INTRODUCTION

Polymeric materials and plastic products have significantly contributed to the advancement of modern society. Because of their malleability and flexibility, these materials have been used in many applications. These characteristics are mainly possible by incorporating plasticizers, which decrease molecular interactions among polymer chains, increase elasticity, and reduce the glass transition temperature (T<sub>g</sub>) (1). Plasticizers can constitute a significant fraction of some polymers (up to 80% wt.), being the phthalates, the most widely used general-purpose plasticizers. In particular, phthalates are mainly employed in polyvinyl chloride (PVC) products, including flexible films and sheets, hoses, pipes, windows, cable jacketing, flooring, rainwear, shoes, etc. Considering their significant use and that they are not chemical-bonded to the polymers, they can migrate from the material. This

has increased concerns regarding environmental pollution and public health due to the potential toxicity of plasticizers (2). In particular, the negative health impacts caused by phthalates has led to restrictions on their use in sensitive applications, prompting the search for alternative molecules that are non-toxic, renewable, and biodegradable. Among these, bio-based plasticizers like citric acid esters have gained attention.

Citric acid esters, particularly tributyl citrate (TBC) and its acetylated form have performed similarly to phthalates in different applications (3). However, citrates have the advantage of being biocompatible, biodegradable, and renewable. TBC is produced via esterification of citric acid (CA) with a large excess of 1-butanol (BuOH) using acid catalysts [4,5]. The process involves long processing times in a semi-batch operation and high-purity anhydrous CA (6). This last requirement is a major challenge because purification of fermentation-derived CA

requires highly materials- and energy-intensive processes. As a result, the cost of TBC is highly dependent on that of CA, and it is usually higher than that of phthalates; this limits an extended industrial use of TBC.

Production of bioderived anhydrous CA requires a complex train of physicochemical separation operations. The fermentation broth is filtered to remove biomass and then treated with lime to precipitate CA as a calcium salt. The salt is then separated by filtration, resuspended in water, and finally acidified with sulfuric acid. At this point gypsum is produced and precipitated, releasing CA in the aqueous solution. This aqueous solution is then taken to ion exchange to remove minerals, followed by concentration via multistage evaporation, crystallization, filtration, and drying processes (7). This complex downstream separation train removes nearly 10 kg of water per kg of CA, thus being highly energy intensive. Finally, refined CA is subjected to esterification with BuOH. Anhydrous CA is required as raw material in the esterification process as it produces water, and the reaction conversion is limited by chemical equilibrium. The complete process is depicted in Figure 1.

**Figure 1:** Conventional TBC production process

As an alternative approach, this work proposed and assessed an innovative scheme to overcome most of the steps required to purify CA to produce TBC, by using calcium citrate as raw material. This process is similar to previous reports on the recovery of succinic acid (8) and involves a solid-solid-liquid reaction in which insoluble calcium citrate is suspended in an alcoholic medium (i.e., BuOH), where acidification with sulfuric acid is carried out. As a result, CA is released into the alcoholic medium, where it undergoes simultaneous esterification to TBC catalyzed by the remaining  $H_2SO_4$ . The proposed process, described in Figure 2, denoted as simultaneous acidification-esterification (SAE), avoids the conventional purification of CA. Additionally, a reduction in the dissolution times required in the traditional esterification reaction is expected. Furthermore, calcium sulfate is produced as a by-product in an alcoholic phase, reducing salts' solubility and helping to remove water by forming hydrated salts, thus facilitating the separation of esters.

**Figure 2:** Proposed SAE TBC production process

To assess the proposed SAE process against the conventional one using anhydrous CA, rigorous simulation of both processes was carried out in Aspen Plus® using validated kinetic and thermodynamic models [5,10]. The operating conditions and the configuration of the conventional process were based on data from an existing industrial facility for TBC production.

## MODELING AND SIMULATION

### Reaction Kinetics: Conventional Process

In the conventional industrial process (Figure 1), the multistep esterification reaction of CA with BuOH (Figure 3b) is catalyzed using methanesulfonic acid (MSA). A validated kinetic model for the multiple sets of parallel-sequential reactions was previously reported (4) and used for simulations here.

**Figure 3:** Scheme of reactions during the proposed simultaneous acidification-esterification of calcium citrate in 1-butanol using sulfuric acid. a) (top) acidification. b) (bottom) esterification.

### Reaction Kinetics: SAE Process

As previously mentioned, the acidification occurs between solid calcium citrate and liquid  $H_2SO_4$  in an alcoholic media. Then, released CA undergoes esterification with BuOH (Figure 3). The remaining or excess sulfuric

acid acts as a catalyst in this reaction. As a result, a certain degree of conversion to intermediate citrates is achieved (i.e., monobutyl citrate - MBC and dibutyl citrate - DBC). This would facilitate the recovery of CA and reduce the time required for complete esterification [4, 10].

The corresponding kinetic model of the simultaneous acidification-esterification process was previously reported and was used to simulate the process (10). As the esterification to TBC is incomplete, this is finished in a subsequent reactor using MSA as catalyst (4). The kinetics of the acidification-esterification reaction and the corresponding kinetic parameters are presented in the supplementary material.

## TBC Production Conventional Process

The simulation of the conventional process was carried out considering the two main sections involved in the production of TBC. First, there is CA production from precipitated calcium citrate. This section relies upon highly energetic demanding separation stages (e.g., evaporation, crystallization, and drying). Then, the esterification stage, where CA is transformed into the desired plasticizer via a fed-batch operation. Here, reactants loading and operating temperature change follow a pre-programmed protocol as performed in the industry (11).

## Citric Acid Production

The details of the CA process and the production capacity (30,000 tons/year) corresponded to those of an existing industrial plant (11). For simplicity, it is assumed that all the commercialized CA corresponds to the anhydrous form. Approximately 95% of produced CA is sold directly; the remaining fraction is used to produce citrate esters. This small portion corresponds to the remnant CA that doesn't meet specifications regarding particle size or that is recovered from equipment walls like hoppers, filters, centrifuges, or dryers. CA is produced from submerged aerobic fermentation of sugarcane molasses using *Aspergillus niger*. The produced acid is released into the aqueous medium, so precipitation is carried out using  $\text{CaOH}_2$  to generate insoluble calcium citrate. This process separates the citric acid in salt form and allows its extraction from the culture medium via filtration. For comparative purposes, both the modeling of the conventional process and the proposed process considered the resulting stream of precipitated and filtered calcium citrate as the raw material in the TBC production process. As the precipitated calcium citrate corresponds to an intermediate stream in the CA process, its commercial price is unknown. This price was estimated at \$0.43/kg, based on the cost of the raw materials necessary to generate the calcium citrate. Although all high energy-intensive steps in the synthesis of CA were included in the model, polishing the acid and TBC using activated carbon absorption to remove colors and other impurities is not considered.

- **Acidification reaction:** The CA recovery from calcium citrate in an aqueous medium occurs by ion exchange with a stoichiometric amount of  $\text{H}_2\text{SO}_4$ . This solid-liquid reaction is carried out in a stirred reactor at 30 °C with a residence time of 3 hours. As a result, the stoichiometric amount of solid gypsum is produced, and the obtained liquid effluent corresponds to a 30% wt. CA aqueous solution.
- **Filtration:** Conveyor belts or rotary filters are commonly employed to separate the solid gypsum (i.e., calcium sulfate) from the effluent CA solution generated in the acidification process. The filters are connected to vacuum pumps to facilitate filtration and enhance liquid phase recovery. In the simulation a separator filter module is used to describe  $\text{CaSO}_4$  removal.
- **Evaporation:** the aqueous solution is processed in an evaporation train to concentrate up to the crystallization point of the organic acid. Since the process is energetically demanding, multiple interconnected stages are typically employed (1 to 4 steps, depending on the production capacity) to reduce steam consumption. Here, a triple-effect co-current configuration is considered for a capacity of 30,000 tons/year of CA (Figure 4). Multi-effect evaporators were simulated via Heater modules that serve as calandrias for the condensation of the steam, releasing latent heat. This heat is provided to flash vessel modules, where concentration of CA is performed. A vacuum profile in the effects is assumed (0.89, 0.67, and 0.40 bara). The final concentration of the solution depends on the desired hydrated form of CA in the crystallization stage.

Figure 4: Triple-effect evaporation configuration

- **Crystallization:** CA can precipitate as anhydrous or monohydrate depending on the concentration and temperature. An operating temperature of 45°C is set to obtain anhydrous CA crystals. In this case, a concentration of  $\geq 70\%$  wt. of CA is required to ensure the saturation of the mixture at the operating temperature. Aspen Plus® Crystallizer model and CA solubility data in water (12) were used for the calculation of the saturation conditions in the crystallization modeling.

- **Centrifugation:** The use of two-stage centrifuges is common for the separation of crystallized solids. CFuge model that simulates centrifuge filters (rotating baskets), with no residual solids in the outlet filtrate, is used to separate crystallized CA from the liquor. A residual moisture of 10% by weight on a wet basis was assumed.
- **Drying:** Continuous fluidized bed dryers enable a low moisture content in the final product (< 5% wt.). Steam was used as heating utility to provide the required heat duty for the drying air that is in direct contact with the fluidized crystals. A conveyor belt coupled to a vibratory system allows better air-solid contact and prevents agglomerated solids. In this case, a convective dryer type in the dryer module is used, with a crossflow (through-the-bed) air-solid arrangement.

Vacuum was provided using a steam-jet ejector system. The steam required for the vacuum system can be calculated considering the air leakage in the vessels. This can be determined by knowing the operation pressure and the volume of the vessel (13).

### Citric Acid Dissolution-Esterification

Once anhydrous CA is obtained, it is sieve-classified, and the fines fraction is rejected according to market specifications. Additionally, it is common to find solid CA fines adhered to equipment or clumps in some units. First, this material is fed to a 23.7 m<sup>3</sup> dissolution tank alongside with BuOH, to enhance a total homogeneous reaction mix. Afterwards, the mix, together with the catalyst is fed to SS316 jacketed reactor with a capacity of 26 m<sup>3</sup> to perform the esterification reaction. During esterification, removal of produced water is desired to shift the chemical equilibrium. For this reason, the reactor is coupled to a distillation column that operates at the bubble temperature of the BuOH-H<sub>2</sub>O mixture. As the reaction proceeds, a vapor stream of BuOH-H<sub>2</sub>O is generated, and it is separated in the rectifying column up to the azeotropic condition. Since this azeotrope is heterogeneous, two immiscible phases are generated and separated in a decanter after condensing the column's top vapor. The BuOH-rich organic phase is returned to the column as reflux, whereas the aqueous phase is removed from the system to overcome chemical equilibrium limitations. The process of transforming CA into TBC can be divided into three stages:

- **Dissolution:** Due to the low solubility of CA, dissolution must be carried out by dosing the fed solids under heating and constant agitation. In this case, an excess of BuOH and the catalyst (MSA) are added to promote the reaction and to facilitate the dissolution of CA in the alcohol.

- **Esterification:** Once the necessary CA has been dissolved, the temperature of the reactive mixture is increased up to its bubble point to promote reaction. At this point, the vapor outlet line of the reactor is opened to connect with the distillation column, seeking to encourage water removal. The progress of the reaction is monitored through the measurement of the acid value of the mixture over time.
- **Purification:** Once the desired acid value is reached, separating the excess BuOH in the final mixture is necessary. For this, the system's pressure is reduced in the same reactor, and evaporation of all the remaining alcohol and water is carried out. Finally, the catalyst is neutralized using a sodium hydroxide solution.

**Figure 5:** Batch and BatchSep module for esterification and acidification-esterification stage modeling.

Based on the above-described stages, the simulation of the citric acid dissolution-esterification stage was performed using both RBatch and BatchSep modules (Figure 5), enabling the dissolution of CA in BuOH, catalyst adding, temperature profile programming, and purification stages as reported in a previous study (11). The CA production is estimated considering a maximum processing capacity of 8t CA per batch. It is also assumed that 180 batches could be processed in a year. According to this, it is estimated that ~ 1440 t/yr of CA fines are generated in the production plant which are used for further esterification.

### Proposed SAE Process

Unlike the conventional process, the proposed process involves directly using calcium citrate from the precipitation stage with CaOH<sub>2</sub> and its subsequent acidification in BuOH, as seen in Figure 2. A pre-treatment stage is considered in which the calcium citrate is washed to remove impurities and ions from the culture medium. Subsequently, it is filtered and dried to avoid the presence of water in the reactive medium. For these pre-treatment stages, the acquisition of new equipment is not considered since these processes can be carried out

**Figure 6:** Mass fraction profiles **a)** conventional process, **b)** SAE process. (—) BuOH, (—) CA, (—) MBC, (—) DBC, (—) TBC, (—) H<sub>2</sub>O, (—) H<sub>2</sub>SO<sub>4</sub>

**Table 1:** Utility costs per batch in the production of TBC for the conventional and novel processes

Utility	Conventional process		Novel Process
	Citric Acid Production	Dissolution - Esterification	Acidification - Esterification
Steam	\$266.58	\$66.88	\$106.914
Electricity	\$107.09	\$244.27	\$209.41
Process Water	\$43.04	\$4.81	\$18.46
Cooling Water	\$2.28	\$0	\$6.15
Solid Waste Disposal	\$310.53	\$0	\$270
<b>TOTAL</b>	<b>\$1045.514</b>		<b>\$610.94</b>

within existing equipment in the CA plant (stirred tank, filters, and fluidized bed dryers).

- **Washing:** Contact with water (1 kg water / 1 kg calcium citrate) is done to remove impurities from the precipitated calcium citrate. A contact time of 1 hour is considered. The batch module is considered to perform the mixing.
- **Filtration:** Conveyor belt filters separate calcium citrate from the washing water.
- **Drying:** The remaining moisture from the calcium citrate is removed through the fluidized bed dryers. This ensures that no water enters the acidification-esterification stage.

Similar to the filtration and drying steps in conventional CA production, solid separator and crossflow convective dryer modules are used to simulate these operations in calcium citrate pretreatment. When the clean calcium citrate is obtained, it is fed into the simultaneous acidification-esterification process. This process is assumed to be carried out in the same dissolution vessel and esterification reactor used in the conventional process. Considering that, as experimentally verified in the solid-liquid reactive system, the solubility of the evolved citric species in

alcohol is rapid (10), the dissolution stage of CA in BuOH is not required. Therefore, the time of addition of the citric species will depend on the feeding capacity of the reactor. Then, a feeding rate of calcium citrate of 4126 kg/h is considered. This feeding rate can be achieved through hoppers coupled to screw conveyors. The mass of calcium citrate fed to the reactor (9583.33 kg) is equivalent to the same citrate moles considered in the previous section.

Once the calcium citrate is introduced into the BuOH, sulfuric acid is added to the reactor to promote the release of CA. A slight excess of H<sub>2</sub>SO<sub>4</sub> ensures complete acidification and facilitates the esterification reaction. The process is halted when the amount of MBC (Monobutyl Citrate) produced is equal to that generated in the dissolution stage of the conventional process. Once this point is reached, a stoichiometric amount of calcium citrate is added to neutralize the slight excess of sulfuric acid. This addition ensures that no residual H<sub>2</sub>SO<sub>4</sub> remains in the subsequent stages of the process.

Subsequently, the acidified and partially esterified mixture is filtrated to remove the calcium sulfate that is produced. It is assumed that the remaining solid fraction, discarded as waste, constitutes 4% by weight of the

reactive mixture. This assumption is made because separation in a filtration process is not 100% efficient. Therefore, two additional batches must be processed to achieve the same amount of TBC production. After filtering the reactive mixture, it is returned to the esterification reactor, and MSA is added. Once the esterification process is completed, the pressure within the system is reduced to remove the remaining BuOH and water. Operating conditions are presented in the supplementary Information.

Similar to the simulation of the CA dissolution and esterification in the conventional process, the novel process is performed using the RBatch and the BatchSep modules. These modules enabled the implementation of the simulation for the novel process and its specific operating policies (e.g., single feeds or scheduled feed configuration) using the same equipment. RBatch module enables modeling mixed, batch, and fed-batch operation conditions employed in the industrial production of TBC. On the other hand, the BatchSep module allows the modeling and scheduling of batch distillation columns when connected to the batch reactor.

Continuous water removal is possible because the more volatile compounds ( $H_2O$ -BuOH) are distilled off from the reactive media during the esterification when operating at the bubble point of the mixture. Nevertheless, BuOH removal is not desired since the reaction driving force would be diminished, striking esterification performance. Thus, assessment of the impact of simultaneous reaction and water removal is paramount to identifying the best operating policies to improve TBC yield.

With all previous considerations, we present a TBC production cost analysis focused on the utility costs of the conventional process concerning those of the SAE process. Capital costs were not considered because it is assumed that the same equipment is used in both processes and they are already available in the studied industrial facility. A composition profile of the two scenarios was merged, allowing the comparison with previous reports on the behavior of the conventional process. Also, a novel fed-batch operating policy developed during the experimental evaluation of simultaneous acidification-esterification (10) was tested and analyzed for the SAE process.

## RESULTS

### TBC Production Conventional Process

The mass concentration profiles over time during the production of TBC using the conventional industrial process are illustrated in Figure 6a. These profiles match those reported in a previous study (11) where a dilution stage ( $t < 18h$ ) enabled MBC production as the main citrate ester and accumulation of water is observed. Due to the low solubility of CA in the medium, alternating feeding

is required to ensure all the acid dissolves. A high temperature ( $\sim 60^\circ C$ ) is also necessary to accelerate the dissolution process.

Once the CA dissolution is completed, the temperature of the reactive medium is increased to the bubble point of the mixture ( $\sim 130^\circ C$ ). From this point, the production of DBC and TBC is increased and a vapor stream is generated, allowing for the removal of water from the top of the distillation column. However, there are differences compared to the previous report (11), as a higher concentration of DBC was observed in the reactor. This difference is caused by the remaining water in the reactive liquid, limiting the conversion towards TBC. Therefore, the final product will have a higher acidity content than required (acidity  $> 0.5\%$ ). The results coincide with what is reported for the industrial process, as the reactor effluent usually requires a subsequent neutralization stage to remove the remaining citric acidity and the catalyst. As observed, the process includes CA loading, dissolution, and esterification and the process lasts around 45 hours.

Regarding the costs derived from the utilities required in the production of TBC, it can be seen that the stage of obtaining anhydrous citric acid constitutes  $\sim 72\%$  of the overall operating costs. This result was expected considering the significant dilution of CA in the fermentation broth and the large amount of water to be evaporated from the CA crystals. Another substantial cost is the handling of solid waste generated in the acidification of the calcium citrate. Notably, a large amount of low-added value gypsum is produced during acidification in the existing industrial process. Although the obtained gypsum could be a salable by-product, purification to meet commercial specifications involves significant costs. So, in this case, this stream was assumed to be a waste and the disposal costs were estimated and internalized.

### TBC Production Proposed Process

As observed in Figure 6b, the direct feeding of calcium citrate reduces dissolution times to carry out the esterification reaction. Additionally, the recovery of the citric species can occur at lower temperatures (e.g.,  $40^\circ C$ ). Using an excess  $H_2SO_4$  ensures that the esterification process concurs as CA is released. As a result, the process with calcium citrate achieves a concentration of 18% wt. MBC in the liquid phase in 6 hours of reaction. In contrast, during the dissolution in the conventional process, 15 hours are required to achieve the same MBC content.

After the acidification-esterification stage, conventional esterification is carried out with MSA as a catalyst, and vacuum purification enables excess BuOH and remaining water removal (Figure 6b). As in the conventional process, achieving the purity required to commercialize the TBC would be difficult, and a neutralizing stage is

needed to remove the remaining acidity. While the process would be completed in 36 hours, the system seems to reach equilibrium in about 18 hours, considerably shorter than the 25 hours required for reaction in the conventional process, counting for a reduction by about 25% in reaction time to reach equilibrium condition.

Finally, as presented in Table 1, it is observed that the cost related to steam consumption for CA purification presented a higher difference. It can be seen that the steam-related costs are the lowest for the novel process compared to the conventional configuration related to the 68% reduction in steam usage per unit of citrate esterified in the SAE process. This is mainly attributed to the direct use of calcium citrate as the CA backbone carrier for TBC synthesis, avoiding all concentration stages commonly used in the purification of CA. The concentration stages in pure CA production (e.g., evaporation, crystallization, and drying) need a great amount of energy to evaporate close to 10 kg of water per kg of CA, to achieve the purity conditions necessary to perform esterification. As seen in Table 1, the cost associated with pure citric acid production accounts for ~70% of the utility costs in the conventional process. The other utility costs in the conventional process summarized in Table 1 do not show a massive reduction compared with the SAE process (mixing, vacuum, solid disposals, etc.) since these operations remain almost unaltered.

Despite both processes generating calcium sulfate, the one obtained from the novel process is in the form of a semi-hydrated form. This form may have potential as a valuable industrial by-product. Moreover, by crystallizing in an organic medium, the particle size distribution and the purity of the obtained crystal may generate commercial interest (14). The cost associated with the utilities used in the SAE process reflects cost savings of 41% compared to those of the conventional process. Such reduction allowed a 1.8% decrease in the TBC operating costs.

The SAE process could also be helpful in a possible continuous configuration for TBC production. As reported previously, continuous reactive distillation (RD) has arisen as a promising alternative for TBC production(5)(10). Since RD allows for the simultaneous esterification reaction and water removal, inherent equilibrium limitations are overcome. In these works, it has been identified that using a pre-reactor stage is beneficial to reduce RD column size or increase TBC production capacity (5). This pre-reaction stage could be performed via SAE processes. As described, this process has a fed-batch configuration. Also, some stages like calcium citrate feed and calcium sulfate removal would make it difficult to couple the SAE process with RD. Some strategies like equipment redundancy or using tanks for pre-reacted mixture storage, could help to overcome these issues. This configuration will be evaluated in future work.

## CONCLUSIONS

This work presented a comparative assessment of a conventional and innovative process for the industrial production of TBC. The novel SAE process employs calcium citrate as raw material instead of CA to produce citric acid esters. Based on experimentally established reaction kinetics and validated thermodynamic models, it was possible to simulate the solid-solid-liquid reaction occurring during the simultaneous esterification-acidification stage in the SAE process. Reduction in the utility costs and in the time to perform the esterification reaction could lead to a significant increase in TBC's production and capacity, alongside an increase in the economic viability of TBC (1.8% cost decrease due to operating costs) using the existing industrial infrastructure. Moreover, although not quantified in this work, the reduction in process units also leads to potential capital cost reduction. As a follow-up to this work, an optimization-based cost analysis will be carried out to minimize the total (fixed and operational) process costs for a new industrial facility using the novel SAE process. This analysis can also be done to retrofit an existing TBC production plant using the conventional process.

## ABSTRACT

Rapid and robust convergence of a process flowsheet is critical to enable large-scale simulations that address core scientific questions related to process design, optimization, and sustainability. However, due to the highly coupled and nonlinear nature of chemical processes, efficiently solving a flowsheet remains a challenge. In this work, we show that graph representations of the underlying physical phenomena in unit operations may help identify potential avenues to systematically reformulate the network of equations and enable more robust topology-based convergence of flowsheets. To this end, we developed graph abstractions of the governing equations of vapor-liquid and liquid-liquid equilibrium separation equipment. These graph abstractions consist of a mesh of interconnected variable nodes and equation nodes that are systematically generated through PhenomeNode, a new open-source library in Python developed in this study. We show that partitioning the graph into separate mass, energy, and equilibrium subgraphs can help decouple nonlinearities and guide decomposition algorithms. By employing the graph abstraction on an industrial separation process for separating glacial acetic acid from water, we implemented a new block decomposition scheme in BioSTEAM and demonstrated that this can accelerate convergence over a traditional sequential modular approach.

## INTRODUCTION

The evaluation of thousands of potential scenarios in a chemical process enables researchers to navigate uncertainties in market conditions and technological performance to create optimized designs, form conclusions on sustainability, and chart development pathways for new processing technologies. Automating the evaluation of such a large number of simulations is limited by computational challenges in rapid and robust flowsheet convergence. While many algorithmic paradigms exist (e.g., classical sequential modular simulation [1], parallel modular simulation [2], equation-based simulation [3], dynamic numerical methods [4], and the design of surrogate models [5,6]) only a limited set of approaches exist that are able to leverage the mathematical topology of the underlying phenomenological equations across the flowsheet [7,8].

In classical sequential-modular simulation, each unit operation is treated as a separate model with only

material streams as inputs and outputs. All mass, energy, and thermodynamic equations are formulated and solved independently within each unit operation. While specialized convergence strategies are employed to converge individual units, the convergence of recycle systems can be challenging due to nonlinear coupling between unit operations. Equation-based modeling leverages the sparsity of the full set of equations and employs algebraic differentiation to guide convergence of the entire system. Equation-based modeling may be faster than the sequential modular approach particularly when the initial guess is close to the steady state solution. However, highly coupled and complex networks of equations introduce instabilities and can lead to convergence failure [3].

If a process flowsheet could become aware of the connectivity of the governing phenomenological equations, robust solution strategies could be formulated that aggregate linear relationships and decouple nonlinearities. With the wealth of decomposition algorithms and computing architectures that enable the solution of

complex and large-scale problems, it may be feasible to screen for alternative problem formulations of a production process that result in more rapid and robust convergence. The problem formulation and the selection of a suitable solution method, however, is not a simple task. To address this challenge, we propose the use of graph-theoretic representations of the process equations and variables to better understand the topology of a chemical process at the *phenomenological level*. Leveraging graph abstractions in this manner can provide an avenue to systematically reformulate the equations and enable advanced, topology-aware decomposition schemes of flowsheets.

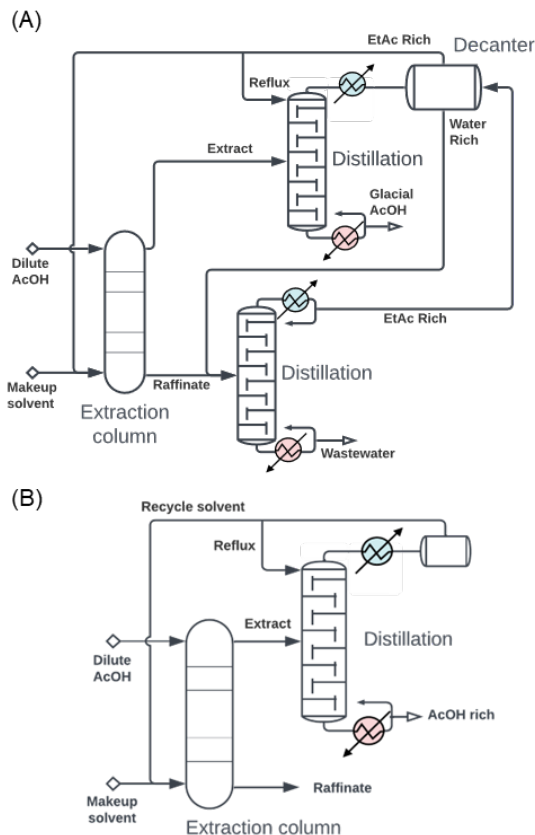

In classical representations of a chemical process, units are represented as nodes and streams as edges. Fundamentally, each unit encapsulates a set of equations with internal variables and each stream carries a set of variables with a unique connection. At the phenomenological level, however, each variable may describe multiple equations and may not have a unique connection. For example, temperature may play multiple roles in thermodynamic phase equilibrium, energy balances, and reaction rates. Graph abstractions of process phenomena may unfold the sets of equations and variables present in unit operations to capture how mass, energy, equilibrium, reaction, and transport equations are related through common variables.

A potential use of graph abstractions is the identification and development of robust decomposition algorithms whereby a subset of variables is decoupled to solve for sets of equations iteratively. Distillation column models are a classical chemical engineering example where decomposition algorithms are commonly employed. For example, the Wang-Henke bubble point method converges all stages by iteratively solving mass, equilibrium, summation and enthalpy (MESH) equations [9]. In fact, MESH partitioning within an equation-oriented approach has already been integrated to solve distillation trains within an equation-oriented approach [7]. At the flowsheet level, however, no unified approach for decomposition exists yet.

In this study, we developed a graph abstraction framework for process phenomena that can be used to systematically represent, analyze, and visualize the structure of a chemical process. To automate the generation of phenomenological graphs of complex chemical processes, we developed PhenomeNode, an open-source library in Python. We leverage PhenomeNode to form graph representations of an industrial separation process for separating glacial acetic acid from water and develop a preliminary convergence algorithm that leverages the mathematical topology. We benchmark this new algorithm against classical sequential modular simulation to understand its benefits and limitations.

## MATERIALS & METHODS

### Benchmark Acetic Acid Purification Process

**Figure 1.** Process flowsheet for the industrial separation of acetic acid from water.

The industrial separation of acetic acid from water (Figure 1A) was chosen as a representative case to benchmark the new convergence algorithm against sequential modular simulation. The system includes highly coupled vapor-liquid equilibrium (VLE) and liquid-liquid equilibrium (LLE) stages and recycle loops that connect the end of the process with the start. In this process, ethyl acetate (EtOH) is used to extract acetic acid from a dilute aqueous mixture [10]. The extract is distilled to recycle the solvent and recover glacial acetic acid. The raffinate is also distilled to recover EtOH from the wastewater. Both distillates are sent to a decanter to separate the aqueous phase that forms after condensation. Additionally, a smaller system composed of a liquid extraction column and a distillation column for solvent recovery (Figure 1B) is used as a benchmark for small, highly coupled systems.

The phenomena graph includes only the equations pertinent to flowsheet convergence, including duties and

material flows across unit operations and stages. Equations for sizing and costing of unit operations are not included as they can be directly calculated based on the steady state results. Process simulations were performed 10 times for each configuration to accurately measure convergence errors and material and energy balance errors as a function of computation time. The convergence error for a given variable at iteration  $k$  is defined as the absolute difference between the current value and the last value (i.e.,  $X_{\text{error}} = |X_k - X_{k-1}|$ ). The material balance error is defined as the difference between outlet flow rates and inlet flow rates (i.e.,  $F_{\text{error}} = \sum_c |\sum_o F_{c,o} - \sum_i F_{c,i}|$ ). The energy balance error is defined as the difference between outlet enthalpy and inlet enthalpy divided by the outlet heat capacity flow (i.e.,  $T_{\text{error}} = |\sum_o H_o - \sum_i H_i| \cdot (\sum_o C_o)^{-1}$ ).

## Phenomenological Graph Architecture

The graph abstractions in this study represent both variables and equations as nodes. Edges between variables and equations provide information on the variables present in each equation. Variables in the nodes are labeled by a shorthand name and their context. The context differentiates variables by information such as the phase and the parent unit operation. For example, the vapor mol fraction within a vapor-liquid equilibrium (VLE) stage may be labeled as  $z_{\text{gas}, s=0}$ , where “ $z$ ” denotes the mol fraction, “gas” denotes the phase, and “ $s$ ” denotes the stage number. Table 1 lists the subscript contexts and Table 2 lists the variable definitions used in this study. The “inlet source” refers to a neighboring stage that feeds the reference stage. Similarly, the “outlet sink” refers to a neighboring stage that is fed by the reference stage. It is possible to obtain different graph representations by reformulating the equations. For example, variable nodes can be eliminated via substitution of equations and new edges may be formed to reflect these changes. Aggregating equations in this manner may be helpful to represent a particular convergence algorithm. The graph representations in this study employ as many variables as possible to provide a starting point for future studies to strategically collapse nodes and/or partition the graph.

**Table 1.** Contexts of variable subscripts.

Subscript	Context	Subscript	Context
c	Chemical	gas	Gas
p	Phase	liq	Liquid
i	Inlet source	ext	Extract
o	Outlet sink	raf	Raffinate

Drawing, positioning, and labeling nodes for a large network of unit operations is a time-consuming task. To automate the systematic generation of graphical abstractions for complex chemical processes, we developed a new open-source Python library called

PhenomeNode [11] that leverages the Graphviz software [12] to generate graphical abstractions from the phenomenological equations within unit operations. In the spirit of expanding the use of graph representations at the phenomena level—not just at level of unit operations or superstructures of units—the PhenomeNode software developed in this study is made open-source and readily available for others to leverage. The roadmap for PhenomeNode includes expanding the built-in equation library, refining core features for aggregation and decoupling of equations, and creating educational tools for student learning of the underlying phenomena behind production processes.

**Table 2.** Variable definitions.

Variable	Definition
F	Molar flow rate
H	Enthalpy flow rate
Q	Duty
V	Molar fraction of vapor phase
$\Phi$	Ratio of top and bottom phase flow rates
L	Molar fraction of extract or liquid phase
T	Temperature
P	Pressure
Z	Molar composition
K	Partition coefficient
C	Heat capacity rate
t	Top phase split fraction
b	Bottom phase split fraction
h	Specific molar enthalpy
f	Fugacity

## Mathematical Relationships within Graphs

The equations describing the physical phenomena within the graph abstractions are agnostic to the thermodynamic property package. Equations for pure component and mixture properties are abstracted by black-box function calls. For example, the VLE criteria is represented by equation 1, where  $f_{c,\text{gas}}$  and  $f_{c,\text{liq}}$  are function calls to calculate the gas and liquid fugacities, respectively, for an arbitrary chemical. Other key equations include the Rachford-Rice, material balance, energy balance, and pressure drop (eqs 2–5, respectively).

$$f_{c,\text{gas}}(z_{c,\text{gas}}, T, P) = f_{c,\text{liq}}(z_{c,\text{liq}}, T, P) \quad (1)$$

$$\sum_c \frac{z_c(K_{c,\text{gas}} - 1)}{1 + V * (K_{c,\text{gas}} - 1)} = 0 \quad (2)$$

$$F_{c,\text{liq}} \left( 1 + \frac{V}{1-V} K_{c,\text{gas}} \right) - F_c = 0 \quad (3)$$

$$F_{\text{liq}} \left( \frac{V}{1-V} h_{\text{gas}} + h_{\text{liq}} \right) - H = 0 \quad (4)$$

$$P_{o=0} = P_{o=1} - \Delta P \quad (5)$$

A liquid-liquid equilibrium (LLE) stage has two liquid phases, “ext” and “raf”, which correspond to the extract

and the raffinate phases, respectively. The material and energy balance equations for an LLE stage are analogous to a VLE stage. The pressure drop across LLE stages is neglected assuming that liquid fugacities are a weak function of pressure. LLE criteria (eq 6) requires that the total Gibb's free energy of all phases is minimized.

$$\min_{z_{c,raf}} G(F_c, z_{c,raf}, z_{c,ext}, T, P) = z_{c,raf} \quad (6)$$

These are the fundamental equations for distillation and liquid-liquid extraction algorithms. However, they can be reformulated to fit a specific solution scheme. For example, in the case of LLE, the enthalpy is a stronger function of temperature than the phase fraction and the energy balance is formulated in terms of temperature (assuming an average heat capacity flow for each phase and a reference temperature and enthalpy):

$$(H_{ext}^{ref} + H_{raf}^{ref}) + (T - T^{ref})(\bar{C}_{ext} + \bar{C}_{raf}) - H = 0 \quad (7)$$

### Phenomena-Oriented Simulation Algorithm

We developed a new flowsheet convergence algorithm that expands and integrates MESH-based multistage equilibrium algorithms together with the sequential modular approach. Additional details on the algorithm architecture and performance are discussed in the RESULTS & DISCUSSION section. The material and energy balance equations are used to tie in all the phenomenological equations together. A stage includes all mixing and splitting of inlet and outlet streams, respectively, without limitation on the number of connected stages. For a given stage,  $F_c$  for all streams can be computed through the material balance equations (8–11):

$$\Sigma_o F_{c,o} - \Sigma_i F_{c,i} = 0 \quad (8)$$

$$\Phi K_{c,gas} \Sigma_o F_{c,liq,o} - \Sigma_o F_{c,gas,o} = 0 \quad (9)$$

$$F_{c,gas,o} - t_o \Sigma_o F_{c,gas,o} = 0 \quad (10)$$

$$F_{c,liq,o} - b_o \Sigma_o F_{c,liq,o} = 0 \quad (11)$$

The mass balance equations apply to both LLE and VLE stages, with either extract and raffinate or gas and liquid phases. Note that subscripts  $i$  and  $o$  refer to upstream and downstream stages, respectively, which are directly connected to the reference stage. For computational efficiency, the energy balance equation solves for the change in linearized variables (i.e.,  $T$  for a LLE stage and  $\Phi$  for a VLE stage) in each iteration (e.g., we solve for  $\Delta T$  where  $T_{i+1} = T_i + \Delta T$ ). Combining equations 4 and 7 (and taking  $\Delta T$  and  $\Delta \Phi$  as the linearized variables) the energy balance for an adiabatic VLE stage becomes:

$$\Delta \Phi h_{gas} \Sigma_o F_{liq,o} - \Sigma_i C_{liq,i} \Delta T_i - \Sigma_i \Delta \Phi_i h_{gas,i} F_{liq,i} = \Sigma_o H_o - \Sigma_i H_i \quad (12)$$

Similarly, the energy balance for an adiabatic LLE stage becomes:

$$\Delta T \Sigma_o C_{liq,o} - \Sigma_i C_{liq,i} \Delta T_i - \Sigma_i \Delta \Phi_i h_{gas,i} F_{liq,i} = \Sigma_o H_o - \Sigma_i H_i \quad (13)$$

Given the coupling between the material and energy balances through  $F_c$  and  $\Phi$ , solving for  $T$  at each stage may help close the energy balance for large systems with strong compositional dependencies on specific enthalpies:

$$\Delta T \Sigma_o C_o - \Sigma_i C_i \Delta T_i = \Sigma_o H_o - \Sigma_i H_i \quad (14)$$

The VLE criteria (equation 1) is used to solve for  $K$  and  $T$ . The equilibrium temperature of an LLE stage, however, is not unique for a bulk composition. Instead, the LLE criteria (equation 6) is used to solve for  $K$  and  $\Phi$ . In the special case of multistage LLE, where equilibrium is highly sensitive to bulk compositions, the pseudo-equilibrium concept is employed for more rapid and robust convergence of the equilibrium criteria across all stages [13]. Given the equilibrium criteria variables and initial guesses for  $\Phi$  and  $T$ , component flow rates across all stages can be linearly solved by the material balance equations (8–11), and  $\Phi$  of VLE stages and  $T$  of LLE stages can be linearly solved by the energy balance equations (12–13). However, an algorithm employing solely equilibrium, material, and energy equations may fail due to poor conditioning of the initial guess. For this reason, we integrate sequential modular simulation—a robust approach used by leading process simulators—within the simulation algorithm for more robust convergence. All together, we propose the following algorithm as a preliminary architecture:

### Phenomena-oriented simulation algorithm

1. In the absence of an initial guess for  $F_c$ ,  $K$ ,  $T$ , and  $\Phi$  for each stage, run each unit operation sequentially to find initial guesses.
2. For each unit operation:
  - 2.1 Solve the unit operation and update variables  $K$ ,  $T$ , and  $\Phi$ .
  - 2.2 Solve for  $F_c$  across all unit operations as a system of linear equations (eqs 8–11) and update.
  - 2.3 Solve  $\Delta \Phi$  for each VLE stage and  $\Delta T$  for each LLE stage as a system of linear equations (eqs 12–13) and update  $\Phi$  and  $T$ .
3. Solve for the equilibrium criteria variables at each stage. For multistage LLE, solve for all stages simultaneously using the pseudo equilibrium approach.
4. Run steps 2.1, 2.2, then 2.1 again to close the material balance.
5. Solve for  $\Delta T$  as a system of linear equations (eq 14) and update  $T$  to close the energy balance.
6. If partition coefficients, phase ratios, temperatures, and flow rates have not converged under a specified tolerance, repeat steps 2–6.

**Figure 3.** A phenomena graph representation of (A) a VLE stage and (B) a LLE stage. Equations related to material, energy, equilibrium, and pressure are colored black, red, purple, and green, respectively. Each grey ring node and its label represents a variable. Edges denote the variables present equations.

This algorithm was implemented in BioSTEAM —an open-source process simulation software [14]—and benchmarked against sequential modular simulation using a flowsheet for the industrial separation of acetic acid (also modeled in BioSTEAM). The thermodynamic property package estimates phase equilibrium using modified Raoult’s law with activity coefficients estimated through Dortmund UNIFAC interaction parameters [15,16]. Pure component properties (e.g., heat capacity) of fluids are estimated using higher order polynomial fits to the fundamental Helmholtz equation of state (a state-of-the-art property prediction model)[17,18] and recommended correlations from a critical review on thermodynamic properties [19]. Mixture properties are estimated using a molar weighted average of the pure chemical properties.

## RESULTS & DISCUSSION

### Single and Multistage Equilibrium Graph

Material, energy, equilibrium, and summation equations are tightly coupled for both a VLE stage and a LLE stage (Figures 3 A and B, respectively). Note that the designation of what constitutes an equilibrium, material balance, or energy balance equation is based on the unit dimensionality of the equation as well as the decomposition scheme requirements. For example, the Rashford-Rice equation may be regarded as a material balance equation, but it is denoted here as an equilibrium relationship to maintain linear relationships within the material balance (assuming partition coefficients and phase fractions are decoupled).

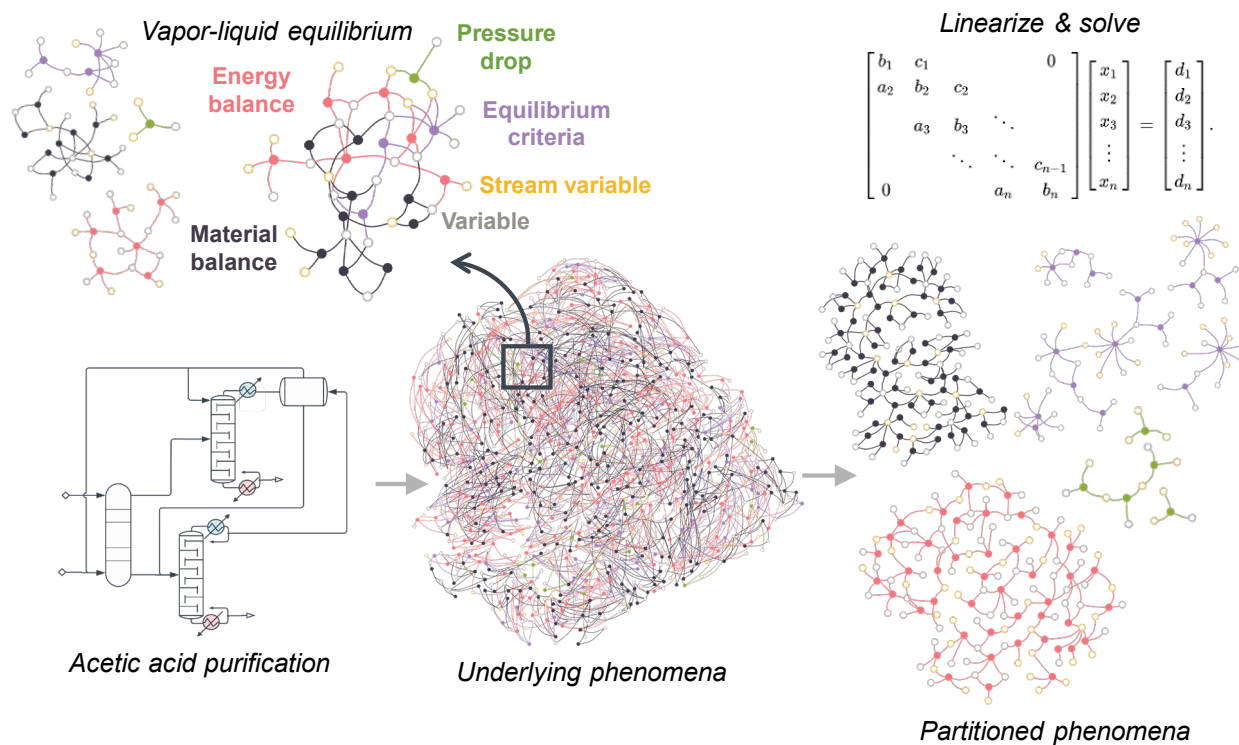

A classical chemical engineering method to solve an adiabatic flash vessel consists of a 3-step fixed-point iteration: (1) compute partition coefficients and temperature assuming the vapor and liquid compositions (e.g., by computing the bubble point), (2) estimate the vapor and

liquid compositions through material balances, and (3) solve for the vapor fraction using an energy balance [20]. In this iterative method, the equilibrium, energy, and material balances are decoupled. Given that non-linearities stem from the equilibrium criteria and the enthalpy of streams, this decomposition algorithm may offer greater stability than derivative-based numerical methods when employed for larger systems.

Partitioning the equations by equilibrium, energy, and material phenomena results in a more manageable problem formulation that is often used by published algorithms for multistage VLE and LLE. Assuming the temperature, pressure, and phase fraction (i.e., vapor or extract fraction) are held constant, the material balance for an arbitrary component becomes a linear combination of liquid (or vapor) flow rates and can be represented as a tridiagonal matrix that is convenient to solve. Similarly, if bulk liquid flow rates, compositions, and temperature are held constant, the energy balance becomes a linear combination of the boil-up ratio. The new phenomena-oriented simulation algorithm proposed in this study leverages this partitioning scheme towards the complete flowsheet to accelerate convergence.

Block convergence methods for distillation (e.g., Wang-Henke’s bubble point method) and liquid-liquid extraction —which iteratively solve equilibrium, material, and energy equations— are still subject to instabilities and may not converge. Russell’s inside-out method leverages approximate models for stage temperature and specific enthalpy to converge an inner loop of stage temperatures and phase flow rates [21]. Employing approximate models for highly coupled non-linear variables (i.e., partition coefficients, enthalpy, and temperature) allows for more robust convergence if the approximate form is better behaved than the strict form. Future work may

**Figure 5.** A phenomena graph representation of an industrial process for the separation of acetic acid from a dilute aqueous mixture to produce glacial acetic acid depicts how decoupling material (black), energy (red), and equilibrium (purple) equations may result in a more manageable formulation even for complex recycle systems. Equation nodes for repeated adiabatic stages in the partitioned phenomena are aggregated for clarity. Variable nodes are shaped as silver and gold rings to denote intermediate variables and stream variables.

seek to reformulate the system of equations with approximate models that can describe the complete system and propose more advanced numerical methods to accelerate flowsheet convergence.

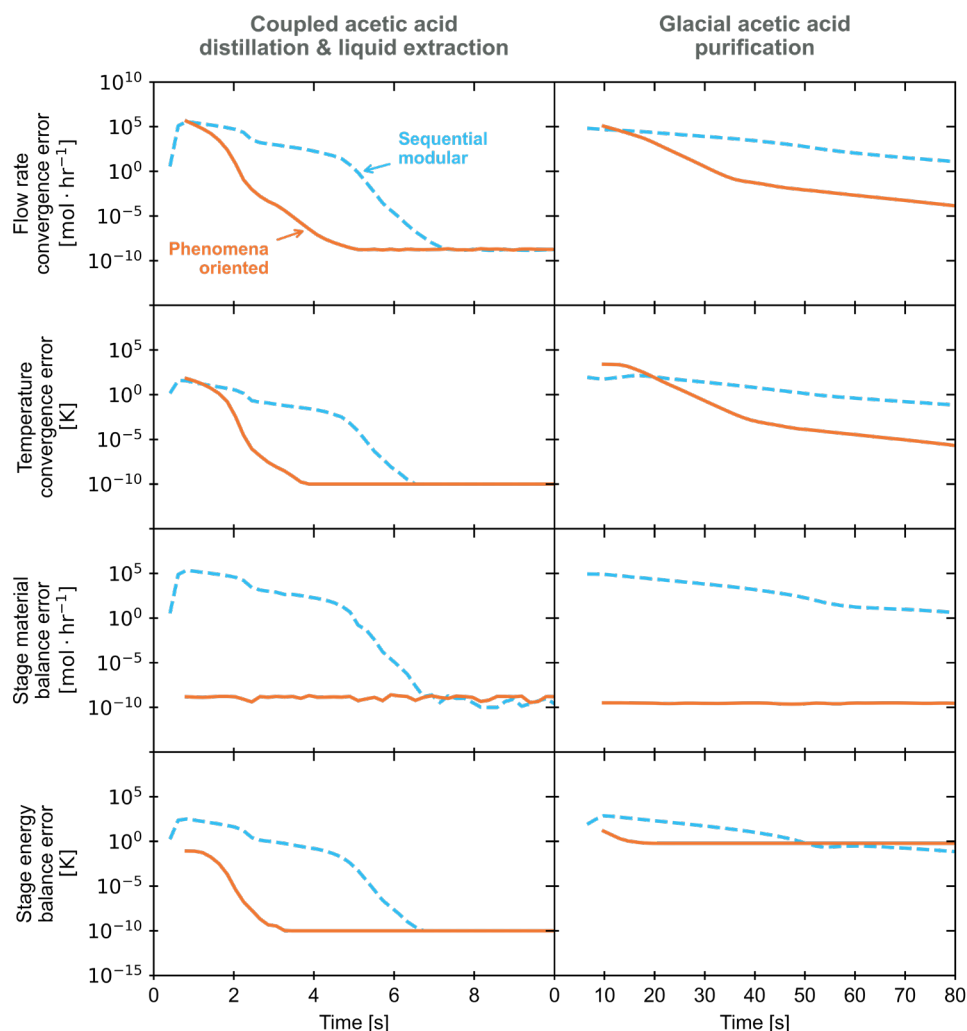

### Acetic Acid Separation Graph

A graph of an industrial separation process for separating glacial acetic acid from water suggests that it may be feasible to extend MESH equations as a decoupling strategy for integrated convergence of the complete flowsheet (Figure 5). While the graphical representation may seem more coupled due to the recycle loops, the resulting problem is essentially the same as in multistage equilibrium. In the proposed phenomena-oriented algorithm, equilibrium variables of each stage are calculated in parallel while energy and material balances result in sparse matrices that are linearly solved (steps 3–5). It is possible recycle loops between distillation columns and the liquid-liquid extraction destabilizes stage-wise material and energy balances and lead to ill-conditioned matrices and infeasible results (e.g., negative flows) which would break the model. To resolve such issues, we integrate sequential modular simulation as a robust method to rigorously estimate equilibrium criteria variables (step 2.1). The system-wide mass and energy balances (steps

2.2 and 2.3) helps propagate the information of how an individual unit simulation impacts the flowsheet, enforce mass and energy balances, and accelerate simulations.

### Phenomena-Oriented Simulation Speed

In both the benchmark cases, the preliminary phenomena-oriented simulation algorithm converged faster than the sequential modular approach (Figures 6 A, B, C, and D). The error in the mass and energy balance per stage was quickly minimized in the phenomena-oriented algorithm (Figures 6 E, F, G, and H) due to how mass and energy balances of the complete flowsheet are consolidated at the end of each iteration (steps 4 and 5). In comparison, sequential modular simulation has difficulties in closing the mass balance for the complex system even after 60 seconds of simulations (Figure 6H). By speeding up flowsheet convergence, phenomena-oriented simulation may enable large-scale simulations necessary for robust optimization and rigorous uncertainty and sensitivity analyses. It may be possible, however, that the proposed phenomena-oriented algorithm may not be as robust as sequential modular in other systems and more cases should be evaluated for more generalizable insight. Additionally, only one initial condition (starting with empty

**Figure 6.** The convergence error of the flow rate (A, B), temperature (C, D), as well as the error in the material balance (E, F), and the energy balance (G, H) was evaluated across computation time for a simple configuration with liquid-liquid extraction and distillation and a more complex system for acetic acid purification (left and right columns, respectively). The blue curve represents values using the sequential modular approach and the orange curve represents values using the new phenomena-oriented approach.

streams) was tested yet simulations used in optimization and uncertainty analyses may leverage more informed guesses. Future studies may seek to analyze the robustness of this new convergence algorithm more rigorously through Monte Carlo methods. It is possible certain algorithms scale better with large, sparse systems than with small, highly coupled systems.

It is important to note that this separation process is limited to only phase-based separations and does not encapsulate reactions and mass and energy transfer-based unit operations that are common in a production process. Still, the equations and decoupling strategies leveraged here can be extended to include other physical phenomena. For example, equilibrium approaches to reactive distillation extend Russell's inside-out method to include reaction terms and decouples the kinetic terms

from the equilibrium criteria [22]. We envision a family of phenomena-oriented simulation architectures that are optimized for different problems based on the relevant phenomena of the system, level of connectivity between unit operations, and chemical interactions that drive coupling between phenomenological equations. Ultimately, the phenomena graph representations introduced in this study may aid in the development of unified decoupling and linearization strategies that can allow for more rapid and robust flowsheet convergence.

## CONCLUSIONS

Efficiently solving a flowsheet remains a challenge due to the tightly coupled, non-linear nature of chemical processes. While a variety of methods exist for

converging a flowsheet, there is no clear winner in terms of speed, flexibility, and robustness. The phenomena graph representations developed in this study helped identify how decoupling equations into material, energy, and equilibrium blocks (and potentially other phenomena such as reactions) can be used to formulate a strategy to converge the complete flowsheet. While the proposed algorithm showed promising advantages in convergence speed composed to sequential modular, further analysis is needed to fully characterize the speed, robustness, and applicability to a broader set of chemical processes. The PhenomeNode library in Python can be used as an educational tool to help students visualize a chemical process not just as a flowsheet of unit operations, but also as a coupled network of physical phenomena.

## ABSTRACT

Maintaining product integrity in multi-product oil pipelines is crucial for efficiency and profit. This study presents a strategy combining design and process improvement to enhance flushing protocols, addressing the challenge of residual batch contamination. A pilot plant, mirroring industrial operations through dimensionless residence time distribution, was developed to identify and rectify bottlenecks during product transition. The pilot plant's success in replicating industrial operations paves the way for targeted experiments and modelling to enhance optimized flushing, ensuring product quality and operational excellence.

**Keywords:** Process Design, Optimization, Modeling, Flushing

## 1. INTRODUCTION

Multi-product pipelines are large-diameter lines used to transport different grades of the same product or different petroleum products. Such transport is performed by batching the products in a continuous succession [1]. Owing to this mode of transport, ensuring the quality and purity of each product processed in this network of pipelines is crucial for operational success [2]. Multi-product pipelines, tailored for various applications, are comprised of an array of components. These interconnected pipeline networks typically include straight segments, flow meters, valves, assorted fittings, bends, tees, and various other supplementary equipment.

Transporting different grades of products in multi-product pipelines often leads to residue accumulation, impacting the quality of subsequent products. Residues from previous batches adhere to the pipeline walls, compromising product yield, and integrity, and causing financial losses. Therefore, regular cleaning is essential during product changeovers in the multi-product pipeline industry. This study aims to develop an enhanced and comprehensive flushing process specifically for the generic lube oil industry.

**Figure 1:** Multi-Product Pipeline Configuration of the Generic Lube Oil Industry (The illustrated network details the sections of variable diameters and A, B, C, D, E represents sample different grades of products processed within this industry).

In this industry, various product grades are processed using multi-pipeline systems, as shown in Fig 1. These systems consist of straight and varying diameter sections, flow control mechanisms, U-bends, tees, fittings, and filters. To remove residues from previous products, pipelines are flushed between each product transition. This cleaning process involves two alternatives: using a pipeline inspection gauge (PIG) for straight sections and using the next product in line to flush the variable

diameter sections. The PIG, a squeegee-like device, is 97% effective in cleaning the straight pipelines but less efficient for variable-diameter sections due to its size, shape limitations, and potential damage risks. Therefore, sections that cannot be cleaned by the PIG, known as "un-piggable sections," are flushed with the finished product (the next new oil to be packaged in the line).

This creates an optimization challenge to determine the volume of new oil needed for residual displacement. Therefore, we have designed and constructed a 1/5<sup>th</sup> scale pilot plant to replicate industrial processes, focusing on optimizing the flushing operation in the unpiggable sections of the multi-product pipeline system.

## 1.1 Flushing

Flushing in multiproduct pipelines is a crucial process involving the removal of residual products from the pipelines to prevent contamination when transitioning between several grades of products. This operation is particularly important considering systems where different grades of products are processed, as it ensures product quality and integrity [3]. Considering a changeover operation where a new product is to be processed through the pipeline, residues of the previous products need to be displaced. Referencing the generic lubricating oil industry with the pipeline configuration shown in Figure 1, entrapped residual oil within the unpiggable sections is flushed with the next product.

This process results in the creation of mixed or commingled oil systems, which are lower in value and considered downgraded. Consequently, large quantities of the subsequent product must be used to flush out the residuals and the commingled oil. As depicted in Figure 2, during the flushing operation, the tail ends of the pipeline contain the residuals, and the middle section is a blend of both oils, which are gradually and completely displaced over time. In sections of pipelines where pigging is not feasible, significant residue accumulation is often observed in U-bends, filter areas, and along the entire inner walls of the pipelines.

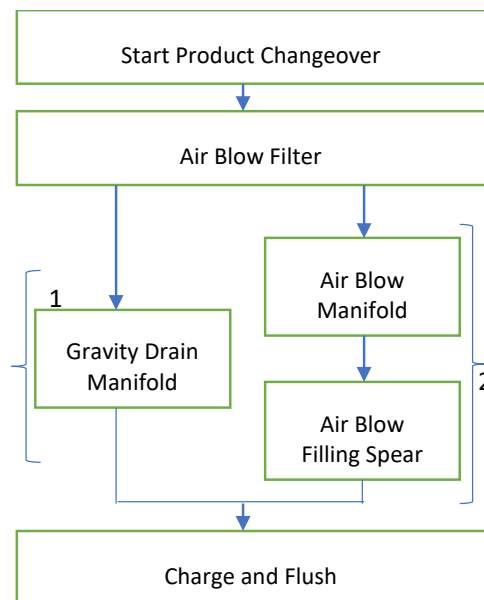

**Figure 2:** Illustration of Flushing Process During Product Changeover Operations

### 1.1.1 Review and Improvement of Industrial Flushing Operations

To enhance the flushing process in pipeline operations, it is crucial to analyze existing systems, identify inefficiencies, and devise improvements. This approach includes reviewing current practices, suggesting enhancements, and incorporating these into scaled pilot

plant designs to create effective flushing models. Before switching products in the pipeline, it's standard to remove the residue of the previous product. This is typically done by air blowing through filters and gravity draining the manifold line, effectively removing a significant portion of the residual oil. However, this method doesn't fully clear oil remnants in other parts of the pipeline, resulting in the use of excessive volumes of the next product to flush out these residuals. This leads to the formation of large quantities of mixed oil, highlighting a key area for process improvement.

To overcome this limitation, an enhanced process has been developed, combining experimental analysis with optimization techniques. This new approach aims to significantly lower the volume of residual materials, ensuring that only minimal amounts of finished products are employed in the flushing process. This reduction minimizes the creation of mixed oils. The improved methodology is depicted in Figure 3 contrasting it with the current operational mode, highlighting the key differences. This advanced process, tested, and refined through pilot plant studies, is designed to mirror and optimize industrial-scale operations.

**Figure 3:** Schematic Diagram of Flushing Operation. The existing operation is #1 and improved procedure is shown in #2

## 2. PILOT PLANT DESIGN AND ARCHITECTURE

The pilot plant aims to replicate the industrial scale operation to study the product changeover operations and optimize the flushing operation. Also, with this pilot plant the effects of changes in the process parameters like flowrate, viscosity of products, and temperature

is studied. The pilot plant is designed to mirror the generic lube oil industry on a smaller scale. The pilot plant features a detailed pipeline system where lube oil passes through the various components, including a filter, U-bends, manifold, and flow control devices, before being packaged. The process flow diagram of the designed pilot plant is illustrated in Figure 8 (the bottom figure).

## 2.1 Scale-Down Factors

An appropriate scale down factor must be used when designing and fabricating a pilot plant to replicate the characteristics of a much larger operational system.

### 2.1.2 Reynolds Number

The study concentrates on the mixing characteristics of viscous fluids in pipeline systems, using Reynolds Number as the scaling criterion for both systems. Matching the Reynolds Number ensures that the pilot plant accurately replicates the mixing behavior of an incompressible fluid. Considering an incompressible fluid,

$$N_{Re} = \frac{\rho v D}{\mu}$$

The Reynolds number,  $N_{Re}$  influenced by density, velocity, and viscosity, is a crucial factor. The pipeline at the lubricating industry is divided into two segments based on internal diameter (ID). The first segment, running from external tanks to the manifold, uses 3-inch schedule 40 carbon steel pipes with an ID of 3.068 inches. The shorter second segment comprises 2-inch schedule 40 carbon steel pipes with an ID of 2.067 inches. In contrast, the pilot plant's pipeline has been scaled down to a 1/2-inch schedule 40, with an ID of 0.602 inches. The product's viscosity plays a significant role in determining the dynamics during product change-over, affecting both the Reynolds number and the residual product amount in the system. Since the pilot plant operates at room temperature, it is necessary to adjust product viscosities to match the higher temperatures seen in full-scale operations. Additionally, the system's volumetric flow rate is crucial. Choosing a pump with the right flow properties is essential for accurately replicating the pilot plant's design at scale.

### 2.1.3 Volumetric ratio

The second metric used in the scale down process is the system volume ratio. This ratio is defined as the volume of the filter by the volume of the remaining system. Replicating this ratio for the pilot plant system was a crucial aspect for the design. The pilot plant system was modelled by theorizing the configuration as a combination of tanks (CSTR) and tubular (PFR) sections. The filter acts as the tanks and the pipe sections the tubular sections. The system volume at the industrial scale was determined to be approximately 32 gallons, with the filter containing 13 gallons of product. Thus, given the

expression for this ratio as follows;

$$V_R = \frac{V_{filter}}{V_{system}}$$

the ratio is calculated to be 0.4.

## 2.2 Designed Pilot Plant

The pilot plant features three product tanks, each with a 30-gallon capacity, serving distinct functions: a tank for residual oil, another for flush oil (the next product in line for processing), and a third for collecting the mix of these two oils. The tanks, made from high-density polyethylene for compatibility with petroleum lubricants and water, are set on a steel stand with rounded bottoms and bulkhead fittings for efficient drainage. They are linked to the main pipeline via flexible buna-nitrile hydraulic hoses. The plant also includes a suite of equipment: measuring balances placed under each tank for precise product tracking, spear gear pumps, a pressure relief valve, a compressed air system, a filter, various fittings and valves, an inline viscometer, and a sophisticated data acquisition system. This design ensures effective monitoring and management of the processing activities.

**Figure 4:** Pilot Plant CAD Design (Top) and Fabricated Pilot Plant Design at the Laboratory (Bottom)

When selecting an electronic balance for our system, key factors included its maximum weight capacity, size, response speed, and cost. Considering the density

of water and weight of tank stand, a balance capable of measuring up to 300 pounds was required for accurate safety testing. This was vital for monitoring the subtle, rapid weight changes during pump operation. Ultimately, we chose a balance with a 600-pound capacity and a width of 19.75 inches, ensuring it not only met our immediate needs but also accommodated larger loads for future experiments.

Due to the high viscosity of the fluid, a peristaltic (spear gear) pump is used for fluid flow in the pipeline, with a maximum capacity of 7 GPM. This pump features a cast iron interior and 3/4" NPT ports reduced to 1/2" outer diameter tubing. To ensure safety and prevent overpressure, a pressure relief valve (PRV) is installed, set at 70 PSI - above the normal operating pressure but below the filter's 100 PSI maximum. This PRV setting accommodates the system's needs, particularly considering the performance of lubricant oils up to 108 cSt, where the maximum pressure drop through the valve is 25 PSI, within the filter's safety threshold.

Viscosity is a critical factor in lubricating oil, essential for optimal machinery performance. Choosing an oil with appropriate viscosity for specific operating conditions is vital. Viscosity tests are key to ensuring product quality and the success of flushing operations. Traditional viscosity measurement involves labor-intensive sampling and lab analysis using glass capillary viscometers. However, this method can be time-consuming and error-prone. Automating the viscosity testing process can reduce manual labor and costs, while real-time viscosity measurement in product batches offers environmental and logistical advantages by minimizing repeated flushing operations. An inline viscometer, integrated into the pilot plant system, demonstrates the advantages of real-time measurement over traditional methods. This viscometer features a seamless bore, no moving parts, and requires minimal maintenance.

Integrating a data acquisition system into the pilot plant was essential for accurate, real-time recording of experimental data, crucial for understanding the process being studied. This system facilitates efficient collection, processing, and analysis of data from various equipment, including scales, inline viscometers, and thermocouples. It plays a key role in monitoring and controlling experimental variables, greatly aiding in system modeling and enabling swift decision-making. The selected data acquisition system features an eight-slot chassis, accommodating multiple input modules, chosen based on compatibility with the pilot plant's equipment, signal measurement types, maximum sampling rates, and the supported number of channels. The signal measurement type, the interacting equipment and the individual acquired modules are illustrated in Table 2.

**Table 1:** Pilot Plant Process Equipment Specifications

Equipment	Description	Capacity
<b>Spear Gear Pump</b>	Cast Iron, 3/4" NPT	7 GPM
<b>Inline Viscometer</b>	Flow-through viscometer, no internals and compactible with pigging systems	0 to 10,000 cP, accuracy +/- 0.1 cP, 100 bar, -50 °C – 100°C
<b>Pressure Relief Valve</b>	Buna-nitrile seal with stainless steel material	11 GPM, 60-175 PSIG

**Table 2:** Components of the Data Acquisition System, Measurement Signal Type and Interacting Process Equipment

Components	Measurement Signal	Interacting Equipment
<b>9212</b>	Current (4-20 mA)	Thermocouple
<b>9870</b>	Voltage (9 V DC)	Balance
<b>9203</b>	Current (4-20 mA)	Inline Viscometer

### 3. PILOT PLANT VALIDATION

In comparing two systems, which are of different scales, it is useful to assess the dimensionless residence time distribution between both systems. If the scaled down version (pilot plant) exhibits similar behavior and characteristics to the larger system (industrial plant), it indicates that the smaller system effectively replicates the larger system [4]. This comparison is crucial for validating and ensuring the pilot plant can reliably mimic the industrial system, providing a basis for scaling up processes with confidence.

#### 3.1 Residence Time Distribution

The prediction and modeling of residence time distributions (RTDs) are essential for understanding material flow in a process. Each component, such as filters and pipes, has its own RTD. By linking these RTDs using convolution integrals, the overall process RTD is calculated. This helps in estimating the average time materials spend in the process, understanding the system's response to material stream fluctuations, and devising process control strategies [5].

Residence time distribution modeling serves not only to characterize entire manufacturing lines but also to explain the intricate behaviors of individual units in a network. In reactor networks, the continuous stirred tank reactor (CSTR) and plug flow reactor (PFR) are the most prevalent types. While these reactors are overly idealized to accurately represent real reactors, combining these

basic models in a network allows for an effective depiction of actual unit operations, accounting for phenomena like dead zones and areas of insufficient mixing [6].

The residence time distribution (RTD) experiments in the pilot plant involved using diluted salt water and fresh water. These experiments are crucial as they bridge theoretical concepts with the pipeline system's practical application. The step change method was employed for these RTD experiments, reflecting the complexities of the flushing process. This approach effectively demonstrates the fluid dynamics and various mixing mechanisms operational within the pilot plant.

By comprehending the complex fluid flow dynamics in the pilot plant, we can fine-tune the system for a more precise emulation of industrial processes.

### 3.2 Methodology

The RTD experiment involved using diluted salt water as the flushing fluid and pure water as the residual fluid. The experiment began with a sudden switch from one fluid to the other at  $t = 0$ , and the outlet concentration was monitored. To simulate oil flushing operations where oils are miscible and compactible, water-soluble salts were used. NaCl was selected as the preferred salt, as indicated in Table 3. The conductivity of these diluted salt solutions was measured using a Vernier Conductivity Probe™, substituting the inline viscometer in the pilot plant. The recorded conductivities (S) were then converted to concentrations (C) using relations shown below.

$$C = aS^2 + bS + c$$

**Table 3:** Candidate salts and parameter values for conductance to concentration conversion

Salt	mS/cm	a	b	c
NaCl	0-55	1.95	609	0
KCl	0 - 19	0	631.32	0
	19 - 143	0.2816	708.07	-913.51
KI	0 - 11	0	1340.4	0
	11 - 113	0.7556	1449	-233.9
NaBr	0 - 16	5.6327	967.2	0
	16 - 100	2.4823	1067.2	44.46

### 3.3 Governing Equations

The first step in RTD modelling is obtaining the residence time distribution. The experimental setup introduces a conductive solution as a tracer and its concentration measured at the outlet. The concentration profile of the tracer is  $C(t)$ . The cumulative RTD,  $F(t)$  is obtained as below.

$$F(t) = \frac{C(t)}{C_{in}}$$

$$F(t) = \int_0^t E(t) dt$$

The  $E(t)$  curve describes the distribution of exit times. Its peak indicates the time where most of the tracer material is discharged.  $E(t)$  is known as the RTD function. Statistical indicators (mean residence time  $\tau$ , standard deviation  $\sigma$ ) can be evaluated directly from the  $E(t)$  curve.

$$E(t) = \frac{d(F(t))}{dt} = \frac{d}{dt} \left( \frac{C(t)}{C_{in}} \right)$$

The mean residence time,  $\tau$  is computed as below.

$$\tau = \frac{\int_0^\infty tE(t)dt}{\int_0^\infty E(t)dt} \cong 1$$

$$\tau = \int_0^\infty tE(t)dt$$

Normalised RTD function,  $E(\theta)$  is the metric used in the comparison of the pilot plant system with the industrial plant.

$$E(\theta) = \tau E(t)$$

### 3.4 Cubic Splines

Cubic Spline is piecewise defined curve that provides a balance between flexibility and smoothness. Splines utilizes interpolation and smoothing to fit a curve through data points [7]. Cubic splines are designed to have continuous first and second order derivatives, ensuring a smooth transition between each polynomial segment. The smoothness is particularly useful in requiring a smooth curve without abrupt changes in slope.

From the python SciPy Library, spline is defined as below.

$$spline = UnivariateSpline(x, y, s, k)$$

Where  $x, y$  are the data points,  $s$  and  $k$  the smoothing factor and degree of fit respectively. The spline function was used in curve fitting and the finding the derivative of the data points for the RTD studies.  $E(t)$  can be calculated using the derivative of the spline where  $n$  represents the order of the derivative.

$$E(t) = spline(x, n)$$

## 4. RESULTS

The RTD studies for the pilot plant was evaluated looking at two extreme flowrates of 2.34 GPM, 1.15 GPM and also varying filter configurations of 0.5 L and 1L. The variation of filter configuration was necessary in satisfying the volumetric ratio scale down criterion. The industrial RTD studies were performed based on industrial data with oils as the simulant fluids as against the preliminary pilot plant studies involving conductive solutions. The step change tracer profile of  $F(t)$  for both the industrial and pilot plant system is shown in Figure 5.

**Figure 5:** Cumulative RTD  $F(t)$ : Pilot Plant (top) and Industrial Plant (bottom)

**Figure 6:** Sample RTD function  $E(t)$  of Pilot Plant Studies

The RTD function,  $E(t)$  of the pilot plant studies is illustrated in Figure 6. The peak of the profile indicates the most probable exit time for the conductive solution from the pipeline system.

Hence, providing insights into the point at which the highest concentration of the conductive solution (tracer)

exists the pipeline system. The mean residence time, representing the time average the tracer spends in the system is evaluated by inferring at the balance point of the area under the  $E(t)$  curve.

The Normalized RTD functions,  $E(\theta)$  is plotted against the dimensionless time,  $\theta$  shown in Figure 7. This plot is used as the metric for validating the pilot plant and the industrial plant. Inferring from the profile, we observe a sharp rise which suggests a rapid initial exit of the material, followed by a steadily decline after the peak, indicating a slower exit of the remaining material. Considering the pilot plant studies, at the highest flowrate, the peak is rapid and higher compared to the observed peak at the lower flowrate indicating high tracer concentrations exiting the system. Considering the two filter configurations, the distribution in both systems is symmetrical since the peak is closer to the mean of the distribution.

**Figure 7:** Dimensionless RTD of Industrial Plant Comparison with Pilot plant at 2.34 GPM and 1.15 GPM Considering 0.5 L Filter (top) and 1 L Filter (bottom)

The width of the peak reflects the spread in exit

times, which is related to the standard deviation. A narrow peak suggests that most of the tracer (residuals) exits at around the same time, indicating a small spread. Inferring from the pilot plant and the industrial plant, we observe a sharp and narrow peak, indicating approximately that a significant portion of the tracer exits the system. Hence, it can be said that low dispersion is observed and that both systems have a relatively uniform residence time. A measure of the spread of the distribution in both the pilot plant and industrial plant systems, can be inferred to be relatively small due to the sharpness of the peak, but not minimal to the noticeable tail. This indicates some variance in the residence time, however not a significant one.

The skewness of the curve is observed to be asymmetrical, with a longer tail to the right of the peak. This is an indication that, some of the tracer materials takes longer to exit the system than average, which could be due to areas of slower flow within the system.

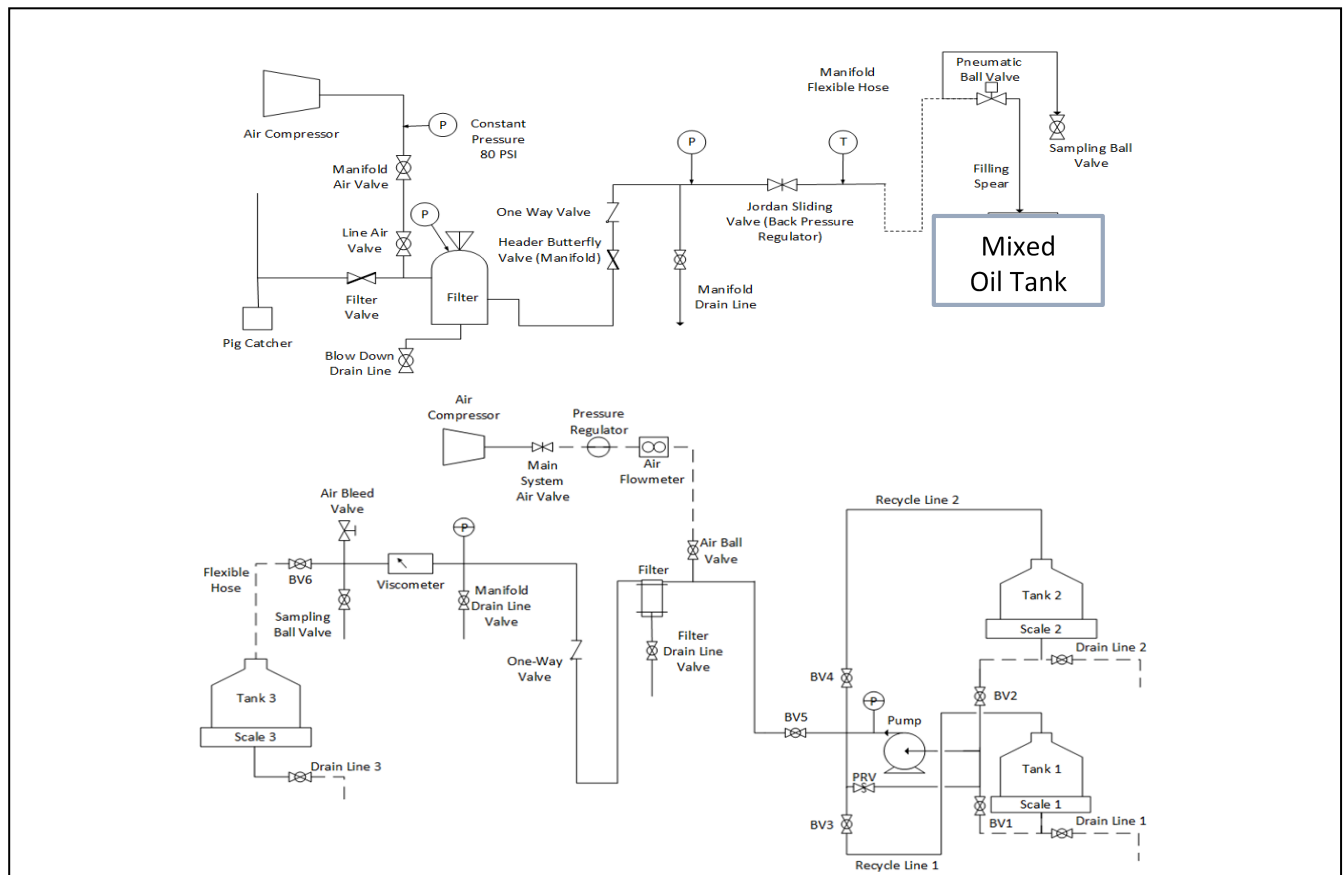

#### 4.1 Model Uncertainty

Model uncertainty in our RTD study primarily arises from the substitution of oil with salt water as a tracer, introducing discrepancies in flow behavior due to differing physical properties. Measurement precision of the

conductivity probe presents additional variability to the tracer concentration data obtained. Furthermore, the pilot plant's scale down from the industrial scale presents additional complexities; even with careful scale down factors to match industrial ratios, scale-dependent phenomena like flow regimes can behave unpredictably, impacting the RTD results. Thus, although our method offers a robust approximation in drawing similarities between the industrial plant and the pilot scale plant, acknowledging these uncertainties are crucial for the robust application and translation of our findings to the industrial scale operations.

#### 5. CONCLUSION

This study encapsulates the comprehensive process of enhancing operations through the design and construction of pilot plant, meticulously scaled down from an industrial scale. The analysis employs residence time distributions to draw parallels between the two systems. Aligning with the scaled dimensions, a 0.5 L filter was judiciously selected to maintain the requisite volumetric ratio of 0.4, mirroring the industrial setup. The RTD studies affirm that the pilot plant not only exhibits analogous dynamism but also effectively emulates the

**Figure 8:** Process Flow Diagram of Scaled-Down Pilot Plant (bottom) Replicating a Generic Lube Oil Industry (top)

industrial plant at a reduced geometry ratio of 1/5. This underscores the pilot plant's fidelity as a robust model for the industrial scale.

## ABSTRACT

We present new modifications to superstructure optimization paradigms to i) enable their robust solution and ii) extend their applicability. Superstructure optimization of chemical process flowsheets on the basis of rigorous and detailed models of the various unit operations, such as in the state operator network (SON) paradigm, is prone to non-convergence. A key challenge in this optimization-based approach is that when process units are deselected from a superstructure flowsheet, the constraints that represent the deselected process unit can be numerically singular (e.g., divide by zero, logarithm of zero and rank-deficient Jacobian). In this paper, we build upon the recently-proposed modified state operator network (MSON) that systematically eliminates singularities due to unit deselection and is equally applicable to the context of both simulation-based and equation-oriented optimization. A key drawback of the MSON is that it is only applicable to the design of isobaric flowsheets at a pressure fixed *a priori*. In this paper, as a first step towards the synthesis of general flowsheets with variable pressures, we extend the MSON to the synthesis of a gas-liquid absorption column at variable pressure (i.e., the pressure is a degree of freedom that may be optimized). We illustrate the use of the extended MSON on a carbon-capture process. The extended MSON is robust and enables the design of the column on the basis of detailed thermodynamic models and simulation-based optimization.

## INTRODUCTION

Process synthesis is central to the conceptualization of new chemical processes that can meet the manifold constraints of a circular economy. Process synthesis is the activity of identifying an optimal flowsheet which entails choosing a) process units (e.g., unit operations) from a set of alternatives, b) the connectivity of selected process units, and c) the degrees of freedom of selected units such that a design objective is optimized and all process constraints are satisfied.

Superstructure optimization is a mathematical programming approach to process synthesis. While there are several representations of a process superstructure [1], here, we focus our attention on the State Operator Network (SON) representation [2] of the process superstructure. A key feature of the SON is that each allowed process unit is described by its rigorous model which includes MESH equations and equipment sizing and costing correlations. The SON relies on a network of

conceptual mixers and splitters that enable up to full connectivity between the set of selected process units. A mixer and a splitter are located at each inlet and outlet, respectively, of each process unit.

The optimization of the SON is a challenging mixed-integer nonlinear programming problem (MINLP). A particular issue in the optimization of the SON, which is the subject of this paper, is the fate of a process unit that is deselected, that is, excluded from the flowsheet. Naturally, when a process unit is deselected, mass flowrates at each inlet of the unit must be set to zero. However, the models of many process units are well defined only at strictly positive mass flows. At zero-valued inlet flows, several numerical singularities (including undefined behaviour) in the constraint functions that describe the unit and/or in their derivatives can occur. For example, consider an isobaric-isenthalpic flash unit. At zero-valued flows, a two-phase solution to the phase-equilibrium problem does not exist. Further, the Jacobian of the mass-balance constraints of the unit is rank-deficient [3]

and costing and sizing correlations that depend on the flowrates may become numerically singular. As a result, the optimization of the SON may fail to converge.

To overcome this challenge, one may reformulate the SON MINLP using Generalized Disjunctive Programming (GDP) [4]. However, the application of GDP to simulation-based superstructure optimization is limited and computationally expensive [5]. Specifically, the initialization of the master problem in Logic-based Outer Approximation is computationally expensive when applied to simulation-based superstructure optimization [6]. Other reformulations include the Big-M reformulation of all the constraints that describe each unit, or multiplication of the constraints of each unit by the corresponding binary variable [7]. Not only do these modifications not fully eliminate singularities due to zero flows [6], but these also require modifications to the high-dimensional number of constraints that describe each process unit.

In this paper, we build upon the recently developed Modified State Operator Network (MSON) [6]. The MSON modifies mixers by introducing fictitious inlet streams that become active when a unit is deselected and take on strictly positive flowrates as well as intensive property values chosen to guarantee successful evaluation of the model of the corresponding process unit. The MSON modifies splitters to reject any flows at the outlets of the deselected process unit that arise due to these fictitious inlet flows. Further any quantities computed in the deselected unit that result in non-zero contributions to the flowsheet objective, design constraints and so on are also modified to take a zero value when the unit is deselected, thus resulting in an exact reformulation.

The SON and MSON are only applicable to the synthesis of isobaric flowsheets. The MSON is further limited as the pressure needs to be fixed *a priori*. In this paper, we present advances to the MSON towards the synthesis of general flowsheets in which: i) the pressure of any unit operation does not have to be fixed *a priori* and ii) unit operations can operate at different pressures. We address the first stipulation in the context of the synthesis of a counter-current separation column. We note that Smith (1996) [8] briefly outlined the use of pressure-driven flows between process units via a network of compressors and expanders to address the second stipulation.

A particular arena of superstructure optimization that has received much attention in the literature [9-10], including the pioneering work of Sargent and Gaminbandara (1976) [11], is the synthesis of separation columns (that is, the optimal design of number of stages and column degrees of freedom), especially distillation columns. The problem is of renewed importance today as separations are highly energy and capital intensive and improved designs are crucial to the success of emerging areas such as carbon capture and biomanufacturing [12].

The consideration of varying pressures is particularly important in this context, e.g., it can facilitate the design of separation solvents for carbon capture as the optimal choices of solvent, pressure and column configuration are intrinsically linked [13]. While we do not model any pressure drop in the column, the column pressure is a degree of freedom that we optimize, unlike our previous work [6]. The proposed extensions of the MSON are general and can be applied to any process unit in which the pressure is a degree of freedom. Additionally, the formulations presented here are amenable to both simulation-based optimization and equation-oriented optimization.

In the next section we present three different counter-current column synthesis formulations: (i) a counter-current column SON based on the R-graph decomposition of columns previously given by Farkas et al. (2008) [14] where we show how the standard formulation of the SON can suffer from numerical singularities, (ii) an exact MSON formulation of the same column that relies on a simple modification to the mixers and splitters to eliminate singularities due to deselection of stages, (iii) an extended MSON formulation so that the column pressure may be treated as a degree of freedom. We then present details of the implementation of the extended MSON and the application of the extended MSON to the design of carbon capture column. Lastly, we present results and conclusions.

## COLUMN SYNTHESIS FORMULATIONS

Consider a counter-current separation column such as a gas-liquid absorption column, liquid-liquid extraction column or the rectifying section of a distillation column. The column separation is driven by the contacting of two phases, labelled vapour and liquid here for convenience.

The column synthesis problem may be formulated as follows: Given a multi-component vapour feed to be separated, a solvent that is the mass separation agent and a maximum of  $N^U$  theoretical (equilibrium) stages, find the optimal number of stages and values of the column degrees of freedom such that the design objective is minimized and constraints on product purity and recovery are satisfied. The MSON formulation for column synthesis has previously been derived formally in full detail [5]. Here, we present the details of the SON and MSON in the context of column synthesis for completeness.

### SON

We decompose a column of  $N^U$  stages into equivalent conditional subsections [14]. Each subsection  $i$  has  $2^{i-1}$  identical equilibrium stages and an associated binary variable  $z_i$  that takes the value 1 when the subsection is selected, where  $i \in \mathcal{R}$ , where  $\mathcal{R}$  is the set of conditional subsections. For example, a column with a maximum of 15 stages is decomposed into four subsections of 1, 2, 4

and 8 stages, respectively as shown in Figure 1. As an alternative example, a column of 31 stages is decomposed into five subsections of 1, 2, 4, 8 and 15 stages, respectively. The number of subsections  $|\mathcal{R}|$  is equal to the minimum number of bits required to express integer  $N^U$  in binary notation. Each subsection has a vapour outlet, a vapour inlet, a liquid outlet and a liquid inlet as shown in Figure 1. We further include the following permanent units in the column superstructure: a vapour source, a liquid source, a vapour sink and liquid sink as shown in Figure 1. Each sink and source have one inlet and outlet each. The vapour feed to be separated and the fresh solvent enter the column via the vapour and liquid sources, respectively. The product and the spent solvent leave the column via the vapour and liquid sinks, respectively. We assume that all unit operations operate at pressure  $P$ .

### Mixer-splitter network

For each phase (vapour or liquid), we use a network of mixers and splitters to enable flows between the column subsections, and the corresponding source and sink. A mixer is placed at each of the inlets of the column subsections and at the inlet of the sink. A splitter is placed at each of the outlets of the column subsections and at the outlet of the corresponding source. The vapour mixer at inlet  $i \in \mathcal{J}^V$ , where  $\mathcal{J}^V$  is the set of vapour inlets, allows the mixing of vapour streams that leave from splitters at the outlets of the subsections  $i + 1, \dots, \mathcal{R}$  and the vapour source. Similarly, the liquid mixer at inlet  $i \in \mathcal{J}^L$ , where  $\mathcal{J}^L$  is the set of liquid inlets, allows the mixing of liquid streams that leave splitters at the outlets of subsections  $1, \dots, i - 1$  and the liquid source. An example column subsection with its mixers and splitters and their connections in detail is shown in Figure 2. Splitters and mixers are assumed to be isenthalpic and ideal. We consider a multi-component mixture with  $K$  components.  $f_i^{\text{in},V}$ ,  $\mathbf{q}_i^{\text{in},V}$  and  $T_i^{\text{in},V}$  represent the flowrate, composition and temperature of the vapour stream at inlet  $i$ .  $f_o^{\text{out},V}$ ,  $\mathbf{q}_o^{\text{out},V}$  and  $T_o^{\text{out},V}$  represent the flowrate, composition and temperature of the vapour stream at outlet  $o$ .  $f_{o,i}^V$ ,  $\mathbf{q}_{o,i}^V$  and  $T_{o,i}^V$  represent the mass flowrate, composition and temperature, respectively of the vapour stream that flows from splitter  $o$  to mixer  $i$ . All streams are assumed to be at constant pressure  $P$ . The following balances hold for vapour mixers:

$$f_i^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V \quad (1)$$

$$f_i^{\text{in},V} \mathbf{q}_{i,c}^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V \mathbf{q}_{o,i,c}^V \quad \forall c \in \{1, \dots, K\} \quad (2)$$

$$f_i^{\text{in},V} h_{en}^V(T_i^{\text{in},V}, P, \mathbf{q}_i^{\text{in},V}) = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V h_{en}^V(T_{o,i}^V, P, \mathbf{q}_{o,i}^V) \quad (3)$$

where  $\mathcal{M}_i^V$  denotes all the vapour splitters that a vapour mixer  $i$  may be connected to, and for vapour splitters:

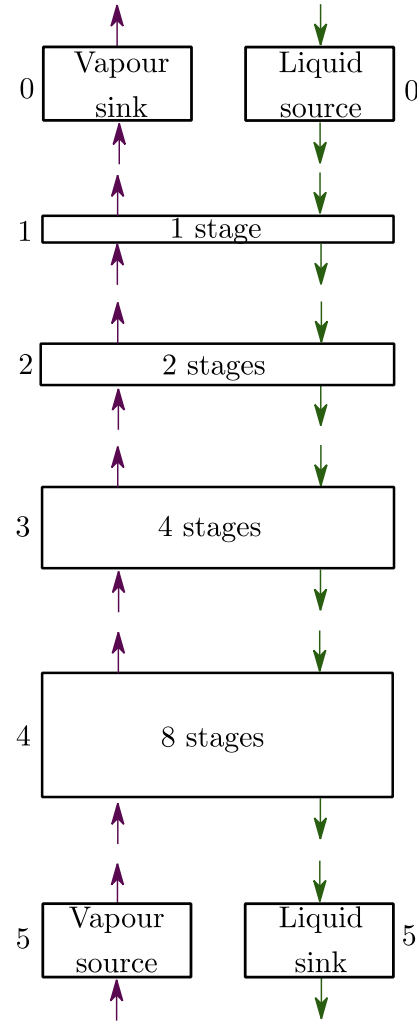

$$f_o^{\text{out},V} = \sum_{i \in \mathcal{S}_o^V} f_{o,i} \quad (4)$$

$$T_o^{\text{out},V} = T_{o,i}^V \quad \forall i \in \mathcal{S}_o^V \quad (5)$$

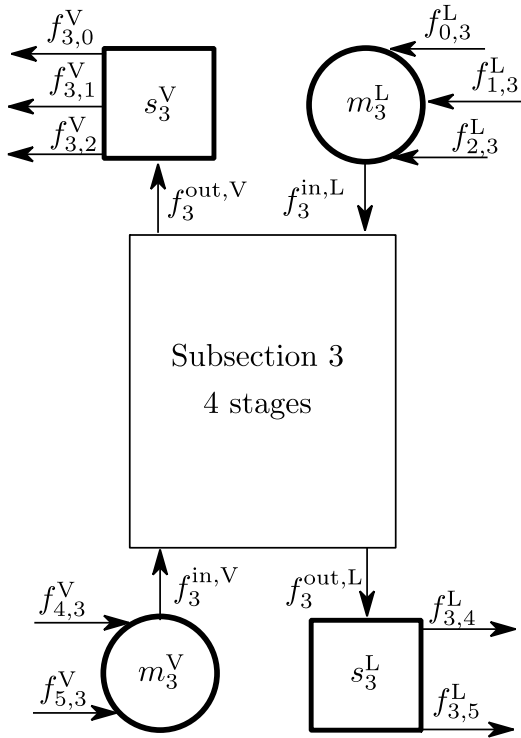

$$\mathbf{q}_o^{\text{out},V} = \mathbf{q}_{o,i}^V \quad \forall i \in \mathcal{S}_o^V \quad (6)$$

where  $\mathcal{S}_o^V$  denotes all the mixers that splitter  $o$  may be connected to. Analogous relationships may be written for the liquid mixers and splitters.

Note that the mixers and splitter alone cannot guarantee flow in the desired direction between two units at different pressures, and thus, limit the SON to the synthesis of isobaric flowsheets.

**Figure 1:** Schematic of the vapour source, liquid source, vapour sink, liquid sink, and the 4 column subsections with 1, 2, 4 and 8 stages in a column superstructure with at most 15 stages. The vapour and liquid sources and sinks have one inlet and outlet each. Each column subsection has one vapour inlet, one liquid inlet, one vapour outlet and one liquid outlet. Process units in the superstructure are labelled by numbers.

**Figure 2:** Detailed schematic of subsection 3 with 4 stages from Figure 1. The vapour mixer  $m_3^V$  allows the mixing of vapour streams that flow from subsection 4 and the vapour source. The liquid mixer  $m_3^L$  allows the mixing of vapour streams that flow from the liquid source, subsection 1 and subsection 2. The vapour splitter  $s_3^V$  allows the vapour that leaves subsection 3 to go to mixers at the inlets of subsections 1 and 2 and the vapour sink. The liquid splitter  $s_3^L$  allows the liquid that leaves subsection 3 to go to mixers at the inlets of subsection 4 and the liquid sink.

### Flow-validity constraints

Flow validity constraints ensure that the flows to a column subsection that is deselected,  $z_i = 0$ , are zero. Further constraints, given in [6], ensure that the flows do not bypass selected subsection.

### Process unit-level constraints

Each process unit (the sources, the sinks and the conditional subsections) is represented in the column superstructure via its rigorous model, which is referred to as process unit-level constraints here. Each source and sink may be represented by simple constraints that equate the state at the inlet to that at the outlet. Each column subsection is represented by a rigorous model for each of the equilibrium stages in the subsection. This includes the MESH equations. As the pressure drop is assumed to be zero, the pressure at the vapour and liquid outlets of each stage (and subsection  $i$  where  $i \in \mathcal{R}$ ) is set equal to the pressure at the inlet. Thus,

$$P_i^{\text{out},V} = P_i^{\text{out},L} \quad (7)$$

$$P_i^{\text{out},V} = P_i^{\text{in},V} \quad (8)$$

$$P_i^{\text{in},V} = P \quad (9)$$

For each subsection, we compute variables  $\widehat{\rho}_i^L$ ,  $\widehat{\rho}_i^V$  and  $\widehat{v}_i^V$ :

$$\widehat{\rho}_i^L = \sum_{j \in \mathcal{Z}^{i-1}} \rho_j^L \quad (10)$$

$$\widehat{\rho}_i^V = \sum_{j \in \mathcal{Z}^{i-1}} \rho_j^V \quad (11)$$

$$\widehat{v}_i^V = \sum_{j \in \mathcal{Z}^{i-1}} v_j^V \quad (12)$$

Where  $\rho_j^L$ ,  $\rho_j^V$  and  $v_j^V$  are the mass density of the liquid stream that exits stage  $j$ , the mass density of the vapour stream that exits stage  $j$  and volumetric flowrate of the vapour stream that exits stage  $j$ , respectively.

### Column-level constraints

We use column-level equations (also known as flowsheet-level equations in [6]) to compute the total dimensions and cost of the column. Some of these flowsheet-level constraints may depend on a few “output variables” whose values are obtained by solving the process unit-level constraints.  $D$ , the diameter of the column and  $H$ , its height, are computed using [15]:

$$N = \sum_{i \in \mathcal{R}} 2^{i-1} z_i \quad (13)$$

$$\overline{\rho}^L = \frac{\sum_{i \in \mathcal{R}} \widehat{\rho}_i^L}{N} \quad (14)$$

$$\overline{\rho}^V = \frac{\sum_{i \in \mathcal{R}} \widehat{\rho}_i^V}{N} \quad (15)$$

$$\overline{v}^V = \frac{\sum_{i \in \mathcal{R}} \widehat{v}_i^V}{N} \quad (16)$$

$$u^{\text{flood}} = (-0.1711t^2 + 0.271t - 0.047) \sqrt{\frac{\overline{\rho}^L - \overline{\rho}^V}{\overline{\rho}^V}} \quad (17)$$

$$D = \sqrt{\frac{4\overline{v}^V}{\pi u^{\text{flood}}}} \quad (18)$$

$$H = 1.15 \frac{lt}{E} N \quad (19)$$

where  $lt$  and  $E$  are the tray spacing and stage efficiency, respectively. We also introduce flowsheet-level constraints to compute the total capital investment ( $TCI$ ), the annual operating expenses ( $OPEX$ ) and the total annualized cost ( $TAC$ ) using costing correlations [6,16]. We also impose constraints on the minimum purity and flowrate of the vapour stream that exits the flowsheet.

### Numerical singularities

When a column subsection is deselected, all flows into the unit are driven to zero by the flow-validity constraints. Due to this, within each column subsection, a solution to the phase equilibrium equations at each stage does not exist. The mass-balance equations are also

rank-deficient. Sizing, costing or even mass transfer correlation that depends on the flowrates associated with a deselected stage can become singular (that is, the function or derivative may be numerically undefined).

## MSON

To overcome numerical singularities for any deselected process unit, we have developed the MSON formulation [6], which relies on the modification of mixers and splitters associated with the conditional subsections. The mixers and splitters associated with the sources and sinks remain unchanged and the pressure of all column subsections is a constant and fixed *a priori*.

### Modified mixer

We introduce a fictitious stream into each modified vapour mixer  $i$  (associated with column subsection  $i \in \mathcal{R}$ ) with mass flowrate  $f_i^{M,V}$ , composition  $\mathbf{q}_i^{A,V}$  and temperature  $T_i^{A,V}$ , as shown in Figure 3. Due to Equations (20) – (22), the flowrate, composition and temperature at the inlet of subsection  $i$  are  $f_i^{M,V}$ ,  $\mathbf{q}_i^{A,V}$  and  $T_i^{A,V}$ , respectively, when subsection  $i$  is deselected and all other flows into the mixer are zero. Further, due to Equation (23),  $f_i^{M,V}$  takes the constant value  $f_i^{A,V}$  when the conditional subsection is deselected and takes the value zero otherwise. Due to this, when the subsection is selected, the modified mixer equations are fully equivalent to a standard mixer. Analogous relationships are written for the modified liquid mixers.

$$f_i^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V + f_i^{M,V} \quad (20)$$

$$f_i^{\text{in},V} \mathbf{q}_{i,c}^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V \mathbf{q}_{o,i,c}^V + f_i^{M,V} \mathbf{q}_{i,c}^A \forall c \in \{1, \dots, K\} \quad (21)$$

$$f_i^{\text{in},V} h_{en}^V(T_i^{\text{in},V}, P, \mathbf{q}_i^{\text{in},V}) = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V h_{en}^V(T_{o,i}^V, P, \mathbf{q}_{o,i}^V) + f_i^{M,V} h_{en}^V(T_i^{A,V}, P, \mathbf{q}_i^{A,V}) \quad (22)$$

$$f_i^{M,V} = f_i^{A,V} (1 - z_i) \quad (23)$$

$f_i^{A,V}$ ,  $\mathbf{q}_i^{A,V}$  and  $T_i^{A,V}$  and the corresponding constants for the modified liquid mixer are chosen such that the two fictitious streams are in vapour-liquid equilibrium at pressure  $P$ . When a column subsection is not selected, thanks to the fictitious streams that enter via the modified vapour and liquid mixers, a two-phase solution exists in each stage. Thus, no singularities are encountered in the MESH equations and sizing correlations that describe the subsection.

### Modified splitter

We modify the splitters associated with the conditional column subsections as shown in Figure 4. With the modified splitters we can correct for the fictitious non-

zero flows at the outlets of deselected process units caused due to fictitious mixer streams. We describe each modified vapour splitter  $o$ , (associated with column subsection  $o \in \mathcal{R}$ ) using Equations (5) and (6) and,

$$f_o^{\text{out},V} = \sum_{i \in \mathcal{S}_o^V} f_{o,i} + f_o^{S,V} \quad (24)$$

$$0 \leq f_o^{\text{out},V} - f_o^{S,V} \leq f^U z_o \quad (25)$$

$$0 \leq f_o^{S,V} \leq f^U (1 - z_o) \quad (26)$$

where  $f^U$  is an upper bound on the flowrates.

Equations (24)-(26), ensure that when the subsection is deselected, any vapour that leaves the subsection (due to the fictitious flows in the modified mixers) leaves the splitter  $o$  via a fictitious stream with flowrate  $f_o^{S,V}$ , composition  $\mathbf{q}_o^{\text{out},V}$  and temperature  $T_o^{\text{out},V}$  and is not propagated to the rest of the flowsheet. On the other hand, when the subsection is selected, the fictitious stream is constrained to have a zero flowrate, and hence has no effect on the rest of the flowsheet. As before, the composition and temperature of the streams that leave the splitters are set equal to that at the inlet of the splitter. A vapour splitter and a modified vapour splitter are shown in Figure 4. The modified liquid splitter is analogous.

**Figure 3:** A vapour mixer (denoted by an open circle) at inlet  $i$  and a modified vapour mixer (denoted by a shaded circle) at inlet  $i$ .

### Modified output variables

As a result of the fictitious flows into a deselected unit, several of the variables associated with the unit may take a spurious non-zero value. However, only a small subset of these variables, the output variables, is used in column-level computations. We introduce a “corrected output variable”  $x_j^S$  for any output variable  $x_j$  and enforce the following Big-M constraints:

$$-M(1 - z_i) \leq x_j - x_j^S \leq M(1 - z_i) \quad (27)$$

$$-Mz_i \leq x_j^S \leq Mz_i. \quad (28)$$

We further modify the column-level constraints that

depend on an output variable  $x_j$  to depend on the corrected output variable  $x_j^S$ . In the case of column synthesis, we reformulate constraints (10)-(12) in terms of these corrected output variables to obtain:

$$\overline{\rho^L} = \frac{\sum_{i \in \mathcal{R}} \rho_i^L S}{N} \quad (29)$$

$$\overline{\rho^V} = \frac{\sum_{i \in \mathcal{R}} \rho_i^V S}{N} \quad (30)$$

$$\overline{v^V} = \frac{\sum_{i \in \mathcal{R}} v_i^V S}{N} \quad (31)$$

### Process unit-level constraints

The process unit-level constraints and all column-level constraints that do not depend on any of the output variables are unchanged. Numerical singularities by the use of the MSON are entirely averted as shown in [6].

**Figure 4:** A vapour splitter (denoted by an open square) at outlet  $o$  and a modified vapour splitter (denoted by a shaded square) at outlet  $o$ . A fictitious stream (denoted by the dashed arrow) with flowrate  $f_o^{S,V}$  leaves the modified splitter.

### EXTENDED MSON (E-MSON)

In the derivation of the SON and MSON we assume that the pressure at the inlet of any unit (that is, the outlet of any mixer) is fixed at  $P$ . The operating pressure of any column subsection is also fixed at  $P$ , thanks to Equations (7)-(9). Further, we introduce fictitious streams in the modified mixers with states such so that when the unit is deselected, a two-phase solution is guaranteed for a column subsection at pressure  $P$ . However, if the deselected subsection is at any other pressure, the states of the fictitious stream may not necessarily result in a two-phase solution. Indeed, for any general process unit, the state of the fictitious stream in the mixer may not lead to the successful solution of the unit constraints when the operating pressure varies.

To overcome this limitation we first add the following constraint to each vapour splitter as well as each

modified vapour splitter  $o$  in the superstructure:

$$P_{o,i}^V = P_o^{\text{out},V} \quad \forall i \in \mathcal{S}_o^V \quad (32)$$

where  $P_{o,i}^V$  is the pressure of a vapour stream that flows from splitter  $o$  to mixer  $i$ . Analogous constraints are added to the liquid splitters.

We also modify the mixers in the flowsheet. The ‘‘mixing’’ of two streams that arise from two process units at unequal pressures may physically result in unintended flows, e.g., mass flows from the high-pressure unit into the low-pressure unit. Thus, in the extended MSON, only the mixing of streams that are at equal pressures is allowed. We note that this mixing rule is trivially satisfied for the column synthesis problem studied here (as all streams are at  $P$ ). The following pressure-mixing equation is introduced into the model of each vapour mixer  $i$  to describe the pressure at each vapour inlet:

$$f_i^{\text{in},V} P_i^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V P_{o,i}^V \quad (33)$$

Due to the pressure-mixing constraint, the pressure at the inlet  $i$  is equal to that of stream(s) with strictly positive mass flowrates into unit  $i$ . The enthalpy balance for each mixer is modified to incorporate the pressure of each stream, yielding:

$$f_i^{\text{in},V} h_{en}^V(T_i^{\text{in},V}, P_i^{\text{in},V}, \mathbf{q}_i^{\text{in},V}) = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V h_{en}^V(T_{o,i}^V, P_{o,i}^V, \mathbf{q}_{o,i}^V) \quad (34)$$

A similar pressure-mixing equation is introduced into the modified vapour and liquid mixers. The pressure of the fictitious vapour and liquid streams in the modified mixer  $i$  is denoted by  $P_i^A$ .

$$f_i^{\text{in},V} P_i^{\text{in},V} = \sum_{o \in \mathcal{M}_i^V} f_{o,i}^V P_{o,i}^V + f_i^{\text{M},V} P_i^A \quad (35)$$

Due to Equation (35), the pressure at the inlet  $i$  is equal to that of stream(s) with strictly positive mass flows into unit  $i$ . When the unit  $i$  is deselected, the pressure at the inlet takes the value  $P_i^A$  that leads to successful evaluation of the process unit-level constraints that describe  $i$ . The enthalpy balance in modified mixers is also adapted, in an analogous matter to Equation (34).

The E-MSON only requires the modification to mixers and splitters. All process unit-level constraints and column-level constraints are the same as the MSON. The E-MSON can be used to model a process unit with variable pressure and ensures successful solution when the unit is deselected, irrespective of its operating pressure. Further, the extended mixers and splitters are also necessary to allow the E-MSON to be applied to the synthesis of flowsheets in which the unit operations are at different pressures. However, to fully address the latter case for a general flowsheet, additional logical constraints as well as compressors and expanders are needed and we leave this for future work.

## IMPLEMENTATION

The E-MSON problem formulation is a mixed-integer nonlinear programming problem (MINLP) that is solved using the outer approximation equality relaxation augmented penalty (OA-ER-AP) algorithm [17] that we have implemented in C++ [6]. All constraints of the primal problem are implemented and solved in gPROMS Model-Builder 7.0.7 [18]. Each stage in the column is modelled as an equilibrium stage and all thermodynamic properties are computed using the SAFT- $\gamma$  Mie equation of state [19,20]. The master problem is solved using Gurobi 10.0.2 [21] via its C++ application programming interface (API).

## CASE STUDY DESCRIPTION

We consider the synthesis of a gas-liquid absorption column with at most 15 theoretical stages. The column must recover methane from a carbon dioxide and methane stream, by physical absorption at high pressure. Given a feed of carbon dioxide and methane at flowrate  $1 \text{ kmol s}^{-1}$ , 298 K and pressure  $P$  with 20%  $\text{CO}_2$  and tetra(oxyethylene)dimethylether ( $\text{CH}_3\text{O}(\text{CH}_2\text{O})_4\text{CH}_3$ ) as a solvent at 298 K and pressure  $P$ , find the optimal theoretical number of stages  $N$ , flowrate of fresh solvent  $F$  as well as column pressure  $P$  such that the treated gas has a flowrate of at least  $0.66 \text{ kmol s}^{-1}$  and is at least 97% methane and the total annualized cost  $TAC$  is minimized. The  $TAC$  depends on the total capital investment  $TCI$  and the annual operating expenses  $OPEX$ . We assume  $E$  is 0.8,  $lt$  is 0.6m, the cost of capital is 15%, the column lifetime is 10 years and that  $2 \text{ MPa} \leq P \leq 7.5 \text{ MPa}$ . Details of the model can be found in [6, 16].

## RESULTS

The superstructure for the column to be designed has 4 conditional subsections with 1, 2, 4 and 8 equilibrium stages, respectively. The results of the case study are summarised in Table 1. The optimal column has 4 theoretical stages, obtained by selecting only subsection 3. The OA-ER-AP algorithm converges to a solution in 8 major iterations, 5 of which are found to be feasible. With the E-MSON, the primal problems are solved robustly, no singularities are detected, and a solution is obtained for the equations of the deselected subsections, despite the variation of the column pressure in the course of optimization. The primal problem in the E-MSON has 910 equality constraints (excluding the equations corresponding to SAFT- $\gamma$  Mie), 87 inequality constraints and 49 degrees of freedom to be optimized (including fictitious flowrates in the modified mixers and splitters). The runtime (wall clock time) of the primal problem solution is 65 s on average with the standard deviation of 22 s. Across the five feasible iterations, the

primal problems take 72.2 s to converge to a solution, with the standard deviation of 14.5 s.

**Table 1:** Results of the E-MSON for the synthesis of a counter-current carbon-capture column. The first row shows the results for the variable-pressure case with the use of the E-MSON. The second row shows the results of the same case study in the fixed-pressure case with the use of the MSON where all streams and the column are at an *a priori* fixed pressure of 7.5 MPa.  $F$  is in  $\text{kmol/s}$ ,  $P$  is in MPa and  $TAC$ ,  $TCI$  and  $OPEX$  are in Million USD.

Case	$P$	$F$	$N$	$TAC$	$TCI$	$OPEX$
E-MSON	2.6	1.9	4	0.37	0.58	0.26
MSON	7.5	0.6	6	0.59	1.37	0.32

We compare the results of the E-MSON with that of the MSON in which the column pressure and that of the feed and pure solvent are arbitrarily fixed at 7.5 MPa. The *a priori* fixed-pressure column has a minimum  $TAC$  that is 59% higher than the column in which pressure has been optimized, a  $TCI$  that is 136% higher and 2 more equilibrium stages. In the fixed pressure case, a column with 4 stages was found to be infeasible. The 6-stage column at 7.5 MPa has a 34% higher  $TAC$  than a 6-stage column at the optimal pressure of 2.6 MPa. The pressure heavily impacts the relative solubilities of  $\text{CO}_2$  and  $\text{CH}_4$ , product recovery, product quality and the capital cost of the absorber. The comparison across the two cases highlights the importance of making the pressure an additional degree of freedom in separation column synthesis both for the study of specific separation solvents as well as for solvent design. As we only use local optimization algorithms, the inferior performance of the fixed-pressure column could also be due to convergence of the MSON to low-quality local minima. However, to assuage discrepancies across formulations, we used the same initial guesses, solvers and solver parameters in both cases.

In our future work we shall extend the design envelope to also consider i) the compression/expansion of the feed, ii) the solvent regeneration and recycle and iii) the cost of make-up solvent.

## CONCLUSION

In this paper, we extended the state operator network paradigm of superstructure optimization that was previously implicitly limited to the synthesis of isobaric flowsheets. We built upon the recently-developed MSON that guarantees convergence of deselected units, thus, making the MSON robust and amenable to high-fidelity simulation-based optimization. We developed E-MSON, the extended MSON which retains the robustness of the MSON while making it applicable to the synthesis of columns as well as isobaric flowsheets in which the operating pressure is a variable.

By introducing pressure as an additional degree of freedom in absorption column synthesis, we found in our case study that overall costs decreased by 37%. The extended-MSON is a first step towards fully general superstructure optimization within the SON paradigm in which all unit operations are at variable pressures. The results of the paper indicate that modelling the effects of pressure rigorously can lead to superior designs. Furthermore this work expands the applicability of the state operator network to superstructure optimization problems with rigorous process models.

## ABSTRACT

Optimization-based process design is a central task of process systems engineering. However, solely relying on steady-state models may potentially lead to dynamic constraint violations, hinder robust performance, or simply reduce the controllability of a process. This has led to the consideration of process dynamics in the design phase, which is commonly termed integration of design and operation / control. Recently, we proposed a framework to carry out this integrative task by formulating a large-scale nonlinear programming problem that is solved simultaneously. To this end, the dynamic process model was discretized, and dynamic variability and parametric uncertainty were included. However, the proposed framework only operates on constant lengths of the finite elements. The discretization error was not assessed. Within this contribution, a method for quantifying this discretization error and adapting the number of finite elements accordingly is incorporated into the recently proposed framework and applied on the case study of a continuous tank reactor. The obtained results with and without discretization error control are compared and, based thereon, a more suitable way to apply the control variables on the process is proposed.

**Keywords:** Integration of design and operation, Process design, Grid refinement, Nonlinear programming

## INTRODUCTION

Process design is a central task of process systems engineering. This is conventionally achieved by using flowsheet simulators or other software to determine a suitable flowsheet. Based on this flowsheet, the process is designed using methods such as sensitivity analysis. A possible alternative is optimization-based process design in which the whole flowsheet is optimized for a given objective function. Both approaches typically rely on assumptions of stationarity. However, simply relying on steady-state models may potentially lead to dynamic constraint violations, hinder robust performance, or simply reduce the controllability of a process [1]. This has led to the consideration of process dynamics in the design, which is commonly termed integration of design and operation / control (IDO). Among the approaches to solving IDO problems is the dynamic optimization approach, which assesses the problem using rigorous dynamic models, and the robust approach, which ensures that no constraint violations occur at any point in time. For more information on the possible approaches to solving IDO

problems, the reader is referred to the literature [1,2]. In recent years, we have proposed a framework for the solution of IDO problems, which can be seen as a hybrid of the dynamic optimization approach and the robust approach. The concept is based on a full discretization of the dynamic problem via orthogonal collocation, which yields a large-scale nonlinear programming problem [3]. The framework was then extended to account for parametric uncertainty [4] and to a larger case study [5]. Note that we limit ourselves to deterministic solutions in this contribution. The extension to optimization under uncertainty is, however, straightforward.

So far, the proposed framework has considered a constant number and length for the finite elements in the discretized dynamic model, which may potentially introduce notable discretization errors. Therefore, this contribution addresses this drawback by adding a method for quantifying and controlling the integration error. The extended framework is applied on a case study containing a continuously stirred tank reactor (CSTR) for which previous results are available so that the former and the new approach can be compared fairly.

## STATUS QUO OF THE IDO FRAMEWORK

The current formulation of the IDO problem reads as follows [6]:

$$\min_{d, u_{cp,fe,sp}} \mathbb{E} [f(d, u_{cp,fe,sp}, x_{cp,fe,sp}, \xi_{sp}, v_{cp,fe})] \quad (1)$$

s.t.

$$0 = g(d, u_{cp,fe,sp}, x_{cp,fe,sp}, \xi_{sp}, v_{cp,fe}) \quad (2)$$

$$0 \leq h(d, u_{cp,fe,sp}, x_{cp,fe,sp}, \xi_{sp}, v_{cp,fe}) \quad (3)$$

$$0 = h_0(d, u_{0,sp}, x_{0,sp}, \xi_{sp}, v_0, t_0 = 0) \quad (4)$$

$$0 = h_t(d, u_{t,sp}, x_{t,sp}, \xi_{sp}, v_t, t_t) \quad (5)$$

$$d \in \mathcal{D} \quad (6)$$

$$u_{cp,fe,sp} \in \mathcal{U} \quad (7)$$

$$x_{cp,fe,sp} \in \mathcal{X} \quad (8)$$

$$v_{cp,fe} \in \text{APRBS} \quad (9)$$

$$v_{cp,fe} \sim \mathcal{N}(\mu, \Sigma) \quad (10)$$

Therein, the expected value of the objective function is minimized by varying the design  $d$  and the control variables  $u$  at all collocation roots  $cp$ , every finite element  $fe$ , and for all sigma points of the uncertainty space  $sp$ . The constraints include the dynamic process model  $g$ , path constraints, initial and terminal constraints  $h_0$  and  $h_t$ . The variability of dynamic inputs is represented by an amplitude-modulated pseudo-random binary sequence (APRBS) [7] with normally distributed amplitude whereas the uncertain parameters  $\xi$  and the resulting probability density function of the uncertain inequality constraints, i.e., chance constraints, are represented by a point estimation method, e.g., a cubature rule. All design, state, and control variables are defined on their respective domain. The problem is solved simultaneously as large-scale nonlinear problem in Python, which is interfaced with the model formulation in AMPL [8] and the optimization algorithm IPOPT [9] via AmplPy.

## METHODOLOGY

We now describe the theoretical basis of the error calculation. Afterwards, the solution of the optimization problem is sketched, including the initialization of the new variables that appear due to the increasing number of finite elements. Afterwards, the case study in this contribution is outlined.

### Error calculation

There are several options to assess the discretization error. In many situations, one can compare the error between a highly resolved solution and the solution obtained with the current mesh grid to find an appropriate

number of finite elements [10,11]. While this might be suitable for the solution of a standard boundary value problem, the additional challenge of this work are the relatively long time horizons and the additional degrees of freedom in terms of the design variables of the process. As a results, the highly resolved solution might require significant computational effort and careful initialization. To avoid that, we chose an error estimation that does not compare the difference between two solutions, but the residual between the left-hand and the right-hand side of the differential equations. This estimation of the discretization error is based on the work by Chen et al. [12,13]. In their first publication, they formulated the search for an appropriate number and length of the finite elements as a bilevel optimization problem. As they pointed out, this entails significant computational demand [12]. Hence, they proposed in their subsequent publication to estimate the discretization error by evaluating the residual of the orthogonal collocation  $T_{fe}$  [13]:

$$T_{i,fe} = \frac{dx_i}{dt}(t_{fe,nc}) - \Delta t_{fe} f(x, u, d, t_{fe,nc}). \quad (11)$$

Therein, the residual for the  $i$ -th state variable is evaluated at one (or several) non-collocation points (subscript  $nc$ ), i.e., points different from the used Radau roots. In their approach, Chen et al. also included the residuals of the algebraic equations. Here, we limit ourselves to the differential equations of the model although the extension to algebraic equations is straightforward. Based on the residual, the discretization error is estimated as:

$$err_{i,fe} = C \|T_{i,fe}\|. \quad (12)$$

The constant  $C$  is given by the following integral:

$$C = \frac{1}{A} \int_0^{\tau_{fe,nc}} \prod_{j=1}^K (s - \tau_j) ds, \quad A = \prod_{j=1}^K (\tau_{fe,nc} - \tau_j) \quad (13)$$

This constant only depends on the choice of the non-collocation point(s) and the type of collocation points (in this case Radau) and can thus be calculated once at the beginning. The discretization error must be smaller than a user-defined tolerance:

$$err_{i,fe} \leq \text{tol}_i \quad (14)$$

A similar scheme was recently proposed in [14].

### Solution

The algorithmic approach of this contribution is as follows: First, the optimization problem above is initialized, e.g., via a steady-state optimization. Afterwards, the dynamic system is added, and dynamic variability of the inputs is introduced. Then, the optimization problem is solved by minimizing the objective using a nonlinear optimization algorithm, in this case IPOPT [9]. Based on the obtained results, the discretization error is calculated as described in Equations (12) and (13). If the error within one finite element is larger than the tolerance, the

respective finite element is split into two. These two finite elements are now initialized based on the current solution. This could be done via simple linear interpolation, but as we use collocation, the new initial guesses are calculated by evaluating the Lagrange interpolation polynomial, i.e., the sum of the Lagrangian basis polynomials of the collocation, at the new collocation points. This is repeated for all finite elements. Both approaches to initialize the finite elements have their advantages and disadvantages. For the simple case study below, both would probably work equally well. Finally, the optimization problem is solved again and the error calculation is repeated. This step continues until all errors of the finite elements are smaller than the set tolerance.

## Case study

The case study is a CSTR as shown in Figure 1. Component A enters the reactor via the volume flow  $q_F$  and reacts to B. The volume flow  $q$  then leaves the system with concentration  $c_A$  and temperature  $T$ . The feed flow and the feed temperature are assumed as variable, dynamic inputs. The cooling duty  $Q_C$  can be manipulated with cooling water whose stream is change via the valve position  $VP_1$ . The outlet flow can be manipulated using valve position  $VP_2$ .

**Figure 1.** Flowsheet of the CSTR in this case study [6].

For the process model, the following three assumptions are made [6]:

1. Density and heat capacity of the flows are constant and thus independent of temperature, pressure, or composition.
2. The liquid phase in the reactor is ideally mixed.
3. The pressure remains constant during operation.

This results in the following mass, component, and energy balances:

$$\frac{dV_{\text{CSTR}}^L}{dt} = q_F - q \quad (15)$$

$$\frac{dc_A}{dt} = \frac{q_F}{V_{\text{CSTR}}^L} (c_{A,F} - c_A) - k_0 \exp\left(-\frac{E}{RT}\right) c_A \quad (16)$$

$$\frac{dT}{dt} = \frac{q_F}{V_{\text{CSTR}}^L} (T_F - T) + k_0 \exp\left(-\frac{E}{RT}\right) c_A (-\Delta_R h) - \frac{\dot{Q}_C}{\rho c_p V_{\text{CSTR}}^L} \quad (17)$$

Therein,  $k_0$  and  $E$  are the pre-exponential factor and the activation energy of the reaction, respectively,  $\Delta_R h$  is the enthalpy of reaction,  $\rho$  is the density, and  $c_p$  is the heat capacity. Moreover, the cooling duty is a function of  $VP_1$ , whereas the liquid outlet depends on the liquid volume within the reactor and  $VP_2$ . The operating costs depend on the outgoing mole flow of component A, the investments costs depend on the diameter and the height of the CSTR. The objective function is the sum of both costs. The control variables can be changed from one collocation point to another. However, this change is bounded:

$$\|u(t_i) - u(t_{i+1})\| \leq \Delta u_{\text{max}} \quad (15)$$

The maximum change of  $u$  is specified by the user. We call this control formulation 1. For the temperature, an upper bound of 480 K is specified. Not violating this upper bound must be ensured by the process design in combination with the allowable range of the control variables. More details on the equations and the specifications for mean and standard deviation of the dynamic variability of feed flow and feed temperature can be found in [6].

For the results shown below, 0.5 was chosen as non-collocation point based on the work by Chen et al. [13], and a tolerance of 0.1 was specified for the discretization error. This value will be critically discussed at the end of the following section.

## RESULTS AND DISCUSSION

The proposed optimization problem in combination with the method for quantifying the discretization error was solved for the presented case study. The obtained dynamic profiles are shown in Figure 2 (top). It can be observed that the temperature (black continuous line) is very close to but below the upper bound, meaning the IDO problem was solved successfully. In blue, the variation of the feed temperature is shown as a result of the APRBS. Lastly, the gray curve visualizes the change of the control variable  $VP_1$ . For comparison, the obtained temperature profile with fixed number and length of finite elements is shown [6]. We frequently observe situations in which the temperature lies below the upper bound (where conversion is the largest) to ensure that the process can be sufficiently cooled.

Figure 2 (bottom) shows, however, the negative impact of the refined discretization scheme. As more and more very small finite elements appear, these elements

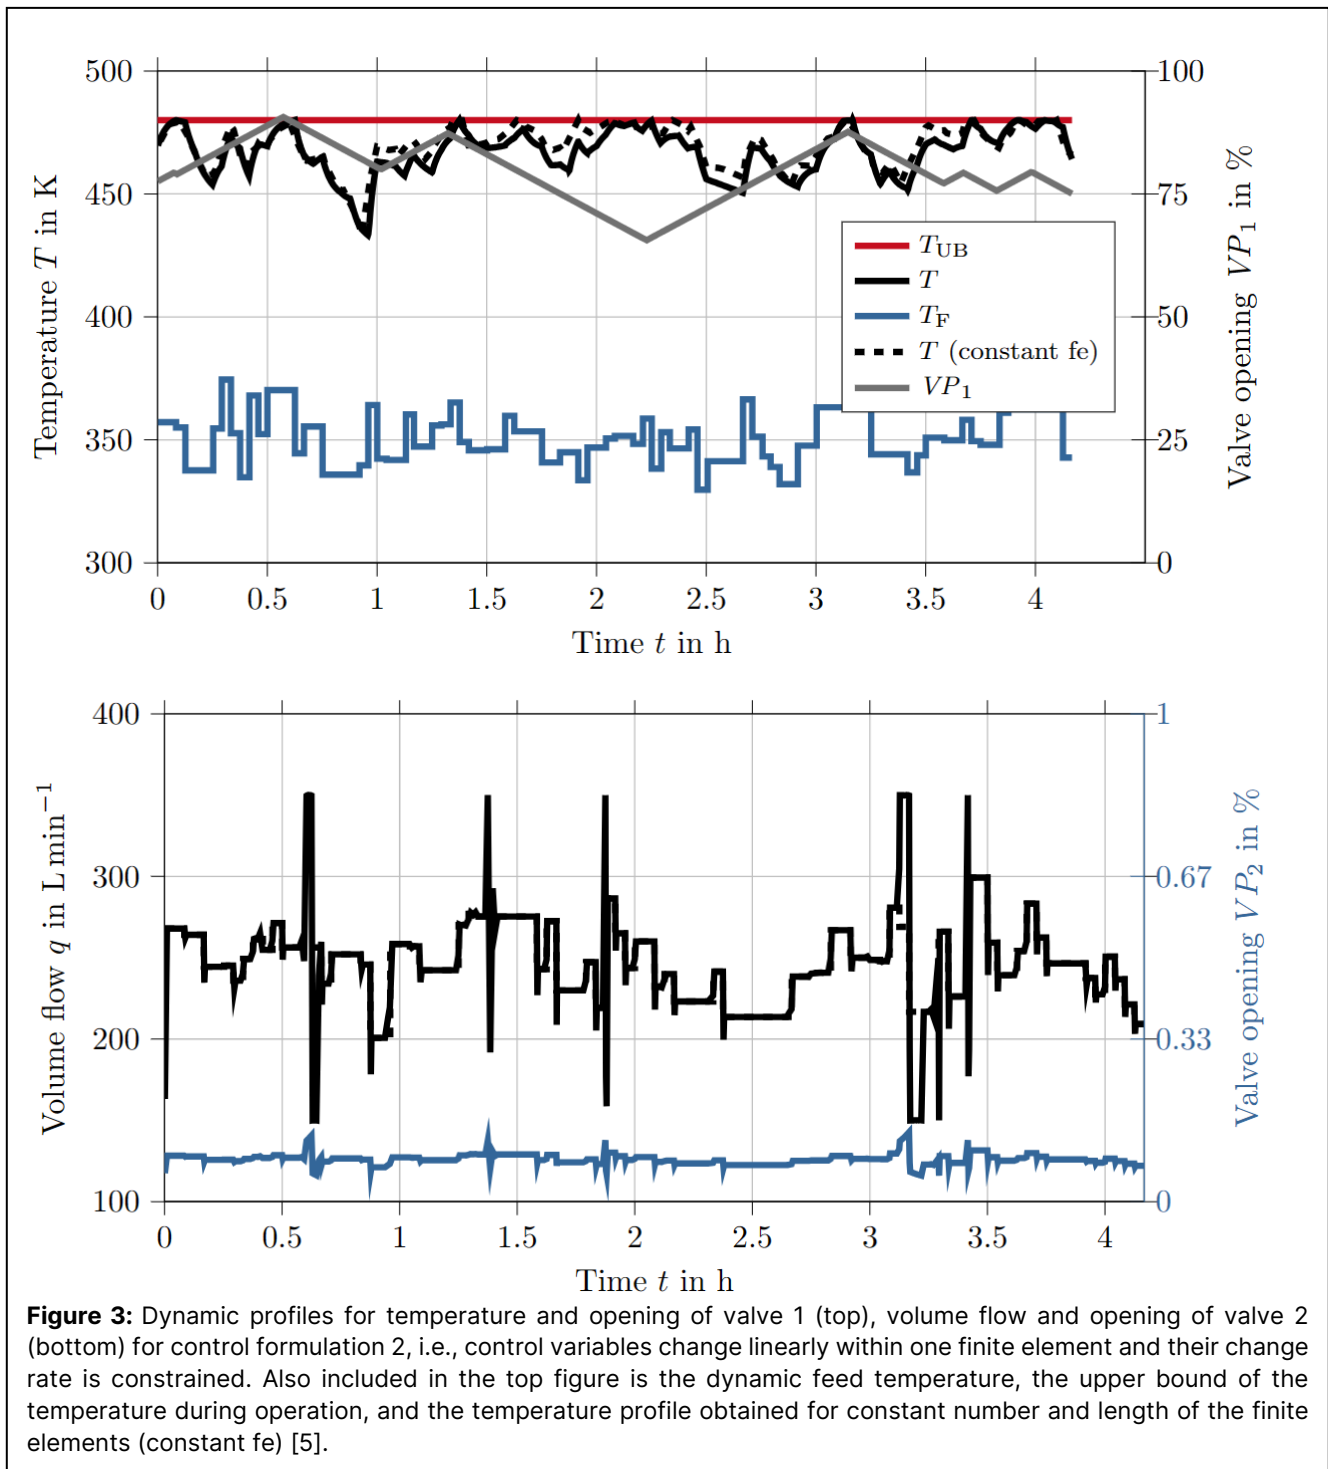

**Figure 2:** Dynamic profiles for temperature and opening of valve 1 (top), volume flow and opening of valve 2 (bottom) for control formulation 1, i.e., control variables change between collocation points and can change by a certain range. Also included in the top figure is the dynamic feed temperature, the upper bound of the temperature during operation, and the temperature profile obtained for constant number and length of the finite elements [6].

allow the same control changes as longer elements. This results in very undesirable bang-bang solutions for the volume flow from the reactor, which would be deemed unrealistic (at best) or would render the process inoperable in practice. As a result of these observations, an alternative formulation had to be found that allowed a varying length of finite elements but also a generically applicable bound on the control changes. For this reason, control formulation 2 is proposed:

$$\frac{du_{i,fe}}{dt} = u_{\text{ramp},i,fe} \text{ with } \|u_{\text{ramp},i,fe}\| \leq u_{\text{ramp,max},i} \quad (18)$$

This means that the control variables are linear functions in each finite element. In addition, the control profiles must be continuous, i.e., the endpoint of control  $i$  in finite element  $fe$  is equal to the starting point of control  $i$  in finite element  $fe+1$ . For this control formulation, the IDO

problem was solved again. The results are shown in Figure 3. The temperature profile is now much closer to the original solution with fixed number and length of the finite elements. The difference is, of course, that the number of finite elements is now much higher (here: 451 instead of 50) and that the profiles of the control variables are linear function in every finite element. In consequence, the IDO problem is successfully solved as well, but does

not show the bang-bang solutions of control formulation 1 (Figure 3, bottom). We conclude that the approach of linearizing the control profiles is suitable in the context of this contribution in which the process design can change to make the process resilient with respect to sudden changes in inputs, such as feed flows. We would necessarily recommend this approach for other applications, such as parameter estimation.

**Table 1:** Design specifications and cost functions for steady-state solution, dynamic solution with fixed number and length of finite elements ("previous solution", taken from [6]), and dynamic solutions with control formulation 1 and 2. The investment costs are given as annuity.

Variable	Unit	Steady-state solution [6]	Previous solution [6]	Control formulation 1	Control formulation 2
$V_{CSTR}$	$m^3$	$4.58 \cdot 10^{-1}$	$7.31 \cdot 10^{-1}$	$4.86 \cdot 10^{-1}$	$8.10 \cdot 10^{-1}$
$d_{CSTR}$	m	$5.26 \cdot 10^{-1}$	$6.15 \cdot 10^{-1}$	$5.37 \cdot 10^{-1}$	$6.37 \cdot 10^{-1}$
$L_{CSTR}$	m	$2.11 \cdot 10^0$	$2.46 \cdot 10^0$	$2.15 \cdot 10^0$	$2.55 \cdot 10^0$
$C_{inv}$	$\$ y^{-1}$	$2.21 \cdot 10^{+2}$	$4.70 \cdot 10^{+2}$	$3.65 \cdot 10^{+2}$	$5.01 \cdot 10^{+2}$
$C_{op}$	$\$ y^{-1}$	$3.51 \cdot 10^{+2}$	$2.29 \cdot 10^{+2}$	$2.17 \cdot 10^{+2}$	$2.38 \cdot 10^{+2}$
$f$	$\$ y^{-1}$	$5.72 \cdot 10^{+2}$	$6.99 \cdot 10^{+2}$	$5.82 \cdot 10^{+2}$	$7.39 \cdot 10^{+2}$

It should be noted here that the approach might benefit from techniques to combine finite elements again where the discretization error is significantly below the set tolerance as, for example, described by Liu et al. [11], to keep the computational effort as low as possible. However, repeatedly adding and removing finite elements could potentially slow down convergence of the overall design problem, which is why this has not yet been implemented.

Table 1 compares the design results of our previous study [6] and the results of this work. The smallest reactor volume is still found for the steady-state case as this solution does not have to account for dynamic variability. The solution obtained for control formulation 1 results in a smaller reactor volume (and a smaller objective function) as the short-finite elements provide much more flexibility of the control variables at the cost of bang-band solutions. Control formulation 2 results in a larger reactor volume. This might be due to the combination of the linear profiles for the control variables, but also because constraint violations hidden in the previous solution are now removed because of the controlled discretization error. Lastly, the role of the non-collocation point used for quantifying the discretization error shall be discussed.

**Table 2:** Necessary number of finite elements under variation of the non-collocation point for control formulation 2. The case at 0.9 automatically satisfies the condition because C is negative and thus the error is automatically smaller than zero.

Non-collocation point	Constant C	Number of finite elements
0.1	0.2250	368
0.4	0.0000	50
0.5	0.1250	305
0.6	0.6000	355
0.9	-0.0592	50

The very pronounced increase of the necessary finite elements by a factor of about 10 was very surprising, given that the system is not very complex. Hence, the specific location of the non-collocation point was varied to determine how the number of finite elements changes (Table 2). It is observed that the location of the non-collocation point has a notable effect on the necessary number of finite elements. Specifically, the constant C has roots in the interval from zero to one (so the discretization error estimate is automatically zero as well), and it can become negative for non-collocation points closer to one. Hence, better criteria for its selection must be found. Until now, this remains an open research question and has, to the author's knowledge, not been discussed so far in other contributions.

The impact of the continuously refined mesh is visualized in Figure 4. The design starts off with a reactor volume of  $0.84 m^3$  and declines to approximately  $0.81 m^3$  (see also Table 1). Although this impact is (in this case small) relatively small, it shows that it should still be investigated, especially for larger flowsheets with varying time constants. For the objective function, however, there is no clear trend observable (Figure 5).

**Figure 4.** Reactor volume with increasing number of finite elements for a non-collocation point of 0.5.

**Figure 5.** Objective function with increasing number of finite elements for a non-collocation point of 0.5.

## CONCLUSION AND OUTLOOK

This contribution extended our recently proposed framework for solving IDO problems by incorporating a measure of the discretization error to avoid incorrect profiles and, in consequence, possibly hidden constraint violations in these badly resolved regions. The extended framework was applied on a CSTR case study for which its geometry, i.e., volume, height, and diameter, was determined while satisfying operational constraints, such as an upper bound of the temperature, for all timepoints in the horizon. Based on the presented findings, a reformulation for control variables is recommended, i.e., the linearization of the profiles within one finite element, which prohibits strongly oscillating control profiles in highly resolved regions of the time horizon.

In the future, this error-controlled approach shall be extended to parametric uncertainty. This is of particular interest as the probability distribution of the uncertain parameters will influence the time constants of the individual scenarios, which will potentially result in completely different numbers and lengths of the finite elements for each uncertainty scenario.

## ABSTRACT

Although global efforts for CO<sub>2</sub> capture are underway, large-scale CO<sub>2</sub> capture projects still face economic risks and technical challenges. The Rotating Packed Bed (RPB) provides an alternative solution by mitigating location constraints and enabling a gradual increase in the scale of CO<sub>2</sub> capture through compact modular sizes. However, the main challenge in RPB-based CO<sub>2</sub> capture processes lies in the limited experience with implementing industrial-scale RPB processes. The intricate relationship between RPB unit design, operating conditions, and process performance further complicates the process-level analysis for scale-up. To address these challenges, we propose an optimization-based process design for RPB-based CO<sub>2</sub> capture. Leveraging rigorous process modeling and simulation, we aim to make simultaneous decisions on RPB unit design and operating conditions. Ultimately, our goal is to develop a cost-effective and optimal RPB-based CO<sub>2</sub> capture process, supported by comprehensive cost evaluations. This modularized and cost-effective approach is expected to facilitate rapid implementation and gradual scale-up, thereby reducing entry barriers to CO<sub>2</sub> capture technology for industries.

## INTRODUCTION

In the ongoing efforts to combat climate change, CO<sub>2</sub> capture is expected to play a pivotal role for the foreseeable future. Among the available capture techniques, amine-based absorption stands out as a mature technology, with several industrial-scale CO<sub>2</sub> capture facilities in operation worldwide [1]. However, experiences such as the Petra Nova project, one of the largest industrial-scale CO<sub>2</sub> capture projects, have revealed the economic risks and technical complexities associated with building and operating such large-scale CO<sub>2</sub> capture processes. While economies of scale can benefit large-scale processes, the substantial initial cost and space requirement for vast CO<sub>2</sub> capture facilities make them less favorable investments [2]. Process intensification, particularly through technologies like the Rotating Packed Bed (RPB), offers a potential solution to address this hurdle.

RPB, as a form of process intensification, enhances mass transfer and unit throughput with the rotation of a packed bed. The increased centrifugal force widens the

selection window for packing materials and facilitates the use of highly viscous solvents. This improved throughput can significantly reduce the required volume for column units, which typically account for approximately 50% of the capital expenditures (CAPEX), by up to 65% [3].

Driven by the potential benefits of RPB in shrinking mass transfer units, there have been numerous lab-scale experiments [4-6]. On the other hand, its application to industrial-scale CO<sub>2</sub> capture has been limited. Recent studies have explored RPB-based CO<sub>2</sub> capture on a scale of approximately 2200 tons per day (TPD)[7]. However, these studies have overlooked certain important factors, such as the pressure drop, in the RPB design, hindering the provision of realistic insights. Moreover, the overall lack of large-scale RPB-based process implementations poses challenges in extrapolating findings to larger and more practical scales. Notwithstanding the potential economies of scale, the practical viability of large-scale RPB units raises questions, especially considering that their characteristics are more aligned with small-to-medium scale applications.

The central question addressed in this research revolves around establishing a cost-effective design and optimal operating conditions for the RPB-based CO<sub>2</sub> capture process. The efficacy of applying RPB for CO<sub>2</sub> capture at an industrial scale remains uncertain, primarily due to a lack of experience in establishing such processes. Furthermore, limited insights exist regarding unit design guidelines and operating conditions for an industrial-scale RPB-based CO<sub>2</sub> capture process. While Agarwal et al. [8] presented a systematic RPB column design procedure, it is heuristics-based and can only address minimal design requirements to prevent flooding of the liquid or jet ejection of the vapor. Furthermore, the RPB column's design is contingent upon the initial assumptions about some process operating variables, e.g., the rotation speed of packing. The design of the RPB column influences mass transfer and hydraulic phenomena, impacting optimal conditions and overall performance. The inherent characteristics of the RPB demand iterative design and operating condition decisions, pointing to the limited effectiveness of the conventional sequential process design approach.

To address these limitations, we adopt a simultaneous optimization-based approach for both RPB design and operating conditions. Utilizing a comprehensive model for an RPB-based CO<sub>2</sub> capture process with a reference MEA solvent, we seek cost-effective RPB design and operating conditions for the compact CO<sub>2</sub> capture process. The envisioned modularized RPB-based CO<sub>2</sub> capture process aims to expedite implementation, enabling a phased scale-up of the CO<sub>2</sub> capture process and thus reducing entry barriers for the industry.

## SYSTEM DESCRIPTION

### RPB Column and Process Model

A process model for the RPB-based CO<sub>2</sub> capture process is constructed using the gPROMS custom modeling environment, building upon the foundation established in our prior publication [9]. The enhancement factor and effective surface area models have been updated for improved accuracy, incorporating a wider range of pilot plant operation data in this study. To ensure consistent insights into design and energy consumption, we selected the widely used MEA amine as the reference solvent. The increased centrifugal force in RPB units facilitates the application of high-viscosity solvents, prompting exploration into concentrated amine solvents, often enhanced with anti-degradation additives. MEA concentrations ranging from 30 to 75wt% MEA solvents are typical for RPB-based CO<sub>2</sub> capture, and we employed the eNRTL (electrolyte Non-Random Two-Liquid) model with updated parameters for this broad range of MEA concentrations [10] as our thermodynamic model. The RPB column model adopts the two-film theory for the

calculation of mass and heat transfer rates, complemented by an enhancement factor model.

**Figure 1.** Conceptual scheme of RPB column model.

**Figure 1** illustrates the conceptual scheme of the developed RPB column model, where vapor and liquid phases flow counter-currently along the radial axis, resulting in the formulation of the partial differential equation (PDE) with radial distribution:

$$\varepsilon^L \frac{\partial C_i^L}{\partial t} = -\frac{1}{2\pi rz} \frac{\partial(F^L x_i)}{\partial r} + a^L N_i \quad (1)$$

$$\varepsilon^V \frac{\partial C_i^V}{\partial t} = \frac{1}{2\pi rz} \frac{\partial(F^V y_i)}{\partial r} - a^L N_i \quad (2)$$

$$\varepsilon^L C_{tot}^L C_p^L \frac{\partial T^L}{\partial t} = -\frac{F^L C_p^L}{2\pi rz} \frac{\partial T^L}{\partial r} + a^L (h^L (T^V - T^L) + N_{H_2O} \Delta H_{H_2O}^{vap} + N_{CO_2} \Delta H_{CO_2}^{abs}) \quad (3)$$

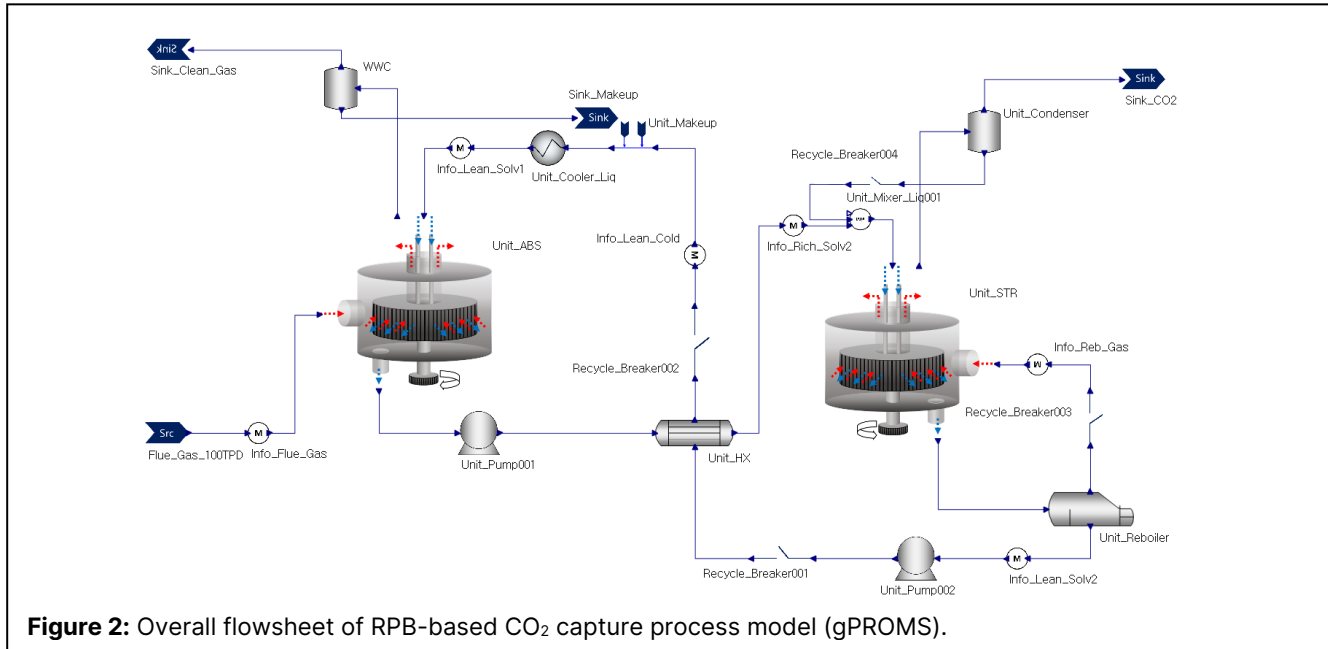

$$\varepsilon^V C_{tot}^V C_p^V \frac{\partial T^V}{\partial t} = \frac{F^V C_p^V}{2\pi rz} \frac{\partial T^V}{\partial r} - a^L h^L (T^L - T^V) \quad (4)$$

Here,  $r_{inner}$ ,  $r_{outer}$  and  $z$  represent the inner radius, outer radius, and height of the RPB unit, respectively.  $C$  and  $F$  denote concentration and molar flowrate, respectively. As the control volume changes along the radial axis, the continuity equations  $F = 2\pi rz C_{tot} u$  hold for both vapor and liquid phases. The mass transfer rate of CO<sub>2</sub>,  $N_{CO_2}$ , is calculated using the two-film theory with an enhancement factor as follows:

$$N_{CO_2} = K_{CO_2}^{overall} (P_{CO_2} - P_{CO_2}^*) \quad (5)$$

$$K_{CO_2}^{overall} = \frac{1}{\frac{RT^V}{k_{CO_2}^V} + \frac{H_{e_i}}{E_{CO_2} k_{CO_2}^L}} \quad (6)$$

Here,  $K_{CO_2}^{overall}$ ,  $P_{CO_2}$  and  $P_{CO_2}^*$  represent the overall mass transfer coefficient, CO<sub>2</sub> partial pressure, and equilibrium CO<sub>2</sub> partial pressure, respectively. **Table 2** provides the transfer correlation and reaction models used for the column model. **Figure 2** illustrates the overall flowsheet of the RPB-based CO<sub>2</sub> capture process, encompassing the developed RPB model and additional process units within

**Figure 2:** Overall flowsheet of RPB-based CO<sub>2</sub> capture process model (gPROMS).

the gPROMS simulation environment.

**Table 2:** Transfer correlation and reaction models

Variables	Model
Effective surface area ( $a'$ )	Xie et al. [11]
Liquid transfer coefficient ( $k^L$ )	Tung et al. [12]
Vapor transfer coefficient ( $k^V$ )	Onda et al. [13]
Heat transfer coefficient ( $h'$ )	Chilton-Colburn analogy
Enhancement factor ( $E_{CO_2}$ )	Wellek et al. [14]
Reaction kinetics ( $k_{app}$ )	Luo et al. [15]

### Process Model Validation

Given the lack of comprehensive operational data for the overall RPB-based CO<sub>2</sub> capture process in existing literature, we subjected our developed process model to a validation process using operation data from separate absorber and stripper pilot plants. We utilized pilot plant operation data from Jassim's (Run 1 to 16) [4] and Kolawole's study (Run 1 to 36) [16] for absorber column validation and Cheng's study (Run 1 to 12) for stripper column validation.

As shown in **Figure 3** and **Figure 4**, our validation results affirm the satisfactory fidelity of the developed RPB column model. The RPB model demonstrates robust predictive capabilities, with an error range of about  $\pm 10\%p$  for CO<sub>2</sub> capture rate and  $\pm 20\%$  for energy consumption. Even under a range of MEA concentration and various operating conditions, the RPB model maintains a mean absolute relative error (MARE) of 11.4 % and 9.2% for CO<sub>2</sub> capture rate and energy consumption, respectively.

**Figure 3.** Comparison of pilot plant and process model (CO<sub>2</sub> capture rate).

**Figure 4.** Comparison of pilot plant and process model (Energy consumption).

## ANALYSIS OF LARGE-SCALE PROCESS

### Target Scale and System

The implementation of an excessively large-scale RPB-based CO<sub>2</sub> capture process faces inherent challenges, given the quadratic increases in both rotational energy and pressure drop. The rotational nature of the RPB introduces escalating demands for momentum and centrifugal energy as the process unit size expands. In addition, the heightened angular acceleration and torque as the plant scale increase can require additional maintenance and safety concerns due to the intricate system control, increased mechanical strain on components, impact on the lifespan of process units, elevated risk of failures, and potential discomfort for operators [17, 18]. Consequently, the preference leans towards favoring an industrial-scale RPB-based process in the small-to-medium range, deviating from the conventional CO<sub>2</sub> capture process with fixed packed beds.

In this study, we explore a medium-scale process at 100 TPD CO<sub>2</sub> capture, specifically targeting flue gas from a coal-fired power plant. This choice aligns with a pragmatic compromise, as the flue gas flow rate for the 100 TPD scale equates to the flue gas from an approximately 6 MW scale power plant. **Table 3** shows the considered inlet flue gas stream condition in this study.

**Table 3:** Inlet flue gas stream condition

Variables	Value
Scale (TPD CO <sub>2</sub> capture)	100
Flow rate (kg/s)	5.94
Temperature (°C)	40
Pressure (bar)	1.1
Mole fraction, CO <sub>2</sub> (%)	14.5
Mole fraction, H <sub>2</sub> O (%)	6.8
Mole fraction, N <sub>2</sub> (%)	76.6
Mole fraction, O <sub>2</sub> (%)	2.1

### Simultaneous Optimization of RPB Design and Operating Condition

The highly coupled nature of RPB design and operating conditions often leads to local optima when a heuristic-based and sequential process design approach is applied. Consequently, the simultaneous determination of process unit design and operating conditions can offer a more cost-effective solution.

In our simultaneous design approach, an optimization problem is formulated to minimize the total annual cost (TAC) per the amount of captured CO<sub>2</sub>, utilizing both RPB design parameters ( $d$ ) and operating variables of the overall process ( $x$ ) as decision variables. The formulation is as follows:

$$\min_{d,x} \frac{TAC}{\dot{m}_{CO_2,Captured}} = \frac{ACC+AOC}{\dot{m}_{CO_2,Captured}} \quad (7)$$

$$d \in [r_{inner,j}, r_{outer,j}, H_j] \quad (8)$$

$$x \in [F_{Solv}, T_{Reb}, P_{Str}, \omega_j] \quad (9)$$

$$\text{s.t. } \eta_{Cap} \geq 90\% \quad (10)$$

$$T_{Reb} \leq 120^\circ\text{C} \quad (11)$$

$$0\% \leq \phi_{flood,j} \leq 80\% \quad (12)$$

$$r_{min,j} \leq r_{inner,j} \leq r_{outer,j} \quad (13)$$

$$H_j/r_{outer,j} \leq 1 \quad (14)$$

In the above formulation,  $ACC$  and  $AOC$  represent the annualized capital and operating cost, respectively. The index  $j$  represents the RPB units, encompassing absorber ( $Abs$ ) and stripper ( $Str$ ) columns. We employ the Lang factor method, based on the free-on-board (FOB) cost with a value of 5.93 for continuous process [19], to estimate the capital cost. Meanwhile the operating cost is calculated from the energy consumption using rigorous process simulation. The details on decision variables as summarized in **Table 4**.

**Table 4:** Considered decision variables

Process variables	Symbols
RPB inner radius (m)	$r_{inner,j}$
RPB outer radius (m)	$r_{outer,j}$
RPB height (m)	$H_j$
Solvent flowrate (kg/s)	$F_{Solv}$
Reboiler temp. (°C)	$T_{Reb}$
Stripping pressure (bar)	$P_{Str}$
RPB rotation speed (RPM)	$\omega_j$

Constraints include a lower bound on 90% capture rate, an upper bound of 120°C on reboiler temperature to prevent thermal degradation of solvent, and a constraint on the 80% flooding condition to govern the RPB design parameters. Additionally, constraints on the minimum RPB inner radii [8] and mechanical recommendations for RPB design [20] are incorporated to ensure the reliability of RPB design.

Due to the absence of a specialized capital cost estimation model for industrial-scale RPB units in existing literature, we adopt a cost estimation model designed for centrifuges. The FOB purchase cost for the RPB unit is assumed to be the aggregate of costs associated with the rotation components (motor and rotor) and the packing bed. Leveraging cost models developed for centrifuges, the cost model unfolds as follows:

$$C_{RPB}^{FOB} = C_{Centrifuge}^{FOB} + V_{RPB}^{Packing} C_{RPB}^{Packing} \quad (15)$$

$$C_{Centrifuge}^{FOB} = \$6180 \cdot (D_{outer})^{0.94} \quad (16)$$

In the above equations,  $V_{RPB}^{Packing}$  and  $C_{RPB}^{Packing}$  represent the volume and cost of packing, respectively, with a

packing price of \$285/ft<sup>3</sup>.  $D_{outer}$  denotes the diameter of centrifuges (RPB in this study) in inches. For utility cost calculations, \$8/GJ, \$19.2/GJ, and \$0.015/GJ are applied for steam, electricity, and cooling water, respectively.

## RESULT AND DISCUSSION

The cost model developed for the simultaneous design approach enables a comparative analysis of CO<sub>2</sub> capture costs against the sequential heuristics-based design. In the heuristics-based method, RPB units were designed using Agarwal's RPB design procedure [8], and operating conditions were determined through an optimization problem aimed at minimizing energy consumption per captured CO<sub>2</sub> as follows:

$$\min_x E_{cap} = E_{steam} + C_{conversion} E_{Elec} \quad (17)$$

The decision variables in eq (9) were employed, and a conversion factor of 1/0.4 was applied to align energy types.

**Figure 5.** Comparison of CO<sub>2</sub> capture cost with heuristic and simultaneous design approach according to varying MEA concentrations.

**Figure 5** illustrates the total CO<sub>2</sub> capture cost at varying concentrations of MEA solvent for both heuristics-based and simultaneous design approaches. The estimated total capture costs with RPB units range from \$60.0 to 88.1/tCO<sub>2</sub>, with the primary contributors being utility cost from steam, RPB column CAPEX, and fixed operation costs. Notably, the energy consumption by packing rotation does not constitute a significant portion of the overall cost. Given that the RPB CAPEX constitutes a large portion of the CO<sub>2</sub> capture cost, obtaining empirical data and developing appropriate cost estimation models will be a crucial for future scale-up studies of RPB-based processes.

The results reveal that employing the simultaneous

decision results in an 9.4–12.7% reduction in CO<sub>2</sub> capture cost. This reduction is predominantly attributed to a decrease in column CAPEX, highlighting the effectiveness of incorporating RPB design parameters into the optimization problem as decision variables. The limitations of the sequential and heuristic design approach become more evident through the optimal design parameters and process variables shown in **Table 5** and **Table 6**. The optimized RPB design parameters and rotational speed exhibit significant differences in both approaches. The optimization results align with our understanding that maintaining the inner radius at a minimum is advantageous. However, the RPB design from the simultaneous solution shows the increased RPB height and reduced outer radius. Such a tall and stout RPB design is expected to contribute not only to reducing RPB CAPEX but also rotation energy and pressure drop, while maintaining the same unit throughput.

**Table 5:** RPB design and optimized process variables (Heuristics-based approach)

Variables	30wt%	50wt%	70wt%
ABS-Inner radius (m)	0.18	0.18	0.18

ABS-RPM (rpm)	491	498	502
STR-RPM (rpm)	503	415	425

\*Constraint active

**Table 6:** Optimized RPB design and process variables (Simultaneous optimization approach)

Variables	30wt%	50wt%	70wt%
ABS-Inner radius (m)	0.18*	0.18*	0.18*
ABS-Outer radius (m)	1.03	0.91	0.80
ABS-Height (m)	1.03	0.91	0.80
STR-Inner radius (m)	0.10*	0.10*	0.09*
STR-Outer radius (m)	0.27	0.21	0.18
STR-Height (m)	0.27	0.21	0.18
Solvent flowrate (kg/s)	21.7	13.8	10.0
Reboiler temp. (°C)	120*	120*	120*
Stripping pressure (bar)	1.88	1.62	1.13
ABS-RPM (rpm)	269	279	292
STR-RPM (rpm)	786	756	888

\*Constraint active

Variations in MEA concentration also exert a significant influence on process performance and total capture costs. Increasing the MEA concentration from 30wt% to 70wt% results in notable savings in energy consumption

and capture cost, ranging from 28.6 to 31.3% and 22.1 to 25.0%, respectively. This observed improvement is mainly attributed to the reduction in the amount of water evaporation heat in the reboiler. Furthermore, there is a notable reduction in the size of the RPB units, which can be attributed to the accelerated CO<sub>2</sub> absorption reaction rate associated with the increased amine concentration. While the widespread adoption of highly concentrated MEA solvent on an industrial scale is constrained by concerns about solvent degradation, the expanded solvent selection window offered by the RPB unit proves advantageous in saving energy consumption and reducing the total CO<sub>2</sub> capture cost.

The interdependence of rotational speed and RPB design is evident, as alterations in the RPB unit design necessitate adjustments in the rotation speed. Particularly in larger-scale processes, lowering the rotation speed becomes advantageous to counteract the quadratic rise in energy consumption with packing rotation.

## CONCLUSION

The RPB-based CO<sub>2</sub> capture process is anticipated to find application across diverse industries owing to its enhanced processing capacity and reduced space requirements. To address the lack of process-level cost evaluation and a systematic design procedure for scaling up on this system, we undertook an exploration of a cost-effective capture process through modeling, simulation, and optimization. Initially, a first principle-based process model was developed and validated. By simultaneously optimizing RPB design and process operating conditions, we realized cost savings of 9.4-12.7% compared to sequential and heuristics-based design approaches. The estimated total CO<sub>2</sub> capture cost with RPB units ranged from \$60.0 to 88.1 per ton of CO<sub>2</sub>, varying with MEA concentration. The optimal RPB design found in this study, characterized by a taller height and shorter diameter, deviates from the heuristics-based approach. Given the strong correlation among RPB design, operating conditions, and process performance, our simultaneous design approach for RPB-based process holds promise for insightful process analysis across various scales in the future.

## ABSTRACT

Early stage exploration of reaction systems, including catalyst selection, operating conditions' specifications, reactor design, and optimization, is critical in the engineering field. It is general practice in the reaction engineering field to explore systems against certain performance metrics, of which yield is one of the most commonly utilized objectives. While the yield provides a quantitative measure of how efficiently reactants are converted into target product(s), its definition is ambiguous, particularly in the presence of side/ incomplete reactions, and multiple products. Most of the yield definitions focus on a specific target product; however, conditions within the reactor search space that provide a maximum yield for one product may not be the same as those for another. Moreover, the presence of other undesired products that are not considered may reduce the overall efficiency of the system. This necessitates the utilization of a more holistic metric that encompasses the value of all the generated products. Attempts to address this consider lumping components into a total yield metric. However, this assumes equal weights on all components without adequately capturing their individual significance on the actual performance. This study proposes the utilization of an "economic-value yield" objective that captures all the products' value by using the market price as a weight factor. The traditional yield metric for the various products is contrasted against the economic one to highlight its ability of providing insight into regions within the reactor search space that are associated with high-value products that are otherwise not observed in the conventional definition. This is illustrated with a case study utilizing propane as a feedstock in the novel piston reactor technology.

## INTRODUCTION

The development of optimized and novel reactors is key for sustainable technology design and development [1]. Early-stage exploration and design of reaction systems is of paramount importance in reaction and chemical engineering for a plethora of reasons including the identification and screening of promising reactions, selection of raw materials and catalysts, understanding reaction mechanisms, optimization of reaction conditions, and assessing the overall feasibility of a reaction system. It is general practice in the catalysis and reaction engineering field to study reaction systems against certain performance metrics that assist in evaluating the efficiency of reactors and chemical reactions. Various objectives are utilized to evaluate reactors, depending on the

characteristics of the reaction and nature of the process. Some of the most commonly used metrics include conversion, selectivity, and yield.

While the yield is a fundamental and widely used metric in chemical engineering and reaction optimization, there is no universally agreed upon definition for such a term. It remains associated with limitations including the ambiguity of its definition, as it can refer to conversion yield, selectivity yield, total yield, or other variations that may result in misinterpretations. Moreover, most of the yield definitions focus primarily on the desired product without accounting for the formation of by-products or undesired side reactions that can be crucial for assessing the system's overall performance. For instance, a reaction with high yield may be deemed undesirable if it results in the production of substantial amounts of

unwanted by-products. Maximizing the yield for one product may not result in the conditions that reflect optimum performance. A more holistic approach is required to account for the contribution of multiple products in a reaction system. Attempts to address this issue consider lumping the components into a total yield term [2]. However, this assumes equal weights on all the generated products. A proper weighted yield term is required to account for the contribution of multiple products in a reaction system based on their significance.

The concept of economics can serve as a powerful tool to practically evaluate chemical reactions. This study proposes the utilization of an “economic-value yield” (EVY) metric, by assigning weights to the various components based on their market price, and contrasts it against traditional yield metric definitions to highlight its ability of providing insight into regions within the reactor search space that are associated with high-value products. To the authors’ knowledge, there are no peer-reviewed publications utilizing metrics that capture the economics of the reaction products when assessing reaction chemistries. Such a metric is particularly helpful in the assessment of novel reactor technologies.

One of the emerging novel reactor concepts is the piston reactor technology, which is essentially a repurposed internal combustion engine that focuses primarily on the production of chemicals, in addition to the power and heat associated with the conventional combustion engine. Its advantages include high temperature and pressure conditions at short residence times, thereby enhancing the performance of numerous chemical reactions. The cyclic nature of the reaction system offers a novel mode of carrying out chemical reactions, where the fast temperature quench enables a target non-equilibrium state where the desired product could be generated at optimal yield and efficiency [3].

In this study, the EVY objective is utilized to assess the performance of the piston reactor technology to screen chemistries using propane as a feedstock to determine economically attractive regions within the reactor search space. Results are contrasted against the traditional yield metric, highlighting the importance of utilizing economics when assessing the performance of reactor systems.

## CONVENTIONAL YIELD METRICS

There is no universally agreed upon definition for the “yield” concept [4] as it is applied in numerous contexts, and its definition varies depending on the application, or process. Table 1 depicts a summary of the most common definitions of yield used in the literature. The presence of multiple descriptions for the yield metric introduces uncertainty, particularly when studies fail to explicitly define the parameter utilized in their

evaluations. This lack of terminology hinders the comparability of research results and findings within the reaction and engineering fields. Most of the published studies use the “overall reactor yield” term, on a molar basis, to define the reactor’s yield [5]. In this case, the yield is defined as the ratio of the target product formed to the reactant fed. This is observed in numerous studies including methanol formation from syngas [6], naphthalene oxidation to phthalic anhydride [7], and hydrogen production from methane reforming [8], to name a few.

The issue with such a definition, and its variations in Table 1, is highlighted when there are multiple products formed, as these common definitions neglect the impact of formation of by-products and undesired products. Conditions representing a high yield of one product are not the same as those for another product, leading to a misrepresentation of the actual conditions that pertain to the reactor’s optimal performance. Moreover, a high yield of a certain component does not necessarily guarantee a high overall performance efficiency particularly if substantial amounts of undesired components are formed.

To alleviate this issue, some studies lump certain components together to formulate a total yield term, as in the case of oxidative coupling of methane (OCM). In OCM, methane, co-fed with oxygen, react to produce primarily ethane and ethylene [2]. Since both ethane and ethylene are the main products, a “C<sub>2</sub> Yield” term is utilized to account for the formation of the two products by summing up the yield of each component. In other studies, a C<sub>2+</sub> yield term is utilized, corresponding to the total yield of ethane and ethylene, in addition to propane and propylene [9]. While this takes into consideration the formulation of other products, it automatically assigns equal weights to them, potentially overlooking the variations in their significance, thereby also leading to a misrepresentation of the overall results.

Moreover, such definitions cannot be applied in situations where the target product is not known from the offset. This is particularly highlighted in the technology assessment and chemistry screening cases phases of early-stage reaction exploration, such as the case of the piston reactor.

## ILLUSTRATION: PISTON REACTOR

As an illustration, the concept of yield is applied on screening chemistries within the piston reactor. The piston reactor is essentially a repurposed internal combustion engine (ICE) that is utilized primarily as a reactor to produce chemicals, in addition to the electricity and heat associated with the conventional ICE [10]. The piston reactor operates in a cyclical manner by

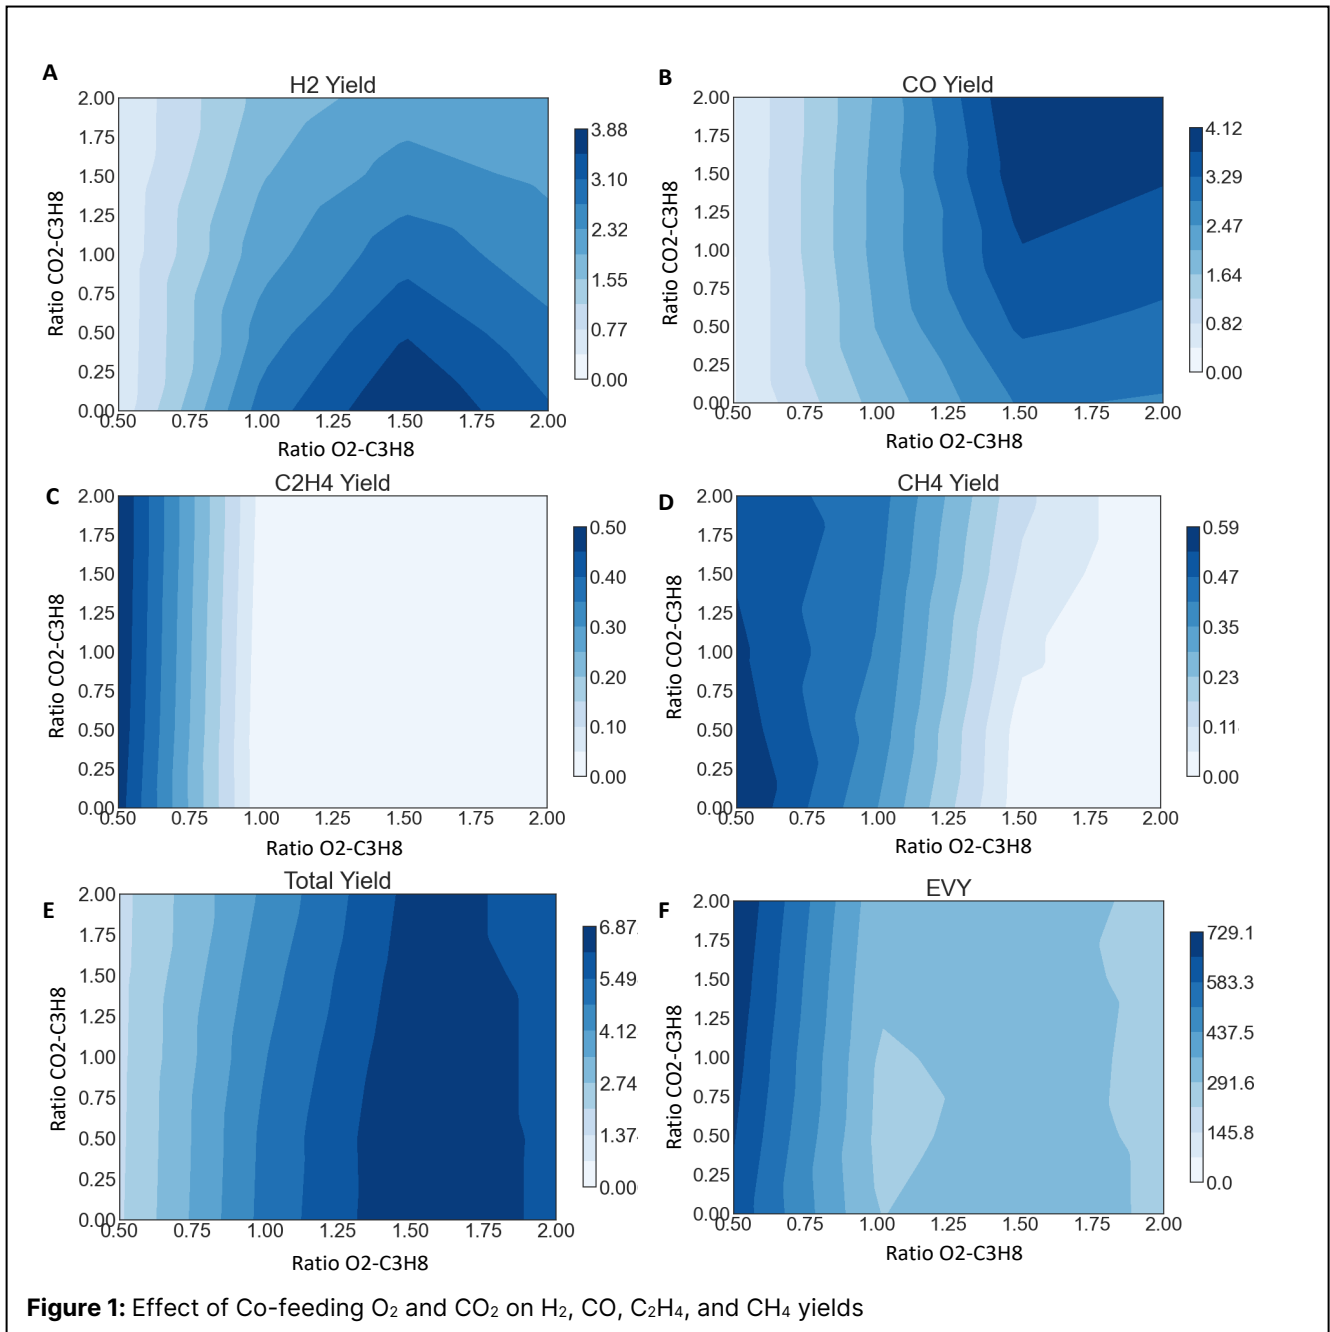

**Table 1:** Common Definitions for the Yield Metric

	Definition	Formula	Ref.
Overall reactor yield	Overall reactor efficiency in converting the reactants to target products	$Y = \frac{\text{Target product formed (mol)}}{\text{Reactant fed (mol)}}$	[17]
Reaction Yield	Ratio of actual amount of product formed to the maximum amount that could be generated (theoretical yield)	$Y_{th} = \frac{\text{Actual amount of product made (mol)}}{\text{Theoretical yield (mol)}}$	[18]
Yield	Amount of desired product generated to the amount formed if there were no by-products and main reaction reached completion	$Y = \frac{\text{Desired product generated (mol)}}{\text{Products generated (no byproducts) (mol)}}$	[19]
Overall fractional Yield	Ratio of all the products formed to the reactants that have reacted	$\Phi = \frac{\text{All product formed (mol)}}{\text{All reacted reactant (mol)}}$	[20]
Instantaneous Fractional Yield	Rate of generation of a desired product relative to rate of consumption of a key reactant	$\varphi = \frac{\text{Rate of product generation}}{\text{Rate of reactant consumption}}$	[7]
Weight Yield	Mass of target product as percentage of total reactant mass	$\text{Weight Yield} = \frac{\text{Target product (mass)}}{\text{Total reactant (mass)}}$	[21]
Total Yield	Ratio of total products formed to the reactor fed	$\text{Total Yield} = \frac{\text{Total products formed}}{\text{Reactant fed}}$	[9]

compressing the feed gas and expanding within short time-frames in the order of milli-seconds [11]. The compression phase results in elevated temperatures and pressures that enhance the efficiency of certain reactions, whereas the expansion results in a rapid quenching of the mixtures enabling the formation of products at optimal conditions [12].

We illustrate the metrics for the case of exploring propane conversion in the piston reactor, based on the piston reactor results of Abousrafa et al. [13]. There are multiple variables that can be explored for a piston reactor applied to propane conversion such as the impact of co-feeding the propane with both O<sub>2</sub> and CO<sub>2</sub> as performed by Abousrafa et al. [13]. Adding O<sub>2</sub> to the reaction promotes the autoignition of propane, resulting in heat generation that can be utilized to co-generate power from the piston reactor. As for CO<sub>2</sub>, in addition to the environmental benefit of utilizing it as a feedstock, CO<sub>2</sub> addition facilitates the occurrence of several reactions such as dry reforming and oxidative dehydrogenation. This analyzes data for an intake temperature and pressure of 773K, 1 bar, and an RPM of 3000 [13]. Products from the reaction include H<sub>2</sub>, CO, C<sub>2</sub>H<sub>4</sub>, CH<sub>4</sub>, C<sub>3</sub>H<sub>6</sub>, C<sub>2</sub>H<sub>2</sub>, C<sub>6</sub>H<sub>6</sub>, and C<sub>4</sub>H<sub>6</sub>. At complete propane conversion, the impact of co-

feeding O<sub>2</sub> and CO<sub>2</sub> on the overall reactor yield of the major generated species is shown in Figure 1 (a-d). For the four main components formed in the piston reactor, H<sub>2</sub>, CO, C<sub>2</sub>H<sub>4</sub>, and CH<sub>4</sub>, maximum yields are obtained at CO<sub>2</sub>/C<sub>3</sub>H<sub>8</sub> and O<sub>2</sub>/C<sub>3</sub>H<sub>8</sub> ratios of 0 and 1.5, 2 and 1.5, 2 and 0.5, 0 and 0.5, respectively. To account for all the components, a total yield metric, similar to the one utilized in the OCM studies [9], is calculated, and the results are illustrated in Figure 1e. The figures show that the yield maxima for all four species and also the total yield are different, highlighting the difficulty in using yield as a performance metric for the optimal search of reactions systems with multiple potentially desired species formed as products. The total yield metric considers all formed species; however, the metric assumes each product with equal weight.

**Table 2:** Price assumptions for the EVY calculation

Component	Formula	Price(\$/t)	Ref.
Hydrogen	$H_2$	1,200	[14]
Carbon Monoxide	$CO$	55	[15]
Methane	$CH_4$	278	[16]
Ethylene	$C_2H_4$	882	[16]
Acetylene	$C_2H_2$	1313	[16]
Benzene	$C_6H_6$	865	[16]
Propene	$C_3H_6$	1488	[16]
Butadiene	$C_4H_6$	1357	[16]

### Economic-Value Yield

Rather than assuming equal weighted total yield or individual component yields as objectives, a differently weighted yield metric that considers the formation of multiple valuable reaction products would be preferred. Considering that the implementation of most production systems is to a large extent based on the value of products formed from raw materials, this work proposes the utilization of an economic-value yield metric for the reactor performance that uses the product prices as a weight

factor to obtain an overall reactor-yield metric:

$$EVY = \sum_j P_j \times WY_j \quad (1)$$

Where:

- EVY is the economic-value yield (\$/t feed)
- $P_j$  is the market value, or price, for product  $j$  (\$/t product)
- $WY_j$  is the weight yield of the product  $j$  as percentage of the total reactant weight (t product/ t reactant)

Table 2 contains the prices of the chemicals produced in the piston reactor. Figure 1f shows the results for EVY at various  $O_2/C_3H_8$  and  $CO_2/C_3H_8$  ratios. Results show that the EVY profile does not match any of the individual yield components. It also shows opposite trends to those observed in the total yield metric (Figure 1e). The maximum total yield is observed at  $CO_2/C_3H_8$  and  $O_2/C_3H_8$  ratios of 0.5 and 1.5, whereas maximum EVY is at  $CO_2/C_3H_8$  and  $O_2/C_3H_8$  ratios of 2 and 0.5. However, these results assume equal weights for all those four main components. Although the maximum EVY is in line with maximum  $C_2H_4$  yield, there are regions within the  $C_2H_4$  figure that show zero yield, yet are associated with substantial value, highlighting the importance of utilizing a properly weighted total yield metric to obtain more representative conclusions. Another important observation is the presence of trace components including  $C_3H_6$ ,  $C_2H_2$ ,  $C_6H_6$ , and  $C_4H_6$  that have a substantial contribution to the EVY. Although they are present in concentrations <2 mol%, and are associated with overall reaction yields <0.1, there are cases where they result in double the EVY. These results further emphasize the importance of adding appropriate weight, in terms of product value, to the conventionally utilized yield terms.

## CONCLUSIONS

It is general practice in the reaction engineering field to evaluate reactions based on certain performance metrics, of which reaction yield is one of the most utilized objectives. There is no universal definition for the yield metric, resulting in challenges including lack of consistency, and results comparability. Moreover, most of the definitions focus on a single desired product without taking into consideration the formation of other undesired or by-products. This leads to difficulty in pinpointing regions of optimal reactor performance, as the yields of one component are associated with different conditions than another. Moreover, the presence of undesired products that are not considered could lead to an inefficient overall performance. A more comprehensive metric is required to account for the contribution of all the generated products in a reaction system. Some studies

attempt to alleviate these issues by lumping the components into a total yield term. However, the assumption of equal weights of components may not be representative of actual performance. This necessitates the utilization of a proper weighted yield term to account for the contribution of all the generated products in a reaction system. This study proposes an “economic-value yield, EVY” metric, where the prices are utilized as weight factors. In addition to its simplicity, using chemical prices reflects actual market value, thereby indicating the relative contribution, or importance, of each generated component. The piston reactor technology is used as an illustration to contrast the EVY results against the traditional yield metric. Results showed that regions within the reactor search space that are associated with high-values do not match the individual yield results, nor the conventional total yield metric. Moreover, the contribution of elements that are associated with low-yield, yet high value, are not shown in the traditional calculations. This highlights the importance of utilizing economics when assessing the performance of reactor systems.

## ABSTRACT

Adsorption-based Atmospheric Water Extraction (AWE) is an energy-efficient distributed fresh-water supply method. This research focuses on AWE's kinetic analysis and stochastic optimization, investigating the impact of ambient conditions, kinetics, and weather variability. A one-dimensional fixed-bed system was numerically analyzed using the validated isotherm of MIL-100 (Fe), assuming different kinetic parameters within the linear driving force model. Stochastic optimization, based on annual weather data from Georgia (GA), illustrates the influence of weather conditions on AWE process performance, operation, and cost. Our study offers valuable insights for future research, including site selection, adsorbent material development, and process design. We outline three critical areas for further exploration: experimental verification, material screening, and meteorological site selection.

**Keywords:** Atmospheric Water Extraction (AWE), Metal-Organic Framework (MOF), Kinetic Analysis, Meteorological Analysis, Two-stage Stochastic Programming (TSSP)

## 1. INTRODUCTION

Global warming significantly threatens our climate, rendering it increasingly unpredictable. In particular, it changes the natural water cycle, leading to a growing regional freshwater scarcity problem.

The Atmospheric Water Extraction (AWE) process offers a promising solution for sustainable freshwater production (Wang et al., 2022). Among the various AWE techniques, adsorption-based AWE stands out due to its scalability, energy efficiency, and environmental resilience advantages (Xu & Yaghi, 2020).

This study aims to establish a connection between the characteristics of adsorbent materials, kinetic performance, and the variability of weather conditions, contributing to the development of the AWE process from a process systems engineering perspective. In this brief 6-page paper, the AWE process description is very brief; the analysis methods in Sections 2.1 on the S-Shaped Isotherm and Section 2.2 on the Kinetics Analysis are abbreviated, as are many aspects of the process analyses for their temperature and vacuum-swing, adsorption-desorption processes.

## 2. METHOD

### 2.1 S-shaped isotherm

MIL-100 (Fe) was selected as the reference MOF material because of its high capacity for moisture uptake ( $\sim 0.75 \text{ g}_{\text{H}_2\text{O}} \text{ g}_{\text{ads}}^{-1}$ ), and the isotherm model was mathematically formulated in Eqn (1)-(2) by using four isotherm parameters that were previously validated (Kim et al., 2024).  $q_{0,max}$  is the theoretical maximum that the MOF can take moisture inside of the structure,  $K$  is the distributional factor, which is the function of temperature, and  $m$  is the shape factor determining the steepness of the S-shaped isotherm (Sun & Chakraborty, 2014), and  $h_{\text{evap}}$  is the evaporation heat of moisture.

$$q_{eq} = q_{0,max} \frac{KRH^m}{\{1+(K-1)RH^m\}} \quad (1)$$

$$K = \alpha \exp\left(\frac{m(Q_{\text{sat},0} - h_{\text{evap}})}{RT}\right) \quad (2)$$

### 2.2 Kinetic analysis

A one-dimensional model of the AWE contactor is proposed in Eqn (3), and a linear-driving force (LDF)

model for the kinetic analysis is defined in Eqn (4). The simulation conditions, including  $K_{LDF}$  parameter uncertainty, are shown in **Table 1**.

$$\frac{\partial C_i}{\partial t} + \frac{\partial(uC_i)}{\partial z} + \rho_{ads}(1 - \epsilon) S = 0 \quad (3)$$

$$S \equiv \frac{dq}{dt} = k_{LDF}(q_{eq} - q) \quad (4)$$

**Table 1:** Simulation conditions for the numerical analysis.

Physical dimension	Value
Length (L)	200 mm
Area (A)	0.5 m <sup>2</sup>
Charged mass	2.91 kg <sub>MOF</sub> /m <sup>3</sup> <sub>Bed</sub>
Ambient conditions	
Air velocity (u)	1.0 m/s
Temperature (T)	0, 10, 20, 30 °C
Humidity (RH)	20, 40, 60, 80 %
Kinetic parameter	
$K_{LDF}$	0.5, 0.05, 0.005, 0.005 1/s

## 2.3 Key Performance Indicators

For the intrinsic performance measures of the AWE process, the average bed utilization was analyzed in Eqn (5). From an economic perspective, we introduced the cost of moisture capture (CoMC) as an objective function for stochastic programming. The detailed formulation of cost and energy was taken from the previous work (Kim et al., 2024).

$$Bed_{util}(\%) = \frac{q}{q_{eq}} \times 100 \quad (5)$$

$$CoMC (\text{¢ kg}_{H_2O}^{-1}) = \frac{\text{Annualized capital+operating}}{\text{The total captured moisture}} \quad (6)$$

## 2.4 Two-stage stochastic programming

Two-stage stochastic programming (TSSP) was developed to address the variability of ambient weather conditions and ensure the operability of the process.

To solve the 1<sup>st</sup> stage, a grid search was performed over a sufficiently wide range of capital costs. A conservative weather condition was selected to decide the upper bound on capital cost. Capital cost was evenly gridded out in the range of +/-20% of base cost as shown in Eqn (7). After defining the grid, the minimization problem in the 2<sup>nd</sup> stage was iteratively solved in Eqn (8). The binary decision variables represented whether or not to operate at a given weather condition. The  $i^{\text{th}}$  objective function was the sum of the  $i^{\text{th}}$  annualized capital cost and the expectation of the operating cost divided by the expectation of the harvesting performance. Here, the operating cost and the swing capacity were the functions of capital cost,  $C_i$ .

The more capital invested the better the performance in specific weather scenarios but with reduced effectiveness as the capital investment increases further.

The performance decreases at lower capital and eventually this reduced performance increases the overall average cost. The minimum of the overall cost was located within the grid search for all examples we have studied. Should it appear at the extreme of a range a further expansion of the grid should be performed.

By separating the decision-making process from weather uncertainties within the two-stage framework, we achieved scalable solutions for screening potential MOF candidates and identifying a favorable site.

$$C_i = \text{Grid of } [0.8 \min(C_{cons}), 1.2 \max(C_{cons}), 8] \quad (7)$$

$$\text{minimize } Obj_i = \frac{C_i \times f_{an} + E[B^T OPEX(C_i)]}{E[B^T q_{swing}(C_i)]} \quad (8)$$

## 3. RESULTS AND DISCUSSION

### 3.1 Numerical code verification

The original PDE was semi-discretized and then numerically analyzed in MATLAB using an ode15s solver. The simulation results are consistent with those simulated by the commercial software (Oh et al., 2020), gPROMS, and the relative numerical error of the mass balance in Eqn (9)-(11) was under 0.05%.

$$m_1 = Au \int_0^t (C_{init} - C_{exit}) dt \quad (9)$$

$$m_2 = (1 - \epsilon_{bed})(1 - \epsilon_s)\rho_s AL \frac{10^3}{18} \int_0^z q dz \quad (10)$$

$$Err_{rel} = 100 \times \frac{|m_1 - m_2|}{m_1} \quad (11)$$

The following section illustrates the impacts of ambient conditions and hypothetical kinetic parameters. Finally, we provide TSSP results for the example of the state of Georgia, USA, using weather data.

### 3.2 Saturation time

Saturation time gives direct information for the process design and operation variables such as the dimension of the bed, adsorption time, and required amount of MOF, etc. We showed how the saturation time changes alongside the value of absolute humidity, as shown in **Fig. 1**, by simplifying that the value is relatively unchanged during the diurnal cycle.

This fluctuation implied that the operating variable, adsorption time should be adaptively designed considering the ambient condition. Each variable was parametrically studied, focusing on the breakthrough behavior and bed saturation as follows.

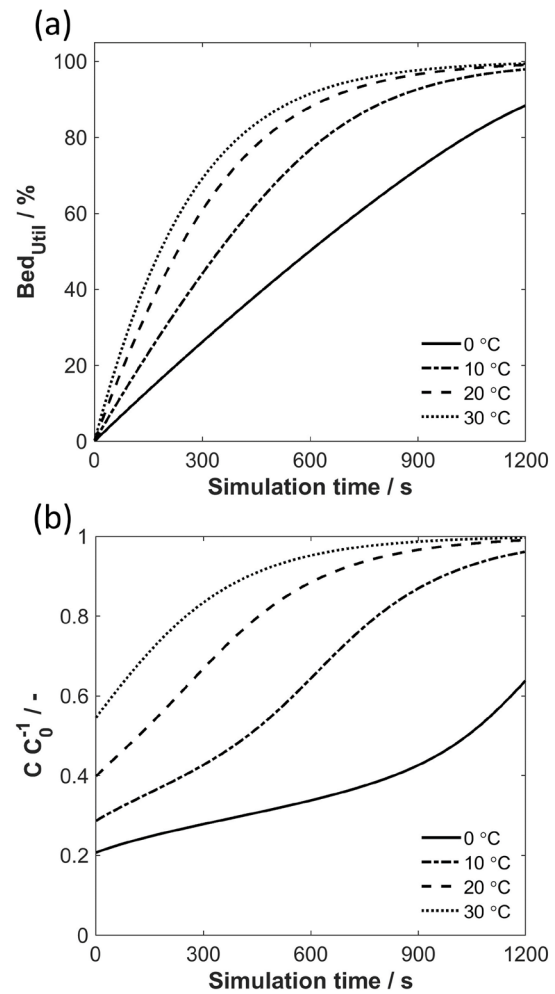

**Figure 1:** Saturation time variation according to the level of absolute humidity.

### 3.3 Effects of ambient temperature

The ambient temperature directly affects the bed utilization ratio, and the high-temperature conditions enable the bed to reach a faster saturation state, as shown in **Fig. 2a**. This was determined by the concentration difference given the fixed kinetic parameter in every condition. In **Fig. 2b**, the normalized exit concentration profiles showed that breakthrough occurred slower in the low-temperature condition, consistent with **Fig. 2a**. The experiments on temperature sensitivity should be supported to support the simulation results, which should be the future work.

### 3.4 Effects of ambient humidity

The effects of relative humidity are shown in **Fig. 3** by fixing the ambient temperature. The RH and the bed utilization were not directly related, as shown in **Fig. 3a**. Firstly,  $q_{eq}$  increased as RH increased following the S-shape. Secondly, the moisture concentration increased as RH increased linearly. These two compensated each other, causing a minimal impact on performance. Although the bed saturation behavior showed similar results, the absolute amount of moisture and the regenerability directly affect the performance, which should be discussed further. As seen in **Fig. 3b**, RH had apparent effects on breakthrough behavior. Because of the low concentration and the low  $q_{eq}$ , the driving force of moisture capture was low in low-temperature conditions.

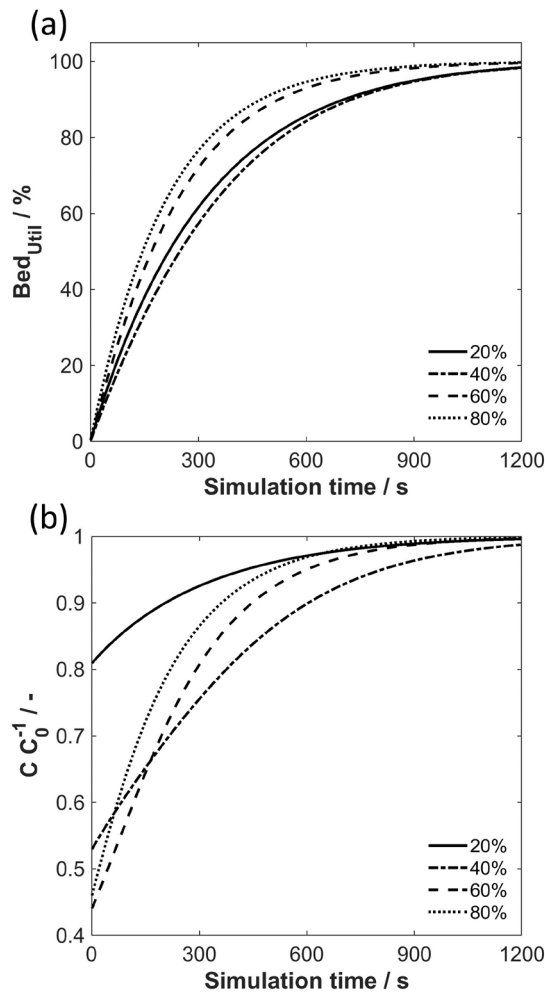

**Figure 2:** The effects of ambient temperature on (a) bed utilization ratio and (b) breakthrough curve on normalized moisture concentration at RH 50% condition ( $k_{LDF}$  assumed as  $0.005 \text{ s}^{-1}$ ).

### 3.5 Effects of kinetic parameter

Finally, the sensitivity of the hypothetical kinetic parameters was analyzed in **Fig. 4**. By taking the ranges of LDF parameters reported in the literature, the expected profiles on the bed utilization and the breakthrough were predicted. Regarding bed utilization, the impact of the kinetic parameters was asymmetric in **Fig. 4a**. As the kinetic parameters became smaller, utilization decreased monotonically. However, the utilization curve converged when the kinetic parameters became more prominent. It failed to observe the breakthrough curve in the slowest case, and the breakthrough behavior in the fastest case was observed in **Fig. 4b**.

For the stochastic optimization, we fixed the  $k_{LDF}$  as  $0.005 \text{ s}^{-1}$ , taken from the moisture uptake systems over Silica gel (El-Sharkawy, 2011).

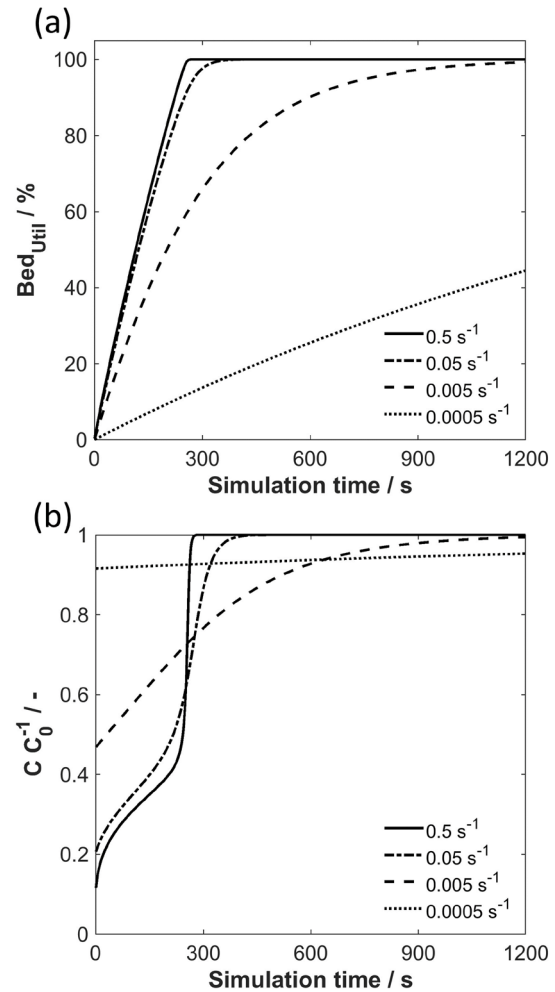

**Figure 3:** The effects of ambient relative humidity on (a) bed utilization ratio and (b) breakthrough curve on normalized moisture concentration at temperature 25°C condition ( $k_{LDF}$  assumed as  $0.005 \text{ s}^{-1}$ ).

### 3.6 Optimization results

The original weather data was plotted as a function of temperature and RH. The data source originated from the Automated Surface Observing Systems (ASOS) of daily measurements during 2022. In **Fig. 5**, probability distribution was plotted, and the 100 random samples were marked in 'x,' representing the original distribution well. The source and sampling algorithm was provided in previous work (Kim et al., 2024). Stochastic optimization was conducted utilizing the random samples.

**Fig. 6a** shows stochastic optimization results by dividing the economically feasible and infeasible regions from the programming algorithm. It was observed that the feasible region was clustered in the mild RH range (>40 %) and mild temperature range (2~25°C). **Fig. 6b** shows how the capital cost was selected in the design grid. The programming results were repeated three

times, and the average and standard deviation were plotted to consider the randomness of the sampling. The 5<sup>th</sup> grid point was selected for the first-stage decision because it balanced capital against performance and hence achieved the minimum cost without sacrificing the swing capacity. These results showed the tailored optimal solution based on selecting the optimal capital investment, operating degrees of freedom and conditions in which to operate simultaneously.

**Figure 4:** The effects of kinetic parameter on (a) bed utilization ratio and (b) breakthrough curve on normalized moisture concentration at temperature 25°C and RH 50% condition.

**Fig. 7** demonstrates the relationship between performance and cost. The color shows the economic feasibility, red or blue, for infeasible and feasible respectively. Blue has an average performance of  $0.67 \text{ kg}_{\text{H}_2\text{O}} \text{ kg}_{\text{Ads}}^{-1}$  with  $4.04 \text{ ¢ kg}_{\text{H}_2\text{O}}^{-1}$ . Red has a performance of  $0.36 \text{ kg}_{\text{H}_2\text{O}} \text{ kg}_{\text{Ads}}^{-1}$  with  $5.38 \text{ ¢ kg}_{\text{H}_2\text{O}}^{-1}$ .

**Figure 5:** Weather variability as a joint probability function for Georgia, USA, and random sampling ( $n = 100$ ) for the stochastic optimization.

### 3.7 Future work

Three areas should be expanded on to better understand the adsorption-based AWE process. First, experiments are required to refine the kinetic parameter value from the hypothetical range given here. Different temperature and RH conditions should be experimentally measured together for rigorous validation. Second, different types of material should be compared to derive the main factors that influence design and operation, including isotherm shape and moisture uptake. Molecular simulation will be appropriate for the massive screening (Zhang et al., 2023). Lastly, various meteorological sites could be investigated further, including varying the operation based on the time of day.

## 4. CONCLUSION

Based on the critical issues summarized herein, the AWE process is promising for producing fresh water. Process design and weather uncertainties are discussed together, starting from the isotherm features at the material level. This work aims to bridge the gap between material and process development to realize robust design and operation. It directs the future research of adsorption-based AWE systems in perspectives on process systems engineering. From this initial work, a generalized framework for simultaneous material-process selection in different climates accounting for weather variability can be developed in the future.

Through this work, we contribute to two areas (i) understanding the system's dynamics and (ii) quantifying the meteorological characteristics, thereby giving insights into process systems engineering (PSE) aspects of the AWE process.

**Figure 6:** Two-stage stochastic programming results for (a) the identification of the feasible weather conditions and (b) the decision of conservative capital cost from average swing capacity.

**Figure 7:** The relationship between water extraction performance and cost of moisture capture according to the weather feasibility in terms of economics.

## ABSTRACT

Superstructure optimization for process synthesis is a challenging endeavour typically leading to large scale MINLP formulations. By the combination of phenomena-based building blocks, accurate thermodynamics, and structural screening we obtain a new framework for optimal process synthesis, which overcomes prior limitations regarding solution by deterministic MINLP solvers in combination with accurate thermodynamics. This is facilitated by MOSAICmodeling's generic formulation of models in MathML / XML and subsequent decomposition and code export to GAMS and C++. A branch & bound algorithm is implemented to solve the overall MINLP problem, wherein the structural screening penalizes instances, which are deemed nonsensical and should not be further pursued. The general capabilities of this approach are shown for the distillation-based separation of a ternary system.

---

**Keywords:** Process Synthesis, Optimization, Distillation, Phase Equilibria, Phenomena Building Block

## MOTIVATION & INTRODUCTION

### Optimal Process Synthesis

Thermal separation processes make up a large part of energy consumption in the US and worldwide [1]. Given the drive to reduce greenhouse gas emissions, it is imperative to explore more energy efficient solutions, e.g., through heat integration, novel separation process concepts, or novel equipment, etc. Exploring these options is complex and a continuing challenge. Mathematical methods with mechanistic models for process synthesis help overcome this hurdle. However, process synthesis is quite a challenging field, for which Chen et al. [2] emphasize the delicate trade-off between generality, fidelity, and tractability in process synthesis methods. So far, methods for process synthesis try to reduce the search space either by focusing on individual synthesis tasks (lower generality) or by simplifying models (lower fidelity).

Synthesis methods based on rigorous superstructure optimization promise to overcome these shortcomings. Formulating and solving these process synthesis problems as large-scale mixed-integer nonlinear programming (MINLP) or generalized disjunctive

programming (GDP) problems is tough. While, it is well understood how these should be formulated, tractability is the main challenge here.

Three approaches for superstructure optimization build on phenomena-based formulations. The group of Pistikopoulos developed the generalized modular framework (GMF), which builds on a multipurpose mass / heat transfer module. GMF has, e.g., been applied for synthesis of distillation processes [3, 4] and even reactive distillation [5].

Similarly, the group of Hasan has derived abstract building blocks (ABB), which are arranged in a chessboard-like two-dimensional block superstructure. The boundaries to adjacent blocks and physical attributes of the blocks can be modified during optimization [6, 7]. The ABB formulation is highly versatile. However, application to synthesis of more complex processes so far requires simplification of the ABB model [8] or specialized iterative solution sequences [9].

Finally, Kuhlmann and Skiborowski [10] developed a Phenomena-based Building Blocks (PBB) approach. These building blocks consist of thermodynamically accurate equilibrium stage models and kinetics to form a general state-space superstructure. The capabilities of

this approach have been demonstrated for the synthesis of a membrane reactor [11] and membrane-assisted reactive distillation [12]. So far, solving the formulated MINLPs relied on an evolutionary strategy for the mixed-integer side and local solution of the nonlinear sub-problems in Aspen Custom Modeler. This heavily limits the capabilities of the solvers and poses challenges for the formulation, initialization, and solution of larger examples.

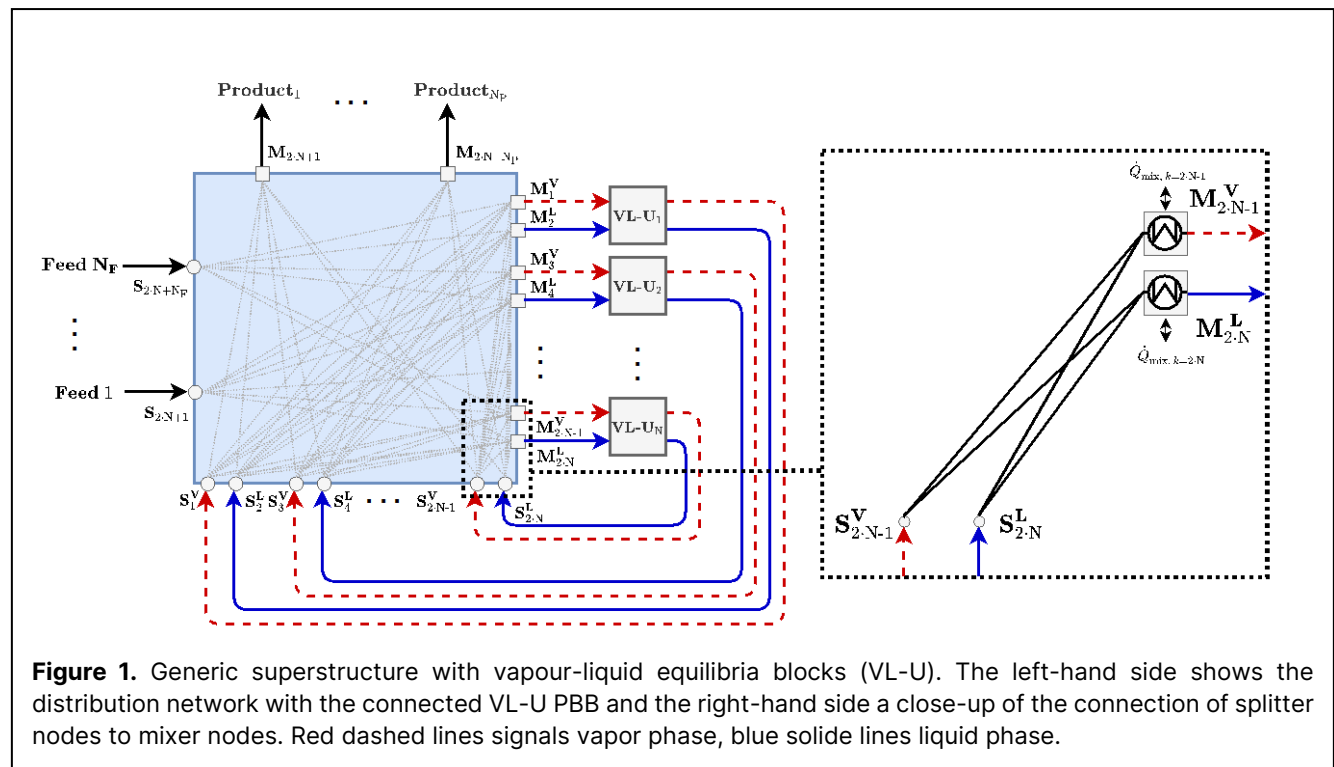

## Challenges & Approach

In the current work, the limitations of the approach by Kuhlmann and Skiborowski [10] will be addressed by suggesting a new framework for formulation and solution of the MINLP problems. In this contribution, we advance the prior work in two directions: (1) formulating and generating large-scale superstructures and (2) facilitating the solution through structural screening. Towards (1) the modeling environment MOSAICmodeling [13, 14] is here extended for the formulation of superstructures of phenomena-based building blocks and their decomposition and code generation for a target language, i.e., the modeling language for the actual solution, e.g., GAMS, AMPL, Python, etc. The implementation in MOSAICmodeling involves formulation of the superstructure problem as a meta model in MathML / XML. With this formulation, executable code for different program components can be obtained automatically, including a mathematical programming platform, an external CAPE-OPEN thermodynamic engine, and a platform for structural screening. This is achieved through the utilization of separate User-defined Language Specifiers (UDLS) [15] within the

web-based modeling and optimization tool MOSAICmodeling, developed at TU Berlin [16]. All thermodynamic property calculations are outsourced to a CAPE-OPEN-compliant property package, while the MINLP is exported to GAMS (version 40.4.0).

Towards the structural screening (2), a number of pruning and screening techniques have been previously suggested, e.g., in [10, 17]. These typically operate at a local level, i.e., the connections surrounding a module or PBB. In our contribution, we deviate from this approach and add towards screening / pruning techniques, which also analyse the entire superstructure instance. The wider perspective aligns with the axioms for generating feasible superstructures within the P-graph framework [18].

Here, a branch and bound-type algorithm is implemented in GAMS and augmented with a middle layer, which pre-screens based on binary decision variables of the superstructure. The middle layer performs a set of graph- and rule-based analyses of a structural instance, which are further detailed in section "Structural Screening". In case of violations of these rules, i.e., an instance will not lead to a physically sensible solution, this structure is penalized without solution of the underlying MINLP. While a similar concept is also present in the approach by Kuhlmann and Skiborowski [10], the MINLP framework extends the screening process with additional rules and algorithms from graph analysis.

**Figure 1.** Generic superstructure with vapour-liquid equilibria blocks (VL-U). The left-hand side shows the distribution network with the connected VL-U PBB and the right-hand side a close-up of the connection of splitter nodes to mixer nodes. Red dashed lines signals vapor phase, blue solide lines liquid phase.

# METHODOLOGY & IMPLEMENTATION

## Generic Superstructure Model

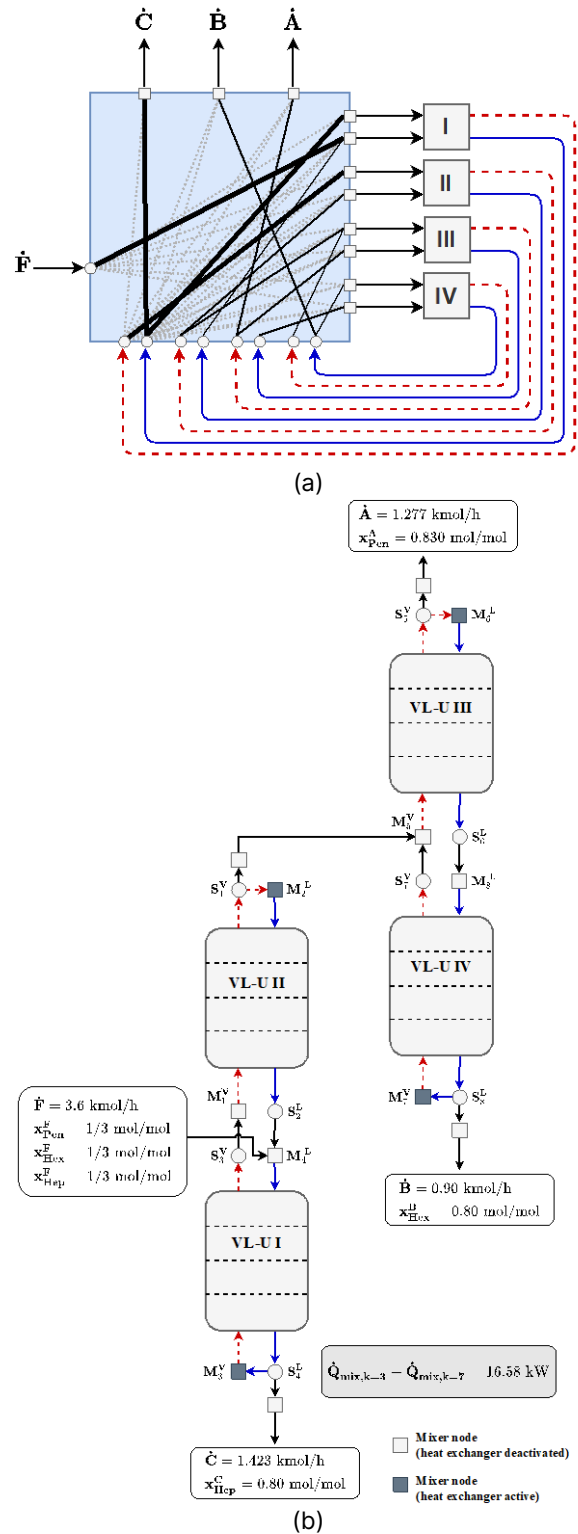

The superstructure formulated here is based on the work of Kuhlmann and Skiborowski [10], which combines a distribution network connecting feed and product streams (blue box in Fig. 1) with a fixed number of PBBs (light grey boxes in Fig. 1). The following extensions are made compared to prior work:

In the distribution network, separate energy flows for pressure manipulation and heat exchange are present. This should allow for deactivation of equipment based on (in-)existence of preceding or subsequent blocks. For the current contribution, we focus on PBBs featuring vapor-liquid equilibrium units (VL-U). In the distribution network, splitter nodes connect the recycles and inlets to mixer nodes and product nodes. Restrictions are implemented on the mixer nodes based on each connected VL-U PBB: By default, the outlet must either be in boiling liquid state or saturated vapor. Binary variables govern the distribution of splitter outlets to mixer nodes. A stream is (for now) split into at most two streams to limit computational complexity. This shall be relaxed later but is deemed for now of low importance. The distribution network changes temperatures before streams enter a PBB.

Here, the formulation for the distribution network is implemented as given on the right-hand side of Fig. 1 (dashed box). Each mixed stream flows through a heat exchanger. The temperature is adjusted according to the input requirements of the connected VL-U, i.e., heated or cooled to the respective boiling or dewpoint temperature of the mixture. Compression and expansion are implemented as isentropic state changes with fixed efficiencies. Each VL-U block is a countercurrent multi-stage contactor in accordance with Kuhlmann and Skiborowski [10]. On each stage, mixing of liquid and vapor and separation take place.

As stated before, phase constraints are enforced on both inlets of a VL-U PBB. This implies that the preceding heat exchangers must be active to ensure that the inlet is either in vapor or liquid state. Nevertheless, as a results of the superstructure optimization, combinations of the VL-U should be able to form conventional equipment, e.g., distillation towers. For these, the heat exchangers at the connecting point of two VL-U sitting "on top of" one another, should be deactivated (see, e.g., VL-U I and VL-U II in Fig. 2).

For this purpose, additional binary variables are included in the model, which (de-)active these heat exchangers and hence also the phase constraints at the respective inlet of the VL-U PBB. This allows for increased flexibility of the overall superstructure. An inactive heat exchanger is bypassed, and the fluid is supplied to the VL-U in whatever state it might currently be in.

**Figure 2.** Optimization results for the separation of a feed stream of n-pentane, n-hexane, and n-heptane by 4 VL-U: (a) resulting connections in the superstructure, (b) interpretation as a sequence of two columns.

Further details regarding the model formulation, e.g., activation / deactivation of heat exchangers, can be

found in [19].

As a result of deactivated heat exchangers, the superstructure also allows, e.g., a vapor stream to enter a VL-U by its dedicated liquid inlet. In addition to this, further uncommon situations within each VL-U may arise during superstructure optimization. Therefore, the VLE formulation on each stage of the VL-U is augmented by relaxation through complementarity constraints [20, 21] as shown in Krone et al. [13] to account for liquid-only or vapor-only scenarios on each stage.

For a given synthesis task, we implement an objective function, which minimizes the total annualized costs consisting of investment costs for heat exchangers, and operation costs for heating utilities. A penalty term is added to the objective for regularization of the complementarity constraints. The penalty converges to zero at a feasible solution.

### Thermodynamic Properties

Within the MathML / XML model in MOSAICmodeling, all thermodynamic properties are denoted as external function calls, i.e., enthalpies, entropies, equilibrium coefficients, temperatures of boiling or dew point. For these, only the appropriate input variables are assigned to compute the desired output, e.g., enthalpy as a function of temperature, pressure, and composition. These are linked in accordance with the CAPE-OPEN standard for thermodynamic engines using COBIA (version 1.2.0.8) as architecture. TEA (version 3.5) provided by AmsterChem is used as thermodynamic engine.

### Code Generation and MINLP Framework

The novel MINLP framework is illustrated in Fig. 3. Starting from MOSAICmodeling, code is automatically

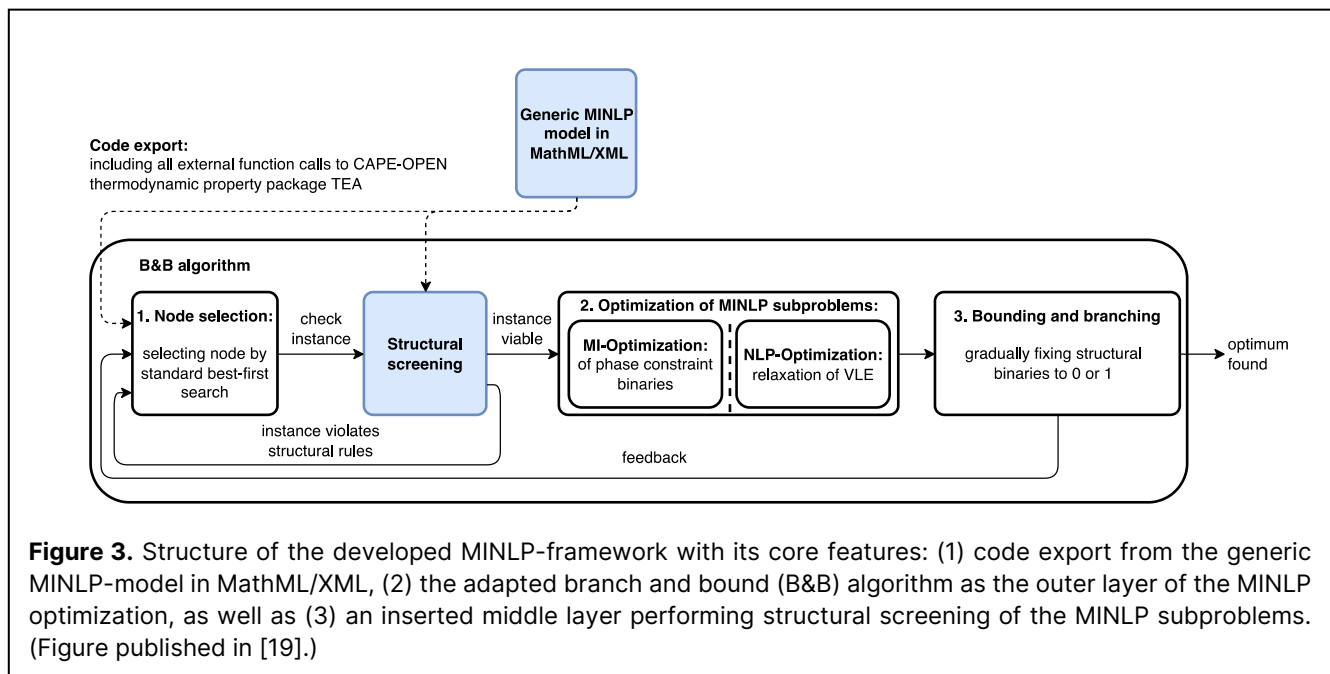

generated for GAMS and C++ (see Krone et al. [13]). The GAMS code then contains the entire MINLP including the state-space superstructure. The thermodynamic properties are marked as external equations and further detailed in the linked C++ code. Therein, the prerequisites for CAPE-OPEN function calls and the COBIA architecture are implemented, function values and derivatives are obtained and returned to GAMS. The overall system is a mixed integer nonlinear programming (MINLP) problem. There are two types of binary variables for the superstructure and for activation or deactivation of phase constraints of the mixers in the network. The superstructure variables by themselves cause a very high computational complexity.

Tractability of the problem is achieved through an augmented solution strategy: The MINLP is solved by a branch and bound algorithm combined with a middle layer that analyzes individual structures. For details on the branch and bound implementation see [19] and [22]. This is implemented in GAMS. The middle layer with the structural screening, however, is formulated within MATLAB (version R2023b).

In each iteration of the branch and bound solver, the current structural instance is passed on to MATLAB, where the screening is carried out regarding the rules specified in the section on “Structural Screening” below. These subproblems are still MINLP as there are further binaries, which are not elemental to the superstructure but form further options within the model formulations, e.g., phase constraints (see above).

### Structural Screening

As a novelty of our contribution, we employ graph- or network-based constraints in addition to algebraic

constraints. At the moment, we assume that the graph-based constraints can only be resolved (efficiently) algorithmically and not implemented as algebraic constraints in a straightforward fashion. This remains to be analyzed in future work.

For graph-based analysis, the current superstructure is exported as a directed graph. The following seven rules are implemented to screen structures at intermediate iterations of the branch and bound algorithm; three of the rules implemented for structural screening are formulated similarly to [10]:

Rule 1: An active VL-U PBB without a connected stream to the inlet mixers needs to be avoided. This PBB will be considered degenerate and the according structure is discarded.

Rule 2 (cf. [10]): During superstructure optimization, it could occur that a subsection of a structural instance is not connected to any feed or product streams – not even indirectly, i.e., a structure which is fully closed to the outside. Such a substructure might cause a host of numerical issues, definitely does not contain any added value, and will hence be discarded.

Rule 3: Within the superstructure several equivalent formulations exist. One example is the interchange of two split streams. To limit the number of equivalencies, rule 3 is implemented to ensure that a connected product node is always served by the first split stream coming from a connected splitter node.

Rule 4: Connections to the product outlets, which appear nonsensical, should be ruled out. For example, this includes connection of two splitter nodes in the distribution network to a product node. This is deemed to be unnecessary entropy generation.

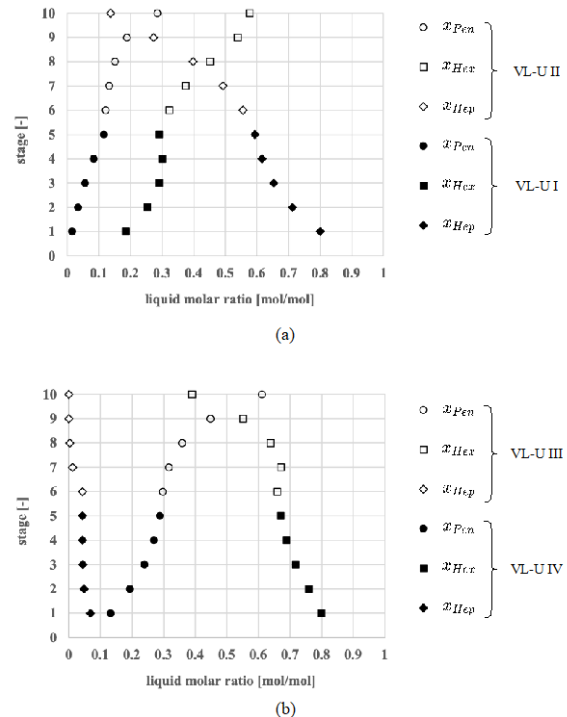

Rule 5 (cf. [10]): A stream that leaves a VL-U PBB should not be fed back to an inlet of the same VL-U PBB. This is considered a “direct recycle”, which also does not appear to be logical from a thermodynamic point of view.

Rule 6: The two inlets of a VL-U PBB should not originate from the same splitter node. Yet again, this rule should be well-founded in thermodynamic considerations and always apply to PBBs of type VL-U.

Rule 7 (cf. [10]): Two outlet streams of a VL-U PBB should not be fed back to the same mixer node. This would counteract any previously achieved separation and hence also amounts to entropy generation.

## CASE STUDY

The formulation described above is applied on a process synthesis task to separate a mixture of n-pentane, n-hexane, and n-heptane by a network of up to six building blocks each representing a counter-current cascade of five vapor-liquid equilibrium stages (VL-U).

**Figure 4.** Liquid composition profiles inside of the optimal structure determined for the separation of an n-pentane, n-hexane, and n-heptane mixture by 4 VL-U: (a) liquid molar ratios on the stages of VL-U I & II, (b) liquid molar ratios on the stages of VL-U III & IV.

This leads to an optimization problem with 1303 (in-)equalities, 62 binary, and 1123 continuous variables. The problem is implemented in MOSAICmodeling and solved in GAMS combining the branch and bound solver with DICOPT [23] for MINLP subproblems, CONOPT3 (version 3.17) [24] for relaxed MINLPs, and IPOPT (version 3.14) [25] for NLP subproblems. The structural screening in Matlab is performed in each iteration of the branch and bound solver.

For now, the system pressure is fixed at 100 kPa and the desired product qualities are specified at purities of 80 mol/mol % each for n-pentane, n-hexane, and n-heptane. The feed stream is specified at 3.6 kmol/h as saturated vapor and features equal amounts of all three components.

## Results

Fig. 2 shows the results for four VL-U PBB in the network (a) and an interpretation as a sequence of two columns (b) and Fig. 4 shows the respective liquid mole fractions of all three components. The results appear to be consistent and are cost-optimal compared to alternative configurations.

This result is obtained after 94 iterations of the Branch & Bound algorithm with roughly 172 h of CPU time. Computation is done on an Intel® Core™ i7-2600

processor (3.8 GHz and 4 cores) with 16 GB of RAM. This is still quite computationally expensive but shows the general feasibility of the overall approach. It should be noted at this point that no particular initialization strategy is applied for the continuous nonlinear variables during the superstructure optimization. Each MINLP and NLP subproblem is solved with the currently available prior values. We assume that a considerable speedup could be achieved by implementing some kind of rigorous initialization strategy or homotopy to guide the NLP solver to the solution.

We would like to stress at this point that all these results are obtained using no specific / manual initialization of the state variables. At the moment, all variables are initialized at the mid-points of their intervals. This mediocre initialization will cause a large part of the CPU time. Furthermore, the VLE formulation including the interfacing via CAPE-OPEN is not yet very efficient. In future work, we shall evaluate different formulations for the external computation to achieve a speedup. Prior work by [11, 5] promise a sizable speedup using different formulations.

The inclusion of the structural screening procedure proved to be vital for the overall set-up. Without the middle layer, the optimizer failed to solve the system at all. In our case studies, we observed behavior which we interpret in two different ways: First of all, some of the otherwise penalized nodes in the branch & bound algorithm consume a lot of time and typically the solution is aborted based on our maximum of around 1000 h. Second, solution to local infeasibility of some of the otherwise penalized subsystems leads to a degradation of the initial values of all continuous variables, which causes infeasibility in a subsequent node, which might otherwise have been successfully solved.

Of the 94 iterations, 23 iterations involved penalization of the current structure based on the screening rules. In these cases, the lower-level solvers would otherwise have probably failed to solve to any reasonable solution, so this also implies a great save in computational expenditure. Overall, we can observe a great contribution of the structural screening and pruning towards ensuring feasibility of these type of MINLP problems. Given that without screening, the optimization did not converge to a feasible solution within the given time frame, we cannot further quantify how great the speed-up due to the structural screening is.

## CONCLUSIONS & OUTLOOK

The presented, novel approach for formulation and solution of process synthesis problems through superstructure optimization can reliably solve the challenging MINLP determining the optimal structure of a separation train and find its energetic optimum. The implemented

structural screening is vital to ensure solvability depending on the problem formulation at hand.

The main advantage in using the MathML / XML-based model formulation lies in flexibility regarding setting up even larger superstructure problems and in flexibility regarding the solution environment. A switch from the GAMS / MATLAB / C++ combination to, e.g., a Python-based setting should be straight forward.

In future work, we shall attempt to further decrease the computational complexity by employing GDP-type formulations for the superstructure and export the model to other platforms, e.g., PYOMO, to speed up the solution and make use of state-of-the-art GDP solvers. Also, we will investigate reduced order models to implement the initialization of the structural instances during the optimization.

## ABSTRACT

Within an Industry 4.0 framework, a variety of new considerations are of increasing importance, such as securing processes against cyberattacks on the control systems or utilizing advances in image processing for image-based control. These new technologies impact relationships between process design and control. In this work, we discuss some of these potential relationships, beginning with a discussion of side channel attacks and what they suggest about ways of evaluating plant design and instrumentation selection, along with controller and security schemes, particularly as more data is collected and there is a move toward an industrial Internet of Things. Next, we highlight how the 3D computer graphics software tool set Blender can be utilized to analyze a variety of considerations related to ensuring safety of plant operation and facilitating the design of assemblies with image-based sensing.

**Keywords:** Industry 4.0, Dynamic Modelling, Nonlinear Model Predictive Control, Simulation, Cybersecurity, Instrumentation, Image-Based Control

## INTRODUCTION

Industry 4.0 is introducing new considerations in production environments, including considerations with respect to cybersecurity, imaging, and control. While these concepts are important considerations for process operation, they also have implications for next-generation design selections (and their interactions with controllers). This work considers the implications of cybersecurity concerns and the application of image-based control on the specifications and design of modern-day processes, as well as their coupling to controllers.

## CYBERSECURITY

In this section, we use a discussion of cryptography and side channel attacks to present possible future research directions related to the intersection of process design, control, and cybersecurity. Traditionally, cybersecurity has been considered to be a problem most relevant to computer scientists and information technology (IT) professionals. The details of how attacks occur can

require an understanding of details of computer hardware and software that typically go beyond traditional chemical engineering fundamentals (e.g., understanding operating system fundamentals related to bootloaders, kernels, and assembly language). However, there has been a growing interest in investigating the relevance of cybersecurity to chemical engineering decisions (e.g., process control [1,2]). Cybersecurity has also begun to be discussed from a process design perspective. For example, in [3], we discussed how different designs lead to different worst-case operating conditions under an attack (similar to an inherent safety perspective). [4] refers to using a Computer Systems/Controls Hazard and Operability Analysis, highlighting interactions between the design of the computer systems and controls safeguards and the process design. This section seeks to make additional connections between process design and control system cybersecurity, with the intent to showcase potential directions in which the process design community might be able to contribute to securing systems in a manner that seeks to promote efficiency. We focus on two areas: design concepts inspired by active detection strategies, and design concepts inspired

by side channel attacks.

## Design Lessons from Active Detection

In the first of the two cybersecurity design perspectives, we discuss learnings from our recent work in cybersecurity of control systems. Our prior work has investigated how to use control signals to disturb the process operation in a manner that would be (ideally) difficult for an attacker to predict, such that they are unlikely to evade detection because they will create process state trajectories that are not in accordance with operating expectations [5,6]. Active detection strategies such as these that attempt to probe for attacks have an advantage over passive detection strategies that they can attempt to use clever operating policies to make it difficult for an attacker to remain undetected. However, they also disrupt operation and thus may be challenging to use in practice. However, this raises the question of whether equipment could be designed that could facilitate locally disruptive behavior but global meeting of process specifications (e.g., through designs that might promote mixing in some areas and laminar flow in others to attempt to allow for active probing with certain cleverly placed actuators and sensors within the design but in a manner that would overall have a minimal impact on actual process output/performance). This analysis indicates that one potential future direction in process design (and particularly in simultaneous design and control) is to analyze whether process and equipment designs that promote an ability to probe for cyberattacks using controllers could be developed.

## Cryptography and Encryption

The second potential design direction related to cybersecurity that we discuss is inspired by side channel attacks that attempt to locate decryption keys by monitoring the power supplied to a computing system. To facilitate the discussion, we begin with a high-level discussion of encryption and then of side channel attacks, and then discuss a conceptual example indicating the potential direction in process design for cybersecurity.

### An Overview of Cryptography

Cryptography has received attention in a control context, including with respect to strategies referred to as homomorphic encryption which is a method that allows for certain mathematical operations to be performed on ciphertext such that the decrypted result of an operation on two ciphertexts is equal to the result of operating on the corresponding plaintexts. This has been considered of interest for investigating the implementation of control laws on encrypted data on the Cloud to attempt to improve the privacy of information which might be sent to the Cloud for processing (e.g., [7,8]). A fundamental aspect of cryptography entails the encoding of publicly-readable 'plaintext' into 'ciphertext' (i.e., encrypted data)

such that meaningful information can only be retrieved by intended parties. A popular kind of encryption is public key cryptography, which utilizes two separate keys to encode and decode information. This is done so that any party may encrypt a message using a widely available public key, but only the intended recipient has access to the secret key needed to decrypt. Public key cryptosystems have four main components: the public key, the secret key, and the encryption and decryption algorithms.

One way to promote privacy of information transferred throughout a control loop is to encrypt state measurements to be sent to a controller, where they must then be decrypted before computations can be performed. The resulting control action is then re-encrypted and returned to the actuators to be decrypted and actuated. This setup protects against so-called man-in-the-middle attacks, in which private information is intercepted in transmission. However, in general, side channel attacks can lead to information being obtained from a computing device that might reveal encryption keys. Thus, we discuss side channel attacks in the following section.

### Side Channel Attacks

Side channel attacks take information from the processes that generate them [9]. This information is known as a trace. Operations in circuits follow cryptographic algorithms, and the implementation of these cryptosystems can leak data about these operations. For example, timing of the messages may reveal information. Power usage is a form of information leakage as a computer would use different amounts of power based on what it is computing. There are different types of power analysis (e.g., differential power analysis (DPA) and simple power analysis (SPA)). As a side channel attack, the focus is on data leakage from an encryption-decryption process. The cryptographic operation will require power as the device computes and this is where the data leakage occurs.

[10] details how power consumption is directly related to data transmission. Data busses, metal wires within the circuitry, function as mini capacitors by charging and discharging as they transfer data between device components. This charging and discharging consumes power. In a data bus, there is a power line, or rail, that represents the states 1 or 0, and there is a ground line. Data is transmitted as states of on, 1, or off, 0. The size of the bus determines how many bits of data can be transmitted. As data is processed and transferred, electronic switches known as FETs, or field-effect transistors, open and close depending on the state.

The state can change depending on what the bit needs to be set to in the data. To change the state, charge is applied or discharged and this requires some work to be done and power consumed. On a data bus line, the transmission follows a counter and every time a bit is set to either 0 or 1. The electronic switches control

the state; if the bit is first set to 0 and then set to 1 in the next iteration, the power rail switch will close and the ground rail switch will open. When the power rail switch closes, 5 volts is now being supplied and the bit is set to 1, or “on”. The 5 volts supplied increases the power consumption, which when graphed visually could be represented by a spike in power consumption. This is important to a side channel attack because data sent through the chip will travel through these data busses, having an effect on the power consumption of the device. As there is a change in state and power is consumed, we can consider that power consumption is equivalent to the number of bits set to 1. Then, when trying to attack a system using power analysis, one can look for similarities in power consumption.

In [11], an example in which plaintext interacts with a secret key through the exclusive or (XOR) operation is performed (XOR yields a true output if only one of two conditions is true); this output is then sent to a look up table of values, which are further processed. Information is obtained after some of these operations from the circuit toward guessing keys for the encryption.

The purpose of a power analysis attack is to find patterns in the power consumption. We would expect that the number of bits set to 1 relates to power consumption, so the power consumption should be similar for outputs that share the same number of 1’s. When attacking, multiple attacks will be done to test different hypothetical keys and then an attempt will be made to determine which key is best supported by the power consumption data. Using the model of encryption and decryption with the hypothetical keys, one can obtain a hypothetical output, with its number of ones. If one of the keys chosen was right, the number of ones should relate to the power consumption, and correlations should be present in the data when evaluated for multiple rounds of the hypothetical key.

A power attack is considered a physical attack because, for example, a digital oscilloscope managed by a computer would be connected to the device under attack. While the device performs its rounds of cryptographic operations, traces of the power consumption are recorded and stored on a computer with the corresponding cryptographic data. Then, an informed guess is made for what selection function to use when partitioning the sets of traces into subsets for the averaging step used for determining if correlations exist between the partitioning strategy and the power consumption data (an example of a selection function is the predicted value of a certain bit). A piece of the hypothetical key is related to selection functions that will be used to define the subsets of traces. The averages of the subsets defined by the selection function outputs are computed for each selection function used in the previous stage. The final stage of

analysis is to analyze the test results with either data visualization or data automation, like scripts, to determine which of the hypothetical keys is best supported by the data to be the unknown key. With the key, one can work backwards to the original plaintext.

## Concepts for Process Design

Power analysis targets the consumption of power in a device to glean information from the possible operations underway; this raises the question of whether an industrial process leaks information that is intended to be encrypted or otherwise protected from attackers. To demonstrate one concept, consider an extreme case in which a process is designed where the process dynamics are fully known, and it is desired to keep track of the energy consumption of the process as a whole since that might be reflective of a sustainability objective. If the power requested of the actuators is exactly what is applied, and the only other sources of power usage are in executing known computations (except the encryption schemes), there may be a possibility that the data on the power usage could contain some information of value in a type of side channel attack based on the discussion above. This indicates that another potential direction for process design (and its intersection with control) with respect to cybersecurity is attempting to identify how process designs, combined with the measurements being taken in an era of Big Data and the industrial Internet of Things, may or may not cause hidden details of algorithms intended to promote security and privacy to be compromised.

## IMAGE-BASED CONTROL

In this section, we move away from the discussion of cybersecurity in process design toward a discussion of the role of an 3D graphics tool set called Blender in design principles, both related to how to design/research safety monitoring strategies (with the aid of simulations that allow testing of visualization components) and in the design of advanced assemblies with image-based actuation.

### Blender

Blender is a 3D graphics tool set with capabilities for modeling, animation, and image rendering. It contains a Python interface that can be used to interface codes with the animations, providing a framework for testing ideas for design and control that require an image component. Our group has recently begun to investigate the potential of the 3D graphics software Blender toward image-based control design, with an example of a render of a rod moving stochastically and under a control policy selected based on value iteration [12]. The image-based control simulation performed using the rod utilizes the coloring of the rod at both ends to help differentiate the

rod from the background for the image processing algorithm. If the rod does not have these types of features, procedures such as edge detection may be required to help identify the boundaries of the rod, and the different sides of the rod may not be visually distinguishable. This example indicates that the selection of the process design (e.g., how the visuals will appear in a camera) can directly affect the available image-based control techniques and methodologies, again highlighting an intersection between design and control for next-generation manufacturing systems. The remaining examples of this section that utilize Blender (focused on object detection for safety purposes and materials design) highlight other potential uses of Blender in ensuring safe plant operation and in setting specifications of advanced assemblies as a step toward designing them.

### Object Detection and Safe Processes

One of the key features of Blender that suggests its utility for researching the testing and designing of safety features at a plant based on images is that it has both visualization capabilities as well as an ability to import image processing Python packages that can then be used to analyze images generated from the software. To showcase this, Blender was used to represent hose and nut assembly shown in Fig. 1, where an object detection algorithm was created utilizing the Python API. The first objective of the code is to create an animation of the nut being loosened, recording a series of key frames. A second Python code was then created that performs an image detection algorithm. The position of the nut is determined by calculating the changes in red channel values in pixels between adjacent pixel rows and columns and subsequently using these to determine a central point as the location of the nut.

**Figure 1.** A render of the hose and nut assembly represented in Blender.

Another key opportunity for using Blender to aid with the design of safety enhancements at a plant is that it can be used to represent non-process components as well, such as human interactions with a process. To see this, consider the human walking in a hose room at a plant as modeled in Fig. 2. One idea for a safety algorithm would be to use images to capture the position of a human in this room and then to map those to whether the human is in a safe or an unsafe area. Without a visuali-

zation software such as Blender for testing such an algorithm, it may be harder for a process systems engineering researcher to contribute to the development of algorithms which can be used for image-based safety enhancements unless they had a physical system. Blender opens the option of being able to generate images for which tests of whether a proposed safety-enhancing algorithm is applicable can then be tested in simulation for research purposes and for better safety algorithm design. For example, using the Python programming interface in Blender, the coordinates of the human can be extracted in the image in Fig. 2 to serve as a ground truth and then compared with any coordinates obtained from an image processing algorithm to analyze how accurate the proposed image processing algorithm is. Blender thus presents a possible strategy for testing non-traditional safety monitoring components.

**Figure 2.** An image of a human walking in a hose room.

### Image-Based Control in Assemblies: Blender to Aid with Specification Determination

In this section, we describe another potential use of Blender toward design, in this case focused on how it might be used in first steps toward designing complex assemblies where images are a component. In this example that showcases its potential, we focus on a stimuli-responsive material, and how to set high-level specifications for how it should respond to visual stimuli that could then be passed downstream in the design pipeline to those who design the molecular structure to see if the material can be designed to meet those specifications that were elucidated through the Blender simulations. Stimuli-responsive material assemblies which react to external signals, including optical, audio, chemical, temperature, and physical signals by means of changing configuration, from the macroscopic assembly to molecular, may have many interesting applications in the future. In this section, we explore the process of creating an initial design of an optical stimuli responsive material assembly. An important aspect of any design phase which we expect to be incorporated in the design of stimuli responsive materials is simulation, in order to understand the dynamics of the material assembly's behavior as well as

controller performance under certain situations; as a motivating example, we develop a simulation within the 3D graphics software Blender to provide insights on what considerations should be made in the design of an optical stimuli responsive material assembly.

### Material Assembly with Image-based Control

In this example, we explore a potential use case for a stimuli-responsive material assembly which is useful when handled properly, however potentially destructive or harmful when misused or exposed to undesired situations. The concept is that we would like to design a strategy for causing this material to “sense” that it is going to be used in the harmful way, and then to break apart when it thinks it will be used in this harmful way to prevent harm. This is a complex design concept that raises many questions, both in terms of how the material should be physically designed (e.g., which molecules may even achieve such a goal), as well as a from a control and sensing point of view. However, we argue that a first step toward attempting to develop such an assembly is to attempt to design the specifications that we want it to follow, which are not obvious. For example, one could consider many ideas for how the assembly should be set up. The material might be intended to break apart immediately when it sees some type of negative signal in image data, or might be intended to do so gradually. The type of negative signals in the images should also be defined to enable testing of whether the proposed material design would work as intended or whether there would be unexpected corner/edge cases for which it breaks in an undesired manner. We suggest that the flexibility of Blender for simulating objects and their interactions physically and through image processing makes it an interesting candidate for developing potential scenarios, evaluating different “breaking” concepts in these scenarios, and then ultimately providing a test framework to evaluate whether the developed algorithms perform as intended in new scenarios (i.e., in the presence of new image-based sensor signals). In the remainder of this section, we show with a simple case study how Blender could be used toward such pathfinding studies for setting specifications for advanced assembly designs involving image sensing, which serves to suggest Blender’s utility for further use and investigation in this direction. This also is meant to motivate discussion on how new paradigms in material design and control are thought of and how they may be used to improve physical safety and provide a line of defense against physical attacks on a system.

We use Blender to create a simple macroscopic model of a non-specific material assembly composed of four blocks connected in a row down the x-axis. Attached to the first block on the long side is a camera pointed away from the assembly down the y-axis, providing optical sensing of the environment. In the camera's field of

view is a block which rotates around the z-axis, where each face is a different color, representing different stimuli. These stimuli will be used to indicate whether the block should “break apart” or not. Views of the environment with the assembly and rotating block are shown in Figures 3 and 4 where a camera can be seen attached to the assembly and facing the rotating block. The camera's initial view of the rotating cube is shown in Figure 5. We assume the assembly is equipped with a controller and actuation capable of separating the end block from the rest of the assembly. The simulation begins with the camera looking at the black face of the rotating cube; when the block rotates to reveal the blue face, the controller “breaks” the cube farthest from the camera off of the assembly. As the cube rotates, each time the center pixel changes colors, another block is broken off of the assembly until only the block with the camera remains.

Figure 3. Initial view of assembly and rotating cube.

Figure 4. Alternate initial view of assembly and rotating cube.

Figure 5. Initial view of rotating cube from the camera.

More specifically, Blender's Python API is used to initialize the scene described above, where four identical, non-interacting  $2 \times 2 \times 2$  unit cubes are placed in a row down the x-axis. The first block is centered at  $(0,0,0)$ , the second block at  $(2,0,0)$ , and so on, so that the blocks are placed to give the appearance of an assembly. Each block is placed with a rotation of  $(0,0,0)$ . The camera is

placed on the block centered at (0,0,0), with a position of (0,1,0) and rotation  $(\pi/2,0,0)$ . The rotating block is placed down the positive y-axis at (0,8,0) with a rotation of (0,0,0). Each of the faces on this block has a different base color, four of which will be seen as the block rotates (the "bottom" and top" faces are both colored black for simplicity). The colors are set using RGBA values (red, green, blue, alpha), where blue is (0,0,1,0), green is (0,1,0,0), red is (1,0,0,0), and black is (0,0,0,0). The block rotates around the z-axis according to the dynamic equation  $\frac{d\theta_z}{dt} = \frac{\pi}{2}$ , numerically integrated using Euler's method with a time step of 0.001 h. At every sampling period  $\Delta = 0.1$  h, a 1920x1080 pixel image of the rotating cube is rendered to a portable network graphics (PNG) file, reflecting the taking of an image by a camera sensor as a measurement of the system. This image is processed by first opening it using the Python package Pillow and loading the image's pixel map to a matrix and checking the RGB value of the center pixel (960,540) to determine which of the four colors it corresponds to. The controller has four modes of action, one associated with each of the possible colors the center pixel can hold in this simulation. Specifically, when the center pixel is black, no action is taken. When it is blue, the first cube is moved away from the assembly. When it is green, the first and second cube are moved away from the assembly, and when it is red, all three cubes are moved away from the last cube holding the camera. When signaled, each cube moves down the x-axis according to the dynamic equation  $\frac{dx}{dt} = 2$ , again numerically integrated using Euler's method and the same time step as before. The simulation is run for 2 h (equating to one full rotation of the rotating cube so that each control action is performed).

In this simulation, control actions are applied at the beginning of each sampling period based on a signal received from the image. Figure 6 demonstrates the control action applied to the first block. Specifically, at time  $t = 0.2$  h, no control action has been applied as the black face still occupies the center pixel. Between  $t = 0.2$  h and  $t = 0.3$  h, the blue face crosses over the center pixel, however the control action is not applied until  $t = 0.3$  h when the first block begins to break off from the assembly.

**Figure 6.** View the assembly and camera view of the first

control action taken at  $t = 0.3$  h (bottom left; the effect of the action at 0.3 h is shown at 0.4 h on the bottom right) compared to the system at  $t = 0.2$  h (top left; the effect of the action at 0.2 h is shown at 0.3 h on the top right).

### Remark 1

One important step in verifying the performance of the controller was determining how to use pixel data to set the behavior of the controller. In this simple case, this was "calibrated" by determining the RGB value returned by the loaded image for each color in the set of colors the controller is to see, where black corresponded to a value of (9,9,9), blue to (9,9,73), green to (9,73,9), and red to (73,9,9). When the image processing algorithm returned one of these values, a control action associated with the value is applied. This however is highly idealized; many aspects which require consideration in real processes could be analyzed using this testbed, including the effects of material properties, lighting properties, and sensor measurement noise. For example, one could imagine that instead of one discrete pixel value being used to represent a color, a range of similar values may be needed to account for variations caused by lighting, or perhaps similarly a number of pixels may need to be analyzed so that pixels affected by intense lighting variations such as glare do not negatively impact the controller.

### Remark 2

Colors were set using filter intensities between 0 and 1, however .PNG files store the values between 0 and 255. It is noted that the value of the pixels read back may not correspond to what is expected analytically; for example, setting the color blue as (0,0,1,0), one may expect a read back of a blue pixel to be (0,0,255) (where the alpha filter is not considered), however, a value of (9,9,73) was found. This sheds light on how the complexities of using a simulated environment for setting colors as well as capturing and processing images need to be carefully considered in the design of a controller which utilizes image data.

### Remark 3

The assumptions that the assembly is equipped with a controller and actuation is non-trivial. With regard to a controller, depending on the size of the assembly, it may be difficult to integrate the proper hardware with the assembly. Similar problems arise with actuation, however this is further complicated by considerations of the dynamics of the assembly which are desired under a stimulus. For example, the controlled material assembly in this simulation can be thought of to be progressively "breaking" as it is exposed to certain optical stimuli; depending on the design and material of the device, it may be difficult to not only actually provide actuation which breaks the device, but is also able to perform the action

to receive a deterministic result.

#### Remark 4

The idea of progressively breaking the material assembly reflects the desire to make material changes in a reversible or continuous manner. The reason for this is that, especially when dealing with intention, uncertainty may arise where it may be desirable from a safety perspective to begin to take actions to disable the device pre-emptively before any harm can be done, but the function of the assembly may also be lost when actions are taken to disable the device in the case harm is present (i.e. the device breaks before harm can be done). This motivates the use of a simulation test bed to fully characterize the control behavior under a wide variety of possible conditions.

#### Remark 5

The choice of having the controller only move one block at some times and one or more at other times was arbitrary and made so that the blocks do not collide after "breaking" off of the assembly. Many different assembly and actuation models of varying complexity could have been considered here depending on the intended function of the material assembly. Instead, this simulation is intended to demonstrate the potential for Blender to be used as part of a testbed framework for developing optical stimuli responsive materials, including those equipped with intent recognition.

#### Material Assembly with Image Prediction-Based Control

Utilizing the same simulation, we now demonstrate the integration of image predictions in the control law. Specifically, at each sampling time, the controller receives an image of the current system (i.e. an image of the rotating cube from the camera attached to the material assembly). By integrating the dynamics of the rotating cube forward in time, predictions of future images captured by the assembly camera can be generated by Blender and used to preemptively signal control actions to be applied. In this simulation, the dynamics of the system are integrated forward in time to produce image predictions at 0.1, 0.2, and 0.3 h into the future at every sampling time. Using the same algorithm to determine control actions (i.e. analyzing the color of the center pixel of each image), each predicted image is processed. In the current algorithm, the control action signaled by the prediction from 0.3 h in the future is applied at the beginning of the sampling period (this is demonstrated in Figure 7 where the image prediction for  $t = 0.3$  h signals the first block to begin to break off at the beginning of the first sampling period at  $t = 0$  h, where the effect is shown at time  $t = 0.1$  h in Figure 8).

**Figure 7.** At the beginning of the first sampling period at  $t = 0$  h, the controller receives the top left image. The controller integrates the dynamics of the rotating cube forward in time to produce predictions of the image it will see at  $t = 0.1$  h,  $t = 0.2$  h, and  $t = 0.3$  h in the future.

The ability of the controller in this simulation to pre-emptively act based on predicted images demonstrates how the behavior of image responsive systems (in this case, an image responsive material assembly) can be compared with and without image predictions to design a desired response. Further testing may be conducted to tune the desired controller response; for example, consider that the response of the predictive controller in the example above is considered too aggressive in the sense that control actions are being applied based on predictions of images which are too far in the future (i.e. irreversible control actions are being applied based on predictions which we are less confident in). It may be desired to change how the control signals are used, for example using the prediction from 0.1 h in the future (instead of 0.3 h) to signal the controller, or changing how the controller responds to signals (such as breaking each cube off of the assembly at a slower rate) to achieve a desired response. This indicates that Blender may be used as a simulation testbed to design controlled material assemblies and tune aspects of their behavior, including control design and the integration of image predictions, as well as image processing algorithms. These simulations more broadly showcase the ability of Blender to be used to develop simulations which facilitate the testing of integrated image-based and image prediction-based control strategies and image processing algorithms.

**Figure 8.** View of the assembly at  $t = 0.1$  h after the predictive controller signaled a control action at  $t = 0$  h to

break the first cube off the assembly.

## Conclusions

This work provided a perspective on two areas in which process design (and its integration with control) could be impacted, and new avenues opened, by Industry 4.0 considerations related to control system cybersecurity and the use of image-based control and safety systems. We began with a discussion of two ideas of potential avenues for cybersecurity in process design, one which was inspired by the impacts of active attack detection mechanisms on process objectives (i.e., that designs be developed which can facilitate probing for attacks during operation but without impacting overall profits) and one which was inspired by the ability of power supply attacks to use physical measurements on a computing device to backtrack encryption information (i.e., that designs and instrumentation/information availability strategies be analyzed for whether they have any ability to leak information that could reduce security/privacy). We then discussed the potential utility of Blender for testing various considerations related to images in next-generation manufacturing systems design, including in the design of safety monitoring schemes, as well as for advanced assemblies (e.g., stimuli-responsive materials that should respond to certain image data).

## ABSTRACT

The determination of the design space (DS) in a pharmaceutical process is a crucial aspect of the quality-by-design (QbD) initiative which promotes quality built into the desired product. This is achieved through a deep understanding of how the critical quality attributes (CQAs) and process parameters (CPPs) interact that have been demonstrated to provide quality assurance. For computational inexpensive models, the original process model can be directly deployed to identify the design space. One such crucial process is the Tablet Press (TP), which directly compresses the powder blend into individual units of the final product or adds dry or wet granulation to meet specific formulation needs. In this work, we identify the design space of input variables in a TP such that there is a (probabilistic) guarantee that the tablets meet the quality constraints under a set of operating conditions. A reduced-order model of TP is assigned for this purpose where the effects of lubricants and glidants are used to characterize the design space to achieve the desired tablet CQAs. The probabilistic design space, which takes into account interactions between crucial process parameters and important quality characteristics including model uncertainty, is also approximated because of the high cost associated with the comprehensive experiments.

**Keywords:** design space, tablet press, direct compression, pharmaceutical process, optimization

## INTRODUCTION

The “quality-by-design” (QbD) paradigm put forward by the ICH Q8 guideline on pharmaceutical development states that quality should be built into the products instead of tested into them [1]. The QbD concept allows the practitioner to embrace a thorough and comprehensive approach towards pharmaceutical processes and product development. This leads to a more systematic understanding of the intricate relationships between material attributes, process parameters (CPPs), and product quality (CQAs) for the manufacture of new drugs. The manufacturer may get an advantage from this understanding and receive regulatory clearance to manufacture at any condition and within a broad operating regime if there is sufficient scientific proof that the process will produce a product of acceptable quality. Such an operational regime is called the design space and is also introduced in the ICH guideline. The regulatory approval provides the boundaries within which the material attributes and process parameters can be changed without further approval. However, changes beyond the design space

values mandate a regulatory post-approval change process.

The most widely available literature for design space identification uses an empirical approach and generally follows the steps of: identifying the knowledge space; design-of-experiments (DoE) measuring the relation between the CPPs and CQAs within the knowledge space; using empirical regression methods to define boundaries of the design space; and validation experiments to confirm the design space [3]. The empirical approach is highly favorable when the model is complicated (e.g., multiple unit operations, integrated flowsheet model), and the design space analysis can be challenging due to the computational cost associated with the simulation of the process model.

However, in the presence of a relatively inexpensive computational model, the original model based on the mechanistic equations of the process can be directly used to characterize the design space. Instead of using experimental data to generate empirical relationships, the equations in these models are constructed from a series of presumptions about the physical system and

conservation principles of physics and chemistry. The degree to which these assumptions are true determines whether these models hold up when applied to novel situations. There are instances of mechanistic models being applied to the identification of design spaces; however, fewer examples exist for pharmaceutical processes [4-5].

The design space concept has been based on empirical relationships since its beginning; however, the current practice is to evolve by using models that are more mechanistic. The discussion remains about how much experimental evidence is necessary to establish the design space, which changes across regions and application scenarios. There are three broad approaches to identifying design spaces that result in desirable quality attributes: optimization methods, Bayesian inference, and knowledge space sampling. Optimization techniques help identify operational parameters, which ensures that the process acquiesces to a constraint set by performing the flexibility analysis [6]. Bayesian approaches use limited process data and variability and can also incorporate prior knowledge about the process to define a design space that includes uncertainty [7]. Another alternative approach to identifying the design space is to generate a mesh of sample points in the process parameter space and perform simulations at each of those points to determine if the predicted product quality disobeys any constraint [8].

The current work contributes to this fast-evolving domain, where we investigate a steady-state mechanistic tablet press (TP) model [2]. For the purpose of using QbD methods in a direct compression tableting process—where the dry blended component materials are compressed into tablets—the TP model may be used to predict the CPPs and CQAs of tablets. The reduced-order TP model has been used previously to describe the effects of glidants and lubricants on tablet CQAs [2] and implement moving horizon estimation-based non-linear model predictive control (MHE-NMPC) for the tablet press at Purdue’s pharmaceutical continuous manufacturing pilot plant [9]. In the current study, the mechanistic model is deployed for identifying the design space using explicit knowledge space sampling, and the importance of various process parameters is discussed based on the optimal areas of operation that follow a set of constraints. The study investigates the effects of glidants and lubricants and other process parameters on making desired quality tablets via two separate experimental campaigns and their probabilistic design spaces are characterized.

The paper is organized as follows: the next section explains the reduced-order model for the TP, where the role of glidants and lubricants on tablet quality is explained. Subsequently, the design of experiments and the parameter estimation of the mechanistic model are described. We then present the design space results and

recommend the optimal areas of process operation to manufacture tablets of the desired quality. The robust design space is also determined when the process model includes uncertainty by performing Monte Carlo simulations for different probability values as acceptable minimum.

**Figure 1.** Steps in a rotary tablet press process (taken from [10])

## TABLET PRESS MODEL

The tablet press is a multi-stage process that involves the following primary actions at each station: die filling, metering, pre-compression, main-compression, tablet ejection and take-off from lower punch. The metering stage adjusts the dosing position to change the amount of powder within the die after die filling the feed frame. The die is then locked between the upper and lower punches throughout the pre-compression and main-compression stage until tablet ejection and take-off takes place. While the main compression works to compact and solidify the powder into tablets, the pre-compression helps to release trapped air in the die and reorganize the particle packing.

In order to lower frictional losses and improve powder flow during die filling and the mechanical compression-formed solid tablet formation process, lubricants and glidants are essential components. Consequently, the porosity and tensile strength of tablets will be monitored and controlled using models for lubricant/glidant effects in die filling and compression operations. The effects of glidant and lubricant concentrations and mixing conditions are specifically captured by these mechanistic models.

The tablet weight,  $W$ , formed using NATOLI D-type tooling is affected by the process parameters such as dosing position ( $h_{fill}$ ), turret speed ( $n_T$ ), and diameter of the tablet ( $D$ ) and is computed as

$$W = \rho_b V_{fill} \left( -\varphi_1 \frac{n_F}{n_T} + \varphi_2 \frac{h_{fill}}{D} + \varphi_3 \left( \frac{h_{fill}}{D} \right)^2 \right) \quad (1)$$

Where  $\varphi_1$ ,  $\varphi_2$ ,  $\varphi_3$  refer to the model parameters (to be estimated using the experimental data) and  $V_{fill}$ ,  $\rho_b$ , and  $n_F$  is the die cavity volume, powder bulk density, and feed frame speed, respectively. The powder bulk density  $\rho_b$  is dependent on the glidant/lubricant concentration ( $c$ )

and mixing time (or shear imparted during mixing) ( $\gamma$ ) which follows the asymptotic relationship as

$$\rho_b = \rho_{b,\infty} - \frac{\rho_{b,\infty} - \rho_{b,0}}{1 + C_p} \text{ with } C_p = \frac{c_l^{r_1}(\gamma + \gamma_0)^{r_2}}{r_3} \quad (2)$$

where  $\rho_{b,\infty}$ , and  $\rho_{b,0}$  represent the bulk densities when the shear imparted during mixing is infinite and zero respectively,  $\gamma_0$  is the initial shear imparted during pre-mixing, and  $r_1, r_2, r_3$  are model parameters estimated from the experimental data. The bulk density in (2) increases with increase in concentration or mixing time of glidant/lubricant and reaches an asymptotic value. The die cavity volume is calculated as follows

$$V_{fill} = \frac{\pi D^2 h_{fill}}{4} + \frac{\pi h(\frac{3D^2}{4} + h^2)}{6} \quad (3)$$

where  $h$  is the cup depth. The main compression force ( $F_{main}$ ) which is an important process variable can be estimated using the Kawakita equation [11] for the effect of silica (independent of the glidant conditions) by

$$F_{main} = \frac{\pi D^2(\rho_{in-die} - \rho_c)}{4b(\rho_{in-die}(a-1) + \rho_c)} \quad (4)$$

where  $a$  and  $b$  are the Kawakita parameters,  $\rho_c$  is the critical density of the powder and the in-die relative density,  $\rho_{in-die}$  is given by

$$\rho_{in-die} = \frac{W}{\rho_t V_{in-die}} \quad (5)$$

where  $\rho_t$  is the true density of the powder and  $V_{in-die}$  is the die-cavity volume with main compression thickness  $h_{in-die}$  given by

$$V_{in-die} = \frac{\pi D^2 h_{in-die}}{4} + \frac{\pi h(\frac{3D^2}{4} + h^2)}{3} \quad (6)$$

The lubrication conditions are found to affect the compression force for the MgSt blends and this is incorporated by modifying  $a$  as

$$a = a_\infty - \frac{a_0 - a_\infty}{1 + C_c} \text{ with } C_c = \frac{c_l^{p_1}(\gamma + \gamma_0)^{p_2}}{p_3} \quad (7)$$

where  $a_0, a_\infty, p_1, p_2,$  and  $p_3$  are model parameters. Here, the compaction force increases with increasing lubrication. The elastic recovery ( $\varepsilon_p$ ) model which is part of the tablet ejection stage is insensitive to the glidant mixing conditions and can be calculated by

$$\varepsilon_p = \varepsilon_0 \frac{\rho_{in-die} - \rho_{c,\varepsilon}}{1 - \rho_{c,\varepsilon}} \quad (8)$$

However, the lubricant conditions affect the elastic recovery and an increase in the former increases the latter. This behavior is captured by modeling  $\varepsilon_0$  as

$$\varepsilon_0 = \varepsilon_\infty - \frac{\varepsilon_\varphi - \varepsilon_\infty}{1 + C_\varepsilon} \text{ with } C_\varepsilon = \frac{c_l^{q_1}(\gamma + \gamma_0)^{q_2}}{q_3} \quad (9)$$

where  $\varepsilon_\varphi, \varepsilon_\infty, q_1, q_2,$  and  $q_3$  are model parameters. The tablet density  $\rho_{tab}$  can then be calculated using

$$\rho_{tab} = \rho_{in-die} (1 - \varepsilon_p) \quad (10)$$

The tensile strength ( $\sigma_t$ ) of a tablet is a crucial CQA which affects the tablet dissolution along with the tablet weight  $W$ . Both lubricant/glidant concentration and mixing time affect the tensile strength and the relationship is governed by Kuentz and Luenberger, 2000 [12]

$$\sigma_t = \sigma_0 \left[ 1 - e^{(\rho_{tab} - \rho_{c,\sigma})} \left( \frac{1 - \rho_{tab}}{1 - \rho_{c,\sigma}} \right) \right] \text{ with } \sigma_0 = \frac{\sigma_{0,\varphi}}{1 + C_\sigma}$$

$$\rho_{c,\sigma} = \rho_{c,\sigma,\infty} - \frac{\rho_{c,\sigma,\infty} - \rho_{c,\sigma,\varphi}}{1 + C_\sigma} \text{ and } C_\sigma = \frac{c_l^{b_1}(\gamma + \gamma_0)^{b_2}}{b_3} \quad (11)$$

Where  $\rho_{c,\sigma,\varphi}, \rho_{c,\sigma,\infty}, b_1, b_2, b_3$  are the model parameters [13] and  $\sigma_{0,\varphi}$  and  $\rho_{c,\sigma,\varphi}$  represents the tensile strength and critical relative density when there is no lubrication,  $C_\sigma = 0$ . As a result of the tensile strength model, soft tablets with lower tensile strength are formed as the concentration or mixing time of glidant or lubricant in the formulation increases. However, the decrease in tablet tensile strength manufactured using silica blends is solely because of the variations in the blended material properties, but the lower tensile strength of tablets formed using Magnesium Stearate (MgSt) blends would in addition be due to the increased elastic recovery of lubricated tablets.

## METHODOLOGY

Tablets are the most common oral solid dosage form that can be produced by direct compression or enhanced by either wet or dry granulation to meet specific formulation needs. The direct compression line in the pharmaceutical continuous manufacturing pilot plant at Purdue University was used for the studies in this work. The materials used in the current study include 10% w/w acetaminophen (APAP) as the API, microcrystalline cellulose Avicel PH200 (MCC) as the excipient, and glidant colloidal silica and lubricant Magnesium Stearate (MgSt) at different concentrations. Colloidal silica is an excipient which is useful for improving powder flowability and MgSt helps reduce internal friction during compaction and tablet-tooling friction during ejection. These excipients have a substantial impact on the powder's surface characteristics, such as the strength of the solid bridges created during compaction, as well as bulk properties, including bulk density, even when added in very small amounts [14]. This shift in the blend's characteristics naturally affects the tableting procedure and the final tablet's CQAs, including its dissolving profile [13, 15], which in turn affects the active pharmaceutical product's (API) bioavailability.

For the experimental campaigns, APAP and MCC were mixed in a tote blender with 0-0.2% w/w silica in the first experimental campaign and with 0-2% w/w MgSt in the second campaign for 10-30 minutes. The dosing

position and the in-die (main compression) thickness values were maintained between 7–11 mm (9–13 for lubricant MgSt) and at 3.1 mm, respectively, to manufacture tablets that have a wide range of relative densities. The design-of-experiments DoE was conducted separately for the two experimental campaigns to study the effects of silica and MgSt on tablet quality. The MATLAB function lhsdesign was used to build a Latin hypercube sampling (Viana, 2013) of turret speed, dosing position, concentration, and mixing time to generate 30 experiments for the silica blends and 20 experiments for the MgSt blends. Next, the powder blends were compressed into tablets using a NATOLI-NP400 tablet press using D-type tooling with shallow cup of depth 0.33 mm, which features a total of 22 punch-die stations with die-size 8 mm. A SOTAX AT4 tablet tester was utilized to measure the weight, hardness, diameter, and thickness of 50 tablets under steady-state manufacturing conditions for each run in the DoE. At the beginning of each experimental run, 0.5 kg of the mix was added to the tablet press hopper.

The TP model parameters are estimated by minimizing the least squares which is typically solved as an optimization problem where the objective is to minimize the sum of squared errors (*SSE*) between the model predicted and observed values.

$$SSE = \sum_{i=1}^n (y_{mod,i} - y_{obs,i})^2 \quad (12)$$

where  $y_{mod,i}$  and  $y_{obs,i}$  are the  $i$ th estimated value using the TP model and  $i$ th experimental data of the tablet CQAs (tablet weight, main compression force, and tablet tensile strength), respectively, and  $n$  is the number of experimental samples. The sum of squared errors is minimized, and the corresponding optimal values of model parameters and their uncertainty are stored for design space characterization.

There are 4 CPPs in the DoE namely turret speed, dosing position, concentration, and mixing time. In the tablet press, the feed frame speed gets automatically adjusted to be ~15 rpm greater than the turret speed. While high feeder to turret speed ratios can lead to uneven die-filling and tablet weight variability, the current DoE maintains low turret and feeder speeds, minimizing their impact on tablet weight. The dosing position ( $h_{fill}$ ) determines the tablet weight, while the main compression thickness ( $h_{in-die}$ ) affects the tablet density and hence the tensile strength of the tablet. Therefore, the crucial CPPs for the design space are the dosing position, main compression thickness, concentration, and mixing time and their realizable bounds are shown in Table 1. The main compression thickness is flexible enough to vary within operable limits and can be used to widen the useful design space regions. The tablet CQAs considered in this study include main compression force, tablet weight, and tensile strength, and the desired specifications are mentioned in Table 2. The compression force is essentially

not included in the tablet CQAs but it helps in regulating the lower bounds of dosing position and main compression thickness that results in useful design space regions. Therefore, it is included as a quality constraint. The objective of this study is to identify the design space of input variables ( $h_{fill}$ ,  $h_{in-die}$ ,  $c_L$ ,  $\gamma$ ) such that the tablets are guaranteed to meet the quality constraints ( $W$ ,  $F_{main}$ ,  $\sigma_t$ ) under the operating limits of the tablet press.

**Table 1:** The critical process parameters (CPPs) and their bounds

CPP	Low limit	High limit
Dosing position ( $h_{fill}$ )	6 mm	11 mm
Comp. thickness ( $h_{in-die}$ )	1.5 mm	3 mm
Silica conc. ( $c_i$ )	0.1 %	0.2 %
MgSt conc. ( $c_i$ )	0.1 %	2 %
Mixing time ( $\gamma$ )	10 mins.	30 mins.

**Table 2:** The critical quality attributes (CQAs) and their specifications

CPP	Low	High
Tablet weight ( $W$ )	125 mg	175 mg
Compression Force ( $F_{main}$ )	2 kN	50 kN
Tensile strength ( $\sigma_t$ )	2 MPa	15 MPa

As previously stated, an explicit sampling of the knowledge space is used to identify the design space. For the deterministic design space, the process parameters are discretized by creating a fine mesh of sample points within their predefined bounds. To determine if the projected CQAs jointly observe the constraints for each discretized sample, simulations are performed for each of these discretized CPPs. A deterministic design space is the outcome of this mapping.

For the probabilistic design space, additionally, at each of the discretized CPPs, Monte Carlo simulations are executed on the full model  $N$  times using the model parameter values in the space of their uncertainty bounds. The uncertainty information is incorporated in the design space using the computed standard deviation values of model parameters from the least squares approach. The fitted model predictions against experimental data for different CQAs can be seen in Figure 2. Then, for each of the discretized process parameter samples, the probability of meeting the constraints jointly is estimated. The probability is computed based on the fraction of times the Monte Carlo simulations resulted in CQA values that complied with all the constraints. For each discretized sample, the probability is set equal to this fraction. This allows for the propagation of model uncertainty to the predicted CQAs, and the Monte Carlo simulation serves well in showing the possible values of the model prediction as explicit probability maps which

accounts for model variability and common cause variability.

**Figure 2.** Fitted TP model predictions versus experimental data for (a) tablet weight, (b) tensile strength, (c) compaction force.

The explicit sampling method is effective in identifying the probabilistic design space, and the process parameter grid can be made finer through discretization, and there is no restriction on the sampling size of the uncertain parameters. It is worth mentioning that a major limitation of this approach lies in the large number of simulations that need to be performed, and the design of effective strategies for knowledge space sampling is an active research area but that is beyond the scope of this work. Despite the computational challenges, the explicit sampling method is the most straightforward approach to estimate even complex design spaces. However, the goal here is to recommend optimal areas of operation for the tablet press within the process parameter space that results in quality tablets utilizing the straightforward and

effective explicit sampling approach.

**Figure 3.** Design space plots for silica blends following CQA constraints mentioned in Table 2. Blue region is the deterministic design space (without accounting for model uncertainty) and green region is the probabilistic design space with 85% confidence.

## RESULTS AND DISCUSSIONS

From the tablet press model described in the second section, it can be seen that the CPPs dosing position  $h_{fill}$ , lubricant or glidant concentration  $c_L$ , and mixing time  $\gamma$ , affect the CQA tablet weight  $W$  (from equations 1, 2, and 3). The main compression force  $F_{main}$ , which is another CQA, is additionally influenced by the main compression thickness (equations 4, 5, 6, and 7). The tensile strength  $\sigma_t$  is also dependent on all the CPPs (equations 8, 9, 10, and 11). Therefore, the tablet press model can be lumped into three equations: one for tablet weight, a second for main compression force, and a third for tensile strength. The equations have not been mentioned here due to their comprehensiveness. However, the equations can be used to solve for the design space variables within the bounds shown in Table 1, and the equations themselves would be constrained due to the limits specified in Table 2.

Figure (2) depict the multidimensional design space in simplified graphical form for the silica blends. Several simulations were performed for various combinations of process parameters and sampling model parameters within their uncertainty bounds in order to identify the multidimensional design space. For demonstration, 1000 Monte Carlo simulation realizations were used in this case, with an acceptable minimum probability of 85%.

The blue region is where the three quality constraints are met without accounting for the model uncertainty and the green region is where the probability of meeting all the quality constraints is acceptable. It is important to emphasize here that the lower feasible bounds of the dosing position and the compression thickness is regulated by the main compression force and their upper feasible bounds is controlled by the tensile strength constraint. From the design space plots of silica blends, it is observed that the closer you operate near the nominal value of compression thickness (~ 2.1 mm) and dosing position (~6.9 mm), wider would be the probabilistic design space. Although the comprehensive probability maps have not been shown here, but the variation in design space can be explained as follows: for lower dosing positions values (closer to lower bound in Table 1), lower thickness values are favorable and for high dosing positions values (closer to upper bound), higher thickness values are required for tablet quality to obey the constraints. This is only valid within the feasible limit of process parameters. The design space plots for the lubricated blends were found to very narrow and small even

for the deterministic case and are therefore not reported.

**Figure 4.** Design space plots for different tablet weight CQA limits. Blue region is the deterministic design space (without accounting for model uncertainty) and green region is the probabilistic design space with 85% confidence.

We also demonstrate the effectiveness of the TP model in capturing the design space boundaries by showing the design space plots with varying tablet weight limits. The other two CQA constraints remain unchanged as mentioned in Table 2. To illustrate the case, we have considered a new limit for tablet weight  $W = [100, 150]$  mg and compare it with the original case but the operating conditions on dosing position and compression thickness is kept fixed at (6.3 mm, 1.5 mm) and other constraints also remain unchanged. The silica blends are used for this case study. The change in feasible region boundary for the probabilistic design space is shown in Figure 4. Here the green region shrinks towards bottom left for smaller tablet weight CQA.

## CONCLUSIONS

The study investigated the determination of design space for the tablet press operation to achieve desired tablet quality. The design space plots showed the effects of glidant or lubricant on the tablet quality. Tablets made from silica blends showed much promise where a design space point in a sufficient broad feasible region can be used to perform validation experiments. The efficacy of the TP model is also depicted in the case where the variation in probabilistic design space boundary is captured when the required tablet weight changes. An immediate future work includes performing the validation experiments based on the identified design space plots.

The future work includes various improvisation to the current study. First, the TP model needs to be tested against variations in measured tablet CQAs. Second, to develop design space plots for much smaller or larger tablets and to study the effect of die size on such tablets and how the TP model performs with such variations. Finally, an empirical approach such as Bayesian modeling based on the DoE can be used to explore the design space of the TP and compare its efficacy against the model-based methodology.

## ABSTRACT

In this work, we present recent algorithmic and implementation advances of the nonconvex two-stage robust optimization solver PyROS. Our advances include extensions of the scope of PyROS to models with uncertain variable bounds, improvements to the formulations and/or initializations of the various subproblems used by the underlying cutting set algorithm, and extensions to the pre-implemented uncertainty set interfaces. The effectiveness of PyROS is demonstrated through the results of an original benchmarking study on a library of over 8,500 small-scale instances, with variations in the nonlinearities, degree-of-freedom partitioning, uncertainty sets, and polynomial decision rule approximations. To demonstrate the utility of PyROS for large-scale process models, we present the results of a carbon capture case study. Overall, our results highlight the effectiveness of PyROS for obtaining robust solutions to optimization problems with uncertain equality constraints.

## INTRODUCTION

Two-stage robust optimization (RO) is a useful framework for obtaining robust designs of process and energy systems. Optimization models for process and energy systems are often subject to parametric uncertainty, arising from the use of empirical correlations for property models, temporal variations in feedstock quality, or economic stochasticity [1]. Since any changes in the prevailing values of these uncertain parameters may significantly affect the model outputs, deterministic optimization may yield system designs which are suboptimal or infeasible under off-nominal scenarios. Moreover, the design of a plant should account for any built-in controllability that will allow the operator to adjust plant response during operation.

The recently developed two-stage RO solver PyROS [2, 3] is designed to obtain robust solutions to process models. A typical process design model features nonconvexities, design and recourse degrees of freedom, and a prevalence of equality constraints constituting the

“simulation part” of the model. The equality constraints are often highly complex, to the extent that they cannot, in general, be reformulated out of the model. Until recently, there were no existing RO tools capable of solving nonconvex two-stage RO problems with general nonlinear inequality constraints. Based on a generalization [1] of the robust cutting set algorithm of [4], PyROS is the first two-stage RO solver that systematically handles the equality constraints without reformulation requirements [3].

In this work, we present an overview of the cutting set methodology upon which the PyROS solver is based, recent algorithmic and implementation advances of the PyROS solver, a high-throughput benchmarking study to demonstrate the effectiveness of PyROS for a wide range of small-scale nonconvex two-stage RO instances, and a post combustion carbon capture case study to show the utility of PyROS for obtaining risk-averse designs for critical systems with large-scale nonconvex optimization models.

## METHODOLOGY OVERVIEW

### Formulations

Let  $x \in R^{n_x}, z \in R^{n_z}, y \in R^{n_y}, q \in R^{n_q}$  denote the first-stage variables, second-stage variables, state variables, and uncertain parameters, respectively, for a model of interest. The first-stage variables may be assigned a value from a known domain  $\mathcal{X} \subseteq R^{n_x}$ , described by nonlinear constraints involving  $x$  only. We assume the uncertain parameters  $q$  are restricted to an *a priori* known, compact, exogenous uncertainty set  $Q \subset R^{n_q}$ , containing a nominal value  $q^{\text{nom}}$ . For fixed  $x$  and  $q$ , the second-stage variables  $z$  can be adjusted freely, and the state variables  $y$  are then implicitly determined from the model constraints.

In a deterministic optimization setting, the model of interest is a nonlinear program (NLP) of the form

$$\begin{aligned} \min_{\substack{x \in \mathcal{X} \\ z \in R^{n_z} \\ y \in R^{n_y}}} \quad & f_1(x) + f_2(x, z, y; q^{\text{nom}}) \\ \text{s.t.} \quad & g_i(x, z, y; q^{\text{nom}}) \leq 0 \quad \forall i \in \mathcal{J} \\ & h_j(x, z, y; q^{\text{nom}}) = 0 \quad \forall j \in \mathcal{J} \end{aligned} \quad (1)$$

in which  $f_1: \mathcal{X} \rightarrow R$  denotes the first-stage objective function,  $f_2: \mathcal{X} \times R^{n_z} \times R^{n_y} \times Q$  denotes the second-stage objective function,  $g_i: \mathcal{X} \times R^{n_z} \times R^{n_y} \times Q, i \in \mathcal{J}$  denotes the inequality constraint functions, and  $h_j: \mathcal{X} \times R^{n_z} \times R^{n_y} \times Q, j \in \mathcal{J}$  denotes the equality constraint functions. The two-stage RO counterpart of the model (1) is

$$\begin{aligned} \min_{x \in \mathcal{X}} \quad & \max_{q \in Q} \quad \min_{\substack{z \in R^{n_z} \\ y \in R^{n_y}}} f_1(x) + f_2(x, z, y, q) \\ \text{s.t.} \quad & g_i(x, z, y, q) \leq 0 \quad \forall i \in \mathcal{J} \\ & h_j(x, z, y, q) = 0 \quad \forall j \in \mathcal{J} \end{aligned} \quad (2)$$

### Solution Approach: Generalized Robust Cutting Set Algorithm

The two-stage RO problem (2) can be solved using the generalized robust cutting set algorithm presented in [1, 3]. We now present a brief overview. First, the adjustability of the second-stage variables with respect to the uncertain parameters is approximated with decision rules. For each  $l = 1, 2, \dots, n_z$ , let  $d_l \in R^{n_{d,l}}$  be a vector of *decision rule coefficients*, each of which is considered an additional first-stage variable. We model the second-stage variable  $z_l$  as a scalar function  $v_l: R^{n_{d,l}} \times Q \rightarrow R$  of the coefficients  $d_l$  and the uncertain parameters  $q$ . In this case, the RO problem (2) becomes

$$\begin{aligned} \min_{\substack{x \in \mathcal{X} \\ d \in R^{n_d}}} \quad & \max_{\substack{q \in Q \\ z \in R^{n_z} \\ y \in R^{n_y}}} \quad \min_{\zeta \in R} \zeta \\ \text{s.t.} \quad & \zeta \geq f_1(x) + f_2(x, z, y, q) \\ & g_i(x, z, y, q) \leq 0 \quad \forall i \in \mathcal{J} \\ \text{s.t.} \quad & h_j(x, z, y, q) = 0 \quad \forall j \in \mathcal{J} \\ & z_l = v_l(d_l, q) \quad \forall l \in \mathcal{L} \end{aligned} \quad (3)$$

in which  $d = (d_1, d_2, \dots, d_{n_z})$  and  $\mathcal{L} = \{1, 2, \dots, n_z\}$ . We

assume that for fixed  $x \in \mathcal{X}, z \in R^{n_z}, q \in Q$ , the state variables  $y \in R^{n_y}$  are *uniquely* determined by the equality constraints  $h_j(x, z, y, q) = 0 \forall j \in \mathcal{J}$ .

Observe that (3) constitutes a restriction of (2) through the addition of the decision rule equations. Given (3), we may then obtain a feasible first-stage solution  $(x, d)$  with the following iterative approach. For each iteration  $k = 0, 1, \dots$ :

- A sampled relaxation of (3), termed the *master problem*, is solved to obtain a candidate solution  $(x^*, d^*)$ .
- For each  $i \in \mathcal{J}$ , a *separation problem* is solved to determine, if it exists, a parameter realization  $q \in Q$  for which there is no feasible adjustment of  $z, y$  satisfying the inequality constraint  $g_i(x^*, z, y, q) \leq 0$ , subject to the model's equality constraints and decision rule policy (with  $d_l = d_l^*$  fixed for every  $l \in \mathcal{L}$ ). A similar separation problem is solved for the epigraph constraint.
- If a realization for which infeasibility is detected is found in the previous step, then the constraints subject to this realization are added to the master problem, and we proceed with iteration  $k + 1$ . Otherwise,  $x^*$  is said to be *robust feasible*, and the algorithm terminates. If  $x^*$  is robust feasible, and the master problem has been solved to global optimality, then  $x^*$  is said to be *robust optimal*.

To reduce the risk of numerical issues, we are careful to initialize the variables of the master problem of each iteration  $k = 1, 2, \dots$  to an optimal solution of a closely related slack variable-based feasibility problem.

In [1], a procedure for empirically evaluating the quality of the robust feasible or robust optimal solution returned by the cutting-set algorithm is provided.

## PYROS SOLVER INTERFACE

### Implementation

The Pyomo Robust Optimization Solver (PyROS) is a Python-based implementation of the cutting set algorithm presented in the previous section; the official documentation is contained in [2]. Built on top of the open-source algebraic modeling language Pyomo, PyROS has been designed for ease of use, such that a user can quickly extend a deterministic optimization workflow to a two-stage RO workflow. Successful invocation of the PyROS two-stage RO solver requires only the following arguments:

- The deterministic model
- The first-stage degree-of-freedom variables
- The second-stage degree-of-freedom variables

- The uncertain model parameters
- The uncertainty set
- Subordinate NLP optimizers. At least one optimizer must be capable of solving nonconvex NLPs to global optimality.

For a Pyomo user with a modest level of experience, the uncertainty set is the only argument for which instantiation may immediately pose a challenge. Therefore, to facilitate the construction of uncertainty set objects, PyROS provides an abstract uncertainty set class, and a suite of pre-implemented concrete subclasses, based on uncertainty quantifications often used in the RO literature. The pre-implemented classes include hyperrectangular, polyhedral, ellipsoidal, and discrete uncertainty set types; full descriptions of all available set types are provided in [2, 3]. If none of the pre-implemented classes meet the user's modeling needs, then the user may implement a custom-written subclass of the abstract uncertainty set class.

## Recent Updates

Below, we synopsise a number of implementation features that were contributed to the PyROS codebase in recent months.

### Improved Subproblem Initializations

Given that the master and separation subproblems of the underlying cutting set algorithm may, in general, be nonconvex NLPs, the success of solving these subproblems may be heavily contingent on the initial point provided to the subordinate NLP optimizers. To this end, we have opted to initialize the master problems with the solution to a slack-based feasibility problem formulation, such as to obtain a feasible, or near-feasible, initial point. To reduce the level of infeasibility of the initial point for the feasibility problem, the variables of the feasibility problem of iteration  $k$  are initialized based on the solution to the master and separation problems of the previous iteration  $k - 1$ . Similarly, each of the separation subproblems of iteration  $k$  is initialized based on the solution to the master problem of iteration  $k$ .

### Acceleration of the Separation Step

The separation problem subroutines have been refactored to enhance the performance of those subroutines, and by extension, the PyROS solver, and facilitate improvements to the initializations of subproblems in subsequent iterations. Moreover, based on the assumption that the equality constraints of (3) uniquely determine the state variables  $y$  for fixed  $x \in \mathcal{X}, z \in R^{n_z}, q \in \mathcal{Q}$ , we have implemented an efficiency to significantly reduce the computational expense of the separation step for problems with discrete uncertainty sets.

### Extensions to the Uncertainty Set Interfaces

The budget and factor model set classes of the original PyROS release have been generalized.

### Updated Solver Log Output

PyROS now features a solver output logging system which provides a breakdown of the model component statistics, a summary of the progress of the underlying cutting set algorithm at the end of each iteration, and a summary of the solver termination statistics.

## BENCHMARKING STUDY

### Test Set and Computational Environment

To evaluate the performance of the PyROS solver, we sought to establish a comprehensive library of small-scale benchmark instances upon which a high-throughput computational study could be performed. Ten deterministic NLP models of varying size and nonlinearity were collected from the open deterministic NLP modeling libraries [5, 6]. From this collection of deterministic NLPs, a library of 8,591 two-stage RO problem instances was assembled by varying the degree-of-freedom partitioning, subset of model parameters considered uncertain, uncertainty set type and parameterization, and decision rule order specification.

All two-stage model instances were instantiated and solved in a Python 3.9 virtual environment with Pyomo 6.6.1dev0/PyROS 1.2.7. Instances were solved on a single core of an Intel® Xeon® CPU E5-2687W v3 @ 3.10 GHz, running Ubuntu Linux 20.04 with 64 GB RAM. For the subordinate local and global NLP optimizers, we used IPOPT 3.14.6/MA27 [7] and BARON v23.6.23/CPLEX 22.1.0 [8], respectively. Instances were solved to a robust feasibility tolerance of  $1 \times 10^{-3}$  and wall time limit of 400 s. For the `hydrothermal` and `optmass` benchmark instances, the master problems were solved to local optimality; otherwise, all subproblems were solved to global optimality. Additional details about the instances and computational environment used in this study are presented in [3].

### Results

Table 1 summarizes the results of our computational study. Of the 8,591 instances, 88.9% were solved to the desired robust optimality or feasibility target. The average wall time and iteration requirements for successfully solved instances were found to be low. The relatively high wall time and iteration requirements for `himmel6`, `haverly`, `hydro`, and `hydrothermal` instances were found to be attributable to the size and/or nonlinearities present in the original deterministic models, which rendered the master and/or separation subproblems more difficult to solve. For instances in the model library that were not successfully solved, the outcome was most often found to be attributable to a pathological separation

subproblem which could not be solved successfully by the subordinate global optimizer due to the wall time requirements exceeding the specified limit of 400s. Regardless, the success rate of 88.9% and low iteration and wall time requirements suggest that PyROS is able to obtain robust feasible or robust optimal solutions to non-convex two-stage robust NLPs with a high level of reliability.

**Table 1:** Computational performance statistics for high-throughput computational study of the PyROS solver. Averages are reported for the successfully solved instances only.

## CASE STUDY: AMINE-BASED POST COMBUSTION CARBON CAPTURE

### Introduction

Carbon capture and storage technologies are considered vital to minimal cost pathways for reducing the carbon footprints of process systems to meet global climate targets [9, 10]. Along with other organizations worldwide, the United States Department of Energy has spearheaded initiatives for developing computational tools to accelerate the design and deployment of carbon capture and storage systems [11, 12]. One issue with computational model-based tools is the susceptibility of the underlying mathematical optimization models to parametric uncertainty. Towards developing a computational framework for risk-averse carbon capture process designs, models for amine-based CO<sub>2</sub> absorption processes have been identified as benchmarks, given the relative maturity of amine-based absorption technologies [11, 12]. In this section, we present a case-study based on a model of a CO<sub>2</sub> absorption column using monoethanolamine (MEA) solvent.

### Modeling Framework

Our case study involves a high-fidelity, one-dimensional, steady state, rate-based model for an MEA-based CO<sub>2</sub> absorption column. Figure 1 shows a schematic

diagram. The column length and diameter are denoted by  $L$  and  $D$ , respectively, and we assume the column heads are hemispherical. Flue gas, rich in CO<sub>2</sub>, enters the base of the column from an upstream process. A stream of CO<sub>2</sub>-lean MEA solvent enters the top of the column at a molar flow rate  $F$  to remove CO<sub>2</sub> from the gaseous mixture prior to emission.

**Figure 1:** Schematic for the MEA-based CO<sub>2</sub> absorption column model. The column length and diameter are denoted by  $L$  and  $D$ , respectively. The lean solvent flow rate is denoted by  $F$ .

The axial dimension of the column is discretized into a grid of  $N = 40$  finite elements. For each  $i = 1, 2, \dots, N$ , we denote the flooding fraction in the  $i$ th finite element by  $u_i$ . We are free to adjust the column dimensions  $L, D$  during design of the system (i.e. as first-stage variables) and the solvent flow rate  $F$  during operation (i.e. as a second-stage variable). The length-to-diameter ratio of the column must fall between 1.2 and 30. We require that the CO<sub>2</sub> capture rate of the column meet a pre-specified target, and that the flooding fractions  $u_1, u_2, \dots, u_N$  fall within pre-specified bounds.

Using the notation of the previous paragraphs, the deterministic optimization model can be written as

$$\begin{aligned}
 \min_{L, D, F, u, y} \quad & \frac{1}{4}\pi D^2 L + \frac{1}{3}\pi D^3 + \frac{F}{2} \\
 \text{s.t.} \quad & h(L, D, F, u, y; q) = 0 \\
 & 1.2D \leq L \leq 30D \\
 & r^L - f^{\text{CO}_2}(F, y) \leq 0 \\
 & 0.5e \leq u \leq 0.8e
 \end{aligned} \tag{4}$$

in which  $u = (u_1, u_2, \dots, u_N)$  is a vector whose components are the finite element flooding fractions;  $y$  is a vector of approximately 5,000 state variables;  $h$  denotes a nonlinear vector of approximately 5000 +  $N$  equality constraint functions, governed by material and energy balances and transport and thermodynamic property models;  $q$  is a vector of six uncertain model parameters, discussed later in the text;  $r^L$  is a constant denoting the CO<sub>2</sub> capture

**Table 2:** Deterministic optimization results for MEA-based CO<sub>2</sub> absorption column model.

Capture Target (%)	Capture Rate (%)	$L$ (m)	$D$ (m)	Volume ( $10^3$ m <sup>3</sup> )	$L/D$ Ratio	Flow rate $F$ (kmol/s)	Optimal Cost
85.0	85.0	18.19	15.19	6.93	1.2	13.24	13.55
87.5	87.5	18.24	15.20	6.99	1.2	13.63	13.81

**Table 3:** PyROS-based robust optimization results for MEA-based CO<sub>2</sub> absorption column model.

Minimum Capture Rate (%)	Robust Column Proxy Cost and DOF ( $L, D, F$ ) Values [m, m, kmol/s] (Expected $\pm$ Standard Deviation)			
	0% confidence (deterministic)	90% confidence	95% confidence	99% confidence
90.0	14.02 $\pm$ 0.08 (18.30, 15.25, 13.93 $\pm$ 0.17)	14.28 $\pm$ 0.11 (18.46, 15.38, 14.07 $\pm$ 0.22)	14.29 $\pm$ 0.11 (18.47, 15.39, 14.02 $\pm$ 0.22)	14.31 $\pm$ 0.12 (18.49, 15.41, 14.08 $\pm$ 0.25)
92.5	14.28 $\pm$ 0.09 (18.35, 15.29, 14.32 $\pm$ 0.17)	14.50 $\pm$ 0.10 (18.49, 15.41, 14.41 $\pm$ 0.20)	14.51 $\pm$ 0.10 (18.50, 15.42, 14.41 $\pm$ 0.20)	14.55 $\pm$ 0.13 (18.52, 15.43, 14.41 $\pm$ 0.26)
95.0	14.53 $\pm$ 0.09 (18.40, 15.34, 14.81 $\pm$ 0.18)	14.74 $\pm$ 0.11 (18.52, 15.44, 14.81 $\pm$ 0.23)	14.76 $\pm$ 0.11 (18.54, 15.45, 14.85 $\pm$ 0.23)	robust infeasible

target, and  $f^{\text{CO}_2}$  is a scalar function which evaluates the CO<sub>2</sub> capture rate. The nonlinearity of the component functions of  $h$  renders the deterministic model (4) non-convex.

We reiterate that  $L, D, F$  are degree-of-freedom variables, such that the flooding fractions  $u$  and other state variables  $y$  are implicitly determined by the equality constraints of (4). The objective of (4) is a proxy for the total capital and operating cost of the column. In particular, the capital cost is represented by the column volume  $(1/4)\pi D^2 L + (1/3)\pi D^3$ , while the operating cost is represented by the solvent flow rate, scaled by a factor of  $1/2$ , so that both costs share the same order of magnitude.

The uncertain parameters  $q$  consist of two liquid phase chemical reaction equilibrium constants and four vapor-liquid equilibrium constants, downselected according to the results of an uncertainty propagation study

of the deterministic optimization model and associated thermodynamic and physical property submodels. The resulting six-dimensional uncertainty set takes the form of a confidence ellipsoid centered on the nominal uncertain parameter realization, with a pre-specified confidence level and covariance matrix.

### Deterministic Optimization Results

Subject to the nominal realization of the uncertain parameters  $q$ , the deterministic absorption column model was solved to local optimality with GAMS 45.0/CONOPT3 [13] for capture targets  $r^L$  ranging from 85.0% to 97.5%. Table 2 shows the results. In all cases, the capture target constraint of (4) was found to be active, and the  $L/D$  ratio was found to achieve the lower bound of 1.2. Observe that the optimal column volume, flow rate, and objective were all found to increase as the capture target was

increased. We also note that, based on the model thermodynamics, a theoretical upper bound for the CO<sub>2</sub> capture rate is 98.2%, and we were unable to obtain nominally feasible designs for capture targets above 98.1%.

## Robust Optimization Results

Through rigorous sensitivity analysis studies, we were able to establish that the nominally optimal column designs are robust infeasible subject to quantifications of uncertainty in the VLE and reaction equilibrium parameters. To this end, the two-stage robust counterpart of the deterministic model (4) was solved with PyROS, subject to the degree of freedom partitioning and confidence ellipsoidal uncertainty quantification discussed previously, and a static decision rule approximation. We have elected to optimize for each of three different CO<sub>2</sub> capture targets and three levels of ellipsoidal confidence.

Table 3 summarizes the RO results for the MEA-based absorption column model. For all capture targets, the robust feasible column designs were found to be significantly more expensive than their deterministic counterparts. Nevertheless, the robust optimal designs for a given capture target were found to be comparable in cost to nominally feasible designs for higher capture targets. Observe, for example, that the robust feasible cost of  $14.31 \pm 0.12$  for 90% capture under a 99% confidence ellipsoidal uncertainty, is significantly lower than the cost  $14.53 \pm 0.09$  of the deterministic design for a 95% capture target. For the case of a 95% capture target and 99% confidence level, the robustness requirements were too stringent for the resulting problem to admit a risk-averse design. We expect that incorporating additional recourse, through the usage of a full CO<sub>2</sub> capture flowsheet model in lieu of the standalone absorption column model used in the present study, will afford robust designs for capture targets and confidence level requirements as high as 95% and 99%, respectively. It is worth noting that the difference between the robust feasible cost and the deterministically optimal cost provides an upper bound for the value worth investing in uncertainty reduction through additional data acquisition. Overall, our results highlight the ability of the PyROS solver to obtain economical, risk-averse designs of an amine-based post combustion carbon capture system with a high-fidelity NLP model.

## CONCLUSIONS

We have presented recent advances in the non-convex two-stage RO solver PyROS. The interface is designed to facilitate extensions of deterministic optimization models to two-stage RO workflows. Our computational benchmarking study demonstrates the effectiveness of PyROS for identifying robust feasible or robust optimal solutions to general nonlinear two-stage RO problems for a broad range of uncertainty

quantifications. Finally, our post combustion carbon capture case study shows the applicability of PyROS to the robust design of process systems. In future work, we intend to perform additional improvements to the initializations of the various subproblems, perform RO studies of the MEA-based absorption column model subject to non-static decision rule approximations, and extend the post combustion carbon capture case study to a full flowsheet optimization model.

## ACKNOWLEDGEMENTS

This work was conducted as part of the U.S. Department of Energy's Institute for the Design of Advanced Energy Systems (IDAES) and Carbon Capture Simulation for Industry Impact (CCSI2) initiative supported by the Office of Fossil Energy and Carbon Management, through the Simulation-based Engineering/Crosscutting Research Program and Carbon Capture Program. ## ABSTRACT

Developing methods for rapid, large-scale deployment of carbon capture systems is critical for meeting climate change goals. Optimization-based decisions can be employed at the design and manufacturing phases to minimize the costs of deployment and operation. Manufacturing standardization results in significant cost savings due to economies of numbers. Building on previous work, we present a process family design approach to design a set of carbon capture systems while explicitly including economies of numbers savings within the formulation. Our formulation optimizes both the number and characteristics of the common components in the platform and simultaneously designs the resulting set of carbon capture systems. Savings from economies of numbers are explicitly included in the formulation to determine the number of components in the platform. We show and discuss the savings we gain from economies of numbers.

**Keywords:** Optimization, Process Design, Energy Systems, Carbon Capture

## INTRODUCTION

Effectively combatting climate change relies on large-scale deployment of critical chemical process systems, such as carbon capture or water desalination. In traditional process system design approaches, engineers uniquely design each installation focused on economies of scale. However, this approach is expensive and leads to long deployment timelines. Modular design approaches derive savings from economies of numbers by offering a catalog of small, stackable designs. However, a pure modular approach neglects the benefits of economies of scale.

In this paper, we develop a rigorous, optimization-based design method, inspired by product family design literature [1], that designs a family of process variants while simultaneously optimizing a platform of unit module designs that can be shared across this set of processes. This approach seeks to exploit both economies of scale and economies of numbers to minimize costs while achieving manufacturing standardization and reduced deployment timelines. While well-developed

technologies can benefit from this approach, we apply it to novel process systems like carbon capture due to the importance of making this technology widely available within a short time period.

This work builds on our optimization formulation for process family design [2] and extends it to explicitly include the benefits of economies of numbers. Economies of numbers (sometimes referred to as economies of learning) is a well-documented cost-saving phenomenon [3,4]. It characterizes the manufacturing cost savings due to standardization; in particular, it captures the correlation between cost reduction and the number of times a particular product has been manufactured. Following an approach like that described by Gazzaneo et al. (2022), we develop a costing expression that captures total manufacturing costs as a function of the number of unit modules produced.

If the platform has a small number of unit module designs, there are fewer options to share across all the process variants. Therefore, we will be manufacturing more of each design and gaining increased benefits from economies of numbers. However, increasing the number

of unit module designs in the platform gives each process variant more options leading to a more “optimized” design (at the cost of reducing savings due to economies of numbers). With the optimization formulation in Stinchfield et al. (2023), the number of unit module designs included in the platform must be pre-specified. In this work, by including the economies of numbers explicitly, we allow the mathematical programming formulation to determine the optimal number of unit module designs to include in the platform. We demonstrate this approach on multiple case studies, including an MEA-based carbon capture system and a water desalination process.

## LITERATURE REVIEW

Modular and product family design approaches have been studied in many different industrial applications. Gonzales-Zugasti (2000) describes how a product family approach can be applied to NASA’s exploratory space missions beginning with a two-stage optimization approach [7]. Simpson et. al. (2004) used a genetic algorithm for product family design optimization for the selection of parts of aircraft [14]. Pirmoradi et al. (2015) devised a two-phase platform configuration approach utilizing sensitivity analysis, metamodeling, and a black-box optimization strategy to craft a variety of universal electric motor designs [9]. In general, research focused on product family design focuses on heuristic and stochastic optimization techniques, rather than employing rigorous deterministic mathematical programming algorithms.

Product family design derives significant savings from the standardization of elements within a product. Manufacturing cost savings associated with standardization are due to *economies of numbers* (sometimes referred to as *economies of learning*). Increasing the number of products to be produced results in lower per unit costs, as documented by Wright et al. (1936). Specifically, the authors reported how the per unit cost of manufacturing an airplane *decreased* with respect to the number of airplanes manufactured [10]. This correlation has since been documented across many industries with different levels of cost reduction.

The effect of economies of numbers can be captured mathematically as a function of the number of units manufactured,  $n$ , and their resulting discount factor,  $F_n$ . The learning rate  $\alpha$  captures the impact of production levels on cost, as shown in (1).

$$F_n = n^{-\alpha} \quad (1)$$

Equation (1) is also referred to as the learning curve and is shown graphically in Figure 1, with an  $\alpha = 0.2$ .

**Figure 1.** Example Learning Curve<sup>[13]</sup>  
( $\alpha = 0.2$ )

Learning curves are product specific. They exhibit the general behavior shown in Figure 1 but vary significantly depending on the specific industry and unit manufactured. In practice,  $\alpha$  is selected based on experience or data. Argot and Epple (1990) explored factors affecting this parameter, including organizational forgetting, turnover, and transfer of productivity gains, and how they can potentially reduce costs [11].

Economies of numbers has been mentioned occasionally, but favorably, in literature related to chemical and process systems engineering. Liebermann (1984) investigated this concept and used a many-shot approach to try and determine which factors affected the learning rates in a plant or chemical manufacturing context [3]. Weber et al. (2019) described how economies of numbers apply to the chemical process industries [12]. Gazzaneo et al. (2022) proposed a novel techno-economic framework for costing intensified modular systems in the process engineering industry [4].

This cost benefit from manufacturing standardization applies only to part of the overall process cost (e.g., labor but not materials). Therefore, we expect these learning curves to decay toward an asymptote. Gazzaneo et al. (2022) define a piecewise function that includes a lower limit on the discount factor, as shown in (2).

$$F_n = \begin{cases} n^{-\alpha}, & \text{if } n^{-\alpha} \geq F_{bound} \\ F_{bound}, & \text{if } n^{-\alpha} < F_{bound} \end{cases} \quad (2)$$

This modified relationship is shown in Figure 2 with  $\alpha = 0.2$  and  $F_{bound} = 0.7$ .

**Figure 2.** Example Learning Curve with Maximum Discount<sup>[4]</sup>  
( $\alpha = 0.2$  and  $F_{bound} = 0.70$ )

In this work, we use a similar economies of numbers correlation that also includes a maximum discount,  $F_{bound}$ , with a smooth transition. Our work then incorporates this correlation into a mixed-integer linear programming formulation for the simultaneous design of process families.

## PROBLEM APPROACH

In previous work, we have presented a discretization-based Mixed Integer Linear Program (MILP) to solve the process family design problem [2]. In this section, we present modifications to this formulation that include cost trade-offs associated with economies of numbers and avoid explicitly specifying the size of the platform. To find a comprehensive description of the problem, please see Stinchfield et al. (2023).

### Problem Description

Given a process architecture, we wish to specify the designs for a set of *process variants*. A process variant  $v$  requires customization of the process architecture to meet a set of specific requirements; the specifications are parameterized in the vector  $\mathbf{r}_v$ . For example, take an industrial refrigeration system that a grocery store chain wishes to deploy at 10 different stores. While the general refrigeration system architecture will be the same at each location (i.e., the units required to build the system), the design details for each store (e.g., the size and maximum cooling capacity) can be different.

The *process system architecture* refers to the flow-sheet of the process system; this defines all the *unit module types* necessary to build an instance of the process. In the case of the refrigeration system example, unit module types could include the compressor, condenser, valve, and evaporator. We store this set of unit module types in the set  $M$ . Each variant  $v$  will have exactly one of each unit module type  $m \in M$ . The variable vector  $\mathbf{d}_{v,m}$  is the *unit module type design* for each unit module type  $m$  and each variant  $v$ .

Our goal is to design and deploy multiple variants  $v \in V$  in a cost-optimal manner by determining the unit module type designs  $\mathbf{d}_{v,m}$  and operating variables  $\mathbf{o}_v$ . We wish to save on engineering and manufacturing costs by optimizing a platform of common unit module designs to share across the process variants. This means there are fewer unique units to design and reduced manufacturing costs for the shared designs due to economies of numbers. We separate the unit module types  $M$  into those that are designed *commonly* (stored in the set  $C$  and included in the platform) and the remaining ones that are designed *uniquely* for each variant (stored in the set  $U$ ). The sets  $C$  and  $U$  are disjoint ( $C \cap U = \emptyset$ ) while their union recovers the set  $M$  ( $C \cup U = M$ ). The design specifications for the shared platform unit module types are captured by the corresponding variable vectors  $\mathbf{d}_{c,l}$ . We index the

common designs by a label  $l \in L_c$  to differentiate between options (e.g., different sizes of a compressor). The collection of common designs  $\mathbf{d}_{c,l}$  for all common unit module types  $c \in C$  determines the platform  $\mathcal{P}$ . All unique unit module types  $u \in U$  are designed specifically for each variant; they do not require any standardized elements.

### Problem Formulation

To determine an optimal process system design for a single variant with a set of design requirements, a traditional approach would start by building the set of equations that defines the system (i.e., physics, costing, etc.). An optimization could then be performed, parameterized with the requirements, where the designs for all unit module types  $m \in M$  and operational decisions are decision variables. In most applications, this system of equations will be a nonlinear program (NLP). In our approach, we must design *multiple* systems, one for each variant  $v \in V$ . Additionally, the unit module designs included in the platform are optimized simultaneously. And, for each variant, the common unit module design must be selected from those in the platform. This introduces discrete decisions and leads to a Mixed-Integer Nonlinear Program (MINLP).

Successful optimization of MINLPs in process systems engineering can be a challenge; oftentimes, it is an active area of research. In the process family design setting, it can quickly become impractical to directly solve the MINLP with the entire set of design, costing, and performance equations in the overall formulation. Our approach to this challenge was to develop a Mixed-Integer Linear Programming (MILP) formulation that relies on a discretized set of *candidate* designs for the common unit module types  $c \in C$ . For each possible combination of candidate common unit module designs and each process variant  $v \in V$ , we optimize the process system for the unique unit module designs, operating variables, and cost. We call this a design *alternative* for variant  $v$ . From here, we build a set of feasible and infeasible design combinations and their associated costs. These form the input data for the MILP formulation.

We select a combination of common unit module designs to assign to a particular variant using the binary decision variable  $x_{v,a}$ . Here,  $a$  refers to a particular design *alternative*, and all feasible alternatives for a variant  $v$  are stored in the set  $A_v$ . The binary decision variables  $y_{c,l,n}$  determine the designs of common unit module types to include in the platform and the number that are manufactured. The parameter  $M_c$  sets the upper limit on the number of designs of unit module type  $c$  to include in the platform. Of course, the problem is constrained to ensure we do not select alternative  $a$  for a variant  $v$  unless we have also selected the corresponding unit module designs in the platform.

As described in the previous section, we aim to capture cost savings associated with economies of numbers within our formulation. Like Gazzaneo et al. (2022), we use a function that approaches  $F_{bound}$  as  $N \rightarrow \infty$ , and the smooth formulation is shown in (3).

$$F_n = F_{bound} + (1 - F_{bound}) \times n^{-\beta} \quad (3)$$

This function captures the cost reduction due to economies of numbers while accounting for fixed costs (e.g., materials) that do not decrease with increasing  $n$ . The parameter  $\beta$  also represents a learning rate. However, since this is only applied to a portion of the overall manufacturing costs, we use different values from  $\alpha$  to capture similar behavior to that in Gazzaneo et al. (2022), as shown in Figure 3.

**Figure 3.** Learning Curve with Asymptotic Approach towards Max. Discount ( $\alpha = 0.2$ ,  $F_{bound} = 0.70$ ,  $\beta = 0.8$ )

We pre-compute each possible discounted unit module cost based on the number of times the unit module type could be manufactured. The base cost of each unit module type  $c$  design  $l$  is stored in  $p_{c,l}$ . We store the discounted costs in  $\widehat{p}_{c,l}^n$ , where each entry represents the cost of unit module type  $c$  for common design  $l$  if it is manufactured  $n$  times. We introduce the binary variable  $y_{c,l,n} \in \{0,1\}$  to indicate the number of manufactured units of unit module type  $c$  and common design  $l$ .

Formulation (4) describes the MILP we used to design a process family from a set of candidate common designs with discounts from economies of numbers.

$$\min_{x,y,\rho} \sum_{v \in V} w_v \sum_{a \in A_v} x_{v,a} c_{v,a} - \rho \quad (4a)$$

$$\text{s. t.} \quad \sum_{a \in A_v} x_{v,a} = 1 \quad \forall v \in V \quad (4b)$$

$$\sum_{l \in L_c} (1 - y_{c,l,0}) \leq M_c \quad \forall c \in C \quad (4c)$$

$$x_{v,a} \leq 1 - y_{c,l,0} \quad \forall c \in C, l \in L_c, (c, l) \in Q_a$$

$$\sum_{n=0}^N y_{c,l,n} = 1 \quad \forall c \in C, l \in L_c$$

$$\sum_{n=0}^N n \times y_{c,l,n} = \sum_{v \in V} \sum_{a \in A_{v,c,l}} w_v x_{v,a}$$

$$\rho = \sum_{c \in C} \sum_{l \in L_c} \sum_{n=0}^N n \times y_{c,l,n} \times (p_{c,l} - \widehat{p}_{c,l}^n)$$

$$0 \leq x_{v,a} \leq 1$$

$$y_{c,l,n} \in \{0,1\}$$

$$\rho \in \mathbb{R}^1$$

This formulation generally performs two main functions, (1) selecting which candidate design should be included within the process platform and (2) which common designs should be used at each variant, all while considering the effects of economies of numbers. The objective (4a) minimizes the total weighted cost of all variants, including the total savings from economies of numbers, contained in the variable  $\rho$ . Constraint (4b) ensures only one alternative (i.e., combination of common unit module designs) is selected for each variant. Constraint (4c) sets an upper limit of  $M_c$  on the number of common designs selected to be in the platform. Constraint (4d) ensures an alternative can only be selected if we also choose to select the required unit module designs for the platform. (4e) and (4f) constrain the binary indicator  $y_{c,l,n}$  to be 1 if design  $l$  for unit module type  $c$  has been selected to be manufactured  $n$ -times and 0 otherwise. (4g) calculates the total cost savings attributed to unit module manufacturing standardization for the given process family and stores the entire discount in the variable  $\rho$ . (4h) – (4j) defines the domain for the three optimization variables. Notably, (4g) defines  $x_{v,a}$  to be a continuous variable between the bounds of 0 and 1. For all case studies,  $x_{v,a}$  converges to binary decision, most likely due to similarities in the formulation to the  $P$ -Median optimization problem [13].

## CASE STUDY

In this section, we describe the case study used to demonstrate our optimization approach. We chose a monoethanolamine solvent-based carbon capture system simulated in Aspen Plus® as a part of the CCSi2 initiative [6]. The CCSi2 initiative focused on developing computational tools and models for accelerating the commercialization of carbon capture technologies. The flowsheet described by Morgan et al. (2022) is shown in Figure 4.

Solvent-based processes, particularly amines, are a mature class of technology for CO<sub>2</sub> capture from point sources of power generation and industrial processes. The solvent-based CO<sub>2</sub> capture process is shown schematically in Figure 4.

(4d)  
(4e)

Figure 4. MEA Carbon Capture Flowsheet

As shown in Figure 4, the point source flue gas containing CO<sub>2</sub> enters the bottom of the absorber and is contacted countercurrently with solvent flowing down the column. The CO<sub>2</sub>-lean solvent stream enters at the top of the column. The transfer of CO<sub>2</sub> from the gas to the liquid occurs through reactive absorption, and the mass transfer area is generally provided by structured packing. Since the reaction of CO<sub>2</sub> with amine is exothermic, solvent intercooling is often included in the process design to expel the heat of absorption associated with the reaction. At one or more locations in the column, a portion of the solvent is extracted and cooled by cooling water before being returned to the column. This generally results in lowering the temperature profile in the absorber and thus increasing the driving force for CO<sub>2</sub> uptake in the liquid. The flue gas with reduced CO<sub>2</sub> content exits the top of the absorber, and the CO<sub>2</sub>-rich solvent exits the bottom. The rich solvent is pressurized to avoid flashing at higher temperatures required for solvent regeneration and is heated in the lean/rich heat exchanger by the lean solvent exiting the bottom of the stripper. In the stripper the CO<sub>2</sub> is separated from the solvent with the energy requirement for the endothermic reaction provided by the steam input to the reboiler. The stream exiting the top of the stripper primarily contains CO<sub>2</sub> and H<sub>2</sub>O, the latter of which is condensed and returned to the stripper as reflux. This results in a high purity stream of CO<sub>2</sub>, which is compressed and sent for sequestration or utilization. The lean solvent exits the bottom of the stripper and is cooled by the rich solvent in the lean/rich heat exchanger. The trim cooler, which uses cooling water, provides the residual duty required to cool the solvent prior to its return to the top of the absorber column.

This model has been adapted in this work for a process family design problem that accommodates a variety of flue gas feed conditions including a range of flowrates and CO<sub>2</sub> concentrations representing different industrial flue gas sources. We define the set of variants  $v \in V$  to be different combinations of flue gas flow rates and flue gas CO<sub>2</sub> concentrations. This was motivated by the fact that these quantities vary significantly by carbon capture application, and the design decisions depend heavily on these two quantities but differ significantly at each potential carbon capture location, depending on the

capacities of the plants and the source of CO<sub>2</sub>. For this case study, we consider seven flue gas flow rates and nine CO<sub>2</sub> concentrations.

The set of unit module types for this system contains all of those types defined in the flowsheet, which is to say  $M = [\text{absorber, pump, heat exchanger, regenerator, condenser, flash drum, cooler, mixer}]$ . For the commonly designed absorber and regenerator (identified by the blue units shown graphically in Figure 4), we design for a specific *volume* of each column. To run simulations in Aspen Plus®, absorber and regenerator designs were specified using reported parameters from NCCC [6] as a baseline. We tested six absorber diameters (0.5m, 0.6m, ..., 1.0m) and eight regenerator diameters (0.3m, 0.4m, ..., 1.0m). Furthermore, to optimize the lean loading, we considered five different CO<sub>2</sub> lean loading concentrations (0.16, 0.17, 0.18, 0.19, 0.20) and selected the best lean loading for each combination of design for the absorber, regenerator, and process variant based on lowest total annualized cost. Given the 63 different process variants we wish to design, six absorber designs, eight regenerator designs, and five CO<sub>2</sub> lean loadings considered in this case study required 15,120 simulations. After running each simulation, the results were used to calculate the total annualized cost for each design alternative.

## RESULTS & DISCUSSIONS

In this section, we present the results from the case study described in the previous section by employing the methodology described in the Problem Approach section. We discuss key findings from the results.

We designed the process family using the optimization formulation described in (4). We do not include (4c), instead allowing the formulation to select however many of the candidate unit module designs to include in the platform. We built this optimization formulation in Python using the open-source algebraic modeling language, Pyomo [5]. The optimization resulted in the selection of four common designs for the absorber (out of six possible) and four common designs for the regenerator (out of eight possible), as shown in Figure 5.

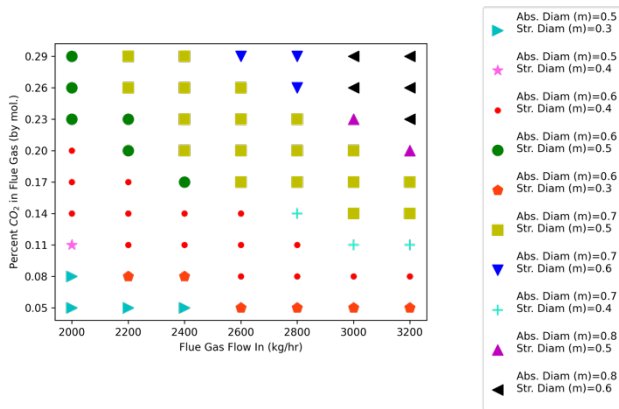

Figure 5. Carbon Capture Platform,  $\mathcal{P}$

The common designs selected for the platform are identified by the blue shaded boxes. To differentiate between the designs,  $l$  corresponds to the diameter (in  $m$ .) of the design.

The design of the platform  $\mathcal{P}$  is determined simultaneously with the design of the process family  $\mathcal{F}$  in the optimization formulation. From the process platform constructed and shown in Figure 5, the corresponding optimal design of the process family is shown in Figure 6.

**Figure 6.** Carbon Capture Process Family,  $\mathcal{F}$

Figure 6 describes which combinations of absorber and regenerator designs offered in the platform  $\mathcal{P}$  (shown in Figure 5) are assigned to each variant  $v \in V$ . The x-axis corresponds to the flue gas flow rate that describes a particular variant  $v$ ; the y-axis corresponds to the percentage of  $\text{CO}_2$  in the flue gas at variant  $v$ .

Using Gurobi<sup>®</sup>, it took under a second to solve this problem. The formulation presented in (4) for this case study resulted in 1,376 constraints, 646 continuous variables, and 896 binary variables. The objective of this optimization resulted in a total annualized cost, discounted by savings due to economies of numbers, of \$72.5M. We used a learning rate of  $\beta = 0.8$  and a maximum discount factor of  $F_{bound} = 0.7$ . Savings associated with economies of numbers, captured in the value for the variable  $\rho$ , came to approximately \$2.38M annually. The percentage of savings associated with the overall cost is approximately 3.3%. If we only consider the capital costs for this system, the percent savings is 26.8%.

To compare this approach to a more traditional method, we optimized each carbon capture variant independently. To do this for the case study presented, we selected the combination of candidate absorber and regenerator designs that minimized the cost of the variant, with no discounts due to economies of numbers or limitations on the number of common designs that could be used. In this way, we design each variant *individually* rather than as a family. The overall objective cost of this individual optimization came to \$74.86M, which is more than \$2M more expensive than taking the

process family design approach. This demonstrates the importance of considering economies of numbers in the design of chemical process systems due to the benefits it can provide.

## CONCLUSIONS & FUTURE WORK

Process family design lends insight into how standardization within the process systems engineering manufacturing industry can potentially save money. In particular, the optimization approach described in this paper aims to capture and fully exploit cost savings by quantifying the impact of economies of numbers on the design of a process family. We demonstrated this approach in a carbon capture case study motivated by the need to deploy these systems rapidly and cost-effectively to combat the effects of climate change. The results of this case study showed a decrease in total annualized cost compared to taking the discretized approach described in Stinchfield et al. (2023) and a traditional engineering approach. The optimization formulation presented in this work selected the size of the platform, rather than having to pre-define the size, which further allowed the formulation to determine the optimal trade-off between standardization and customization of the system. We are investigating decomposition strategies for the MINLP formulations from Stinchfield et al. (2023).

## ABSTRACT

Cyclic adsorption processes attain a cyclic-steady state (CSS) condition by undergoing repeated cycles in time, owing to their transient and modular nature. Mathematically, solving a set of underlying nonlinear partial differential equations iteratively for different steps in a cycle until the CSS condition is attained presents a computational challenge, making the simulation and optimization of cyclic adsorption processes time-consuming. This paper focuses on expediting the CSS convergence in adsorption process simulations by implementing two vector-based acceleration methods that offer quadratic convergence akin to Newton's methods. These methods are straightforward to implement, requiring no prior knowledge of the first derivatives (or Jacobian). The study demonstrates the efficacy of accelerated convergence by considering two adsorption processes that exhibit complex dynamics, namely, a four-step vacuum swing adsorption and a six-step temperature swing adsorption cycles for post-combustion CO<sub>2</sub> capture. The case studies showcase the potential for improved computational efficiency in adsorption process simulations.

## INTRODUCTION

Cyclic adsorption processes are widely employed for industrial gas separations [1, 2]. The underlying separation mechanism involves the solid adsorbent to selectively adsorb one or more gases from a gaseous mixture. Depending on the choice of regeneration, i.e., by either varying temperature or pressure or both, the adsorbed gases are recovered or removed. Accordingly, different process operational modes such as pressure swing adsorption (PSA), vacuum swing adsorption (VSA), temperature swing adsorption (TSA), etc. are implemented [3].

Unlike distillation and absorption, which typically operate at steady-state conditions, cyclic adsorption processes are transient in nature and are operated cyclically in a sequence of constituent steps, thus attaining a cyclic steady-state condition (CSS), instead of a true steady state [2]. From a process design perspective, these processes are dictated by the set of nonlinear partial differential equations (PDEs) resulting from mass, momentum, and energy balances. Further, the modular nature allows these processes to undergo several

constituent steps in each cycle. The choice and the sequence of steps, as well as the direction of flows, can give rise to several process configurations [4], which need to be optimized [5]. Another critical design parameter is the choice of the solid adsorbent and the contactor structure. Therefore, designing cyclic adsorption processes for a given adsorbent requires solving the nonlinear PDEs for each step repeatedly until CSS and then calculating the key process performance indicators based on the transient profiles of state variables obtained at the CSS. The CSS ensures that these profiles no longer vary as the numerical iterations are continued.

Despite such flexibility in adsorption process design, the main bottleneck for designing optimal process configurations lies in very high computational costs associated with repeated solving of nonlinear PDEs in process simulations to attain the CSS condition from an arbitrary initial condition. Although simulating one process configuration for a given adsorbent takes a few minutes of computational time [5], process models are often coupled with optimizers where thousands of operating conditions are probed, which makes the process design and

optimization computationally demanding. Given the flexibility of synthesizing different process configurations and the recent advent of a multitude of adsorbents for gas separations [6], the problem of finding the optimal design for a given separation further exacerbates as evaluating different process configurations and adsorbents will be a computationally daunting task.

To speed up adsorption process simulations, there have been some previous efforts to accelerate the determination of CSS [7-13]. For instance, Croft and LeVan in their first paper [7] incorporated Newton's method to speed up the iterations to attain CSS. Newton's method provided quadratic convergence near the CSS solution and converged faster than the cycle iterative procedure. However, the extra computation time for the calculation of the Jacobian matrix in each Newton iteration impaired the convergence acceleration [7, 8]. In the third paper of the series [9], Ding and LeVan developed several acceleration algorithms for the convergence of adsorption process simulations, which include a hybrid Newton-Broyden method, an iterative secant method, a sensitivity interpolation method, and a dynamic error tolerance method. These methods achieved better accelerations

compared to the Newton's method [9]. Despite this, some of the methods rely on the prior knowledge of the Jacobian matrix. On the other hand, Nilchan and Pantelides [11] completely discretized the PDEs into algebraic equations and imposed the CSS condition as a constraint. Perturbation techniques have also been explored for accelerated convergence of CSS [12]. Moreover, Pai et al. [13] recently developed machine learning models to predict approximate CSS condition which is then fed as an initial condition to the PDE-based process model for rapid determination of CSS condition. The machine learning model for initial condition prediction was developed for a four-step VSA cycle based on the CSS profiles from hundreds of different operating conditions. In the context of other related separations, methods such as the single shooting method were considered for the convergence of semicontinuous distillation process simulations [14].

This study focuses on implementing two acceleration methods for the convergence of the CSS condition in adsorption process simulations, with an overall goal of significantly reducing the computational times of current adsorption process design and optimization tools. These acceleration methods require no prior knowledge of the

$$\frac{1}{P} \frac{\partial P}{\partial t} - \frac{1}{T} \frac{\partial T}{\partial t} = - \frac{T}{P} \frac{\partial}{\partial z} \left( \frac{P}{T} v \right) - \frac{RT}{P} \frac{1 - \varepsilon}{\varepsilon} \sum_i^m \frac{\partial q_i}{\partial t}$$

**Column energy balance**

$$\left[ \frac{1 - \varepsilon}{\varepsilon} \left( \rho_s C_{p,s} + C_{p,a} \sum_{i=1}^m q_i \right) \right] \frac{\partial T}{\partial t} = \frac{K_z}{\varepsilon} \frac{\partial^2 T}{\partial z^2} - \frac{C_{p,g}}{R} \frac{\partial(vP)}{\partial z} - \frac{C_{p,g}}{R} \frac{\partial P}{\partial t} - \frac{1 - \varepsilon}{\varepsilon} C_{p,a} T \sum_{i=1}^m \frac{\partial q_i}{\partial t} + \frac{1 - \varepsilon}{\varepsilon} \sum_{i=1}^m (-\Delta H_i) \frac{\partial q_i}{\partial t} - \frac{2h_{in}(T - T_w)}{\varepsilon r_{in}}$$

**Wall energy balance**

$$\rho_w C_{p,w} \frac{\partial T_w}{\partial t} = K_w \frac{\partial^2 T_w}{\partial z^2} + \frac{2r_{in} h_{in}(T - T_w)}{r_{out}^2 - r_{in}^2} - \frac{2r_{out} h_{out}(T_w - T_a)}{r_{out}^2 - r_{in}^2}$$

**Darcy's pressure drop**

$$v = \frac{4}{150\mu} \left( \frac{\varepsilon}{1 - \varepsilon} \right)^2 r_p^2 \left( - \frac{\partial P}{\partial z} \right)$$

**Linear driving force model**

$$\frac{\partial q_i}{\partial t} = k_i (q_i^* - q_i)$$

Jacobian matrix and are easier to implement for any cyclic process. Simulation of two different adsorption processes is chosen to test the two acceleration methods. As a first case, a four-step VSA cycle designed for post-combustion CO<sub>2</sub> capture [5] was used for the process simulation. The second case explores the simulation of a six-step TSA cycle designed again for post-combustion CO<sub>2</sub> capture [15]. Despite both processes exhibiting complex dynamics and taking several cycles to achieve CSS, they differ in their process dynamics and how they converge to CSS. This makes them an ideal case study for testing the vector-based acceleration methods.

## METHODOLOGY

### Adsorption Process Model

The mathematical model for simulating adsorption column dynamics consists of a system of nonlinear PDEs obtained by solving mass, momentum, and energy balances [5]. The model assumptions include (1) ideal gas, (2) axially dispersed plug flow representing the bulk flow, (3) linear driving force model describes the bulk-to-surface mass transfer, (4) there exist no radial gradients for state variables, i.e., composition, pressure, and temperature, (5) Darcy law used for pressure drop calculations, (6) thermal equilibrium between the gas and the solid phases, and (7) uniform column properties. The resulting governing equations based on these assumptions are provided in **Table 1**.

The model is numerically solved by discretizing the spatial terms in PDEs into 30 finite volumes with a total variation diminishing (TVD) scheme involving the van-Leer flux limiter [5]. The resulting ordinary differential equations (ODEs) are then integrated based on standard ODE solvers in Python [16]. The process simulations are carried out using a uni-bed approach where a single column undergoes all constituent steps sequentially. The column is initialized with feed composition at low pressure and the cycle is simulated until the CSS condition. At CSS, state variables such as composition, pressure, and temperature profiles are obtained.

### Cyclic-steady state (CSS) condition

Several mathematical criteria can be employed for the attainment of CSS from a pre-defined initial condition in adsorption process simulations [5, 17-19]. For instance, few studies assumed that the process reaches CSS after a very large number of cycle iterations [16]. Most of the other studies, however, assume that the CSS criterion is met when absolute integral differences in axial profiles of state variables [5] or absolute overall mass balance errors [5, 18] fall below a tolerance limit. Effendy et al. recently proposed a rigorous CSS criterion, reducing the differences between the current and CSS states of axial profiles to a set tolerance limit without needing prior

knowledge of the CSS [19].

This study uses the same definition for the CSS condition as that of the case study [5], which assumes that the CSS criterion is met when the overall mass balance error for the process is less than 0.5%.

### Methods for Accelerated Convergence of CSS condition in process simulations

An important basis for implementing the acceleration methods in the present study is that the process simulation of cyclic adsorption processes is a fixed point (or Picart) iteration problem [19]. Schematically shown in **Figure 1**, a number of cycles are simulated (cycle iterations) from an arbitrary initial condition to a fixed-point CSS condition. If  $f$  is a function representing the adsorption process simulator, then the fixed-point iteration problem can be written as

$$\Delta_{n+1} = f(\Delta_n) \quad (1)$$

In the above equation, the adsorption process simulator,  $f$ , takes the previous state of the adsorption column ( $\Delta_n$ ) as an input and returns the subsequent state of the adsorption column ( $\Delta_{n+1}$ ). Note that  $\Delta$  represents a vector of state variables such as gas-phase composition, solid-phase concentrations, pressure, and column and wall temperatures across the adsorption columns. After

**Figure 1.** Schematic of a cyclic adsorption process simulator. Adapted from [19].

several iterations, the CSS condition is achieved. Although fixed point iterations are the simplest way to obtain nonlinear solutions without any prior knowledge of  $f$  and its derivative [20], linear convergence to CSS makes it computationally slow [19].

Alternatively, Eq. 1 can be reformulated as a root-finding problem:

$$\varphi(\Delta) = f(\Delta) - \Delta = 0 \quad (2)$$

A common approach for solving Eq. 2 is Newton's method,

$$\Delta_{n+1} = \Delta_n - \frac{\varphi(\Delta_n)}{\varphi'(\Delta_n)} \quad (3)$$

which provides a quadratic and faster convergence to solutions, compared to fixed-point iterations. The main drawback of Newton's method as a convergence

accelerator is the prior knowledge of first derivatives or Jacobian, i.e.,  $\varphi'(\Delta)$ , which is not straightforward to calculate for many realistic systems.

Without affecting the order of convergence, Newton's method can be modified into "derivative-free" algorithms such as Steffensen's methods or its equivalents [19, 20]. Steffensen's convergence acceleration for a scalar nonlinear fixed-point equation,  $x = g(x)$ , can be represented as:

$$x_{n+3} = x_n - \frac{(x_{n+1} - x_n)^2}{(x_{n+2} - 2x_{n+1} + x_n)} \quad (4)$$

Practical problems such as adsorption process simulations often deal with many unknown variables and systems of nonlinear PDEs. Obtaining the solutions typically requires the spatial discretization of PDEs which introduces a vector of state variables ( $\Delta$ ) across the column. Several vector-based acceleration methods are available in the literature to deal with vector nonlinear fixed-point problems [20].

In this study, two vector-based acceleration methods proposed in the literature are considered for the accelerated convergence of the CSS condition in adsorption process simulations. Particularly, the acceleration algorithms proposed by Irons and Tuck [22] and Graves-Morris [23] are evaluated for CSS convergence acceleration. It is worth noting that both methods are the vector extensions of Steffensen's scalar method (Eq. 4).

### Irons and Tuck Acceleration Method

The vector acceleration method proposed by Iron and Tuck [22] can be expressed as:

$$\Delta_{n+3} = \Delta_{n+2} - \frac{(\Delta_{n+2} - \Delta_{n+1}) \cdot (\Delta_{n+2} - 2\Delta_{n+1} + \Delta_n)}{\|\Delta_{n+2} - 2\Delta_{n+1} + \Delta_n\|^2} (\Delta_{n+2} - \Delta_{n+1}) \quad (5)$$

Note that this acceleration method is invoked alternately with a basic fixed-point cycle iteration.

### Graves-Morris Acceleration Method

The approach of Graves-Morris [23] is given by:

$$\Delta_{n+3} = \Delta_{n+1} - \frac{\|\Delta_{n+2} - 2\Delta_{n+1} + \Delta_n\|^2}{(\Delta_{n+1} - \Delta_n) \cdot (\Delta_{n+2} - 2\Delta_{n+1} + \Delta_n)} (\Delta_{n+2} - \Delta_{n+1}) \quad (6)$$

This accelerator is also applied alternately with a basic fixed-point iteration in adsorption process simulations.

## RESULTS AND DISCUSSION

Two case studies involving different adsorption processes are considered to test the convergence accelerator methods. The first examines a VSA cycle, where the process dynamics are heavily influenced by the pressure swing between the adsorption and desorption steps. The second explores a TSA cycle, where the dynamics are driven by the temperature swing during the process. Thus, the two cases differ in terms of their process dynamics and their convergence to CSS.

### Case 1: Four-step VSA cycle

Here, the vector acceleration methods are incorporated into the process simulation of a four-step VSA cycle separating the binary mixture of CO<sub>2</sub>/N<sub>2</sub> for postcombustion CO<sub>2</sub> capture [5]. The VSA process was designed to recover CO<sub>2</sub> from a binary mixture of 15% CO<sub>2</sub> and 85% N<sub>2</sub> at ambient pressure, which represents dry flue gas from coal-fired power plants.

**Figure 2.** Four-step vacuum swing adsorption cycle designed for post-combustion CO<sub>2</sub> capture [5].

**Figure 2** illustrates the schematic of the four-step VSA cycle. The cycle consists of feed pressurization (FP), adsorption (ADS), co-current blowdown (BLO), and counter-current evacuation (EVAC) steps. Each step can be implemented using appropriate boundary conditions and isotherm parameters provided by Haghpanah et al. [5]. Commercial zeolite 13X was used as the adsorbent. The example considered represents the complex dynamics of adsorption processes, and several cycles are needed to reach CSS. Similar to reference work, CO<sub>2</sub> and N<sub>2</sub> isotherms on zeolite 13X were described using the competitive dual-site Langmuir isotherm model. Finally, the cycle operating conditions used for the simulation are as follows:  $P_H = 1$  bar,  $P_I = 0.2$  bar,  $P_L = 0.1$  bar,  $v_0 = 1.0$  m s<sup>-1</sup>,  $t_{FP} = 15$  s,  $t_{ADS} = 15$  s,  $t_{BLO} = 30$  s,  $t_{EVAC} = 40$  s. Note that  $P_H$ ,  $P_I$ , and  $P_L$  are the feed, intermediate, and low pressures in adsorption, blowdown, and evacuation steps, respectively. The feed is introduced into the column in the adsorption step with an interstitial velocity  $v_0$ .  $t_{FP}$ ,  $t_{ADS}$ ,  $t_{BLO}$ , and  $t_{EVAC}$  are the step durations of feed pressurization, adsorption, blowdown, and evacuation steps, respectively. The column was first initialized with feed composition, and the simulation was conducted until CSS.

**Figure 3.** Convergence of overall mass balance error for the four-step VSA process simulation using the fixed-point iteration, Irons and Tuck [22] algorithm, and Graves-Morris method [23].

**Figure 3** shows the convergence of the overall mass balance error for the simulation. Without any accelerator, the fixed-point iteration took 291 cycles to reach the CSS. The four-step VSA process simulations are repeated for the same operating conditions with the two acceleration methods. The convergence of the overall mass balance for the simulation with the accelerators can also be seen in **Figure 3**. Using the acceleration algorithm by Irons and Tuck, the CSS convergence was achieved after 199 cycles. The computations were reduced by approximately one-third. On the other hand, Graves-Morris's acceleration method almost reduced the number of iterations to CSS by less than half, i.e., 130 cycles, outperforming the Irons and Tuck algorithm. The CO<sub>2</sub> purity and recovery obtained at CSS using all the three methods are reported in **Table 2**. The acceleration methods offered faster convergence to CSS while achieving the same performance as that of the conventional fixed-point iteration with rather straightforward implementation.

**Table 2:** Performance of the VSA process using three different approaches for the convergence of CSS.

Method	CO <sub>2</sub> purity (%)	CO <sub>2</sub> recovery (%)
Fixed-point iteration	79.64	37.36
Irons & Tuck [21]	79.65	37.36
Graves-Moris [22]	79.64	37.36

### Case 2: Six-step TSA cycle

In this case study, the vector acceleration methods are employed in the process simulation of a six-step TSA cycle proposed by Joss et al. [15] to separate the binary

feed mixture of 12% CO<sub>2</sub> and 88% N<sub>2</sub> using commercial zeolite 13X. **Figure 4** shows the six-step TSA cycle consisting of the adsorption (ADS), recovery (REC), two heating (HEAT), purge (PUR), and cooling (COOL) steps. For simulating this process, the cycle operating conditions and the simulation parameters have been retrieved from Joss et al. [15]. The adsorption step occurs under a constant pressure of 1.3 bar and at an ambient temperature of 300 K. In the heating steps, the column is externally heated to 420 K to desorb CO<sub>2</sub>. The cycle is simulated for the following operating conditions: T<sub>COOL</sub> = 300 K, T<sub>HEAT</sub> = 420 K, v<sub>0</sub> = 1.4 m s<sup>-1</sup>, t<sub>ADS</sub> = 150 s, t<sub>REC</sub> = t<sub>PUR</sub> = 25 s, t<sub>HEAT1</sub> = 150 s, t<sub>HEAT2</sub> = 600 s, t<sub>COOL</sub> = 600 s. It is worth noting that the durations of TSA cycles are much longer compared to VSA cycles due to heat transfer limitations. Here, a column that is completely saturated with N<sub>2</sub> is used as an initial condition to simulate the cycle until CSS.

**Figure 4.** Six-step temperature swing adsorption cycle proposed by Joss et al. [15] for post-combustion CO<sub>2</sub> capture.

**Figure 5.** Convergence of overall mass balance error for the six-step TSA process simulation using the fixed-point iteration, Irons and Tuck [22] algorithm, and Graves-Morris method [23].

**Figure 5** and **Table 3** present the comparative performances of the vector acceleration methods for this

simulation. As can be seen from **Figure 5**, the fixed-point iteration needed 23 cycles to reach CSS, where the overall mass balance convergence is less than 0.5%. When the accelerators are incorporated into the process simulations, the cycle converges to CSS in 18 and 14 cycles using Irons and Tuck and Graves-Morris's methods, respectively. While the TSA cycle reached CSS in fewer cycles compared to the VSA cycle, each TSA cycle requires a significantly longer computational time. Hence, utilizing accelerator methods facilitated almost 1.25 – 1.67 times faster CSS convergence compared to the fixed-point iteration. The true impact of accelerators on computational speeds up will further be realized in process optimizations. It is worth reiterating that the implementation of the considered acceleration methods is straightforward. Table 3 reports the comparable CO<sub>2</sub> purity and recovery obtained at CSS using all the methods.

**Table 3:** Performance of the TSA process using three different approaches for the convergence of CSS.

Method	CO <sub>2</sub> purity (%)	CO <sub>2</sub> recovery (%)
Fixed-point iteration	93.08	99.02
Irons & Tuck [21]	93.06	98.92
Graves-Morris [22]	93.06	98.94

## CONCLUSIONS

The computational complexity in cyclic adsorption process simulations mainly arises from solving a set of nonlinear partial differential equations iteratively for every cycle until the cyclic-steady state (CSS) is achieved making the simulation and optimization routines of these processes exceedingly time-consuming. Despite prior efforts to expedite CSS convergence, the computational burden of CSS still persists in adsorption process simulations.

This study contributes to overcoming the computational challenges of CSS determination in adsorption process simulations by implementing two vector-based acceleration methods proposed previously in the literature. The acceleration methods of Irons and Tuck and Graves-Morris can offer quadratic convergence near the CSS solutions, like Newton's method without requiring the prior information of the first derivatives or Jacobian. These methods are straightforward to implement in adsorption process simulations. The acceleration capabilities of these methods are demonstrated by considering two different adsorption processes, namely, a four-step VSA cycle and a six-step TSA cycle, which undergo complex dynamics and take multiple cycles to reach CSS. The results showed that the Graves-Morris accelerator provided expedited convergence by speeding the convergence of VSA simulations more than double. For the same case, Irons and Tuck's method reduced the cycle

iterations to CSS by one-third. When the accelerator methods are incorporated into the process simulations of a six-step TSA cycle, the Graves-Morris accelerator marginally provides better convergence than Irons and Tuck's method by reducing the number of iterations to 14 from the original 23 fixed-point cycle iterations. In the context of process optimization, where thousands of operating conditions must be probed, these acceleration methods can significantly reduce the overall computational times with no extra effort. This work is a first step in addressing the computational challenges associated with adsorption process simulations. In the future, these methods will be extended to different adsorption processes and efforts will be directed to further improve the convergence of CSS. For instance, incorporating machine learning principles into the acceleration framework can further boost CSS convergence speeds.

## ACKNOWLEDGEMENTS

This work was carried out as a part of the project "Removing non-CO<sub>2</sub> greenhouse gas emissions to support ambitious climate transitions (REPAIR)" (Project number: 101069905) funded by the European Commission via the European Climate, Infrastructure and Environment Executive Agency (CINEA) within the Horizon Europe framework.

## ABSTRACT

Solvent-based carbon capture processes typically suffer from the temperature rise of the solvent due to the heat of absorption of CO<sub>2</sub>. This increased temperature is not thermodynamically favorable and results in a significant reduction in performance in the absorber column. As opposed to interstage coolers, which only remove, cool, and return the solvent at discrete locations in the column, internal coolers that are integrated with the packing can cool the process inline, which can result in improved efficiency. This work presents the modeling of these internal coolers within an existing generic, equation-oriented absorber column model that can cool the process while allowing for simultaneous mass transfer. Optimization of this model is also performed, which is capable of optimally choosing the best locations to place these devices, such that heat removal and mass transfer area are balanced. Results of the optimization have shown that optimally placed cooling elements result in a significant increase in the capture efficiency of the process, compared to a similar column with no internal cooling, with a common trend being the cooling of the column in the temperature bulge region. It is observed that by optimally placing an internal cooler, the solvent flow rate can be decreased, and the CO<sub>2</sub> lean loading can be increased while still maintaining the same efficiency. These process changes can lead to a substantial reduction in costs due to lower reboiler duty.

## INTRODUCTION

Post-combustion CO<sub>2</sub> capture is a critical approach for achieving net-zero emissions. Among many potential technologies for post-combustion CO<sub>2</sub> capture, solvent-based capture technologies are at the forefront due to their maturity, ease of operation, availability of efficient contactors for solvent-based capture systems, and many other advantages.

A common family of aqueous solvents utilized in this process is one that contains amine functional groups. The solvent absorption process excels compared to other capture methods, such as solid sorbents, due to its ability to react with carbon dioxide even at low partial pressure, as well as having a high capacity of absorption [1]. There are, however, two key disadvantages associated with

this process. The first disadvantage is that the high concentration of water in these solvents requires a significant amount of steam for the use of the reboiler in the regeneration process [2]. This steam utilization results in the energy intensity of the process being up to 4 MJ per ton of CO<sub>2</sub> captured, which accounts for the majority of the operating cost. The second disadvantage is the high exothermic heat of absorption for CO<sub>2</sub>. In the case of a 30 wt% MEA solvent, the heat of absorption can range from 84 to 100 kJ/mol CO<sub>2</sub> [3, 4]. This heat can cause temperatures within the absorber tower to rise substantially, thus increasing the equilibrium pressure of CO<sub>2</sub> by several orders of magnitude, resulting in a reduced mass transfer rate [3].

To keep the solvent capture process operating as efficiently as possible, heat needs to be removed from

the absorber column to operate the tower under more favorable conditions. Therefore, it is common to use inter-stage coolers [5, 6], which withdraw a portion of the solvent or the entire solvent from discrete locations within the column, and cool and return it in the next stage below. Karimi et al. showed that optimal placement of an inter-cooler within the absorber column can result in energy savings as high as 7.27% by reducing the amount of solvent flow required for operation [7]. However, while cooling is achieved at discrete locations, intercoolers fail to achieve continuous heat removal along the height of the tower to reach an optimal temperature profile to maximize performance and/or economics. Therefore, the use of a cooling method that is integrated with the packing of the tower is needed.

Additive manufacturing has become a rapidly growing method of developing innovative technologies, with advancements in 3D printing leading to products that would be impossible to create using traditional manufacturing methods. A recent novel application of 3D printing is structured metal packing that can be utilized for a packed column. The intensified packing device created at Oak Ridge National Laboratory is a 3D printed structured packing element with a double-walled design, which creates two disjoint flow channels in which the process fluid can be kept in a flow channel separate from the cooling fluid in the other [8]. Tests utilizing this device have shown that carbon capture can be increased between 3 to 15% compared to columns with no cooling [9, 10].

A disadvantage of such a device is that the cooling water channels reduce the total amount of available process volume, which reduces the mass transfer area. In addition, there are several other aspects that need to be evaluated for the optimal configuration of absorbers in the presence of such intensified towers. This work seeks to answer the following questions. Where are the optimal locations at which to implement internal cooling such that performance is maximized? What is the best configuration of cooling water flow within the devices? How does variance in operating set points affect the optimal design and performance of the internal coolers?

## MODELING

### Column Model

The absorber column model employed in this work was developed by Akula et al. [11]. This model is a rate-based solvent absorber model that can be applied to many processes by using the built-in physical and chemical property models. For convenience, this work uses 30 wt% MEA as the solvent.

For the reactive absorption process, rate-based models are significantly more accurate than equilibrium-based models, but are more computationally expensive

due to the consideration of transport through the films, especially the liquid film. To reduce this computation expense through removing the need to model film interactions, an enhancement factor method is used that accounts for the increase in mass transfer due to chemical reactions by using a set of algebraic equations [12]. Equations 1 and 2 are used to describe the enhancement factor,  $E$ , in terms of dimensionless concentration of MEA,  $Y_{MEA}^i$ .

$$E = 1 + (E_{\infty}^* - 1) \frac{(1 - Y_{MEA}^i)}{(1 - Y_{CO_2}^b)} \quad (1)$$

$$E = Ha \sqrt{Y_{MEA}^i} \frac{(1 - Y_{CO_2}^*)}{(1 - Y_{CO_2}^b)} \quad (2)$$

The phase energy balance of the model considers three heat transfer mechanisms/sources/sinks: convective heat transfer between phases, heat of absorption of  $CO_2$ , and heat of vaporization of water. The interphase heat transfer is calculated by using a corrected heat transfer coefficient, which is required for high mass fluxes (Equation 3). Both heat of absorption and vaporization are accounted for in the liquid phase energy balance (Equation 4). The heat of absorption is fixed at -85 kJ/mol  $CO_2$  for simplicity [13], while the heat of vaporization being used was derived from [14].

$$Q_V = h'_V a_e (T_L - T_V) \quad (3)$$

$$Q_L = Q_V + N_{CO_2,V} \Delta H_{abs} - N_{H_2O,V} \Delta H_{vap} \quad (4)$$

### Internal Heat Exchanger Model

The modeling for the internal heat exchanger packing was modified from Moore et al., which considered a single bed absorber column. This model was modified to account for individual discretized elements of the column in which an internal heat exchanger can be independently placed from other elements. In this model, it is assumed that all heat removal from the process to the cooling water occurs through the liquid phase due to the higher wetted area and conductivity in the liquid phase leading to a negligible amount of heat being directly transferred to the gaseous phase. It was also assumed to be smooth transition between standard and intensified packing, if flooding velocity is not surpassed. The two decision variables are a binary variable,  $y$ , for each column element to indicate placement of an internal heat exchanger and a voidage term,  $\epsilon^{cw}$ , that accounts for the volume occupied by the intensified cooler. Equation 5 calculates this heat transfer in each column element where the overall heat transfer coefficient, assumed to be constant, is from [9], which is a conservative estimate using the packing area, rather than wetted area, and is based on experimental data. In this equation,  $i$  is length index of the column,  $U$  is the overall heat transfer coefficient,  $a$  is the specific geometric area of the packing,  $T^{cw}$  and  $T^L$  are the temperatures of the cooling water and solvent phase,

respectively, and  $Q^{cw}$  is the heat transfer rate through the boundary. Equation 6 calculates the updated voidage by accounting for the volume occupied by the intensified coolers where  $\varepsilon^\circ$  is the standard voidage of the packing being used, and  $\varepsilon$  is the resulting voidage of the process.

$$Q_i^{cw} = y_i U a_i (T_i^{cw} - T_i^L) \quad (5)$$

$$\varepsilon_i = \varepsilon^\circ_i - \varepsilon_i^{cw} \quad (6)$$

**Figure 1.** Configuration of cooling water flow through absorber tower

Modeling the different possible flow configurations of the cooling water through the intensified packing is necessary since different flow configurations can result in a significant difference in heat removal efficiency. Three different flow directions were included in this model: co- and counter-current flow, relative to liquid phase flow, and single pass flow. In this case, the single pass flow is a limiting case for the model since the cooling water enters and exits the column in the same finite element of the model resulting in the best case for heat removal rate. Figure 1 shows how each of these configurations moves cooling water through the column. These flow directions are selected through an integer variable,  $d^{cw}$ , which can take the values of -1, 0, or 1 corresponding to co-current, single pass, and counter-current configurations, respectively. The energy balance of the cooling water is performed by creating lower bound inequality

constraints, which will be active depending on the value of  $d^{cw}$ .

To determine the best placement locations for the internal heat exchanger, an objective function is required. Three objective functions are utilized in this work, the first of these is minimization of CO<sub>2</sub> emissions,  $F_{CO_2}^{V,out}$  (Equation 7). The next two are minimization of column height,  $H$  (Equation 8) and minimization of liquid to gas ratio (Equation 9) in which  $F^{L,in}$  and  $F^{V,in}$  is the molar inlet flow rate of the solvent and gaseous phases, respectively. An additional performance constraint is included with the last two objectives, which sets a lower bound on the allowed capture efficiency. These last two objectives were chosen as each can be used to estimate potential reductions in costs of the system since the absorber column is a large factor in the total capital cost and solvent flow rate is directly proportional to reboiler duty, which is greatest factor in operational costs.

$$\min_{\varepsilon^{cw}, y, d} F_{CO_2}^{V,out} \quad (7)$$

$$\min_{\varepsilon^{cw}, y, d} H \quad (8)$$

$$\min_{\varepsilon^{cw}, y, d} \frac{F^{L,in}}{F^{V,in}} \quad (9)$$

The absorber and internal cooler models were implemented using the IDAES platform, which is built on top of the Pyomo optimization suite [15].

## RESULTS

**Figure 2.** Optimal and suboptimal internal heat exchanger placement for minimizing CO<sub>2</sub> emissions.

The base configurations for the column design and process specifications are shown in Table 1. This first set of results utilizes the pilot scale configuration. Using this configuration, the placement of the internal heat exchangers was optimized by minimizing CO<sub>2</sub> emissions. Figure 2 shows the placement and area of the heat exchangers in the optimal solution, which were in the top and bottom 15% of the column. A separate case was also

**Table 1.** Column and process configurations for pilot-scale and process-scale models.

Case 1 (Pilot Scale)	15	0.65	22	0.12	1.77	0.15
Case 2 (Process Scale)	20	12	12,000	0.042	1.83	0.22

**Figure 3.** Solvent temperature profile for base case, base case with suboptimal cooling, and optimized case.

simulated in which the internal heat exchangers were placed in the center of the column with a similar amount of total available heat transfer area.

The liquid phase temperature profile for the base case without cooling, base case with suboptimal cooling, and optimized cooling are shown in Figure 3, with the capture efficiencies for each case shown in Table 2. The profile base case with out cooling exhibits a much higher average temperature across the length of the column. This higher temperature results in larger thermodynamic limitations to the mass transfer of CO<sub>2</sub>, especially in the upper end of the column where a significant portion of mass transfer is occurring (indicated by the peak in temperature). The base case with suboptimal cooling appears to have a greater extent of heat removal when compared to the optimal case but results in lower capture efficiency. This is due to the given operating conditions. As previously mentioned, the majority of CO<sub>2</sub> mass occurs at the top 10–20% of the column, which is where the peak of the temperature bulge caused by the absorption energy is located in the base case. This causes this section of the column to be heavily thermodynamically limited, as opposed to physical limitations, such as mass transfer area, which explain the optimality of placing an internal cooling element in this region. The temperature profile in the bottom 15% of the column is comparatively level indicating very little mass transfer of CO<sub>2</sub>. In this region, mass transfer is being solely limited by the reduced driving force due to higher loading in the solvent, which results in placement of the intensified packing as a means to

further increase the total amount of heat removed from the system.

**Table 2.** Comparison of capture efficiency for cases with and without internal cooling

Case	Capture Efficiency
Base Case	72.46%
Base Case w/ Cooling	75.63%
Optimized Case	76.94%

As opposed to the top region of the column, the middle region is mass-transfer limited; therefore, maximizing mass transfer area to obtain high performance is desired. Finally, the bottom section of the column becomes thermodynamically limited; therefore, the optimal configuration is to include the cooling section there.

Using these optimized placements, a study was then conducted that investigated the variance of capture performance in different cooling water flow directions and flow rates. Both counter-current and co-current configurations were simulated using cooling water flow rates between 1.5 and 50 mol/s. The capture efficiencies for each of these configurations are shown in Figure 4. Below 20 mol/s of cooling water, the co-current configuration shows a slight advantage, which is due to how the solvent temperature changes in the upper internal cooler section. Analyzing these temperature profiles shows that the solvent enters the upper heat exchanger at the inlet temperature of 320 K and exits it at 338 K at a column height of 0.85. So, if cooling water is flowing in the

counter-current direction, there is a pinch at the top of the column limiting the heat removal rate. However, once flow rates increase above 20 mol/s, the difference in performance between the two configurations is nearly the same.

**Figure 4.** Capture efficiency at varying cooling water flow rates and flow direction.

The next results shown are from using the objective functions for minimizing the height and liquid-gas ratios (Equations 8 and 9). These objective functions are useful since each of these values correlates with major costs within the process, in which the column height accounts for an investment cost and the solvent flow correlates with the steam requirement in the reboiler. For these studies, the process scale model configuration was utilized, and each aspect was optimized at different CO<sub>2</sub> lean loadings and at different minimum capture efficiencies. The minimization of the column height in Figure 5 shows a maximum reduction of 6 meters when operating at a lean loading of 0.25 with a capture efficiency of 94%. The minimization of the liquid gas ratio in Figure 6 shows that the solvent rate can be reduced by upwards of 20% at the same lean loading of 0.25 operating at a capture efficiency of 91%.

Results for the column height minimization are shown in Figure 5. This data can be interpreted in two ways. When picking any point along the dotted line representing a column without internal cooling, moving down from this point to the corresponding solid line shows how much the column height can be reduced at a fixed capture efficiency. Alternatively, the horizontal shift shows how the capture efficiency can be increased with optimally placed internal coolers at a fixed column height. The improvement of reduced column height when using internal cooling units increases at higher capture rates and higher lean loading of the solvent. This same trend can be seen in the results for minimizing the liquid-gas ratio (Figure 6).

**Figure 5.** Variation is column height subject to capture efficiency, and lean loading without internal cooling (dashed line) and with internal cooling (solid line).

**Figure 6.** Variation is column height subject to capture efficiency, and lean loading without internal cooling (dashed line) and with internal cooling (solid line).

The reduction in both column height and solvent flow rate with the use of intensified packing has substantial implications on the cost saving for the process. The ability to reduce the height absorber bed, by up to 6 meters, while still retaining equal capture performance suggests that capital costs can be significantly reduced. Similarly, being able to reduce solvent flow rate by up to 20% corresponds with a similar reduction in the operating costs of the steam reboiler in the solvent capture process, which is a major factor in the determination of the levelized cost of capture of CO<sub>2</sub>. Due to the infancy of this technology, an accurate cost model for the intensified packing is still required to allow for a robust economic optimization of the process to determine the trade off of these potential cost savings for the cost of the packing.

There are still other factors of this technology yet that need to be further investigated. The first of which is overall heat transfer coefficient of the packing. In a

dynamic process, this coefficient is likely to vary based on the variance of the loading of flue gas to the column which can influence the heat removal rate. In terms of performance rating, due to the significant reductions found in process conditions through placement optimization and the use of a conservative value for heat transfer coefficient, the intensified packing is likely to retain an advantage over conventional structured packing even with a wide margin of uncertainty in heat transfer performance. Another factor to further consider is the comparison in performance to and absorbent system utilizing intercoolers, which again raises the need for an accurate cost for the intensified packing to determine if the cost of the complexity of the design outweighs the benefit of providing in-line, continuous cooling to the process.

## CONCLUSION

An existing model for solvent-based carbon capture is modified to implement a model for an internal cooling element that is integrated within the structured packing of the column. The internal cooling model was designed so that the placement of these elements can be used as a decision variable in an MINLP problem. The flow direction of the cooling water is also taken into consideration with the possibility of co- and counter-current flows, along with a single pass option.

The results of this work have shown the feasibility of utilizing internal heat exchangers to boost the capture performance of a solvent capture system. Depending on the configuration, the capture efficiency is shown to increase as much as 5%, which can account for a significant reduction in CO<sub>2</sub> emissions being released into the atmosphere. As shown, the optimization for the placement of internal heat exchangers is necessary since a deviation from optimum placement leads to a reduction in capture efficiency. The results also show that when comparing co- and counter-current flows of cooling water through these elements, it is optimal to use the co-current configuration. In the counter-current configuration, a pinch point is created that significantly affects the effectiveness of cooling.

The case studies on optimizing the height and solvent flow rates have shown that significant reductions of up to 20% in each can be made. This reduction is even greater when operating at higher capture efficiencies, which can make this technology ideal for that area of implementation. Although a reduction in the absorber column height can result in significant cost reduction, the real benefit of implementing internal coolers is the reduction in steam costs from reboiler operation. This cost is heavily affected by the solvent flow rate and CO<sub>2</sub> loading of the lean solvent. Thus, the placement of an intensified absorber not only improves the performance of the absorber but the economics of the overall process due to

the resulting effect on the stripper operation.

## ABSTRACT

Chemical recycling of plastics is a promising technology to reduce carbon footprint and ease the pressure of waste treatment. Specifically, highly efficient conversion technologies for polyolefins will be the most effective solution to address the plastic waste crisis, given that polyolefins are the primary contributors to global plastic production. Significant challenges encountered by plastic waste valorization facilities include the uncertainty in the composition of the waste feedstock, process yield, and product price. These variabilities can lead to compromised performance or even render operations infeasible. To address these challenges, this work applied the robust optimization-based framework to design an integrated polyolefin chemical recycling plant. Data-driven surrogate model was built to capture the separation units' behavior and reduce the computational complexity of the optimization problem. It was found that when process yield and price uncertainties were considered, wax products became more favorable, and pyrolysis became the preferred reaction technology.

## INTRODUCTION

Global plastic waste has been on the rise, making efficient plastic recycling process design imperative [1]. Chemical recycling and upcycling strategies not only reduce the mismanaged plastic waste, but also has the potential to reduce the carbon footprint to meet sustainable goals [2].

One challenge in plastic recycling process design arises from uncertain feedstock compositions. The type and proportion of plastic waste can exhibit variations influenced by factors like geographic location, resulting in substantial differences in both economic and energy values [3]. In addition, feedstock compositions affect the strategies for plastic recycling. For instance, one advantage of the pyrolysis process is that it can easily handle a mixed plastic waste feedstock with different ratio, especially noncatalytic pyrolysis unit. However, most of other chemical recycling technologies, including hydrogenolysis, typically requires relatively pure feedstock after careful sorting or impurity removal to ensure good catalyst performance [4,5].

Polyolefins (PO), including polypropylene (PP) and polyethylene (PE), are main source of plastic waste. Their inert carbon-carbon backbones make it challenging to breakdown the long chains and produce valuable products [6]. Many reaction pathways have been developed recently to effectively deconstruct PO, among which pyrolysis and hydroconversion (i.e., hydrocracking and hydrogenolysis) have shown promising potentials. Thermal pyrolysis reactions operate at elevated temperature and shorter residence time, which generates products a wider distribution and more gas that are most useful as fuels [7]. Hydroconversion, on the other hand, operates at milder conditions and produces liquid hydrocarbon within the fuel or lubricant ranges [6,8].

Depending on the feedstock composition, different technologies operate at different conditions to produce different products [3,9]. As the product selectivity and the use of catalyst depend on the plastic waste type [3], feedstock variability could affect not only the process performance but also its feasibility.

Existing studies in process design of plastic recycling typically focus on a particular recycling strategy and

its operating conditions [9]. For instance, Hernandez *et al.* compared the costs and emissions for four waste LDPE treatment processes – gasification, pyrolysis, hydrogenolysis [4]. Bora *et al.* performed life cycle assessment and techno-economic analysis on waste PP treatment processes and demonstrated that chemical recycling had low emissions but only profitable at large scales [10]. Zhao and You utilized the superstructure framework to optimize the net present value and greenhouse gas emissions of monomers, aromatic mixtures, and fuels production from waste HDPE [11].

An integrated plastic waste recycling technology selection and product separation provide opportunities for performance improvement. Moreover, it is important to consider the feedstock variability when designing such integrated chemical recycling facilities to ensure feasible operations among each connecting subunit. Robust optimization has been established as a computationally efficient framework to incorporate uncertainties and improves process performance [12]. Li *et al.* applied robust optimization to refinery production planning problem considering yield, cost, and price uncertainties [13].

This study proposes a methodology for the development of a chemical recycling facility for plastic waste. The design involves the selection of reaction technology and product separation guided by an optimization model. Since feedstock composition variability and product yield distribution are unavoidable in waste plastic treatment and affects the separation efficiencies, it is vital to guarantee feasible operation and good performance under these uncertainties. Rigorous process flowsheet simulations in Aspen Plus (Aspen Technology) [14] were carried out to obtain surrogate models of separation processes. Design decisions include chemical treatment technologies, distillation column design and unit connectivity. A robust optimization model is formulated to maximize profit under the worst case and ensure process feasibility (e.g., normal process operation) for all scenarios [6]. This robust optimization model will improve the chemical recycling process feasibility and performance under the worst uncertain case than the traditional deterministic optimization model [2,13]. Applying robust optimization instead of stochastic programming will also largely reduce the computational complexity, especially in the process design problem with high dimensionality arising from feedstock variability feedstock variability, yield uncertainty, and price fluctuation [15,16].

## MODEL FORMULATION

### Deterministic Superstructure Optimization

The superstructure elements for the chemical recycling facility includes plastic waste, other feedstocks, products, reaction technologies, and separation alternatives (Figure 1). In this study, decisions are made on three

levels. First, the combination of reaction or separation technologies is selected. Second, we determine the connectivity among feed, technologies, and products. Third, we decide the exact realization of a technology (e.g., distillation column operation conditions) by choosing an option. On this third level, incompatible connections, such as a liquid/solid stream entering a gas separator or an inappropriate reactant used by a particular reactor, could occur. Consequently, the connectivity of the superstructure elements is sorted *a priori* to eliminate those unproductive links. This step reduces the overall model size without cutting off potential candidate solutions [17].

As illustrated in Figure 2, the superstructure is connected with the inlet mixer and outlet splitters. The superstructure mass balance is established with the equations (1-4) for flow rate of each process stream going from  $i'$  to  $i$  for species  $k$  ( $F_{i',i,k}^I$ ). Equation (1) specifies the mixer balance for  $F_{i,k}^I$ , the flow rate of an inlet stream into a superstructure element  $i$  for species  $k$ . The splitter balance is enforced in equation (2) for the outlet stream of a superstructure element  $F_{i,k}^O$ . While a splitter with split ratio to multiple outlet stream is possible, we choose to maintain the linearity of the problem by allowing exactly one destination  $i'$  for each superstructure element  $i$  with the binary variable  $\eta_{i,i'}$ . To ensure the feasibility of each unit, a capacity limit is imposed as shown in (5-7). The total flow rate  $F_i^T$  is decided from (5), and the technology capacity  $F_i^{CAP}$  is enforced with (6). A big M constraint (7) is used to ensure if a technology is not selected ( $y_i = 0$ ), the capacity is 0.

$$F_{i,k}^I = \sum_{i' \in \text{inlets}(i)} F_{i',i,k}^I \quad \forall i \in I^{TECH} \forall k \quad (1)$$

$$F_{i,k}^O = \sum_{i' \in \text{outlets}(i)} F_{i,i',k}^O \quad \forall i \in I^{TECH} \forall k \quad (2)$$

$$\sum_k F_{i,i',k}^O \leq M \cdot \eta_{i,i'} \quad \forall i \in I^{TECH} \forall i' \in \text{outlets}(i) \quad (3)$$

$$\sum_{i' \in \text{outlets}(i)} \eta_{i,i'} = 1 \quad \forall i \in I^{TECH} \quad (4)$$

$$F_i^T = \sum_{k \in K} F_{i,k}^I \quad \forall i \in I^{TECH} \quad (5)$$

$$F_i^T \leq F_i^{CAP} \quad \forall i \in I^{TECH} \quad (6)$$

$$F_i^{CAP} \leq M \cdot y_i \quad \forall i \in I^{TECH} \quad (7)$$

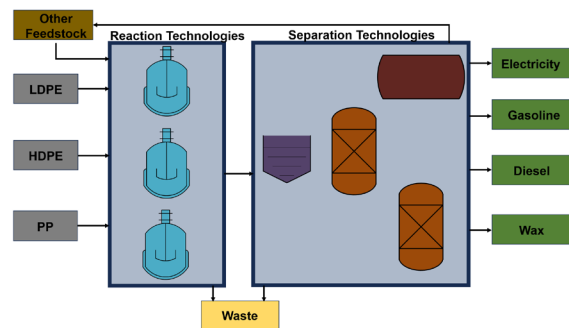

Figure 1. Elements of the chemical recycling plant superstructure.

**Figure 2.** Possible connectivity of chemical recycling plant's separation units

The reaction conversion and selectivity of the chemical recycling technologies are taken from the literature to model stoichiometric reactor units in the superstructure. A basis in the reaction feed stream  $F_i^{Ref}$  and a conversion coefficient  $\epsilon_{i,k}$  is used to determine the composition of the product streams as shown in (8). For some reactions, especially the hydroconversions [6,8], some undesired solid (e.g., coke) and gas formation are not well-characterized, leading to inaccurate estimation product yields thus violations of mass balance. To close the mass balance gap, we make a conservative assumption by including a waste stream that is not usable in the downstream operations (9). Admittedly, this assumption may not reflect the actual reaction. Thus, the effects of wax yield uncertainty are addressed in the robust optimization.

$$F_{i,k}^l + \epsilon_{i,k} \cdot F_i^{Ref} = F_{i,k}^p \quad \forall i \in I^{RXN} \quad \forall k \in Products(i) \quad (8)$$

$$\sum_k F_{i,k}^l - \sum_{k \neq WASTE} F_{i,k}^p = F_{i,WASTE}^p, \quad \forall i \in I^{RXN} \quad (9)$$

All separation units in this study are designed to achieve sharp separation (i.e., separators always isolate nearly all the light species to the light outlet stream  $F_{i,k}^{OL}$  and the heavy species to the heavy outlet stream  $F_{i,k}^{OH}$ ). The gas and fuel range products are separated in distillation columns with a sequence based on the target boiling points. To ensure that sharp separation is attainable with our design, surrogate models (12) are built to estimate the reflux ratio needed for 99% purity and the associated utilities from rigorous Aspen Plus process simulation. In practice, the distillation columns cannot deviate too much from the nominal reflux ratio once designed and installed. To ensure the operating feasibility, different design options are provided for the same distillation technology but at most one will be active as shown in (13). A 30% flexibility around the reflux ratio at nominal conditions is allowed for each design option  $p$  as presented in (13)-(15). When an option is selected ( $w_{i,p} = 1$ ), two big M constraints are used for to ensure the reflux ratio does

not deviate from the design value for more than 30% (14,15).

$$F_{i,k}^l = F_{i,k}^{OL} \quad \forall i \in I^{SEP} \quad \forall k \in light(i) \quad (10)$$

$$F_{i,k}^l = F_{i,k}^{OH} \quad \forall i \in I^{SEP} \quad \forall k \in heavy(i) \quad (11)$$

$$f_i(Light, Heavy) = (RR_i, Q_i^{cool}, Q_i^{heat}) \quad \forall i \in I^{SEP} \quad (12)$$

$$y_i = \sum_p w_{i,p} \quad \forall i \in I^{SEP} \quad (13)$$

$$-M(1 - w_{i,p}) + 0.7RR_p^{nom} \leq RR_i \quad \forall i \in I^{SEP} \quad (14)$$

$$RR_i \leq M(1 - w_{i,p}) + 1.3RR_p^{nom} \quad \forall i \in I^{SEP} \quad (15)$$

A supply constraint is imposed to the plastic waste feedstock in (16).

$$\sum_{i' \in outlets(i)} F_{i,i',k} \leq F_{j,k}^{SUP} \quad \forall i \in I^{Plastic} \quad \forall k \in plastic \quad (16)$$

For fuel range products, we impose a maximum for the olefin content [17] as a product requirement (17). In addition, we specify the limit of product quantities below or above the typical boiling point ranges for fuel product such as gasoline and diesel (18,19). Equations (18,19) represent a linear simplification of the blending rule by only considering boiling point and olefin content, although more rigorous blending rule can be incorporated.

$$\sum_{k \in K^{olefin}} F_{i,k}^{prod} \leq \phi^{olefin} \sum_{k' \in K} F_{i,k'}^{prod} \quad \forall i \in I^{Fuel} \quad (17)$$

$$\sum_{k \in K^{BPLO}} F_{i,k}^{prod} \leq \phi_k^{klo} \quad i \in I^{Fuel} \quad (18)$$

$$\sum_{k \in K^{BPUP}} F_{i,k}^{prod} \geq \phi_k^{kup} \quad i \in I^{Fuel} \quad (19)$$

The general deterministic formulation of this chemical recycling process design is presented as a mixed-integer linear programming (MILP) problem in equation (20):

$$(20) \quad \max (R^{PROD} + R^{ELEC} - C^{CAPEX} - C^{OPEX})$$

## Surrogate Model for Distillation Columns

The distillation column surrogate model is an essential part of the superstructure optimization to create a mapping between the inlet flow rates for both the light and heavy components and the actual reflux ratio, condenser duty, and reboiler duty. Artificial neural network (ANN) is selected as surrogate models given its excellent fitting performance and its ability to maintain the linearity of the problem. We refer to our previous work and use Rectified Linear Unit (ReLU) as the activation function with a feed-forward ANN [18]. The predicted value  $a_m^k$  of layer  $k$  and node  $m$  is calculated using a linear combination of the values from the previous layer as shown in

(21). The activation function ReLU,  $z_n^k = \max(0, a_n^k)$ , is modelled using the big M constraints as shown in (22a-22d)

$$a_m^k = W_{n,m}^{k-1} z_n^{k-1} + b_m^{k-1} \quad (21)$$

$$-M \cdot (1 - \delta_m^k) \leq a_m^k \quad (22a)$$

$$a_m^k \leq M \cdot \delta_m^k \quad (22b)$$

$$0 \leq z_m^k \leq M \cdot \delta_m^k \quad (22c)$$

$$a_m^k \cdot (1 - \delta_m^k) \leq z_m^k \leq a_m^k + M \cdot (1 - \delta_m^k) \quad (22d)$$

## Robust Optimization

The uncertainty in this study arises from three sources. The first source is the dynamic supply of sorted bale plastic waste, which leads to uncertain feedstock flowrates. The second source arises from the product yield. For instance, not all solid products of hydroconversion of recycled plastic could be treated as waxes [6]. Instead, depending on the reaction condition, some solid plastic waste could remain unreacted or form coke. To reflect this, we incorporate a process yield uncertainty for waxes in hydrocracking and hydrogenolysis. Furthermore, the product selling price uncertainty is also included to reflect the price volatility of the petroleum refinery products. The fuel range product tends to be more volatile than waxes [19]. Therefore, a larger deviation should be considered.

To formulate the robust counterpart of the problem, we refer to the work of Li. *et al.* [13], in which the robust counterpart formulations have been derived for linear and mixed-integer linear programming with different uncertainty set. In this study, we consider box uncertainty set for all uncertain parameters. The robust counterpart for an inequality constraint (23) when considering left-hand-side (L.H.S.) uncertainty is presented in (24), and right-hand-side (R.H.S.) uncertainty in (25).

$$\sum_j a_{i,j} x_j \leq b_i \quad (23)$$

$$\sum_j a_{i,j} x_j + \sum_j \widehat{a}_{i,j} |x_j| \leq b_i \quad (24)$$

$$\sum_j a_{i,j} x_j + \widehat{b}_i \leq b_i \quad (25)$$

In this study, uncertainty parameters for process yield and product sale price occurs in equations instead of inequalities, which drastically restricts the feasible space of mathematical model and often causes infeasibility [16]. Therefore, we use the inequality constraints instead for process yield and sale price as presented in previous work in petroleum refinery by Leiras *et al.* [15] as shown in (26,27). Using this upper bound on wax produced and product sales, we now have L.H.S. uncertainty instead. While we acknowledge this reformulation creates a relaxation of the original problem mathematically, the profit objective typically encourages producing more products when possible. Therefore, these reformulated inequalities (26,27) are likely to be active at optimal

solution. The robust formulation is obtained by applying the properties of box uncertainty set as presented in (24,25).

$$F_{i,WAX}^{FEED} + \epsilon_{i,WAX} \cdot F_i^{Ref} \geq F_{i,WAX}^{PROD} \quad \forall i \in I^{RXN} \quad (26)$$

$$Revenue^{PROD} \leq Price \cdot F^{PROD} \quad (27)$$

## ILLUSTRATIVE EXAMPLE

In this example, we considered three categories of reaction technologies (i.e., hydrocracking [6], hydrogenolysis [8], and pyrolysis [7]), three types of plastic waste streams (i.e., PP, LDPE, and HDPE), one solid separation, two distillation (each with five options), and a pressure-swing absorption unit for hydrogen recovery. The details for the technologies are summarized in Table 1-3. For reaction technologies that allow mixture plastic waste, we enforced the feed composition to be the same as reported from experiments in the literature. Gasoline, diesel, and waxes are selected as the product. Additionally, another stream for electricity generation is available for mixture outlet streams that do not meet the product requirement for fuels.

**Table 1:** Reactions considered

Code	Reaction Type	Feed
R1A	hydrocracking	LDPE
R2A	hydrocracking	HDPE
R3A	hydrocracking	PP
R1B	hydrogenolysis	PP
R2B	hydrogenolysis	PP/PE(1:1)
R1C	pyrolysis	PE
R2C	pyrolysis	PE/PP(3:2)
R3C	pyrolysis	PE/PP(2:3)
R4C	pyrolysis	PP

**Table 2:** Separations considered

Code	Separator Type	Separation Task
FL1A	solid/fluid	fluid/wax
DT1A	distillation	C4/C5
DT2A	distillation	C12/C13
PSA1A	pressure swing absorption	hydrogen/alkanes

**Table 3:** Reflux ratios at nominal operating conditions for different options

Option	1	2	3	4	5
Reflux Ratio(molar)	1	1.83	3.43	6.37	11.83

The data for the surrogate model training for distillation columns were obtained by running sampled simulations in Aspen Plus [14] with Python interface. The

model was trained in PyTorch [20]. The ANN models for both distillation columns had 4 layers with 15, 18, 12 neurons in the hidden layers and 3 neurons at the output layer. The  $R^2$  of the ANN for DT1A was 0.9586 and for DT2A, 0.9675.

The operational basis of this example was based on the previous techno-economic analysis [4,11] with a supply of 12 tonne/hr PP, 10 tonne/hr HDPE, and 2.5 tonne/hr LDPE. The cost for the plastic collection and sorting depends on the population density and geographic variation [9]. The plastic waste collection and sorting cost was estimated in the work of Hernandez *et al.* [4] to be in the range of 250 to 700 \$/tonne. In this example, we assumed an overall cost for the sorted plastic to be \$500/tonne. The price for waxes was estimated to be \$1000/tonne [21]. Moreover, the fuel price at nominal condition was estimated to be \$960/tonne for gasoline [19] and \$920/tonne for diesel [19]. A wax yield of 0.5 was assumed for hydroconversions. The associated uncertainty type and deviations from the nominal value considered in this example is shown in Table 4.

**Table 4:** Uncertain parameters for illustrative example

Uncertain Parameter	Type	Deviation (%)
Plastic supply	RHS	10
Wax yield	LHS	40
Fuel price	LHS	30
Wax price	LHS	10

All optimization models were implemented in Pyomo [22] and solved with Cplex 22.1 solver [23] on a computer with Intel Xeon E-2274G CPU @ 4.00GHz 32 GB RAM. The deterministic model was solved under nominal condition, and the robust formulation was applied to include the uncertainty set in Table 4.

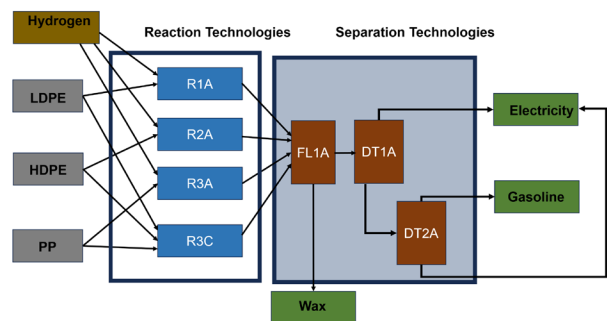

**Figure 3.** Cost breakdown of the plastic chemical recycling system.

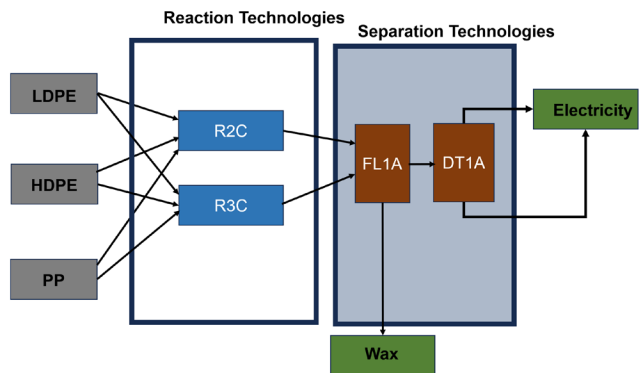

As shown in Figure 3, under nominal condition, the optimal integrated chemical recycling process has a

revenue of 139.58 million dollars/year and a total cost of 96.40 million dollars/year. The feedstock cost comprises of 89% of the total cost, which accounts for all upstream cost for plastic waste collection and sorting. The profit of the process is 43.18 million dollars/year. However, when the uncertainties are considered in the robust formulation, the total revenue of the best design dropped to 117.45 million dollars/year with a total cost of 92.5 million dollars/year. This leads to a profit of 25.95 million dollars/year.

Under the nominal condition, the distillation column DT1A operates at a 6.64 molar reflux ratio, and operating condition option 4 is selected. For distillation column DT2A, the actual molar reflux ratio is 2.24, and option 2 is selected. When robust optimization is performed, the actual reflux ratio for DT1A becomes 0.07, and option 1 is selected. The technology DT2A is not selected at all as no gasoline product is pursued as shown in Figure 5.

**Figure 4.** Superstructure under the nominal condition

**Figure 5.** Superstructure under the robust formulation

**Figure 6.** Reactor loads for process designs from both deterministic and robust optimization

**Figure 7.** Product quantities for process designs from both deterministic and robust optimization.

As illustrated in Figure 4, the reaction of a combination of hydrocracking (R1A, R2A, R3A) and mixed olefin pyrolysis (R3C) is selected in the nominal case, and the reactor load is presented in Figure 6. When uncertainties are considered, only mixed olefin pyrolysis is chosen (R2C, R3C). The product produced changes from a combination of gasoline and wax to only wax. This change occurs primarily as a result of the price volatility of fuel products, which makes the wax product relatively more profitable than the nominal condition. In addition, the hydrocracking reactions are less economically favorable after the uncertainty in the wax yield of hydroconversions is included.

## CONCLUSIONS

In this work, we have proposed the robust optimization framework for designing plastic waste valorization system. We used an illustrative example to demonstrate the how the feedstock supply availability, process yield, and product price uncertainties affect the optimal process design and operation. In the future, this model could be extended to include more considerations including more types of products, upgrading technologies, upstream sorting process, reaction technologies, and more kinds of plastic waste.

## ABSTRACT

Design problems for process systems engineering applications often require multi-scale modeling integrating detailed process models. Consequently, black-box optimization and surrogate modeling have continued to play a fundamental role in mission-critical design applications. Inherent in surrogate modeling applications, particularly those constrained by “expensive” function evaluations, are the questions of how to properly balance “exploration” and “exploitation” and how to do so while harnessing parallel computing in techniques. We devise and investigate a one-step look-ahead GRASP heuristic for balancing exploration and exploitation in a parallel environment. Computational results reveal that our approach can yield equivalent or superior surrogate quality with near linear scaling in the number of parallel samples.

---

## INTRODUCTION

In recent years, there has been an increased utilization of high-fidelity digital twins (HFDTs) in the design, development, and/or operation of complex systems and enterprise-wide supply chains. These digital twins typically originate from data-driven models, physics-based models, or some combination thereof. Depending on their physical location, which can lead to data latency issues, scale, underlying structure, evaluating them can be computationally expensive given a set of static and/or dynamic input parameters and they tend to come with only zeroth order information. This can be problematic for practitioners who would like to utilize them directly or within larger workflows to optimize and/or conduct sensitivity analyses on the system or supply chain in which they were originally intended to simulate [1].

These challenges have led practitioners to utilize black-box optimization (also known as derivative-free optimization) methods and/or surrogate modeling techniques to achieve their desired goals. Excellent overviews and reviews of derivative free optimization methods and surrogate modeling techniques are presented in [2], [3], [4], and references therein. Even with the recent

advances in the literature, there are still many open questions, such as how to properly balance “exploration” and “exploitation” and how to harness parallel computing in techniques, such as Bayesian optimization (BO), that were originally designed to be executed serially [5].

To this end, we present a BO procedure to allow the practitioner to be judiciously sample the design space in parallel. At the heart of the procedure lies a non-convex acquisition function that generates a batch of  $B$  different points that are intended to be evaluated by the HFDT parallel. Due to the difficulty in solving the non-convex acquisition function, we have created a greedy randomized adaptive search procedure (GRASP) that is quickly able to generate quality solutions via a construction heuristic and then subsequently improve on these initial solutions via a local search procedure – for a detailed treatise on GRASPs, specifically for problems with a continuous design space, please see [6] and references therein.

The remainder of this work is organized as follows: i) first, we present a brief literature review on BO; ii) next, we present the problem statement; iii) we then present our workflow; iv) next, we conduct computational experiments on 6 standard benchmark test functions to illustrate the effectiveness of our workflow; and v) finally we offer conclusions and future research directions.

## LITERATURE REVIEW

Several research groups have attempted to accelerate Bayesian optimization for the setting known as “batch Bayesian optimization,” i.e., when a “batch” of costly-to-evaluate function calls can be performed in parallel. As noted in one of the earliest works on batch BO [7], sequential BO (i.e., the traditional approach in which a single function evaluation is made per iteration) has a fundamental advantage over batch BO because, when applying the former, each function evaluation is immediately used to obtain a more accurate posterior. This improved posterior should, in theory, lead to a better, or more information-rich, sequence of function evaluations that accelerate convergence to a global optimum. Thus, researchers have attempted to design batch BO methods to compete with one-sample-per-iteration approaches in terms of information gain per sample.

One key computational challenge in batch BO is to find a jointly optimized batch of inputs. This challenge is mainly because of the lack of analytical formula and differentiability of the underlying selection criteria, i.e., expected improvement, for a batch of size greater than 2. To resolve this issue, Daxberger and Low [8] noted that there are two extremes to designing batch BO methods. On one end of the spectrum, greedy batch BO algorithms, e.g., [7], rely on the current (and therefore a single) posterior distribution to select the batch of points to sample. This single-step lookahead approach eases scalability, but each prospective sample in the batch does not account for the potential impact of the other prospective samples. On the other end of the spectrum, one can attempt a multi-step lookahead batch selection by considering the joint impact of all prospective samples, as is done in parallel predictive entropy search [9], and the parallel knowledge gradient method [10]. The downside is that these approaches tend to scale poorly in the batch size. To mitigate the scalability issue, [11] developed a stochastic gradient method for multipoints expected improvement (q-EI) computation, however, it requires many Monte Carlo samples for estimating a stochastic gradient and q-EI. These could be much more expensive than evaluating a single point EI (with  $q=1$ ) using its closed form solution.

De Ath et al. [12] introduced an epsilon-shotgun method that “leverages the model’s prediction, uncertainty, and the approximated rate of change of the landscape to determine the spread of batch solutions to be distributed around a putative location”. The initial target location is selected either in an exploitative fashion on the mean prediction, or - with probability  $\epsilon$  - from elsewhere in the design space. This results in locations that are more densely sampled in regions where the function is changing rapidly and in locations predicted to be good,

i.e., close to predicted optima, with more scattered samples in regions where the function is flatter and/or of poorer quality.” Kandasamy et al. [13] analyzed a randomized selection procedure known as Thompson sampling, which selects a point to evaluate by maximizing over a random sample from the posterior distribution and find that “making  $n$  evaluations distributed among  $M$  workers is essentially equivalent to performing  $n$  evaluations in sequence” [13]. Thompson sampling, however, is less common/popular than popular algorithms that choose evaluation points based on expected improvement (EI) or upper confidence bounds (UCB). Wang et al. survey recent advances in BO [14].

As the algorithm’s name suggests, Bayesian optimization is primarily, if not entirely, dedicated to the task of optimizing an unknown function. It is also of interest to generate a high-fidelity surrogate, which is locally or globally valid, for design applications. One can control the degree of exploration in BO by modifying the acquisition function. Chen et al. [15] after choosing multiple acquisition functions, identify Pareto-optimal solutions (based on a so-called minimum-diverse-exploitative strategy) of a multi-objective optimization problem to select candidate sample points.

## PROBLEM STATEMENT

Consider a decision maker (DM) who would like to utilize a HFDT to design, develop, and/or operate a complex system and/or enterprise-wide supply chain. The relationship between the inputs and the scalar output of the HFDT is given by  $f: \mathcal{X} \mapsto \mathbb{R}^1$ , where  $\mathcal{X}$  is a compact subset of  $\mathbb{R}^N$ . The scalar output,  $y$ , of the computationally intensive function can be noisy, consequently it is assumed that  $y = f(x) + \epsilon$ , where  $x \in \mathcal{X}$  and  $\epsilon \sim N(0, \sigma^2)$  i.i.d.

The DM would like to utilize BO, with a batch size of  $B$ , to optimize and/or create a surrogate model of the HFDT. It is assumed that the DM has access to  $B$  different machines, such that each sample point,  $b \in \mathcal{B}$ , in the batch,  $\bar{x}_{k,b} \in \mathcal{X}$ , can be evaluated by the HFDT in parallel at each major iteration,  $k \in \mathcal{K}$ , of the BO procedure, where  $\mathcal{B} := \{1 \dots B\}$  and  $\mathcal{K} := \{1 \dots K\}$ . Therefore, the goal of the DM is to ensure that the points generated by the acquisition function are judiciously selected, such that whether “exploration” or “exploitation” is preferred, the points will provide valuable “learnings”.

## METHODOLOGY

In this section, we present the BO procedure, which allows the practitioner to judiciously sample the design space in parallel. We also present a novel GRASP, that generates locally optimal solutions to the acquisition function, given by Eq. 1, quickly, by first randomly generating quality solutions via a construction procedure and

then subsequently improving them via a local search procedure.

$$\max_{\{\bar{x}_b \in \mathcal{X}\}_{b \in \mathcal{B}}} \sum_{b \in \mathcal{B}} \alpha(g(\bar{x}_b), \kappa) + \gamma \cdot \sum_{(b, \bar{b}) \in \mathcal{B} \times \mathcal{B}} \|\bar{x}_b - \bar{x}_{\bar{b}}\| \quad (1)$$

The first summation in the objective function of the optimization problem given in Eq. 1 sums the weighted outputs of the Gaussian process model for each of the selected points,  $\{\bar{x}_b^* \in \mathcal{X}\}_{b \in \mathcal{B}} - \alpha(\tilde{y}, \kappa)$  is equivalent to  $\mathbf{mean}(\tilde{y}) + \kappa \cdot \mathbf{var}(\tilde{y})$ , where  $\mathbf{mean}(\cdot)$  is a function that returns mean value of the Gaussian process model evaluated at  $\tilde{x} \in \mathcal{X}$  and  $\mathbf{var}(\cdot)$  is a function that returns variance of the Gaussian process model evaluated at  $\tilde{x} \in \mathcal{X}$ . The second summation sums the weighted Euclidian distances between the selected points,  $\{\bar{x}_b^* \in \mathcal{X}\}_{b \in \mathcal{B}}$ , where  $\gamma$  is a regularization term – this indirectly ensures that the selected points are sufficiently separated in the design space from each other.

The pseudo-code for the BO procedure is explicitly given in Algorithm 1. The procedure is a function of: i)  $f(\cdot)$ , the HFDT; ii)  $S$ , the number of random samples generated in the construction procedure of the GRASP; iii)  $\mathcal{K}$ , the set of major iterations for batch BO procedure; iv)  $\mathcal{B}$ , the set of batches; v)  $\mathcal{D}$ , initial set of inputs and outputs of the HFDT; vi)  $\mathcal{X}$ , continuous set of feasible inputs for the HFDT; vii)  $\alpha(\cdot, \cdot)$ , function that returns a weighted scalar output of the Gaussian process model parameterized by  $\kappa$ ; viii)  $\kappa$ , weighting parameter that balances “exploration” and “exploitation”; ix)  $\delta$ , minimal scaled distance between any two points in a batch; x)  $\sigma$ , variance for the noise utilized in generating the sorted restricted candidate list of selectable points in the construction procedure; and xi)  $\epsilon$ , incremental decrease in the minimal scaled distance between points in successive iterations of the construction procedure.

**Algorithm 1:** BO procedure.

```

BBOSM( $f, S, \mathcal{B}, \mathcal{K}, \mathcal{D}, \mathcal{X}, \alpha, \kappa, \delta, \sigma, \epsilon$ )
1 # initialization phase
2  $g \leftarrow \mathbf{ConstructGaussianProcess}(\mathcal{D})$ 
3 # iteration phase
4 for  $k \in \mathcal{K}$  do
5    $\{\bar{x}_b\}_{b \in \mathcal{B}} \leftarrow \mathbf{GRASP}(g, S, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \delta, \sigma, \epsilon)$ 
6   parallel for  $b \in \mathcal{B}$  do;  $y_b^* \leftarrow f(\bar{x}_b^*)$ ; end;
7    $\mathcal{D} \leftarrow \mathcal{D} \cup \{(\bar{x}_b^*, y_b^*)\}_{b \in \mathcal{B}}$ 
8    $g \leftarrow \mathbf{ConstructGaussianProcess}(\mathcal{D})$ 
9 end
10 return  $g$ 

```

In the initialization phase of the procedure, a Gaussian process model,  $g(\cdot)$ , is created using the initial set of inputs and outputs,  $\mathcal{D}$ . In the iteration phase of the procedure, a set of  $|\mathcal{K}| \cdot |\mathcal{B}|$  points are judiciously selected to be evaluated. In each iteration,  $|\mathcal{B}|$  points are generated by the GRASP, and subsequently passed to the HFDT – the pseudo-code for the GRASP is given in Algorithm 2.

Once the points are evaluated, they are appended to the data set  $\mathcal{D}$ . Then the new updated data set,  $\mathcal{D}$ , is then utilized to create a new Gaussian process model and then the iterative procedure is continued for another  $|\mathcal{K}| - 1$  iterations.

**Algorithm 2:** GRASP to produce a high quality local optimal solution for the non-convex acquisition function.

```

GRASP( $g, S, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \delta, \sigma, \epsilon$ )
1 # construction phase
2  $\{\bar{x}_b\}_{b \in \mathcal{B}} \leftarrow \mathbf{Construction}(g, S, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \delta, \sigma, \epsilon)$ 
3 # local search phase
4  $\{\bar{x}_b\}_{b \in \mathcal{B}} \leftarrow \mathbf{LocalSearch}(g, S, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \epsilon)$ 
5 return

```

In the first phase of the GRASP, an initial quality solution is generated by a construction procedure which randomly selects discrete points in the input space. In the second phase, the initial solution produced by the construction procedure is passed to a local search procedure to be improved, it should be noted that the solution is improved on in the continuous design space. The pseudo-codes for the construction procedure and the local search procedure can be seen in Algorithm 3 and Algorithm 4 respectively.

At the beginning of the construction procedure, two sets are created: i) the first set,  $\mathcal{S}$ , stores all the indices of all the selectable points; and ii) the second set,  $\bar{\mathcal{S}}$ , stores the indices of the selected points, since no indices have been selected the set is empty. Then  $|\mathcal{S}|$  random points are uniformly sampled from  $\mathcal{X}$  and subsequently evaluated by  $\alpha(\cdot, \cdot)$ . After the initialization phase, an iteration phase commences that selects  $|\mathcal{B}|$  candidate points. At the beginning of the iteration phase, in line 7 of Algorithm 3, a sorted list of unselected indices is generated by the function  $\mathbf{sort}(\cdot, \cdot)$ , which sorts the indices,  $\mathcal{S} \setminus \bar{\mathcal{S}}$ , in descending order based upon the value  $z_s + N(0, \sigma \cdot \mathbf{range}(\bar{z}))$ , where  $\mathbf{range}(\cdot)$  is a function that returns the maximum value of its input minus the minimum value of its input. Once the list of sorted indices is generated, a for loop is initiated and the Euclidian distance of the sample point corresponding to the index,  $s \in \mathcal{S} \setminus \bar{\mathcal{S}}$ , is compared to all the currently selected indices,  $\bar{\mathcal{S}}$ , and if the distance is greater than  $\delta$  away from all the currently selected points, the index is appended to the set  $\bar{\mathcal{S}}$ . This continues until  $|\bar{\mathcal{S}}| = |\mathcal{B}|$ . If by chance,  $|\bar{\mathcal{S}}| \neq |\mathcal{B}|$  then  $\delta$  is increased by  $\epsilon$  and the iteration phase continues until  $|\bar{\mathcal{S}}| = |\mathcal{B}|$ . We note that since we control the variability of samples in line 8 of Algorithm 3, we would prefer random uniform sampling over other sampling methods such as Latin hypercube sampling so that we can balance between exploration and exploitation.

**Algorithm 3:** Construction procedure to generate an initial set of candidate points.

**Construction**( $g, \mathcal{S}, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \delta, \sigma, \epsilon$ )

```

1 # initialization phase
2  $\mathcal{S}, \bar{\mathcal{S}} \leftarrow \{1 \dots S\}, \emptyset$ 
3  $\{\bar{x}_s\}_{s \in \mathcal{S}} \leftarrow |S|$  random uniformly sampled points in  $\mathcal{X}$ 
4 for  $s \in \mathcal{S}$  do;  $z_s \leftarrow \alpha(g(\bar{x}_s), \kappa)$ ; end;
5 # iteration phase
6 while  $|\bar{\mathcal{S}}| < |\mathcal{B}|$  do
7   for  $s \in \text{sort}(\delta \setminus \bar{\mathcal{S}}, s: z_s + \mathcal{N}(0, \sigma \cdot \text{range}(\bar{\mathcal{Z}})))$  do
8     if  $\text{all}(\{\|\bar{x}_s - \bar{x}_{\bar{s}}\| \geq 1/(\delta \cdot |\mathcal{B}|)\}_{\bar{s} \in \bar{\mathcal{S}}})$  do
9        $\bar{\mathcal{S}} \leftarrow \bar{\mathcal{S}} \cup \{s\}$ 
10    end if
11    if  $|\bar{\mathcal{S}}| = |\mathcal{B}|$  do; break; end;
12  end
13   $\delta \leftarrow \delta + \epsilon$ 
14 end
15 return  $\{\bar{x}_s\}_{s \in \bar{\mathcal{S}}}$ 

```

Once the initial of points are generated in the construction procedure, they are passed to a local search procedure. In the local search procedure, each of the points are refined by solving the optimization problem given in line 2 of Algorithm 4, where  $\mathcal{N}(\cdot, \cdot, \cdot) \subseteq \mathcal{X}$  is a convex neighborhood in the output space of  $\alpha(\cdot, \cdot)$  evaluated at the point  $\bar{x} \in \mathcal{X}$ .

**Algorithm 4:** Local search procedure to refine the initial set of candidate points.

**LocalSearch**( $g, \mathcal{B}, \mathcal{X}, \alpha, \kappa, \{\bar{x}_b\}_{b \in \mathcal{B}}$ )

```

1 for  $b \in \mathcal{B}$  do
2    $\bar{x}_b \leftarrow \max_{\bar{x} \in \mathcal{N}(\bar{x}_b, \alpha, g, \kappa)} \alpha(g(\bar{x}), \kappa)$ 
3 end
4 return  $\{\bar{x}_b\}_{b \in \mathcal{B}}$ 

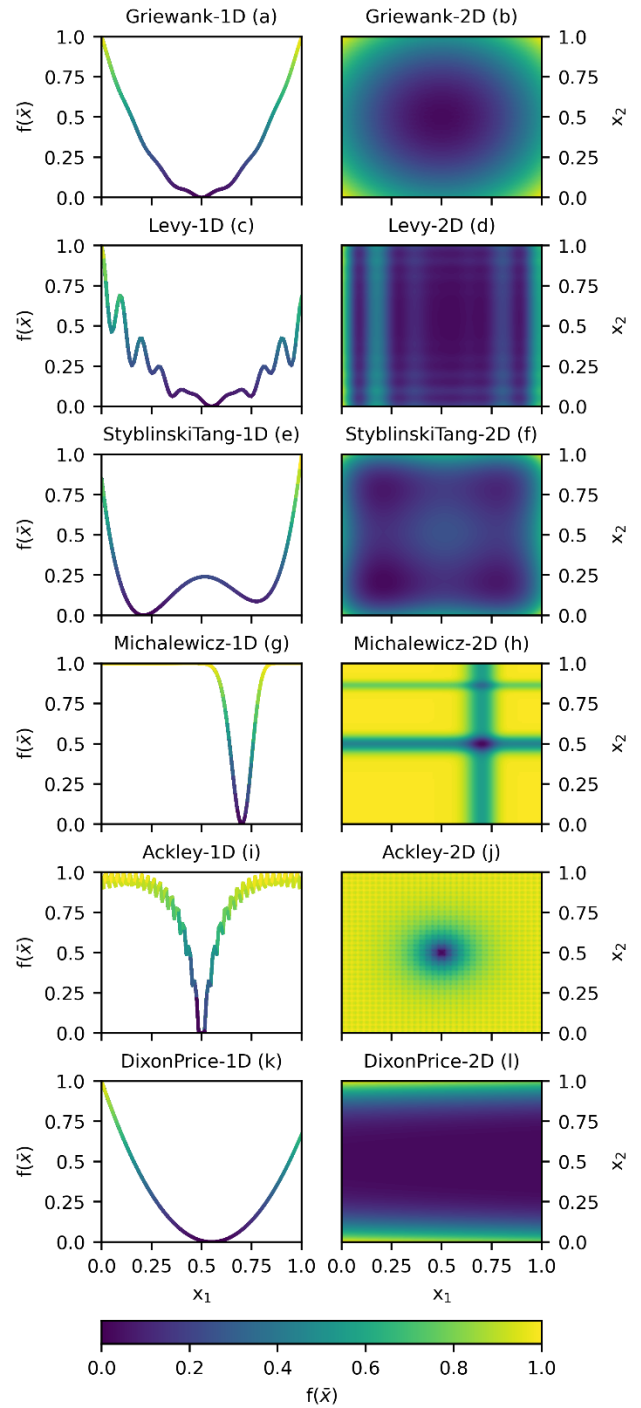

```

## COMPUTATIONAL EXPERIMENTS

This section presents the results of our computational experiments and highlights the ability of our parallel BO procedure to generate quality batches of sample points. The effectiveness of our BO procedure is compared against standard BO utilizing a batch size of one. In the first subsection, we present the benchmark test instances utilized in the computational experiments and the parameters utilized in our BO procedure. In the second subsection, we illustrate how our BO procedure generates a batch of points over sequential iterations for one of the benchmark test functions in two dimensions. In the final subsection, we illustrate the effectiveness of our parallel BO procedure, which produces a batch of samples to be evaluated in parallel per iteration, against standard BO, which evaluates a single point per iteration.

### Experimental set up

#### Benchmark test functions

**Figure 1.** Gallery of 6 test functions plotted in two input domains,  $\mathbb{R}^1$  (1D) and  $\mathbb{R}^2$  (2D).

We illustrate the effectiveness of our methodology on 6 standard benchmark test functions (StyblinskiTang, Griewank, Levy, Michalewicz, Ackley, and DixonPrice) across 4 input domains —  $\mathbb{R}^1$ ,  $\mathbb{R}^2$ ,  $\mathbb{R}^4$  and  $\mathbb{R}^6$ . The analytical form of the test instances were taken from the BoTorch library [16]. DixonPrice is the only strictly convex function and is, in general, thought to be “easy” to solve.

The remaining functions are non-convex and are thought to be “hard” to solve.

Figure 1 depicts each of the test functions in two input domains,  $\mathbb{R}^1$  and  $\mathbb{R}^2$ . For sake of illustration, the input domains and the output domains have been scaled on the unit cube, i.e. linearly spaced between 0 and 1. Subfigures a, c, e, g, i, and k are line plots and have an input domain of  $\mathbb{R}^1$ , while subfigures b, d, f, h, j, and l are contour plots and have an input domain of  $\mathbb{R}^2$ . For the figures with an input domain of  $\mathbb{R}^1$ , the input,  $x_1 \in \mathcal{X} \subset \mathbb{R}^1$ , is on the x-axis and the output,  $f(\bar{x})$ , is on the y-axis of the figure; the line color also corresponds to  $f(\bar{x})$ . For the figures with an input domain of  $\mathbb{R}^2$ , the inputs,  $(x_1, x_2) \in \mathcal{X} \subset \mathbb{R}^2$ , are on the x- and y-axis respectively and the color at two corresponding points represents the output,  $f(\bar{x})$ .

### Setting up the computational experiments

Here we briefly present the parameters passed to our BO procedure for conducting our computational experiments. We also describe our scaling procedure to ensure that exploration and exploitation are properly weighted. Table 1 presents the parameters passed to our BO procedure for each of the test instances.

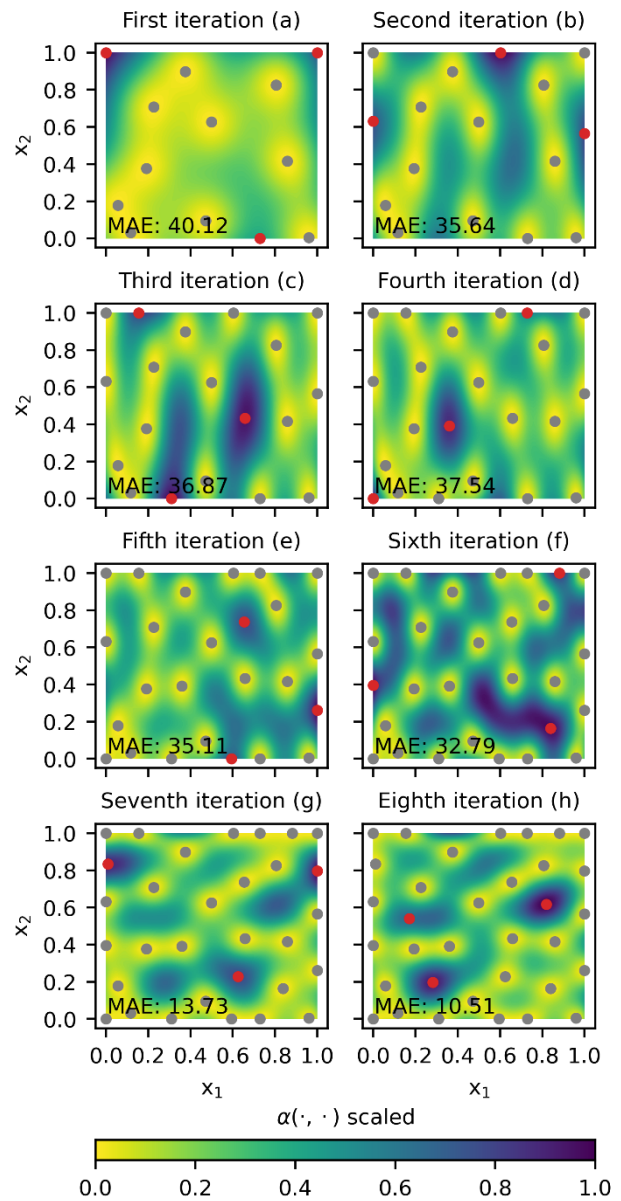

**Table 1:** Parameters passed to our BO procedure for each of the test instances.

Parameter	Value
$S$	300
$\kappa$	3
$\delta$	1
$\sigma$	0.1
$\epsilon$	0.1

To ensure that “exploration” and “exploitation” is properly scaled within  $\alpha(\cdot, \cdot)$ , we ensure that when a vector of design points are passed to the function their corresponding mean and variance are scaled to the unit cube i.e. all mean values are spaced linearly between 0 and 1 and all variance values are scaled between 0 and 1.

### Illustrative example

In this subsection, we use the StyblinskiTang test function with an input domain of  $\mathbb{R}^2$  to illustrate how the GRASP within our BO procedure generates new points in the design space to be evaluated by the HFDT in sequential iterations. For this illustrative example, 10 points in the design space were randomly sampled to build the initial set of ground truth data, subsequently these points were evaluated by the HFDT, and finally utilized to construct the initial Gaussian process model, in conjunction with the outputs from the HFDT. The batch size was set to 3 and the number of major iterations was limited to 8, giving rise to a total of 24 (plus the original 10) HFDT function evaluations.

**Figure 2.** Illustrative example showing how the GRASP in our BO procedure generates points to be sampled in the design space. Gray dots indicate points in the design space that have already been sampled. Red dots indicate points that the GRASP generated, which will be evaluated before the subsequent iteration commences.

Figure 2 depicts the results to the illustrative example. There are 8 subfigures, each representing a major iteration in our BO procedure. Each subfigure contains a surface plot and a scatter plot. The x- and y-axis in each subfigure represents the first input and second input variable to the HFDT respectively. The surface plot color represents the output of  $\alpha(\cdot, \cdot)$  scaled to the unit cube. The mean absolute error (MAE) of the Gaussian process model compared to the actual HFDT for 2000 randomly

selected points is stated in the bottom left corner of each subfigure. From inspection of each of the subfigures it is clear the GRASP within our BO procedure produces points to be evaluated by the HFDT with high values computed by the function,  $\alpha(\cdot, \cdot)$ , while simultaneously ensuring that these points are significantly far apart from each other, such that the “information gain” per iteration of the BO procedure is maximized. For instance, in the final iteration of the BO procedure, as illustrated in Fig 2.h, the 3 points generated to be sampled are conveniently located at what appears to the naked eye, as the three global maximums of the function  $\alpha(\cdot, \cdot)$ .

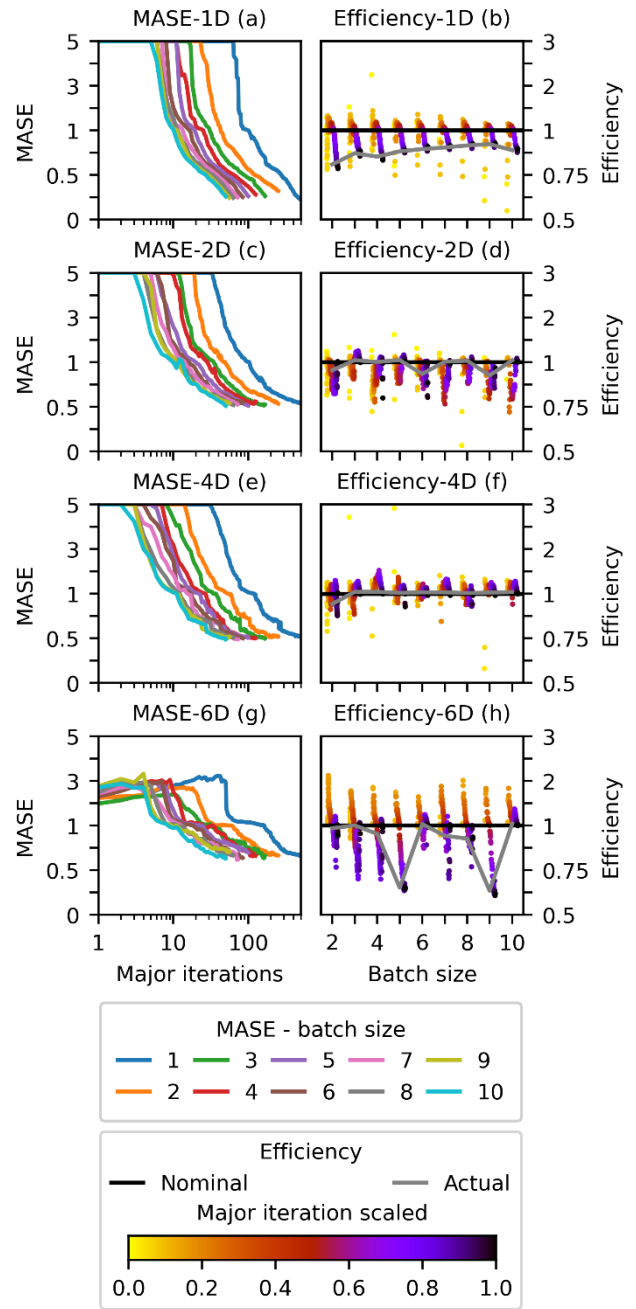

### Results from the computational experiments

To illustrate the benefits of our parallel computation framework, we present the computational results over our 6 test functions in various dimensions. In Figure 3, we show the aggregated mean absolute scaled error (MASE) and efficiency on the left and right, respectively. For each instance and batch size, we first compute its MASE defined in Equation (1), where the numerator is the MAE of the prediction of a Gaussian process (GP) model denoted by  $y_i^{GP}$  measured over  $N$ , 2000, ground truth values denoted by  $y_i^{GT}$ , and the denominator represents the MAE of the prediction of a reference GP model denoted by  $y_i^{GP,ref}$ . The MASE represents the relative performance of a surrogate model compared a reference model. We note that  $y_i^{GP,ref}$  is obtained from the BO after 100 function evaluations with a batch size of 1. Therefore, the denominator value does not change over iterations, whereas  $y_i^{GP}$  can change as we improve a GP model through iterations so can the numerator value. For fair comparison, the number of function evaluations is set to 500 across different batch sizes. Once MASE’s are computed for all instances, we aggregate them by taking their average to display the results of all instances in a single figure.

$$\text{MASE} := \frac{\frac{1}{N} \sum_{n \in \{1 \dots N\}} |y_i^{GP} - y_i^{GT}|}{\frac{1}{N} \sum_{n \in \{1 \dots N\}} |y_i^{GP,ref} - y_i^{GT}|} \quad (1)$$

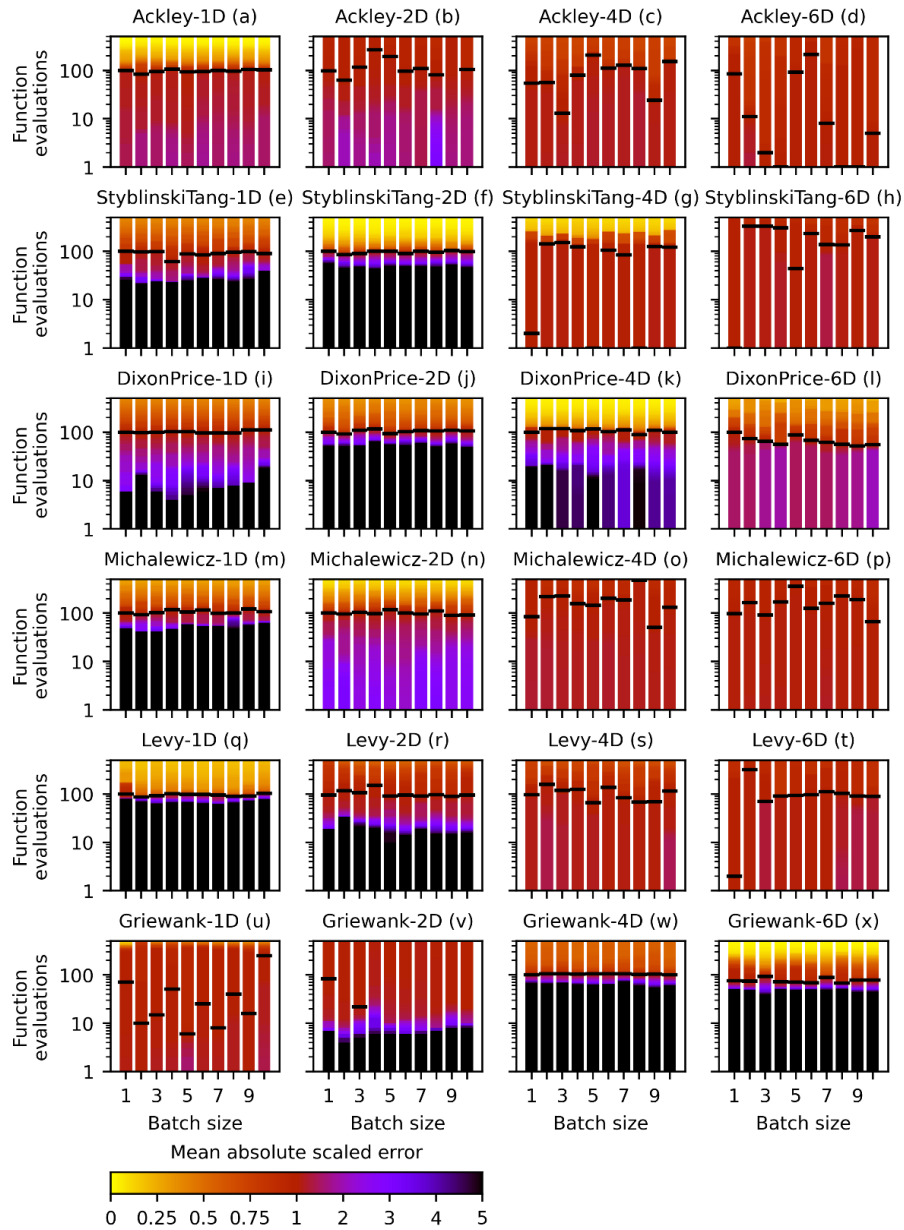

From the figure we see that the larger the batch size the quicker it reaches a MASE of 1 with a fewer number of iterations. For example, it took about 10 iterations for batch size 10 to reach a MASE of 1, while 100 iterations were needed for a batch size of 1 to arrive at that value. This result implies that we can gain a significant speed-up in computing a solution at high quality from parallel function evaluations.

As we increase dimensions, we observe that the MASE value tends to be smaller in early iterations. We think this is because the problem becomes harder as its dimension increases, leading to a smaller performance difference between the reference model and a model with less than 100 function evaluations.

**Figure 3.** Mean absolute scaled error (MASE) and efficiency of the aggregated test functions that were grouped by major iteration, dimension and batch size in subfigures a, c, e, and g; as well as the scaled efficiency of the aggregated test functions grouped by major iteration and batch size in subfigures b, d, f, h.

Whereas **Figure 3** illustrates surrogate quality aggregated over all test functions, **Figure 4** depicts the mean absolute scaled error for each test function in each

**Figure 4.** Mean absolute scaled error (MASE) as a function of the batch size and number of function evaluations for each function in 1, 2, 4, and 6 dimensions.

dimension of interest. Consistent with our intuition, for each batch size shown on the x axis, the MASE decreases as the number of function evaluations increases. As before, MASE is scaled relative to default BO with 100 function evaluations and a batch size of 1, which is shown in the first column of each subplot. In each column, a black horizontal line shows the number of function evaluations required for each batch size to attain an MASE of 1. Thus, the black horizontal line in the first column of each subplot is positioned at 100 function evaluations since this

column corresponds to default BO. As the batch size increases, however, the number of function evaluations required to attain the same MASE as default BO may differ. For example, in 1, 2, and 4 dimensions, the DixonPrice function indicates that, for all batch sizes, 100 function evaluations are needed. However, in 6 dimensions, fewer than 100 function evaluations are needed, suggesting that our approach is superior to default BO. In summary, from inspection of **Figure 4**, it is evident that in general the batch size does not affect the efficiency of our approach, i.e., the efficiency is roughly the same for a batch

of 1, which corresponds to sequential, to a batch size of 10. Consequently, our approach allows for increased parallelization, with minimal loss of efficiency.

## CONCLUSIONS AND FUTURE RESEARCH DIRECTIONS

Expensive-to-evaluate black-box functions often appear in challenging design problems involving multi-scale model integration. We devised and analyzed a GRASP heuristic embedded within a parallel Bayesian optimization framework to accelerate surrogate construction without sacrificing surrogate quality. Computational results revealed that our approach can yield equivalent or superior surrogate quality with near linear scaling in the number of samples evaluated in parallel.

As for future research directions, it would be interesting to investigate multi-fidelity BO, which makes use of lower fidelity observations available with a lower sampling cost. Specifically, it may be possible to query a lower-fidelity model when constructing a surrogate, which then introduces the additional complexity regarding how to sample: Take high- or low-fidelity samples in parallel.

## ABSTRACT

This paper proposes an AI-assisted approach aimed at accelerating chemical process design through causal incremental reinforcement learning (CIRL) where an intelligent agent is interacting iteratively with a process simulation environment (e.g., Aspen HYSYS, DWSIM, etc.). The proposed approach is based on an incremental learnable optimizer capable of guiding multi-objective optimization towards optimal design variable configurations, depending on several factors including the problem complexity, selected RL algorithm and hyperparameters tuning. One advantage of this approach is that the agent-simulator interaction significantly reduces the vast search space of design variables, leading to an accelerated and optimized design process. This is a generic causal approach that enables the exploration of new process configurations and provides actionable insights to designers to improve not only the process design but also the design process across various applications. The approach was validated on industrial processes including an absorption-based carbon capture, considering the economic and technological uncertainties of different capture processes, such as energy price, production cost, and storage capacity. It achieved a cost reduction of up to 5.5% for the designed capture process, after a few iterations, while also providing the designer with actionable insights. From a broader perspective, the proposed approach paves the way for accelerating the adoption of decarbonization technologies (CCUS value chains, clean fuel production, etc.) at a larger scale, thus catalyzing climate change mitigation.

## INTRODUCTION

Climate change has become a crucial problem, where massive efforts are underway to mitigate its disastrous outcomes [Ref. Paris Agreement]. In this regard, there is a major trend to develop efficient carbon capture technologies, recognized as one of the promising solutions to the challenges posed by climate change. Furthermore, the research is accelerating in this hot field due to the clear and prioritized need for developing cost-efficient and environmentally friendly carbon capture processes. Various methods based on mechanistic models and combined with traditional operation research methods, including linear and non-linear programming, are

used to optimize existing carbon capture processes. Nevertheless, despite their robustness, most existing methods for optimizing process design suffer from certain limitations that hinder the development and optimization of carbon capture systems. These limitations include time consumption, high computational costs, and a lack of adaptability and transferability.

Therefore, there is a pressing need for the development of new methodologies to help overcome the above-mentioned limitations. Artificial intelligence (AI) and its related machine learning (ML) technologies holds significant promise to address this critical gap. Specifically, reinforcement learning (RL), as a prescriptive machine learning technique, offers an effective approach due to

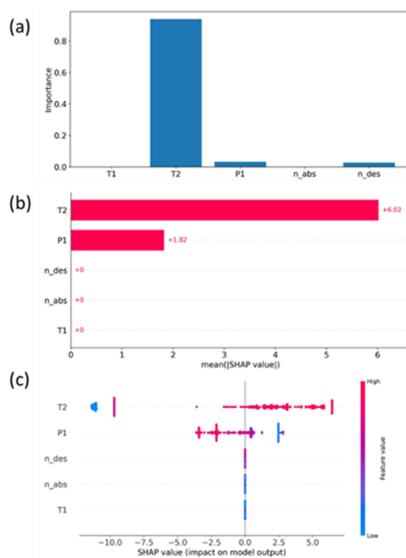

**Figure 1.** General simulation-based optimization approach.

being a learnable optimizer. In addition, its application has been successful in various fields, including process control [1], [2] which underscores its potential for accelerating chemical process design. RL encompasses various types, ranging from model-free to model-based algorithms, as well as policy-based and value-based agents. Examples of policy-based RL agents include deep Q-network (DQN) [3] and proximal policy optimization (PPO) [4]. Besides, there are agents that combine both policy-based and value-based calculations, such as deep deterministic policy gradient (DDPG) [5]. These diverse types offer versatile tools for enhancing chemical process design acceleration.

Recently, several research studies have employed RL within the realm of chemical engineering to optimize process sequences and to suggest new process flow diagrams for simple processes [6]–[12]. For instance, in [10], the authors used a hierarchical deep RL (DRL) agent to automate the synthesis of flowsheets for the ethyl tert-butyl ether (ETBE) production process. The study adopted the *SynGameZero* approach outlined in [13]. The Soft Actor Critic (SAC) algorithm was used in [9] to

design a distillation train to separate a mixture of benzene, toluene, and *p*-xylene. The SAC agent interacts with a Distillation Gym environment that interfaces with *COCO* open-source simulator. The paper [14] conducted a survey on the RL-assisted flow sheet synthesis, highlighting the interaction with other simulators, i.e. DWSIM, and the concept of transfer learning for process design [8]. Nonetheless, some of these attempts are still at early stages as the agents developed suggest technically infeasible flowsheets in some cases due to the lack of reasoning for the trained agent. Besides, one major limitation of these studies is the absence of causality. Analyzing the historical data gathered during the optimization process can offer new insights to the designers, enabling them to identify the causal variables that impact selected key performance indicators (KPIs), e.g. costs. Extracting knowledge from causality analysis part will lead to more generalizable results and provide actionable insights into hidden information and relationships that can be transferred to enhance other processes.

The novelty of the current work lies in the introduction of causal DRL to accelerate the design of chemical

processes. Two systems were considered for illustration: 1) ammonia-water system (hypothetical physical absorption-desorption process as a simplified example) and 2) mono-ethanolamine (MEA)-based carbon capture process. Introducing the concept of causal reinforcement learning to process design, specifically in applications related to solvent-based capture processes, can enhance the agent's reasoning capabilities, and enrich the knowledge of design experts with new insights. This approach can be generalized to other systems, under the full supervision of human experts, to streamline and accelerate the design process. The specific research objectives of this study are outlined as follows: 1) Develop an incremental DRL (IDRL) simulation-based optimization methodology to accelerate the design of steady state processes; 2) Integrate a newly developed causality analysis methodology, employing various algorithms with the IRDL to capture the underlying cause-effect relationships among different process variables and the specified KPI(s); 3) Deploy the developed IDRL coupled with causality analysis methodology to optimize different processes, including absorption-based carbon capture process utilizing amine solvents.

## METHODOLOGY

### General DRL Simulation-based Optimization Approach

The general simulation-based optimization approach and its underlying methodology achieving its objectives is depicted in **Figure 1**. A DRL agent is linked with a simulation environment in an interactive and learnable manner that minimizes the search space. Within this approach, the term "rewards" is used to denote the key performance indicators, whereas the term "states" is used to represent the observations defining the current condition of the process. The agent provides "actions" (representing design variables including equipment sizing and operating conditions) to the simulation environment based on the current state and the observed reward. The agent tries to find the optimal point without sticking in local minima where it may follow the shortest path, depending on factors such as problem complexity, reward formulation, the RL algorithm selected, and available computational resources. Unlike most of the traditional optimizers, DRL-based optimization is driven by the concept of reward and penalty. The agent receives a reward when following the right path of optimizing the objective function, i.e. minimizing the process costs, or minimizing its environmental impact. Conversely, a penalty is incurred if the agent followed the wrong direction, where the actions result in cost or environmental impacts exceeding specified values. To avoid settling in local minima, the agent poses the ability to explore new scenarios, aiming to identify paths leading to the global minimum point. Balancing

between exploitation and exploration is crucial to speed up achieving the optimal solution. Additionally, achieving an accelerated optimization requires proper formulation of reward function and optimization of the agent's hyperparameters.

#### DRL and problem formulation as Markov Decision

**Process.** From a mathematical standpoint, when employing RL, the problem is typically formulated as a *Markov Decision Process* (MDP). This formulation involves a set of observations that characterize the state of the environment, along with a distribution of initial states. Additionally, it entails a set of actions, whether continuous or discrete, that can modify the state of the environment based on rewards received by the agent. An MDP comprises transition dynamics or probabilities, which describe the relation between states and actions. Two other important components are the immediate rewards and the discount factor (which ranges from 0 to 1), a lower discount factor places greater emphasis on the immediate reward. For a more detailed explanation of the mathematical formulation of RL and MDP, refer to this study [3]. It is worth noting that one of the primary differences between dynamic and steady-state problems lies in the definition of discount factor during MDP formulation. The discount factor is an optional element in defining an MDP and can be disregarded (assigned a zero value) when considering the optimization of steady-state processes, where immediate rewards take precedence over long-term ones. Disregarding the discount factor in case of steady-state processes facilitates the design optimization problem definition/formulation. Nevertheless, finding the optimal policy based on the cumulative reward for the RL agent remains relevant. This design problem adheres to the *Markov Property*, resulting in a memoryless agent, where the current state depends only on the previous state and influences the selection of the subsequent actions that modify the successive states. Consequently, the transition dynamics or probabilities over time and the whole states history will not be taken into consideration. The transition probabilities between two successive states based on the proposed or taken actions are primarily deterministic. In chemical process design, these transitions may involve thermodynamic/equilibrium relations, kinetic/rate equations, or heuristic rules.

**RL Algorithm selection & development of the simulation environment.** Various RL algorithms can be developed, optimized, and then utilized for process design optimization. As previously mentioned, the PPO and SAC algorithms were employed process flowsheet synthesis. In this work, we consider the DDPG algorithm [5], which is one of the promising algorithms. It combines the value-based and policy-based optimization principles.

Upon developing the simulation environment, the potential actions (design variables) under consideration include equipment sizing and process operating

conditions. Additionally, parameters such as recycle rate, purge percentage and flowrates of inlet streams are deemed significant actions to be prescribed or optimized. Equipment sizing varies according to the equipment type. For instance, the number of stages is a crucial variable for separation columns, defining their heights and costs. Continuous stirred reactors (CSTRs) are sized by volume, which is also related to the percentage conversion of limiting reactants. Heat exchange equipment sizing is determined by the heat exchange area, which is also related to other process operating conditions. Process operating conditions encompass different streams/equipment temperatures and pressures. Key observations describing the simulation environment's state include the purities of specified product streams/components, recovery rates of components of interest, and utilities consumption. These states and actions vary from a problem to another depending on the specific requirements of the problem and the specifications set by the process expert.

**Reward definition (formulation).** The reward function can take various forms, depending on the specified objective defined by the process expert. For instance, it can be formulated as the relative production cost, i.e. production cost per kg of product or material. Alternatively, it could represent the total capital investment (TCI), net present value (NPV) or any other form of economic KPIs. Furthermore, it might be a combined value of both techno-economic KPIs such as relative production cost per material/product recovery or purity. One objective function that can serve as a highly relevant reward function is the total environmental impact or the relative emissions per kg of the product. This function holds significant importance in current and future research studies for process design optimization, enabling the assessment of processes' environmental footprints and promoting the development of eco-friendly processes.

**Incremental learning.** It is worth noting that our approach for the DRL-based optimization is built upon the concept of incremental learning. Specified costs, environmental impacts and actions ranges change from one case to another until the maximum allowable performance is achieved, i.e. lowest possible relative production cost and minimum acceptable environmental impact. More specifically, the actions ranges are narrowed or redefined after analyzing the historical data collected from previous RL-assisted optimization cases. In addition, reward function and its value are redefined based on this analysis. For example, the specified cost value may be reduced to explore the agent's ability to surpass it and reach the minimum allowable cost.

## Towards causality analysis for causal and rational DRL

Following the incremental learning-based optimization, historical data representing the simulation runs

resulting from the agent-simulation interactions are stored in spreadsheets for the causal analysis, where each run represents a data point (observation). This is to gain more actionable insights into the root causes and the importance of design variables impacting the KPIs. Three methods were employed to perform a preliminary causality analysis based on observations. These methods include combined interpretable ML (IML)-Explainable AI (XAI), Granger causality (GC), and Bayesian causal discovery & inference.

**Combined IML-XAI.** Initially, the decision tree classification algorithm (i.e. IML) is combined with XGBoost and SHAP explanation algorithm (i.e. XAI) to extract the patterns, assess variables importance and analyze the relationships governing the dependence of the specified KPI (reward) and observations (state) on the design variables (actions). The IML extracts the patterns (ranges of design variables) that lead to processes with reasonable feasibility. Additionally, it assesses the variables importance, determining the most significant ones. The XAI gives relative magnitudes and directions of the effect of each input variable on the final KPI (process overall production cost). This will help afterwards in the incremental learning procedure, helping to select/redefine the relevant input variables ranges for guided optimization.

**Granger causality (GC).** This method is used preliminary to validate the relations between the actions (especially the most significant ones identified by the combined IML-XAI method) and the KPI. Since actions are provided continuously by agent and they depend on the previous set of actions and states, consequently actions, states, and rewards/KPIs are treated as a form of time series data, leading to the application of GC. As mentioned earlier, in case of optimizing steady-state processes, the current state (representing the current process configuration) is solely influenced by the preceding one, rendering longer-term relationships negligible. The dependence between each successive pair of states ( $S_t$  &  $S_{t+1}$ ) and their associated set of actions based on the reward provided to the agent, justifies the utilization of approximated time series assumption to apply GC.

**Bayesian causal discovery & inference.** This method is used to generate causal graphs to discover the root causes that significantly affect changes of the KPI. It also reveals the interdependence among actions, discovering the root cause design variable that affects both other design variables and KPI. **Figure 2** summarizes the proposed causality analysis methodology. Further details regarding the combined IML-XAI method can be found in our recent study [15]. The insights gained from this causality analysis will upgrade/enrich the experts' knowledge, where they can redefine the baselines/rewards and the range of actions to retrain the agent, thereby fostering further improvement in design optimization.

This methodology can be applied in flowsheet synthesis to enhance the DRL agent's reasoning capability by providing it with the extracted knowledge and causal graphs. This empowers the agent to operate as a rational causal DRL agent that avoids the synthesis of technically infeasible flowsheets/processes, thus accelerating the synthesis and design process. In addition to the other design variables, equipment and their sequencing will be added to the list of actions. Consequently, the causal graphs will account for these two crucial categorical variables and quantify their impact on the defined KPI/reward. Furthermore, integrating domain knowledge from process designers and operators as constraints into the causal DRL agent's structure will enhance its rationality. These domain knowledge-informed constraints ensure the avoidance of invalid streams/equipment selection, placement, and sequencing, e.g. separation train sequencing [16] and chemical reactors sequencing [17]. This will further shorten the time needed for the agents to converge on the optimal new process, thus ensuring the desired ML-assisted design acceleration.

## SIMULATION CASE STUDIES

Aspen HYSYS was selected as the simulation software for constructing the process flow diagrams and conducting the process design. Two simulation case studies were developed to validate the proposed CIRL approach. The simplified process flow diagrams of the two case studies are presented in the supplementary materials and their details are summarized in the following subsections.

### Case study 1: Ammonia water system

An ammonia-water absorption-desorption system was developed with a stream of air contaminated with ammonia is introduced to the absorption column, where pure water is utilized as a physical solvent to separate ammonia from air. The captured ammonia is then removed from the water solvent using steam in a re-boiled stripping column. Heat exchange between the stream entering the stripping column and its bottoms product stream enables heat integration, minimizing the reboiler heat load. A condensation and a flash separation are applied for the top product stream of stripping column to remove any water associated with the separated ammonia, thus enhancing its purity and recovering any escaped solvent. Recycle was not considered in this simplified case study. The NRTL simulation fluid package was used [18]. The actions considered include number of stages in both absorption and stripping columns, temperatures of fresh solvent and inlet contaminated gaseous stream, and the pressure of the inlet contaminated gaseous stream.

### Case study 2: Mono-ethanolamine (MEA)-based carbon capture system

This case considers chemical absorption (CO<sub>2</sub>-MEA system), where flue gas enters the absorption column after solids removal, pressurization, and cooling to the desired operating temperature. The absorption-desorption setup is like the case of ammonia (case study 1). However, in this case, lean MEA is recirculated, after carbon dioxide stripping, to the absorption column and mixed with a makeup stream to enhance the process feasibility. A purge stream is used to avoid excessive accumulation of carbon dioxide in the system and the recycled lean MEA stream. Effect of temperature and pressure of inlet flue gas stream and temperature of makeup solvent were considered as actions. Effect of recycle percentage and temperature of stream entering the stripping column were also considered for optimization. The *Acid Gas - Chemical Solvents* Aspen built-in fluid package was used to perform the simulation calculations. The stream of flue gases comes from a power plant, where all conditions defined according to that study [19]. A baseline/reference for the carbon dioxide recovery cost of 1.12 USD/kg was adopted from a published study [20] that ultimately achieved the lowest cost after several iterations.

### Reward definition

Important observations that describe the state of simulation are purity of purified gas stream, recovery of contaminants (for ammonia and carbon dioxide), purity of the product stream, and utilities consumption. The reward function is defined as the relative removal cost, i.e. removal cost per kg of captured material. The procedure for calculating the removal cost and other related costs follows the guidelines outlined in this textbook [21] and these two studies [22], [23]. Utilities and MEA prices were sourced from a study published in [24]. The reward was determined as follows: if the agent progresses in the specified direction (new cost  $\leq$  specified cost), it receives a value equivalent to the total production cost (unity factor); otherwise, it receives a zero value. Furthermore, if the new cost in current step is lower than the cost of previous step, the agent receives the full total production cost value; otherwise, it receives zero.

## RESULTS AND DISCUSSION

### Optimized DRL agent

The agent developed and adopted in this study is based on DDPG, a policy-based model-free reinforcement learning algorithm. It comprises two neural networks, one for the actor and one for the critic. For a deeper understanding of the mathematical underpinnings of the DDPG, interested readers can refer to [1], [25], [26]. The structure and crucial hyperparameters of

the optimized DDPG agent are summarized in **Table 1**.

**Table 1:** DDPG optimized hyperparameters.

Hyperparameter	Value
Action noise standard deviation	0.2
Actor learning rate	0.001
Critic learning rate	0.002
Discount factor (gamma)	0
Tau parameter used to update target networks	0.005
Total number of episodes	100-1000
Activation function for the critic neural network dense layers	ReLU
Activation function for the actor neural network inputs dense layers	ReLU
Activation function for the actor neural network outputs dense layer	Tanh

The *Tanh* activation function was selected to standardize the range of actions between -1 to 1, which are then converted back to their real values before being used in the simulation.

## Process design optimization

### Ammonia-water system

For the ammonia-water absorption system, the initial range for both inlet solvent and flue gas streams temperatures was set between 20 to 100 °C, with pressure ranging from 600 to 950 kPa. It is important to mention that the absorption column pressure was set equal to the inlet pressure of flue gas. This simplification facilitates the manipulation of the absorber pressure in the simulation environment by the RL agent. It is important to note that the inlet flue gas pressure must be higher than that of the absorber to ensure proper flow inside the column. Hence, a pressure drop value will be added to specify the pressure of inlet flue gas to the designer to incorporate it in real life operations. Additionally, the range of number of stages for both absorption and desorption columns was from 3 to 15. The initial desired cost (baseline) had the value of 2 USD/kg of ammonia based on a simulation of base case. As a result, after 220 episodes, a cost of almost 0.880 USD/kg of ammonia was obtained initially, which is significantly lower than the specified baseline. Accordingly, following the proposed incremental learning method, this value was given as a new baseline to the agent for further improvement of the process economic optimization, where the ranges of variables were the same. Surprisingly, the agent could reach another lower production/recovery cost of 0.775 USD/kg of ammonia. The preliminary causality analysis methodology was applied to extract some other knowledge about the most effective variables and the patterns to achieve lower process costs. Thus, the historical data from these two first

optimization iterations was collected, preprocessed, and analyzed. The preprocessing was done through dividing the observations to high cost (above 0.9 USD/kg of ammonia) observations and labeled as Class (0). The other portion was labeled as Class (1), which represented the low cost (below 0.9 USD/kg of ammonia) observations. **Figure 3** represents the results of employing IML+XAI to get the dependency graphs.

As shown, the most effective two variables are T2 (temperature of flue gases entering the absorption column) and the pressure of the solvent stream. These results were validated through performing the GC analysis to test the dependency of the continuous cost change corresponding to the continuous actions given by the agent, in which the new actions depend on the previous actions, state and reward. *p*-value of the dependence between T2 and cost was < 0.001 which indicates high GC. Besides, according the XAI dependency graphs, higher values of T2 lead to lower costs (Class (1)). The variable P1 possesses clearly lower significance, where, after data preprocessing/analysis, the lower values in the range of 830-900 kPa (around 850 kPa) lead to lower costs (Class (1)). These results of the current case mean that the operating costs dominate the removal cost. In addition, upon analyzing the available data, to achieve higher purities and recoveries of ammonia, it is preferred to utilize absorption columns with low number of stages and stripping column with a higher number of stages. The causal incremental learning methodology aims at minimizing the search space to accelerate the process design optimization. Hence, after obtaining the dependency graphs, the ranges of the variables were redefined and narrowed to see if further improvement can be obtained. The new ranges are (85-99 °C) for T2, (25-41 °C) for T1, (800-900 kPa) for P1, (3-5) for absorption number of stages and (10-15) for stripping column number of stages. In addition, a new baseline was set to 0.75 USD/kg of ammonia. As a result, a new lower production cost of 0.719 USD/kg of ammonia was obtained at the new conditions of T1 = 40.5 °C, T2 = 99 °C, P1 = 900 kPa, absorption number of stages = 4.8 (almost 5) and stripping column number of stages = 15. At these conditions, the purity of outlet air and ammonia recovery were 97.2% and 96.3%, respectively. **Figure 4** summarises the results of the proposed causal incremental learning methodology for process design optimization. The Bayesian causal graph showed that the temperature of the flue gas stream is one of the root causes of changing the KPI (removal cost) and can even affect other design variables (absorption column stages (*n\_abs*) & stripping column stages (*n\_des*)) and state. This graph supports the results of the first two methods and is provided in the supplementary materials.

### MEA-based Carbon Capture system

In the case of MEA-based carbon capture system, the first ranges, according to literature [19], were inlet solvent and flue gas temperatures (T1 and T2) of 30-90 °C and inlet flue gas pressure (P1) of 150-500 kPa. Besides, recycle percentage ranged initially between 90% and 98%, while the range of temperatures of rich MEA stream entering the stripping column was 77-85 °C. As in the case of ammonia-water system, the same assumption of considering the absorption column pressure as the inlet flue gas pressure is still applicable. After using the first baseline of 1.12 USD/kg CO<sub>2</sub>, this initial optimization led to a lower production cost of almost 0.190 USD/kg CO<sub>2</sub>. The collected data was then preprocessed and labeled to the IML-XAI based low level causality analysis of the historical simulation data collected from this iteration show that the most significant variables are flue gas inlet temperature and its pressure. The GC analysis confirmed this where the  $p$ -value in the case of cost dependence on T2 did not exceed 0.0001. It is worth mentioning that when the test was done in the reverse direction the  $p$ -value exceeded 0.9; this means that T2 causes the change in the cost but not the vice versa. In addition, the  $p$ -values in the case of the other variables T1, Rec%, T before stripping column and the fresh solvent flowrate exceeded 0.1, which indicates low to no significance of these variables compared to T2 in the current study within the specified range. Figure 5 shows the results of the combined IML+XAI approach in the current case of MEA-based carbon capture system. According to these results the ranges of the variables were narrowed/redefined for the sake of exploration for further optimization through retraining the agent considering the extracted causal knowledge, which gives it more reasoning. This reasoning/causality accelerates the retraining step and the subsequent design optimization. In this regard, the ranges of the actions were narrowed/redefined to become inlet solvent and flue gas temperatures (T1 & T2) of 23-35 °C and inlet gas pressure (P1) of 250-400 kPa in the second iteration. In addition, the new range of the recycle percentage was 85%-95% and accordingly the range of temperatures of rich amine stream entering the stripping column changed to 71-81 °C. Furthermore, the baseline was decreased to 0.185 USD/kg CO<sub>2</sub>. A third baseline, based on the expertise of carbon capture and process engineering experts, was put at 0.155 USD/kg CO<sub>2</sub> for comparison and more improvement in future research. Figure 6 summarizes the results of the two training iterations with their corresponding baselines. As shown, the minimum relative removal cost obtained was about 0.175 USD/kg CO<sub>2</sub>. This cost was obtained after 25 episodes during the second iteration (agent retraining step). The conditions that achieved this value were T1 of 24 °C, T2 of 25 °C, P2 of 270 kPa, recycle percentage of 85 % and temperature of the rich amine entering the desorption column of 71 °C, respectively. Additionally, the

carbon capture percentage at these conditions was 92.5% with a carbon dioxide purity of 98%. The causal graph based on Bayesian framework showed that one of the clear root causes of changing the KPI and can even affect other design variables and state is the temperature of the flue gas stream in agreement with what was obtained by the first two methods. This graph is put as supplementary material.

## RECOMMENDATIONS FOR FUTURE WORK

In forthcoming research, we aim to incorporate emissions and other environmental impacts as crucial optimization objectives. In particular, the net emissions should be considered as a reward, where the emissions of the capture process itself should be minimized as possible. We advocate for exploring the application of transformers-based RL for flowsheet synthesis and process design acceleration. This will allow adding more reasoning to the causal incremental learning-based RL agent to help in generating/suggesting new technically feasible process flow diagram. This will be done also through defining constraints based on process design experts' domain knowledge and rules as a practical application of the interesting concept of RL with human preferences. This will guarantee the acceleration of process design under the full supervision of human experts to always insure simultaneous technical and economic feasibility of the generated flowsheets. Uncertainty of inlet streams composition and energy/fuel prices will be considered in our future research as well which is one of the advantages of RL to deal with uncertainties.

## CONCLUSION

This study introduced and employed a causal Incremental Reinforcement Learning (CIRL) agent as a learnable optimizer with reasoning capabilities to accelerate efficient process design. Two case studies were considered to validate the approach, physical absorption (ammonia-water system) and chemical absorption (CO<sub>2</sub>-MEA system). In the case of chemical absorption, the causal DRL agent reached an optimal cost after only 25 episodes. The causality analysis revealed that key variables, such as inlet flue gas temperature and absorption pressure, significantly influence the CO<sub>2</sub>-MEA system's production cost. For instance, it showed that the relative production cost of the process is inversely proportional to the flue gas temperature fed to the absorber. Feeding the agent with the extracted knowledge and causal information obtained from the causality analysis helped it to achieve more improved process design. These findings hold relevance beyond the studied systems and offer actionable insights for future absorption system designs.

## ABSTRACT

Explicitly incorporating the effects of chemical phenomena such as chemical pretreatment and mineral scaling during the design of treatment systems is critical; however, the complexity of these phenomena and limitations on data have historically hindered the incorporation of detailed water chemistry into the modeling and optimization of water desalination systems. Thus, while qualitative assessments and experimental studies on chemical pretreatment and scaling are abundant in the literature, very little has been done to assess the technoeconomic implications of different chemical pretreatment alternatives within the context of end-to-end water treatment train optimization. In this work, we begin to address this challenge by exploring the impact of pH control during pretreatment on the cost and operation of a high-recovery desalination train. We compare three pH control methods used in water treatment ( $H_2SO_4$ , HCl, and  $CO_2$ ) and assess their impact on the operation of a desalination plant for brackish water and seawater. Our results show that the impact of the acid choice on the cost can vary widely depending on the water source, with  $CO_2$  found to be up to 11% and 49% more expensive than HCl in the seawater and brackish cases, respectively. We also find that the acid chemistry can significantly influence upstream processes, with use of  $H_2SO_4$  requiring more calcium removal in the softening step to prevent gypsum scaling in HPRO system. Our work highlights why incorporating water chemistry information is critical when evaluating the key cost and operational drivers for high-recovery desalination treatment trains.

## INTRODUCTION

There is growing interest in transforming the linear water economy to a circular water economy, where wastewater is treated for reuse while contaminants are recovered as valuable products [1]. This paradigm shift would significantly reduce freshwater withdrawals and wastewater discharges to the environment and could enable distributed treatment, minimizing transportation costs and externalities. However, technological advances are needed to reduce the energy use and cost of high-recovery treatment trains, which are essential for circular water treatment and minimizing brine generation in inland water reuse applications.

Modeling high-recovery treatment trains is challenging due to complex water chemistry phenomena. As more water is recovered, the concentration of dissolved solids will eventually reach saturation, and the solids will precipitate out of solution. This precipitation can result in mineral scaling on the surfaces of equipment and damage them [2, 3]. While mineral scaling can be prevented or delayed through pretreatment, traditionally with chemical precipitation or the addition of antiscalants, it is critical to explicitly incorporate precipitation and mineral scaling predictions in technoeconomic assessments in order to relate the extent of pretreatment with the water recovery of the system. However, the complexity of these phenomena and limitations on data have

historically hindered the incorporation of detailed chemistry into process-scale water treatment models, particularly for novel, high-recovery systems.

We previously developed a framework for integrating detailed water chemistry into the design of water treatment systems using data-driven surrogates [4]. We demonstrated that scaling mitigation using chemical addition is a substantial component of process cost and a requirement for achieving high recoveries in desalination treatment trains, and that chemical pretreatment must be explicitly accounted for in process design. However, despite a significant body of work on scaling and chemical pretreatment [5, 6], little has been done on assessing the techno-economic implications of different chemical pretreatment alternatives within the context of end-to-end water treatment train optimization. This gap in the literature hinders the development of comprehensive optimization strategies that can effectively integrate chemical pretreatment with other treatment processes to achieve cost-effective desalination.

In this work, we begin to address this knowledge gap by exploring the techno-economic implications of one important chemical pretreatment decision in high-recovery desalination: pH control. The pH of water entering a reverse osmosis (RO) treatment train impacts both mineral-scale formation and membrane longevity, making pH control critical. Using WaterTAP [7], an open-source tool for modeling desalination and water treatment systems, we conduct an in-depth operational and economic assessment of post-softening pH control using acidification in water treatment. We compare three commonly used acids,  $H_2SO_4$ ,  $HCl$ , and  $CO_2$ , for pH control based on system cost, system operation, and safety for an emerging high-recovery desalination technology. Our results show that the choice of pH control acid can significantly impact costs and should account for the feedwater and acid chemistries, highlighting why water chemistry incorporation at the design stage of water treatment systems is critical. Through our analysis, we provide qualitative insights to guide decision-making on achieving high-recovery desalination.

## METHODOLOGY

This section describes the desalination train, our modeling approach, and our optimization problem formulation for cost-optimal system design.

### System Description

We investigate the impact of pH control choice on high-recovery treatment trains for brackish and seawater sources. We consider a medium-sized plant (5000  $m^3/day$ ); feedwater compositions are provided in Table 1.

Fig. 1 shows the schematic for our desalination train. Our proposed high-recovery treatment train uses high-

pressure reverse osmosis (HPRO) technology, an emerging process for water desalination that allows RO systems to operate at significantly higher pressures than the 85-bar limit of traditional seawater RO, thus enabling higher recoveries [8, 9]. Recent work has shown that HPRO can be more energy efficient and cheaper than other high-recovery alternatives [8, 10]. For our case study, we explore the viability of HPRO technology with chemical pretreatment.

Current seawater RO systems are limited to 50% recovery [11]; pretreatment allows the desalination system to increase water recovery before mineral scaling occurs. Our chemical pretreatment is done in two steps: softening followed by acidification [5]. First, soda ash ( $Na_2CO_3$ ) addition softens the water by removing calcium ions as  $CaCO_3$ . Next, acid addition lowers the pH. To assess the impact of pH control on HPRO performance, we consider three acidification alternatives:  $CO_2$ ,  $H_2SO_4$ , and  $HCl$ .

The pretreated water goes through RO/HPRO, where clean water is produced. Energy is recovered from the high-pressure waste via an energy recovery device (ERD), improving the energy efficiency of the process.

**Table 1:** Plant feedwater conditions

	Brackish	Seawater
Capacity ( $m^3/d$ )	5000	5000
Temperature ( $^{\circ}C$ )	25	25
Pressure (bar)	1.013	1.013
$Na^+$ (mg/L)	739	10556
$K^+$ (mg/L)	9	380
$Ca^{2+}$ (mg/L)	258	400
$Mg^{2+}$ (mg/L)	90	1262
$Cl^-$ (mg/L)	870	18980
$SO_4^{2-}$ (mg/L)	1011	2649
$HCO_3^-$ (mg/L)	385	140
pH	7.07	7.56

### HPRO Modeling

The HPRO system model was developed using WaterTAP, an open-source Python framework for the simulation and optimization of water treatment trains, built upon the Pyomo-based IDAES Integrated Platform [12]. We develop the HPRO system as a greybox model, combining mechanistic models for desalination components with surrogate models for water chemistry. The surrogates compute functions for the desired chemical phenomena that are added to the EO model formulation.

Physics-based models of the desalination components (RO, pumps, and ERD) are implemented using WaterTAP's model library which includes unit and costing models for the components. Detailed equations for each of the components may be found in Atia et. al. [13].

Detailed water chemistry and thermodynamic information are necessary to predict the impact of chemical

**Figure 1:** Schematic of the high-recovery treatment train showing surrogate insertion points. For softening and acidification, the surrogates predict the effluent pH and solids concentration directly from the decision variables (pretreatment chemical doses). For scaling, the surrogates predict scaling tendencies at the outlets of the RO units, with the inputs based on the upstream conditions and the RO operating conditions (pressure, recovery).

**Table 3:** Cost parameters for softening and acidification.

Chemical	Capital cost	Operating costs	Source(s)
$\text{Na}_2\text{CO}_3$	$12985x^{0.5901}$ ; $x = \text{lb/day}$	Chemical cost: $\$0.19/\text{kg}$	[16, 17]
$\text{H}_2\text{SO}_4$	$-0.0029x^2 + 48.434x + 22,648$ ; $x = \text{gpd}$	Chemical cost: $\$0.12/\text{kg}$	[18-20]
HCl	$-0.0029x^2 + 48.434x + 22,648$ ; $x = \text{gpd}$	Chemical cost: $\$0.17/\text{kg}$	[18, 21]
$\text{CO}_2$	$\text{CO}_2$ liq. feed system: $9 \times 10^{-8}x^3 - 0.001x^2 + 42.578x + 130,812$ ; $x = \text{lb/day}$	Chemical cost: $\$0.24/\text{kg}$	[18-19, 22]
	$\text{CO}_2$ Basin: $4 \times 10^{-9}x^3 - 2 \times 10^{-4}x^2 + 10.027x + 19,287$ ; $x = \text{ft}^3$	Electricity: $0.11 \text{ kWh}/\text{kg CO}_2$	

pretreatment in membrane systems. We incorporated the required water chemistry information into our WaterTAP model using surrogate models. As shown in Fig. 1, surrogates are used to represent three types of chemical phenomena in our process:

1. Softening – softening precipitates  $\text{CaCO}_3$  from solution, changing the feedwater pH. The surrogate predicts the  $\text{CaCO}_3$  concentration and pH as functions of the  $\text{Na}_2\text{CO}_3$  concentration added to the feedwater. Distinct surrogates were developed for brackish water and seawater.
2. Acidification – the acidification process regulates the pH for desalination. For each acid ( $\text{CO}_2$ ,  $\text{H}_2\text{SO}_4$ , HCl), we develop surrogates that predict post-acidification pH based on  $\text{Na}_2\text{CO}_3$  and acid dose.
3. Mineral scaling – mineral scale formation limits the water recovery attainable in membrane systems. We develop surrogates to represent the scaling tendency (ST), which is the thermodynamic driving force for precipitation [2] and predicts whether scale formation will occur under specific conditions. A

value of  $\text{ST} > 1$  indicates that scaling will occur. We monitor scaling at the RO outlet, with the scaling tendency dependent on the pretreatment conditions ( $\text{Na}_2\text{CO}_3$  and acid doses) and RO operation (recovery, RO pressure). The scalants of interest are calcite ( $\text{CaCO}_3$ ), gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) and  $\text{CaSO}_4$ .

Water chemistry data is obtained from OLI [14], a water chemistry software that provides first-principles-based equilibrium calculations and chemistry models for electrolyte and non-electrolyte streams. To generate surrogate training data, we sweep across the decision variables for each acid; ranges for the decision variables for each acid and water source are shown in Table 2.

We used the PySMO software [15], part of the IDAES-IP, to generate surrogates for the chemical phenomena of interest. PySMO provides several surrogate methods, including radial basis functions (RBFs), Gaussian process models, and polynomial regression. For this application, we used RBFs because they had the best performance and are, in our experience, robust.

## Optimization Problem

For each water source and acid choice, the objective is to minimize the levelized cost of water (LCOW) of the system:

$$\min_d LCOW = \frac{CRF * \text{capital cost} + \text{annual operating cost} [\$/\text{yr}]}{\text{Treated water volume} [m^3/\text{yr}]} \quad (1)$$

where  $d$  is the vector of decision variables ( $\text{Na}_2\text{CO}_3$  dose, acid dose, water recovery, and RO pressure), and CRF is the capital recovery factor (set at 0.1).

Constraints on the optimization problem include:

- equality constraints representing the mechanistic models of the HPRO train components (pumps, RO, ERD).
- inequality constraints representing operational limitations of RO systems. The inlet crossflow velocity is limited to a maximum of 25 cm/s, the minimum allowable salt rejection in the RO is constrained to 98%, and maximum operating pressure of RO1 is limited to 85 bar.
- inequality constraints that ensure that no scale formation occurs based on the scaling tendency surrogates  $\overline{ST}_s$ :

$$\overline{ST}_s(d) \leq 1 \quad \forall s \in [\text{CaSO}_4, \text{CaCO}_3, \text{CaSO}_4 \cdot 2\text{H}_2\text{O}] \quad (2)$$

The optimization problems are solved with IPOPT [26] using the MA27 linear solver in WaterTAP.

**Table 2:** Decision variable ranges and surrogate metrics. For the softening and acidification surrogates, we present the  $R^2$  and maximum absolute errors.

Variable	Range	
	Brackish	Seawater
$\text{Na}_2\text{CO}_3$ , mg/L	0-750	0-1200
Pressure, bar	10-110	50-300
Recovery	50-90%	50-87%
$\text{CO}_2$ , mg/L	0-300	0-50
$\text{H}_2\text{SO}_4$ , mg/L	0-150	0-50
HCl, mg/L	0-150	0-50
Surrogates	Metrics ( $R^2$ , MaxAE)	
Softening pH	1.00, 0.03	1.00, 0.02
Softening $\text{CaCO}_3$ , mg/L	1.00, 7.59	1.00, 5.07
Acidification pH ( $\text{CO}_2$ )	0.99, 0.01	0.99, 0.05
Acidification pH ( $\text{H}_2\text{SO}_4$ )	0.99, 0.01	0.99, 0.04
Acidification pH (HCl)	0.99, 0.01	0.99, 0.03
Min ST classification accuracy (%)	>99.2	>99.2

Cost parameters for the different pretreatment options are shown in Table 3. The capital cost of  $\text{CO}_2$  is made up of two components: the cost of the feed equipment and the cost of the recarbonation basin. All costs

were converted to 2018 dollars using the CEPCI cost index. Acid purities of 99.5%, 93%, and 30% are considered for  $\text{CO}_2$ ,  $\text{H}_2\text{SO}_4$  and, HCl respectively [6, 16, 23], while the liquid  $\text{CO}_2$  is assumed to be at  $-18^\circ\text{C}$  and 20.4 atm [5]. It should be noted that the capacities in our optimization problem are treated in a continuous manner, with the installed capacities for pretreatment assumed to be equal to the minimum capacities required for daily operation.

## RESULTS

### Surrogate Performance

Table 2 summarizes our surrogate performance. For the softening process, RBF models with 13 terms were found to sufficiently capture the curvilinear relationship between the input ( $\text{Na}_2\text{CO}_3$  dose) and outputs ( $\text{CaCO}_3$  precipitation and pH), with  $R^2 \approx 1$  and the mean absolute errors below 1 mg/L and 0.004 for both water sources. The maximum prediction error is 7.59 mg/L for precipitation and 0.03 for pH.

For post-acidification pH, the final RBF surrogates are trained on 100 training points, with the models predicting within  $\pm 0.05$  (less than 1%) of the true pH values observed from OLI. This level of accuracy makes the surrogates useful for comparing directly between the pH values of the different acids considered.

For mineral scaling, the most important factor is accurately determining whether or not scaling will occur. Thus, the critical performance metric for the scaling tendency surrogates is the accuracy in classifying potential operating scenarios into scaling or non-scaling. As shown in Table 2, our scaling tendency surrogates have >99% accuracy in discriminating between scaling/non-scaling cases. This means that our surrogates are accurate enough to provide the optimization model with accurate information about the operational feasibility.

### Impact of Acid Choice on Cost

Figure 2 shows the optimal cost profiles for the different acids across a range of water recoveries for the two water sources. Our model results show that (a) there is a marked increase in cost beyond 66% and 74% recovery for brackish water and seawater, respectively; (b) the choice of acid for pH control has a greater impact on brackish water than seawater.

The cost profiles follow the same pattern: a regime where the cost profile is essentially flat, followed by a regime where the costs increase with recovery in a curvilinear manner. The flat regime corresponds to a region in which only pH control is required to prevent mineral scaling, and no softening is required ( $\text{Na}_2\text{CO}_3$  dose=0). As recovery increases, however, pH control becomes insufficient to prevent mineral scaling, and Ca removal using softening becomes necessary. At this point, the LCOW increases rapidly, with softening costs dominating the

**Figure 2:** Cost profiles for (a) brackish (b) seawater with different pH control acid choices.

cost profile. Softening begins at about 64-66% and 74% for brackish and seawater, respectively.

CO<sub>2</sub> is the most expensive acid choice for both water cases. For brackish water, the cost difference between CO<sub>2</sub> and H<sub>2</sub>SO<sub>4</sub> is as high as 49% in the no-softening region. For seawater, the difference between the costs of the three acids is much lower, particularly at the higher recoveries. CO<sub>2</sub> is still the most expensive, being almost 11.5% higher than H<sub>2</sub>SO<sub>4</sub> in the no-softening regime and up to 5% higher in the high recovery, softening regime. The difference between the magnitudes of the effect of pH control on costs in our two water sources emphasizes the fact that feed water chemistry plays an important role in the acid choice for pH control.

Comparing the cost profiles for HCl and H<sub>2</sub>SO<sub>4</sub> for the Brackish water case yields interesting results. We find that H<sub>2</sub>SO<sub>4</sub> is cheaper than HCl at low recoveries (when softening is not needed) and high recoveries (> 76%). This finding agrees with the literature [6]. However, our results also show that in the mid-recovery regime of 66-76% (at low soda ash dosing requirements), pH control with HCl is cheaper. This results from sulfate-based scale formation that is promoted by the addition of H<sub>2</sub>SO<sub>4</sub> and is discussed in detail in the section below.

It should be noted that while our results consistently show CO<sub>2</sub> as the most expensive of the three acidification options, we do not consider the cost of handling, monitoring, and extra maintenance costs necessary when using H<sub>2</sub>SO<sub>4</sub> and HCl, which may be significant due to their corrosiveness. These additional costs, when combined with the uncertain nature of CO<sub>2</sub> costs [4], suggest that CO<sub>2</sub> may be cost-competitive with HCl and H<sub>2</sub>SO<sub>4</sub> under best-case cost scenarios and thus should remain under consideration as an acidification option.

## Impact on HPRO Operation

### Softening

Fig. 3 shows the optimal Na<sub>2</sub>CO<sub>3</sub> doses for the

brackish water case. The softening profiles mirror the two-regime nature of the cost profiles – a flat regime with no softening, followed by a regime where more Na<sub>2</sub>CO<sub>3</sub> is increasingly required to reach higher recoveries. CO<sub>2</sub> and HCl require the same extent of water softening (same soda ash dose, resulting in the same amount of calcium removal), while use of H<sub>2</sub>SO<sub>4</sub> requires a higher degree of softening. This is because H<sub>2</sub>SO<sub>4</sub> increases the sulfate concentration of the stream, which favors sulfate-based scaling. Thus, additional calcium ion removal is required to counteract the sulfate ion increase and prevent gypsum scaling in the RO membrane. The additional calcium removal required when using H<sub>2</sub>SO<sub>4</sub> depends on the recovery, varying from 2-41% across the recovery range. The challenge with gypsum scaling when using H<sub>2</sub>SO<sub>4</sub> also means that Na<sub>2</sub>CO<sub>3</sub> dosing for gypsum scaling control starts earlier than with the other acids. This finding agrees with the literature which suggests that using HCl may be preferred when calcium sulfate or barium sulfate scaling is a concern [6].

The increased soda ash consumption to prevent gypsum scaling when using H<sub>2</sub>SO<sub>4</sub> for acid control is responsible for the high LCOW values (compared to HCl) observed with H<sub>2</sub>SO<sub>4</sub> between 66-76% for the brackish water case. At low Na<sub>2</sub>CO<sub>3</sub> doses, the additional softening costs incurred when using H<sub>2</sub>SO<sub>4</sub> have a significant impact on the LCOW. However, past 76%, the cost impact of the additional softening required with H<sub>2</sub>SO<sub>4</sub> is overshadowed by the overall cost of pH control pretreatment required to satisfy recovery targets, and H<sub>2</sub>SO<sub>4</sub> becomes the cheapest option due to its higher purity and lower operating costs relative to HCl.

Our results show that softening is primarily required to control gypsum scaling: the recovery at which Na<sub>2</sub>CO<sub>3</sub> dosing starts corresponds to when the gypsum scaling tendency constraint becomes active in the optimization problem ( $\widehat{ST}_{gypsum} = 1.0$ ). Our results also show that the softening step cannot be designed independently of the

downstream chemical operations (e.g. acidification). For the seawater case, softening begins at 74%, with  $\text{Na}_2\text{CO}_3$  consumption levels the same for all acids.

**Figure 3.**  $\text{Na}_2\text{CO}_3$  concentration profile (left axis) and additional Ca removal required when using sulfuric acid (purple, right axis) for Brackish case.

### pH control

Fig. 4 shows acid dose profiles for the two water sources. Seawater requires significantly less acid addition for pH control than brackish water despite its lower starting pH. The high acid requirement in the brackish case is due to its high bicarbonate concentration compared to the seawater source (see Table 1), which produces a buffering effect [24]. The cost-optimal acid doses required for the brackish water cases are between 4-6 times greater than that for seawater when using HCl/ $\text{H}_2\text{SO}_4$ , and 7-10 times greater with  $\text{CO}_2$ . The low acid consumption in the seawater case contributes to why the choice of acid has a smaller effect on the cost profiles. For both water sources, control with  $\text{CO}_2$  requires the highest acid dosing, requiring more than three times the HCl dosing at the highest recovery in the brackish case. The dosage requirements reflect the strengths of the acids: HCl and  $\text{H}_2\text{SO}_4$  are strong acids ( $K_a > 1$ ) and thus require lower acid dosing, while the carbonic acid formed by  $\text{CO}_2$  is a weak acid ( $K_a < 1$ ), meaning that higher concentrations are required. Our analysis of the scaling behavior indicates that pH adjustment is the preferred mechanism for controlling calcite scaling, with the calcite scaling tendency constraint active ( $\widehat{ST}_{\text{calcite}} = 1.0$ ) in the optimization problem over the entire recovery range.

Fig 5. shows the pH exiting the pretreatment stage after acid addition for the Brackish case. Again, we find one acid behaving differently from the other two. HCl and  $\text{H}_2\text{SO}_4$  drop the pH to similar values across the range. However, using  $\text{CO}_2$  necessitates dropping the pH lower. We observed the same pattern in the seawater case (not shown). The reason for this is that  $\text{CO}_2$  addition increases the carbonate ion concentration of the stream, favoring

more calcite scaling. Since pH control is the mechanism for controlling calcite scaling in the system, the pH must be lowered more than in the HCl and  $\text{H}_2\text{SO}_4$  cases to combat the effect of the higher carbonate concentration.

The results of our analysis of the pretreatment process show that while choosing  $\text{H}_2\text{SO}_4$  for pH control impacts gypsum scaling and the operation of the softening step, choosing  $\text{CO}_2$  impacts calcite scaling and the pH of the feedwater to the desalination train. These findings on  $\text{CO}_2$  and  $\text{H}_2\text{SO}_4$  underscore why water chemistry incorporation at the design stage in water treatment is critical.

**Figure 4.** Optimal acid doses for brackish and seawater.

**Figure 5.** pH post-acidification for Brackish case.

### Safety considerations

Safety is a critical factor to consider when dealing with acids in water treatment due to the requirements for onsite storage. Fig. 6 shows onsite acid storage requirements for ten days of plant operation (ten-day storage assumption adopted from [18]). Despite requiring the lowest acid dosing requirements (Fig. 4), HCl requires the highest storage capacity in the seawater case and the joint highest in the brackish case. This is due to its low purity compared to the other two alternatives.  $\text{H}_2\text{SO}_4$  requires the lowest volume for onsite storage due to its high density and typical purity at 93%.  $\text{H}_2\text{SO}_4$  also causes less fuming to the atmosphere than HCl, which results in less corrosion to surrounding metal components [6]. Thus, while the LCOW results are comparable,  $\text{H}_2\text{SO}_4$  is safer than HCl due to its significantly lower storage

requirements and lower corrosiveness. However, of the alternatives considered, CO<sub>2</sub> is the safest choice for pH control. Unlike H<sub>2</sub>SO<sub>4</sub> and HCl, it is non-corrosive, reduces pipe clogging, and requires much lower handling and monitoring costs (not modeled in this work) [25].

**Figure 6.** Onsite acid storage for 10 days of operation.

## CONCLUSION

We present an assessment of the impact of pH control pretreatment choices on the cost and operation of a medium-sized high-recovery RO desalination plant by comparing three common acidification options (H<sub>2</sub>SO<sub>4</sub>, HCl, and CO<sub>2</sub>). We find that the impact of the acid choice on the cost can vary widely depending on the water source, with the seawater LCOW being significantly less sensitive to the acid choice than our brackish water (11.5% vs 49%). Our results show that the choice of pH control acid should account for the properties of the feedwater (e.g., buffer capacity), the chemistry of the acids (e.g., sulfate vs. bicarbonate anions), and the scalants of concern. Water sources with calcite scaling as a primary concern may prefer to avoid CO<sub>2</sub> acidification, while H<sub>2</sub>SO<sub>4</sub> may exacerbate sulfate scaling challenges. Our findings underscore why water chemistry incorporation at the design stage of water treatment systems is critical. The methodology used in this work can easily be applied to evaluate the benefits of process changes and innovations that allow higher maximum allowable scaling tendencies or reduce the cost of chemical precipitation pretreatment. This includes the effect of antiscalants, which can be incorporated into our methodology by increasing the tendency threshold (i.e., RHS of Eq. 2) beyond 1.0, as demonstrated in a previous work [4].

In the future, we will extend this analysis to include an assessment of alternative chemical softening options. We will also consider the impact of electrified pretreatment as an alternative to chemical pretreatment.

## ABSTRACT

In this paper, a hybrid heuristic rule-based and deterministic optimization-driven process decision framework is presented for the analysis and optimization of process flowsheets for end-to-end optimal (E2EO) pharmaceutical manufacturing. The framework accommodates various operating modes, such as batch, semi-batch and continuous, for the different unit operations that implement each manufacturing step. To address the challenges associated with solving process synthesis problems using a simulation-optimization approach, heuristic-based process synthesis rules are employed to facilitate the reduction of the superstructure into smaller sub-structures that can be more readily optimized. The practical application of the framework is demonstrated through a case study involving the end-to-end continuous manufacturing of an anti-cancer drug, lomustine. Alternative flowsheet structures are evaluated in terms of the sustainability metric, E-factor while ensuring compliance with the required production targets and critical product quality attributes.

## INTRODUCTION

The ongoing technological transformations in pharmaceutical manufacturing, driven by emerging paradigms such as quality-by-design (QbD) and quality-by-control (QbC), underscore the importance of model-based digital design tools for informed decision-making in process design and operation [1], [2]. These tools play a crucial role in enabling the comprehensive analysis and optimization of various unit operations as well as integrated process flowsheets to improve manufacturing efficiency while ensuring regulatory compliance and product quality [3], [4]. As the pharmaceutical industry is increasingly leaning towards transitioning from batch to continuous operations, there is a growing demand for modeling tools capable of flexibly simulating diverse operating modes, such as end-to-end batch (E2EB) or continuous (E2EC) flowsheets, as well as hybrid processing schemes, which are often the desired alternatives to

achieve end-to-end optimal (E2EO) manufacturing. To that end, PharmaPy a user-friendly, open-source Python-based tool that has the capabilities of configuring and simulating various manufacturing setups, including batch, continuous, and hybrid systems (containing both batch and continuous unit operations) has been developed as reported in [5].

The optimization of flowsheets, particularly those involving unit operations with diverse operating modes, presents a significant challenge. For pharmaceutical process development, this is crucial, especially during the selection and design of an optimal manufacturing scheme where the design needs to be based on the consideration and analysis of various techno-economic, sustainability, and regulatory compliance considerations rather than relying on pre-existing assumptions [5].

Traditional approaches for solving process flowsheet synthesis problems involve the formulation of a superstructure network, typically solved using mixed-

integer nonlinear optimization (MINLP) or generalized disjunctive programming (GDP) [6], [7]. However, the prevalent use of equation-oriented GDP/mixed-integer optimization tools is often limited to flowsheets modeled with simplified unit operation models and approximate thermodynamic property relations [8]. For flowsheets modeled with rigorous unit operation models, a simulation-optimization-based framework is frequently adopted. Nevertheless, addressing complex process synthesis problems through a simulation-optimization approach presents challenges, either due to the need to exhaustively optimize each flowsheet resulting in high computational cost, or due to the requirement for specialized interfaces between MINLP optimization algorithms and process simulators [9].

As a viable alternative, in this study, a hybrid process-decision framework was devised for the optimization of end-to-end pharmaceutical manufacturing flowsheets, which combines a rule-based selection approach with deterministic optimization steps. By applying a set of heuristic process synthesis rules influenced by user preferences, the goal is to systematically condense the initial master superstructure, encompassing all conceivable alternatives, into smaller, more manageable sub-structures for subsequent optimization. This approach mitigates the computational complexity associated with simultaneously optimizing the entire array of flowsheets. By reducing the problem to smaller sub-structures, the framework enables the exploration of scenario-based practical situations, facilitating practical decision-making in the optimization of diverse manufacturing campaigns.

The structure of the paper is organized as follows: firstly, the framework for hierarchical process generation in the end-to-end pharmaceutical manufacturing routines and the enumeration of all possible process candidate flowsheets are presented. Subsequently, the rule-based decision system for reducing the master superstructure into smaller case-specific sub-structures is formally outlined and discussed. Finally, the efficacy of the devised framework is demonstrated through a case study focused on optimizing end-to-end pharmaceutical flowsheets for the production of the commercial active pharmaceutical ingredient (API), Lomustine.

## METHODOLOGY

### Framework for process synthesis of small molecule pharmaceutical processes

The fundamental structure of a generic pharmaceutical process superstructure template (PPSS) (**Figure 1**) for the production of a small molecule drug substance in solid form consists of a sequence of processing steps including reactions, separations, and purifications before progressing to drug product manufacturing. Beginning with reaction steps, strategic decision points denoted by diamonds in **Figure 1** arise within the template, prompting consideration for the inclusion of separation or solvent swap steps before progressing to subsequent reactions. A separation step becomes essential when isolating specific reaction intermediates is required before moving to further reaction steps, while a solvent swap step is crucial when a change of solvent is needed before proceeding to subsequent reaction or purification steps. The latter part of the template addresses purification and isolation steps to obtain the desired API in solid form.

For each processing step within the generic superstructure, various alternatives exist in terms of unit operations. Furthermore, different operating mode choices such as batch, semi-batch, or continuous are also available for each unit operation. The exponential expansion of the search space over possible flowsheet alternatives becomes apparent with the increasing number of alternative unit operations and their operating modes for each step. Additionally, flowsheets featuring hybrid modes of operations necessitate the addition of supplementary units, such as holding tanks and batch-to-continuous connectors, to ensure seamless connectivity between the batch and continuous components of the flowsheets. This interplay of decision points, alternatives, and considerations underscores the complexity inherent in designing an effective process superstructure for the production of small molecule drug substances in solid form.

In combinatorial process synthesis methods, the superstructure is formulated by listing relevant alternatives for processing steps and connecting them in all possible ways. However, as previously mentioned, this leads to a vast search space for the design problem, resulting in numerous redundant and implausible configurations. The

expanded search space also increases the computational effort required for optimizing all these flowsheets [10].

In-sights-based synthesis methods, on the other hand, utilize a synthesis logic that integrates commercial and engineering insights as input to systematically generate a superstructure [10]. These insights, derived from the problem definition (which involves defining the scope in terms of raw materials, products, and process technologies) and process chemistry, guide the adaptation of the generic superstructure template into a process-specific superstructure containing well-defined processing steps relevant to the specific manufacturing process. Nevertheless, the design search space with the process-specific superstructure can still be considerable, particularly when considering alternative unit operations and their operating modes. This presents a significant computational bottleneck when optimizing all the flowsheets within the superstructure that are represented with rigorous models and optimized using a simulation-optimization framework. Herein, the heuristic rule-based synthesis logic becomes instrumental, facilitating the reduction of the superstructure into smaller, more manageable substructures that can be optimized with moderate computational efforts.

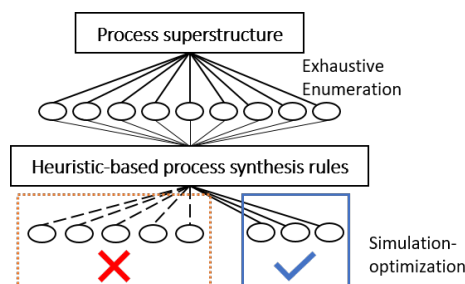

### Rule-based heuristic decision system

The heuristic process synthesis rules are formulated and generalized, taking into consideration common commercial and process engineering decision points in pharmaceutical manufacturing. The rules are categorized into five distinct groups: (1) process feasibility rules, (2) regulatory considerations, (3) equipment availability constraints, (4) experience or knowledge-based rules, and (5) scenario analysis.

*Regulatory considerations* are of utmost importance in pharmaceutical manufacturing, encompassing rules that ensure compliance with regulations and guidance set forth by agencies such as the FDA and EMA. *Equipment availability* constraints are included to anticipate practical limitations that will arise when transferring a conceptual design to existing manufacturing sites, such as the presence or absence of specific unit operations at

these sites. This category ensures that the synthesis rules are grounded in real-world scenarios. *Experience or knowledge-based* rules are formulated by integrating logical process engineering knowledge. Lastly, *scenario analysis* rules are designed to facilitate the comparison and optimization of various industrially relevant and intriguing manufacturing scenarios such as end-to-end continuous (E2EC) manufacturing, end-to-end batch manufacturing (E2EB), telescoped reaction synthesis, etc. While presenting a comprehensive list of all rules is beyond the scope of this work, **Table 1** provides illustrative examples from each category, offering a glimpse into the flexibility offered by the synthesis rules during the optimization of pharmaceutical flowsheets.

Within the framework of the synthesis rules outlined above, a specific set of rules is chosen based on user preferences and insights. These selected rules are then applied to the master superstructure to generate smaller-scale superstructure realizations as shown in Figure 2. Configurations that violate one or more synthesis rules are systematically eliminated from the search space. This exclusion of non-legal configurations streamlines the optimization process, by reducing the computational resources required to optimize different flowsheets. The explicit formulation of synthesis rules also provides a transparent and systematic procedure for both analyzing potential configurations and offering the rationale for the choices made [11].

**Figure 2:** Heuristics reduce the search space of valid superstructure layouts.

### CASE STUDY

**Table 1:** Process synthesis rules with their categories.

No.	Category	Example
1	Regulatory aspects	R-1: Isolation of ISO intermediate after Rxn1, increases drug safety
2	Feasibility rules	F-1: For semi-batch reactors, all reactions are assumed to happen in single reactor
3	Equipment availability constraints	A-1: Semi-batch evaporator is not available
4	Scenario Analysis	S-1: End-end continuous manufacturing S-2: Telescoped reaction synthesis
5	Experience or Knowledge-based rules	E-1: If conversion of reactant in step 1 is not complete, and this reactant is inert for the next reaction, then separation of the reactant is not necessary.

Figure 3: Process specific superstructure template for Lomustine.

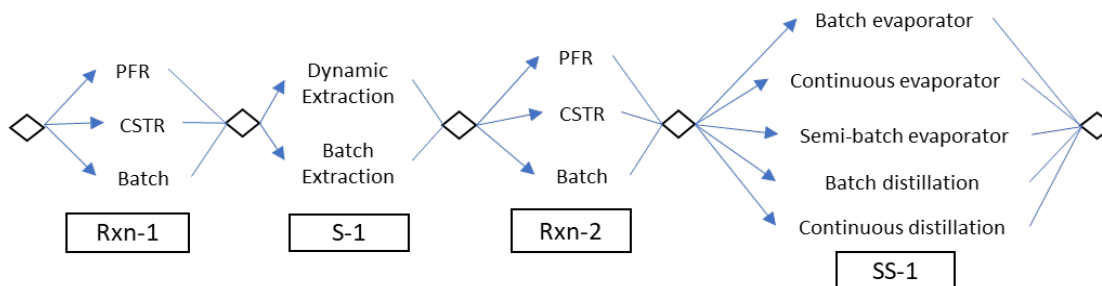

Figure 4: Exhaustive enumeration of possible flowsheet alternatives.

In this study, the above methodology is applied for the optimization of end-to-end flowsheets for the manufacturing of Lomustine. Recent research has identified efficient lab-scale continuous synthesis pathways for Lomustine, which allow replacing environmentally harmful solvents with more sustainable alternatives [12]. This case study aims to supplement the above studies, by designing end-to-end optimal processes using different separation technologies and comparing solvent use as a function of process configuration. Based on the proposed methodology, at first, the process-specific superstructure template was drafted using the process chemistry of Lomustine manufacturing as shown in Figure 3.

It should be noted that the scope of this case study is only limited to the analysis of synthesis, solvent swap, and separation processing steps. For conducting each of the processing steps shown in Figure 3, various alternative unit operations are available with varying operating modes. The process superstructure containing all possible flowsheet configurations is shown in **Figure 4**. An exhaustive enumeration of all potential flowsheets from this superstructure yields a total of 90 unique configurations. Since, the lab studies analyzed continuous manufacturing routes, from the heuristic process synthesis rule database regulatory rule R-1 and scenario analysis rule S-1 were applied to the above superstructure to screen out end-to-end continuous (E2EC) manufacturing flowsheets. With these rules, the search space is significantly narrowed down from 90 flowsheets to 8 E2EC

manufacturing flowsheets to be optimized. The next section provides a detailed description of the optimization problem aimed at optimizing the screened flowsheets of interest.

## Design Problem

The design problem is formulated as a nonlinear constrained optimization problem aimed at minimizing the overall waste produced in the process  $J(\mathbf{x})$ , which is the combination of total mass of solvent (Me-THF, Acetic acid,  $H_2O$ , and Heptane) and the total mass of unreacted reactants. Due to the sequential modular architecture of PharmaPy, solving the optimization problem required a simulation-optimization framework where obtaining gradient information is challenging. To address this, the problem was first transformed into an unconstrained optimization problem by integrating the nonlinear inequality constraints ( $g_i$ ) directly into the objective function via weighted penalties ( $\alpha_i$ ), as represented by Equation (1). This enables the solution of the problem using derivative-free or direct-search methods, and in this work, Nelder-Mead algorithm was used.

$$\min_{\mathbf{x}} J(\mathbf{x}) + \sum_{i \in I} \max(0, \alpha_i \cdot g_i)^2 \quad (1)$$

$$s. t. \text{ PharmaPy Process model}$$

$$\mathbf{x}_{lb} < \mathbf{x} < \mathbf{x}_{ub} \quad (2)$$

The process model consists of set of differential-

**Table 2:** List of inequality constraints.

$$\text{Maximum precursor after extraction} \quad g_2(\mathbf{x}) = C_{extr,ISO} - 8\text{mol/m}^3 \leq 0 \quad (4)$$

$$g_3(\mathbf{x}) = \int_{t_{st}}^{t_f} (C_{SS,API}(t) - C_{solub}(T, C_{Me-THF}, C_{ac-acid})) dt \leq 0 \quad (5)$$

$$\text{Path constraints (Solvent switch)} \quad g_4(\mathbf{x}) = \int_{t_{st}}^{t_f} (T_{SS}(t) - T_{max}) dt \leq 0 \quad (6)$$

$$g_5(\mathbf{x}) = \int_{t_{st}}^{t_f} (0.7 - x_{SS,C7}(t)) dt \leq 0 \quad (7)$$

algebraic equations simulated within PharmaPy. The values of the weighted penalties were carefully selected based on the desired residual values for the constraints at convergence. Decision variables  $\mathbf{x}$  used for all flow-sheet optimizations are shown in **Table 3**.

**Table 3:** Decision variables used in design problem.

Step	Unit operation	Decision Variables
Rxn-1	PFR/CSTR (R01)	$C_{in,ISO}, C_{in,CHA}, V_{R01}, \tau_{R01}$
S-1	Dynamic extractor (EXTR01)	$\tau_{E01}, F_{H_2O,in}$
Rxn-2	PFR/CSTR (R02)	$C_{in,TBN}, \tau_{R02}$
SS-1	Continuous vaporizer (VAP01)	$\tau_{VAP01}, v, F_{Heptane,in}$
	Continuous distillation (DIST01)	$F_{Heptane,in}, x_{LK}, R$

**Table 4:** List of all symbols.

Symbol	Meaning	Unit
$C_{in}$	Inlet concentration	mol/L
$V$	Volume of unit	$\text{m}^3$
$\tau$	Residence time	S
$P$	Pressure	bar
$v$	Vapor fraction	-
$F_{in}$	Inlet flowrate	mol/s
$x_{LK}$	Mole frac. of lowkey component	-
$R$	Reflux ratio	-
$F_{SS}$	Steady state output flowrate	$\text{m}^3/\text{s}$
$C_{SS}$	Steady state concentration	$\text{kg}/\text{m}^3$
$C_{solub}$	Solubility concentration	$\text{kg}/\text{m}^3$
$C_{EXTR}$	Concentration at EXTR01 outlet	mol/ $\text{m}^3$
$T_{SS}$	Steady state temperature	K
$T_{max}$	Maximum allowed temperature	K
$x_{SS,C7}$	Mole frac. of heptane at steady state	-

All the decision variables were scaled within a 0-1 interval. Furthermore, various manufacturing constraints such as weekly production targets, product quality attributes, and process operational constraints were formulated as inequality constraints listed in **Table 3**. A comprehensive list of all the symbols used can be found in **Table 4**.

## Results

Using the optimization framework outlined in the previous section, each flowsheet was optimized while satisfying all the operational constraints, product quality attributes and production targets. The comparative analysis of all optimal flowsheets in terms of waste minimization, is illustrated in Figure 5.

**Figure 5:** Bar graph showing E-factors for different flowsheets.

The bar graph shows the E-factors for various components including solvents and unreacted reactants, across all eight optimal flowsheets, calculated using following equation (8).

$$E - factor = \frac{\text{kg waste component}}{\text{kg Lomustine}} \quad (8)$$

The E-factors for the reaction section for lomustine

synthesis were like the typical E-factors encountered for synthesis steps in pharmaceutical manufacturing (25–80) [13]. Furthermore, it can be seen from the graph that flowsheets with flash separation have higher solvent usage, leading to significantly higher E-factors when compared with flowsheets containing distillation columns. This is because, the start-up times for flash-containing flowsheets were found to be larger than the flowsheets containing distillation columns, leading to a higher waste generation. Lastly, the analysis also prompts that further reduction in E-factor could be achieved by solvent recovery since solvent consumption contributes the highest among all towards waste generation.

## CONCLUSIONS

In this study, a heuristic rule-based process decision framework was developed for the optimization of end-to-end pharmaceutical flowsheets encompassing various operating modes for the different unit operations. The framework was also applied for the optimization and analysis of end-to-end continuous manufacturing flowsheets for the synthesis of Lomustine. The resulting flowsheets were effectively optimized and evaluated in terms of sustainability metric E-factor while ensuring compliance with respect to production targets and product quality attributes.

## ABSTRACT

Water chemistry plays a critical role in the design and operation of water treatment processes. Detailed chemistry modeling tools use a combination of advanced thermodynamic models and extensive databases to predict phase equilibria and reaction phenomena. The complexity and formulation of these models preclude their direct integration in equation-oriented modeling platforms, making it difficult to use their capabilities for rigorous water treatment process optimization. Neural networks (NN) can provide a pathway for integrating the predictive capability of chemistry software into equation-oriented models and enable optimization of complex water treatment processes across a broad range of conditions and process designs. Herein, we assess how NN architecture and training data impact their accuracy and use in equation-oriented water treatment models. We generate training data using PhreeqC software and determine how data generation and sample size impact the accuracy of trained NNs. The effect of NN architecture on optimization is evaluated by optimizing hypothetical black-box desalination processes using a range of feed compositions from USGS brackish water data set, tracking the number of successful optimizations, and testing the impact of initial guess on the final solution. Our results clearly demonstrate that data generation and architecture impact NN accuracy and viability for use in equation-oriented optimization problems.

## INTRODUCTION

Water chemistry plays a critical role in the design and operation of water treatment processes. Detailed chemistry modeling tools use a combination of advanced thermodynamic models and extensive databases to accurately predict phase equilibrium and reaction processes, such as those done by open-source PhreeqC software [1]. The complexity, formulation, and extensive database of these models preclude their direct integration in equation-oriented modeling platforms, making it difficult to use their capabilities for rigorous water treatment process optimization.

Neural networks (NN) can provide a pathway for integrating the predictive capability of chemistry software into equation-oriented models and enable optimization of complex water treatment processes across a broad range of conditions and process designs. A key challenge in developing a broadly applicable surrogate model for aqueous chemistry is the high non-linearity of the phenomena and high problem dimensionality. NNs have the potential to learn chemical phenomena and provide

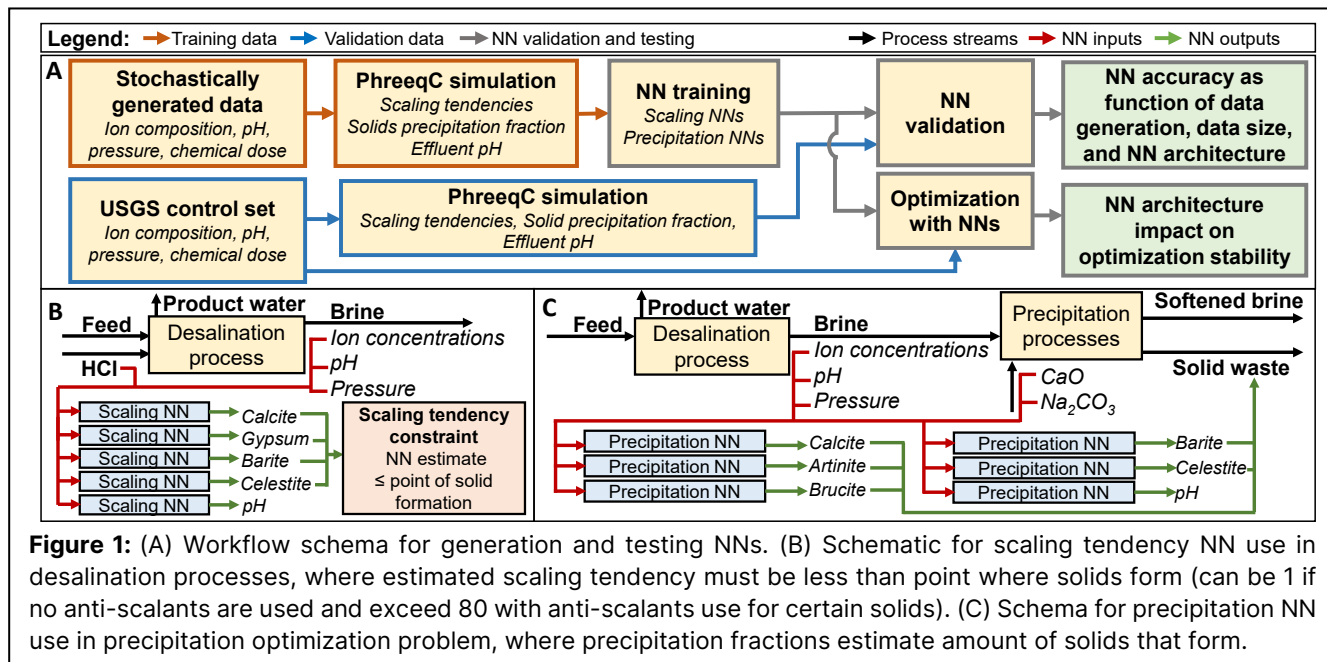

accurate estimates over a broad range of ion and reactant compositions [2].

NNs developed for water treatment optimization must accurately predict three critical chemistry phenomena: scaling tendencies, precipitation fractions, and changes in pH.

Modeling scaling tendency in desalination processes is critical for predicting solid formation, which occurs as ion concentration increases and results in process failure [3]. Typically, scaling is mitigated by reducing water recovery of desalination process, adding acids, which reduce scaling potential, and adding antiscalants that increase maximum allowable scaling tendency [4].

Modeling chemically driven precipitation is important for estimating the performance of pretreatment and softening processes, such as lime (CaO) and soda-ash (Na<sub>2</sub>CO<sub>3</sub>) softening [5]. These processes are commonly used to drive the formation of solids that remove divalent ions and reduce water hardness. Removing divalent ions minimizes the potential for scale formation in downstream processes.

Accounting for pH change due to chemical addition,

**Figure 1:** (A) Workflow schema for generation and testing NNs. (B) Schematic for scaling tendency NN use in desalination processes, where estimated scaling tendency must be less than point where solids form (can be 1 if no anti-scalants are used and exceed 80 with anti-scalants use for certain solids). (C) Schema for precipitation NN use in precipitation optimization problem, where precipitation fractions estimate amount of solids that form.

such as HCl and lime, is critical for modeling full treatment trains. The addition of HCl and lime will change the effluent stream pH and change requirements for chemical addition in downstream processes.

Herein, we investigate how the training data and NN architecture affect NN performance for the three chemistry phenomena (Figure 1). We train NNs using stochastically generated data, and validate NN accuracy and stability in equation-oriented optimization models using USGS data set [6] (Figure 1A). Stochastic data generation is used to simulate a broad range of chemistries and chemical additions, which are used as inputs for PhreeqC to predict chemical phenomena of interest. We investigate the impact of training data by considering the effect of data skewing to sample lower ion concentration distributions preferentially, which better captures real water compositions represented by the USGS brackish water data set. Finally, the developed NNs are integrated into equation-oriented models, and their stability is evaluated by tracking the number of successful solutions and the sensitivity to the initial guess.

## METHODS

### Data generation

We use PhreeqC with the included Pitzer database to estimate scaling tendencies, precipitation fractions, and effluent pH based on feed composition and chemical addition (Figure 1A). Feed is charge neutralized by adjusting Cl ion concentration, and charge neutral composition is used as input for NN.

For NN training, we stochastically generated ion compositions and chemical addition amounts (Table 1). We store PhreeqC result for feed composition without and with chemical addition (Table 2). The precipitation

fraction is the fraction of primary ion in the tracked phase that precipitates from the solution (e.g. precipitate fraction for  $\text{CaCO}_3$  is the ratio of precipitated Ca to total Ca in solution (feed and added reactant) before reaction).

The feed compositions, pressure, pH, and amount of chemical added is sampled using the standard Latin hypercube (LHS) method [7]. The LHS samples are scaled 0-1 and are rescaled to ion concentration, pressure, and chemical addition using the exponential skew function (eq. 1) and for pH using the log skew function (eq. 2). In these equations,  $x$  is the LHS sample,  $S$  is the skew magnitude,  $R_{high}$  is the high range of absolute value, and  $R_{low}$  is the low range for absolute value.

$$f_{exp-skew}(x) = (S^x - 1) * \frac{R_{high} - R_{low}}{S - 1} + R_{low} \quad (1)$$

$$f_{log-skew}(x) = \log_{10}(S * x + 1) * \frac{R_{high} - R_{low}}{\log_{10} S + 1} + R_{low} \quad (2)$$

The exponential skew function rescales the input value to be exponentially lower, such that an LHS sample of 0.1 (range 0-1) would be rescaled to 0.028, 0.006, 0.001, 0.0002 for skew magnitudes of 10, 100, 1,000, and 10,000, respectively. This skewing increases the sampling of low ion concentration distribution typically observed in real waters. The log skew function has an inverse relationship; for an LHS sample of 0.1 (range 0-1) the rescaled samples would be 0.15, 0.34, 0.5, and 0.6 for skew magnitudes of 10, 100, 1,000, and 10,000, respectively. The log skew function is used to increase the number of samples with basic pH (higher pH), where pH sensitive scalants have high scaling tendencies and are filtered out during data generation (described below).

We generate 2 million total samples using PhreeqC for NN training using a range of skew magnitudes only applied to ion composition, pressure, and chemical

addition, while pH skew magnitude is maintained at 10. The data is generated iteratively by taking 10,000 LHS samples at every step, applying the appropriate skew functions to the LHS samples, and keeping samples with total solids concentrations below 360 g per kg of water (g/kgw) and scaling tendency below 100. The procedure is repeated until 2 million samples are generated.

We further use the USGS brackish water data set to test NNs for real water conditions. The data set was filtered to isolate samples that exist in water-stressed regions using the method described by Ahban et al.[8]. This data set was filtered to remove water composition with high silica scaling potential by removing samples with Si concentrations above 50 ppm and  $H_4SiO_2$  concentration above >2 mM at 90% water recovery and pH of 6.5 [9]. This data is referred to as the USGS control set and contains 782 feed compositions.

**Table 1:** Feed composition and inputs in the stochastic data set. Temperature is fixed at 20°C.

<b>Feed composition in stochastic data</b>			
<i>Input</i>	<i>Low range</i>	<i>High range</i>	<i>Unit</i>
Na	0	136	
Cl	0	180	
Ca	0	10	
Mg	0	10	
HCO <sub>3</sub>	0	10	g/kgw
SO <sub>4</sub>	0	100	
K	0	40	
Sr	0	10	
Ba	0	0.1	
pH	4	12	pH

<b>Inputs for scaling tendency prediction</b>			
<i>Input</i>	<i>Low range</i>	<i>High range</i>	<i>Unit</i>
Pressure	1	401	atm
HCl	0	2000	PPM

<b>Inputs for precipitation fraction prediction</b>			
<i>Input</i>	<i>Low range</i>	<i>High range</i>	<i>Unit</i>
CaO	0	2000	PPM
Na <sub>2</sub> CO <sub>3</sub>	0	2000	

The USGS control data set is used to generate test data by imitating a black box desalination process within PhreeqC. The test data set for scaling tendencies includes process operating with water recoveries ranging from 0 to 90% in 10% steps and with HCl addition of 10, 50, 100, 1,000, and 1,500 ppm (N=38,357). The water recoveries for the precipitation fraction test data set were 0, 20, 60, and 90%, and CaO and Na<sub>2</sub>CO<sub>3</sub> addition was 10, 100, and 1,000 PPM (N=27,460). All data sets excluded samples that resulted in scaling tendencies above

100.

## Neural network training and validation

NNs were built and trained using Pytorch 2.0.0 on NVIDIA GPUs using standard CUDA implementation [10]; only stochastically generated data was used for training, with 10,000 samples set aside for testing. Throughout the paper, we only present results that use the USGS control set to quantify errors in NNs.

We build dense networks using 3 and 5 deep layers, with 30, 60, and 90 neurons with either sigmoid or tanh activation function applied to all layers except the output layer. All NNs use the ion composition and feed pH as inputs. Additionally, the scaling tendency NNs include HCl addition and pressure as inputs, while the precipitation NNs include CaO and Na<sub>2</sub>CO<sub>3</sub> as inputs. Each NN predicts only a single output, resulting in five scaling NNs and six precipitation NNs per architecture type. Additionally, each network is trained using two different weight decays of 0.001 and 10<sup>-6</sup>. Thus, a total of 24 NN architectures are evaluated (2 deep layers x 3 neuron types x 2 activation function x 2 weight decays).

**Table 2:** Output scaling tendencies ranges and precipitation fractions.

<b>Scaling tendency data set outputs</b>		
<i>Output</i>	<i>Low range</i>	<i>High range</i>
Calcite	0	98.19
Gypsum	0	14.61
Barite	0	99.03
Celestite	0	97.7
pH	0.56	11.96

<b>Precipitation fraction data set outputs</b>			
<i>Output</i>	<i>Low range</i>	<i>High range</i>	<i>Primary ion</i>
Calcite	0	1	Ca
Artinite	0	0.96	Mg
Brucite	0	1	Mg
Barite	0	1	Ba
Celestite	0	0.99	Sr
pH	4	12.8	N/A

We use Pytorch implementation of AdamW optimizer using cosine annealing with warm restart to train NNs [11]. We train with five cycles, that switch based on the number of gradient updates, performing ~2M gradient updates in total. The learning rates for sigmoid and tanh activation functions were 0.01 and 0.001, respectively, with the final learning rate of 10<sup>-6</sup>. We use mini-batches with a size of 4096 samples. At each epoch, the data is shuffled and sampled without replacement. Finally, we linearly scale all input and output data for training between 0 and 1.

To test the effect of skew magnitude and data size on NN accuracy, we use NN with 5 layers and 60 neurons (5x60) with a sigmoid activation function and trained with a weight decay of  $10^{-6}$  on Calcite scaling tendency, pH after HCl addition, and Calcite precipitation fraction.

We validate NN accuracy by comparing their predictions against the USGS control data sets and presenting errors in all figures as statistical distributions, showing 5<sup>th</sup>, 25<sup>th</sup>, median, 75<sup>th</sup>, and 95<sup>th</sup> percentile errors. The error for scaling tendencies and pH is the percent difference between NN prediction and ground truth (*GT*) generated using PhreeQC, as shown in equation 3.

$$\text{error} = \frac{NN_{\text{prediction}} - GT}{GT} * 100\% \quad (3)$$

We exclude any errors for scaling tendencies below 0.5, as in water treatment no scaling occurs below scaling tendencies of 1. For these samples, the absolute errors remain below 0.2 but can significantly shift error distribution (e.g. for a scaling tendency of 0.1, the prediction could be 0.3, resulting in 200% error but having no implication for optimization of the water treatment process). For precipitation fractions, we present the absolute difference between NN and ground truth in percent, as shown in equation 4.

$$\text{error} = NN_{\text{prediction}} - \text{ground}_{\text{truth}} * 100\% \quad (4)$$

## Neural network integration into waterTAP

The two desalination processes we consider (Figure 1B and 1C) are modeled in WaterTAP, a framework for technoeconomic assessment of water treatment systems. We integrate developed NNs into WaterTAP using the Optimization and Machine Learning Toolkit (OMLT) [12, 13]. We use the reduced smooth formulation in OMLT, which loads the NN as a single large expression into the model. Additionally, we add constraints that convert absolute values to scaled NN inputs and outputs.

We formulate two optimization problems that emulate black box desalination processes with scaling and precipitation NNs (Figure 1B and 1C). The desalination process is emulated using a single feed block that specifies the feed mass flow of ions and water. The ion mass flow is fixed to ion concentrations as specified by a sample from USGS data set. The mass flow of water is unfixed during optimization, imitating a desalination process that removes pure water from the feed block and increases ion concentration in the remaining brine. The difference between the initial and the optimized flow mass of water is equal to the amount of product water, while the optimized water flow mass is equal to mass flow of waste brine.

The scaling tendency problem, as shown in Figure 1B, is where scaling NNs are added to the desalination problem to predict scaling tendencies due to increased ion concentration in feed block, with HCl added as a scaling control mechanism. The scaling tendencies are

constrained to remain below 60 for Calcite, 2.3 for Gypsum, 60 for Barite, and 8 for Celestite, imitating a desalination process operating with anti-scalants [3].

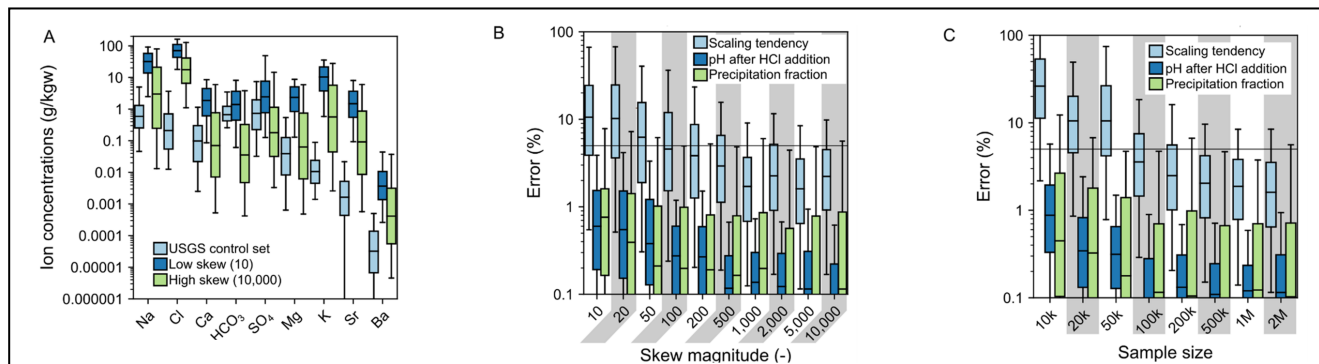

The precipitation problem, as shown in Figure 1C, is where precipitation NNs are added to the desalination problem to predict the removal of solids that form due to increased concentration of ions and chemical addition [5]. Here an additional constraint is added to calculate the final brine hardness after solid formation, which is constrained to be below or equal to 50 ppm of  $\text{CaCO}_3$  as shown in equation 5, where  $Ca_{f\text{-total}}$  is mole flow rate of Ca in feed and Ca added from CaO addition,  $Mg_f$  is mole flow rate of Mg in feed, and  $rm_{\text{Calcite}}$ ,  $rm_{\text{Artenite}}$ , and  $rm_{\text{Brucite}}$  are removal fraction for Calcite, Artinite, and Brucite respectively.

$$\begin{aligned} \text{Total - hardness} = \\ (|Ca_{f\text{-total}} - Ca_{f\text{-total}} * rm_{\text{Calcite}}| * 100.1 + |Mg_f - Mg_f * \\ (rm_{\text{Artenite}} + rm_{\text{Brucite}})| * 100.1) * 1000 \quad (5) \end{aligned}$$

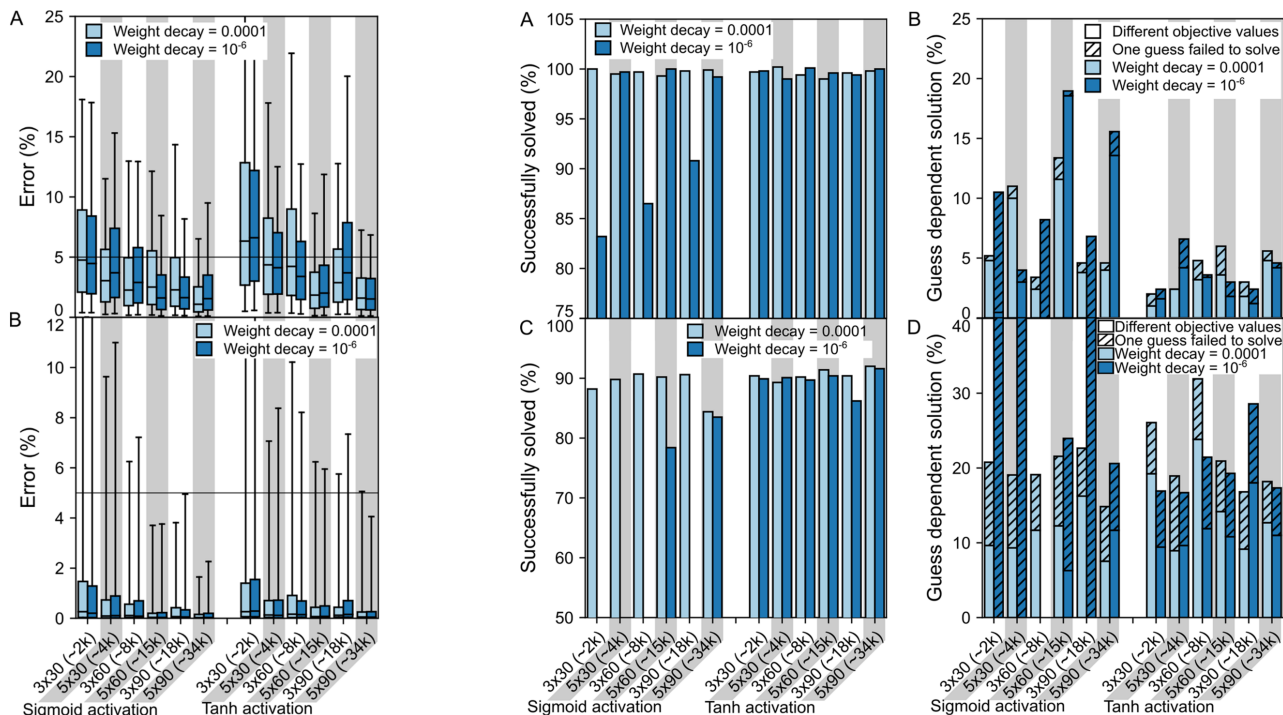

The optimization problems are formulated to maximize the value of produced water from black box desalination processes. In the optimization, the product water can be sold with a value of 0.5 units/kg, while the remaining waste brine is penalized with a cost of 10 units/kg, and the addition of chemicals (HCl, CaO, and  $\text{Na}_2\text{CO}_3$ ) is penalized with the value of 0.19 units/kg. For the scaling tendency problem, there are 2 degrees of freedom: the amount of water to remove and the amount of HCl to add. For the removal fraction problem, there are 3 degrees of freedom: amount of water to remove, amount of CaO to add, and amount of  $\text{Na}_2\text{CO}_3$  to add.

In these optimization problems, removing water increases ion concentration, which increases scaling tendencies and hardness. The scaling tendencies can be decreased for some scalants with HCl addition. Hardness can be reduced by adding CaO and  $\text{Na}_2\text{CO}_3$ , which increase precipitation fractions of Ca and Mg containing solids. Thus, the optimization balances the cost of producing water, disposing of brine, and satisfying scaling and hardness constraints through chemical addition.

We optimize the two problems by randomly drawing 500 feed compositions from the USGS control set, and providing two initial guesses. We provide one guess that is poorly posed where 90% water is removed and 1 PPM of chemicals is added, resulting in a feed composition that is likely violating the scaling tendencies and hardness constraints. The second guess is well-posed, where feed is diluted by 5 times and 1,000 PPM of chemicals are added, resulting in a feed composition that is unlikely to violate scaling tendencies and hardness constraints. The total solvability is evaluated by tracking the percent of total solved samples and guesses ( $N=1000$ ). The NN propensity to solve to a local minimum is quantified by tracking the number of solutions with different objective values caused by different initial guesses for the same feed composition and where one guess failed to solve. The

problems were solved using IPOPT with MA27 linear solver [14].

## RESULTS AND DISCUSSION

### Effect of data on Neural Network accuracy

The ultimate accuracy of NNs in predicting phenomena of interest depends on the statistical distribution of underlying training data and data size. In the case of aqueous chemistry used for water treatment

applications, a common objective is to predict the propensity of ions in solution to form solids as a function of ion composition, pH, temperature, and pressure. Due to the sheer number of dimensions (12 dimensions are considered herein (Table 1)), a stochastic generation methodology must be used to generate data sets that enable the training of surrogate models applicable to different feed water composition and water treatment processes.

The nonlinear nature of aqueous chemistry requires a nonuniform sampling of ion compositions to ensure

relevant data is generated from chemistry software. For example, Calcium is an ion of great interest in water treatment and will form Gypsum ( $\text{CaSO}_4$ ) in the presence of  $\text{SO}_4$ , which has solubility below 2.5 g/kgw and limits Ca concentrations. However, in the absence of  $\text{SO}_4$ , calcium concentrations can exceed 10 g/kgw, although such waters are uncommon, as  $\text{SO}_4$  is ubiquitous in real waters. Thus, uniformly sampling across ion concentrations will generally form ion compositions, scaling tendencies, and precipitation fractions that are not representative of real waters and conditions under which water treatment processes operate.

Skewing the sampling of ion concentrations to prioritize lower concentrations generates ion composition distributions that are more representative of real water compositions (Figure 2A). Increasing skewing magnitude from 10 to 10,000 results in a sampling of much lower ion concentrations on the median that approach USGS control set values but still sample high ion concentrations that occur in desalination processes.

Testing NNs against real ion composition and chemical additions that would be encountered by desalination and precipitation water treatment processes (USGS control set) demonstrates that accuracy increases with an increase in the skew magnitude (Figure 2B). At skew magnitude below 100, the median error for Calcite scaling tendency approached 10%. Increasing the skew magnitude above 200 reduced 75<sup>th</sup> percentile errors to below 5% for Calcite scaling tendency and reduced errors for precipitation fractions and pH.

Testing NNs using stochastically generated test data demonstrated a slight increase in prediction errors of less 0.5 % on the median with an increase in skew magnitude from 10 to 10,000. These test errors were significantly lower than those for USGS control set, with 75<sup>th</sup> percentile errors being less than <1% across all skew magnitudes. This clearly shows that NNs are learning chemistry in underlying training data, and skewing is shifting training to learning chemistry relevant to real water composition, as found in USGS control data set.

Increasing the data size used for training improves NN accuracy (Figure 2C). Training with less than 100,000 samples produces poor NN accuracy for Calcite scaling tendency, with median errors exceeding 10%. Increasing the sample size to above 200,000 samples reduced errors to below 5% in the 75<sup>th</sup> percentile for Calcite scaling tendency and the 95<sup>th</sup> percentile for pH and Calcite precipitation fraction. Increasing the sample size from 200,000 to 2,000,000 provided minimal improvements in overall network accuracy, suggesting that data sizes of around 500,000 could be sufficient for predicting scaling tendency. However, in the case of pH and precipitation fractions, data sizes of 50,000-100,000 samples could be adequate. The data size requirement is expected to increase with the number of inputs.

## Effect of architecture on accuracy

We explore the effect of NN architecture by training 24 different NN types using the 2M sample data set with a skew magnitude of 5,000. Each NN predicts a single output, resulting in five scaling NNs per architecture that predict scaling tendencies for the four scalants and pH, and six precipitation NNs per architecture that estimate precipitation fractions for the five solids and pH, as shown in Table 1 and Table 2. Calcite scaling tendencies and calcite precipitation fractions always have higher errors and are thus used as benchmarks for the performance of scaling tendencies and precipitation fraction prediction.

Prediction error decreased with an increase in the number of NN trainable parameters (Figure 3). The smallest NNs with 3 deep layers and 30 neurons (3x30) have 2,281 trainable parameters and exhibited median error in scaling tendencies on the order of ~5% and ~7% for sigmoid and tanh activation functions, respectively. In contrast, the largest 5x90 networks with 34,021 trainable parameters had errors <3% in 75<sup>th</sup> percentile (Figure 3A). Similar improvements were observed for precipitation networks (3B).

In general, we observed that deeper networks had slightly lower errors than shallow networks with a similar number of trainable parameters. This is demonstrated by the 3x90 network with 17,641 trainable parameters typically exhibiting a higher or similar level of error compared to their 5x60 network counterparts with 15,481 trainable parameters. In theory, the three-layer deep and five-layer deep network should be able to encode the same degree of nonlinear behavior, but it appears that higher depth improves encoding performance.

Activation function type and weight decay had a small effect on prediction error relative to network size impact. On average, NNs with sigmoid activation function had lower errors than NNs with tanh activation function, but the difference was less than 0.5% for median errors. The weight decay did impact the accuracy of NNs, but the impact depends on their architecture, implying that each architecture has an optimal weight decay value.

## Effect of Neural Network architecture on optimization

Surrogate models developed for equation-oriented programming models must faithfully capture underlying phenomena and provide smooth, continuous functions that ensure a successful optimization and avoid local solutions when solved with a local solver such as IPOPT. We test the NNs stability in optimization by integrating them in two black box desalination problems, the scaling tendency problem (Figure 1B), and the precipitation problem (Figure 1C).

The optimization results demonstrate that optimization problems that use NNs with tanh activation function

solve more often, are less likely to fall into a local minimum, and solve more frequently regardless of initial guess (Figure 4). The use of the tanh activation function resulted in >98% of problems successfully solving for the scaling tendency problem and >88% for the removal fraction problem (Figure 4A and 4C). In contrast, the use of the sigmoid activation function in small and shallow networks that use low weight decay ( $10^{-6}$ ) resulted in a large number of failed solves.

The optimization problems that used NNs with tanh activation function were not strongly impacted by initial guess relative to problems that used NNs with sigmoid activation function (Figure 4B and 4D). For the scaling tendency problem, using the tanh activation function resulted in less than 5% of solutions having different objective values caused by different initial guesses across all NNs. This contrasts the results for optimization problems that used NNs with the sigmoid activation function, even when it had a comparable number of solves to tanh, the sigmoid activation function produced a higher number of local solves (exceeding 10% in 4 of the NNs). This trend was not observed in the removal fraction problem, where a similar number of local minimums (~10% of samples) were observed for both activation functions. Similarly, for cases where the number of successful solves is comparable between tanh and sigmoid, the initial guess resulted in a similar number of failed solves.

We hypothesize that tanh function provides a more mathematically stable formulation than the sigmoid activation function, resulting in a higher likelihood that a problem is solved successfully, even as the use of the sigmoid function resulted in more accurate NNs. The tanh function provides larger gradients than the sigmoid activation function, improving the potential for IPOPT in avoiding local minimums. In addition, the sigmoid formulation utilizes an exponential in its denominator, which is prone to overflow errors during computation. The probability of overflow decreases as the network size increases and the weight decay parameter gets higher. Larger network size and weight decay regularize weights and reduce the potential for extreme values being passed into the activation function. This results in a lower likelihood of an exponential overflow occurring when changing NN input values, explaining why the sigmoid function performs better with the increase in trainable parameters and weight decay. With the tanh formulation, however, overflow can not occur, and optimization algorithms can freely vary the inputs.

NN architecture did not impact the number of iterations required to solve an optimization problem, but it did increase computational time. On average, the scaling problem required 20 iterations to solve, with 95<sup>th</sup> percentile of problems requiring 40 iterations, regardless of NNs used. The removal fraction problems required on average 40 iterations to solve, with 95<sup>th</sup> percentile requiring ~100 iterations, regardless of NNs used. The largest impact of

increasing network size was on solving time, with the use of the 5x90 NNs requiring upto ten times more time per iteration than for 3x30 NNs. The activation function type and weight decay did not impact the solve time.

The integration of NNs into optimization problems did not impact their accuracy. The results demonstrated similar error distributions to those observed in USGS control set, confirming the expectation that using NNs in an equation-oriented model does not affect their accuracy.

## CONCLUSION

The results of this work have demonstrated that NNs can be effective surrogate models for accurately predicting scaling tendencies, pH change, and removal fraction across a broad range of real water compositions and use in the equation-oriented programming models of water treatment processes. Our results have extracted a set of generalizable guidelines for data generation and design of NNs for chemistry prediction in water treatment equation-oriented process optimization:

- Sampling of ion compositions and chemical addition should be skewed to lower values to provide good accuracy in real water compositions.
- The number of required stochastically generated data samples depends on the underlying chemistry being modeled.
- Deeper networks provide slightly better performance over shallower networks with the same number of trainable parameters.
- Tanh activation function provides better stability than sigmoid activation functions in equation-oriented models, and should be preferred over sigmoid even at the cost of accuracy. This is a fundamental mathematical limitation and applies to all NNs, regardless of the data they are predicting.
- Weight decay should be optimized to a specific network architecture to extract the highest accuracy.
- Large NNs do not increase the number of iterations but do increase the solving time required per iteration.

The methods presented herein, for the first time, enable optimization studies of water treatment processes to consider a broad range of real water compositions, capturing their performance while faithfully representing real and complex aqueous chemistry.

## ABSTRACT

Machine learning presents opportunities to improve the scale-specific accuracy of mechanistic models in a data-driven manner. Here we demonstrate the use of a machine learning technique called Sparse Identification of Nonlinear Dynamics (SINDy) to improve a simple mechanistic model of algal growth. Time-series measurements of the microalga *Chlorella Vulgaris* were generated under controlled photobioreactor conditions at the University of Technology Sydney. A simple mechanistic growth model based on intensity of light and temperature was integrated over time and compared to the time-series data. While the mechanistic model broadly captured the overall growth trend, discrepancies remained between the model and data due to the model's simplicity and non-ideal behavior of real-world measurement. SINDy was applied to model the residual error by identifying an error derivative correction term. Addition of this SINDy-informed error dynamics term shows improvement to model accuracy while maintaining interpretability of the underlying mechanistic framework. This work demonstrates the potential for machine learning techniques like SINDy to aid simple mechanistic models in scale-specific predictive accuracy.

## INTRODUCTION

Within process design and system analysis, mechanistic models have long stood as pillars for understanding and predicting the behavior of complex systems. Rooted in fundamental physical and chemical principles, these models offer a structured approach to dissecting system dynamics, providing insights that are crucial for industrial applications [1]. However, as we delve deeper into the nuances of these systems, particularly at varying scales, the limitations of mechanistic models become apparent. A key challenge lies in their generalization; while these models are adept at capturing overarching trends and basic interactions, they often fall short in accurately representing the intricate dynamics of specific systems under varied conditions.

This is especially true in biological and ecological modeling, where the complexity of interactions and the sensitivity to environmental variables pose significant hurdles. The modeling of microalgal growth, such as that of *Chlorella vulgaris*, exemplifies this challenge. Here, the

transition from laboratory-scale observations to commercial-scale operations is fraught with complexities, as the models struggle to account for the myriad of factors influencing algal growth dynamics at different scales [3,4].

Yet the uptick of machine learning methods bolstering traditional system identification offer a beacon of hope in this landscape. Among the various machine learning techniques, Sparse Identification of Nonlinear Dynamics (SINDy) emerges as a particularly promising tool. SINDy is a novel algorithm that seeks to identify the governing equations of a dynamical system in a sparse, interpretable form [2-4]. This approach is particularly relevant in process modeling, where understanding the fundamental dynamics is as crucial as achieving predictive accuracy [5].

The objective of this study is to showcase the application of SINDy in refining a mechanistic model of algal growth. Focusing on the microalga *Chlorella vulgaris*, we utilize time-series data collected under controlled photobioreactor conditions at the University of Technology

Sydney (Unpublished Data).

The following paper delves into the methods, where we describe the initial mechanistic model based on light intensity and temperature, followed by the integration of the SINDy algorithm derived error term. The results section presents a comparative analysis between the original and the enhanced models, highlighting the improvements in accuracy and interpretability. In the discussion, we explore the implications of these findings for process design, particularly in the scaling of microalgal growth systems. Finally, the paper concludes with a summary of our key findings and their significance in the broader context of industrial applications.

## BACKGROUND

### Process Design

Historically, process design has been deeply rooted in the principles of chemical engineering, with a strong emphasis on understanding and manipulating material and energy balances [6-8]. Mechanistic models, characterized by their basis in fundamental scientific principles, have been extensively applied across various domains of process engineering [1, 9-13]. These models excel in their ability to predict system behavior under a range of conditions, providing a reliable foundation for process design and optimization. However, their application is not without limitations. One significant challenge is their generalization, which can lead to inaccuracies when applied to specific systems or at different scales [14]. Biological systems are inherently complex, and their dynamics can vary significantly with changing environmental conditions and scales, posing a substantial challenge to traditional mechanistic modeling approaches.

### Machine Learning

In recent years, the emergence of machine learning as a complementary tool in scientific research has opened new avenues in process design. Machine learning's data-driven nature allows it to uncover complex, non-linear relationships within high-dimensional data sets, offering a level of insight and prediction that is often beyond the reach of traditional models [15, 16]. This has been particularly advantageous in process modeling, where machine learning algorithms have been successfully integrated with mechanistic models to enhance their accuracy and adaptability [14].

Among the various machine learning techniques, SINDy has emerged as a promising tool for process design. Developed as an algorithm to identify governing equations of dynamical systems, SINDy distinguishes itself by its ability to distill complex data sets into sparse, interpretable models [2, 3]. This capability makes SINDy particularly suitable for process design applications where understanding the fundamental dynamics is as

crucial as achieving predictive accuracy.

## Microalgae

The modeling of microalgal growth, specifically the growth dynamics of *Chlorella vulgaris*, provides a compelling case study for the application of SINDy in process design [17, 18]. Microalgae, recognized for their potential in industrial applications, present significant challenges in scaling up from laboratory to commercial operations [18]. Traditional mechanistic models, while providing a basic understanding of algal growth, struggle to capture the full complexity of these biological systems at different scales [19, 20]

## METHODOLOGY

### Algae Mechanistic Model

We attempt to improve upon a simplified model that based on two key environmental factors: light intensity and temperature. This model combines the principles of Haldane kinetics and the Cardinal Temperature Model with Inflection (CTMI), offering a comprehensive understanding of algal growth dynamics. The model's first component, based on Haldane kinetics, addresses the effect of light intensity on algal growth. It recognizes that growth rate increases with light intensity up to an optimal level, after which it starts to decline due to photoinhibition. This relationship is mathematically represented by the equation:

$$\mu(I) = \mu_{opt} * I \left( I + \left( \frac{\mu_{opt}}{\alpha} \right) * \left( \left( \frac{I}{I_{opt}} \right) - 1 \right)^2 \right) \quad (1)$$

Here,  $\mu(I)$  represents the growth rate as a function of light intensity  $I$ ,  $\mu_{opt}$  is the maximum growth rate,  $I_{opt}$  is the optimal light intensity, and  $\alpha$  is a parameter that moderates the effect of light intensity on the growth rate.

The second component of the model, the CTMI, quantifies the influence of temperature on algae growth. This model defines the growth rate within a range of temperatures, specifying minimum ( $T_{min}$ ), optimal ( $T_{opt}$ ), and maximum ( $T_{max}$ ) temperatures for growth. The CTMI model is encapsulated in the following equation:

$$\mu(T) = k * \frac{(T - T_{min}) * (T_{opt} - T)}{((T_{opt} - T_{min}) * (T_{max} - T))} \quad (2)$$

In this formulation,  $\mu(T)$  denotes the growth rate as a function of temperature  $T$ , with  $T_{min}$ ,  $T_{opt}$ , and  $T_{max}$  being the minimum, optimal, and maximum temperatures for algal growth, respectively.  $k$  is a scaling constant.

The final model, encapsulating both the temperature and light components, is then the product of  $\mu(T)$  and  $\mu(I)$ .

### Data Source and Preparation

Our study utilizes data collected from the PBR 1250L photobioreactor system from Industrial Plankton as the primary cultivation equipment. This system provides a substantial working volume of 1250 liters, enabling a continuous harvesting capacity of up to 500 liters daily. Data collection was centered around minute measurements of pH level, irradiation, temperature, and relative density of the growth media within the photobioreactor. The pH control was managed by adjusting its setpoint and stabilized through automatic CO<sub>2</sub> injection. Irradiation was provided by LED light columns. Temperature control was maintained externally and the relative density of the algae was monitored through an optical density sensor.

The study involved a batch culture maintained over eleven days with alternating irradiation and pH setpoints, keeping the temperature constant and assuming a sufficient initial nutrient supply. The operational sequence was adjusted bi-daily, and the bioreactor was prepared with specific concentrations of culture media, followed by a regulated air bubbling process to maintain optimal growth conditions. This resulted in 22,301 data points for use in training and testing models.

### SINDy-Derived Error Model

We employ the SINDy algorithm [21] to identify a differential equation to model the rate of change of error between the actual and predicted *Chlorella vulgaris* densities. Here, the error given by Equation 4 as

$$e = \text{Density\_actual} - \text{Density\_model} \quad (4)$$

varies over time. The state data, represented by  $X_{sindy}$ , includes the error, capturing the essential aspects of the model's performance over time. Additionally, control data, denoted as  $U_{sindy}$ , incorporates key environmental factors, namely temperature  $T$ , light intensity  $I$ , and  $pH$  that significantly influence algal growth.

$$\dot{X}_{sindy} = e \quad (5)$$

$$\dot{X}_{sindy} = \dot{e} \quad (6)$$

$$U_{sindy} = [T \ I \ pH] \quad (7)$$

We develop a control-only error model using the SINDy framework with the introduction of a dummy state variable. This dummy variable, a zero-valued array, is designed to match the dimensions of  $X_{sindy}$ , the derivative of the error. Its primary function is not to represent a 'real' state variable in the traditional sense; instead, it serves as a tool for facilitating the SINDy algorithm process of system dynamics identification, which typically expects state variables to influence the system dynamics. The SINDy algorithm is thus attempting to fit sparsity matrix  $\Phi$  such that:

$$\dot{X}_{\{sindy\}} = U_{sindy}\Phi \quad (9)$$

To capture the complexity of biological growth

processes in our SINDy model, we included a variety of custom functions in the feature library. Each function represents a specific biological growth dynamic, such as logistic growth, exponential growth, and other well-known biological models shown in Table 1.

**Table 1:** Functional basis for SINDy library.

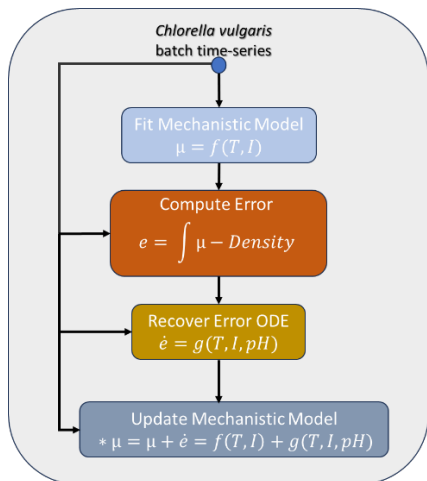

<b>Logistic growth</b>	$f(x) = \frac{1}{\{1 + e^{-x}\}} \quad (10)$
<b>Exponential growth</b>	$f(x) = e^{\{x\}} \quad (11)$
<b>Gompertz function</b>	$f(x, c_1, c_2) = e^{\{c_1 e^{-c_2 x}\}} \quad (12)$
<b>Allee effect</b>	$f(x, A) = \frac{x}{\{A - x + \epsilon\}} \quad (13)$
<b>Michaelis-Menten kinetics</b>	$f(x, K_m) = \frac{x}{\{K_m + x + \epsilon\}} \quad (14)$
<b>Holling's Type II function</b>	$f(x, a) = \frac{ax}{\{1 + ax + \epsilon\}} \quad (15)$

Here, the logistic growth function represents a growth process that accelerates rapidly at first and then slows down as it approaches a maximum limit, commonly used to model population growth. The exponential growth function describes a process where the rate of growth is proportional to the current amount, leading to a rapid increase over time. The Gompertz function models growth that initially accelerates and then decelerates, commonly used in biology to describe the growth of tumors or certain populations [22]. The parameters  $c_1$  and  $c_2$  reflect the maximum value the function will reach and the rate at which that point will be reached respectively. The Allee effect function represents a scenario where population growth is positively correlated with the population size, highlighting the difficulties in growth at very low densities, with  $A$  representing this population threshold value [23]. The parameter  $\epsilon$  is used here as well as the following functions to as a small value that prevents division by zero. The Michaelis-Menten kinetics function is typically used to describe the rate of enzymatic reactions, showing how reaction rate varies with substrate concentration [24]. The parameter  $K_m$  is the substrate concentration at which the growth rate is half of its maximum. Holling's Type II function, models the rate of predation in an ecosystem, increasing linearly at low prey density and saturating at higher densities [25]. The growth rate  $a$  here represents the efficiency of resource consumption by the growing population.

### Mechanistic & Error Model Coupling

After the ODE model for the error derivative is recovered, this sum of functions representing the

derivative is added directly to the original mechanistic CTMI-light model, as shown in Figure 1. This updated, or “corrected,” model can then be integrated overtime to return the specific density from the estimated growth rate.

**Figure 1:** Methodological flow resulting in an updated mechanistic model for *Chlorella vulgaris* rate of change of density.

## Model Evaluation

In the evaluation of the error ODE model, key metrics of RMSE, MAPE, and  $R^2$  are calculated for each fold of the time series cross-validation to assess model accuracy. RMSE is determined by taking the square root of the average of squared differences between predicted and observed values. MAPE is calculated as the average of the absolute differences between predicted and observed values, divided by the observed values, and expressed as a percentage.  $R^2$  is computed as the proportion of variance in the observed data that is predictable from the model inputs.

Visual comparisons of both the corrected and non-corrected models' predictions against the observed cumulative growth data are integrated and tested for each validation fold through a process of data preparation, plotting, visual analysis, and comparison. These plots allow for the assessment of how closely the predicted growth curves follow the observed data and the extent to which the corrected predictions improve alignment with the observed data compared to the non-corrected predictions.

## RESULTS

### Algae Mechanistic Model

We fit the combined CTMI-light model for density using the full 22,301 measurement points available for temperature, light intensity, and density. Since the mechanistic model is built for non-standardized relationships

between components, we choose to pass in the raw data without standardization or normalization. We employed non-linear curve fitting techniques, utilizing the 'curve\_fit' function from the Python 'scipy.optimize' library, to estimate the parameters of the model with  $T_{opt} = 27.329\text{ C}$ .

To check the performance of this model, we integrate the fitted model over time and compare the result to the measured specific density. As seen in Figure 2, the combined model predicts a linear increase in algae density overtime.

**Figure 2:** Combined CTMI-light model for growth rate integrated over time versus measured model specific density over all 22,301 data points. Combined model RMSE is 0.009.

## Data Preparation

To make the SINDy optimization more robust against outliers in feature weights, the inputs, temperature, light intensity, and pH are each normalized by subtracting their time-series mean and dividing by standard deviation. This approach was chosen since the inputs to the batch were periodic, meaning their distribution was close to Gaussian.

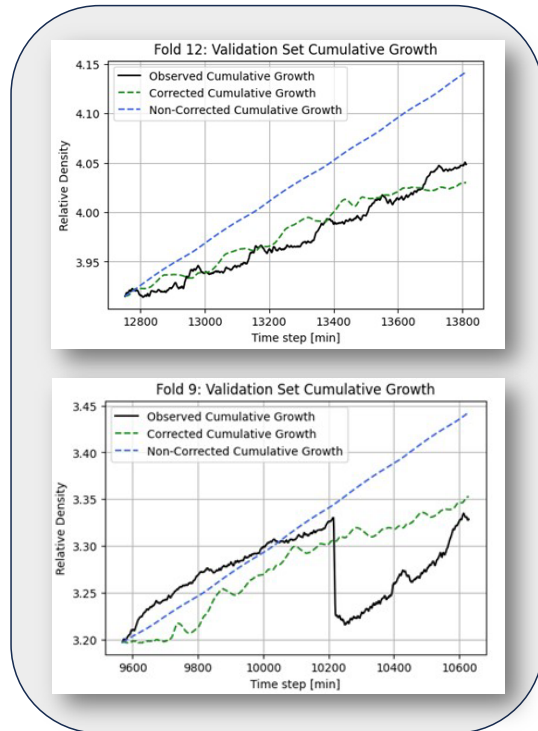

The full timeseries data, with standardized control inputs, is then broken into twenty folds of sequential data. Cross-validation is employed such that in each iteration, the model is trained on an expanding window of past data and validated on a subsequent, non-overlapping window of future data. This strategy allows the model to learn from a progressively larger dataset, capturing more of the underlying temporal patterns and dynamics as it moves through the folds.

## SINDy Error ODE Model Recovery

We leverage the sequentially thresholded least squares (STLSQ) algorithm as the optimization engine for Sparse Identification of Nonlinear Dynamics (SINDy). In this implementation, the STLSQ sparsity threshold is set at 0.0001, allowing the model to focus on the most impactful predictors and enhance its transparency. Additionally, the maximum iteration limit is set to 2000,

balancing computational efficiency with sufficient convergence time for the optimizer. These carefully chosen parameters ensure that the STLSQ algorithm effectively extracts the underlying dynamics of the system while maintaining interpretability and computational efficiency.

**Figure 3:** Updated growth rate model (integrated model versus actual specific density) showing better performance than original CTMI-light model.

We use a combination of custom, Polynomial, and Fourier libraries in SINDy. The custom library included logistic growth, exponential growth, Gompertz, Allee effect, Michaelis-Menten kinetics, and Holling's Type II functions, with all parameters uniformly set to one. This simplified configuration allowed for a consistent and straightforward interpretation of the model's outcomes while retaining the flexibility to model complex biological phenomena. The Polynomial Library, configured to include terms up to the second degree, enables the model to identify both linear and quadratic relationships. Meanwhile, the Fourier Library plays a key role in capturing remaining periodicity.

An ensemble method is utilized to enhance the model's robustness and accuracy [26]. This approach involves fitting the model multiple times using subsets of the training data, allowing for a comprehensive capture of potential dynamics and mitigating the impact of outliers or anomalous data points. The ensemble method generates 1000 models, each trained on a random subset comprising half of the training data.

## Model Performance

A SINDy model is trained for each of the 20 validation folds and the error metric scores for RMSE, MAPE, and  $R^2$  are tabulated in **Table 2**. Scores across the early folds reflect completely unbounded and divergent behavior in the corrected model when integrated over time, due to the limited training data up to that point. Scores continue to improve (RMSE and MAPE decreasing and  $R^2$  increasing) until Fold 6, where a measurement fluke in specific density temporarily biases the training data. These high RMSE and MAPE and highly negative  $R^2$  are seen again in Folds 14 and 15, reflecting completely divergent behavior likely the result of similar poor data quality around that point in time.

**Table 2:** Error metric scores across full 20 validation folds.

Fold #	Uncorrected			Corrected		
	RMSE	MAPE	$R^2$	RMSE	MAPE	$R^2$
1	1.15e+8	2.31e+10%	-7.52e+17	1.055e+12	1.50e+14%	-6.29e+25
2	0.075	5.353%	0.585	1.80e+10	1.25e+12%	-2.38e+22
3	0.0925	inf%	0.160	1.64e+11	inf%	-2.64e+24
4	0.0300	1.34%	0.876	0.399	18.7%	-20.9
5	0.117	4.62%	0.328	0.867	32.5%	-36.1
6	0.0969	3.77%	0.0973	3.92	125%	-1475
7	0.0884	2.75%	0.361	0.0817	2.71%	0.455
8	0.0364	1.06%	0.805	0.0909	1.95%	-0.215
9	0.0827	1.80%	-4.90	0.0479	1.28%	-0.981
10	0.055	1.40%	0.639	0.0684	1.47%	0.443
11	0.0235	0.541%	0.913	0.0480	1.16%	0.635
12	0.0595	1.35%	-1.17	0.0132	0.278%	0.893
13	0.0138	0.242%	0.948	0.0263	0.549%	0.811
14	0.120	2.37%	-310	2.53e+5	3.76e+6%	-1.38e+15
15	0.0949	1.90%	-29.2	12.1	177%	-492000
16	0.0720	1.39%	-7.01	0.223	3.97%	-76.1
17	0.0844	1.65%	-10.8	0.216	4.14%	-76.5
18	0.0144	0.260%	0.942	0.0642	1.19%	-0.144
19	0.0192	0.326%	0.873	0.0484	0.806%	0.197
20	0.0586	0.964%	-2.34	0.109	1.81%	-10.6

The fold models not exhibiting this fully divergent behavior either outperform the original combined CTMI-light model both visually quantitatively (for example models for Folds 9 and 12, see Table 2) or capture some pattern or periodicity not found in the original mechanistic models, while simultaneously slowly diverging from the actual truth specific density (for example models for Folds 8 and 18, see **Table 2**). In Fold 9, we see that the corrected model outperforms the original mechanistic model even with experimental error due to the drop in

specific density.

## Model Trends

The SINDy error-based models are provided as Supplementary Material. The natural functions are given only by name and variable they operate on (see Table 1). For example,  $13.512 \text{ gompertz}(Temperature, Light)$  refers to the Gompertz function applied to both temperature and light variables (separately) but with a coefficient of 13.512 for each.

Early fold equation coefficients (Folds 1-7) show noticeable fluctuation in the impact of temperature. Initially, the effect is strongly negative (e.g., -104689.0 in Fold 1) but shows variability in subsequent folds, indicating changing sensitivity to temperature (see Supplementary Material). Light maintains a predominantly negative coefficient, with large magnitudes (e.g., -43231100.0 in Fold 1). pH coefficients show significant changes, starting positive and large (8179580.0 in Fold 1) but becoming negative by Fold 4, indicating a shifting role of pH in these systems. Squared terms like  $Temperature^2$  and  $Light^2$  indicate evolving non-linear effects, with coefficients varying and reflecting changing dynamics. Interaction terms start to appear and vary in significance, suggesting the evolving interplay between factors. Logistic and exponential growth models are applied with varying coefficients, indicating differing growth dynamics under changing conditions.

Folds (Folds 8-14) see the coefficient of Temperature stabilizing somewhat but continuing to show variation, possibly reflecting a nonlinear role not captured by the supplied function basis for SINDy. Light consistently shows a negative impact but with varying magnitudes, indicating a sustained but dynamically changing influence. The role of pH continues to evolve with coefficient changes. Cyclical terms become more pronounced, with sin and cos functions indicating more significant seasonal or cyclic effects.

Late Folds (Folds 15-20) show temperature coefficients become more moderate, suggesting a refined understanding or a stabilizing effect. The influence of Light remains significant with large negative coefficients, indicating a consistently crucial role. pH effects continue to show variability but within a narrower range, suggesting a more consistent but still variable role. The complexity in terms of diverse interactions and non-linear effects shows signs of convergence, with key relationships and factors becoming more defined. There is a tendency towards more consistent use of growth models, indicating a stabilization in how growth or change processes are being represented.

**Figure 4:** Updated growth rate model (integrated model versus specific density) showing divergent behavior.

## CONCLUSION

This study demonstrates the potential of sparse machine learning techniques like SINDy to enhance the accuracy of mechanistic models while retaining interpretability. However, it also highlights the limitations and challenges that can arise in applying data-driven methods to improve mechanistic insights, especially given constrained data availability.

By focusing solely on a single experimental dataset for the microalga *Chlorella vulgaris* cultivated under tightly controlled photobioreactor conditions, the model's flexibility was restricted. While providing high temporal resolution measurements, spanning just one batch limited the diversity of growth dynamics captured. Periodic disturbances in the data, stemming from operational issues, further hampered efforts to train robust models.

Across 20 validation folds, adding the data-driven error dynamics equation resulted in improved error metrics. However, early folds suffered due to insufficient training data leading to a diverging trajectory with exploding error. Later folds demonstrated closer alignment with observed growth trajectory or responded to oscillation over time neglected by the linear mechanistic model. Inaccuracy in the phase of the oscillatory trajectory predicted may be due to sensitivity to initial conditions and warrants further exploration. The variation in types of biological growth functions applied over folds potentially indicated the model homing in on appropriate

representations for different mechanisms or growth phases as training data and timespan was increased.

These outcomes highlight the power of refining first-principles models with nuanced insights from real system observations. However, the instability across folds underscores the need for more comprehensive datasets before operational deployment. Future efforts should focus on generating measurements encapsulating a wider array of cultivation conditions and durations. Increased scale and variance in datasets may enable machine learning to extract more robust patterns. Beyond SINDy, exploring alternative algorithms could further improve the mechanistic correction.

## ABSTRACT

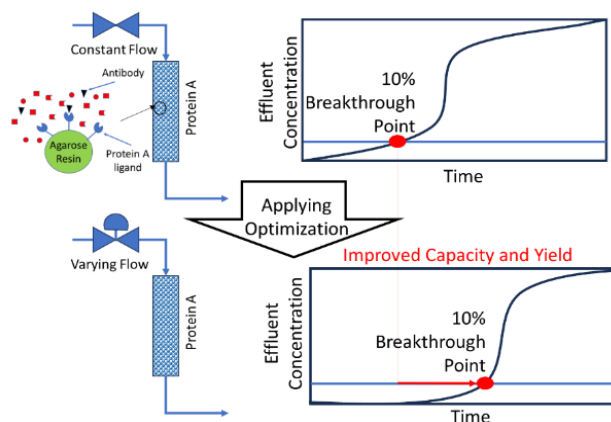

Antibody therapies are important in treating life-threatening ailments such as cancer and autoimmune diseases. Purity of the antibody is essential for successful applications and Protein A selective resin extraction is the standard step for antibody recovery. Unfortunately, such resins can cost up to 30% of the total cost of antibody production. Hence, the optimal design of this purification step becomes a critical factor in downstream processing to minimize the size of the column needed. An accurate predictive model, as a digital twin representing the purification process, is necessary where changes in the flow rates and the inlet concentrations are modeled via the Method of Moments. The system uncertainties are captured by including the stochastic Ito process model of Brownian motion with drift. Pontryagin's Maximum Principle under uncertainty is then applied to predict the flowrate control strategy for optimized resin use, column design, and efficient capturing of the antibodies. In this study, the flow rate is controlled to optimize the process efficiency via maximizing the theoretical plate number with time, the objective for efficient resin usage within a fixed-size column. This work successfully achieved optimality, which was also confirmed via experimentation, leading to higher antibody resin loading capacity. When the work was expanded to 200 cycles of Protein A usage, significant improvements in the downstream process productivity were achieved allowing for smaller footprint columns to be used.

## INTRODUCTION

Antibodies are produced by many pharmaceutical companies to treat various autoimmune diseases [1]. Unfortunately, up to 30% of the production cost of the antibody [2] is based on a single purification step, the Protein A resin, that selectively captures the antibody from the fermentation broth with up to 99% purity. Therefore, the optimal usage of such an expensive resin is necessary. Since the cost of antibody production depends on the cost of this resin, an optimal control strategy is needed to maximize the efficient use of the resin as seen in Figure 1 giving the possibility to use smaller systems.

The effluent concentration of the expensive capture step will also follow a sigmoidal function [3] as seen in Figure 1. With many sigmoidal models used to evaluate packed bed systems [4], the model parameters are highly dependent on flow rates and inlet concentrations [5].

**Figure 1.** Optimal design and operating policy for the Protein A resin step in antibody extraction.

A generalized fixed bed model can be used where the parameters are defined by their relationships to the flow rate and inlet concentration [4]. Pontryagin's maximum principle [6] defines our purification system as requiring an optimization strategy via adjustments of controllable process variables such as flow rate.

To accomplish such optimality, the method of moments is used to simplify the system as a univariate function of time [7]. However since the moments are typically used to represent chromatographic steps [8] with a population distribution curve, the Protein A capture step cumulative curve will need to be transformed via its derivative into a distribution curve (as shown in Figure 2). The Hamiltonian function [9] is then formulated using moments as state variables and introducing adjoint variables to define the path taken during the optimization via maximizing the theoretical plate number [10] for the most efficient use of the resin.

**Figure 2.** Sigmoidal function transformation from a cumulative to a distribution curve via its derivative.

Since the inlet concentrations and model parameters can vary during production, capturing such uncertainties during optimization is important. The stochastic Ito process [11] was picked to capture the variability of the system. The purpose of this work is to confirm that varying the flow rate with time maximizes the resin performance over using fixed flow rates, a standard practice in existing industrial chromatography column operations [12]. While some industries adopted continuous chromatography [13], such as the use of simulated moving beds [14], to maximize the efficient use of the resin, considerable investments in such complex systems are required [15]. The novelty of our approach lies in its simplicity in maximizing the system performance of a single-column system avoiding the high cost of a continuous system.

## METHODOLOGY

The procedure consists of feeding IgG4 antibody [16] through 1 ml of packed Minichrom column (supplied by Repligen) packed with Praesto Jetted A50 Protein A resin (supplied by Purolite). Three different concentrations of the antibody (2, 5, and 7 mg/ml) were used at 4 different residence times (3, 4.8, 6, and 10 min). A standard sigmoidal function [17], predicting the column output is seen below.

$$\frac{C}{C_0} = \frac{1}{1 + \exp(a - b t)} \quad (1)$$

where  $C_0$  - inlet concentration,  $C$  - effluent concentration varying with time,  $a$  and  $b$  - empirical parameters of the sigmoidal function, and  $t$  - time. The model can be further modified into a modified Yoon-Nelson equation [18] where  $t_{\frac{1}{2}}$  - time needed to get to  $C/C_0 = 1/2$ .

$$\frac{C}{C_0} = \frac{1}{1 + \exp\left(b\left(\frac{a}{b} - t\right)\right)} = \frac{1}{1 + \exp\left(b\left(t_{\frac{1}{2}} - t\right)\right)} \quad (2)$$

The parameters in the model can be calculated by minimizing the Sum of Squares of the Error (SSE) between model predictions and experimental measurements [19]. Since the sigmoidal function is represented by a cumulative curve, it is necessary to transform Eq. 2 into a distribution curve, closely depicting chromatographic separations [20]. Such a transformation is achieved by taking the derivative of the sigmoidal model,  $d(C/C_0)/dt$ .

## The Method of Moments

The general form of the truncated temporal moments [21] used in chromatographic separations is defined by the following equation [22]:

$$m_i = \int_0^t t^i \frac{d\left(\frac{C}{C_0}\right)}{dt} dt \quad (3)$$

Eq. 3 is the basic form to present the 4 moments describing our system [23]. In chromatographic operations, the truncated temporal moment equations are represented as follows [24]:

$$\begin{aligned} \text{Zeroth moment} &= m_0(t) = \mu_0(t) \\ &= \int_0^t \frac{d\left(\frac{C}{C_0}\right)}{dt} dt = \frac{C}{C_0}(t) = y_1(t) \end{aligned} \quad (4)$$

$$\begin{aligned} \text{First normalized moment} &= \mu_1(t) \\ &= \frac{\int_0^t t \frac{d\left(\frac{C}{C_0}\right)}{dt} dt}{\int_0^t \frac{d\left(\frac{C}{C_0}\right)}{dt} dt} = \frac{\int_0^t t \frac{d\left(\frac{C}{C_0}\right)}{dt} dt}{\mu_0(t)} = t_m(t) = y_2(t) \end{aligned} \quad (5)$$

$$\begin{aligned} \text{Second central normalized moment} &= \mu_{2c}(t) \\ &= \frac{\int_0^t (t - \mu_1)^2 \frac{d\left(\frac{C}{C_0}\right)}{dt} dt}{\mu_0(t)} = \sigma^2(t) = y_3(t) \end{aligned} \quad (6)$$

$$\begin{aligned} \text{Third central normalized moment} &= \mu_{3c}(t) \\ &= \frac{1}{\mu_{2c}^{1.5}} \frac{\int_0^t (t - \mu_1)^3 \frac{d\left(\frac{C}{C_0}\right)}{dt} dt}{\mu_0(t)} = s^3(t) = y_4(t) \end{aligned} \quad (7)$$

where  $t_m$  - column residence time or the time needed to reach the maximum peak,  $\sigma^2$  - variance or square of the standard deviation, and  $s^3$  - skewness cubed.

## Capturing Uncertainties

As uncertainties can affect the protein A resin performance leading to inefficient removal of the antibodies, it is necessary to account for these variations via the adoption of stochastic process equations and models [25]. One of the simplest stochastic process models is the Brownian motion / Wiener process [26], where one begins at a known initial value and takes equiprobable

steps in any direction [27]. An example of the Brownian motion method is the Ito process with drift [28] defined below as a modified Euler step.

$$y_t = y_{t-\Delta t} + \alpha \Delta t + \kappa \varepsilon (\Delta t)^{1/2} \quad (8)$$

where  $y_t$  – the moment at time  $t$ ,  $y_{t-\Delta t}$  – the moment at time  $t - \Delta t$ ,  $\alpha$  – Ito process drift parameter,  $\kappa$  – Ito process deviation parameter,  $\varepsilon$  – random number with a normal distribution of zero as the mean and a standard deviation of 2, and  $\Delta t$  – time step. The Ito process has been applied to other modes of purification such as crystallization [29] and distillation [30].

### Objective function and boundary conditions

Figure 3 demonstrates that an increase in the normalized first moment,  $t_m$ , results in more antibody extraction, while a decrease in the second central moment,  $\sigma^2$ , results in lower leakage. Therefore, the objective would be to maximize  $t_m$  and minimize the variance  $\sigma^2$ . In chromatography, better purification is achieved when the theoretical plate number (TPN) is maximized [31].

$$TPN = \frac{t_m^2}{\sigma^2} \quad (9)$$

The objective,  $J_{max}$ , is to maximize the theoretical plate number.

$$J_{max(Q)} = \max\left(\frac{t_m^2}{\sigma^2}\right) = \max\left(\frac{\mu_1^2}{\mu_{2c}}\right) \quad (10)$$

The maximum value is achieved when the derivative of the objective function is equated to zero.

**Figure 3.** Effect of increasing the residence time (A) compared to decreasing the variance (B).

### Optimal Control

To simplify the optimization approach, we can linearize the four stochastic moments into a single Hamiltonian function as follows[25]:

$$H = \sum_{i=1}^4 [z_i F_i + \omega_i \frac{g_{y_i}^2}{2}] \quad (11)$$

where  $H$  – Hamiltonian function,  $z_i$  – adjoint variable,  $F_i$  – differential changes of the state variable with time =  $\frac{dy_i}{dt}$ ,

$\omega_i$  – stochastic adjoint variable, and  $g_{y_i} = \sqrt{\frac{var(\Delta y_i)}{\Delta t}}$  (12)

The adjoint variables limit the pathways to achieve the objective and are defined by their derivatives:

$$\frac{dz_i}{dt} = - \sum_{k=1}^4 \left[ \frac{\partial F_k}{\partial y_i} z_k + \frac{1}{2} \frac{\partial g_k^2}{\partial y_i} \omega_k \right] \quad (13)$$

$$\frac{d\omega_i}{dt} = - \sum_{k=1}^4 \left[ 2\omega_k \frac{\partial F_k}{\partial y_i} + \frac{\partial^2 F_k}{\partial y_i^2} z_k + \frac{1}{2} \frac{\partial^2 g_k^2}{\partial y_i^2} \omega_k \right] \quad (14)$$

Pontryagin's maximum principle (PMP) is used to apply the optimal control strategy [32] to our antibody extraction system. PMP utilizes the Hamiltonian by imposing the optimality conditions for the objective function [33]. Another optimization method that could be used is the orthogonal collocation method [34]. The collocation numerical method would simplify our optimization strategy for our deterministic approach [35] but is challenging when dealing with uncertainties captured in the Hamiltonian function used in the PMP method.

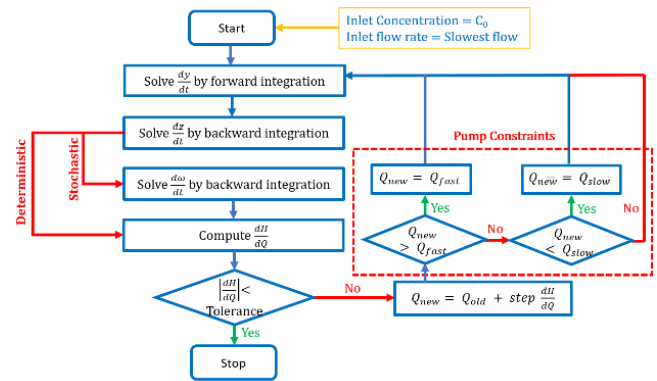

Optimal control is applied using a manageable system parameter such as the flow rate. Derivatization of the Hamiltonian function to the flow rate ( $Q$ ) can be represented by its coordinates (the state and the adjoint variables) using the following expression[29] of a derivative chain rule:

$$\frac{dH}{dQ} = \sum_{i=1}^4 \frac{dH}{dy_i} \frac{dy_i}{dQ} + \sum_{i=1}^4 \frac{dH}{dz_i} \frac{dz_i}{dQ} + \sum_{i=1}^4 \frac{dH}{d\omega_i} \frac{d\omega_i}{dQ} \quad (15)$$

Eq. 15 defines the Hamiltonian gradient where the gradient is nullified when flow rate changes are no longer necessary. The integrations were done using the Euler steps[29]. The initial values of the state variables are obtained from the starting point, and the final values of the adjoint variables ( $z$  and  $\omega$ ) are obtained from the optimal objective for the purification system.

### Optimal Control Solution Strategy

The pump flow rate is bound between 2 flow rates corresponding to residence times of 3 and 10 min in our experimental work. Considering that the inlet antibody concentration enters at 5 mg/ml, the flow rate, initially set at the slow residence time of 10 min, is expected to change to optimize the extraction of the antibody.

**Figure 4.** Flowchart for stochastic optimal control.

Figure 4 summarizes the algorithm using Matlab as the optimization tool for the deterministic and stochastic approach[36]. The main difference between the two

approaches is the bypass loop to calculate the stochastic adjoint variable  $\omega$ . Figure 4 demonstrates how our state and adjoint variables are calculated before calculating the Hamiltonian gradient which is compared to the tolerance picked for the system. Depending on the Hamiltonian gradient value, the optimization would be achieved (below the tolerance) or the flow rate would be adjusted (above the tolerance) between the two flow rate boundaries for another iteration.

## RESULTS

The experimental data for the concentration ratio of antibody igG4 with time from a 1 ml Minichrom column packed with Praesto Jetted A50 resin is seen in Table 1.

**Table 1:** Experimental data.

<i>Inlet Concentration <math>C_0 = 2</math> mg/ml</i>			
Residence Time (min)	Time to $C/C_0 = 0.05$ (min)	Time to $C/C_0 = 0.10$ (min)	Time to $C/C_0 = 0.50$ (min)
3	82.7	90.6	135.2
4.8	157.6	170.3	216.9
6	198.3	216.8	271.3
10	334.8	364.6	456.2
<i>Inlet Concentration <math>C_0 = 5</math> mg/ml</i>			
Residence Time (min)	Time to $C/C_0 = 0.05$ (min)	Time to $C/C_0 = 0.10$ (min)	Time to $C/C_0 = 0.50$ (min)
3	31.5	35.3	57.9
4.8	61.4	67.8	97.8
6	87.4	94.2	123.6
10	162.8	173.2	209.2
<i>Inlet Concentration <math>C_0 = 7</math> mg/ml</i>			
Residence Time (min)	Time to $C/C_0 = 0.05$ (min)	Time to $C/C_0 = 0.10$ (min)	Time to $C/C_0 = 0.50$ (min)
3	23.7	24.9	30.2
4.8	40.9	42.6	49.4
6	52.0	54.1	62.0
10	87.7	92.5	104.9

We extrapolated the sigmoidal model parameters via the minimization of the SSE (sum of square errors).

These parameters are summarized in Table 2 as they vary with changes in inlet concentration and flow rate.

**Table 2:** The sigmoidal function parameters.

Residence Time (min)	Concentration (mg/ml)	Empirical parameter $t_{1/2}$ (min)	Empirical parameter $b$ ( $\text{min}^{-1}$ )
3	2	135.1	0.0519
4.8	2	217.1	0.0480
6	2	271.4	0.0403
10	2	455.8	0.0241
3	5	57.8	0.1031
4.8	5	97.8	0.0762
6	5	123.5	0.0772
10	5	209.2	0.0619
3	7	30.2	0.4317
4.8	7	49.4	0.3344
6	7	61.9	0.2849
10	7	105.0	0.1748

From Table 2, we extrapolate the relationships between the model parameters and system characteristics.

$$t_{\frac{1}{2}} = 82.81 RT \exp(-0.295 C_0) \quad (16)$$

$$b = \frac{1}{-0.57 RT C_0 + 4.49 RT - 1.12 C_0 + 9.08} \quad (17)$$

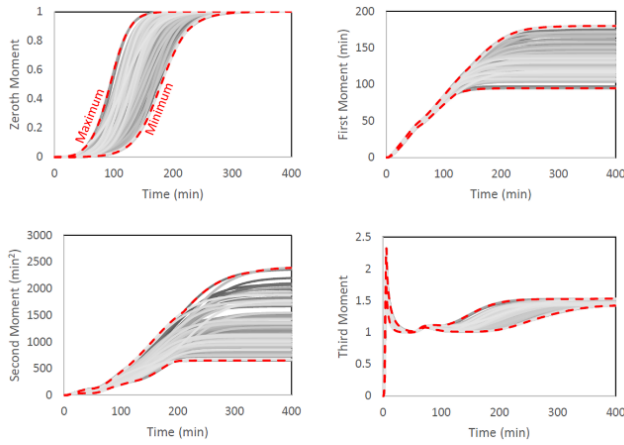

where  $RT$  – residence time =  $RV/Q$ , and  $RV$  – resin volume in the column. The results comparing the empirical parameters with the calculated data from Eq. 16 and Eq. 17 are summarized in Table 3. It displays that the fluctuations in the parameters  $t_{\frac{1}{2}}$  and  $b$  are within  $\pm 10\%$  and  $\pm 20\%$  respectively.

## Capture Uncertainty via Stochastic Processes

When considering an inlet antibody concentration that fluctuates 10% around 5 mg/ml and capturing the parameter fluctuations described by Table 3, we can display the effect of these uncertainties on the 4 moments.

**Table 3:** Results of the sigmoidal function parameters for calculated versus empirical.

Residence Time (min)	Concentration (mg/ml)	Empirical parameter $t_{1/2}$ (min)	Empirical parameter $b$ ( $\text{min}^{-1}$ )	Calculated parameter $t_{1/2}$ (min)	Calculated parameter $b$ ( $\text{min}^{-1}$ )	Percent difference on $t_{1/2}$	Percent difference on $b$
3	2	135.1	0.0519	137.7	0.0592	-1.9	-14.1
4.8	2	217.1	0.0480	220.3	0.0436	-1.5	9.1
6	2	271.4	0.0403	275.4	0.0371	-1.5	7.9
10	2	455.8	0.0241	459.0	0.0248	-0.7	-2.9
3	5	57.8	0.1031	56.8	0.1190	1.7	-15.5
4.8	5	97.8	0.0762	90.9	0.0881	7.0	-15.6
6	5	123.5	0.0772	113.7	0.0751	8.0	2.8
10	5	209.2	0.0619	189.5	0.0503	9.4	18.7
3	7	30.2	0.4317	31.5	0.3650	-4.4	15.5
4.8	7	49.4	0.3344	50.4	0.2747	-2.1	17.8

**Figure 5.** Static uncertainty (100 scenarios via sampling) manifested as Dynamic uncertainty.

Figure 5 shows the effect of static uncertainties in the initial condition or process parameters manifesting as dynamic uncertainties in all the state variables (i.e. the 4 moments with respect to time). Figure 6 demonstrates that the Ito process of Brownian motion with drift can capture the dynamic uncertainties of the 4 moments.

**Figure 6.** Ito process capturing the uncertainties for the four moments.

### Results from Stochastic Optimal Control

We run the Matlab flowchart program seen in Figure 4, for over 40,000 iterations to achieve the optimal flow rate path. While the state variables,  $y_i$ , are integrated in the forward direction from the initial conditions,  $[y_1(0) \ 0 \ 0 \ 0]$ , the adjoint variables,  $z_i$  and  $\omega_i$ , are integrated in a backward direction from the final conditions,  $[0 \ (2\mu_1(t_{final}))/(\mu_{2c}(t_{final})) - (\mu_1^2(t_{final}))/(\mu_{2c}^2(t_{final})) \ 0]$  and  $[0 \ 0 \ 0 \ 0]$ , respectively based on the final optimum of Eq. 11. We use Euler's method for integration with a very small-time step. At each time step, the values of the Hamiltonian and its derivative are

calculated.

Two approaches were evaluated: a deterministic approach, ignoring the uncertainties, and a stochastic approach. During each of the iterations, the flow rate is adjusted until the optimal flow is achieved. Figure 7 displays the changes in the flow rates during the deterministic optimal control approach. It shows that deterministic optimal flow control will start by increasing the flow towards the maximum flow to get as much product processed before it reduces the flow to avoid early antibody breakthrough.

**Figure 7.** Iterations of the flow rate to achieve deterministic optimal control.

### Experimental Validation of Optimal Control

From Figure 8, Both the stochastic optimal flow and the deterministic optimal flow will adjust to the maximum flow rate initially before reducing it to minimum flow rate around 70 minutes. The deterministic optimal flow decreases slightly earlier to the slow flow rate of around 60 minutes. Since running the process at the fast flow rate initially followed by a slowdown improved the process performance, we ran an experiment to confirm the improvement by manually changing the flow from the fastest flow rate to the slowest flow rate after  $C/C_0 = 0.05$  is reached.

**Figure 8.** Optimal flow control for both deterministic and stochastic approaches with manual flow rate adjustment.

Table 4 demonstrates the effectiveness of using an optimal flow rate to maximize the antibody extraction over using a constant flow rate. Both stochastic and

deterministic approaches succeeded in improving the system performance by extracting more antibodies in less time than a fixed slow flow rate. The actual experiment also demonstrated an improvement in antibody extraction over running at a constant flow rate. While the experimental manually controlled work did not duplicate the data obtained from the deterministic or the stochastic approach, the results confirmed that designing targeted operating policies such as the fast flow followed by decreased flow later in the process, will achieve more antibody extraction.

**Table 4:** Optimal control results versus constant flow.

Conditions	Max Flow	Min Flow	Deterministic	Stochastic	Actual test
Antibody Extracted to $C/Co = 0.1$ mg (mg antibody/ml resin)	65.0	73.6	97.1	105.7	105.3
Antibody Extracted to $C/Co = 0.5$ mg (mg antibody/ml resin)	86.0	92.9	112.8	122.6	113.4

When checking the amount of antibody extracted until 10% breakthrough, Table 4 demonstrates that the flow rate adjustment used in the experimental validation resulted in 43% more antibody removed than using the slowest flow rate setting. This validated improvement in the resin capacity leads to efficient utilization of the expensive Protein A resin. As the system residence time is influenced by the size of the column used, the optimization allows for the efficient utilization of any size resin column within the limitations of the system flow rates.

### Multicycle Optimization

Since the Protein A resin is the most expensive step in the downstream processing of antibodies, cycling it for multiple uses is necessary to get the most value out of its resin life. But with every cycle, the Protein A resin will degrade due to caustic cleaning or due to fouling from the various molecules in the fermentation broth.

**Figure 9.** Protein A resin degradation during multicycle operations at 6 min residence time.

Figure 9 shows the actual effect of Protein A degradation during multiple cycles as the breakthrough tends

to occur sooner in late cycles (also called life time study). For example, the time to reach 50% breakthrough dropped from 75 min to 68 minutes after 100 cycles. While the model parameters change with contact time and inlet concentration (as seen in equations 20 and 21), further modification of these parameters can be made to depict the degradation with each cycle. Therefore, it is expected that optimal flow rate pathways might be different as the resin degrades.

**Figure 10.** Optimal flow rate during multicycle use

**Figure 11.** Effect of resin degradation on the optimal flow

Figure 10 confirms that hypothesis showing that the system will not be running at the high flow rates for as long as when using a newer resin. At the end of the 200 cycles, the optimal flow rate is to keep the flow constant at its lowest setting. Figure 11 confirms that the optimal flow rate will get closer to the slowest flow rate as the number of cycles increases. Once optimal conditions cannot be improved beyond running at the slowest flow rates, resin replacement becomes the next logical step.

Table 5 summarizes the effect of using the optimal flow rate over 200 cycles of Protein A resin usage. Table 5 demonstrates that over 20% increase in cumulative binding capacity, over 30% savings on cycle time, and over 80% in productivity can be achieved during the 200-cycle life of the Protein A resin. The impact of such improvement allows the use of any size column while avoiding system overdesign usually necessary for similar results. An 84% improvement in productivity translates to using 46% less resin to get the same performance as the slowest flow rate and therefore 46% less footprint. In addition, reducing the loading time by 34% allows the extracted antibody to have less contact time with the host

cell proteins containing the damaging enzymes that can reduce the process yield [37].

**Table 5:** Performance Improvement in the Resin Usage Capacity over 200 Cycles.

Dynamic binding capacity (total grams/ml-resin)	C/C <sub>0</sub> = 10%	C/C <sub>0</sub> = 50%
Optimal control for 200 cycles	15.2	19.6
Constant low flow at residence time = 10 min for 200 cycles	12.5	16.8
% Improvement over 200 cycles	21.6	16.7
Total time of loading production needed (hours)		
Optimal control for 200 cycles	351	565
Constant low flow at residence time = 10 min for 200 cycles	531	772
% Improvement (200 cycles)	33.9	26.8
Productivity (total grams/liter-resin-hour)		
Optimal control for 200 cycles	43.3	34.7
Constant low flow at residence time = 10 min for 200 cycles	23.5	21.8
% Improvement over 200 cycles	84.2	59.2

## CONCLUSIONS

Protein A resins are the most expensive step in the manufacturing of critical antibody therapies. Successful control strategies become necessary to maximize the efficiency of resin usage in downstream processing. When applying optimal control strategies via flow rate adjustment, we demonstrated through prediction at first and then confirmed through experimentation that optimal design is achieved by varying the flow rates rather than using a fixed flow rate. Optimality is achieved by initially running the resin column at high flow rates to get as much feed processed before reducing the flow to avoid an early breakthrough. During the design of multicycle operation of the Protein A resin, the optimal results show a decreasing trend until it reaches similar results as running at the slowest flow rate. However, optimization during the multicycle operation was able to achieve over 80% productivity in the use of Protein A resin, leading to better column design.

With the successful implementation of such an optimal strategy, we demonstrate that smaller designs can be used more efficiently while expecting savings in resins, buffers/water, and utilities that accompany productivity improvements.

## ACKNOWLEDGEMENTS

The authors thank the Department of Chemical Engineering at Rowan University for their assistance in acquiring computational licenses and resources, and Puro-lite for providing the necessary data and testing the results predicted in this study.

## ABSTRACT

Computer-aided Molecular and Process Design (CAMPD) is an equation-oriented multi-scale decision making framework for designing both materials (molecules) and processes for separation, reaction, and reactive separation whenever material choice significantly impacts process performance. The inherent nonlinearity and nonconvexity in CAMPD optimization models, introduced through the property and process models, pose challenges to state-of-the-art solvers. Recently, quantum computing (QC) has shown promise for solving complex optimization problems, especially those involving discrete decisions. This motivates us to explore the potential usage of quantum optimization techniques for solving CAMPD problems. We have developed a technique for directly solving a class of mixed integer nonlinear programs using QC. Our approach represents both continuous and integer design decisions by a set of binary variables through encoding schemes. This transformation allows to reformulate certain types of CAMPD problems into Quadratic Unconstrained Binary Optimization (QUBO) models that can be directly solved using quantum annealing techniques. We illustrate this technique for the selection of optimal ionic liquids (IL) and the configuration of a reactor-separator process network. We also discuss several challenges that are associated with quantum optimization when solving large scale CAMPD problems.

**Keywords:** Optimization, Multiscale Modeling, Process Design, Quantum Optimization, CAMPD

## INTRODUCTION

Computer-Aided Molecular and Process Design (CAMPD) allows systematic identification of optimal materials and processes, thereby facilitating the transition towards more sustainable and cost-effective chemical processes. CAMPD typically involves solving mixed-integer nonlinear program (MINLP) of the following form:

$$\begin{aligned} \min \quad & C(x_d^{mat}, x_p^{mat}, x_d^{process}, x_p^{process}) \\ \text{s.t.} \quad & g_1(x_d^{mat}, x_p^{mat}) \leq 0 \\ & g_2(x_d^{mat}, x_p^{mat}) = 0 \\ & g_3(x_d^{process}, x_p^{process}) \leq 0 \\ & g_4(x_d^{process}, x_p^{process}) = 0 \\ & g_5(x_p^{mat}, x_p^{process}) \leq 0 \\ & g_6(x_p^{mat}, x_p^{process}) = 0 \end{aligned} \quad (P1)$$

$$x^L \leq x_d^{mat}, x_p^{mat}, x_d^{process}, x_p^{process} \leq x^U,$$

where the decision variables include both discrete and continuous variables. Molecular design is achieved through the optimal choices for a set of design variables ( $x_d^{mat}$ ) that correspond to the molecular fingerprints or groups that constitute the material, as well as performance variables ( $x_p^{mat}$ ) that dictate the material properties. Process design and configuration is achieved through a set of variables ( $x_d^{process}$ ) that represent process design specifications and typically involve both integer variables (such as feed location, number of column stages, etc.) and continuous variables (such as solvent flow rate, reflux ratio, operating pressure, and temperature). The process performance variables ( $x_p^{process}$ ) dictate the separation efficiency, product purity, etc. The objective function  $C$  aims to minimize the overall cost of the process and is subject to a set of constraints. The constraints  $g_1(x_d^{mat}, x_p^{mat}) \leq 0$  and  $g_2(x_d^{mat}, x_p^{mat}) = 0$  include the thermodynamic and transport property

relations and molecular structure-property models. In many cases, empirical structure-property relationships, such as group contribution models [1-2] or trained neural networks [3] are considered. They also contain a set of constraints that describe molecular generation rules to form structurally feasible molecules from a collection of groups or descriptors [4]. For solvent design, for example, these constraints typically involve the octet rule to ensure that the molecule satisfies atom balance. Often, bounds are imposed on the number of groups of a particular type to ensure the generation of a finite number of molecules. The constraints  $g_3(x_d^{process}, x_p^{process}) \leq 0$  are process inequality constraints (e.g., bounds on temperature, pressure, and other operational design decisions), while the constraint  $g_4(x_d^{process}, x_p^{process}) = 0$  pertains to the mass and energy conservation laws governing the process, and thermodynamic models such as the Gamma-Phi model [5-6] or equation of states that dictate the vapor-liquid equilibria (VLE) inside a separation unit, or nonlinear kinetic models integrated with VLE models for reactive-distillation processes [7-8]. Finally,  $g_5(x_p^{mat}, x_p^{process}) \leq 0$  and  $g_6(x_p^{mat}, x_p^{process}) = 0$  are linking constraints that describe the interaction between the material and process level performance through material property, thermodynamic property, and process models.

Several solution techniques and CAMPD approaches have been reported in the past, especially in systematically identifying organic solvents and solvent-based separation processes [9-12]. These approaches can be bottom-up, top-down, or simultaneous [13]. The bottom-up approach decomposes the CAMPD problem by first considering the molecular decisions, and sequentially reducing the feasible space by adding constraints, thereby deriving optimal product and process pairs [10-11]. The top-down approach also decomposes the CAMPD, and first optimizes the process performance by considering an ideal hypothetical molecule, and then optimizes over the molecular design space to match the molecular property targets [9,14]. The simultaneous approach often considers a relatively smaller design space for tractability and simultaneously solves CAMPD using modified outer approximation [15] or generalized benders decomposition algorithm [16]. CAMPD problems are multiscale in nature and often involve models with highly nonlinear, nonconvex terms, or many mixed variables and constraints. Despite significant progress in global optimization [17-18], large-scale discrete-continuous problems, as commonly occurred in CAMPD, can still be daunting, requiring extensive computational time to achieve feasible solutions [19].

Recent advances in quantum computing (QC) show promise to unlock new avenues for solving complex optimization problems [20-21]. Quantum optimization techniques are primarily used to solve Quadratic Unconstrained Binary Optimization (QUBO) problems [21].

Linear and quadratic integer programs can be converted to QUBO, with constraints reformulated as quadratic penalties to the objective function [21-22]. Once formulated, these QUBO models are mapped onto quantum devices, leveraging the principles of quantum annealing to solve these models as energy minimization problems [22]. However, CAMPD problems are characterized by their constraints and continuous decision variables, which do not have direct QUBO reformulations.

To bridge this gap, we have formulated a technique that represents continuous and integer variables by a set of binary variables through efficient encoding schemes. This allows us to reformulate a class of MINLP to QUBO and subsequently solve them using QC platforms, thereby facilitating the solution to certain CAMPD problems. We illustrate our technique for the simultaneous selection of ionic liquids (IL) and the configuration of a reactor separator process network. We convert the CAMPD model into QUBO and then solve them using D-Wave's quantum annealer, with results compared against deterministic solvers. Our results suggest that QC is able to obtain good feasible solutions in terms of process configuration and IL selection, thereby establishing the efficacy of QC for CAMPD.

## COMPUTER-AIDED MOLECULAR AND PROCESS DESIGN WITH IONIC LIQUIDS

Designing efficient separation systems using ILs as solvent is gaining increasing research attention. ILs possess many desirable properties (e.g., high thermal and chemical stability, low vapor pressure, etc.) that make them a suitable choice for solvent, especially for separating gas mixtures [5-6]. ILs are salts that exist in the liquid state at ambient conditions. These are largely constructed by a pair of cation core, anion, and organic functional groups that are attached to the cation core. For example, 1-butyl-3-methylimidazolium chloride, a common IL known as [BMIM][Cl], is formed by an imidazolium cation core, a chloride ion, and a butyl group attached to the cation core. Based on the type and number of groups and ions that are present in an IL, the corresponding material performance can vary. As such, ILs can be molecularly designed for the desired performance that makes them suitable for CAMPD application. However, the design space for ILs is very large, owing to the combinatorial possibilities in the assignment of their anion and cation components as well as side groups. In addition to the optimal choice of IL, process optimization needs to be performed which typically involves identifying the optimal process design variables. A process network synthesis with the consideration of IL selection involves mixed-integer variables across multiple scales, making the optimization highly non-trivial. To illustrate, consider a mixture separation task in an extractive distillation column

using ILs. For this case, the molecular structural constraints for ILs,  $\mathbf{g}_1$  and  $\mathbf{g}_2$  can take the following form [23]:

$$\begin{aligned} \sum_{j \in Ca} c_j &= 1, \sum_{j \in An} c_j = 1 \\ \sum_{j \in Ca \cup Sub} (2 - v_j) \cdot c_j - 2 &= 0 \\ LB &\leq \sum_{j \in Sub} c_j \leq UB \end{aligned} \quad (1)$$

where  $Ca$ ,  $An$ ,  $Sub$  refer to the set of groups or molecular descriptors for the cation core, anion, and side groups respectively.  $v_j$  is the number of bonds for group  $j$ ,  $LB$  and  $UB$  are the minimum and maximum number for each group.  $\mathbf{g}_1$  and  $\mathbf{g}_2$  can also include property models of the following form:

$$\begin{aligned} T_m(K) &= c_1 + \sum_{j \in Ca \cup An \cup Side} n_j G_j \leq T_{max} \\ \ln \mu(cp) &= c_2 + \sum_{j \in Ca \cup An \cup Side} n_j a_j \\ &+ \sum_{j \in Ca \cup An \cup Side} \frac{n_j b_j}{T} \leq \ln \mu_{max} \end{aligned} \quad (2)$$

$$(3)$$

where the set of properties can be a function of the groups, as well as of design variables such as temperature or pressure. Process constraints  $\mathbf{g}_3$  and  $\mathbf{g}_4$  typically enforce bounds on the flowrates, operating temperature, and pressure. These also include mass, energy, and momentum balances of the following form:

$$\sum_{i \in Inlet} x_i = \alpha_k \sum_{i \in Outlet} x_i \quad \forall k \quad (4)$$

where for a separation unit  $k$ ,  $\alpha_k$  is the separation efficiency that is dictated by the choice of ILs. The linking constraints  $\mathbf{g}_5$  and  $\mathbf{g}_6$  relate the process level performance with the material selection, and can take the form as follows:

$$\beta_i = \frac{1}{\gamma_i^\infty} \times \frac{MW_i}{MW_{IL}} \geq \beta_{min} \quad (5)$$

$$S_{ij} = \frac{\beta_j^\infty}{\beta_i^\infty} \geq S_{min} \quad (6)$$

The distribution coefficient ( $\beta_i$ ) and selectivity ( $S_{ij}$ ) can be obtained through a VLE model and are linked with the IL design through the molecular weight,  $MW_{IL}$ . Finally, the objective function can be a nonlinear function of the process streams to minimize the overall cost. Therefore, the overall CAMPD model can be posed as a mixed-integer nonlinear program (MINLP) involving nonlinearities and nonconvexities across multiple scales making them challenging to solve.

## SOLVING MIXED-INTEGER PROGRAMS USING QUANTUM COMPUTING

We will first assume a quadratic approximation of all nonlinear models, making the overall CAMPD a mixed-integer quadratically constrained quadratic program (MIQCQP). Then, we will demonstrate the reformulation of MIQCQP to QUBO. Finally, we will extend it to a class of MINLP by introducing nonlinear encoding.

Assume that the vectors of all material and process level variables ( $\mathbf{x}_d^{mat}$ ,  $\mathbf{x}_p^{mat}$ ,  $\mathbf{x}_d^{process}$ ,  $\mathbf{x}_p^{process}$ ) are aggregated in a vector  $\mathbf{x}$ . We can then express the CAMPD (under quadratic approximation, MIQCQP) in a compact form as follows:

$$\begin{aligned} \min_{\mathbf{x}} \quad & \mathbf{x}^T \mathbf{H} \mathbf{x} + \mathbf{c}^T \mathbf{x} \\ \text{s.t.} \quad & \mathbf{x}^T \mathbf{C}_k \mathbf{x} + \mathbf{a}_k^T \mathbf{x} \leq b_k, \quad k = 1, \dots, u \\ & \mathbf{x} \in \mathbb{R}^n \times \mathbb{Z}^p, \end{aligned} \quad (P2)$$

where  $\mathbf{H} \in \mathbb{R}^{(n+p) \times (n+p)}$  is a symmetric matrix of real constants,  $\mathbf{c} \in \mathbb{R}^{(n+p)}$ ,  $\mathbf{C}_k \in \mathbb{R}^{(n+p) \times (n+p)}$ ,  $\mathbf{a}_k \in \mathbb{R}^{(n+p)}$ , and  $b_k \in \mathbb{R}$ .

### Encoding

To solve the model (P2) using QC, it first needs to be reformulated to a QUBO. For that, we utilize several encoding schemes for an approximate representation of both the continuous and integer variables in terms of binary variables. To illustrate this, let  $x_m \in \mathbb{R}$ , with  $x_m^L \leq x_m \leq x_m^U$ . It can then be scaled to  $\tilde{x}_m \in \mathbb{R}$  with  $0 \leq \tilde{x}_m \leq 1$  as follows:

$$x_m = x_m^L + (x_m^U - x_m^L) \tilde{x}_m \quad (7)$$

Then  $\tilde{x}_m$  can be approximately represented by the binary variables using unary encoding as follows [24]:

$$\tilde{x}_m \approx \sum_{j=1}^J \sum_{i=1}^9 10^{-j} z_{i,j,m} + 10^{-J} z_m, \quad (8)$$

where  $z_{i,j,m} \in \{0,1\}$ , and  $J$  is the number of decimal places. To illustrate this, consider  $\tilde{x}_m = 0.342$ . For  $J = 3$ , we can write  $\tilde{x}_m = 10^{-1}(z_{1,1,m} + \dots + z_{9,1,m}) + 10^{-2}(z_{1,2,m} + \dots + z_{9,2,m}) + 10^{-3}(z_{1,3,m} + \dots + z_{9,3,m})$ . The number of binary variables to represent  $\tilde{x}_m$  can be reduced by using a binary encoding as follows:

$$\tilde{x}_m \approx \sum_{j=1}^J 10^{-j} (z_{1,j,m} + 2z_{2,j,m} + 3z_{3,j,m} + 3z_{4,j,m}) + 10^{-J} z_m \quad (9)$$

For an integer variable, that is,  $x_m \in \mathbb{Z}$  let  $I$  be the least positive integer such that  $2^I \geq |x_m|$ . Then, using binary encoding,  $|x_m| = \sum_{i=1}^I 2^i z_{i,m}$ , where  $z_{i,m} \in \{0,1\}$ .

### Reformulating Mixed-Integer Quadratic Program with Linear Constraints to QUBO

Let us first consider a mixed-integer quadratic

program with linear constraints (MIQP) by setting  $C_k = [0]^{(n+p) \times (n+p)}$ . Then (P2) can be written as:

$$\begin{aligned} \min_{\mathbf{x}} \quad & \mathbf{x}^T \mathbf{H} \mathbf{x} + \mathbf{c}^T \mathbf{x} \\ \text{s.t.} \quad & \mathbf{A} \mathbf{x} \leq \mathbf{b}, \\ & \mathbf{x} \in \mathbb{R}^n \times \mathbb{Z}^p, \end{aligned} \quad (\text{P3})$$

where  $\mathbf{A} \in \mathbb{R}^{u \times (n+p)}$  and  $\mathbf{b} \in \mathbb{R}^u$ . At first, we convert all inequality constraints into equalities by adding slack variables ( $\mathbf{s}$ ) to each constraint. Then we add a quadratic penalty to the objective function by introducing penalty parameters ( $\lambda$ ), as follows:

$$\min \mathbf{x}^T \mathbf{H} \mathbf{x} + \mathbf{c}^T \mathbf{x} + \lambda^T (\mathbf{A} \mathbf{x} - \mathbf{b} + \mathbf{s})^T (\mathbf{A} \mathbf{x} - \mathbf{b} + \mathbf{s}) \quad (10)$$

where  $\lambda \in \mathbb{R}^{u \times u}$ , and  $\mathbf{s} \in \mathbb{R}^{u \times u}$ . We scale the continuous variables  $\{x_m\}_{m=1}^n$  and  $\{s_v\}_{v=1}^u$  to  $\{\tilde{x}_m\}_{m=1}^n$  and  $\{\tilde{s}_v\}_{v=1}^u$ , respectively with  $0 \leq \tilde{x}_m, \tilde{s}_v \leq 1$ . Note that,  $s_v^L = 0, \forall v \in u$ , and  $s_v^U$  can be calculated as follows:

$$s_v^U = \begin{cases} b_v - x_m^L A_{vm}, & \text{if } A_{vm} \geq 0 \\ b_v - x_m^U A_{vm}, & \text{otherwise} \end{cases} \quad (11)$$

After scaling, Equation (10) can be expressed in terms of scaled variables as follows:

$$\min \tilde{\mathbf{x}}^T \tilde{\mathbf{H}} \tilde{\mathbf{x}} + \tilde{\mathbf{c}}^T \tilde{\mathbf{x}}, \quad (12)$$

where  $\tilde{\mathbf{H}} \in \mathbb{R}^{(n+p+u) \times (n+p+u)}$ ,  $\tilde{\mathbf{c}} \in \mathbb{R}^{n+p+u}$ , and  $\tilde{\mathbf{x}} \in \mathbb{R}^{n+p+u}$  with  $\tilde{\mathbf{x}} = [[\tilde{x}_1, \dots, \tilde{x}_n] \quad [\tilde{x}_{n+1}, \dots, \tilde{x}_{n+p}] \quad [\tilde{s}_1, \dots, \tilde{s}_u]]$ , where the first  $n$  decision variables are continuous, the next  $p$  variables are binary, and the remaining  $u$  variables are slack variables. We then represent all these scaled variables using unary or binary encoding, and finally reformulate as QUBO as follows:

$$\begin{aligned} \min_{\mathbf{z}} \quad & \mathbf{z}^T \mathbf{Q} \mathbf{z} \\ \text{s.t.} \quad & \mathbf{z} = \{0,1\}^\beta, \end{aligned} \quad (\text{P4})$$

where  $\mathbf{Q} \in \mathbb{R}^{\beta \times \beta}$  and  $\beta = (n+u) \cdot (9J+1) + p$  and  $(n+u) \cdot (4J+1) + p$  for unary and binary encoding, respectively. Thus, the original  $n+p$  dimensional MIQP (P3) is reformulated into a  $\beta$  dimensional QUBO.

## Reformulating Mixed-Integer Quadratically Constrained Quadratic Program to QUBO

Reformulating a mixed-integer quadratically constrained quadratic program (MIQCQP) to QUBO involves two steps. In the first step, we reformulate MIQCQP to an MIQP. In the second step, we follow the steps described in the previous section to convert the reformulated MIQP to QUBO. For Step 1 we introduce additional binary variables to substitute binary quadratic terms that appear in the constraints and for each of them, add an equivalent penalty function,  $f$  to the objective function as follows:

$$f = P(3w - 2z_1w - 2z_2w + z_1z_2) \quad (13)$$

where,  $w = z_1z_2$ , and  $w, z_1, z_2 \in \{0,1\}$ .  $z_1z_2$  is a binary

quadratic term that appears in the constraint, and  $P \in \mathbb{R}_+$  is a penalty parameter. As shown in Table 1, for a feasible configuration of  $z_1, z_2$ , and  $w$ ,  $f = 0$  whereas infeasible configuration implies  $f > 0$ .

**Table 1:** Penalty function for MIQCQP

$z_1$	$z_2$	$w$	$f$
1	1	1	0
1	1	0	$> 0$
1	0	0	0
1	0	1	$> 0$
0	1	0	0
0	1	1	$> 0$
0	0	0	0
0	0	1	$> 0$

## Illustrative Example

$$\begin{aligned} \min_{x_1, y_1, y_2} \quad & -2x_1y_1 + y_2^2 \\ \text{s.t.} \quad & x_1 + y_1y_2 \leq 1, \\ & 0 \leq x_1 \leq 1; y_1, y_2 \in \{0,1\} \end{aligned} \quad (\text{P5})$$

We substitute  $y_1y_2$  in the constraint by defining  $w = y_1y_2$ , and add the penalty to the objective as follows:

$$\begin{aligned} \min_{x_1, y_1, y_2, w} \quad & -2x_1y_1 + y_2^2 + P(3w - 2y_1w - 2y_2w + y_1y_2) \\ \text{s.t.} \quad & x_1 + w \leq 1, \\ & 0 \leq x_1 \leq 1; w, y_1, y_2 \in \{0,1\} \end{aligned} \quad (\text{P6})$$

Here, Problem P6 is an MIQP with linear constraints. We then encode the continuous variables using binary encoding:

$$\begin{aligned} \min \quad & -2\{10^{-1}(z_{111} + 2z_{211} + 3z_{311} + 3z_{411}) + z_1\}y_1 + y_2 \\ & + P(3w - 2y_1w - 2y_2w + y_1y_2) \\ \text{s.t.} \quad & 10^{-1}(z_{111} + 2z_{211} + 3z_{311} + 3z_{411}) + z_1 + w \leq 1, \\ & z_{111}, z_{211}, z_{311}, z_{411}, z_1, w, y_1, y_2 \in \{0,1\} \end{aligned} \quad (\text{P7})$$

Here, Problem (P7) is a binary quadratic program with linear constraints whose equivalent QUBO model is constructed with the  $\mathbf{Q}$  matrix given in Table 2. For  $J = 1$ ,  $\mathbf{Q} \in \mathbb{R}^{13 \times 13}$  with the last 5 binary variables used to encode the slack variable that corresponds to the constraint. We set  $P = 10$ , and solve the resulting QUBO in D-Wave's quantum annealer [25], and obtain the optimal solution:  $x_1^* = 1, y_1^* = 1, y_2^* = 0$ .

## Encoding Nonlinear Terms

Assume that the CAMPD model consists of terms such as  $\tilde{x}_m^a$ , where  $a \in \mathbb{R}$ . We can then encode this nonlinear term using the same binary variables corresponding to  $\tilde{x}_m$  as follows:

$$\tilde{x}_m^a \approx \sum_{j=1}^J \sum_{i=1}^9 P_{i,j,m} z_{i,j,m} + Q_m z_m, \quad (14)$$

$$z_{i+1,j,m} \leq z_{i,j,m} \quad \forall i = 1, 2, \dots, |I|, j = 1, 2, \dots, |J| \quad (15)$$

Note that the constraints corresponding to Equation (15) have an exact penalty function that can be added to the objective as follows:  $\sum_{j=1}^J \sum_{i=1}^8 P(z_{i+1,j,m} - z_{i,j,m} \cdot z_{i,j,m})$ . Also note that, the parameters  $P_{i,j,m}$  and  $Q_m$  can be precomputed for all instances of  $\tilde{x}_m^a$  since  $a$  is known. Specifically, consider  $J = 1$ . This implies  $\tilde{x}_m = \sum_{i=1}^9 0.1 z_{i,1,m} + 0.1 z_m$ . Then,  $\tilde{x}_m^a = \sum_{i=1}^9 P_{i,1,m} z_{i,1,m} + Q_m z_m$ , where  $P_{i,1,m} = \gamma_{i,1,m} - \gamma_{i-1,1,m} \quad \forall i \in I$ .  $\gamma_{0,1,m} = 0$ , and  $Q_m = 1 - \gamma_{9,1,m}$ , where  $\gamma_{i,1,m} = (0.1i)^a$ . To illustrate, assume that  $\tilde{x}_m$  takes the value 0.3. Then Equation (14) and (15) together ensures that the only valid solution is  $z_{1,1,m} = z_{2,1,m} = z_{3,1,m} = 1$  and the others are 0. This then enforces  $\tilde{x}_m^a = \gamma_{3,1,m} = (0.1 \cdot 3)^a = (0.3)^a$ , as desired.

We can further encode other nonlinear terms that can be approximately expressed in terms of  $\tilde{x}_m^a$ , e.g.,  $\exp(x)$ ,  $\log(x)$ ,  $\sin(x)$ ,  $\cos(x)$ ,  $\log(1+x)$  and  $\log(x)$  using McLaurin expansion. Finally, we can also encode general nonlinear product terms such as  $\prod_m \tilde{x}_m^{a_m}$  using the exp-log-sum technique by encoding  $\exp(\sum_m a_m \log \tilde{x}_m)$ , thereby allowing to reformulate MINLP with signomial terms to QUBO.

## INTEGRATED IL SELECTION AND CONFIGURATION OF REACTOR SEPARATOR NETWORK

We formulate and solve a reactor-separator network synthesis problem with integrated IL selection as shown in Figure 1. The separator performance depends on the choice of ILs, thus making the overall problem a CAMPD. In this illustrative case study, we assume that the selection of ILs is made by choosing one anion and one cation from a pool of anions and cations. Formally, consider  $Cat = \{c_1, c_2, \dots, c_C\}$  and  $An = \{a_1, a_2, \dots, a_A\}$ . Then all possible feasible ILs are constructed by  $IL = \{c \times a \mid c \in Cat, a \in An\}$ . With this construction, we formulate the following optimization model that integrates the selection of ILs with the synthesis of the reactor-separator network.

$$\begin{aligned} \min \quad & \sum_{k \in K} c_k^f y_k + \sum_{i \in I_{K_r}^{in}} c_i^f x_i^{0.6} \\ & + \sum_{k \in K_s} c_k^l \left( \sum_{i \in I_{K_s}^{in}} x_i \right)^2 \\ & + \sum_{k \in K_s} c_k^e \left( \sum_{i \in I_{K_s}^{in}} x_i - \sum_{i \in I_{K_s}^{out}} x_i \right) \\ \text{s.t.} \quad & f_k^l y_k \leq \sum_{i \in I_{K_s}^{in}} x_i \leq f_k^u y_k, \quad \forall k \in K \end{aligned} \quad (P8)$$

$$\sum_{i \in I_{K_r}^{out}} x_i = \alpha_k \sum_{i \in I_{K_r}^{in}} x_i, \quad \forall k \in K_r$$

$$\sum_{c \in Cat} z_c = 1$$

$$\sum_{a \in An} z_a = 1$$

$$x_i \geq \beta_{k,c,a} \sum_{i \in I_{K_s}^{in}} x_i - M(2 - z_c - z_a), \\ \forall i \in I_{K_s}^{out}, k \in K_s, c \in Cat, a \in An$$

$$x_i \leq \beta_{k,c,a} \sum_{i \in I_{K_s}^{in}} x_i + M(2 - z_c - z_a), \\ \forall i \in I_{K_s}^{out}, k \in K_s, c \in Cat, a \in An$$

$$\sum_{i \in I_{K_s}^{out}} x_i \geq d,$$

where  $K$  is the set of all process units,  $K_r, K_s \subset K$  are the sets of all reactors and separators, respectively.  $\alpha_k$  is the stoichiometric reactor conversion factor for a reactor  $k$ ,  $\beta_{k,c,a}$  is the separation factor for a separator  $k$  with an IL constructed by cation  $c$  and anion  $a$ .  $I_{K_s}^{in}$  and  $I_{K_s}^{out}$  are the set of all inlet and outlet streams, respectively, and  $d$  is the demand. The decision variables involve all the flowrate streams  $x_i$  and the selection of cation and anion,  $z_c$  and  $z_a$ , respectively. The objective is to minimize the overall cost that includes the fixed cost, investment cost, operating cost, and cost associated with emissions or waste.  $c_k^f$  are coefficients for fixed cost;  $c_i^f$  and  $c_k^l$  are coefficients for operating cost for reactors and separators, respectively; and  $c_k^e$  are coefficients for the cost associated with waste or emission. The first constraint is related to the unit selection and flowrate bounds. The second constraint is for the overall mass balance around the reactors. The third and fourth constraints ensure that a feasible IL is constructed by choosing only one cation and one anion. The fifth and sixth constraints relate the output flows from the separators to the IL selection. In this way, the effect of the material selection on the process performance is captured. The final constraint ensures that the sum of all output flows must satisfy the demand. The overall problem involves both binary and continuous variables. We solve the optimization problem using a quantum annealer and compare the solution against a deterministic solver that uses classical computing. All the quantum computation is performed on D-Wave's LeapHybrid solver, and the results are compared to that of a deterministic solver (BARON v44.2) run on a Dell Windows system with Intel(R) Core (TM) i7-8750 2.20 GHz CPU and 16 GB RAM.

We select an initial pool of two cations and two anions. The goal is to select the best IL from the cation and anion pool, as well as to select the best reactor-separator network from two reactors and three separators. For that,

**Figure 1:** Schematic of an integrated IL selection and reactor-separator network

the parameters used are as follows:  $\beta_{1,1,1} = 0.7, \beta_{1,1,2} = 0.9, \beta_{1,2,1} = 0.8, \beta_{1,2,2} = 0.9, \beta_{2,1,1} = 0.8, \beta_{2,1,2} = 0.7, \beta_{2,2,1} = 0.9, \beta_{2,2,2} = 0.6, \beta_{3,1,1} = 0.9, \beta_{3,1,2} = 0.6, \beta_{3,2,1} = 0.7, \beta_{3,2,2} = 0.9$ . The conversion factors for the two reactors are:  $\alpha_1 = 0.8, \alpha_2 = 0.9$ . Cost parameters in the objective function are as follows:  $c_1^f = 10, c_2^f = 15, c_3^f = 8, c_4^f = 9, c_5^f = 10$ . Operating cost parameters for the reactors are  $[0.5, 0.7]$ . Operating cost parameters for the separators are  $[0.2, 0.7, 0.5]$ . Emission cost parameters for the separators are  $[1.2, 1.5, 0.9]$ . The upper bound on the flowrate for all streams (see Figure 1) is 2. This results in a MINLP with 39 constraints. Using these model parameters, we first

solve the optimization model in GAMS using BARON v44.2. The optimal objective and the network selections are as follows:  $f_{obj} = 46.009, y_1 = 1, y_2 = 1, y_3 = 1, y_4 = 1, y_5 = 0, z_1^{cation} = 0, z_2^{cation} = 1, z_1^{anion} = 1, z_2^{anion} = 0$ . The optimal IL is constructed by combining the 2<sup>nd</sup> cation with the 1<sup>st</sup> anion. Also, both reactors are selected, and only the first and the second separators are selected.

We then solve the same optimization model in D-Wave's LeapHybrid solver. For that, we first eliminate the constraints for anion and cation selection, that is,  $\sum_{c \in Cat} z_c = 1$  and  $\sum_{a \in An} z_a = 1$ , by observing that, for  $|Cat| = |An| = 2$ , an exact penalty function  $P(1 - z_1 - z_2 +$

$2z_1z_2$ ) can be achieved, where  $P$  is a penalty parameter whose value is set to 2. After removing the two constraints and adding the equivalent penalties to the objective, we now have a reduced MINLP with 37 constraints. We then reformulate it to QUBO by adding a quadratic penalty to the objective function and representing continuous variables by unary encoding ( $J = 5$ ). We obtain a feasible solution as follows:  $f_{obj} = 58.369, y_1 = 1, y_2 = 1, y_3 = 1, y_4 = 1, y_5 = 1, z_1^{cation} = 0, z_2^{cation} = 1, z_1^{anion} = 0, z_2^{anion} = 1$ . From the results, we can observe that all the process units are selected resulting in a higher value for the objective. However, it confirms that it is possible to obtain good feasible solutions using QC.

## CONCLUSIONS

We have developed a technique for solving mixed-integer programs using Quantum Computing (QC) that allows us to solve Computer-aided Molecular and Process Design (CAMPD) problems. Our methodology utilizes efficient encoding schemes and transforms a class of Mixed-Integer Nonlinear Programs into Quadratic Unconstrained Binary Optimization (QUBO) models, thus making them possible to solve using QC platforms. We demonstrate the framework for the selection of optimal ionic liquid and configuration of a reactor-separator process with promising results suggesting QC's potential to solve CAMPD problems. However, scalability and applicability to large-scale industrial problems remain a challenge for the quantum optimization-based approach. Also, the solution quality and feasibility of the QC solution heavily depend upon the penalty parameter. Ongoing works include the decomposition of CAMPD models as well as the QUBO matrix by exploiting their structure, thus enabling the solution to larger CAMPD problems.

## ABSTRACT

We present a string representation for hybrid extraction and distillation using symbols representing phenomena building blocks. Unlike the conventional equipment-based string representation, the proposed representation captures the design details of liquid-liquid extraction and distillation. We generate a set of samples through the procedure of input parameter sampling and superstructure optimization that minimizes separation cost. We convert these generated samples into a set of string representations based on pre-defined rules. We use these string representations as descriptors and connect them with conditional variational encoder. The trained conditional variational encoder shows good prediction accuracy. We further use the trained conditional variational encoder to screen designs of hybrid extraction and distillation with desired cost investment.

**Keywords:** Extraction, Distillation, Machine Learning, Process Intensification

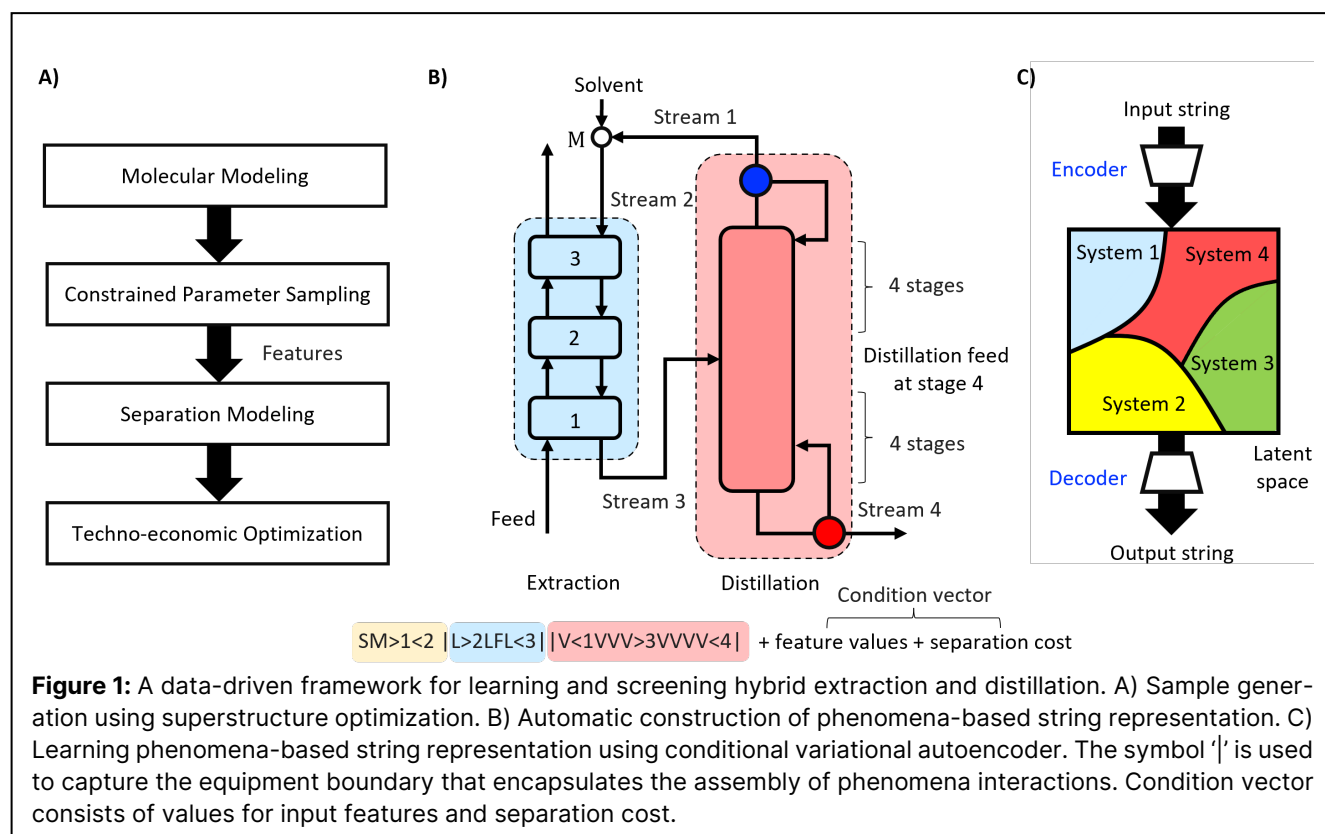

## INTRODUCTION

Separation design is critical for plastic upcycling, biomass valorization, carbon capture and utilization [1-3]. Liquid-liquid extraction and distillation are two commonly used separation methods. Hybrid extraction and distillation further reduces material and energy consumption by leveraging driving forces of solubility difference and volatility difference, which leads to process intensification [4-6]. Global optimization of hybrid extraction and distillation has been reported [7]. To reduce the computational efforts, machine learning shows promise to identify optimal hybrid extraction and distillation design with desired separation cost using machine-readable representations [8]. These motivate the research into constructing machine-readable data representation for learning flowsheets with design details and screening flowsheets that meet design objectives.

Construction of machine-readable representation is an active area in the field of machine learning. Development of such data representation with physical interpretation requires domain knowledge. In the field of molecular modeling, starting from SMILES (Simplified Molecular Input Line Entry System) [9], diverse and inclusive string representations have been reported. These include INCHI strings for standardized searching across databases

and the internet, DEEPSMILES for automated inverse design using deep generative models, CurlySMILES for macromolecules, and BigSMILES for polymers among others [9-13]. These string representations for molecules are constructed based on the molecular structure information such as atoms and their connections (SMILES) [9], information on tautomer, isotope, stereochemistry, and electronic charge (INCHI strings) [10], information on molecular details and extra-molecular features such as non-covalent interactions, surface attachment, solutions, and crystal structures (CurlySMILES) [12], and stochastic object that represents a molecule fragment that is stochastic in the molecular structure (BigSMILES) [13]. In the field of process modeling, d'Anterrosches and Gani proposed SFILES (simplified flowsheet-input line-entry system) using equipment-based flowsheet building blocks [14], which enables the flowsheet similarity comparison in the work of Zhang et al [15]. SFLIES has been recently extended to SFILES2.0 that describes top and bottom products, and the control structure [16] and to eSFILES that integrates process engineering domain knowledge and machine learning [17]. Despite the success in constructing string representation based on equipment, limited representations exist that capture design details and enable the identification of novel design opportunities.

Once these string representations are constructed

as descriptors and the corresponding training samples are generated, these samples are often related with design objectives through machine learning models. In the field of molecular modeling, commonly used machine learning models include graph neural network (GNN) [18], variational autoencoder (VAE) [19], and conditional variational autoencoder (CVAE) [20]. GNNs take molecular graphs as inputs and perform convolutions based on the graph topology by aggregating the features of a node and its connected neighbors. The node features are embedded into a fixed-dimension space where similar nodes are close to each other. VAEs generalize autoencoders, add stochasticity to the encoder which is combined with a penalty term, and encourage all areas of the latent space to correspond to a valid decoding. To identify the optimal molecule structures, VAEs are often jointly trained with a property prediction model [19]. CVAEs distinguish from the VAEs by imposing certain conditions in the encoding and decoding processes and do not require further optimization during the search of new molecular design, which is required for the framework with VAE and an additional neural network jointly trained [21].

In this work, with a novel phenomena-based string representation, we develop a data-driven framework for learning and screening the design details of hybrid extraction and distillation. Firstly, to generate data for automatic construction of phenomena-based string representation, we use superstructure optimization by

modeling hybrid extraction and distillation based on state-by-stage model for extraction column and shortcut model for distillation column. Then, these models are solved to global optimality with sampled input feature vectors to obtain minimum separation cost. These input feature vectors are sampled from the thermodynamic space approximated using Conductor-like Screening Model for Real Solvents (COSMO-RS) and molecular dynamics simulation [3]. We define rules for constructing the string representation with information on the phenomena nodes, equipment boundary, and equipment connections, which is extracted from the solution of superstructure optimization. These phenomena-based string representations are learned using conditional variational autoencoder, where new designs that meet desired cost investment are sampled from the latent space.

## PROBLEM STATEMENT

We consider the hybrid extraction and distillation systems with the following processing conditions: (1) the feed stream only contains water and one product while other components are neglected, and (2) the liquid-liquid extraction and distillation enrich product into a product stream from a ternary system of product (P), water (W), and solvent (S).

Given are (1) specification on the feed stream (i.e., product mole fraction in feed), (2) specifications on the product stream (i.e., total product flowrate, product

recovery from the feed, and product purity), (3) physical properties (liquid-liquid equilibrium constants, relative volatilities), (4) cost coefficients used for determining capital and operating costs of liquid-liquid extraction and distillation (solvent price is an operating cost coefficient for extraction), and (5) the maximum number of liquid-liquid extraction stages. The assumptions in this work include that: (1) we consider ternary systems where the product mole fraction is low such that liquid-liquid equilibrium constants are composition-independent and are identical at all stages of liquid-liquid extraction column, and (2) we consider distillation of near-ideal mixtures, allowing us to assume constant relative volatility.

The goal of this work is to construct a string representation with information on physicochemical phenomena, stream connections, and equipment boundary. With the proposed string representation, we use conditional variational autoencoder to map the discrete separation design space to a continuous latent space. This enables fast sampling within the latent space to screen designs of hybrid extraction and distillation that meets desired cost investment.

## COMPUTATIONAL FRAMEWORK

In this Section, we describe the computational framework for learning and screening hybrid extraction and distillation (Figure 1). This framework consists of (1) sample generation using superstructure optimization, (2) automatic construction of phenomena-based string representation, and (3) learning phenomena-based string representation using conditional variational autoencoder. With the trained conditional variational encoder, we sample within the latent space to screen designs of hybrid extraction and distillation.

### Sample Generation using Superstructure Optimization

To generate the flowsheet samples with design details, we adapted the workflow of integrated molecular modeling and process modeling from Li et al. to the reduced framework (shown in Figure 1A) [22]. Here, we used superstructure model as the first-principle model to generate flowsheet samples with detailed design information. Specifically, we used this framework to (1) predict a physically reasonable space of thermodynamic properties, (2) generate feature vectors by sampling within the space of thermodynamic properties and ranges of feature values, and (3) separation modeling and optimization to obtain the costs and design details of hybrid extraction and distillation for the sampled feature vectors.

The representation, modeling, and optimization of hybrid extraction and distillation were achieved using classic superstructure optimization [23]. The

representation of hybrid extraction and distillation involves stage-by-stage representation of liquid-liquid extraction column, equipment-based representation of distillation column, which were modeled using a shortcut model (detailed design information is extracted following the procedure described in the next subsection), and their stream connections [22]. This representation was modeled as a mixed-integer nonlinear programming (MINLP) problem. Discrete decisions are made on the activation of liquid-liquid extraction stages and the use of the second potential distillation column. We used both stage-by-stage model (for liquid-liquid extraction column) and shortcut Underwood-Fenske model (for distillation column) to balance the accuracy of separation physics and tractability of the proposed mathematical model [22]. The specifications for all hybrid extraction and distillation systems are (1) total product flowrate of 1 kmol/s, (2) 95% product purity, and (3) 90% product recovery. Each MINLP model were solved using BARON for each input feature vector with 1% optimality gap and within 5 CPU hours, using parallel computing resources [24].

In this work, we considered the input features as liquid-liquid equilibrium constants of solvent ( $\kappa_S$ ) and product ( $\kappa_P$ ), relative volatility between water and product ( $\alpha_{W,P}$ ), relative volatility between solvent and product ( $\alpha_{S,P}$ ), and solvent price ( $\pi_S$ ). Here, W, S, P are water, solvent, and product respectively. The bounds for these features are [1, 1000], [1, 50], [1.1, 2], [50, 6000] (\$ per kmol solvent) respectively to focus on a property region with difficult distillation. Liquid-liquid equilibrium constant of water was fixed at 0.01. We considered the product mole fraction as 0.1. Through this adapted framework, we prepared and generated 10,000 samples with values of input features, separation cost, and their corresponding *.st* files containing design details. 9816 samples remain after removing infeasible samples.

### Automatic Construction of Phenomena-based String Representation

Phenomena building blocks enable the identification of novel design opportunities and capture detailed design information compared with equipment-based process design and synthesis [25-27]. We leveraged phenomena building blocks to construct a string representation for learning and screening flowsheets.

We followed the rule of constructing SMILES and considered the criterion of leveraging information that uniquely and discretely represents the solutions of hybrid extraction and distillation models, which are obtained in the previous subsection. Following this criterion, we focus on the identity of physicochemical phenomena nodes and their connections. Specifically, we considered physicochemical phenomena as mixing (M), liquid-liquid phase equilibrium (L), and vapor-liquid phase equilibrium

(V) and constructed separation flowsheet strings with nodes as phenomena for each sample (Figure 1B). We did not consider other common factors for all samples such as system specifications (total product flowrate, product purity, and product recovery) and generic postulated superstructure representation with all equipment options (technology availability) in the proposed string representations since all optimal solutions are obtained based on these specifications and from the same search space represented by the superstructure. Moreover, since we solved each MINLP model to global optimality, we did not consider the initial conditions of solutions in the proposed string representation.

Note that the distillation column is modeled using equipment-based shortcut model and hence only equipment-wide design information can be obtained, which does not include the information on the position of feed stage. To obtain this information, based on the optimal solution for the MINLP model, we used Kirkbride equation [28] to determine the ratio of the number of stages above and below the feed stage. Based on this ratio and the total number of stage number in the distillation column, we located the position of feed stage and part of the python script is shown as follows:

```
def kirkbride(B, D, xFHK, xFLK, xBLK, xDHK):
    lnDB = 0.206*np.log(B/D*xFHK/xFLK*(xBLK/
    xDHK)**2)
    return np.exp(lnDB)
```

Here, the input B, D, xFHK, xFLK, xBLK, and xDHK for the above function are values of bottom flow rate, flow rate of distillate stream, composition of heavy key component in the feed stream, composition of light key component in the feed stream, composition of light key component in the bottom stream, and composition of heavy key component in the distillate stream of the distillation column. The output  $\text{np.exp}(\ln\text{DB})$  is the ratio of the number of stages above and below the feed stage.

The other key components of the proposed string representation are (1) integer number to label different connecting streams, (2) symbol '>' to represent inlet streams for equipment, (3) symbol '<' to represent outlet streams for equipment, and (4) symbol '|' to represent the first or the last stage of equipment to represent equipment boundary, which encapsulates all involved physico-chemical phenomena within certain equipment. Symbols '>' and '<' are always placed next to the right of phenomena nodes where stream connections exist. Multiple stream connections on the same phenomena node are ranked based on the index of stream connection. An example is illustrated in Figure 1B. Firstly, the solution in Figure 1B shows a mixer connected with an inlet solvent (S) stream, inlet stream 1, and outlet stream 2. This gives a substring as SM>1<2. Moreover, the liquid-liquid extraction column contains 3 stages with feed stream supplied

on stage 1. The liquid-liquid extraction column connects with inlet stream 2 on stage 3 and connects with outlet stream 3 on stage 1. This gives a substring as |L>2LFL<3|. Furthermore, the distillation column involves 8 stages with the 4th stage as a feed stage, top stream connected with outlet stream 1, and bottom stream connected with outlet stream 4. Inlet stream 3 enters feed stage. This gives a substring as |V<1VVV>3VVVV<4|. Following the ascending order of stream index, we combine these three substrings, which gives the full string representation for the hybrid extraction and distillation system in Figure 1B. The construction procedure is automatically enabled through a python script with part of codes shown as follows:

```
a = 0
Next = []
open('file_name.lst', 'rt') as f:
    data = f.readlines()
for line in data:
    if line.__contains__('---- VAR Next '):
        num=re.findall("(?<=[AZaz])?(?!\\d*)"[0-9.-+]"",data[a])[3]
        Next.append(num)
    a=a+1
if (Next == []):
    Next=['0']
if (float(Next[-1]) >= 0):
    string = '|L'+>2'+L'+*(int(float(Next[-1]))-2)+'FL<3|'
```

Here, file\_name.lst is the *.lst* file containing the optimal solution of hybrid extraction and distillation model for each sampled feature vectors. The symbol 'Next' is the variable for the stage number of liquid-liquid extraction column in the *.lst* file, which represents the multiplicity of 'L' nodes in the string representation. With the developed python script, we converted 9816 samples obtained in the previous section into a data set with 9816 hybrid extraction and distillation flowsheets represented by phenomena-based strings. Note that the substring of S(M)>1<2 exists for all samples in this work, and hence this substring is redundant. Computational comparison suggests that removing this substring improves the

performance of training CAVE. In the result interpretation, we appended this substring at the beginning of generated string representation.

**Figure 2:** Distribution of separation cost in the full dataset (9816 samples).

Figure 2 illustrates the distribution of separation cost in the full dataset. Most samples involve separation cost ranging from \$20 per kmol product to \$80 per kmol product, which indicates economical separation using hybrid extraction and distillation for a feed with product mole fraction of 0.1. Note that the constant relative volatility assumption does not extend the current work to separation systems with azeotropes due to challenges in sample generation. Future work to allow the sample generation and construction of string representations for systems with azeotropes involves: (1) replacing the features of relative volatility with the features of parameters or grouped parameters in activity coefficient model (e.g., Wilson model and UNIQUAC model) to account for non-ideality in the liquid phase [6], (2) enumeration of representative separation structures that allow azeotropic distillation, and (3) modeling the azeotropic distillation using stage-by-stage model.

### Learning phenomena-based string representation using CVAE

With the phenomena-based string representation constructed in the previous subsection, we canonicalize each representation by adding 'E' at the end of string representation. We combine all strings with 'E' into an input matrix. Each entry of the input matrix is converted to an entry with the size of 200 by adding 'E'. Then, each entry is combined with a condition vector, which results in the final string. We fill the sampled values for  $\kappa_S$ ,  $\kappa_P$ ,  $\alpha_{W,P}$ ,  $\alpha_{S,P}$ ,  $\pi_S$ , and the cost of hybrid extraction and distillation into the condition vector (shown in the bottom of Figure 1B). The condition vector represents the known thermodynamic properties, solvent price, and cost value for an optimized hybrid extraction and distillation system. We combine all final strings with condition vectors into the processed input matrix.

The processed input matrix is related with the encoder of the CVAE to generate a latent space (Figure 1C). We used the recurrent neural network (RNN) with the long short-term memory (LSTM) cell for both the encoder and decoder of the CVAE [29]. The architecture of the RNN consists of (1) 3-layer and (2) 500 hidden nodes on each layer. A layer with softmax function was used in each output of the decoder cell. The latent vector combined with the condition vector becomes an input of the decoder at each time step of the RNN cell. Finally, the output vector of each decoder cell was converted to a vector whose size is identical to that of the vector of the

input matrix. The softmax activation function was applied to each converted vector. The loss function of CVAE is given as follows [20]:

$$E[\log P(X|z, c)] - D_{KL}[Q(z|X, c) \parallel P(z|c)] \quad (1)$$

Here,  $E(f)$  represents the expectation value of function  $f$ .  $P$  and  $Q$  are probability distributions.  $D_{KL}$  is the kullback-leibler (KL) divergence.  $X$ ,  $z$ , and  $c$  indicate the data, latent space, and condition vector respectively. The first term is reconstruction error, and the second term is a regularization term that minimizes the KL-divergence between the variational and true encoders. We used cross entropy in the reconstruction error term of the cost function. To generate a flowsheet for hybrid extraction and distillation with given input feature values and desired separation cost imposed by the condition vector, the cell of the RNN decoder was unrolled for 200 times. The result was considered as invalid if the following conditions exist: (1) no 'L' exists within the 200 characters, (2) no 'V' exists within the 200 characters, (3) no 'E' exists within the 200 characters, (4) no '|' exists on the left side of the first 'L' symbol, and (5) no '|' exists on the right side of the last 'V' symbol. Each output vector of the decoder cell represents the probability distribution of the characters of the proposed phenomena-based representation and 'E'. Finally, the output vector was converted to the phenomena-based string representation. We implemented CVAE using TensorFlow 1.14.0 [30].

We set hyperparameters as follows: (1) 80 % of total samples are used for training and the remaining samples are used for test, and (2) the learning rate was set as 0.0001 and exponentially decayed at a rate of 0.97. The model was trained within 250 epochs. Figure 3 gives the

update of loss function values on training and test sets.

**Figure 3:** Update of loss function values of conditional variation autoencoder on training and test set.

### Results Discussion

In this Section, we use the proposed phenomena-based string representation as the descriptor and leverage the CVAE to generate hybrid extraction and

distillation systems with given thermodynamic property values and solvent price to meet desired cost investment.

The feature values are 4.59, 696.38, 1.42, 1.23, and \$5281.15 per kmol solvent for  $\kappa_P$ ,  $\kappa_S$ ,  $\alpha_{W,P}$ ,  $\alpha_{S,P}$ , and  $\pi_S$ , respectively. The separation cost for this feature vector is \$79.44 per kmol product according to the optimal solution for the hybrid extraction and distillation model. Based on this reference separation cost, we vary the separation cost value for the hybrid extraction and distillation system to screen the most economical design. We consider separation cost values as 10, 60, 80, 100, and 200 (with unit of \$ per kmol product). Five conditional vectors are constructed by filling into the feature values and separation cost value. We combine the condition vector with the latent vector, which are sampled by adding a Gaussian noise to the latent space of separation flowsheets selected randomly from the training set.

Based on the corresponding latent vectors and condition vectors, we generate the string representations and only keep the string representation with smallest length. These generated string representations with the smallest length for five separation cost values are given in Figure 4. The phenomena-based string representation (denoted as string 0) for the obtained optimal hybrid extraction and distillation system is as follows:

```
|L>2LLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLFL<3||V<1VVVVVVVVVVVVVVVVVVVVVVVVVVVV>3VVVVVVV<4|
```

This optimal separation system consists of one liquid-liquid extraction column and one distillation column.

As shown in Figure 4, the proposed data-driven framework has learned the representation of phenomena nodes (L and V), stream connections (< and >), and equipment boundary (|). For the separation cost of \$80 per kmol product, the predicted string representation is close to the one obtained from the optimal solution of MINLP model. This indicates good prediction performance. The differences are (1) the number of nodes (32 nodes) for liquid-liquid phase equilibrium (L) in the

\$10 per kmol product (string 1)	No valid string representations
\$60 per kmol product (string 2)	L>2LLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLFL<3  VV<1VVVVVVVVVVVVVV>3VVVVV<4  VV<1VVVVVVVVVVVVVV>4V
\$80 per kmol product (string 3)	L>2LLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLFL<3  V<1VVVVVVVVVVVVVVVVVVVVVV>3VVVVVVV<4
\$100 per kmol product (string 4)	L>2LLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLFL<3  V<1VVVVVV>3VVVVVVVVVVVVVVVVVVVVVVVVVVVVV<4
\$200 per kmol product (string 5)	L>2LLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLLFL<3  V<1VVVVVVVVVVVVVV>3VVVVVVVVVVVVVVVVVVVVVVVVVVV<4

predicted string representation is more than those (31 nodes) in the string representation obtained from the solution of separation process optimization, and (2) the number of nodes (38 nodes) for vapor-liquid phase equilibrium (V) in the predicted string representation is more than those (37 nodes) in the string representation obtained from the solution of separation process optimization.

**Figure 4:** Generated phenomena-based string representations with varying separation costs.

At the separation cost of \$10 per kmol product, no valid string representations exist, which indicates that the desired separation cost of \$10 per kmol product can not be achieved. Moreover, we observe that comparing the string representations for \$60 per kmol product and \$80 per kmol product, the predicted string representation has larger length for \$60 per kmol product, which indicates more stages in liquid-liquid extraction column or distillation column. The increase of stage number in liquid-liquid extraction column or distillation column can decrease operating costs related with solvent or utility consumption. We also note that string 2 for \$60 per kmol product shows a separation system with two distillation columns. For the design of liquid-liquid extraction column, the separation system for string 2 has more extraction stages (49 stages) than the separation system for string 3 (32 stages). For the design of distillation column, the separation system for string 2 has more distillation stages (39 stages) than the separation system for string 3 (38 stages). This case indicates that other factors that influence separation costs are solvent and utility consumption, which are continuous variables and are not captured in the proposed string representation. When the desired separation cost is higher than \$80 per kmol product, we also observe string representations with larger length. This is because more stages in liquid-liquid extraction column or distillation column make capital costs for separation systems represented by string 4, 5 higher than the capital cost for separation system represented by string 3.

Moreover, the above analysis also indicates that more economical separation design can be achieved by adjusting solvent and utility consumption. Specifically, we observe an improved solution (string 2) for designing hybrid extraction and distillation system. To validate this, we fix the design of liquid-liquid extraction column, and activate two distillation columns in the MINLP model, and we obtain the optimal solution as \$75.5 per kmol product. Although this improved solution is still not identical to the desired separation cost of \$60 per kmol product, we expect to improve exploration performance of CVAE when using a training set with more samples.

## CONCLUSION

In this work, we propose a phenomena-based string presentation for learning and screening the designs of hybrid extraction and distillation. In the proposed representation, we leverage the phenomena building blocks of liquid-liquid phase equilibrium, vapor-liquid phase equilibrium, and mixing while considering stream connections and equipment boundary. We train conditional variational autoencoder with condition vector on the feature values of liquid-liquid equilibrium constants of solvent, and product, relative volatilities, and solvent price. The trained conditional variational autoencoder shows good prediction performance. We apply the proposed framework for learning and screening separation systems for product separation with product mole fraction in the feed as 0.1. With the trained conditional variational autoencoder, we fix the values of input features, vary the values of separation cost, and predict the corresponding optimal designs of hybrid extraction and distillation represented by phenomena-based strings. Our proposed approach shows promise as a bottom-up data representation for flowsheet learning, data standardization, and generation of flowsheet database. Future work involves the consideration of more phenomena node options, automatic conversion of phenomena-based string representations to equipment-based chemical flowsheets, and conversion among different representations of flowsheet data.

## ABSTRACT

Adaptive and self-optimizing intelligent systems such as digital twins are increasingly important in science and engineering. Digital twins utilize mathematical models to provide added precision to decision-making. However, physics-informed models are challenging to build, calibrate, and validate with existing data science methods. Model-based design of experiments (MBD<sub>oE</sub>) is a popular framework for optimizing data collection to maximize parameter precision in mathematical models and digital twins. In this work, we apply MBD<sub>oE</sub>, facilitated by the open-source package Pyomo.DoE, to train and validate mathematical models for batch crystallization. We quantitatively examined the estimability of the model parameters for experiments with different cooling rates. This analysis provides a quantitative explanation for the heuristic of using multiple experiments at different cooling rates.

**Keywords:** Model-based Design, Batch Crystallization, Intelligent Systems, Pyomo, Digital Twins

## INTRODUCTION

### Digital Twins and Model-based Design of Experiments

Spearheading the data-driven revolution, the industrial implementation of inexpensive sensors and other data-capturing technologies has increased the availability of information [1]. However, the collected data has significant analysis limitations due to existing software and modeling capabilities [2]. At the confluence of these challenges, digital twins, i.e., virtual representations of physical systems, are increasing across industries ranging from agriculture to medicine [3,4]. At the heart of many digital twins are science-based mathematical models with physically meaningful parameters estimated from sensor data, often in real-time. These science-based models are created, maintained, and updated using data science tools, including model selection, parameter estimation, sensitivity and uncertainty analysis, and model-based design of experiments (MBD<sub>oE</sub>). MBD<sub>oE</sub> supports improved parameter precision or model discrimination for science-based models with physically meaningful parameters [5] through the following form:

$$y_i = m(x_i, \theta) + \epsilon_i, \epsilon_i \sim \mathcal{N}(0, \sigma_\epsilon^2) \quad (1)$$

where  $y$  represents the  $i$ -th measurement from an experiment with an observation error  $\epsilon_i$  following an assumed probability distribution, e.g., independent and identically normally distributed with mean 0 and variance  $\sigma_\epsilon^2$ . Here,  $m(\cdot, \cdot)$  denotes the mathematical model,  $x_i$  depicts the input and control variables for the  $i$ -th measurement, and  $\theta$  are the model parameters.

Training and validating a mathematical model using MBD<sub>oE</sub> is done sequentially. The model is updated and recalibrated before determining the next best set of experimental conditions to maximize information gain [6]. MBD<sub>oE</sub> aims to improve parameter precision in the estimated parameters by minimizing the associated uncertainty [5,7]. Encoding the mathematical model requires initial parameter values. Estimating the values for these parameters is done by using data collected from simulations of the experimental procedure. Model parameters are estimated from data using nonlinear regression:

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \Psi := \frac{1}{2} \sum_i [y_i - m(x_i, \theta)]^2 \quad (2)$$

For more sophisticated observation error assumptions,

maximum likelihood estimation, variational inference, or Bayesian methods are used instead of Eq. (2).

Next, we consider the Hessian matrix  $\mathbf{H}$  to quantify the sensitivity of least-squares objective  $\Psi$  to the perturbations in  $\theta$ :

$$\mathbf{H} = \begin{bmatrix} \frac{\partial^2 \Psi}{\partial \theta_1^2} & \dots & \frac{\partial^2 \Psi}{\partial \theta_n \partial \theta_1} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 \Psi}{\partial \theta_1 \partial \theta_m} & \dots & \frac{\partial^2 \Psi}{\partial \theta_m^2} \end{bmatrix} \quad (3)$$

When the residuals  $y_i - m(x_i, \theta)$  are small,  $\mathbf{H} \approx \mathbf{Q}^T \mathbf{Q}$ , where  $\mathbf{Q}$  is the sensitivity of the model predictions with respect to the model parameters  $\theta$  [8]. The sensitivity matrix  $\mathbf{Q}(\theta)$  is as follows:

$$\mathbf{Q}(\theta) = \begin{bmatrix} \frac{\partial m(x_1, \theta)}{\partial \theta_1} & \dots & \frac{\partial m(x_1, \theta)}{\partial \theta_m} \\ \vdots & \ddots & \vdots \\ \frac{\partial m(x_n, \theta)}{\partial \theta_1} & \dots & \frac{\partial m(x_n, \theta)}{\partial \theta_m} \end{bmatrix} \quad (4)$$

MBDoE uses the Fisher information matrix (FIM)  $M_{\hat{\theta}}$  to measure the information content about parameters  $\theta$  contained in proposed experiment(s)  $x_i$  for the model  $m(x_i, \theta)$ :

$$\mathbf{M}_{\hat{\theta}} \approx \Sigma_{\hat{\theta}}^{-1} \approx \frac{1}{\sigma_{\epsilon}^2} (\mathbf{Q}^T \mathbf{Q}) \quad (5)$$

where  $\sigma_{\epsilon}^2$  is the variance of the measurement uncertainty  $\epsilon$  and  $\Sigma_{\hat{\theta}}$  is the covariance of the estimated parameters. Finally, the MBDoE optimization formulation is given by:

$$\mathbf{x}^* = \underset{x}{\operatorname{argmax}} \Phi[\mathbf{M}(\hat{\theta}, x) + \mathbf{M}_0] \quad (6)$$

where  $\mathbf{x}^*$  are the optimal conditions for the next experiment considering prior information  $\mathbf{M}_0$ .  $\Phi(\cdot)$  is a matrix operation such as determinant (D-optimality), trace (A-optimality) or smallest eigenvalue (E-optimality).

Let  $\lambda_i$  and  $\mathbf{v}_i$  represent the eigenvalues and eigenvectors of  $\mathbf{M}_{\hat{\theta}}$ . Because  $\mathbf{M}_{\hat{\theta}} \approx \Sigma_{\hat{\theta}}^{-1}$ , the eigenvalues and eigenvectors of  $\Sigma_{\hat{\theta}}^{-1}$  are approximately  $\lambda_i^{-1}$  and  $\mathbf{v}_i$ . The covariance matrix  $\Sigma_{\hat{\theta}}$  is often represented as a confidence ellipsoid with axes  $\lambda_i^{-1} \mathbf{v}_i$  [5].

Model  $m(\cdot, \cdot)$  is identifiable if there exists a (possibly infinite) dataset for which it is possible to uniquely estimate the model parameters [9]. Structural issues, such as a parameter appearing only in a sum ( $\theta_1 + \theta_2$ ) or product ( $\theta_1 \times \theta_2$ ) will cause a model to be not identifiable; even with an infinite amount of data it is impossible to uniquely estimate both parameters ( $\theta_1$  and  $\theta_2$ ). In contrast, this short paper analyzes the practical identifiability, i.e., estimability, [10] of parameters in a batch crystallization model considering specific sets of experiments.

## Crystallization

Crystallization is a fundamental unit operation for the purification of substances necessary for objectives relating to separations for critical mineral recovery [11],

agriculture [12], food [13], fine chemicals [14], and pharmaceuticals [15]. Depending on the application (i.e., fertilizers, product quality and shelf life, fine chemicals, and active pharmaceutical ingredients), different critical quality attributes (i.e., crystal size, distribution) greatly impact the efficacy of the final product [16-19]. Tailored experimental procedures are required for each application to identify desired crystal properties. This remains difficult due to the highly nonlinear nature of crystallization dynamics and the need to control the operating conditions necessary for crystallization [20]. Due to the experimental design conditions of crystallization, open challenges include developing processes in confined volumes [21] as well as continuous manufacturing with time and material constraints [22].

The basic driving mechanisms for crystallization are nucleation and growth, which are thermodynamically favorable through a concentration gradient (i.e., supersaturation). Kinetic parameters for these processes are traditionally found through experimental procedures [23]. As such, determining the size and shape distribution of crystals is attainable through crystallization modeling [24]. Understanding crystallization processes with kinetic parameters is often achieved through population balance modeling [25]. However, estimating these parameters in crystallization models from experimental data is challenging due to the numerical complexities in a population balance equation (PBE) [26].

## Crystallization DoE Heuristics

For *in-silico* processes, we focus on the heuristics in crystallization for designing improved experimental campaigns. It is common practice to estimate primary nucleation ( $k_{p_1}$  and  $b_1$ ) through induction time measurements, i.e., unseeded with no cooling ( $\beta=0$ ), then later estimating secondary nucleation ( $k_{b_2}$  and  $b_2$ ) from seeded experiments. An aging process is necessary after the seeding process, and the decline of supersaturation can arise from growth only ( $k_g$  and  $g$ ) or secondary nucleation and growth, which is based on the kinetics [27]. For unseeded experiments, a suitable seed for secondary nucleation is obtained from primary nucleation [28]. The growth of the crystal nuclei is necessary for detecting primary nucleation and activating secondary nucleation [29]. The rates for nucleation as well as crystal growth are usually dependent on the power law relations of supersaturation [30].

## Paper Contribution

This paper uses practical identifiability analyses to provide mathematical insights into the above-mentioned crystallization modeling heuristics.

## CRYSTALLIZATION MODEL

We now describe a simple batch crystallization model. We then analyze the practical identifiability of crystallization kinetics parameters  $k_{b_1}, b_1, k_{b_2}, b_2, k_g,$  and  $g$  (described below) using one or more unseeded experiment performed at different cooling rates  $\beta$ .

## Population Balance Equation

A standard PBE represents the change in particle population for a specified volume. For the given problem, a one-dimensional PBE was used to describe the batch crystallization system with the form:

$$\frac{\partial n(L,t)}{\partial t} + \frac{\partial Gn(L,t)}{\partial L} = B\delta(L - L_0) \quad (7)$$

where the number of crystals per crystal length and the volume of slurry are depicted by the number density function  $n(L, t)$ ,  $G$  is the crystal growth rate,  $B$  is the nucleation rate,  $L$  is the length of the crystals,  $L_0$  is the nuclei size,  $\delta$  is the Dirac delta function,  $\sigma$  is relative supersaturation, and  $t$  represents the time. The kinetics for growth and nucleation of particles can be described with power laws:

$$\sigma = \frac{C - C_{sat}}{C_{sat}} \quad (8)$$

$$G = k_g \sigma^g \quad \text{if } \sigma > 0 \quad (9)$$

$$B_p = k_{b_1} \sigma^{b_1} \quad \text{if } \sigma > 0 \quad (10)$$

$$B_s = \varepsilon M_T k_{b_2} \sigma^{b_2} \quad \text{if } \sigma > 0 \quad (11)$$

$$B = B_p + B_s \quad (12)$$

Total nucleation rate ( $B$ ) is often described with both primary ( $B_p$ ) and secondary ( $B_s$ ) mechanisms. Here  $k_g, k_{b_1}, k_{b_2}$  and  $g, b_1, b_2$  are the rate constants and the power law exponents for growth, primary nucleation, and secondary nucleation, respectively. These six parameters are the focus of our analysis.  $M_T$  is the slurry density and  $\varepsilon$  is the power density.  $C_{sat}$  is the saturation concentration for the system temperature given in the equation below:

$$C_{sat} = A_1 \exp(A_2 T) \quad (13)$$

where  $A_1$  and  $A_2$  are parameters found through a solubility study. For an unseeded system (i.e.,  $n=0$ ), the initial and boundary conditions for this PBE are given by:

$$n(L, 0) = 0 \quad (14)$$

$$n(0, t) = \frac{B\delta(L-L_0)}{G} \quad \text{if } \sigma > 0 \quad (15)$$

where we assume that the initial birth rate is negligible and growth rate is independent of crystal length. As time progresses, a solute mass balance equation is used to define the change in concentration inside the crystallizer such that:

$$\frac{dC}{dt} = -3\rho_c K_v \int_0^\infty nGL^2 dL \quad (16)$$

with  $C$  as the solute concentration,  $\rho_c$  as the solid density

of a crystal, and  $K_v$  as the volumetric shape factor.

## Method of Moments

To reduce the complexity of the PBE, the method of moments converted the partial differential equations of the PBE to a set of ordinary differential equations [32] by solving the equations in the model using the first four moments calculated through the population density function:

$$\frac{d\mu_0}{dt} = B \quad (17)$$

$$\frac{d\mu_i}{dt} = iG\mu_{i-1} \quad \forall i \in \{1,2,3,4\} \quad (18)$$

$$\frac{dC}{dt} = -\frac{dM_T}{dt} = -3\rho_c K_v G \mu_2 \quad (19)$$

where  $\mu_i$  is the  $i$ -th moment of the crystal size distribution. The moments represent a physical significance per unit volume for total crystal number, total crystal length, total crystal surface area, and total crystal volume.

## Model Implementation in Pyomo

A typical experiment was defined for a batch crystallization system in the Pyomo modeling environment. We fixed the parameters for a solid density of a crystal  $\rho_c$ , volume shape factor  $K_v$ , and the solubility parameters  $C_1$  and  $C_2$ . For the linear cooling of the crystal suspension, an ordinary differential equation was used to describe temperature of the form:

$$\frac{dT}{dt} = -\beta \quad (20)$$

where  $\beta$  refers to the cooling rate. Empirical equations were used to define the growth and birth rate in the crystallizer [33,34]. The FIM  $\mathbf{M} \in \mathbb{R}^{6 \times 6}$  was calculated using Pyomo.DoE [31] for the following six parameters:  $k_{b_1}$  and  $b_1$  for primary nucleation,  $k_{b_2}$  and  $b_2$  for secondary nucleation, and  $k_g$  and  $g$  for growth.

## RESULTS

We simulated the batch crystallization experiment at four different cooling rates:  $\beta=0, \beta=0.1, \beta=0.2,$  and  $\beta=0.3$  in  $^\circ\text{C min}^{-1}$ . For each experiment, we calculated the FIM. Finally, we analyzed the practical identifiability of each experiment and several collections of multiple experiments. All experiments start as a 1% supersaturated solution.

## Simulation Profiles

Figure 1 shows the temperature decreases linearly with time for  $\beta=0.1, 0.2,$  and  $0.3 \text{ }^\circ\text{C min}^{-1}$  as expected. As noted previously, when applying cooling to a vessel, solubility of the solute generally decreases. Therefore, when the temperature of a solution changes, supersaturation is generated thermodynamically, causing the solute to crystallize out of solution.

**Figure 1.** Change in temperature (K) over time for  $\beta=0.1$ , 0.2, and 0.3 ( $^\circ\text{C min}^{-1}$ ).

Subsequently, Figures 2 to 4 show the decrease in solute saturation concentration and operating concentration as a function of time for  $\beta=0.1$ , 0.2, and 0.3  $^\circ\text{C min}^{-1}$ . As expected, these concentrations decrease the fastest with the fastest cooling. This makes sense because the solubility will decrease as temperature decreases such that the solute separates from the solution as crystals form.

**Figure 2.** Operating and saturation concentration ( $\text{g cm}^{-3}$ ) over time for  $\beta=0.1$  ( $^\circ\text{C min}^{-1}$ ).

**Figure 3.** Operating and saturation concentration ( $\text{g cm}^{-3}$ ) over time for  $\beta=0.2$  ( $^\circ\text{C min}^{-1}$ ).

**Figure 4.** Operating and saturation concentration ( $\text{g cm}^{-3}$ ) over time for  $\beta=0.3$  ( $^\circ\text{C min}^{-1}$ ).

**Figure 5.** Change in average particle size ( $\mu\text{m}$ ) over time for  $\beta=0.1$ , 0.2, and 0.3 ( $^\circ\text{C min}^{-1}$ ).

Figure 5 investigates the change in average particle size over time for three different cooling rates to understand the growth distribution. As the cooling rate increases, the average particle size grows at a faster rate. This is likely due to incubation time (time to first nuclei forming) decreasing as the cooling rate increases, resulting in a longer period of low supersaturation where growth is the dominant mechanism.

### Eigendecomposition of the FIM

We now analyze the eigendecompositions of the FIMs from proposed experiments to explore the estimability of the model. Recall, the basis of eigenvectors is defined with respect to the model parameters. In Tables 1 to 6 (after references), each row (except the last) corresponds to a model parameter. Each column is an eigenvector. The last row reports the eigenvalues. Within each column, the largest absolute eigenvector element is highlighted in blue. For example, in Table 1, the fifth and sixth columns report  $\lambda_5 = 9.270 \times 10^{-10}$  and  $\lambda_6 = 2.622 \times 10^{-12}$ .

Both eigenvalues are small, indicating significant practical identifiability issues. Specifically, the largest components of  $\mathbf{v}_5$  and  $\mathbf{v}_6$  correspond to the secondary nucleation parameters  $k_{b_2}$  and  $b_2$ . In other words, these eigenvectors are predominantly in the direction of  $k_{b_2}$  and

**Table 1:** Eigendecomposition of the FIM for the  $\beta=0$  (no cooling) candidate experiment. The columns are eigenvectors, and the rows are model parameters. The last row are the eigenvalues. The largest absolute elements in each vector are highlighted in blue.

$k_g$	-0.743	-0.605	0.174	0.228	0.022	0.011
$g$	-0.203	-0.205	-0.634	-0.713	-0.080	-0.014
$\lambda_i$	$6.317 \times 10^4$	$3.206 \times 10^3$	$2.081 \times 10^1$	$1.897 \times 10^0$	$3.127 \times 10^{-2}$	$6.362 \times 10^{-6}$

$b_2$ . Because  $\lambda_5$  and  $\lambda_6$  are small, the proposed experiment contains little information about these two parameters. On the other hand, we can see for the largest eigenvalues,  $\lambda_1$  and  $\lambda_2$ , the predominant direction of  $\mathbf{v}_1$  is growth ( $k_g$ ), and  $\mathbf{v}_2$  is primary nucleation ( $b_1$ ), which contain the most information for this experiment. This makes sense since this experiment is not seeded, so we obtain information about primary nucleation  $b_1$ .

Table 2 shows a significant increase in the magnitude of the smallest eigenvalues and the number of eigenvalues above one for  $\beta=0.1$  ( $^{\circ}\text{C min}^{-1}$ ) compared to  $\beta=0$  ( $^{\circ}\text{C min}^{-1}$ ) (Table 1). This corresponds with an improved practical identifiability in the growth parameter ( $g$ ). This is likely because using a non-zero cooling rate disposes the system to the thermodynamic driving force:

solute supersaturation. As the cooling rate increases, the smallest eigenvalue decreases from order  $10^{-3}$  (Table 2) to  $10^{-6}$  (Table 3). In both tables,  $\mathbf{v}_6$  is predominantly in the direction of  $k_{b_1}$ .

As the cooling rate increases (Table 4), the magnitude and primary direction of the eigenvalues and eigenvectors change. The smallest eigenvalue increases from order  $10^{-6}$  (Table 3) to  $10^{-5}$  (Table 4). Primary nucleation  $k_{b_1}$  remains the parameter with the least information for Tables 2 to 4.

Often, in crystallization studies, multiple cooling rates are used to identify growth. Thus, we consider two possible experiment campaigns: (1) two experiments at  $\beta=0.2$  and  $\beta=0.3$  and (2) three experiments at  $\beta=0.1$ ,  $\beta=0.2$ , and  $\beta=0.3$ . For both scenarios, the FIMs are

summed before computing the eigendecomposition. Consistent with intuition, considering two experiments (Table 5) results in a larger smallest eigenvalue (order  $10^{-3}$ ) compared to each cooling rate separately (order  $10^{-6}$  to  $10^{-5}$ ). Similarly, three experiments (Table 6) further increase the smallest eigenvalue (order  $10^{-2}$ ).

## Optimality of the FIM

We now examine the A-, D-, and E-optimality measures of the FIMs from the proposed set of experiments to explore the information content of the cooling rates. Recall, the optimality criterion is defined by the trace (Eq. 21), determinant (Eq. 22), and smallest eigenvalue (Eq. 23) of the FIM:

$$\text{trace}(\mathbf{M}) = \sum_i \lambda_i \quad (21)$$

$$\det(\mathbf{M}) = \prod_i \lambda_i \quad (22)$$

$$\min(\text{eig}(\mathbf{M})) = \min(\lambda_1, \dots, \lambda_n) \quad (23)$$

where  $\lambda_i$  is the eigenvalue of the FIM.

As denoted in Figure 6, the optimality measure has an overall increase for the experiments with the multiple cooling rates as opposed to the experiments with individual cooling rates. We can see that for no cooling (i.e.,  $\beta=0$ ), there is minimal optimal measure. However, for the individual cooling rates, A-optimality is nearly constant, D-optimality decreases slightly, and the optimality measure is marginally better for E-optimality with  $\beta=0.1$  °C min<sup>-1</sup>. As expected, when we consider two measurements, we have more information for A- and D-optimality. Overall, the experiment set with the three cooling rates contains the most information.

## Computational Environment

The computational results were conducted using the following software versions: Python 3.10.12, Ipopt 3.13.2, Pyomo 6.7.1, and CasADi 3.6.5. The computer specifications include Windows 11 Version 22H2, Intel(R) Core (TM) i7-10510U CPU @ 1.80 GHz 2.30 GHz, and 16.0 GB RAM. For each individual cooling rate ( $\beta=0$ ,  $\beta=0.1$ ,  $\beta=0.2$ , and  $\beta=0.3$ ), we found the average computational times for running the model, computing the FIM, and the eigendecomposition of the FIM which were approximately 0.078 s, 8.881 s, and 0.124 s respectively.

## CONCLUSIONS

Through our analysis of the practical identifiability of parameters for a batch crystallization system, we found that growth appears to be the most estimable parameter as it consistently corresponds to the largest eigenvalues. As expected, the secondary nucleation parameters  $k_{b_2}$  and  $b_2$  were not estimable in constant temperature experiments ( $\beta=0$ ). If only one experiment is possible, a modest cooling rate ( $\beta=0.1$  °C min<sup>-1</sup>) is

recommended to maximize estimability. However, performing experiments at multiple cooling rates is the most informative, as expected. Further analysis for the optimality measure of the FIM demonstrated an increase of information content when changing the cooling rate or adding multiple experiments.

In conclusion, MBD<sub>oE</sub> and practicable identifiability analysis provides a mathematical context for a common replicate crystallization heuristic. This analysis is limited to this model, and although the framework is general, the specific conclusions may not generalize. Analysis like that performed in this work demonstrates a mathematical impetus for fitting selective parameter sets for specific experiments. There is an opportunity to integrate these insights with existing crystallization parameter estimation workflows and tools [35].

## ABSTRACT

Machine learning (ML) has become a powerful tool to analyze complex relationships between multiple variables and to unravel valuable information from big datasets. However, an open research question lies in how ML can accelerate the design and optimization of processes in the early experimental development stages with limited data. In this work, we investigate the ML-aided process design of a microwave reactor for ammonia production with exceedingly little experimental data. We propose an integrated approach of synthetic minority oversampling technique (SMOTE) regression combined with neural networks to quantitatively design and optimize the microwave reactor. To address the limited data challenge, SMOTE is applied to generate synthetic data based on experimental data at different reaction conditions. Neural network has been demonstrated to effectively capture the nonlinear relationships between input features and target outputs. The softplus activation function is used for a smoother prediction compared to the Rectified Linear Unit activation function. Ammonia concentration is predicted using pressure, temperature, feed flow rate, and feed composition ratio as input variables. For point-wise prediction based on discrete operating conditions, the proposed SMOTE integrated neural network approach outperforms with 96.1% accuracy compared to neural networks (without SMOTE), support vector regression, and linear regression. The multi-variate prediction trends are also validated which are critical for design optimization.

**Keywords:** Process Design, Process Intensification, Machine Learning, Neural Networks, Ammonia Production

## INTRODUCTION

Machine Learning (ML) offers the capability to surpass the constraints of mechanistic modeling by enabling the learning of complex relationships between process variables and the target outputs, offering cost-effective model development, and proving advantageous for optimization [1-2]. To reliably transform the data into valuable predictions, ML aims to acquire rules and patterns from a sufficiently large number of samples [3-4]. However, in certain cases, data availability may be intrinsically limited such as during the early development stage of novel experimental technologies. The scarcity of the datasets may hinder the accuracy of ML predictions. The prediction error typically follows a consistent power-exponential decline as the dataset size increases [5]. To give a more intuitive idea, doubling the number of training samples can result in approximately 20% reduction in

prediction error [6]. As such, a key research challenge is how ML can successfully aid process design and optimization at early-stage process developments using sparse experimental data.

To address this challenge, several approaches have been developed in recent research work which can be categorized as: (i) Sampling, encompassing both over and under sampling techniques [7,8], (ii) Cost sensitivity, which involves modifying the cost function to prompt models to prioritize minority samples [9], (iii) Adversarial network generation, which can produce spurious data [10]. However, these methods show inefficacy in handling continuous target output prediction in the regression context which is essential for the data-driven modeling of chemical process systems.

In this work, we present a neural network-based method integrating synthetic minority oversampling technique (SMOTE). The proposed strategy is applied to

the design of a microwave-assisted ammonia production process with little experimental data. The remainder of this paper is organized as follows: Section 2 introduces the motivating case study of a microwave-assisted reactor for ammonia production. Section 3 details the SMOTE-integrated neural network method. Section 4 showcases this method for the data-driven modeling and optimization of the microwave reactor. Section 5 presents concluding remarks and ongoing work.

## CASE STUDY: MICROWAVE-ASSISTED AMMONIA PRODUCTION

The use of microwaves in chemical synthesis has sparked considerable interest in recent years. Compared with traditional thermal heating, microwave offers the capability of direct and selective volumetric heating which can result in higher reaction selectivity, shorter reaction times, and milder reaction conditions [11,12]. One of the key applications of microwave reactor is ammonia production under ambient/moderate pressure and moderate temperature [13]. This provides a promising technological alternative to the current ammonia synthesis route via the highly energy intensive Haber-Bosch process.

**Figure 1.** Schematic of a cylindrical microwave reactor.

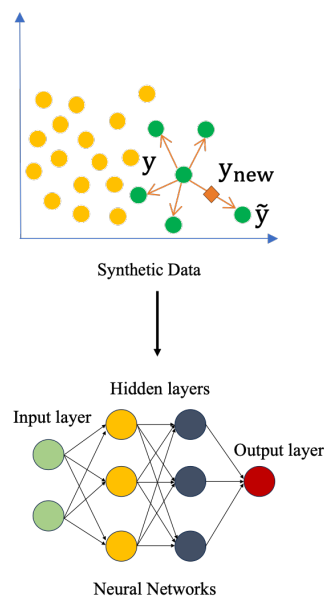

A schematic of the microwave-assisted ammonia reactor is shown in Fig. 1 which is adapted as the case study of this work [14]. Ru-based catalyst is used which has been demonstrated to exhibit high activity for ammonia synthesis under moderate reaction conditions, particularly when alkali metal Cs is used as a promoter. A total of 46 data points is collected from the microwave reactor at different operating conditions. Table 1 gives examples of such measured data. Our research objective is to predict the optimal reaction conditions for ammonia synthesis based on these experimental data.

**Table 1:** Experimental data – an indicative list.

T (°C)	F (ml/h·g <sub>cat</sub> )	NH <sub>3</sub> %	F (ml/h·g <sub>cat</sub> )	NH <sub>3</sub> %
280		0.56		0.27
320		1.57		1.02
340	6000	1.63	15000	1.21
360		1.55		1.25
400		1.28		1.06

## THE PROPOSED METHODOLOGY

As depicted in Fig. 2, a neural network approach is developed leveraging SMOTE and softplus activation function. Neural network is employed to capture the non-linear input-output relationship. SMOTE regression [6,7] is applied to overcome the challenge of limited data availability, which can generate new synthetic data to be used for ML training together with the original experimental data. Soft plus activation function is applied to obtain smooth and differentiable output predictions. In what follows, we briefly introduce the key components of the proposed methodology.

**Figure 2.** SMOTE integrated Neural Networks.

### SMOTE Regression

SMOTE [7] is commonly employed for data simulation to create distribution-dependent neighbor samples for the minority class. Unlike the random oversampling algorithms, SMOTE can dynamically generate the necessary number of samples for the minority class. The use of SMOTE aims to explore new samples that closely resemble the original data distribution. This is instrumental for generating experimentally relevant data with similarities to the existing dataset. In the data generation algorithm of SMOTE, several samples are randomly chosen from the  $k$  neighbors for each sample  $y$ , in the minority class. A new sample is constructed for each randomly selected neighbor from the original sample, as shown by Eq. 1. The new synthetic data points are then merged with the original experimental data to be fed to neural network training.

$$y_{new} = y + rand(0,1) \times (y - \tilde{y}) \quad (1)$$

## Neural Network with Soft plus Activation

Neural network models are comprised of nodes, where each node has the capacity to host several neurons. The neural network architecture used in this work comprises of one input layer, two hidden layers, and one output layer. Each neuron is associated with weights and biases which get updated to minimize the difference between the true labels and predicted labels of the input datasets. The output of a neuron becomes input for the consecutive neurons. The output is expressed by Eq. 2.

$$y^t = \text{softplus}(w^t x^t + b^t) \quad (2)$$

where  $w^t$  is the weight vector,  $x^t$  is the vector for input data,  $b^t$  is the bias.

The role of activation function in a neural network architecture is that it transforms the linear combination of summed weights and biases into a nonlinear output. Activation function normalizes the data that imposes a restriction to convert the output of a neuron into a specific bound. The Rectified Linear Unit (ReLU) and Softplus activation functions are compared as shown in Fig. 3. ReLU activation function is a non-differentiable function which may provide non-smooth predictions compared to Softplus, i.e.  $f(x) = \log(1 + e^x)$ . A major advantage of using Softplus is that it does not suffer from the “dying ReLU” problem which refers to the situation when some of the neurons become inactive, and they cannot update their weights and biases resulting in non-smooth predictions.

Figure 3: Comparison of activation functions.

## MACHINE LEARNING-AIDED MICROWAVE DRIVEN REACTION DESIGN

In this section, we apply the SMOTE-integrated neural network approach to model the microwave-assisted ammonia reaction. Specifically, we will investigate:

- Point-wise prediction for  $\text{NH}_3$  concentration based on discrete operating conditions (i.e., temperature, pressure, inlet  $\text{H}_2$  to  $\text{N}_2$  ratio, inlet gas flow rate).
- Continuous prediction to capture the variation trend of  $\text{NH}_3$  concentration under varying operating conditions.
- Reaction design optimization for maximum  $\text{NH}_3$  concentration.

## Point-wise Prediction

Two hidden layers are used for the neural networks with 128 and 64 nodes, respectively. 40,589 synthetic data are generated via SMOTE. The training and testing data are separated by an 80-20% split. The adam optimizer is applied utilizing the mean squared error as the loss function. The number of epochs is set as 100 with a learning rate of 0.0001. The average discrete prediction accuracy of SMOTE-integrated neural network is 96.10% as shown in Table. 1. This accuracy is superior to other regression methods such as neural networks (without SMOTE, 95.10%), support vector regression (88.70%), and linear regression (86.30%).

Table 2: SMOTE-integrated NN pointwise prediction.

Actual $\text{NH}_3$ Concentration	Reaction Conditions [T(°C), P(psig), R, F (ml/h <sub>cat</sub> )]	Prediction Accuracy (%)

1.57	320, 80, 1, 6000	92.31
...	...	...
		Avg. = 96.10

## Continuous Prediction

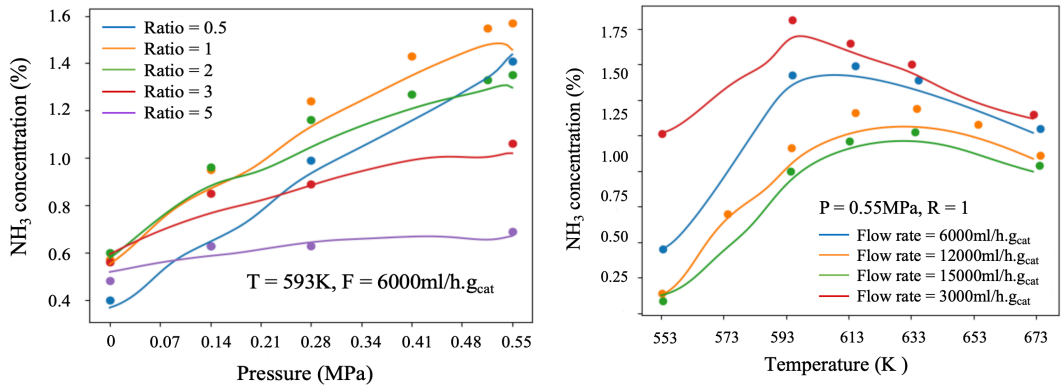

Herein, the primary goal is to verify that the resulting data-driven model can also capture the continuous variational trend of ammonia concentration versus operating conditions. We first develop a SMOTE-integrated neural network model for two inputs and one output. For example,  $\text{NH}_3$  concentration is computed from the two-input one-output data-driven model at varying pressures and inlet  $\text{H}_2$  to  $\text{N}_2$  ratios while temperature and inlet gas flow rate are kept constant. Two separate models are developed for the prediction of  $\text{NH}_3$  concentration, respectively using 11,340 and 4,180 synthetic data generated by SMOTE. The total number of synthetic data is reduced to avoid overfitting. The prediction results are validated against the original experimental data as shown in Fig. 4, in which the markers represent the original experimental data, and the solid lines depict the continuous prediction using the above trained SMOTE-integrated NN model.

On this basis, we proceed to build a single data-driven model considering all the four input variables (i.e., temperature, pressure,  $\text{H}_2$  to  $\text{N}_2$  ratio, and feed flow rate).

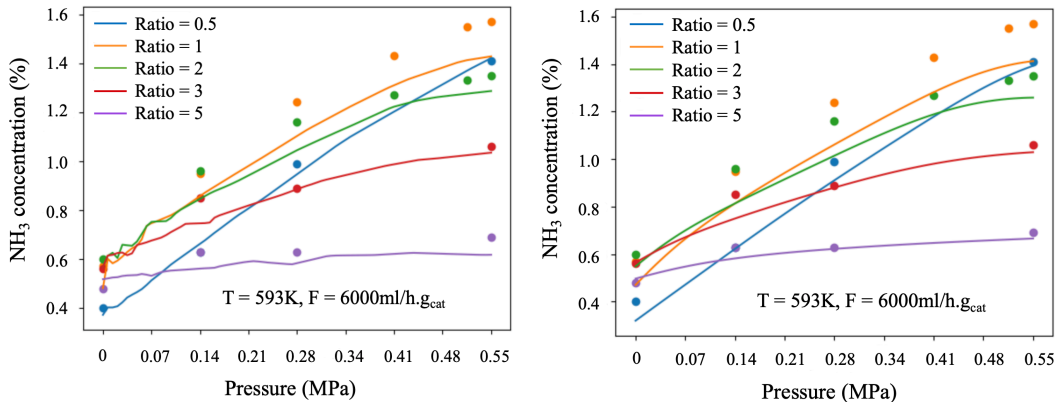

**Figure 4:** Continuous prediction with two-input one-output data-driven model. (Markers: Original experimental data, Solid lines: SMOTE integrated NN prediction)

**Figure 5:** Continuous prediction with four-input one-output data-driven model.

**Figure 6:** Role of activation function. (Left) ReLU. (Right) Soft plus.

As the input dimensions increase, the input-output relationship becomes more nonlinear and complex. Namely, the resulting data-driven model should simultaneously capture the nonlinear relationship between ammonia concentration versus temperature, pressure, inlet  $H_2$  to  $N_2$  ratio, and inlet gas flow rate. 23,000 synthetic data generated via SMOTE are used to train the four-input one-output neural network. As illustrated in Fig. 5, the

continuous prediction using a higher dimensional data-driven model can also effectively capture the variational trend while featuring larger deviations than the two-input one-output models. The role of activation functions is also investigated as shown in Fig. 6. It can be noted that the use of ReLU activation function may result in non-smooth predictions compared with that of Softplus activation function. This is consistent with the observations

reported in open literature [15].

## Comparison with SVR and NN

The continuous predictions from our proposed methodology were compared to the support vector regression (SVR) and NN (without SMOTE). For SVR, Radial Basis Function (RBF) is identified as the best kernel function for our datasets. As illustrated in Fig. 7, SVR identifies a pseudo-linear multi-variate relationship instead of capturing the correct nonlinear trends. The predictions using NN (without SMOTE) are depicted in Fig. 8. Even if NN offers a point-wise prediction accuracy of 95.10%, it introduces excessive nonlinear directional changes in the continuous prediction. In other words, NN cannot effectively capture the continuous variational trend. If this data-driven model is applied for design optimization, it may fail to identify the correct direction toward optimality.

## Design Optimization

Finally, we performed the design optimization to determine the optimum reaction conditions. A mesh grid of data points is created and fed to the afore-trained SMOTE-integrated neural networks (Fig. 9). The ammonia concentration for each of the input data is obtained from the data-driven model prediction and the index of maximum ammonia concentration is located. The optimum temperature, pressure, H<sub>2</sub> to N<sub>2</sub> ratio, and inlet gas flow rate are identified as 324.37°C, 80psig, 1, and 3000ml/h·g<sub>cat</sub> respectively. The optimum operating conditions obtained from experimental data are at the temperature of 320°C, pressure of 80psig, H<sub>2</sub> to N<sub>2</sub> ratio of 1, and inlet gas flow rate of 3000ml/h·g<sub>cat</sub> which well justifies the validity of data-driven model prediction.

## CONCLUSION

In summary, this work has developed a machine learning-aided method to design and optimize microwave-assisted ammonia reaction conditions with little experimental data. The efficacy of the proposed approach is demonstrated on the point-wise and continuous prediction of ammonia concentration under varying reaction temperature, pressure, H<sub>2</sub> to N<sub>2</sub> ratio, and feed flow rates. Ongoing work is investigating the systems-level analysis leveraging this data-driven microwave reactor model.

## ABSTRACT

Modern industrial processes are continuously monitored by a large number of sensors. Despite having access to large volumes of historical and online sensor data, industrial practitioners still face challenges in the era of Industry 4.0 in effectively utilizing them to perform online process monitoring and fast fault detection and diagnosis. To target these challenges, in this work, we present a novel framework named “FARM” for Fast, Accurate, and Robust online process Monitoring. FARM is a holistic monitoring framework that integrates (a) advanced multivariate statistical process control (SPC) for fast anomaly detection of nonparametric, heterogeneous data streams, and (b) modified support vector machine (SVM) for accurate and robust fault classification. Unlike existing general-purpose process monitoring frameworks, FARM’s unique hierarchical architecture decomposes process monitoring into two fault detection and diagnosis, each of which is conducted by targeted algorithms. Here, we test and validate the performance of our FARM monitoring framework on Tennessee Eastman Process (TEP) benchmark dataset. We show that SPC achieves faster fault detection speed at a lower false alarm rate compared to state-of-the-art benchmark fault detection methods. In terms of fault classification diagnosis, we show that our modified SVM algorithm successfully classifies 17 out of 20 of the fault scenarios present in the TEP dataset. Compared with the results of standard SVM trained directly on the original dataset, our modified SVM improves the fault classification accuracy significantly.

## INTRODUCTION

Safe and efficient operation of an industrial plant depends on effective, continuous process monitoring (e.g., fault detection and diagnosis), which is enabled by advanced sensory systems that continuously generate streams of data to dictate the state of the plant. Despite having access to large volumes of historical and online sensor data, challenges remain in how these data could be used for effective online process monitoring. Existing techniques for process monitoring are inadequate because (a) fault scenarios in industrial systems and plants are complex, (b) sensors continuously produce massive arrays of big data streams that are often nonparametric (i.e., data streams may not follow any specific distribution) and heterogeneous (i.e., data streams may not

follow the same distribution), and (c) there is an intrinsic trade-off between fault detection time and diagnostic accuracy.

To address this need, several process monitoring solutions have been developed over the past decades. Among them, dimensionality reduction techniques, such as principal component analysis (PCA), partial least squares (PLS) regression, as well as their different variations, are the most popular ones in the literature [1–3]. Dimensionality reduction techniques assume that the statistics characterizing the in-control profiles also span the subspace where out-of-control states (faults) lie in [4]. However, this assumption is generally invalid for industrial process monitoring as the process dynamics are quite complex and out-of-control states cannot be fully enumerated a priori. Also, plant operators often find it

difficult to interpret the results from PCA/PLS-based methods because the features are in the reduced space and do not have one-to-one mapping to the original sensor data sources. In addition, monitoring only the most significant subset of features often causes significant errors, as the fault may not be noticeable in the selected features. Lastly, dimensionality reduction techniques have no statistical guarantee on false alarm rate, making them unreliable for actual plant monitoring which requires false alarm to be low and controlled (e.g.,  $\leq 0.0027$ , the classic three-sigma limit) due to the significant money loss and safety issues of unplanned unit shutdown.

More recently, various machine learning (ML) tools such as support vector machine, decision tree, and deep neural network, have also been proposed and applied to process monitoring [5–8]. Nevertheless, existing ML methods still face problems such as overfitting and poor predictive accuracy. For example, while most published ML algorithms perform well during training and validation, their fault detection accuracies deteriorate and rarely exceed 90–95% in test sets. Considering the severe consequences in case of fault detection failure, such predictive accuracy is unacceptable. Furthermore, ML methods do not scale well with rare or new fault scenarios due to the lack of sufficient training data.

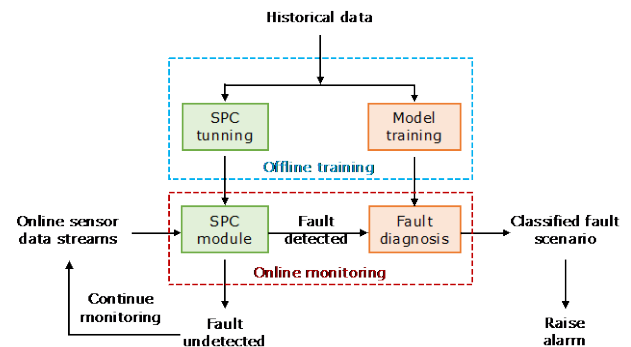

To target these challenges, in this work, we present a novel industrial process monitoring tool, which we named it as “FARM”, for fast, accurate, and robust online fault detection and diagnosis. FARM is a holistic monitoring framework that integrates (a) advanced multivariate statistical process control (SPC) for fast anomaly detection of nonparametric, heterogeneous data streams, and (b) a modified support vector machine (SVM) for accurate and robust fault classification. Unlike existing general-purpose process monitoring frameworks, FARM’s unique hierarchical architecture (see Figure 1) decomposes process monitoring into two fault detection and diagnosis, each of which is conducted by targeted algorithms. Only if a process anomaly is detected will the online data be sent to the fault classification/diagnosis module for accurate fault classification. Such hierarchical architecture successfully bypasses the intrinsic trade-off between fault detection speed and accuracy that is present in existing monitoring tools. Furthermore, using FARM, plant operators can choose a user-specified false alarm rate based on their expert knowledge of the process.

## STRUCTURE AND WORKFLOW OF FARM

As mentioned earlier, FARM consists of two distinct yet interconnected modules. The first module performs fault detection by adopting the state-of-the-art quantile-based non-parametric SPC proposed by Ye and Liu [9]. Quantile-based nonparametric SPC can detect any

process mean shift or anomaly from heterogeneous high-dimensional sensor data streams as early as possible while maintaining a pre-specified incontrol average run length. Inspired by the work of Smith et al. [10], the second module conducts fault classification through a modified SVM model. Both modules are connected as shown in Figure 1. FARM’s workflow contains two steps: (1) offline training with historical data, followed by (2) online monitoring of real-time sensor data streams. During offline training, the parameters of the SPC module to be used for online monitoring are obtained using the historical in-control data. Also, the modified SVM module is trained by treating the faulty data’s covariance matrices as features and the corresponding faulty scenario as labels.

Once offline training of FARM is complete, online sensor measurements will continuously be sent to FARM for simultaneous fault detection and diagnosis. First, they are monitored by the SPC module to detect any process anomaly in real time. Only if a process anomaly is detected will the online data be sent to the fault diagnosis module for accurate fault classification. Unlike general-purpose process monitoring frameworks, FARM’s hierarchical architecture decomposes process monitoring tasks into two subtasks (fault detection and diagnosis), each of which is accomplished by specialized techniques. This allows fast, accurate, and robust fault detection and diagnosis to be simultaneously accomplished by FARM.

**Figure 1.** FARM’s hierarchical structure consisting of fault detection and diagnosis modules.

### Fault Detection

The backbone of FARM’s fault detection module is the quantile-based non-parametric SPC algorithm proposed by Ye and Liu [9]. Jiang modified the original quantile-based SPC formulation of Ye and Liu [9] to monitor fully observable data streams [11]. Here, a brief description of the modified SPC formulation is presented. In offline training, the sensor measurements in each of the  $M$  historical in-control data streams  $X_j$  ( $j = 1, 2, \dots, M$ ) are sorted in ascending order and partitioned into  $d$  number of quantiles  $I_{j,1}, \dots, I_{j,d}$  defined as:

$$I_{j,1} = (-\infty, q_{j,1}], I_{j,2} = (q_{j,1}, q_{j,2}], \dots, I_{j,d} = (q_{j,d-1}, +\infty) \quad (1)$$

For each  $q_{j,i}$ , two intervals called positive and negative cumulative intervals are defined as:

$$CI_{j,i}^+ = [q_{j,i}, +\infty) \quad \text{and} \quad CI_{j,i}^- = (-\infty, q_{j,i}] \quad (2)$$

for every  $i = 1, \dots, d-1$  and  $j = 1, 2, \dots, M$ . With these positive/negative cumulative intervals identified from historical in-control data, one can detect anomalies in real time by detecting any upward/downward mean shift of online sensor data streams. To do this, for an online sensor data stream  $X_j(t)$  where  $t$  stands for time, we define a binary variable  $A_{j,i \in [1, \dots, d-1]}^+$  and  $A_{j,i \in [1, \dots, d-1]}^-$  to indicate which positive and negative cumulative interval  $X_j(t)$  lies in at time  $t$ , respectively:

$$A_{j,i \in [1, 2, \dots, d-1]}^+ = \begin{cases} 1 & \text{if } X_j(t) \in CI_{j,i}^+ \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

$$A_{j,i \in [1, 2, \dots, d-1]}^- = \begin{cases} 1 & \text{if } X_j(t) \in CI_{j,i}^- \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

With this, we obtain two vectors  $\mathbf{A}_j^+(t)$  and  $\mathbf{A}_j^-(t)$  as:

$$\mathbf{A}_j^+(t) = [A_{j,1}^+, A_{j,2}^+, \dots, A_{j,d-1}^+], \quad (5)$$

$$\mathbf{A}_j^-(t) = [A_{j,1}^-, A_{j,2}^-, \dots, A_{j,d-1}^-]. \quad (6)$$

One can show that  $\mathbb{E}[\mathbf{A}_j^+(t)] = [1 - \frac{1}{d}, 1 - \frac{2}{d}, \dots, 1 - \frac{d-1}{d}]$  and  $\mathbb{E}[\mathbf{A}_j^-(t)] = [\frac{1}{d}, \frac{2}{d}, \dots, \frac{d-1}{d}]$  for  $j = 1, \dots, M$  and  $i = 1, \dots, d$ . Therefore, by defining  $\mathbf{A}_j^+(t)$  and  $\mathbf{A}_j^-(t)$ , the idea is to convert the task of detecting any mean shift in the distribution of  $X_j(t)$  with respect to the distribution of historical in-control data into an equivalent task of detecting the upward (resp. downward) mean shift in the distribution of  $A_{j,i}^+$  (resp.  $A_{j,i}^-$ ) with respect to  $\mathbb{E}[A_{j,i}^+]$  (resp.  $\mathbb{E}[A_{j,i}^-]$ ). This transformation presents at least two major advantages. First, it has been shown that  $A_{j,i}^+$  (resp.  $A_{j,i}^-$ ) is more sensitive to upward (resp. downward) mean shifts than the original data streams themselves [9], thus allowing faster fault detection. And second, it allows nonparametric, heterogeneous data streams to be successfully monitored for the first time.

Quantile-based SPC implements the multivariate cumulative sum (CUSUM) procedure first proposed by Qiu and Hawkins [12, 13] to monitor multivariate big data streams of  $\mathbf{A}_j^+(t)$  and  $\mathbf{A}_j^-(t)$  for  $j = 1, \dots, M$ . This is achieved by defining  $C_j^+(t)$  and  $C_j^-(t)$  as:

$$C_j^\pm(t) = \left[ \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right) - \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}[\mathbf{A}_j^\pm(t)] \right) \right]^T \cdot \left( \text{diag} \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}[\mathbf{A}_j^\pm(t)] \right)^{-1} \cdot \left[ \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right) - \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}[\mathbf{A}_j^\pm(t)] \right) \right] \right) \quad (7)$$

In Equation (7),  $\mathbf{S}_j^{\pm, \text{obs}}(t)$  and  $\mathbf{S}_j^{\pm, \text{exp}}(t)$  are four vectors of size  $d-1$  that are the CUSUM statistics initiated at  $\mathbf{S}_j^{\pm, \text{obs}}(t=0) = \mathbf{S}_j^{\pm, \text{exp}}(t=0) = 0$ :

$$\begin{cases} \mathbf{S}_j^{\pm, \text{obs}}(t) = 0, \mathbf{S}_j^{\pm, \text{exp}}(t) = 0, & \text{if } C_j^\pm(t) \leq k \\ \mathbf{S}_j^{\pm, \text{obs}}(t) = \frac{(C_j^\pm(t)-k)}{C_j^\pm(t)} \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right) \\ \mathbf{S}_j^{\pm, \text{exp}}(t) = \frac{(C_j^\pm(t)-k)}{C_j^\pm(t)} \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}[\mathbf{A}_j^\pm(t)] \right) & \text{if } C_j^\pm(t) > k \end{cases} \quad (8)$$

In Equation (8),  $k$  is an allowance parameter that restarts the CUSUM procedure if no evidence of significant shift is detected after a while [14]. The value of  $k$  is obtained during offline training using historical in-control data. Then, one-sided local statistics  $W_j^+$  and  $W_j^-$  for respectively detecting upward and downward mean shifts of data stream  $j$  can be defined as:

$$W_j^+(t) = \max(0, C_j^+(t) - k), \quad (9)$$

$$W_j^-(t) = \max(0, C_j^-(t) - k). \quad (10)$$

If one wants to detect either upward or downward mean shifts, then a two-sided local statistic  $W_j(t)$  can be defined as the maximum of the two one-sided local statistics:

$$\begin{cases} W_j(t=0) = 0, \\ W_j(t > 0) = \max(W_j^+(t), W_j^-(t)). \end{cases} \quad (11)$$

Finally, to determine the stopping time  $T$  for raising the alarm by declaring the process is out-of-control, the top- $r$  approach proposed by Mei [15] is adopted. First, at each time step  $t$ , the values of individual local statistics  $W_j(t)$  for all data streams are ranked from largest to smallest:  $W_{(1)}(t) > \dots > W_{(k)}(t) > \dots > W_{(M)}(t)$ , in which  $W_{(k)}(t)$  corresponds to the  $k^{\text{th}}$  largest local statistic. Next, the top  $r$  of the local statistics at time  $t$  is calculated, and the stopping time  $T$ , also known as the out-of-control run length, is defined as:

$$T = \inf \{ t > 0 : \sum_{(k)=1}^r W_{(k)}(t) \geq h \}, \quad (12)$$

where  $h$  is a threshold value that corresponds to the pre-specified false alarm rate and can be obtained during offline training using historical in-control data. A commonly used  $h$  is obtained based on the false alarm rate of 0.27% (the classic  $3\sigma$  limit).

## Fault Classification and Diagnosis

**Figure 2.** Flowchart of the modified SVM algorithm for improved fault classification.

In this section, we discuss how accurate fault

diagnosis can be achieved using a modified SVM module in FARM. Figure 2 illustrates how we modify standard SVM for fault classification by adding a data pre-processing step in the training step. To train the SVM model using the historical sensor data corresponding to different fault scenarios, we first compute the covariance matrix of the historical faulty data streams, followed by training the SVM model over the covariance matrix instead of the original faulty data streams. This modification is inspired by the fact that covariance matrices are symmetric and positive definite, and thus always lie on a Riemannian manifold. It has been recently shown that, by respecting this important geometric insight, one can greatly enhance the accuracy and interpretability of classification, regression, dimensionality reduction algorithms by conducting these computations on the tangent space of the manifold [10]. Inspired by this finding, we map the generated covariance matrices to their tangent space, which intersect the Riemannian manifold where these covariance matrices reside at the geometric mean of the covariance matrices (see Figure 3). This mapping is done through the logarithm operation as:

$$\hat{\mathbf{A}}_i = \log_{\bar{\mathbf{A}}}(\mathbf{A}_i), \quad (13)$$

where  $\mathbf{A}_i$  is the covariance matrix of sensor data streams for dataset  $i$  calculated as:

$$\mathbf{A}_i = \frac{1}{N-1} \mathbf{X}_i \mathbf{X}_i^T, \quad (14)$$

where  $\mathbf{X}_i$  is the original sensor data matrix containing  $M$  number of data streams values over  $N$  time steps.  $\bar{\mathbf{A}}$  is the geometric mean of covariance matrices ( $\mathbf{A}_i$ ), and  $\hat{\mathbf{A}}_i$  is the mapped matrix of matrix  $\mathbf{A}_i$  to the tangent space as shown on Figure 3. The reader is encouraged to read the main reference explaining this mathematical calculation if interested [10].

**Figure 3.** Illustration of (a) a Riemannian manifold and (b) the associated tangent space. The logarithmic map as well as the geodesic between the geometric mean  $\bar{\mathbf{A}}$  and each covariance matrix  $\mathbf{A}_i$  are also shown.

After this data preprocessing step, the mapped covariance matrices are used as input features, whereas the corresponding fault scenarios are used as labels to train a standard SVM model using a radial basis function (RBF) kernel.

During online monitoring stage, real-time sensor

data streams are processed in the fault/anomaly detection module first. Only when a process anomaly is detected will the data streams be sent to the fault classification/diagnosis module. Such an arrangement will further enhance the accuracy and reliability of fault diagnosis module, as the data streams are certain to be faulty. Next, the covariance matrix for the sensor data streams is calculated, mapped to the tangent space of the Riemannian manifold, and used as the input to the trained SVM model to classify its fault label.

## CASE STUDY: TENNESSEE EASTMAN PROCESS

Abstracted from a real chemical process, the Tennessee Eastman Process (TEP) is a nonlinear open-loop unstable process that has been widely used in various computational studies as benchmark case for plant-wide control, process monitoring, and data-driven optimization [16]. As shown in the schematic of Figure 4, the TEP consists of 4 major unit operations: a reactor, a stripping column, a separator, and a product condenser. The process involves the production of two liquid product components G and H from four gaseous reactants A, C, D and E with an additional inert B and a by-product F. The process is continuously monitored by a total of 52 process variables, including 11 manipulated and 41 measured variables.

**Figure 4.** Schematic of TEP (figure extracted from [17]).

### Fault Detection Module Performance

Table 1 lists the comparison results of our SPC module with respect to two benchmark fault detection algorithms, which are PCA-T<sup>2</sup> and SVM [11]. The data used for this study is obtained by the MATLAB graphical user interface (GUI) originally developed by Andersen et al. [18]. Overall, a total of 50 hours (simulation) of normal operation data were generated using this GUI to determine the threshold value  $h$  in Equation (12) and to construct the quantiles  $I_{j,1}, \dots, I_{j,d}$  as well as the cumulative intervals  $CI_{j,i}^{\pm}$ . In addition to normal operation (in-control) data, the

GUI can generate process data for 28 different fault scenarios. Here, we select three faults, namely IDV 2, 3, and 13 (see Table 1 for description), to compare the performance of the SPC algorithm with other benchmarks.

**Table 1.** Description of faults for comparison study of multiple fault detection benchmarks.

Fault #	Description	Fault Type
IDV 2	B composition in stream 4 with A/C ratio constant	Step
IDV 3	D feed temperature in stream 2	Step
IDV 13	Reaction kinetics	Slow drift

Table 2 summarizes the comparison results of fault detection speed and the corresponding false alarm rate of all three monitoring frameworks, quantified by out-of-control run length (i.e., how many additional observations are needed to declare out-of-control status and raise alarm after the actual fault is introduced) for each algorithm. As we can see, among the three monitoring frameworks, quantile-based SPC framework yields the fastest fault detection speed in all three fault scenarios, while maintaining the lowest false alarm rate. Given that a lower false alarm rate generally sacrifices fault detection speed due to more conservative monitoring behavior, the quantile-based SPC framework achieves a win-win situation compared to other benchmark algorithms.

**Table 2.** Fault detection results in terms of out-of-control run length (false alarm rate) for SPC, PCA-T<sup>2</sup> and SVM for TEP dataset [11].

Fault #	SPC	PCA-T <sup>2</sup>	SVM
IDV 2	125 (0.27%)	216 (0.5%)	180 (0.8%)
IDV 3	95 (0.27%)	366 (0.5%)	16815 (83%)
IDV 13	128 (0.27%)	1131 (0.5%)	675 (12.7%)

### Fault Diagnosis Module Performance

For fault diagnosis, we experimented various classification algorithms using the TEP dataset developed by Rieth et al. [19], which consists of 500 simulation cases of normal (in-control) operation as well as 20 fault scenarios. To illustrate, we present three representative models here.

First, we highlight the “best model” obtained by following training procedure illustrated in Figure 2. Figure 5 shows the confusion matrix obtained through 10-fold cross-validation of these 20 faults. Clearly, the modified SVM model demonstrated outstanding classification performance for all faults except for faults IDV 3, 9, and 15. This result outperforms a number of fault diagnosis algorithms in the literature. It is worth noting that faults IDV 3, 9, and 15 correspond to “step change in temperature of

reactor feed D”, “random variation in temperature of reactor feed D”, and “sticking value failure for condenser cooling water valve”, respectively. And these three faults are well-known to be particularly challenging to differentiate due to the close similarity of their dynamic behaviors to the overall process. To tackle this longstanding challenge of successful differentiation of these faults, new, creative methodologies need to be developed.

**Figure 5.** Confusion matrix (after 10-fold cross validation) of fault diagnosis results for our proposed modified SVM model.

As a direct comparison, Figure 6 shows the confusion matrix for the case where standard SVM without any data pre-processing is used for training and validation. It is clear that fault classification accuracy deteriorates significantly in this case.

**Figure 6.** Confusion matrix (after 10-fold cross validation) of fault diagnosis results for standard SVM model without the introduced data pre-processing step.

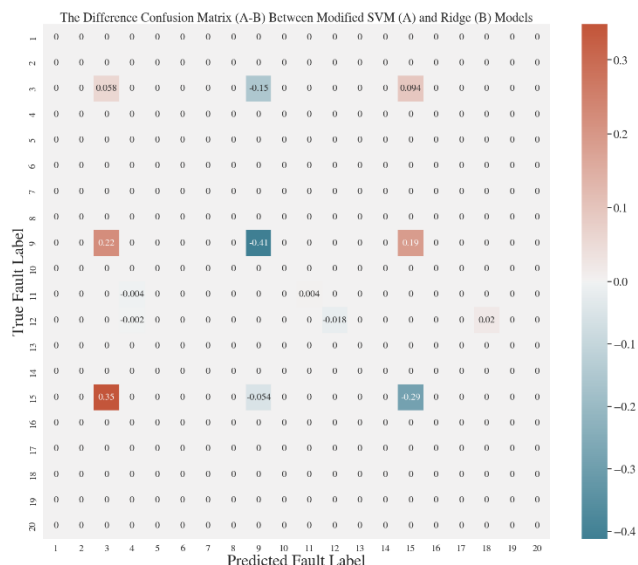

Finally, we present the results for another fault diagnosis algorithm based on principal geodesic analysis (PGA) discussed by Smith et al. [10]. PGA is a counterpart of principal component analysis (PCA) applied on the tangent space of the Riemannian manifold, as it identifies the geodesics that capture the most variance in the data. In other words, in PGA, we simply apply PCA technique to the mapped covariance matrices of faulty data streams for dimensionality reduction. To determine the number of principal geodesics (which are the “principal components” in PGA) needed, we perform sensitivity analysis and identify that 29 principal geodesics are required to capture 99% of the variance in the original dataset containing covariance matrices on the Riemannian manifold. Furthermore, four distance measures, namely Euclidean, Mahalanobis, Manhattan, and Cosine are tested and compared. Clustering is done by assigning a point to its closest cluster based on the distance measure used. We identify that, among these four measures, the cosine distance offers the best fault classification performance. Figure 7 shows the confusion matrix of PGA-cosine approach with the 10-fold cross validation. As we can see, in general, 12 out of the 20 faults can be fully classified, whereas faults IDV 3, 5, 9, 10, 12, 13, 15, and 18 cannot. Although its accuracy is yet to match with the best model, the PGA-Cosine algorithm performs much better than standard SVM without data pre-processing.

Since the modified SVM model showed superior performance over PGA-Cosine method, the confusion

matrix of this method is compared with 10-fold confusion matrix of the ridge classifier model presented by Smith et al. [10], which trained on the mapped covariances. Figure 8 depicts the difference of confusion matrices between the modified SVM (A) and Ridge (B) classifiers. Positive numbers show that the prediction probability values of modified SVM model were higher than Ridge classifier. Conversely, the negative values indicate that the Ridge model's prediction probabilities were more than the modified SVM. Lastly, zero means that both models had the same prediction probability. As can be seen, both models have the same accuracy for all faults excepts faults 9 and 15, which the ridge classifier had a better accuracy than the modified SVM model by looking at the diagonal values of the difference matrix.

**Figure 7.** Confusion matrix (after 10-fold cross validation) of fault diagnosis results for PGA-Cosine classification algorithm with 29 principal components being selected.

**Figure 8.** The difference confusion matrix between 10-fold cross validation matrices of the modified SVM classifier presented in this study (A) and the ridge classifier presented by Smith et al. (B) [10].

## CONCLUSION

In this work, we present a fast, accurate, and robust algorithmic framework named FARM for industrial process monitoring. FARM is a holistic framework that synergistically performs fault detection and diagnosis tasks to improve monitoring performance. The fault detection module inside FARM adopts an advanced quantile-based SPC approach that can detect any mean shift of non-parametric and heterogenous multivariate data streams as soon as possible while maintaining a pre-specified false alarm rate. Meanwhile, the fault diagnosis module inside FARM implements a modified SVM algorithm for fault classification. Compared to standard SVM approach, our modified SVM algorithm includes an important data pre-processing step that makes use of the manifold insight of covariance matrix to greatly enhance classification accuracy. By validating and evaluating the performance of our FARM framework using the TEP dataset, we observe that 1) our fault detection module can achieve fast anomaly detection speed at a low false alarm rate, and 2) our fault diagnosis module successfully classifies 17 out of 20 fault scenarios at 100% accuracy. Unfortunately, faults IDV 3, IDV 9, and IDV 15 of the TEP dataset, which are known to be hard to classify, still face challenges in differentiating among one another with high accuracy. Our future work involves revamping the FARM framework to improve the classification accuracy of these hard-to-differentiate faults.

## ABSTRACT

This paper presents the development of algorithms for mass-energy constrained neural network (MECNN) models that can exactly conserve the overall mass and energy of distributed chemical process systems, even though the noisy steady-state/transient data used for optimal model training violate the same. For developing dynamic mass-energy constrained network models for distributed systems, hybrid series and parallel dynamic-static neural networks are used as candidate architectures. The proposed approaches for solving both the inverse and forward problems are validated considering both steady-state and dynamic data in presence of various noise characteristics. The proposed network structures and algorithms are applied to the development of data-driven models of a nonlinear non-isothermal reactor that involves an exothermic reaction making it significantly challenging to exactly satisfy the mass and energy conservation laws of the system only by using the available input and output boundary conditions.

## INTRODUCTION

Complex first-principles models are often needed to represent the complicated physics and chemistry associated with many chemical engineering applications. While the first-principles models can exactly satisfy mass and energy conservation, their development can consume considerable time, and resources, and require good understanding of the physics/chemistry that may not be available or may be difficult to obtain. One alternative is the data-driven / artificial intelligence (AI) modeling tools, that are relatively easier to develop, simulate, and adapt online for many chemical engineering applications [1,2]. Recent advances of machine learning (ML) have significantly influenced a wide range of scientific and engineering fields with applications to thermofluidic processes [3,4], computational fluid dynamics [5,6], as well as varieties of other complex industrial applications [7]. More recently, physics informed neural networks [8] (PINNs) have gained popularity due to their effectiveness in solving realistic practical problems with noisy data and often partially missing physics, with implementations ranging from solving systems of partial differential equations

[9,10] to modeling different chemical processes such as photochemical systems [11], hydrofluorocarbon refrigerant mixtures [12], biomass pyrolysis process [13], heat transfer problems [7], etc. In all these works, the physics conservation equations have been either augmented in the loss (objective) function as additional penalty terms to penalize the violation of such constraint(s) or by integrating them into sequential conservation layers following the data-driven model. If the system conservation laws are included in the objective function for training the neural network (NN) models, they serve as soft constraints and do not ensure an 'exact' satisfaction of the physics constraints. However, in numerous chemical engineering applications, it is desired that certain mathematical relationships (such as mass and energy balances) are exactly conserved and not only approximated<sup>3</sup>. In very few recent publications [3,14] that seek to satisfy the physics constraints exactly, the proposed algorithms are either highly system specific, or require rigorous understanding of the chemical process to impose appropriate physics conservation laws pertaining to the system. These approaches can lead to higher errors, especially during the forward problem. Another common approach

in the open literature is to send the NN model outputs through a linear transformation block to satisfy mass and energy balances. However, physics-conserving equations are not necessarily linear. Furthermore, the corrections applied to the network output in the conservation layer, if applied simultaneously while training the network rather than sequentially, can affect the training of the NN model.

It is also desired that the physics constraints be exactly satisfied not only during solving the inverse problem, but also during the forward problem for unknown inputs. In this work, 'inverse' problem refers to the training approaches for optimal NN models, whereas 'forward' problem is represented by model validation / simulation. Most variants of typical PINNs that seek to conserve the mass [3,4,13] and energy [7] of chemical systems are found to satisfy the conservation constraints only approximately through penalty terms included in the objective function. Furthermore, these models may not satisfy the mass/energy balances during the forward problem. Exactly satisfying mass and energy conservation of chemical process systems is critical to ensure that model predictions remain realistic and bounded by physical laws.

Another aspect which poses to be a significant challenge during optimal model synthesis and parameter estimation is to develop accurate constrained network models when the data are noisy [15]. The presence of noise in the training data can corrupt the gradient calculations during estimation of network parameters [16] and can result in biased estimates of parameters during model training. Though variants of PINNs such as Bayesian PINNs [17], fractional PINNs [18], etc. address existence of noise in data while solving systems of partial differential equations, existing algorithms that seek to exactly conserve system physics, especially mass and energy balances, do not consider the presence of uncertainties in training data at all [3,4,15]. However, to the best of our knowledge, although a few papers exist till date trying to exactly conserve mass of a system [3,4], there is currently no work in existing literature focused on exactly conserving the energy of distributed chemical process systems, perhaps due to the complexities associated with distributed nature of energy constraints, energy addition/removal at different spatial locations as well as loss or generation of heat due to complicated mechanisms including endothermic/exothermic reactions in the system. Furthermore, such approaches consider only static feedforward NNs and obviously only steady-state data for model development. Developing a fully data-driven dynamic model that can satisfy system physics, especially mass and energy balance constraints, can be challenging since mass/energy conservation can be adequately applied only to the steady-state data especially if the system is distributed and there is no

measurement available for the system holdup. Though one may desire to satisfy practically any type of physics-based constraint equation through such approaches, in this work we are primarily focused on exactly conserving the mass and energy of a system, hence denoting the corresponding NNs as Mass-Energy Constrained Neural Networks (MECNNs). The primary objective of the paper is to develop optimal NN models that exactly satisfy mass and energy conservation of chemical processes, even in the presence of noise in transient training data. In summary, contributions of this work are as follows:

- Both training (inverse problem) and validation (forward problem) algorithms are developed for MECNNs, where the mass (atom) and energy (enthalpy) balance equations are imposed as equality constraints during parameter estimation to ensure that mass and energy conservation laws are exactly satisfied in a fully data-driven approach.
- It is desired that the proposed approach accommodates nonlinear transformations for constraint satisfaction and is also applicable when there is no close-form equation available for satisfying the desired constraints.
- Different uncertainty characteristics, represented by presence of a constant (time-invariant) and random (time-varying) bias in addition to a zero-mean (known variance) Gaussian noise are simulated.
- In addition to steady-state modeling of nonlinear chemical process systems, our approach also addresses dynamic data-driven model development using noisy transient data. The proposed algorithms are demonstrated for modeling the non-isothermal Van de Vusse reactor system [19].

## MECNN STRUCTURE AND FORWARD / INVERSE PROBLEMS

### Steady-State MECNN Implementation

Novel model structures have been developed for both steady-state and dynamic implementations of MECNNs. The block-oriented structure for steady-state MECNNs, as shown in Figure 1, considers a typical feedforward neural network (FFNN) model followed by a steady-state data reconciliation (SDR) step, where  $\mathbf{y}_{MECNN}$  represent the final outputs from the optimal MECNNs,  $\mathbf{y}_{FFNN}$  refer to the intermediate outputs obtained from the FFNN corresponding to the model inputs ( $\mathbf{u}_{NN}(k)$ ), and  $k$  denotes the indices of steady-state training data. The FFNN model is a single hidden-layered feedforward NN involving logistic sigmoid activation functions and the Levenberg-Marquardt (LM) algorithm for parameter estimation. The choice of FFNN model is completely arbitrary since the proposed approaches can be applied irrespective of the specific network model architecture. More details about various FFNN models can

be found in numerous references [1,20]. The SDR block provides the additional degrees of freedom necessary for solving the equality constrained optimization problem, thus facilitating the simultaneous estimation of parameters for both FFNN and SDR blocks through the inverse problem formulation described by Equation (1). The mass and energy balance equations of the system represent the equality constraints imposed on the MECNN during both inverse and forward problems to guarantee the exact conservation of system physics. The proposed architecture is also flexible to accommodate any linear or nonlinear close-form transformation equations that may be used for constraint satisfaction by substituting the SDR block which requires solving an optimization problem for convergence.

**Figure 1.** General Architecture of Steady-State MECNNs

The inverse problem for steady-state modeling using MECNNs combines optimization problems representing the regression of FFNN model as well as reconciliation of the neural network outputs. Therefore, in such approaches, not only the FFNN model parameters (referred to as  $\theta_{FFNN}$ ) are estimated, but also the outputs from the FFNN model ( $y_{NN}$ ) are reconciled simultaneously, in presence of the mass and energy conservation constraints represented by Equations (1c) and (1d).

$$\min_{\mathbf{y}_{MECNN}, \theta_{FFNN}} \sum \left( (\mathbf{y}_{tar}(k) - \mathbf{y}_{MECNN}(k))^T R^{-1} (\mathbf{y}_{tar}(k) - \mathbf{y}_{MECNN}(k)) \right) + \sum \left( (\mathbf{y}_{MECNN}(k) - \mathbf{y}_{FFNN}(k))^T R^{-1} (\mathbf{y}_{MECNN}(k) - \mathbf{y}_{FFNN}(k)) \right) \quad (1a)$$

$$s. t. \quad \mathbf{y}_{FFNN}(k) = \mathbf{f}_{FFNN}(\mathbf{u}_{NN}(k), \theta_{FFNN}) \quad (1b)$$

$$\mathbf{h}_M(\mathbf{u}_{NN}, \mathbf{y}_{MECNN}, k) = 0 \quad (1c)$$

$$\mathbf{h}_E(\mathbf{u}_{NN}, \mathbf{y}_{MECNN}, k) = 0 \quad (1d)$$

where,  $\mathbf{y}_{tar}$  denotes the target training data for MECNNs.

Although the FFNN model parameters (weights and biases) can be regressed to guarantee the exact satisfaction of mass and energy balance constraints for all data on which the MECNN is trained on, it can still not be ensured that that the optimal FFNN ( $FFNN_{opt}$ ) will continue to exactly conserve mass and energy of a system when subjected to unknown inputs different from those encountered during model training. Therefore, for the forward problem (i.e., model simulation) as well, the SDR block exists following the optimal FFNN model, in a similar configuration as Figure 1, to ensure the exact conservation of system mass and energy even during model simulation (validation). However, for this case, the SDR

block simply acts as a post-processing step leading to the following formulation of the forward problem:

$$\min_{\mathbf{y}_{MECNN}} \sum \left( \left( \mathbf{y}_{FFNN_{opt}}(k) - \mathbf{y}_{MECNN}(k) \right)^T R^{-1} \left( \mathbf{y}_{FFNN_{opt}}(k) - \mathbf{y}_{MECNN}(k) \right) \right) \quad (2a)$$

$$s. t. \quad \mathbf{y}_{FFNN_{opt}}(k) = \mathbf{f}_{FFNN}(\mathbf{u}_{NN}(k), \theta_{FFNN_{opt}}) \quad (2b)$$

$$\mathbf{h}_M(\mathbf{u}_{NN}, \mathbf{y}_{MECNN}, k) = 0 \quad (2c)$$

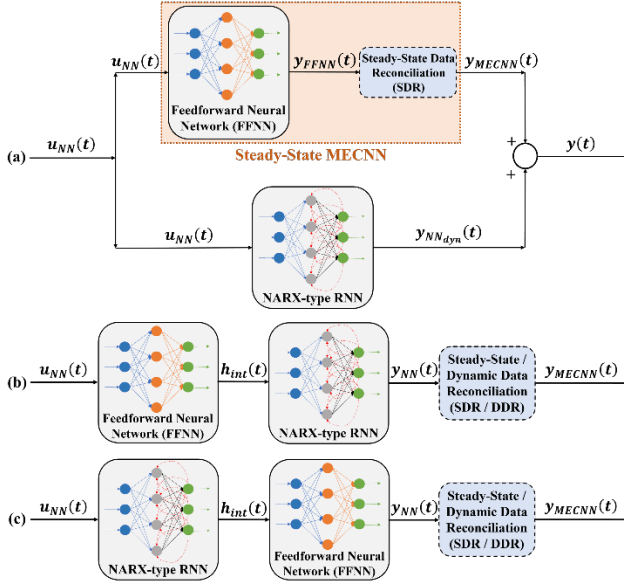

$$\mathbf{h}_E(\mathbf{u}_{NN}, \mathbf{y}_{MECNN}, k) = 0 \quad (2d)$$

## Dynamic MECNN Implementation

Although typical FFNNs feature sufficiently satisfactory performance while modeling various steady-state systems, it may be significantly challenging for static networks to accurately model highly complex nonlinear temporal systems with time-lagged input variables. One of our previous papers [1] has shown that hybrid series and parallel all-nonlinear static-dynamic network models exhibit superior performance than many state-of-the-art recurrent neural networks (RNNs), especially while handling large-sized dynamic training data containing complex nonlinearities. Such hybrid models consider typical FFNNs representing the nonlinear static (NLS) network, while the nonlinear dynamic (NLD) network is characterized by the Nonlinear Auto-Regressive with eXogenous inputs (NARX) type RNN which provide efficient approximations while modeling temporal systems due to presence of feedback connections eradicating the necessity of data windows for time-lagged inputs [21]. The NARX-type RNN models considered in this work also consist of a single hidden layer and the logistic as well as hyperbolic tangent sigmoid activation functions, where the parameters are estimated by the Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm. Furthermore, for different transient systems, local measurements depicting holdup information may or may not be available. Therefore, the algorithms for developing accurate dynamic MECNNs may differ based on whether holdup measurements are available. Since both hybrid parallel and series network models can be considered during development of dynamic MECNNs, two different configurations are possible, namely the hybrid parallel MECNN and the hybrid series MECNN respectively, as shown in Figure 2.

The hybrid parallel MECNN operates under the assumption that the entire time-series data can be distinctly partitioned into steady-state and dynamic zones. This approach of partitioning training data also facilitates the flexibility of solving a sequential optimization problem [1,23] for the overall inverse problem of the hybrid parallel MECNN. In such an approach, the steady-state MECNN is first developed based on only the steady-state zones, i.e., the formulation of the inverse problem

remains exactly same as given by Equation (1), followed by constructing a deterministic NLD deviation model ( $NN_{dyn}$ ) represented by a NARX-type RNN to match the residuals / deviations obtained with respect to the training data and steady-state MECNN model outputs. The deviation data thus generated serve as target data for training the NARX-type RNN model independently during the sequential approach while minimizing the typical squared error objective function as given by Equation (3).

**Figure 2.** General Architecture of (a) hybrid parallel and (b), (c) hybrid series MECNNs

$$\min_{\theta_{NARX}} \left( \mathbf{y}_{tar}(t) - \mathbf{y}_{MECNN}(t) - \mathbf{y}_{NN_{dyn}}(t) \right)^T R^{-1} \left( \mathbf{y}_{tar}(t) - \mathbf{y}_{MECNN}(t) - \mathbf{y}_{NN_{dyn}}(t) \right) \quad (3a)$$

$$s. t. \mathbf{y}_{NN_{dyn}}(t) = \mathbf{g}_{NARX}(\mathbf{u}_{NN}(t), \theta_{NARX}) \quad (3b)$$

Unlike hybrid parallel MECNNs, the hybrid series MECNNs are flexible to accommodate the entire time-series dynamic data, regardless of whether there is access to system holdup information or not. When holdup measurements are not available, then the mass and energy conservation constraints can only be applied to the steady-state zones while formulating the SDR block in the inverse problem due to insufficient information about the system holdup during transients. On the other hand, for the case when the system holdup information is available during formulation of the inverse problem for hybrid series MECNNs, the approach discussed above can readily be extended to exactly satisfy the mass ( $\mathbf{h}_M(\cdot)$ ) and energy ( $\mathbf{h}_E(\cdot)$ ) balance constraints at each time step in the transient profile, thus leading to substituting the SDR step with a dynamic data reconciliation (DDR) based transformation [22]. For systems with no or negligible

spatial distribution, holdup measurements may be available, such as continuous stirred tank reactors (CSTRs). The corresponding forward problems for dynamic MECNNs follow similar formulations based on the sequential architectures involving the SDR / DDR post-processing step.

## Error Characterizations

Measurement data considered for developing optimal accurate data-driven models often contain uncertainties stemming from various factors. The two types of error characterizations (Equations (4) and (5)) that have been considered in this work during both steady-state and dynamic implementations of MECNNs include adding constant (time-invariant) and random (time-varying) biases ( $\boldsymbol{\beta}$ ) respectively, to the true data,  $\mathbf{y}_{true}$  (generated from simulation) in presence of Gaussian noise ( $\eta(0, \sigma^2)$ ). The primary goal is to assess how the presence or absence of noise and its characterization impact the performance of the proposed MECNNs and their capabilities to exactly conserve the mass and energy of a system. It is to be noted that for the case when the measurements are corrupted with a random (time-varying) bias, the inverse problem formulation as given by Equation (1) may lead to lack of identifiability while constructing accurate data-driven models which yield results close to the system truth. Therefore, in this work, additional parametric (linear, quadratic, etc.) noise models have been incorporated into the inverse problem formulation while addressing random (time-varying) bias in measurement data.

$$\mathbf{y}_{tar}(t) = \mathbf{y}_{true}(t) + \boldsymbol{\beta} + \eta(0, \sigma^2) \quad (4)$$

$$\mathbf{y}_{tar}(t) = \mathbf{y}_{true}(t) + \boldsymbol{\beta}(t) + \eta(0, \sigma^2) \quad (5)$$

## CASE STUDY: NON-ISOTHERMAL VAN DE VUSSE REACTOR SYSTEM

The nonisothermal model of the Van de Vusse reactor system is one of the most vastly studied multi-input-multi-output (MIMO) processes due to its high complex nonlinearities [19]. The reaction involves the production of cyclopentenol (B) from cyclopentadiene (A) by acid-catalyzed electrophilic addition of water in dilute aqueous solution. The side products of this reaction are cyclopentanediol (C) and dicyclopentadiene (D). Cooling water flows through the jacket surrounding the reactor to remove excess heat generated due to the highly exothermic reaction within the system, as shown in Figure 3. The detailed mathematical model consisting of the overall material and energy balance equations and nominal values of the involved parameters can be found in the literature [19].

**Figure 3.** Schematic of the Nonisothermal Van de Vusse Reactor for MECNN Implementation

The feed stream contains predominantly component A, with small quantities of B. Following variables are considered to be the inputs to the MECNN model-volumetric flowrate ( $F$ ) and inlet temperature ( $T_0$ ) of the feed, volumetric flowrate ( $F_j$ ) of the jacketing fluid, along with the concentrations of A ( $C_{A_f}$ ) and B ( $C_{B_f}$ ) in the feed stream. Following variables are considered to be the outputs for the model-concentration of all reaction species, i.e., A ( $C_A$ ), B ( $C_B$ ), C ( $C_C$ ), D ( $C_D$ ) in the product stream and the outlet temperatures of the product stream ( $T_{MECNN}$ ) and jacketing fluid ( $T_{j_{MECNN}}$ ). It is assumed that the inlet and outlet volumetric flowrates are the same across the reactor system as well as across the cooling jacket. The steady-state mass balance constraints in terms of elemental atom (C, H, and O) balance equations and the energy balance constraint have been provided in Equations (6) through (9), where  $n_{C_i}$ ,  $n_{H_i}$ , and  $n_{O_i}$  represent the number of C, H, and O atoms respectively in the  $i^{th}$  species,  $\rho_r$  denotes the density of the reactor mixture,  $h_{in}$  and  $h_{out}$  refer to the specific enthalpies of the reactant and product mixtures as functions of inlet ( $T_0$ ) and outlet ( $T_{MECNN}$ ) temperatures,  $m_j$ ,  $V_j$  and  $C_{p_j}$  refer to the mass, volume and specific heat capacity of cooling water flowing through the jacket, and  $T_{j_0}$  represent the inlet temperature of the jacketing fluid (cooling water).

$$\sum_{i=A,B,H_2O} n_{C_i} * F(k) * C_{i_f}(k) = \sum_{i=A,B,C,D,H_2O} n_{C_i} * F(k) * C_{i_{MECNN}}(k) \quad (6)$$

$$\sum_{i=A,B,H_2O} n_{H_i} * F(k) * C_{i_f}(k) = \sum_{i=A,B,C,D,H_2O} n_{H_i} * F(k) * C_{i_{MECNN}}(k) \quad (7)$$

$$\sum_{i=A,B,H_2O} n_{O_i} * F(k) * C_{i_f}(k) = \sum_{i=A,B,C,D,H_2O} n_{O_i} * F(k) * C_{i_{MECNN}}(k) \quad (8)$$

$$F(k) * \rho_r * (h_{in}(T_0(k)) - h_{out}(T_{MECNN}(k))) = \frac{F_j(k)}{V_j} * m_j * C_{p_j} * (T_{j_{MECNN}}(k) - T_{j_0}) \quad (9)$$

Since this case study considers a CSTR system with no spatial distribution, the system holdup information can be explicitly modeled using the outlet boundary conditions and reactor instantaneous volume, since the accumulation term for concentrations / temperature of the

reaction species in a CSTR is exactly same as the corresponding outlet values at every time instance during dynamic modeling. For example, the mass (in terms of C atom) and energy balance constraints which can be imposed at every time step ( $t$ ) for this case study can be expressed in terms of inlet / outlet flowrates ( $F_{in}$ ,  $F_{out}$ ) and instantaneous reactor volume ( $V$ ) as:

$$\frac{d(V C_i)}{dt} - \left[ \sum_{i=A,B,H_2O} n_{C_i} * F_{in}(t) * C_{i_f}(t) - \sum_{i=A,B,C,D,H_2O} n_{C_i} * F_{out}(t) * C_{i_{MECNN}}(t) \right] = 0 \quad (10)$$

$$\frac{d(\rho_r V h)}{dt} - \left[ \rho_r * (F_{in}(t) h_{in}(T_0(t)) - F_{out}(t) h_{out}(T_{MECNN}(t))) - \frac{F_j(t)}{V_j} * m_j * C_{p_j} * (T_{j_{MECNN}}(t) - T_{j_0}) \right] = 0 \quad (11)$$

## RESULTS AND DISCUSSIONS

### Steady-State Modeling

The different types of error characterizations considered for generating measurement data for the steady-state modeling of the non-isothermal Van de Vusse reactor system have been separately analyzed. For presenting both steady-state and dynamic results, the data used for training MECNN models are referred to as 'measurements', irrespective of whether they had been generated from a first-principles model or collected from experiments. Furthermore, the violation of mass and energy conservation constraints by the network models have been quantified in terms of absolute percentage error (APE) in atom and energy (Q) balances defined as:

$$APE_{atom_i} = \left| \frac{\sum_{in} F_{m_{atom_i}} - \sum_{out} F_{m_{atom_i}}}{\sum_{in} F_{m_{atom_i}}} \right| * 100\% \quad (12)$$

$$APE_{energy} = \left| \frac{Q_R - Q_j}{Q_R} \right| * 100\% \quad (13)$$

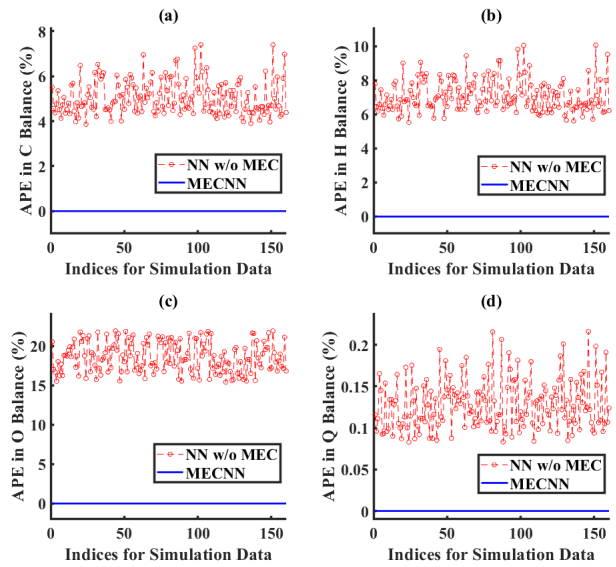

where,  $\sum_{in} F_{m_{atom_i}}$  and  $\sum_{out} F_{m_{atom_i}}$  respectively denote the total mass flowrate of the  $i^{th}$  atom in all inlet and outlet streams, and  $Q_R$  and  $Q_j$  refer to the total heat lost by the reactor mixture and that gained by the jacketing fluid (cooling water) respectively. While the root mean squared error (RMSE) calculated between the measurements / truth and model predictions account for the predictive capabilities of the proposed data-driven models for nonlinear steady-state / dynamic data, the APE in atom and energy balances represent the magnitude of the maximum (worst-case) violation of the mass and energy balance constraints respectively. The specific enthalpy terms involved in the energy balance constraint (as given by Equation (9)) have been appropriately expressed in terms of specific heat capacity of the reactor mixture and the heat of reaction calculated from the

respective heats of formation of the reactants and products. For brevity, only the steady-state results obtained when the measurement data are corrupted with a constant bias along with Gaussian noise, have been included here. Constant biases equal to 5% of the mean of the true concentrations and a constant positive value of 3.5°C for each temperature variables have been added to the respective outputs in presence of a Gaussian noise with  $\mu = 0$  and  $\sigma^2 = 0.25$ . Figure 4 compares the model results vs truth and measurements for MECNN and NN w/o mass-energy constraints (MEC) for simulation data of  $C_A$  ( $\frac{kmol}{m^3}$ ).

**Figure 4.** Comparison of results between MECNN and NN w/o MEC for simulation data of  $C_A$  (noise in measurement data represented by Equation (4))

The unconstrained NN yields an excellent match with about 0.03% RMSE with respect to the measurements but results in biased estimates compared to the truth, thus leading to around 5.3% RMSE with respect to the true data. On the contrary, the MECNN accurately captures the system truth (characterized by approximately 0.01% RMSE) but shows a clear mismatch with the measurements leading to around 4.9% RMSE. The imposition of mass and energy conservation laws as equality constraints, along with modification of the objective function as given in Equation (1a) results in the outputs from MECNN that minimize error with respect to the system truth, as opposed to minimizing error with respect to the measurements (training data). Furthermore, the MECNN exactly satisfies both mass and energy balance constraints during the forward problem as well, as evident from Figure 5, whereas the NN w/o those constraints show maximum APE in C, H, O and Q balance as 7.4%, 10.1%, 21.8%, and 0.22% respectively.

**Figure 5.** Comparison between MECNN and NN w/o MEC in terms of violating (a) C, (b) H, (c) O and (d) Q balance constraints during simulation (noise in measurement data represented by Equation (4))

## Dynamic Modeling

The performance of dynamic MECNNs is evaluated in this paper for the case when a time-varying bias is added to the system truth to generate measurements in presence of Gaussian noise, as given in Equation (5). As discussed before, different parametric forms of a noise (error) model, such as linear, quadratic, etc. have been considered during optimal model synthesis when the measured data are corrupted with a time-varying bias. In this case, time-varying biases in the range of -4% to +6% of the true outlet concentrations have been added to the concentration variables and that within -1°C to 6°C have been incorporated into the true temperature variables to generate training data, along with an additional Gaussian noise distribution with  $\mu = 0$  and  $\sigma^2 = 0.25$ . The linear parametric form of the noise (error) model yielded superior results in terms of percentage RMSE with respect to true data as well as minimum values of the corrected Akaike Information Criteria [1,23] ( $AIC_c$ ) evaluated during model training, as compared to the quadratic form as well as the case when no separate error model was considered during parameter estimation. Figure 6 shows the comparison between the results obtained from the hybrid series MECNN vs standalone series NN without mass-energy constraints (MEC) for simulation data of  $T$ .

While the unconstrained hybrid NLS – NLD model shows an excellent match with the measurements (represented by around 0.09% RMSE), the results obtained violate the mass and energy conservation of the system leading to approximately 2.5% RMSE with the true data. On the other hand, the hybrid series MECNN shows a significant mismatch with the measured data (characterized

by around 2.8% RMSE) but accurately captures the system truth recording an overall percentage RMSE of just 0.04%. The MECNN has also been seen to exactly satisfy the C, H, O, and energy balances at steady state while showing some mismatch during transients. However, the unconstrained NN model show APE in the mass and energy conservation equations as high as 22%, 30%, 60%, and 0.5% respectively. It is to be noted that for process control applications, the dynamic models for MECNNs can be used as soft sensors, especially for those involving an economic measure where such mass / energy imbalances can lead to inaccurate accounting of the control objective. The impact of inaccurate measurements on the key economic measures of the process such as efficiency has been extensively investigated by other researchers [24,25].

**Figure 6.** Comparison of results between hybrid series MECNN and NN w/o MEC for simulation data of  $T$  (noise in measurement data represented by Equation (5))

When holdup measurements are available, the proposed algorithms can be extended to exactly satisfy mass and energy balance constraints even during the transients. Since this case study example is essentially a CSTR, the concentrations of the reaction species and the instantaneous temperature of the reaction mixture inside the reactor at any given point of time can be assumed to be exactly equal to the outlet concentrations and temperature of the same at that time instant. The plots comparing results from unconstrained vs constrained network models when system holdup information is available have not been discussed here for brevity. However, unlike previous cases, the MECNN exactly satisfies the mass and energy conservation even during the transients due to the imposition of mass and energy balance constraints at every time step of the dynamic training / simulation data. The unconstrained NN model, for this case,

shows significantly higher APEs in C, and Q balances recording maximum errors of 9% and 4.5% respectively, as shown in Figure 7.

**Figure 7.** Comparison between hybrid series MECNN and NN w/o MEC in terms of violating (a) C (b) Q constraints (holdup info available) during simulation (noise in measurement data represented by Equation (4))

## CONCLUSIONS

In this study, we have developed algorithms for synthesizing steady-state and dynamic neural network models capable of exactly satisfying mass and energy conservation laws, even when the training data used for training the networks violate these laws. Furthermore, we have also demonstrated that if system holdup information is available during process transience, these algorithms can also exactly satisfy physics constraints during process dynamics. The proposed approaches can be individually applied to different equipment items in interconnected systems assuming that the required boundary information is measured / available. For interconnected reactive systems and systems involving mass / energy integration / losses, application of the proposed approach to the plant-wide system needs further investigation. For all results presented in this paper, the steady-state and dynamic MECNNs consistently exhibited RMSE of less than 1% when compared to the true data for both inverse and forward problems. On the contrary, the corresponding unconstrained networks resulted in significantly higher errors. The MECNN structures developed as part of this work can be applied not only for steady-state modeling, but also in effectively representing dynamic process systems represented by noisy measurements. However, since the proposed approaches work on a minimum-bias principle during estimation of optimal parameters in presence of different types of uncertainties in training data, it is important to clarify that these algorithms do not necessarily guarantee perfect predictions of the true data as expected but do ensure that mass and energy balance constraints are exactly satisfied during both inverse (training) and forward (simulation) problems.

## ABSTRACT

A hybrid model for the fluid bed granulation operation was built. The deterministic component focuses on the mass and energy balances representing the water ingress and egress from the powder bed. The empirical one does on granule growth. Estimability techniques were used to determine which parameters to regress from the available data. A partial least squares approach was used to better understand the impact of the model parameters onto key model responses and sensitivity plots were made to aid operational decisions and support pharmaceutical development.

**Keywords:** Process Operations

## INTRODUCTION

Fluid bed granulation is a common operation in the manufacture of pharmaceutical oral solid dosage forms (i.e. tablets and capsules). The aim of the operation is to agglomerate the blend of primary particles in the incoming powder blend to increase particle size and density. This operation becomes necessary when simpler approaches (e.g. direct compression) are unfeasible due to the poor flowability of the unprocessed powder mixture. The operation typically consists of a closed chamber where powder is loaded, an aqueous solution of a binding polymer

is sprayed onto the powder as drying air is fed through the bottom of the chamber fluidizing the powder and aiding the incorporation of the spray into the powder bed. The operation consists of two main phases after the powder is loaded, a *spray* phase where a pre-defined amount of solution is sprayed onto the powder and a *drying* phase where the spray is stopped, and air continues to be fed to fluidize and dry the agglomerates (granules) to a desired level of humidity (Figure 1).

The common manipulated variables (MV) in this operation are i) the amount of spray added ii) the spraying rate, iii) the temperature of the drying air, iv) the air flow during the spraying phase and v) airflow during the drying phase. A typical constraint is the composition of the powder blend since this is determined to satisfy a desired dose in the final product.

The aim of this study is to approach the design of the operating conditions for this unit for a specific product, utilizing scientific understanding rather than solely through empiricism. We do this through the formulation of a mathematical expression (a model) that captures the combined effect of the multiple driving forces affecting the in the system. Once the model is formulated, we use in-silico studies to define a design space for commercial manufacturing.

**Figure 1.** Schematic of a fluid bed granulation chamber

## MODEL DESCRIPTION

Detailed studies [1] demonstrate the strong coupling between granule growth and drying mechanism. Both mechanisms are tied since the granule size will determine the particle specific surface area available for water intake and drying. Some researchers have focused on studying the granule growth solely [2], while others focus the study on the water intake and egress [3] under the hypothesis that controlling one mechanism will result in control of the other.

Our work approaches the drying phenomena through mechanistic modeling while addressing the granule size through an empirical model.

### Mass and Energy Conservation

Our approach follows that of Ochsenbein et. al [3] with some differences that are discussed. The considered flows of water across the system are illustrated in figure 2. Three distinct phases are considered: spray, powder bed, and chamber (gas phase). Liquid water ingresses the system through the spray and most of it assumed to be immediately transferred to the powder bed. Water vapor is assumed to be lost directly from the spray to the gas phase through an efficiency and transferred between the powder bed and the gas phase through a drying expression.

**Figure 2.** Mass flows across phases

Several key differences separate our work from that of Ochsenbein et al. [3]. The way we calculate the outlet airflow is discussed first. The only inlet of bone-dry air is the inlet air flow. We assume that the volume of humid air leaving the chamber is a natural response to equalizing the pressure in the chamber as it can build up or down depending on the temperature or the water content in the gas phase. This approach is known as a pressure-driven simulation and would typically require complex momentum transfer calculations, we took a short-cut approach. In this work we calculate the pressure in the chamber as a function of temperature and water content using an ideal gas approach (the volume of the chamber is fixed). We determine the necessary volumetric flow of humid air leaving the chamber necessary to keep the pressure in

the chamber steady at atmospheric conditions. This is calculated using the equations of a fictitious PI controller (Equations. 1 and 2) tuned to be fast but stable.

$$\dot{v}_{W+AIR}^{OUT} = K_p \varepsilon + \frac{1}{\tau_i} \int \varepsilon + \dot{v}_{W+AIR}^{IN} \quad (1)$$

$$\varepsilon = P_{CHAMBER} - P_{SP} \quad (2)$$

A second difference is the assumed driving force for the water transfer from powder to the gas phase. In our work we assume that the difference between the absolute humidity in the powder and the equilibrium humidity of the powder when exposed to the current conditions in the gas phase ( $\Delta Hum = \gamma_{bed}^{abs} - \gamma_{bed}^{@eq w air}$ ) is the drying driving force. This equilibrium condition can be obtained in the laboratory using a dynamic vapor sorption instrument. Typically, these equilibrium curves will be produced at ambient conditions, which are not reflective of the powder bed temperatures in the process. In our work we chose to consider the dependency of this equilibrium with respect to temperature. We include this in the model by measuring the water sorption isotherms at multiple temperatures and following the approach by Quirijns et. al. [4] to modify the GAB equation and thus be able to include the temperature effect on the equilibrium condition. This equilibrium is also a function of composition since each different ingredient has a different sorption curve and the composition of the bed changes as binder is added through the spray; a simple mass fraction weighted average is used.

We also consider the inclusion of a spraying efficiency ( $\gamma$ ) equation (Equation 3) to capture the losses of water directly from the spray into the gas phase as a function of the absolute humidity of the powder bed. This expression introduces into the model the phenomena known as “wetting” where water permeation onto a dry powder is more difficult than onto a wet powder. We also consider the inclusion of a modifying scalar  $\omega$  to the available surface area for drying (Equation 4). This scalar is less than one during the spray phase and equal to one during drying. During the spray phase, water is entering the powder bed, and it is assumed that the portion of the total surface area of the powder that is used for water intake cannot be used for drying. The evaporation rate coefficient ( $k_{evap}$ ) is assumed to follow a first order exponential function with respect to the driving force. This allows  $k_{evap}$  to be a constant during the constant drying phase; and to decay when the drying is limited by mass transfer. This approximation Eq (5) enables the drying calculations without formally solving the intra-particle mass transfer problem.

$$\gamma = \left(1 - e^{(-\tau_s \gamma_{bed}^{abs})}\right) \quad (3)$$

$$\dot{m}_{evap bed} = SA_{particles} k_{evap} * \omega \quad (4)$$

$$k_{evap} = \begin{cases} = K_{evap} & \text{if } \Delta Hum \geq \Delta Hum_{crit} \\ = K_{evap}(1 - e^{-\tau_{evap}\Delta Hum}) & \text{if } \Delta Hum < \Delta Hum_{crit} \end{cases} \quad (5)$$

The exchanges of energy across the unit are illustrated in Figure 3, they are the same transfers considered by Ochsenbein [3].

**Figure 3.** Energy transfers across phases

One final parameter to discuss is that of a correction factor for the measured absolute humidity of the outlet air. After discussions with the equipment vendor, it became clear that value reported by this sensor needed a multiplier to be reflective of the true value. This is an additional parameter considered in the model.

### Parameter Estimability

The mass and energy portion of the model consists of 9 model parameters plus the initial wall temperature as quantities that need to be estimated from data.

**Table 1:** Model Parameters

Parameter	Estimability Measure	Rank
u wall_air	6.498	1
k_evap_rate.K	3.313	2
temp wall init	1.245	3
u wall_bed	1.028	4
omega_factor	0.551	5
u bed_air	0.372	6
spraying_efficiency.tau	0.155	7
k_evap_rate.tau	0.003	8
abs.humidity out correction factor	-0.004	9
u wall_env	-1.380	10

The fluid bed granulator unit is fitted with sensors that provide electronic data captured throughout the operation. Specifically for the airflow, the temperatures and

absolute humidity for the air before and after the chamber, the temperature of the powder bed and the spray rate. Additional to these real-time measurements, samples are taken from the unit and analyzed for water content. This is reported in percent weight loss after drying (LOD). With these data available, we analyzed the estimability [5] of the model parameters to determine which parameters to estimate and which to fix. The absolute humidity correction factor and the heat transfer from wall to environment are the least estimable parameters from the data. The low estimability for the heat transfer coefficient from wall to environment was expected since the wall temperature is not measurable in the unit.

Three sets of parameters were obtained for nominal conditions that would incrementally create larger granule sizes (referred to as *under-granulation*, *nominal* and *over-granulation conditions*).

Obtained predicted vs measured values for the LOD and the bed temperature are shown in figure 4 for illustration purposes.

**Figure 4.** Predicted vs observed profiles

### Hybrid component for total particle growth

Through all the mass and energy calculations a fundamental assumption is made that the particle size of the powder is constant. This also fixes the available particle specific surface area which is essential in the calculations of drying kinetics and heat transfers to/from the bed. This mimics the approach taken by Ochsenbein et. al. [3].

A hybrid component is added to the model to account for the effect of the process conditions onto the final granule particle size. This extension adds predictability to the granule size and particle specific surface area, bonding the granule growth and drying mechanisms. A Partial Least Squares (PLS) model is built to predict the final granule properties (including particle specific surface area) as a function of the recipe parameters that also dictate the drying behaviour. The particle specific surface area is predicted with an  $R^2$  value of  $\sim 90\%$ . The hybrid model proves to be adequate to predict the time varying values for the LOD, the powder bed temperature and the humidity of the outlet air. The PLS model was built with open-source code (<https://github.com/salvadorgarciamunoz/pyphi>).

The PLS model was implemented along with the

mass and energy balance using gPROMS (Siemens Industry Software, Ltd).

## MODEL PARAMETERS EFFECT

Once a model is assembled and parametrized a natural question to further the understanding of the model is to explore the effect of the model parameters onto the predictions. We explore this dependency in two ways: a) the effect of parameter uncertainty and b) The effect of true statistically significant changes in the model parameters (beyond uncertainty) onto the responses of interest.

To explore the propagation of parameter uncertainty, a sensitivity analysis is done simultaneously varying the values of each model parameter by three standard deviations above and below the optimal value obtained at the parameter estimation step. The variation of LOD due to this parametric uncertainty is shown in figure 5. The variation is  $\sim 0.125\%$  which is acceptable for the application at hand.

**Figure 5.** Variation in LOD prediction due to model parameter uncertainty.

A second sensitivity study was carried out to understand the numerical effect from meaningful changes to the model parameters onto the predictions of interest: the LOD, the absolute humidity of the outlet air, and the temperature of the powder bed. This analysis was done by simultaneously varying the 10 estimated parameters to random values within 20% (above and below) of its estimated one. Ten thousand simulations were conducted for each of the three scenarios of interest (under, nominal and over granulation). A PLS model was fitted to better understand the multivariate interactions between the model parameters and the time varying profiles for the responses. Three significant latent variables were found across the three scenarios. From the coefficients of correlation (Figure 6) one can conclude that the model parameters that cause the largest change across the time varying profiles for the three model outputs are: the time constant and the gain for the evaporation rate

**Figure 6.**  $R^2X$  and  $R^2Y$  for the PLS model at nominal conditions fitted to meaningful variation in model parameters and its effect onto responses.

Coefficient (Equation 5), and the omega factor that controls the fraction of surface area available for drying during the spray phase. The second latent variable captures the influence of the time constant for the spray efficiency equation (Equation 3) and the initial temperature of the bed onto the LOD and the bed temperature. The third latent variable represents the effect of the outlet absolute humidity correction factor. Interestingly, this analysis also seems to indicate the almost negligible effect of the heat transfer coefficients. The trends and conclusions from Figure 6 are shared (with minor differences) across the three scenarios (*under*, *nominal* and *over* granulation). The overall ranking of importance for the model parameters can be summarized in the Very Important to the Projection (VIP) plot shown in Figure 7. This diagnostic considers the importance for each regressor accounting for the multivariate consequence onto the response. The combined effect on the LOD from of these meaningful variations in model parameters with the necessary adjustments in the process parameters to go from under to nominal to over granulation are shown in Figure 8.

Beyond the correlations illustrated in Figure 6, the PLS model diagnostics could be further analyzed to also uncover the directionality in these correlations. This understanding is useful to determine necessary direction and magnitude for a change in a model parameter to create a positive or negative change in a model response. This information in the PLS model can be embedded with an optimization routine for example to find improved initial guesses for the model parameters for a new product.

**Figure 7.** Very Important to the Projection (VIP) plot for the PLS model fitted to meaningful variation in model parameters and its effect onto responses

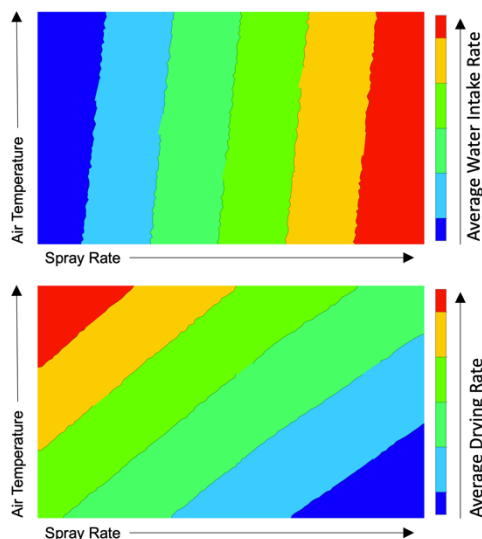

**Figure 9.** Variation in LOD due to changes in Airflow during the spraying phase (top) and drying phase (bottom)

**Figure 8.** Variation in LOD prediction due to meaningful changes in model parameters at different operating regimes.

## PROCESS PARAMETERS EFFECT

The pharmaceutical development process requires the study of the impact of all the MV in the operation of a process onto the quality of the final product. Regulatory agencies encourage practitioners to take a risk-based approach to optimize development efforts [6]. Although the granules produced from the fluid bed granulation operation can be the end-product [7]; more commonly these are intermediate materials to the final oral solid dosage form. As such, the study of this operation is customarily coupled with the study of all downstream operations in a systematic way [8]. Through a combination of experimentation and modeling described elsewhere [9] two intermediate process characteristics were identified

**Figure 10.** Sensitivity of the average water intake and drying by the powder bed with changes in air temperature and spray rate.

as key for this operation: The average rate of water intake into the powder bed and the average rate of drying. These are as indicative of the downstream performance of the granule.

Univariate studies per MV are conducted to help identify initial criticality and isolate the effect per MV. For illustrative purposes, Figure 9 shows the LOD result from variations in volumetric airflow during spraying, and during drying (as two independent MV). Remarkably, the effect of the airflow during *spraying* has a stronger effect on the LOD during the *drying* period than the airflow during *drying*. A similar effect emerges in Figure 10 showing

the effect of the air temperature (which remains constant throughout the operation) and the spray rate onto the average rate of water ingress (top) and the average drying rate (bottom). These figures show that while the spray rate dominates the effect of the water ingress to powder bed, it also has a strong effect onto the drying rate. The strong impact of the manipulated variables defining the water ingress onto the drying rate is because these variables define the initial conditions for the drying phase. This follows what other researchers have also postulated: that the dynamics of water intake and egress from the powder bed are intrinsically coupled with the dynamics of granule growth and thus the final attributes of the granule [1]. The model described here was utilized to better understand the effect of the MV in the process as they affected these two rates. These sensitivity plots can be used in the definition of design spaces once constraints are given for the rates of water intake and drying.

## CONCLUSIONS

The foundations for the assembly of a useful mathematical representation of a process are the initial articulation of the assumptions made, and the systemic enumeration of the driving forces to be considered. In a systemic approach, the latter exercise needs to be done in consideration to the available measurements that can help identify the individual contributions from the sub-systems of the model, and their behavior upon interaction. After the euphoric task of postulating equations and equations to represent a process; the modeler must subject itself to the sobering exercise of statistics, such as performing an Estimability analysis [5] to better understand what level of rigor can be afforded by the available data for the parametrization of the model. This intersection of statistical and deterministic approaches is the key to the construction of a useful model with optimal level of parsimony.

Once a model is built and well parametrized two natural questions arise. One resulting from the need to make operational decisions, and one from the desire to better understand the interaction of the different sub-systems built onto the model. *What is the effect of the process MV onto key model outputs?* and *what is the impact of the model parameters onto the key responses?* And with coupled and non-linear effects at play, the answer to both questions is often of a multivariate nature. Herein we used simple graphical approaches to support operational decisions, these of course are limited to a small number of factors. We present the use of PLS as a useful tool to better understand the multivariable relations between model parameters and responses. In the authors opinion, the visual aids and diagnostics obtained by PLS are richer and provide a more intuitive way to uncover the complex relations represented by the model structure

and its parameters, which ultimately represent the innermost fundamental understanding of the process.

## ABSTRACT

Cardiomyocytes (CMs), the contractile heart cells that can be derived from human induced pluripotent stem cells (hiPSCs). These hiPSC derived CMs can be used for cardiovascular disease drug testing and regeneration therapies, and they have therapeutic potential. Currently, hiPSC-CM differentiation cannot yet be controlled to yield specific heart cell subtypes consistently. Designing differentiation processes to consistently direct differentiation to specific heart cells is important to realize the full therapeutic potential of hiPSC-CMs. A model that accurately represents the dynamic changes in cell populations from hiPSCs to CMs over the differentiation timeline is a first step towards designing processes for directing differentiation. This paper introduces a microsimulation model for studying temporal changes in the hiPSC-to-early CM differentiation. The differentiation process for each cell in the microsimulation model is represented by a Markov chain model (MCM). The MCM includes cell subtypes representing key developmental stages in hiPSC differentiation to early CMs. These stages include pluripotent stem cells, early primitive streak, late primitive streak, mesodermal progenitors, early cardiac progenitors, late cardiac progenitors, and early CMs. The time taken by a cell to transit from one state to the next state is assumed to be exponentially distributed. The transition probabilities of the Markov chain process and the mean duration parameter of the exponential distribution were estimated using Bayesian optimization. The results predicted by the MCM agree with the data.

## INTRODUCTION

Cardiovascular diseases are the leading cause of death worldwide [1]. Almost 695,000 people in the US died of cardiovascular disease in 2022 [2]. Cardiomyocytes (CMs), i.e. contracting heart cells, can be derived from human induced pluripotent stem cells (hiPSCs) to be used for drug testing, regenerative therapies, and disease modeling for cardiovascular diseases [3]. The modulation of the Wnt signaling pathway using small molecules and growth factors provides the standard CM differentiation protocol, yielding CMs with up to 98% purity [4]. However, this benchmark protocol produces mostly left ventricular cells, with a little to no atrial cells, or right ventricular cells [5]. To model specific diseases in the heart requires specific heart cell types. For example,

atrial diseases like atrial fibrillation and Ebstein's anomaly, or right ventricular diseases, such as Tetralogy of Fallot or arrhythmogenic right ventricular cardiomyopathy, require atrial CMs and right ventricular CMs respectively [6].

Designing a differentiation process to consistently yield specific heart cells is essential to fully realize the therapeutic, drug testing, and disease modeling potential of CMs. The first step in designing a differentiation process that directs hiPSCs to specific heart cell subtypes is understanding the temporal changes in the cell type populations during differentiation.

Several mathematical models have been developed to capture cell differentiation process [7-16]. Stiehl et al [7] investigated if stemness (characterization of stem cells) can be defined at the single-cell level, and what

properties are suitable for defining stem cells. The authors proposed a multi-compartment deterministic model, which consists of discrete sets of ordinary differential equations, to describe the dynamics of cell differentiation and self-renewal regulated by extracellular signaling feedback. The cell behavior is characterized by parameters including the proliferative activity, the probability of differentiation, and the probability of dying. The model was developed to predict the cell type population and signaling molecule concentration over time. The model, calibrated with clinical data from multiple myeloma patients undergoing high-dose chemotherapy and stem cell transplantation, aimed to observe stem cell differentiation and determine cell type populations. Each differential equation in the model describes a distinct differentiation stage, reflecting the conventional notion that within each lineage of blood cell precursors, there is a discrete sequence of maturation stages traversed sequentially. Models presented in this paper characterize stem cells as the population that is most sensitive to environmental signals. The stem cell differentiation characterization developed in this paper identified stem cells and other cell types as a population. However, the model could not capture the differentiation mechanism happening in a single cell. The drawback of this deterministic model is that it does not capture the stochastic nature of the differentiation process.

Paździorek [8] investigated the stochastic stability of the model presented by Mar-Czohara and examined its response to noise. The deterministic model from [7] was transformed into a stochastic process using Ito differential equations. Ito calculus addresses processes with evolving random variables over time, where the random variable here is the cell type population. The random behavior of cells, whether differentiating, maturing, dying, or proliferating was modeled as a Wiener process, which is a continuous-time stochastic process. The increments of the Wiener process across disjoint time intervals exhibit a normal distribution. Premslaw demonstrated that the stochastic model achieves asymptotic stability, signifying that over time, stem cells tend to reach stable and well-defined states.

Pisu et al [9] introduced a novel mathematical model to simulate the differentiation of mesenchymal stem cells into specialized cells to study the effect of growth factors on cell proliferation/differentiation mechanisms. The model was built on material balances for extracellular matrix compounds, growth factors, and nutrients, along with a mass-structured population balance that describes cell growth, proliferation, and differentiation. The DNA content and the glycosaminoglycans (GAG) content present in the cells at different time points were used as indicators to identify the cell types. The model incorporated several parameters, with key ones being the kinetic constant of GAG synthesis, kinetic constant of collagen

synthesis, time rate of change of cells, maximum collagen and GAG concentration, concentration of  $O_2$  in saturation condition, and number of cell types. Regression analysis of the model predictions demonstrates that the average error for different differentiation pathways is below 20 percent.

The models presented in [10-16] also incorporate macroscopic analysis, lacking representation of mechanisms occurring at the single-cell level. Capturing the differentiation mechanism at the single-cell level will offer insights into interactions at the cellular level. This paper introduces a microsimulation model (MSM) to study the temporal changes in the cell type populations during cardiac differentiation at cell-level analysis. A microsimulation model, which is a stochastic model, aims to simulate individual entities of the system through stochastic parameters. Each cell is modeled as an individual entity of the MSM, and the differentiation process in each cell is represented with a continuous-time Markov chain model (CTMCM). The states of the CTMCM are cell subtypes representing the developmental stages in hiPSC differentiation to early CMs. They include pluripotent stem cells, early primitive streak, late primitive streak, mesodermal progenitors, early cardiac progenitors, late cardiac progenitors, and early CMs. The transition probabilities define the probability of a cell transitioning from one cell subtype to another or an absorbing state. The holding times, representing the time a cell spends in each state, are modeled using exponential distributions. The MSM is embedded in a Bayesian optimization framework to estimate the CTMCM parameters, i.e., transition probabilities and mean of the exponential distributions.

This paper is structured as follows: Next section discusses the modeling of cell differentiation using the Markov chain model and modeling the duration of state transitions using exponential distribution. The application of the microsimulation model for simulating the differentiation process is introduced next. The results for the microsimulation model parameters and a comparison of the model predictions to experimental data are in Results and Discussion section. Concluding remarks and future directions are given in the last section.

## MODELING DIFFERENTIATION

### Modeling cell differentiation

The data used to build the MSM model was obtained from the single-cell RNA sequencing analysis of 2D cardiac differentiation of two cell lines (WTC cell line and SCVI cell line) [5]. The differentiation was carried out for 6 days and samples were collected from day 1 to day 6 daily. The collected samples were captured, and single-cell RNA sequencing was performed. The gene expression matrix was analyzed and labeled to get the cell type population during differentiation from day 1 to day 6.

Based on the results obtained from 2D cardiac differentiation, the developmental trajectory of hiPSCs to early CMs follows a path. The path includes a series of states: which are pluripotent stem cells, early primitive streak, late primitive streak, mesodermal progenitors, early cardiac progenitors, late cardiac progenitors, and early CMs. At late primitive streaks and mesodermal progenitors state, cells may differentiate into non-CM cells. When a cell begins differentiation, it either moves into the next state in sequence or becomes a non-CM cell type, or remains in the same pluripotent state that it started in. There are two possible states from which cells can become non-CMs; cells from the late primitive streak can differentiate into hepatic endoderm and definitive endoderm, and cells from the mesodermal progenitor state can differentiate into endothelial cells, epicardial progenitors, and epicardial cells. Differing cell types have differing timings for differentiation, and, therefore, the time a cell spends in one state is dependent on the cell type being made. Based on this explanation, to model the cell differentiation, two questions need to be answered:

- 1) What is the next state in the differentiation path?
- 2) If a cell differentiates to the next state in sequence, how long will it stay between those two states?

The important assumptions here are the cells do not die during differentiation and they do not split or divide during the differentiation. Although we recognize the limitations of these assumptions, given the lack of data for modeling cell division and death rates for this differentiation protocol, this preliminary model allows making progress towards modeling hiPSC to early CM differentiation process.

**Figure 1.** Modeling cell differentiation.

### Continuous time Markov chain model

The first question can be answered by transition probabilities of a Markov chain model (MCM). A Markov chain model is a mathematical model that represents a sequence of events in a process in which the probability of transitioning from one state to another depends solely on the current state [17,18,19]. Markov chain models are memoryless, meaning the probability of transitioning to future states depends only on the current state and is independent of the sequence of states that led to the current state. Markov chains are used for modeling dynamic systems like financial markets, weather patterns, and language processing. In a Markov chain, the transition probability describes the probability of moving from one state

to another in the chain at each time step. The general representation of transition probability,  $P_{ij}$ , for the transition from state  $i$  to  $j$ , is given in Equation (1).

$$P_{ij} = P(X_{n+1} = j | X_n = i) \quad (1)$$

In Equation 1,  $X_n$  and  $X_{n+1}$  represent two consecutive states in a Markov chain. The RHS of Equation (1) represents the conditional probability that, given the current state  $X_n = i$ , the system will transition to state  $X_{n+1} = j$ . Markov chains are characterized by a transition matrix that represents the probabilities of moving from one state to another. The transition matrix enables predictions and analysis of system behavior over time.

Markov chain models can be classified into different types based on time homogeneity (homogenous Markov chain and non-homogenous Markov chain), state continuity (finite state Markov chains and continuous state Markov chains), time continuity (discrete-time Markov chains and continuous time Markov chains), absorbing or non-absorbing states (absorbing Markov chains and non-absorbing Markov chains). [20]. The classifications related to cell differentiation based on scRNA-seq data are discrete-time and absorbing Markov chains. In a discrete-time Markov chain, the transitions between states occur at discrete, evenly spaced time intervals. An absorbing Markov chain is used to model systems where certain states, known as absorbing states, act as final destinations from which there is no escape. This means that in a Markov chain, the transitions between states occur with probabilities, however, once the system reaches an absorbing state, it remains there indefinitely. In other words, the probability of transition from an absorbing state to any other non-absorbing state is zero. These chains can be characterized by their probability of transition between transient states (non-absorbing states) and absorbing states, leading to absorption, which represents the final resting places of the system.

A continuous-time absorbing Markov chain model is developed to represent hiPSC to CM cell differentiation. Figure 2 demonstrates the Markov chain model of cell differentiation. Late primitive streak can differentiate into endoderm cells, and mesodermal cells can differentiate into epithelial and epicardial cells. When cells commit to becoming endodermal, epicardial, or epithelial cell types, they can no longer differentiate into CMs. Hence, the transition probability from these cell types to any other cell types in the cardiac trajectory is zero. Two absorbing states, one from the late primitive streak and the other from the mesodermal progenitor state, were included in the MCM to denote cells that differentiate into non-CMs. Absorbing state 1 consists of hepatic endoderm cells and definitive endoderm cells, and absorbing state 2 consists of epithelial cells, epicardial progenitors, and epicardial cells.

The probability  $P_{ij}$  denotes the probability of

transition of the MCM from state  $i$  to state  $j$  in the cardiac differentiation trajectory and  $p_{ij}$  denotes the transition probability in a specific instance of simulating a Markov chain.  $P_{ij}$  is the Markov chain model parameter and  $p_{ij}$  is the probability of transitioning from state  $i$  to state  $j$  during a simulation run. In the simulation, for cell types other than late primitive streak and mesodermal progenitors, if  $p_{ij} \leq P_{ij}$ , the cell will differentiate from cell type  $i$  to cell type  $j$ . If a cell is initially in the late primitive streak or mesodermal progenitors state, there are three potential outcomes for the cell's eventual destination. If  $p_{ij} \leq P_{ij}$ , the cell will differentiate into cell type  $j$ , or if  $P_{ij} < p_{ij} \leq P_{ij} + P_{ia}$ , the cell will differentiate into absorbing state, or if  $P_{ij} + P_{ia} < p_{ij}$ , the cell will stay in the same state  $i$ . Based on the transition probability parameters of the MCM, the cells in the simulation will differentiate into different cell types. The Markov chain stops when the cell reaches either an absorbing state or an early CM state.

**Table 1:** Expansion of the cell types in the MCM.

Abbreviations	Cell types
hiPSCs	Human induced pluripotent stem cells
eps	Early primitive streak
lps	Late primitive streak
as1	Absorbing state 1
mp	Mesodermal progenitors
as2	Absorbing state 2
ecp	Early cardiac progenitors
lcp	Late cardiac progenitors
ec	Early cardiomyocytes

### Modeling state duration in the MCM with exponential distribution

The exponential distribution is a continuous probability distribution commonly used to model the time between events in a Poisson process, where events occur at a constant average rate and are independent of each other [21]. The probability density function  $f(x)$  of the exponential distribution is given by Equation 2.

$$f(x) = \lambda \exp(-\lambda x) \quad (2)$$

In Equation 2,  $x$  is a non-negative variable representing the time between events, and  $\lambda$  is the rate parameter, which is a positive constant. It determines the

average number of events occurring per unit of time and is also equal to the inverse of the average time between events. The rate parameter quantifies the event rate, the frequency, on average, of the events occurring. One of the notable properties of the exponential distribution is memorylessness. It suggests that the probability of the next event occurring in the next time increment is the same, regardless of how much time has already passed. This property of exponential distribution helps modeling systems with no memory of past events.

In the cell differentiation process, the time a cell spends between two states is random, with a constant average rate of occurrence and the events are independent of each other. Therefore, the duration spent by a cell between two states can be modeled using the exponential distribution. The average duration  $d_{ij}$ , spent by the cells between state  $i$  and state  $j$  is the inverse of the rate parameter used to model the time spent by the cells between states.

## MODELING CELL POPULATIONS

### Microsimulation models

Microsimulation models (MSM) are computational models designed to simulate individual-level behavior using individual entities within a population [22,23]. Each entity is represented with specific attributes. In the case of modeling cell populations, the individual entity denotes each cell in the differentiation process, and the attributes denote transition probability and the average duration parameters. MSM consists of three components, the agents, rules, and environment. The agents represent individual cells. The rules denote the behavior and decision-making processes for each cell, which means the transition of cells into different states that are controlled by the Markov chain probabilities. The environment represents the context in which the cells interact. The constraint in the MSM is the sum of probability in each state should add up to one.

In the developed MSM (Figure 3), each cell in the simulation will move into the next state based on the transition probability of the Markov chain model, and whenever the cell moves to the next state, the duration the cell spends in that state is sampled from the exponential distribution. For transition from states  $i$  to  $j$ , excluding absorbing states, the sampled time interval is calculated based on the average duration parameter,  $\lambda_{ij}$ . The age associated with the cell in a state is obtained by adding the sampled time for that state to the age of the cell in the previous state. Since we are modeling the cell population at the end of each differentiation day, the result obtained from the simulation is converted into a binary matrix, in which the rows represent the differentiation days, and the column represents the cell states. For example, let us consider that the age of a cell when it

**Table 2:** Cell population matrix from WTC cell line ( $X_1$ ) used in the optimization problem (Equation 3). All numerical values are expressed as percentages.

Days	hiPSCs	eps	lps	as1	mp	as2	Ecp	lcp	Ec
Day 1	18.9	80.0	1.1	0.0	0.0	0.0	0.0	0.0	0.0
Day 2	0.6	8.3	90.8	0.0	0.3	0.0	0.0	0.0	0.0
Day 3	0.8	1.8	22.8	17.5	50.6	0.0	6.5	0.0	0.0
Day 4	0.4	0.0	1.9	30.2	20.7	4.1	42.6	0.2	0.0
Day 5	0.8	0.0	0.8	31.7	5.8	7.2	36.5	17.3	0.0
Day 6	0.3	0.0	0.0	39.7	0.8	9.2	17.0	31.3	1.7

reaches the early primitive streak is 0.78 days, and the age of a cell when it reaches the late primitive streak is 2.4 days and it stays in the late primitive streak. In the given example, at the end of day 1, the cell state is the early primitive streak, so in the binary matrix, in the day 1 row, the eps column will have a value of 1. From 0.78 days to 2.4 days, the cell remains in the early primitive streak state, meaning at the end of day 2, the cell in the eps column will have a value of one, and the rest of the day 2 row will have a value of 0. From 2.4 days up to day 6, the cell will stay in the late primitive streak, and therefore, for the rows from day 3 to day 6, the lps column will have a value of 1, and the rest equal to zero. Five thousand cells were run in the simulation to generate the cell type matrix for each cell. The number of cells in each cell type at the end of each differentiation day was added and then normalized by the total number of cells. By this procedure, the cell population percentage matrix can be obtained using the microsimulation model with the Markov chain process.

**Figure 3.** Modeling cell population using a microsimulation model.

### Parameter estimation

The MSM parameters, transition probabilities, and the average durations were estimated using Bayesian optimization by minimizing the mean squared error between the model output and the experimental data. Bayesian optimization, driven by Bayesian inference and surrogate modeling, is a versatile and efficient approach for solving complex optimization problems [24,25]. Bayesian optimization uses a surrogate model, typically a Gaussian process (GP) model, to estimate the unknown objective function. Bayesian optimization balances exploration (sampling in uncertain regions), and exploitation (sampling in the regions with the highest estimated

objective value), to find the global optimum efficiently. The objective function (Equation 3) used is the mean squared error between the model output and the experimental data.

$$f = \frac{1}{n}((Y - X_1)^2 + (Y - X_2)^2) \quad (3)$$

$$Y = MSM(P_{ij}, d_{ij}) \quad (4)$$

$$P_{lps,mp} + P_{lps,a1} \leq 1 \quad (5)$$

$$P_{mp,a2} + P_{mp,ecp} \leq 1 \quad (6)$$

$$0 \leq P_{ij} < 1; d_{ij} \geq 0 \quad (7)$$

$Y$  is the MSM output. The variables  $X_1$  and  $X_2$  represent the cell population matrices obtained from the single-cell RNA sequencing of the cell samples. These samples were collected from two cell lines during differentiation days 1-6, as mentioned in the 'Modeling cell differentiation' section. The cell population matrix for WTC cell line,  $X_2$ , is shown in Table 2 as an example. Equation 4 states that the model output is a function of the decision variables  $P_{ij}$  and  $d_{ij}$ . To ensure the probabilities at the cell states having two states always less than or equal to 1, constraints (Equations 5, 6 and 7) were included in the model.

Bayesian optimization begins with generating an initial set of samples from the model. The Gaussian Process (GP) model is built based on the initial samples. The acquisition function selects the next sample for evaluation, balancing the exploration and exploitation. The selected point is evaluated in the true objective function. The surrogate model is updated with new data and the process iterates.

## RESULTS AND DISCUSSION

Five thousand cells were simulated in the Markov chain model embedded within the microsimulation model. The parameters obtained using Bayesian optimization are shown in Table 3. Based on the data, the optimization result showed that the probability of transitioning from psc state to eps state, and eps state to lps state is 1. During these two transitions, the cells spend an

average duration of 0.45 days and 1.32 days, respectively. At the lps state, 16% of cells transition into hepatic endoderm and definitive endoderm cells. These 16% of cells never become CMs. The remaining 84% of the cells take about 1.3 days to enter the mesoderm state, where 42% of these cells (35% of the initial number of cells) become endothelial cells, epicardial progenitors, and epicardial cells. The remaining 42% of the cells take about one day to enter the early cardiac progenitor state. After reaching the early progenitor state, 69% of these cells become late cardiac progenitors. Following this, 31% of the late progenitors become early cardiomyocytes. These cells spend about 3.58 days to become late cardiac progenitors and 2.98 days to become early CMs.

**Table 3:** MSM parameters obtained using Bayesian optimization.

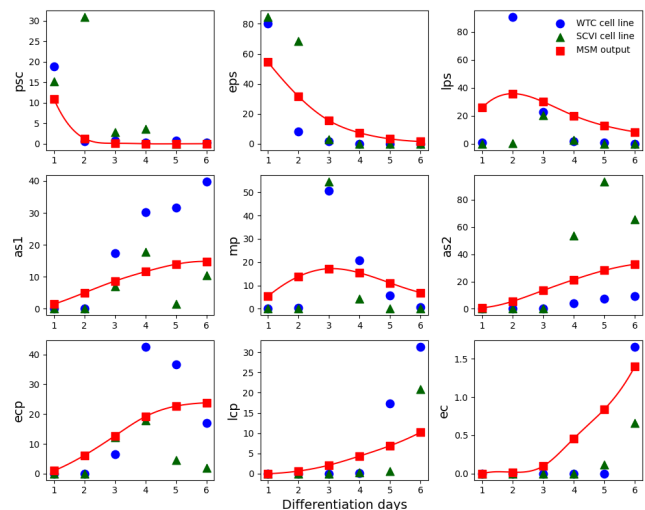

Current state	Next state	Transition probability	Average duration
hiPSCs	eps	1	0.45
eps	lps	1	1.32
lps	mp	0.81	1.30
lps	as1	0.16	-
mp	ecp	0.52	0.98
mp	as2	0.42	-
ecp	lcp	0.69	3.58
lcp	ec	0.31	2.98

Figure 4 shows the predicted cell population versus the experimental data. From the plot, we can see that there are differences between the WTC cell line data and the SCVI cell line data. Since the aim of this work is to develop a model that is independent of the cell line, the effect of the cell line is not introduced in the model. This can also be observed in Figure 4, where the predicted cell type populations by the MSM model are between the two datasets. The mean squared error and the  $R^2$  between the model and the data are 0.004 and 0.43, respectively. The performance of the developed model will undergo validation with further experimental data in the future.

## CONCLUSION AND FUTURE DIRECTIONS

Using the cardiac cell type population obtained from 2D cardiac differentiation, a microsimulation model with a Markov chain model was developed to predict the cardiomyocyte cell type population during differentiation. The model parameters were obtained using Bayesian optimization. The results showed that the simulation model predicted the cell type population with a low mean square error. The developed model can act as a digital twin to the cardiac differentiation experiment. The data for training this model was generated in a 2D environment

following the modulated Wnt signaling differentiation protocol, which mostly yields ventricular cells. This protocol will be tested to analyze if the ventricular cells can be produced on a large-scale using 3D techniques. The model will also be trained with data using the 3D differentiation protocol. If different sets of experimental parameters are used to obtain different cell-type populations, the model can be trained on those datasets, and a set of transition probabilities and average duration parameters can be estimated for each set of experimental parameters. Finding the relationship between the experimental parameters and the model parameters will help tune the experimental parameters to get the desired CM percentage on a certain differentiation day.

## ABSTRACT

Modeling the non-linear dynamics of a system from measurement data accurately is an open challenge. Over the past few years, various tools such as SINDy and DySMHO have emerged as approaches to distill dynamics from data. However, challenges persist in accurately capturing dynamics of a system especially when the physical knowledge about the system is unknown. A promising solution is to use a hybrid paradigm, that combines mechanistic and black-box models to leverage their respective strengths. In this study, we combine a hybrid modeling paradigm with sparse regression, to develop and identify models simultaneously. Two methods are explored, considering varying complexities, data quality, and availability and by comparing different case studies. In the first approach, we integrate SINDy-discovered models with neural ODE structures, to model unknown physics. In the second approach, we employ Multifidelity Surrogate Models (MFSMs) to construct composite models comprised of SINDy-discovered models and error-correction models.

## INTRODUCTION

Present modeling approaches of intricate dynamic systems rely on ordinary and/or partial differential equations (ODEs, PDEs) to describe their behaviors. These governing equations are conventionally obtained from rigorous first principles like conservation laws or derived from phenomenological knowledge-based approaches. However, many dynamic systems remain unexplored, lacking comprehensive analytical descriptions. Exploiting advances in data acquisition, digitization, and storage, data-driven 'black box' models have emerged as an alternative [1, 2]. These data-driven methods excel in regression and classification tasks, yet their resultant black-box nature commonly lacks physical insight and exhibits limitations in extrapolation beyond the training data's boundaries. Certain systems exist, such as biological processes or intricate design problems, that necessitate a deeper understanding of governing equations. Consequently, recent developments focus on the integration of data-driven techniques into modeling system dynamics. Early attempts utilized symbolic regression [3] and genetic programming algorithms [4]. However,

challenges like overfitting and the computational demands arising from their combinatorial nature limited their applicability to low-dimensional systems and small initial candidate sets of symbolic expressions. An alternative approach called SINDY [5] was proposed, that reconstructs the underlying equations based on a large-space library of candidate terms and transforming the discovery problem to sparse regression and over time, several extensions to SINDY and alternative approaches on similar ideas were also introduced [6-9]. More recently, another such approach (DySMHO) [10] was proposed that uses moving horizon optimization for identifying the governing equations. Nevertheless, the effectiveness of these techniques relies on the identification and selection of terms from an array of potential candidate terms. While an exhaustive pool covering all potential terms might aid in building a highly accurate mechanistic model, this presents a challenge, especially in cases involving complex nonlinear systems and when the system dynamics are not fully known. A potential solution is to use hybrid modeling techniques with these methods. These hybrid models (HMs), also referred to as 'grey-box' models have the advantages of both mechanistic and the

black-box models [1, 11]. Figure 1 shows the comparison between the mechanistic, grey- and black-box models. Early implementations of these hybrid models can be found in works that date back to 1980's.

**Figure 1:** A comparison between white-box/mechanistic, grey-box and black-box models.

In this work, we combine a hybrid modeling paradigm with sparse regression, with the goal of simultaneous hybrid model development and model identification. Specifically, in our study, we investigate two distinct methods. In the first method, we employ the SINDy formulation to establish the initial physics-based model from the incomplete candidate library. Subsequently, we integrate this with neural ordinary differential equations (NODEs) [12-14], to improve the accuracy of the final model. Leveraging the NODE formulation to model unknown or missing physics within a mechanistic model has previously proven to be successful [12, 15, 16]. For the second approach, we employ composite structures known as Multifidelity Surrogate Models (MFSMs) [17, 18] using true data/high-fidelity (HF) and the low-fidelity (LF) data. The model output from SINDy constructed using the incomplete candidate library is treated as the LF model. In the subsequent step, we develop MFSMs that use HF and LF data to refine the model accuracy.

In the following sections of this paper, we introduce the methods for our proposed HM approaches and a workflow to build the HMs. In the subsequent sections, we utilize two non-linear case studies to test our HM models and show their prediction accuracy. Furthermore, we show our analysis on the impact of sampled data density and noise on the accuracy of the HMs, as well as the HMs extrapolation capabilities.

## 2. METHODS

### 2.1 Sparse identification of nonlinear dynamics

In [6], the authors leveraged the fact that most physical systems have only a few relevant terms that

define the dynamics, making the governing equations sparse in a high-dimensional nonlinear function space. Consider the example first-order ODE system with  $n$  states which are denoted by  $\mathbf{X}$ . We denote the derivative with respect to time for  $\mathbf{X}$  as  $\mathbf{X}'$ . The right-hand side of the ODE is given by the derivative with respect to time,  $t$ , denoted by the function  $f$ ,

$$\mathbf{X}' = \frac{d\mathbf{X}}{dt} = f(\mathbf{X}) \quad (1)$$

Next, a library  $\theta(\mathbf{X})$ , consisting of candidate nonlinear functions of the columns of  $\mathbf{X}$  is constructed. For example, the library may consist of constant, polynomial, and trigonometric terms. Finally, a sparse regression problem is set up to determine the sparse vectors of coefficients  $\boldsymbol{\varepsilon} = [\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n]$ , which determines the nonlinearities that are active.

$$\theta(\mathbf{X}) = \begin{bmatrix} | & | & | & | & \dots & | & | & | \\ 1 & \mathbf{X} & \mathbf{X}^2 & \mathbf{X}^3 & \dots & \sin(\mathbf{X}) & \cos(\mathbf{X}) & \dots \\ | & | & | & | & & | & | & | \end{bmatrix} \quad (2)$$

$$\mathbf{X}'_{SINDy} = \theta(\mathbf{X})\boldsymbol{\varepsilon} \quad (3)$$

$$\mathbf{X}_{SINDy} = \text{ODEsolver}(\theta(\mathbf{X})\boldsymbol{\varepsilon}, \mathbf{X}_0, t) \quad (4)$$

Discovering the mechanistic equations from state data with SINDy is subject to a) estimating the derivatives accurately with data limitations and b) formulating the candidate library  $\theta(\mathbf{X})$  to contain all the terms that could potentially form an accurate mechanistic equation. While several extensions to SINDy have been proposed over the years to address the former issue, the latter is still a challenge. This is especially a major issue when we are dealing with state data from non-linear systems where the potential terms in the candidate library are not known. To address this, we propose to use the following hybrid modeling approaches.

### 2.2 Neural Ordinary Differential Equations for Error Correction

Neural networks (NNs) are one of the widely used ML models in data-driven modeling due to their ability to approximate complex nonlinear relationships. Since the early 90s, NNs have been used to model dynamic systems within differential equations [19]. Recently, NODEs have emerged, integrating NNs with automatic differentiation tools [12-14]. NODEs predict system derivatives directly during training, capturing both state and derivative data. The potential of this approach was shown in better capturing curvature in dynamic data when compared to data-driven models that ignore derivative information. A neural ODE is essentially a NN used to model  $f(\mathbf{X})$  from Eq (1). We denote the modeled derivative by  $\mathbf{X}'_{NN}$ . We can obtain the predicted ODE solution  $\mathbf{X}_{NN}$  by employing any preferred ODE solver.

$$\mathbf{X}'_{NN} = \frac{d\mathbf{X}_{NN}}{dt} = NN(\mathbf{X}) \quad (5)$$

$$\mathbf{X}_{NN} = \text{ODEsolver}(\text{NN}, \mathbf{X}_0, t) \quad (6)$$

Training the NODE can be done either by minimizing the error between the predicted and true states  $\text{Error} = \text{MSE}(\mathbf{X}, \mathbf{X}_{NN})$  by passing the NN through an ODE solver [14] or, utilize a collocation-based approach [13] and avoid using explicit ODE solver by minimizing the loss function  $\text{Error} = \text{MSE}(\mathbf{X}'_{est}, \text{NN}(\mathbf{X}_{est}))$ . In [13], the authors show that by using the collocation based approach, training a NODE is faster. We utilize this collocation-based approach to train our HM with NODE formulation for model identification from state data. In the first step, we generate a low-fidelity (LF) mechanistic model using SINDy by assuming few terms in the candidate library  $\theta(\mathbf{X})$ . In the next step, we correct the error resulting from the LF model with a NODE. We utilize the following formulation shown in Eq (7).

$$\mathbf{X}'_{HM} = \frac{d\mathbf{X}_{HM}}{dt} = \theta(\mathbf{X})\boldsymbol{\varepsilon} + \text{NN}(\mathbf{X}) \quad (7)$$

$$\mathbf{X}_{HM} = \text{ODEsolver}(\theta(\mathbf{X})\boldsymbol{\varepsilon} + \text{NN}(\mathbf{X}), \mathbf{X}_0, t) \quad (8)$$

To train the NODE we take the collocation-based approach and minimize the error between the derivatives directly. In the next step, we calculate the difference between the derivatives values between the HF and the LF derivatives at the sampled data. This derivative difference corresponds to the mismatch between the true model and the LF model. A NN model is then trained to predict this difference when given the true state data. Finally, the hybrid model states  $\mathbf{X}_{HM}$  are estimated by using an ODE solver.

### 2.3 Multifidelity Surrogate Models for Error Correction

In recent years, hybrid composite structures that can learn from both HF and LF data were proposed to improve the LF model predictions by correcting the error between the HF and LF data. These composite structures are referred to as multi-fidelity surrogate models (MFSMs) [17, 18, 20]. A widely used structure of MFSMs is  $y_H = \rho(x)y_L + \delta(x)$ , where  $y_L, y_H$  represent the low and high-fidelity data respectively,  $\rho(x)$  is multiplicative correlation surrogate and  $\delta(x)$  is the additive surrogate. It can be re-written as  $y_H = F(x, y_L)$ . To establish a connection between the HF and LF data, it's necessary to have both a HF model and a LF model that can produce this data. Similar to the NODE model correction approach, we use SINDy to obtain the LF model. The LF model from SINDy is then integrated using an ODE solver to obtain  $\mathbf{X}_{SINDy}$  using Eq (4). We then formulate the MFSM by utilizing a NN to model the error. The NN model is trained to minimize the loss function  $\text{Error} = \text{MSE}(\mathbf{X}, \mathbf{X}_{MFSM})$ , and takes both time and LF states as input to predict  $\mathbf{X}_{MFSM}$ .

$$\mathbf{X}_{MFSM} = \text{NN}(t, \mathbf{X}_{SINDy}) \quad (9)$$

### 2.3 Workflow for constructing hybrid models

We utilize the workflow shown in Table (1) for constructing the hybrid models under approach 1 and approach 2. Here  $\mathbf{X}_{HF}$  represent the true state data.  $\beta_1, \beta_2, \beta_3$  are the regularization coefficients.

**Table 1:** Workflow for constructing the hybrid models to correct error for NODE and MFSM formulations.

## 3. RESULTS AND DISCUSSION

In this section, we first introduce the case studies that we use to test and compare the approaches from 2.1 – 2.3. In the subsequent sections, we show the analysis on the model accuracy, effect of density of data and noise on the model accuracy and the extrapolation ability of the models.

### 3.1 Case Studies

To test the two approaches, we utilize two non-linear case studies. The first case study is a non-isothermal continuously stirred tank reactor (CSTR) problem, and the second case study is a penicillin biosynthesis problem.

#### 3.1.1 The non-isothermal CSTR problem

The CSTR's governing equation, Eq (11), represents mass conservation. But, in non-isothermal operating scenarios which is common in practical applications, the energy balance must also be considered. Thus, temperature is added as an extra state variable, along with obtaining temperature measurements in addition to composition data, as depicted in Eq (12). We utilize the model equations and assumptions from [10].

$$\frac{dC_A}{dt} = \frac{q}{V}(C_{A,i} - C_A) - k_0 e^{-\frac{E_a}{RT}} C_A \quad (11)$$

$$\frac{dT}{dt} = \frac{q}{V}(T_i - T) + \frac{(-\Delta H_R)}{\rho c} k_0 e^{-\frac{E_a}{RT}} C_A(t) + \frac{U_A}{V\rho c}(T_c - T) \quad (12)$$

### 3.1.2 The penicillin biosynthesis problem

For the second case study, we chose to model the production of penicillin via yeast fermentation. The level of nonlinearity in the system differs significantly between state variables. The process is modeled by four differential equations on the following states: volume ( $V$ ), concentrations of biomass ( $B$ ), product ( $P$ ) and substrate ( $S$ ). The system of ODEs is defined as shown in Eq (14) and Eq (15). The parameter values have been taken from [12].

$$\begin{aligned} \frac{dB}{dt} &= B(\mu - D - c_L) \\ \frac{dS}{dt} &= -\sigma B + (S_f - S)D \\ \frac{dP}{dt} &= q_p B - P(D + c_1 k) \\ \frac{dV}{dt} &= F \end{aligned} \quad (13)$$

$$\begin{aligned} \mu &= \frac{\mu_m S}{k_x X + 10} \\ \sigma &= \frac{\mu}{Y_x} + \frac{q_p}{Y_p} + m_x \\ q_p &= \frac{1.5 q_{pm} S B}{4k_p + B S \left[1 + \frac{S}{3k_i}\right]} \\ c_L &= \frac{c_{Lmax} B \exp\left(-\frac{S}{100}\right)}{K_L + B + 1} \\ m_x &= m_{xm} \frac{B}{B + 10} \end{aligned} \quad (14)$$

### 3.2 Analysis with no noise in true state data

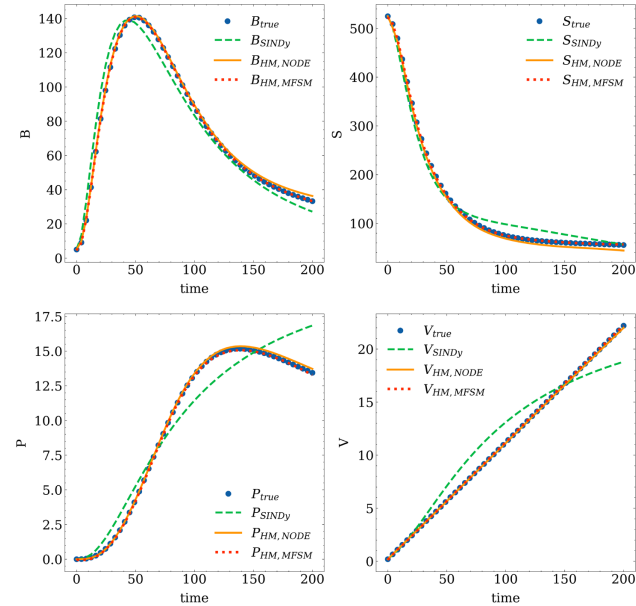

The case study shown in 3.1.1 and 3.1.2 were simulated with the initial conditions  $[C_{A,0}, T_0] = [0.5 \frac{mol}{L}, 350K]$  and  $[B_0, S_0, P_0, V_0] = [5 \frac{g}{L}, 525 \frac{g}{L}, 0 \frac{g}{L}, 0.2L]$  respectively, to generate 50 HF data points for each case. In the next step, the workflow shown in Table (1) was utilized to generate the Hybrid model with NODE and MSFM formulations to correct the error from SINDy – LF model. The results for both the approaches are shown below. Figure (2) shows the prediction using hybrid models with NODE MFSM formulation for case study 3.1.1 and Figure (3) shows the results for case study 3.1.2. In both Figures (2) and (3), the solid blue dots represent true (HF) state data. The green dashed line represents SINDy-LF model predictions. The solid orange line and the dotted red lines represent the HM model predictions with NODE and MFSM formulations respectively.

Figures (2) and (3) illustrate the limitation of the constructed SINDy model in accurately predicting the true states. This mismatch between the HF state data and the SINDy model stems from the candidate library's inability to comprehensively encompass all potential nonlinear terms contributing to the final mechanistic model equation. Consequently, the mechanistic model derived lacks accuracy in predicting the HF states. However, the HMs built using this SINDy model as the LF model,

employing both NODE and MFSM formulations, demonstrate the ability to accurately predict the HF state profiles. This HM structure effectively compensates for mismatch and missing terms within the LF model.

**Figure 2:** Concentration ( $C_A$ ) and temperature ( $T$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulation for case study 3.1.1, compared with true state data.

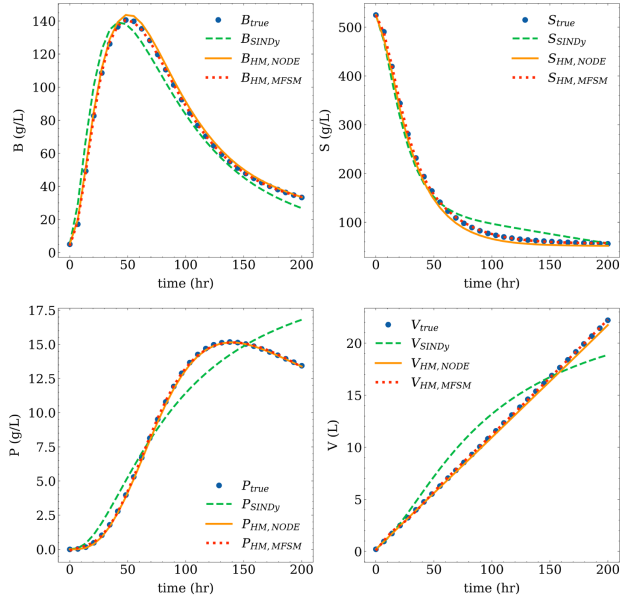

**Figure 3:** Volume ( $V$ ), Biomass ( $B$ ), product ( $P$ ) and substrate ( $S$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulation for case study 3.1.2 with 50 HF data points, compared with true state data.

### 3.3 Effect of density of sampled data on HMs

To analyze the effect of density of sampled data on the HM model, we repeated the experiment from 3.2, by decreasing the amount of HF data available. For this analysis, we reduced the data size to 30 HF samples. The case study shown in 3.1.1 and 3.1.2 were simulated with the initial conditions in 3.2 to generate 30 HF data points. In the next step, using the workflow from Table (1) HMs are built. Figures (4) and (5) show the prediction from the SINDy and HMs.

**Figure 4:** Concentration ( $C_A$ ) and temperature ( $T$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.1, with 30 HF datapoints.

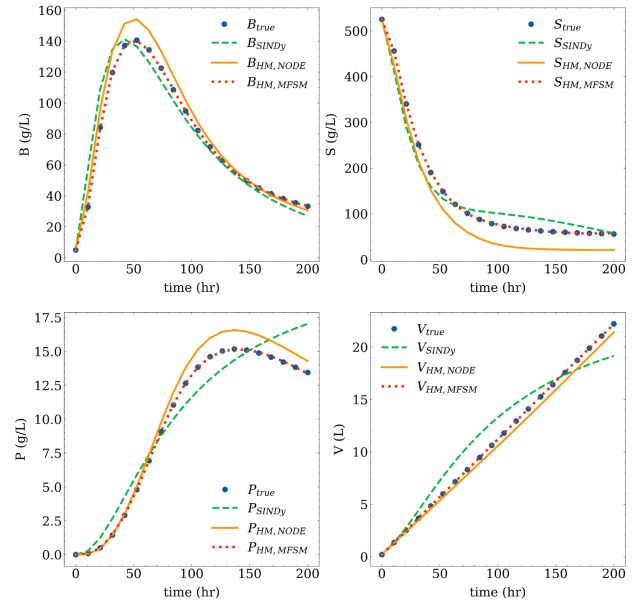

**Figure 5:** Volume ( $V$ ), Biomass ( $B$ ), product ( $P$ ), substrate ( $S$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.2, with 30 datapoints

We repeat the analysis once again, but this time by reducing the data size to 20 HF samples. We simulate the case studies from 3.1.1 and 3.1.2 with the same initial conditions to generate 20 HF data points to train the SINDy and HM models. Figures (6) and (7) show the prediction from the SINDy model and HMs.

**Figure 6:** Concentration ( $C_A$ ) and temperature ( $T$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.1, with 20 HF datapoints

formulations for case study 3.1.1, with 20 HF datapoints.

**Figure 7:** Volume ( $V$ ), Biomass ( $B$ ), product ( $P$ ), substrate ( $S$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.2, with 20 HF datapoints

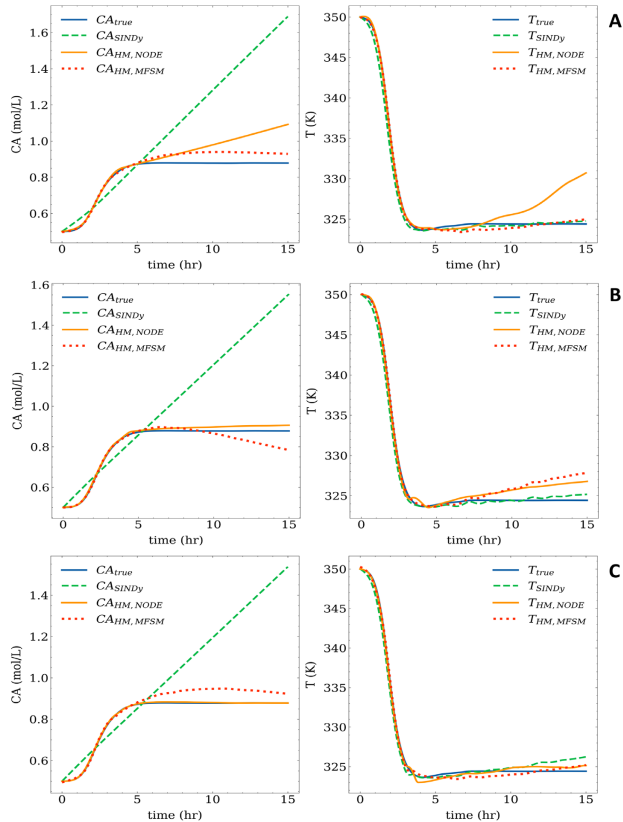

Figures (4-7) show that the HMs constructed with both NODE and MFSM approaches are robust to the low densities of sampled data and can still predict the true states with decent accuracy and capture the profile trends better than the SINDy model. We can also notice that the decrease in density of the data affects the model accuracy, and we start to observe a slight mismatch in HM predictions, and this increases as the density of sampled data decreases. Among the two HM approaches, the HM-MFSM approach performs marginally better than the HM-NODE approach. This is because we take a two-step approach for correcting the error, and decreasing the density of data affects the LF model in step 1. Consequently, the LF model directly affects the NODE approach which is aimed at correcting the derivative space error and results in low errors as we integrate it forward in time for the state profiles. On the other hand, we see an improved fit with MFSMs in the training range. This is because the MFSM approach corrects the error in the state space and does not need integrating the states forward in time.

### 3.3 Extrapolation of the HMs

To analyze the extrapolation ability of the constructed HMs, we show the model predictions with a test dataset that contains input to the HM model from outside the training dataset region. We also compare the results with the SINDy model we obtained in the first step and with decreasing data density. Figure (8) shows three scenarios aimed at illustrating extrapolation using HMs for the case study 3.1.1. Specifically, Figures (8A, 8B, 8C)

correspond to instances with 50, 30, 20 HF samples, respectively. It is evident that HMs utilizing both NODE and MFSM formulations demonstrate better extrapolation capabilities. On the other hand, predictions obtained from the SINDy model show limited extrapolative power.

We can also notice that as data density decreases, the extrapolation performance of these HM with NODE formulation is slightly better than the MFSM formulation. This observation can be attributed to the manner in which error correction is implemented in both approaches. As the NODE approach corrects error in the derivatives, it has an edge in capturing profiles compared to MFSMs when extrapolating the corresponding HM.

**Figure 8:** Extrapolated ( $C_A$ ) and ( $T$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.1 with 50, 30, and 20 HF samples.

Figure (9) shows the same analysis for the case study 3.1.2. Figures (9A, 9B, 9C) correspond to instances with 50, 30, 20 HF samples, respectively. We observe a similar behavior for this case study as well. HMs with NODE and MFSM formulations demonstrate better extrapolation capabilities than the SINDy. We can also observe a similar trend that shows HM with NODE formulation is slightly better than the MFSM formulation.

### 3.4 Effect of noise on the HMs prediction

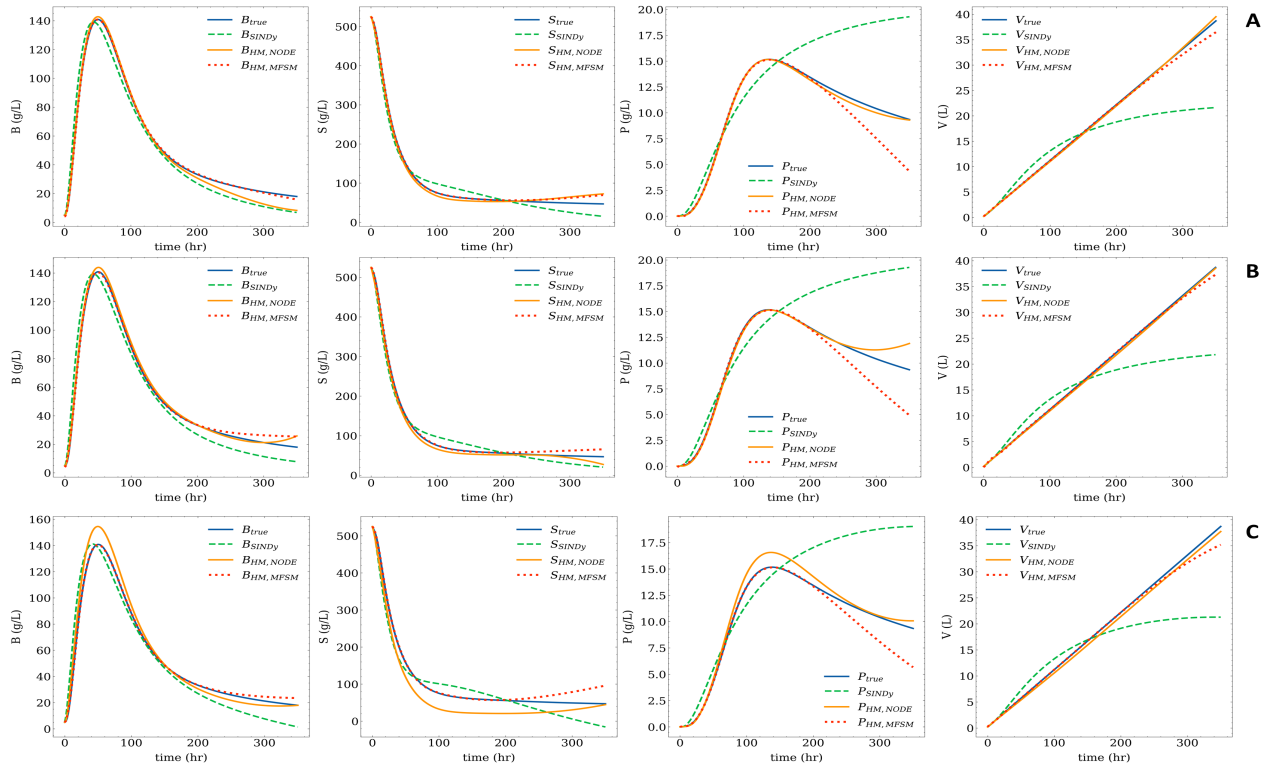

In most practical applications, there is noise associated with the true state measurements. It is necessary to

evaluate the model performance with noise in the true state data and check for robustness. To test our approach, we replicate a practical scenario by adding noise to the simulated data. The true state dataset was modified by adding Gaussian-distributed noise to each state variable data for the two case studies 3.1.1 and 3.1.2. The noise was simulated using a normal distribution, where the mean was set to zero and the standard deviation was adjusted to represent 3%, 5% of the range of the uncorrupted data. To test the methods at challenging scenarios, we present results with 20 HF samples and varying levels of noise.

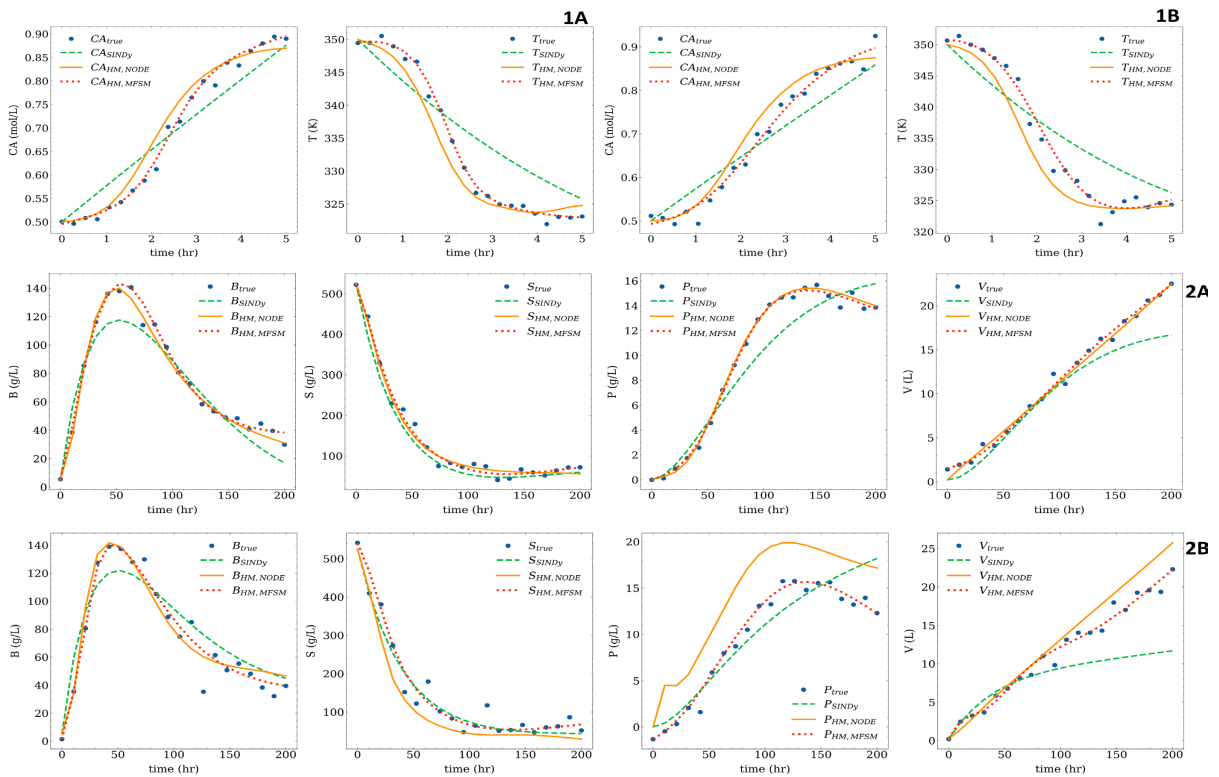

Figure (10) shows the results for this analysis. The legend (A) in Figure (10) represents the 3% noise and (B) represents 5% noise in data. We can notice the robustness of the HM approach towards the noise in data and both HM approaches are able to still predict the profiles accurately in both cases studies 3.11 and 3.1.2. But we can also observe that increasing the noise for the same sparsity reduces the accuracy of predicted profiles. This is expected because modeling accuracy becomes a challenge with increasing sparsity and noise. When comparing the two methods, the HM-MFSM approach performs better because the HM-MFSM structure directly fits the state values for each variable and proper tuning of the model helps in making it more robust towards noise. On the other hand, the HM-NODE fits the derivative values and estimating the derivatives in the presence of noise and sparsity becomes a challenge. While there exist many noise filtering techniques to smoothen the noisy data and mitigate this issue, we intend to include those as the future work.

## 4. CONCLUSIONS

In this work, we address the complexities inherent in data-driven model identification, especially when the underlying physics of the model remains unknown. We investigate the limitations of current state-of-the-art tools like SINDy when the available candidate library inadequately covers all potential terms contributing to the final mechanistic model equation. To tackle this challenge, we propose combining hybrid modeling techniques with sparse regression with the goal of simultaneous hybrid model development and model identification. To achieve this, we outline a workflow that employs two distinct methods: a) utilizing a NODE formulation, and b) employing an MFSM formulation as hybrid modeling approaches integrated with SINDy. Our study demonstrates the effectiveness of this hybrid model architecture in constructing accurate models capable of predicting profiles that predict the true data accurately, while integrating the mechanistic model knowledge.

**Figure 9:** Extrapolated Volume ( $V$ ), Biomass ( $B$ ), product ( $P$ ), substrate ( $S$ ) profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.2 with 50, 30, and 20 HF samples.

**Figure 10:** Predicted profiles from SINDy model, HM-NODE and HM-MFSM formulations for case study 3.1.1 (1A, 1B), and 3.1.2 (2A, 2B) with noise in the data. A, B correspond to 3% noise and 5% noise respectively.

We also showcase the robustness of hybrid models in handling low densities in sampled data and their ability to extrapolate. At lower amounts of sampled data, HM-NODE formulation can extrapolate better and HM-MFSM formulation can predict the states more accurately. Furthermore, we investigated the effect of noise in the true state data on these hybrid models. While the HM formulations could still predict the true profiles with a good accuracy, we saw that reducing the sampling data and increasing the noise can affect the model performance directly and make them less accurate. Future directions on this work will be focused on testing our methods with experimental data to formulate the models and proposing more efficient techniques to train hybrid models and improving their robustness towards data sparsity and noise.

## ABSTRACT

Continuous manufacturing in pharmaceutical industries has shown great promise to achieve process intensification. To better understand and justify such changes to the current status quo, a technoeconomic analysis of a continuous production must be conducted to serve as a predictive decision-making tool for manufacturers. This paper uses PharmaPy, a custom-made Python-based library developed for pharmaceutical flowsheet analysis, to simulate an annual production cycle for a given active pharmaceutical ingredient (API) of varying production volumes for a batch crystallization system and a continuous mixed suspension, mixed product removal (MSMPR) crystallizer. After each system is optimized, the generalized cost drivers, categorized as capital expenses (CAPEX) or operational expenses (OPEX), are compared. Then, a technoeconomic and sustainability cost analysis is done with the process mass intensity (PMI) as a green metric. The results indicate that while the batch system does have an overall lower cost and better PMI metric at smaller manufacturing scales in comparison with the continuous system, the latter system showed more potential for scaling-up for larger production volumes.

## INTRODUCTION

As technology develops and industries advance into the “Industry 4.0” era, the sector of chemical and pharmaceutical manufacturing is no exception. As such, the pharmaceutical industry has been working tirelessly to discover and apply innovations to the field [1]. In particular, the concept of Quality-by-design (QbD), which was first adopted by the FDA as a means to ensure quality in the development, manufacturing, and regulation of drugs [2], has been augmented by the Quality-by-Control (QbC) framework, which employs real-time process observation and control [3]. The paradigm of QbC has notably been applied to concept of continuous crystallizers [3,4]. Continuous manufacturing has been accepted as a promising technology to achieve process intensification in pharmaceutical manufacturing [4,5]. Such methods are important as it promises flexibility and efficiency for both high volume products as well as personalized medicine

[4-6]. However, before the entire industry can adopt a new method of production, technoeconomic cost analyses of continuous production are necessary as a predictive decision-making tool for manufacturers. This is because an intimate understanding of the cost drivers and performance of continuous crystallizers is necessary for manufacturers to adopt change in an already batch system dominated industry [7]. But beyond the importance of technoeconomic analyses in industry, the issue of sustainable processes has also become more pressing. The importance of coupling technoeconomic models with sustainable metrics for a technoeconomic sustainability analysis, not just chemical processes, but for process design in general has been noted [8]. Thus, the application of sustainability metrics, either in forms of life cycle assessment or simple quantitative standards is important for chemical manufacturing [9].

In this paper, a preliminary investigation on the comparison of conventional batch crystallizers and mixed

suspension, mixed product removal (MSMPR) continuous crystallizers is conducted. First, simulated models of the annual performance of both types of systems are constructed using PharmaPy, a custom-made library for pharmaceutical flowsheet analysis [10]. For both layouts, the common active pharmaceutical ingredient (API) of paracetamol (PCM), a common analgesic drug, has been selected. Then, given three different fixed annual production volumes, operational parameters, and desired critical quality attributes (CQAs), each system is optimized for both overall cost as well as sustainability, using the process mass intensity (PMI) as a quantitative metric. For each case, a derivative-free optimizer was used.

## METHODOLOGY

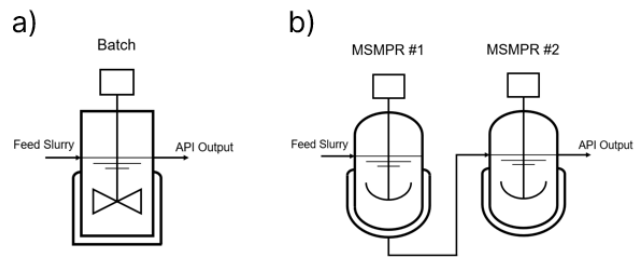

### Modeled Flowsheets

For this study, the analyses were conducted on the crystallizer unit operation. For both batch and continuous crystallizer layouts, the selected API for simulation was paracetamol. The kinetic parameters for the API have been adapted from Szilagyi et al. [11]. Additionally, an arbitrary number of annual workdays were selected wherein the system was set to produce three different annual production volumes. For the batch cooling crystallizer setup, a single unit is set as the default. However, as part of the decision variables, up to three parallel units are considered, thus allowing for the batch crystallizer to be optimized for numbering-up as well as scaling-up. In comparison, the continuous crystallizer setup is comprised of two chained MSMPR crystallizer units. The reason for this setup is because while a single batch cooling crystallizer has the flexibility to operate with a dynamic cooling profile, each MSMPR unit can only be operated under a static temperature value. Thus, by setting up two MSMPR units, the optimizer can affect the process with two different crystallizer dimensions, residence times, and operating temperatures, which enable to manipulate both throughput and critical quality attributes (CQAs), thus allowing for sufficient control and complexity for comparison with the batch process.

For the batch layout, the API is produced in batch, wherein the number of total batches are calculated from the optimal cycle time, which factors in a static one-hour ramp-down/cleanup time. However, for the continuous crystallizer, API is produced continuously in a singular campaign duration. This optimal campaign duration is calculated by multiplying the residence time of the secondary MSMPR,  $\tau_{CR02}$ , by the optimal steady state horizon multiplier,  $H_{ss}$ . This determines the duration at which the MSMPR system operates at steady state and continuously produces API. Additionally, the optimal value for  $\tau_{CR02}$  was obtained from a preliminary optimization sequence prior. Like the batch system, the MSMPR system also has a ramp-down/cleanup time, but it is only initiated

once after the campaign. However, the MSMPR also has ramp-up time wherein it must reach steady state, which was estimated for the temperature decision variables of the MSMPR units.

Finally, for each setup, an inlet of feed slurry is defined. This feed slurry serves to represent an input from a reactor unit. However, as the focus of this work is to analyze the performance of the crystallizer unit, the reactor unit has been omitted. Then, the output of each crystallizer is run through a filtration process step. However, like the reactor, the filtration unit operation has been omitted. A schematic summary of the two setups can be seen in **Figure 1**.

**Figure 1.** Schematic summary of the two different crystallization unit operations, a) batch crystallization and b) continuous crystallization.

Both crystallization configurations were simulated using PharmaPy. As previously mentioned, PharmaPy is a custom-made Python-based library for the analysis of pharmaceutical flowsheets. Using this tool, the defined unit operations can have operational parameters, such as inlet flows, initial conditions, and pharmacokinetic parameters assigned to in an object-oriented software structure [10]. Then, once the unit operations are defined as such, a simulation object of the flowsheet is created. This coupled with a callback function, decision variables can be set as inputs and PharmaPy operations as outputs allows for an optimization framework to be established.

### Optimization Formulation

For this study, the optimization problem is expressed as a non-linear constrained design problem wherein the objective is to minimize either the total cost of the manufacturing the API or the sustainability metric, PMI. The proper definition can be seen in Equation (1) [12].

$$\min_x J(\mathbf{x}, \mathbf{y}, \mathbf{z}) \quad (1)$$

$$\text{s. t. } \frac{d\mathbf{y}}{dt} = \mathbf{f}_1(t, \mathbf{y}, \mathbf{z}, \mathbf{u}(t)),$$

$$\mathbf{f}_1(t, \mathbf{y}, \mathbf{z}, \mathbf{u}(t)) = \mathbf{0}, \quad (2)$$

$$\mathbf{y}(t = 0) = \mathbf{y}_0, \mathbf{z}(t = 0) = \mathbf{z}_0,$$

and

$$g_i(x, y, z, u) \leq 0, \quad \forall i \in I, \quad (3)$$

$$\mathbf{x}_{lb} \leq \mathbf{x} \leq \mathbf{x}_{ub}$$

The equations in Equation (2), adapted from Casas-Orozco *et al.* [12], correspond to the process model of a differential-algebraic equation (DAE) system, with  $\mathbf{y} \in \{y_1, \dots, y_j, \dots, y_{n_y}\}$  being the set of differential states and  $\mathbf{z} \in \{z_1, \dots, z_{n_z}\}$  being the set of algebraic states, and  $\mathbf{y}_0$  and  $\mathbf{z}_0$  being their respective initial values. Additionally, the model inputs are represented by the variables,  $u(t) \in \{u_1(t), \dots, u_{n_u}(t)\}$ . The entirety of the DAE system is represented by the PharmaPy simulation. Finally, Equation (3) shows the nonlinear constraints and decision variable bounds for the problem.

For this study, the decision variables are dependent on the type of crystallizer that is being simulated. Consequently, the lower and upper bounds represented in Equation (3) vary by the system. Thus, the decision variables that are considered as well as their bounds are listed in **Table 1**.

**Table 1:** Description of decision variables considered in the optimization problem along with their bounds.

Variable	System	Description	Bounds
$V_{CR}$	Batch	Cryst. Volume	0.1 ~ 7.5 [m <sup>3</sup> ]
$t_{CR}$	Batch	Cycle Time	10 ~ 720 [min]
$n_{CR}$	Batch	No. of parallel process lines	1 ~ 3 [lines]
$T_{CR,i}$	Batch	Cryst. <i>i</i> th Temp. Point	273 ~ 330 [K]
$V_{CR01}, V_{CR02}$	Cont.	Cryst. Volume	0.1 ~ 7.5 [m <sup>3</sup> ]
$T_{CR01}, T_{CR02}$	Cont.	Cryst. Temp.	273 ~ 330 [K]
$H_{SS}$	Cont.	Steady state multiplier	1 ~ 100,000

Finally, the function  $g_i(x, y, z, u)$  represent the nonlinear constraints that are being applied to the problem. These constraints are representative of CQAs or standards that would be an important metric for determining the success of the system. The first constraint is that the API produced in a system must be at least a certain diameter. This an important CQA for a crystallization unit as the mean size of the crystals, and to an extent the crystal size distribution (CSD) can determine the flowability and filterability of the API produced [13]. This then has large implications for how easily the API is handled, or even how effective the drug is. The second constraint is the production volume. This is simply to ensure that the optimal results always at least produce enough API product to meet the fixed annual production volume. The third constraint is the yield constraint, which is in place to make sure that the optimal results would produce a certain percentage of the theoretical maximum yield, thus ensuring a certain level of efficiency. The fourth constraint is an operational constraint to make sure that the

temperature profile for the batch and the temperatures in the consecutive MSMPRs are monotonically decreasing. Finally, the fifth and final constraint are implemented to make sure that the total calculated time for manufacturing does not exceed the allotted annual workdays. This is in place because while the total time for the batch system is divided into distinct batches, the continuous system simply has a single campaign to continuously create API. These constraints are summarized in **Table 2**. In addition, **Table 2** also lists the weights for each constraint. These weights were then applied to a penalty function for the constraints to ensure that the optimal solution wasn't trivial or impractical.

**Table 2:** Description of the constraints considered in the optimization problem and their respective weights.

Variable	Description	Weight	Constraint
$g_1$	Mean Crystal Size	$w_1 = 10^2$	$40 [\mu\text{m}] < \bar{L}$
$g_2$	Production Volume	$w_2 = 10^3$	$PV_{target} < PV_{actual}$
$g_3$	Overall Yield	$w_3 = 10^2$	$0.9Y_{max} < Y_{actual}$
$g_4$	Decreasing Temp.	$w_4 = 10^0$	$T_{i+1} \leq T_i$
$g_5$	Total Time	$w_5 = 10^1$	$260 [\text{days}] > t_{total}$

For this simulation, the defined optimization problem was then solved with the adaptive Nelder-Mead algorithm included in the SciPy library. Thus, to translate the problem to an unconstrained optimization problem for the derivative-free Nelder-Mead algorithm, the nonlinear constraints were reformulated into an augmented objective function. It should be noted that given the non-convexity of the problem and due to the challenges of employing a gradient-based method in a simulation-optimization approach to the problem, a derivative-free algorithm was preferred. Furthermore, to improve optimizer performance, the objective function and constraint values were normalized. Thus, the objective function was transformed to Equation (4) and the constraints were transformed to Equations (5).

$$J_{norm}(\mathbf{x}, \mathbf{y}, \mathbf{z}) = \left[ \frac{J(\mathbf{x}, \mathbf{y}, \mathbf{z}) - J_{min}(\mathbf{x}, \mathbf{y}, \mathbf{z})}{J_{min}(\mathbf{x}, \mathbf{y}, \mathbf{z})} \right]^2 \quad (4)$$

$$g_{norm,i} = \begin{cases} i \in [1,4], & 1 - \frac{g_{i,target}}{g_i} \\ i = 5, & \frac{g_{i,target}}{g_i} - 1 \end{cases} \quad (5)$$

where  $J_{min}(\mathbf{x}, \mathbf{y}, \mathbf{z})$  is the overall lowest function evaluation the optimizer found and  $g_{i,target}$  is the constraint value for  $g_i$ . Thus, the final augmented and normalized objective function is shown in Equation (6).

$$\min_{\mathbf{x}} J_{norm}(\mathbf{x}, \mathbf{y}, \mathbf{z}) + \sum_{i \in [1,5]} [\max(0, w_i \cdot g_{norm,i})]^2 \quad (6)$$

## Cost Calculation

As previously mentioned, one of the objective functions used to evaluate the simulation is the overall cost of the system. The cost of the system can be broken down into two categories, capital expense (CAPEX) and operational expense (OPEX).

### CAPEX Calculation

CAPEX involves all the terms that are related to the purchase of equipment. However, while the volume of the crystallizers as a decision variable are not discrete values, in reality, equipment are usually made and sold at discrete capacities. Thus, to account for this, a cost-capacity correlation equation is from Diab *et al.* [6] is used:

$$C_B = f C_A \left( \frac{S_B}{S_A} \right)^n \quad (7)$$

Wherein, the  $C_i$  is the cost of the equipment and  $S_i$  is the capacity of the given equipment. Next,  $f$  are equipment-dependent coefficients to account for indirect costs that may be involved for certain equipment. Finally,  $n$  is a value is the cost exponent to represent the exponential increase in cost of equipment as capacity increases. The index of  $A$  in Equation (7) represent existing equipment while the index of  $B$  refer to the equipment selected for the simulation. The specific values for base equipment values in Equation (7) are based on the Chemical Engineering Plant Cost Indices (CEPCIs) [14]. However, for this study, the values are identical as the ones used by Diab *et al.* [6].

Furthermore, to provide a more realistic estimation for the technoeconomic cost model, rather than taking the flat equipment cost, a battery limit installed cost (BLIC) is calculated. Thus, the additional indirect costs associated with installing the equipment are considered. To calculate the BLIC, the Chilton method is employed [6]. In summary, the BLIC is a factor of the total physical plant cost (TPPC), which is the sum of the installed equipment cost (IEC) and the process piping and instrumentation (PPI) cost. The PPI is a percentage of the IEC while the IEC is a factor of the previously calculated equipment cost. The exact coefficients and factors for these calculations are the same as the ones used by Diab *et al.* [6].

Finally, once the BLIC was calculated, rather than apply the flat equipment cost, an equivalent uniform annual cost (EUAC) was calculated. This is to reflect the fact that while it is not unheard of for a company to outright purchase all the required equipment for a new setup, it is more customary for the annual equipment cost of a production line to be expressed as an annuity [15]. The calculation can be seen in Equation (8). An interest rate,  $i_{rate}$  of 5% and a project timeline,  $t_{PL}$  of 20 years is taken from literature [6].

$$EUAC = BLIC \left( \frac{i_{rate}(1+i_{rate})^{t_{PL}}}{(1+i_{rate})^{t_{PL}} - 1} \right) \quad (8)$$

In addition to the equipment cost, the CAPEX for this

simulation also takes into consideration for the working capital (WC) and the contingency costs (CC) of the plant. The WC and CC are set to be 3.5% of the annual material costs and 20% of the total BLIC, respectively. These values can be found in literature [16].

Summary of the total CAPEX calculation is summarized in Equation (9).

$$CAPEX_{total} = EUAC + WC + CC \quad (9)$$

### OPEX Calculation

As opposed to CAPEX, which represented expenses that are investments that need to be made prior to establishing a setup, OPEX represents all expenses that are incurred during the hours of plant operation. The major cost drivers here are the cost of the materials that serve as inputs for the pharmaceutical process and the cost involved with dealing with the waste material of a process. The material cost,  $C_{material}$ , can be straightforwardly calculated as the product of the total mass of each chemical species  $m_i$  and their respective cost per mass,  $C_i$ . Finally, the waste cost,  $C_{waste}$ , can be calculated as a certain percentage of the total cost of solvents,  $C_{solv}$ , involved in the process. The exact percentage, while it may vary on a plant-by-plant basis, was set as 35%. The summary of these calculations as well as the final total OPEX calculation can be seen in Equations (10-12).

$$C_{material} = \sum_i C_i m_i \quad (10)$$

$$C_{waste} = 0.35 \sum_i C_{solv,i} \quad (11)$$

$$OPEX_{total} = C_{material} + C_{waste} \quad (12)$$

Thus, the objective function when calculating for minimal costs can be seen in Equation (13).

$$\min_x J_{cost}(x, y, z) = CAPEX_{total} + OPEX_{total} \quad (13)$$

### Sustainability Calculation

In the previous section, the method of calculating the cost of a crystallization unit operation has been outlined. However, while cost is an important metric for a technoeconomic model, sustainability, or "green processing", is an ever-growing concern for the future of the sustainable pharmaceutical industry [17]. Thus, optimizing the manufacturing system in regard to a sustainability metric in addition to the cost is a necessary perspective to take. Over time, many different metrics for sustainability have emerged. Notably, the E factor, seen in Equation (14), has often been used in studies as a metric for efficiency of pharmaceutical manufacturing [17].

$$E \text{ factor} = \frac{\text{total mass of waste from a process [kg]}}{\text{total mass of product [kg]}} \quad (14)$$

However, as the E factor serves as a ratio of the API produced and the waste material produced from the entire process, the E factor can be a misleading metric as it only represents the waste material, thus not guaranteeing the efficiency or lack thereof in regard to the other materials involved in the process [18]. Thus, as a correction, the process mass intensity (PMI) metric has been introduced. The PMI, shown in Equation (15), serves a ratio of the total API produced with the mass of all chemical species that was involved in the process [18].

$$PMI = \frac{\text{total mass from a process [kg]}}{\text{total mass of product [kg]}} \quad (15)$$

Thus, with PMI as a secondary objective function, the manufacturing system can also be investigated regarding sustainability as well as minimized costs.

## RESULTS AND DISCUSSION

With the optimization problem defined in the previous section as well as the layout of the batch and continuous crystallization manufacturing units, we can then compare the differences in performance and cost for the systems. For both batch and continuous systems, the simulation was optimized for minimal total cost, which was the sum of the CAPEX and OPEX, and for minimal PMI. The results of the optimization for both systems with the two different objective functions and at three different target annual production volumes can be seen in **Figure 2**. Additionally, it is important to note that the CAPEX and

OPEX have been graphed separately on different axes. This is because while the techno-economic cost model was created to provide a holistic view of the unit operations, the inclusion of CAPEX is not always relevant for some industries, for example where the equipment is already in place. Also, the numerical values of the simulations, optimal decision variables as well as some additional performance metrics for the batch system and the continuous system can be seen in **Table 3** and **Table 4**, respectively.

When first observing the results of the simulation, it is important to note that from **Figure 2**, we can observe that the overall OPEX for the continuous system, regardless of annual production volume, is higher than that for the batch system. This is a logical outcome as one of the drawbacks of MSMR crystallizers is that a constant feed of slurry needs to be input. However, it should also be noted that the CAPEX values for continuous systems are always lower than their batch counterparts across the board. This is even with the consideration that a single production line of continuous crystallization requires two MSMR units in cascade. This is reflective of the result that, due to the higher throughput of the continuous systems, a smaller crystallizer unit is sufficient to meet the annual production targets. However, this result comes with the caveat that the inclusion of CAPEX may not be significant for manufacturers who are not looking to create a new manufacturing line from scratch, thus making the difference in CAPEX irrelevant.

<b>Cost/Kg</b>	\$16.77 /kg	\$16.76 /kg	\$16.76 /kg	\$16.76 /kg	\$16.87 /kg	\$16.85 /kg
<b>PMI</b>	5.774718E+00	5.768896E+00	5.755303E+00	5.755237E+00	5.750923E+00	5.745559E+00
<b>Cost Change</b>		0.933%		2.268%		0.371%
<b>PMI Change</b>		-0.101%		-0.001%		-0.093%
<b>Optimal Decision Variables</b>						
$V_{CR01}$	2.020 m <sup>3</sup>	1.653 m <sup>3</sup>	1.396 m <sup>3</sup>	1.531 m <sup>3</sup>	1.288 m <sup>3</sup>	1.213 m <sup>3</sup>
$V_{CR02}$	4.123 m <sup>3</sup>	3.833 m <sup>3</sup>	3.068 m <sup>3</sup>	3.332 m <sup>3</sup>	2.752 m <sup>3</sup>	2.821 m <sup>3</sup>
$T_{CR01}$	273.00 K	273.00 K	273.00 K	273.00 K	273.00 K	273.00 K
$T_{CR02}$	273.00 K	273.00 K	273.00 K	273.00 K	273.00 K	273.00 K
$H_{ss}$	9078.73	11156.65	9774.24	8940.25	7065.28	7534.09

In addition to this observation, we can see from **Table 3** and **Table 4** that despite the differences in CAPEX, the overall cost for the batch system is lower than their continuous counterparts. However, that comparison does not provide a full view of the comparison. An important aspect of continuous crystallization is the efficiency in terms of throughput and availability. This is observed in the simulation results in **Table 4**. The results show that for all annual production volumes, the continuous system resulted in a more consistent throughput rate while **Table 3** indicates that the batch system has a steeper drop in throughput. This is also reflected in the fact that for all three annual production volumes, the batch system needed to use all 260 days for all cases, even though the batch cases have already optimized for 2 parallel lines.

Additionally, we can see that for the continuous system, the overall optimized crystallizer volume is lower than for the batch scenario. In conjunction with this, we can see that the total availability, which is the percentage of time in which the system is actually running and not ramping up, ramping down or cleaning, the continuous system predictably has a higher percentage. With all these observations, we can see that the MSMR setup, while for the selected parameters may have an overall higher cost, shows a better potential for scaling up and provides a more agile manufacturing alternative.

Finally, the previously made observations can also be seen when considering the PMI. From the same tables, we when we see the results for optimizing for PMI rather than cost, we can compare the sustainable nature of both setups. As expected, the continuous system has a higher PMI value due to the necessity for a continuous input of slurry. However, when comparisons with cost in mind, we can see that while optimizing for PMI decreases the resultant PMI by less than 1%, the cost in continuous systems increases less significantly than the batch systems. Thus, while the significance of decreasing PMI would be different on a case-by-case basis, we can observe that the continuous system has a lower cost necessary for improving the overall sustainability of the process.

## CONCLUSION

This study was an example to show the capabilities of the technoeconomic cost model simulation to serve as a decision-making tool for manufacturers. By employing a simulation-optimization strategy with the annual production of paracetamol as a generic representative API and applying CAPEX and OPEX calculations that have been standardized in literature, a good first simulation result was achieved. Furthermore, with the simulation, other than directly comparing cost, the potential

capabilities of continuous production methods in the pharmaceutical industry could be explored. While the overall costs of continuous systems may be higher than the existing batch production setup, the potential for continuous systems to scale up and maintain efficiency in both availability and throughput shows promise. Furthermore, in the light of sustainability for pharmaceutical processes, we could see that the trade-off in cost for improving PMI metrics would be much less than that for batch processes, thus additionally showing how continuous systems could be more easily adapted to be more sustainable and embody the idea of “green chemistry”.

## ABSTRACT

Copolymers are commonplace in various industries. Nevertheless, fine-tuning their properties bears significant cost and effort. Hence, an ability to predict polymer properties a priori can significantly reduce costs and shorten the need for extensive experimentation. Given that the physical and chemical characteristics of copolymers are correlated with molecular arrangement and chain topology, understanding the reactivity ratios of monomers—which determine the copolymer composition and sequence distribution of monomers in a chain—is important in accelerating research and cutting R&D costs. In this study, the prediction accuracy of two Artificial Neural Network (ANN) approaches, namely, Multi-layer Perceptron (MLP) and Graph Attention Network (GAT), are compared. The results highlight the potency and accuracy of the intrinsically interpretable ML approaches in predicting the molecular structures of copolymers. Our data indicates that even a well-regularized MLP cannot predict the reactivity ratio of copolymers as accurately as GAT. This is attributed to the compatibility of GAT with the data structure of molecules, which are graph-representative.

**Keywords:** Reaction Engineering, Polymerization, Artificial Neural Network, Multilayer Perceptron, Graph Attention Network,

## INTRODUCTION

Copolymers are widely used and have a variety of applications such as coatings, in electronic devices, the packaging industry, or pharmaceutical manufacturing[1-3]. Copolymers are often designed with the aim of creating materials that possess the characteristics of their constituent monomers.

The properties of a copolymer are basically determined by the paired monomers' sequence distribution in the constructed copolymers. This distribution is commonly defined by the reactivity ratios, presenting the ratio of each monomer's propensity to react with itself over the inclination to react with another monomer[4]:

$$r_1 = \frac{k_{p,11}}{k_{p,12}}$$

$$r_2 = \frac{k_{p,22}}{k_{p,21}}$$

Here, the  $k_{p,xy}$  is the rate coefficient of propagation of radical  $x$  with monomer species  $y$ . For instance, poly

(ethylene-co-vinyl acetate) or EVA is a commercial polymer in various industries and is constructed from ethylene and vinyl acetate. The reactivity ratios for these monomers are  $r_1=0.88\approx 1$  and  $r_2=1.03\approx 1$ [5]. In a system where both  $r_1$  and  $r_2$  are close to one, the copolymerization tends to produce a random copolymer, and no specific sequence is expected. On the other hand, when  $r_1\ll 1$  and  $r_2\ll 1$ , an alternating copolymer can be expected Like Styrene-Maleic Anhydride copolymer or SMA in which  $r_1=0.02$  and  $r_2=0.003$ [5]. In this condition, each monomer has a preference to react with the other monomer instead of itself. As evident, varying values of reactivity ratios ( $r_1$  and  $r_2$ ) in copolymerization lead to different arrangements in the copolymer structure, subsequently influencing the final properties of the copolymer. Thus, having a reasonable prediction for the sequence of monomers in a copolymer chain facilitates the process of producing fit-for-purpose macromolecules. Traditionally, estimation of the reactivity ratio for a new polymer heavily depends on experimental work and the repeatability of the experiments, which are laborious, sluggish, and costly.

Numerous computational methods, such as Density Functional Theory (DFT), are used for predicting the reactivity ratio in copolymers. However, these methods generally incur significant computational costs, rendering them impractical for certain engineering applications[6].

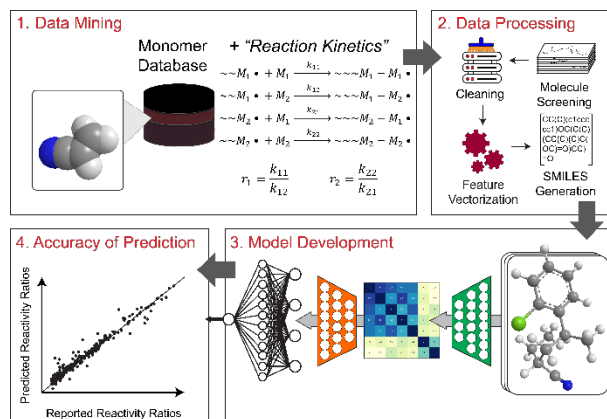

To this end, using of Machine Learning (ML) approaches can be a pragmatic solution for addressing the reaction engineering problems specifically for copolymer synthesis. From a process design perspective, ML models serve as a pivotal tool in predicting the chain topology of copolymers derived from novel monomer pairs. This application, termed the **Forward Design Problem**, utilizes predictive analytics to determine the reactivity ratios of two monomers, thereby identifying the final chain topology of the resultant copolymers. Such predictive capability enables researchers to envision the structural and functional attributes of new materials before their synthesis, streamlining the development process and enhancing the efficiency of material discovery. Conversely, the **Backward Design Problem** represents an equally vital application of ML in polymer science. By integrating ML models with optimization frameworks, it is possible to reverse-engineer the design process to identify monomer structures that yield specific reactivity ratios[7]. This is particularly crucial when aiming for copolymers with precise structural configurations, such as those with alternating monomer sequences achieved when the reactivity ratios of two monomers are significantly less than one. Through optimization, the model identifies 'monomer fingerprints' that are most likely to result in the desired topology, thus guiding the synthesis towards copolymers with predetermined properties and applications. This dual approach—predicting copolymer topologies through forward design and deducing optimal monomer structures for targeted outcomes via backward design illustrates the notable potential of ML in polymer design. This not only accelerates the material development cycle but also opens new realm for the tailored synthesis of copolymers, marking a significant advancement in the field of polymer reaction engineering. The organization of the rest of this paper is as follows. The methodology section presents the data preprocessing and implementation of the Multilayer Perceptron (MLP) and Graph Attention Network (GAT). The result and discussion describe the models' performance in predicting the monomers' reactivity ratios. Eventually, we present some concluding remarks.

## METHODOLOGY

### Data Curation and Preprocessing

In the large view, the development of an ML model constitutes 4 phases including Data Mining, Data Cleaning, Model Construction, and Performance Assessment. Figure 1 presents a general overview of the

development of an ML approach for reactivity ratio prediction in copolymers. In the development of machine learning models, our investigation is positioned within the realm of supervised learning, where each data point is labelled. Our dataset comprises pairs of monomer names, with the associated label being their reactivity ratio during the copolymerization process. Given that the output variable, the reactivity ratio, is a continuous value, our problem is identified as a regression task within the supervised learning framework. A significant challenge in this context is the effective introduction of monomer pairs to the machine learning model (particularly in the development of Multi-Layer Perceptron).

**Figure 1.** Schematic Workflow for Presentation of an ML Approach for Reactivity Ratio Prediction.

After the collection of reactivity ratios of monomers from different references, we evaluated the data in terms of value and distribution. It is generally observed that extracting patterns from a dataset with a distribution close to normal is more effective. To ameliorate the training process of the ML model, we applied a square root transformation to the raw data, aiming to achieve a distribution that is more closely aligned with a normal distribution. Figure 2. represents the original reactivity ratio ( $r_1$  and  $r_2$ ) distribution and also schemes the data distribution when we impose a square root transformation on our data ( $\sqrt{r_1}$  and  $\sqrt{r_2}$ ).

In the next phase, we convert the monomers into the Simplified Molecular-Input Line-Entry System (SMILES) format using open-source cheminformatics toolkits. This allows us to transform the monomers into a machine-readable language, suitable for machine learning development.

### Multi-Layer Perceptron

Here, a Multilayer Perceptron (MLP) for the prediction of the reactivity ratio in copolymers is considered. For converting the SMILES to a numerical vector that is ANN-compatible, a Morgan fingerprint with 2048 bits for each monomer was employed. In the

**Figure 2.** Distribution of original data ( $r_1$  and  $r_2$ ) and distribution of data with applied square root transformation ( $\sqrt{r_1}$  and  $\sqrt{r_2}$ ). As shown in the figure, the skewness of data reduces significantly and make data close to normal distribution. In the quantile-quantile (Q-Q) plot, the degree to which our data aligns with the reference line ( $y = ax+b$ ) provides an indication of how closely the data conform to a normal distribution. A close alignment suggests that the data are approximately normally distributed.

following, the fingerprint vectors of the two monomers were concatenated, and the concatenated vector was considered as the input of the MLP. So, the input of the model is a one-dimensional vector ( $X \in \mathbb{R}^{4096}$ ), and the outputs of the model are  $\sqrt{r_1}$  and  $\sqrt{r_2}$  ( $y \in \mathbb{R}^2$ ).

In defining the structure of the model, a proposed MLP with 4096 inputs, 80 neurons in the first hidden layer, 40 neurons in the second hidden layer, and 2 outputs is used[8]. Regarding the full connectivity of the neurons in all layers, the MLP performance was improved using the dropout technique. **Figure 3** represents a schematic overview of the multilayer perceptron used for reactivity ratio estimation. For a better training process, it was found that the implementation of a regularization technique can improve the Mean Square Error (MSE) significantly. In this regard, a Grid Search Optimization method was implemented to find  $L_1$  Regularization,  $L_2$  Regularization, and Dropout Rate. It was found that using Dropout Rate = 0.65 can significantly ameliorate the MLP performance. Using the optimum dropout rate in the MLP could significantly improve the reported MSE in the modified model (0.1 in the test dataset and 0.08 in the training dataset) compared to the reference model[8].

For the training of our optimized Multilayer Perceptron (MLP), the dataset was allocated as follows: 10% was reserved for testing, while the remaining 90% was utilized for both training and validation. Specifically, of the data allocated for model training and validation, 90%

was used for actual training purposes, and the remaining 10% served as validation data. This approach of incorporating a validation subset within the training data allows for regular assessment of the model's performance against overfitting. By doing so, we ensure that the model not only learns from the training data but also generalizes well to unseen data, thereby enhancing its reliability and applicability in real-world scenarios.

## Graph Attention Network

In the realm of reaction engineering, the structural intricacies of molecular data present unique challenges and opportunities for computational analysis. A promising approach for addressing these challenges is the adoption of graph-based machine learning approaches in which molecules are represented as graphs, atoms as nodes, and chemical bonds as edges. This approach appears to be an encouraging solution for various problems, including reactivity ratio prediction in polymer science. Graph Attention Networks (GAT) are a specific type of Graph Neural Network (GNN) that incorporate attention mechanisms to specify different weights to different nodes in a graph[9,10].

Herein, In the second part, a Graph attention Network with an Attentive Fingerprint was utilized. This approach employs a Recurrent Neural Network (RNN) and an Attention Mechanism for the extraction of the

most important features from the input in a molecule structure. The attention mechanism in the GAT operates based on the three which are mechanism-alignment, weighting, and context operation[11]:

The alignment equation is represented as follows:

$$e_{vu} = (W \cdot [h_v, h_u]) \quad (1)$$

For weighting, the softmax function is applied:

$$a_{vu} = \text{softmax}(e_{vu}) = \frac{\exp(e_{vu})}{\sum_{u \in N(v)} \exp(e_{vu})} \quad (2)$$

The context vector is then calculated using the Exponential Linear Unit (ELU) function:

$$C_v = \text{elu}(\sum_{u \in N(v)} a_{vu} \cdot W \cdot h_u) \quad (3)$$

Here, ' $v$ ' denotes a specific target node or atom, ' $N(v)$ ' its neighboring nodes, ' $h_v$ ' the states vector of node ' $v$ ', ' $h_u$ ' the states vector of a neighboring atom or node ' $u$ ', and ' $W$ ' the learnable weight matrix indicating relationships between the target node and its neighbors. The alignment scores are calculated using Equation 1 and then normalized (Equation 2). Subsequently, the context vector is formulated using the ELU function, allowing a non-zero gradient for negative inputs[11]. Features close to a score of 1 exert more influence on the output, while those closer to 0 are deemed less significant, and negative values result in feature exclusion.

The second stage involves constructing a viable model incorporating a Gate Recurrent Unit (GRU), which enhances the RNN by adding reset and update gates. This allows the GRU to selectively retain and disregard information, thereby augmenting RNN's memory capabilities. The GRU functions in two phases within the model: messaging and readout, described mathematically in Equations (4) and (5).

$$C_v^{k-1} = \sum_{u \in N(v)} M^{k-1}(h_v^{k-1}, h_u^{k-1}) \quad (4)$$

$$h_v^k = \text{GRU}^{k-1}(C_v^{k-1}, h_v^{k-1}) \quad (5)$$

In the messaging stage of the GAT model, the message function, denoted as  $M^{k-1}$  plays a crucial role. This function operates at the  $k - 1$  iteration, where it aids in assimilating the learned features of the nodes. During this phase, the representation of the nodes within the molecules is compiled. The message function aggregates details from neighboring nodes on the graph for each target node. This process is pivotal as the graph attention mechanism focuses on collating data from all adjacent nodes in the messaging phase to effectively update their state in the subsequent read-out phase. In this context, the GRU acts by integrating inputs from the previous state vector  $h_v^{k-1}$  of the target node and the attention context  $C_v^{k-1}$  from its neighboring nodes. In the readout phase, the GRU updates the current hidden state of the target node by employing information obtained from the messaging phase and the node's prior hidden state.

The representations of the target nodes, once learned, are then employed in the read-out phase to predict molecular properties. Detailed explanations of the functioning and application of these processes and equations (1-5) within the GAT framework can be found in the cited references[11]. The model further refines its accuracy by using features such as atom symbols, neighboring atoms, atom masks, bond types, and neighboring bonds to effectively differentiate each target node from its neighbors. In our study, the Multi-Input-Multi-Output Graph Attention Network (MIMO GAT) was used as an advanced version of the Graph Attention Network. This new model includes a special multimodal fusion block, making it different from the Attentive FP model. This network was employed to predict the reactivity ratios of monomers, using SMILES notations of monomers and copolymers. Leveraging multi-task learning, we first converted molecular structures into graph representations using RDKit for feature extraction. These features are then encoded and processed through individual Graph Attention Modules within MIMO GAT. Each module incorporated attentive-layer embedding for both atom and full molecule levels. After that, the outputs from these modules were concatenated and fed to fully connected layers for final prediction. The details of this approach can be found in the reference[10].

## RESULT AND DISCUSSION

Traditional Artificial Neural Networks (ANNs) often employ a black-box methodology for problem-solving, where their primary goal is to identify patterns or relationships within raw input data, without an explicit focus on underlying physical laws or domain-specific knowledge. While these approaches prove effective in numerous scenarios, they may fail to capture crucial

Figure 3. Representation of MLP Architecture

insights tied to the intrinsic properties or governing principles of the system in question.

In contrast, there is an emerging interest in the development of specialized ANNs tailored for particular data types and tasks. For example, Graph Attention Networks (GATs) have shown superior performance compared to Multi-Layer Perceptron (MLPs) in handling graph-structured data. This advancement is largely due to GATs' ability to more accurately represent and process-relational and structural information inherent in such data. Given that chemical science data fundamentally relates to molecular structures, which are naturally representable as graphs, Graph Neural Networks, including GATs, emerge as particularly promising for tackling challenges in polymer science. Their capacity to intuitively map and interpret the complex, interconnected nature of molecular structures positions them as a fitting choice for this field.

In this study, an MLP model was developed for the prediction of the reactivity ratio of paired monomers in copolymerization. It was observed that a regularized MLP predicted the reactivity ratios with improved accuracy, yet the Mean Square Error (MSE) could not be reduced to less than 0.1 in the evaluation of the test dataset. Although this MSE is substantially lower than those reported in other references[8], the model does not seem to be entirely appropriate for accurate prediction in this context.

Figure 4. compares the  $R^2$  score on the test dataset when MLP and GAT are used as the reactivity ratio estimator. As shown in the figure, GAT significantly outperforms in comparison to MLP in the prediction of  $r_1$  and  $r_2$ . While the  $R^2$  score could hardly be more than 10% in using MLP, the GAT could achieve  $85\pm 5\%$ [10].

It is evident that there is a substantial enhancement in the prediction of reactivity ratios for copolymerization when using GATs. This suggests that employing a graph-based machine-learning approach can outperform conventional ANNs. The key advantage lies in the graph-based model's ability to incorporate the natural intrinsic structure of the data into the training process, enabling it to capture patterns more effectively than other machine learning models, which may treat each model completely as a black box without considering the system's inherent nature.

**Figure 4.** Comparing the  $R^2$  score in test data for Graph Attention Network (GAT) and Multilayer Perceptron (MLP)

## CONCLUSION

Here, this study clearly demonstrates the superiority of Graph Attention Networks (GATs) over traditional Multilayer Perceptron (MLPs) in the context of predicting reactivity ratios for copolymers. The substantial improvement in prediction accuracy, as evidenced by the  $R^2$  scores, underscores the effectiveness of GATs in handling complex, graph-structured data inherent in chemical science. By integrating the intrinsic structural information of molecular data into their learning process, GATs not only outperform conventional ANNs but also pave the way for more nuanced and accurate models in polymer science. This comparison highlights the potential of graph-based machine learning approaches to revolutionize data analysis in fields where understanding the interconnected nature of data is critical.

## ABSTRACT

The integrated design and control (IDC) framework is becoming increasingly important for systematic design of flexible manufacturing and energy systems. Recent advances in computing and derivative-free optimization have enabled more tractable solution methods for complex IDC problems that involve, e.g., multi-period dynamics, the presence of high-variance and non-stationarity probabilistic uncertainties, and mixed-integer control/scheduling decisions. Parallely, developments in techno-ecological synergy (TES) have allowed co-design of industrial and environmental systems that have been shown to lead to win-win solutions in terms of the economy, ecological, and societal benefits. In this work, we propose to combine the IDC and TES frameworks to more accurately capture the real-time interactions between process systems and the surrounding natural resources (e.g., forests, watersheds). Specifically, we take advantage of (multi-scale) model predictive control to close the loop on a realistic high-fidelity simulation of the overall TES system. Since this closed-loop simulation is computationally expensive, we propose to solve the resulting design problem using a data-efficient constrained Bayesian optimization method. We demonstrate that the new perspective offered by the proposed TES-IDC framework leads to robust win-win solutions that can more effectively handle uncertainty in future disturbances compared to technology-only solutions on a chloralkali manufacturing unit built in an urban forest.

## INTRODUCTION

Within the discipline of process systems engineering (PSE), the systematic and simultaneous consideration of design and time-varying operation parameters has become paramount for the creation of next-generation manufacturing and energy systems. Over the last four decades, there have been several contributions in PSE that seek to optimize process design with the consideration of future uncertainties and operational decisions. One of the earliest works that provided the quantitative framework for assessing various designs and their ability to handle uncertainty for steady state systems was the concept of flexibility analysis [1, 2], which was later extended to dynamical systems by inclusion of time varying

constraints [3]. More recently, flexibility analysis of black-box functions has also been proposed [4–6]. One of the major shortcomings of the flexibility approach was the fact that this paradigm assumed analysis of open-loop systems, which entails that an attainable operating point according to flexibility analysis, would in fact be intractable under closed-loop conditions. During the development of flexibility analysis, another concept was parallely developed, which assess controllability of process design, namely, the dynamic resilience [7] which was extended to account for other inherent characteristics of the system, such as constraints on manipulated variables, plant-model mismatch, etc. These traditional engineering design approaches, however, considered design and control of processes and systems as separate

problems. The design problem establishes the flow of components within a process, while the control problem addresses the maintenance of process conditions under disturbances and constraints. Addressing these problems separately can lead to decisions that result in sub-optimal process performance operationally, economically, or sustainably. Thus, the advent of concurrent design and control methodologies for process systems gained momentum in the early 1990s [8].

To improve the flexibility and resilience of process systems, the integrated design and control (IDC) framework relies on the fact that achievable plant dynamics are completely tied to the selected process design [9]. Early IDC literature [10–12] framed the problem to consist of an economic objective function constrained by the operating capabilities of classical control strategies such as PI controllers. Incorporation of more advanced optimization-based controller strategies such as model predictive controllers (MPC) were proposed in [13, 14], with assumptions that simplified the overall optimization problem. One can apply coarse approximations to the problem formulation; however, this will fundamentally degrade the quality of the problem/solution – if we miss out on these realistic phenomena then it is not clear that IDC provides any added value over traditional two-stage “design then control” strategies. The requirement of high-fidelity simulated solutions is buttressed by advancements in computational resources that allow implementation of powerful optimization methods, and detailed simulations which can span multiple spatiotemporal scales. The standard formulation of an IDC problem is a challenging stochastic optimization problem; although the design variables are often finite dimensional, the set of all possible feedback control policies is infinite dimensional. Recent work [15, 16] has shown that a combination of efficient derivative-free optimization (DFO) solvers and low-dimensional decision rule approximations can be used to tackle the challenging optimization problem.

These works, however, only consider technocentric solutions and don’t incorporate the interactions between process operations with nature. The coupling of technocentric and nature-based solutions is important because multi-scale dynamics results in complex, unpredictable systems. Historically, engineering has developed a tendency to modify and dominate ecosystems to improve predictability. Building large dams, canals and levees are a consequence of engineering’s tendency to convert the homeorhetic nature of ecosystems into homeostatic behavior. As another example, for air quality regulation, conventional engineering systems would recommend fast-growing genetically modified trees that provide constant air quality regulation services throughout the year. In the short run, such highly engineered systems would be able to meet human needs, by transferring variability to other parts of watershed or airsheds. Unfortunately,

this improvement in “efficiency” comes at the cost of resiliency. Due to poor biodiversity, genetically engineered trees would be more susceptible to pests or diseases as compared to natural forests. Similarly, floods and hurricanes can damage dams and levees leaving them inoperable. To analyse the interaction between nature and technology, we refer to techno-ecological synergy (TES) [17], which is a systems-based framework to account for ecosystems capacity and benefit from its synergy with technological systems. TES offers an opportunity towards resilient systems when compared to technological only systems. However, the resilience comes at a cost of homeorhetic behavior. For gaining maximum benefits from TES, engineering design and operation needs to evolve beyond hemostatic behavior towards a system that adapts nature’s intermittency. In this work, we address the open question - *how to systematically solve the IDC problem with embedded real-time interactions between nature and technology?*

## BACKGROUND AND PRELIMINARIES

In this section we will briefly discuss two important components of the proposed framework, namely the IDC formulation, and Bayesian optimization, which is our selected method for tackling the IDC problem.

### Integrated Design and Control under Uncertainty

The integrated design and control problem can be formulated in terms of the following stochastic optimization problem:

$$\min_{(d,z) \in \mathcal{D}, \mathcal{Z}} C(d) + \mathbb{E}_{\omega} \{O(d, z, \omega)\}, \quad (1)$$

where  $d \in \mathbb{R}^{n_d}$  are the design variables that must be selected from a compact set  $\mathcal{D} \in \mathbb{R}^{n_d}$ ;  $z \in \mathbb{R}^{n_z}$  are the control decisions restricted to compact set  $\mathcal{Z} \in \mathbb{R}^{n_z}$ , which parameterize recourse/control actions in response to uncertainties (only impact operating cost of the process);  $\omega \in \mathbb{R}^{n_{\omega}}$  is a sequence of random variables that describe the complete set of exogenous disturbances/uncertainties in the process. The objective function (1) is the composition of two functions, namely, the capital expenditure  $C(d): \mathcal{D} \rightarrow \mathbb{R}$ , and the expected value  $\mathbb{E}_{\omega}$  of the operating expenditure  $O(d, z(d), \omega)$  with respect to  $\omega$ . In this work, we are interested in computing realistic estimates of operating costs  $\mathbb{E}_{\omega} \{O(d, z, \omega)\}$ , meaning we do not want to make coarse approximations (e.g., steady-state operation). To achieve this, we assume that the system dynamics can be represented by the following generalized time-varying nonlinear system in the presence of uncertainty:

$$\begin{aligned} x_{t+1}(d, z, \omega) &= h_t(x_t(d, z, \omega), u_t(x_t(d, z, \omega), w_t, d), \\ x_0(d, z, \omega) &= b_0(d), \end{aligned} \quad (2)$$

where  $t \in \mathcal{T} := \{0, \dots, T-1\}$  is the discrete time index that ranges over finite number of  $T$  time stages;  $\omega$  is a sequence of random disturbances  $\omega \in \mathcal{W} \subset \mathbb{R}^{n_\omega}$ , which is assumed to be measurable at corresponding  $t \in \mathcal{T}$ ;  $u_t(d, z, \omega) \in \mathcal{U} \subset \mathbb{R}^{n_u}$  are control inputs parameterized by  $z$ ; and  $x_t(d, z, \omega) \in \mathcal{X} \subset \mathbb{R}^{n_x}$  are state variables with initial conditions  $b_0(d)$  that depend on design variables. Our only assumption is that we can simulate the process (2) to get future state sequences  $\{x_0(d, z, \omega), \dots, x_T(d, z, \omega)\}$  for specific realizations of the design  $d$ , control parameters  $z$ , and disturbances  $\omega$ . We do not need closed-form expressions for any of these components – we only need to be able to generate sample trajectories, which could be from some high-fidelity black-box process simulator.

The control inputs are assumed to be set by a parametrized *decision rule* (DR) with the following structure:

$$u_t(d, z, \omega) = \kappa_t(x_t(d, z, \omega), w_t, z), \quad (3)$$

where  $\kappa_t: \mathcal{X} \times \mathcal{W} \times \mathcal{Z} \rightarrow \mathcal{U}$  is a known function with free parameters  $z$ . The value of (3) is twofold: (i) it enables us to work in a reduced-dimensional space through proper selection of  $z$  and (ii) it enforces causality by design such that only past-revealed information can be exploited in the selection of the current control action. We typically select (3) to be some form of advanced control such as MPC due to its nice combination of performance and flexibility.

Given this dynamic model, the operating cost will typically be represented as a sum of stage costs over the entire system lifetime such as:

$$O(d, z, \omega) = \sum_{t=0}^{T-1} \ell_t(x_t(d, z, \omega), u_t(d, z, \omega), w_t, d) + \ell_T(x_T(d, z, \omega, \gamma), d), \quad (4)$$

where  $\ell_t: \mathcal{X} \times \mathcal{U} \times \mathcal{W} \times \mathcal{D} \rightarrow \mathbb{R}$  is the contribution to the operating cost at each time step  $t \in \mathcal{T}$ , and  $\ell_T: \mathcal{X} \times \mathcal{D} \rightarrow \mathbb{R}$  is contribution to the operating cost at the final time step (e.g., recoverable cost from equipment or product).

## The Bayesian Optimization Framework

Bayesian optimization (BO) is a powerful tool for solving black-box optimization problems in the presence of zeroth-order data and expensive to evaluate functions. The objective of BO is to globally minimize a cost function  $f$  such that  $f^* = \min_{\theta \in \Theta} f(\theta)$ , where domain  $\Theta$  is a closed set. The optimization framework usually begins with "warm-starting" a surrogate model with small number of randomly selected function evaluations over the domain of decision variables. In low-data regime, Gaussian process (GP) regression has been most widely used surrogate model since they are both *probabilistic* and *nonparametric*. A GP prior is placed on the objective function  $f(\cdot) \sim \mathcal{GP}(m(\cdot), k(\cdot, \cdot))$ , which can be fully specified by its mean function  $m(\cdot)$ , and covariance kernel  $k(\cdot, \cdot)$ . The mean function and covariance kernels for a pair of inputs  $\theta, \theta' \in \mathbb{R}^{n_\theta}$  is defined as follows:

$$m(\theta) = \mathbb{E}_f\{f(\theta)\}, \quad (5a)$$

$$k(\theta, \theta') = \mathbb{E}_f\{(f(\theta) - m(\theta))(f(\theta') - m(\theta'))\}. \quad (5b)$$

Given a set of inputs  $\theta = \{\theta_1, \dots, \theta_n\}$ , we can update the GP model prior with available data using Gaussian conditioning formula and obtain the following analytical form for mean and variance for a test point  $\theta$ , and noisy measurements  $y_i = f(\theta_i) + \epsilon_i$  for all  $i = 1, \dots, n$  [18]:

$$\mu_n(\theta) = m(\theta) + k(\theta, \theta)(k(\theta, \theta) + \sigma_\epsilon^2 I_n)^{-1}(y_{1:n} - m(\theta)), \quad (6a)$$

$$\sigma_n^2(\theta) = k(\theta, \theta) - k(\theta, \theta)(k(\theta, \theta) + \sigma_\epsilon^2 I_n)^{-1}k(\theta, \theta), \quad (6b)$$

Given a predictive surrogate model, one must now select a so-called "acquisition function"  $\alpha_n(\theta)$  whose value at any  $\theta \in \Theta$  provides a good quantitative measure of the (expected) benefit in querying  $f$  at this point in the future. By definition, the next best sample can then be found by solving an optimization problem:

$$\theta_{n+1} = \max_{\theta \in \Theta} \alpha_n(\theta). \quad (7)$$

Note that this problem is significantly easier to solve the original problem since it is only defined in terms of the GP surrogate model, which can be cheaply evaluated (in the low data limit) and whose derivatives can be computed using established automatic differentiation schemes. A variety of acquisition functions have been proposed for single-level optimization problems [19, 20]. The same concept can also be generalized to other types of problems with additional structure such as optimization with black-box constraints [21] [22], multi-objective optimization [23], robust optimization [24–26], just to name a few.

In this work, we use a high-fidelity, offline simulator to compute cost and operating expenditures for a given  $(d, z)$ . Similar to previous work [15], the decision variable of BO framework is given by the concatenation of design variables and control decisions of the IDC problem, i.e.,  $\theta := (d, z)$ . We leverage steps (5-7) to sequentially search over  $\theta \in \Theta := \mathcal{D} \times \mathcal{Z}$ , and find the optimal solution of (1) in a data-efficient manner.

## CASE STUDY: CHLORALKALI SYSTEM DESIGN

We consider a chloralkali manufacturing process located in Freeport, Texas, which was originally studied by Shah and Bakshi [27]. The energy-intensive process derives its energy from a coal-fired generator, which results in air emissions such as nitrogen dioxide (NO<sub>2</sub>), sulfur dioxide (SO<sub>2</sub>), carbon dioxide (CO<sub>2</sub>) and particulate matter. The NO<sub>2</sub> emissions acts as a precursor to ground level ozone O<sub>3</sub>. Our goal is to design a minimal cost system that can provide effective air quality regulation (such that it is potentially a net benefit to society), even under unknown variability in weather conditions. We specifically

want to leverage the natural ability of trees to uptake air emissions, while accounting for dynamic uncertainty in solar irradiance, wind velocity, and leaf surface area.

## Model Description

For the decision rule, we formulate an economic MPC (eMPC), whose objective is to minimize the total annualized cost,  $Z^{TAC}$  of the chloralkali production unit with hourly sampling, which corresponds to  $T = 8760$  time-steps. Two design variables ( $n_d = 2$ ) can be varied at the BO level; first, is the technocentric choice of the size of selective catalytic reactor (SCR),  $S^{SCR}$  to treat  $\text{NO}_2$ , whereas the second is the eco-centric option of reforestation area,  $A^r$ , in the vicinity of the facility. There are seven uncertain variables in the air quality regulation problem - namely  $\text{NO}_2$  concentration in ambient air,  $\text{O}_3$  concentration in ambient air,  $\text{NO}_2$  dry deposition rate, atmospheric mixing height, photo-chemical destruction rate of  $\text{NO}_2$ , and photo-chemical production rate of  $\text{O}_3$ . Presence of uncertain variables leads to high computational demand because the eMPC not just has to predict the future behavior of the uncertain variable, but also be robust against future changes or deviations. We select a control horizon of one hour ( $N_u = 1$ ) and we take advantage of the fixed total time-steps  $T$  of the closed loop simulation and consider a prediction horizon of  $N_p = T - t_0 + 1$ , where  $t_0$  is the initial time step of simulation. For example, at first hour,  $t_0 = 1$  and  $N_p = 8760$ ; after implementation of control action recommended by the DR, at the next time step (i.e., second hour),  $t_0 = 2$ , prediction horizon decreases to  $N_p = 8759$ . Although the proposed shrinking horizon approach improves computational tractability of the IDC simulation, there would still exist the computational burden for long prediction horizons. To alleviate this drawback, we divide the prediction horizon into two parts; the first 24 hours after  $t_0$ , for which we build a multivariate time series forecasting model using a Gated Recurrent Unit (GRU) neural network using past data of 168 hours; the predictions for time steps after 24 hours to  $N_p$  are allotted values using time series clustering of historical data. The number of time series clusters ( $|\mathcal{D}|$ ) is set to be one of the control decisions ( $n_z = 1$ ) at the BO level. The DR in this setting is given by the minimizer of the below optimization problem:

$$\min_{\{F_{Cl_2}(t+k|t)\}_{k=1}^{N_u}} Z^{TAC}, \quad (8a)$$

subject to chlorine production model and power requirement,

$$P_t = f_1(F_t^{Cl_2}), \forall t \in 1, \dots, N_p, \quad (8b)$$

supply-demand accounting for  $\text{NO}_2$  and  $\text{O}_3$ ,

$$D_{i,t}^E = f_2(P_t, S^{SCR}), \forall t \in 1, \dots, N_p, i = \{\text{NO}_2, \text{O}_3\}, \quad (8c)$$

$$S_{i,t}^E = f_3(A^r), \forall t \in 1, \dots, N_p, i = \{\text{NO}_2, \text{O}_3\}, \quad (8d)$$

air quality constraints,

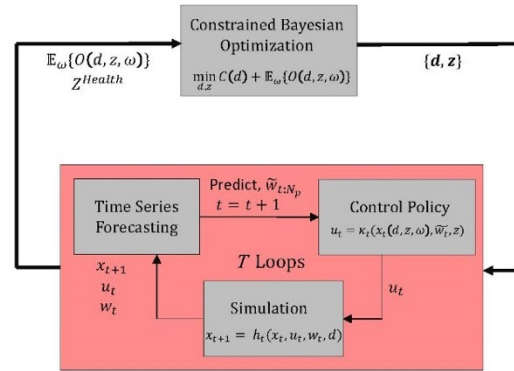

$$C_{i,t}^f = f_4(C_{i,t}^0, D_{i,t}^E, S_{i,t}^E), \forall t \in 1, \dots, N_p, i = \{\text{NO}_2, \text{O}_3\}, \quad (8e)$$

and economic and health impact cost calculation,

$$Z^{TAC} = \sum_{t=1}^{N_p} f_5(F_t^{Cl_2}, A^r, S^{SCR}), \quad (8f)$$

$$Z^{Health} = \sum_{t=1}^{N_p} f_6(C_{i,t}^f, C_{i,t}^0), \quad (8g)$$

where  $F_{Cl_2}$  is the production rate of chlorine. For details about the constraints in the control policy, the reader is referred to Shah and Bakshi [28] (see supporting information). We refer to the same study to define societal health impact cost,  $Z^{Health}$ , which reflects the monetary valuation of the chloralkali facility's operation on the health of neighbourhood. We use iTree Eco v6 to calculate hourly dry deposition velocity of  $\text{NO}_2$  and  $\text{O}_3$ , and atmospheric mixing height. The deposition velocities for year 2006–2015 are obtained using local meteorological conditions obtained from the National Climate Data Center (NCDC) for Clover Field Airport, which is the nearest good quality data source to our study site. The case study assumes the vicinity of the manufacturing facility to be barren i.e. having zero supply capacity and availability of  $15 \text{ km}^2$  for restoration to increase capacity. The cost of reforestation is set at  $\$75/\text{km}^2$  [29]. Native species of White Ash is considered to approximate the capacity of the restored forest ecosystem. Constrained BO [21, 30] is used to make design decisions on  $d = \{S^{SCR}, A^r\}$ , and  $z = \{|\mathcal{D}|\}$ , with constraints that enforce  $Z^{Health} \leq 0$ . The workflow is summarized in Figure 1.

**Figure 1:** Illustration of the proposed efficient TES-IDC framework combining MPC and BO.

## Results and Discussion

The BO algorithm applied to the TES-IDC problem converged to a solution of reforestation area of  $11.798 \text{ km}^2$ , 17 representative cluster days, and no SCR requirement. The optimal total annualized cost of production has a mean value of  $\$920\text{k}$  and standard estimation error of  $\$4.53\text{k}$ . The uncertainty in objective value results from consideration of 10 different meteorological years data used in the simulation. The optimal solution obtains a

societal health impact cost with mean \$-194k (i.e., a net-positive impact on society) and standard estimation error of \$57.72k. The operational solution needs to satisfy hourly air quality constraints. Due to forecasting error and prediction mismatch, it is not possible to satisfy constraints at each and every time step. Thus, the magnitude of constraint violation (8 b-g) is minimized by adding a corresponding weighted exact penalty function to the objective function in (8a), which leads enforcement of soft constraints in the optimization problem (8). The optimal operational solution is expected to have a mean of 10.3 constraints violations with standard measurement error of 5 instances. This is compared with a retrospective scheduling approach, which uses past data to set an operating schedule for the future plant operation [27, 28, 31]. The optimal operational schedule for meteorological year 2010 obtained from TES-IDC framework is depicted in Figure 2b. It should be noted that the operational schedule was obtained in closed-loop manner, where the optimal control actions were updated with each realization of uncertainty. Figure 2a shows retrospective operational schedule of year 2009 applied to year 2010. The retrospective solution (207 violations) has an order of magnitude more hourly constraint violations as compared to TES-IDC solution (10 violations). Therefore, the TES-IDC optimal configuration is robust to changes in meteorological conditions. Assuming meteorological conditions remain similar to that of the last 10 years, the optimal solution (design conditions and controller configuration) found by BO can maintain optimality and constraint satisfaction of the chloralkali unit.

**(a)** Simulation of operations in year 2010 using an optimal retrospective solution obtained for meteorological year 2009 using the previous method by Shah and Bakshi [27].

**(b)** Simulation of operations in year 2010 using solution obtained from proposed IDC-TES. The number of instances of air quality constraint violation decreases significantly as compared to previous retrospective approach.

**Figure 2:** Operational schedule using (a) retrospective and (b) TES-IDC approach. TES-IDC approach allows for better constraint satisfaction as compared to previous approach.

## CONCLUSIONS

In this work, we consider real-time interactions between nature and technology in the IDC simulation, referred to as TES-IDC, which has not been previously addressed in the literature. Furthermore, the proposed solution does not make any assumptions about continuity, linearity or convexity of the underlying design and control problem. Application of TES-IDC framework on air quality regulation problem demonstrates the ability of technological systems to account for intermittency and variability of ecosystems in real-time operations. The operation using TES scheme can ensure long-term net-positive manufacturing goals and societal gain. Explicitly accounting for uncertainty through scenarios, allows us to report expected values of objective along with a measure of uncertainty. This framework motivates application in design and operation of flexible renewable systems. The case study considered in this work has assumed constant spatial capacity of ecosystem. Future work is to formalize the TES-IDC framework and provide the PSE community with access to open-source codes for benchmark. Another interesting avenue for further investigation is the inclusion of spatial dimension to the IDC problem to obtain spatio-temporally explicit work design and operation of TES-IDC problems.

## ABSTRACT

Pharmaceutically elegant tablets are an expectation from pharmacists, health care providers and consumers for solid oral dosage forms. The presence of non-aesthetically pleasing defects in solid oral dosage forms can result in complaints back to the manufacturer and potentially non-compliance with medicines. The purpose of this study was to simulate and analyze the design of a tablet core and the aqueous film-coating process, to gain a better understanding of tablet defect generation, and to help eliminate the defects from the finished product. This evaluation employs Discrete Element Method (DEM) using the software product Altair® EDEM™ to understand the potential mechanisms that are causing the defects, based on the forces tablets experience in the coating operation, along with the number of tablet-to-tablet interactions that occur during the duration of the process. Defects observed during the scale up of the coating process to a commercial production scale confirmed the DEM results where physical damage was observed more on the edges of the tablets than the face of the tablets. Also based on the number of tablet-to-tablet interactions, operating the coating process under thermodynamically wetter processing conditions can result in elevated levels of picking and sticking defects being observed based on the specific tablet design evaluated. The results of these efforts allowed the manufacturing and development team to evaluate improvement opportunities not only in tablet design but also to re-evaluate the thermodynamic design space of the coating operation and the mechanical set up of the coating equipment.

## INTRODUCTION

Pharmaceutically elegant tablets are an expectation from pharmacists, health care providers and consumers. One approach to ensure aesthetically pleasing dosage forms is to apply a film coating [1]. Not only does the coating aid in the appearance and identification of the tablet, but it also helps patients by protecting the product from light, aids in swallowability of the tablets and also protects the caregivers from accidental exposure to the drug substance contained within the film-coated tablet.

Periodically, non-aesthetically pleasing defects can be present in the finished product. These defects have no impact on the safety or efficacy of the tablet but may

garner complaints from the marketplace and impact the company's brand and reputation and patient compliance to the medicine. This is of extreme importance for the Japan market. If the defect level present in each batch of drug product does not meet the current standards, the batch can be considered unfit for sale and then must be sorted or in a worse case discarded. Destruction of a batch of product not only interrupts the manufacturer supply chain because the batch will need to be replaced but can also impact the patients depending on the inventory levels. Batches can be sorted by employing an inspection/sorting step. This step can be manual, mechanical, or electronic based on the nature of the defect. The sorting technique could result in a considerable time

delay in releasing the batch.

Many variables come into effect when applying aqueous film coatings to tablet cores that can impact the elegance of the coated tablet. These include the physical design of the tablet, mechanical strength of the tablet core, mechanical design of the coating equipment, the thermodynamics of the coating operation and handling of coated tablets once the coating process is complete. Each one of these variables will impact the type, severity and number of defects created. In some cases, it takes a combination of the variables to result in the generation of a specific defect.

The purpose of this study was to simulate and analyze the design of a specific tablet core shape with the commercial production coating equipment design i.e., pan size, number of baffles and baffle design and coating pan load. This effort would allow for a better appreciation for the interaction between the tablet shape and the coating equipment and the operation parameters. The defects being observed were a result of a transfer and scale up of a manufacturing process from pilot to commercial scale. The two main defects being observed were edge damage, Figure 1 and picking and sticking, Figure 2. These defects were observed during the end of the batch statistical inspection of the bulk finished product. Understanding of the interactions and the defects being observed can then be applied back to the coating operation, allowing for the appropriate actions to be taken to aid in the reduction or elimination of the defect in future batches of finished product, resulting in increased quality and production yields.

**Figure 2.** Picking and sticking defects on tablet faces

## LITERATURE REVIEW

Since the introduction of discrete element method (DEM) simulation techniques [2], there has been an increasing interest in utilizing DEM to improve understanding of the intricate behavior exhibited by particulate systems. Furthermore, there has been a recent expansion in its application across various industries [3], and more recently in the pharmaceutical industry [4]. The coating operation has been one of the very common applications where the coating uniformity and breakage are the main concerns in the process. Although there are many computational studies on the coating of the tablets [5][6][7], there are few computational studies on the breakage of the tablet core itself.

Computational analyses of breakage have been done for general cases wherein the impact of agglomerate particles across various impact velocities [8] and impact angles [9] were examined. However, there has been little work done on pharmaceutical tablets as opposed to general spherical agglomerates. Bharadwaj et al [10] used DEM to compare the characteristic forces exerted on tablets in a friability tester with those experienced during the operation of lab-, pilot-, and commercial-scale film coating pans. But this study also lacks the prediction of the likelihood of tablet breakage during the coating process. Ketterhagen et al [11] overcomes this limitation by providing a probabilistic model to predict tablet fracture in the film coating process. Ketterhagen uses the impact velocity of the tablets during contact to predict probability of breakage of a tablet using a population balance model proposed by Vogel & Peukert [12][13].

All of the above studies mentioned above have been performed for spherical agglomerates using a “glued-sphere” approach. This present study extends from the previous studies and takes into account the physical shape of a pharmaceutical polyhedral tablet and provides a surface distribution of forces on regions of the tablet to predict localized breakage.

## METHODOLOGY

### Discrete Element Method

Discrete Element Method (DEM) is a numerical method which is used to simulate bulk material. This method was first developed by Cundall and Strack [2] in which all the individual particles in a bulk system are modelled as discrete elements. A Lagrangian-based approach is used in DEM to track these individual particles in the system at every timestep. The contacts between particles are detected at each timestep, and the contact forces are calculated based on this contact. Newton’s second law of motion is applied to each particle to

calculate the accelerations of each particle. Explicit numerical integration is then done twice to calculate the position of each particle in the subsequent timestep. Contact detection is carried out again for these updated positions, and then this cycle repeats for every timestep. DEM is the highest fidelity numerical modelling approach for particulate solids available because the discrete nature of these particulate solids is not ignored, although it comes with very high computational expense compared to other methods.

DEM was traditionally developed for spherical particles. For non-spherical arbitrarily shaped particles in a bulk, the particles are approximated by idealized numerical elements such as clumped spheres or multi-spheres, and this multi-sphere approach has been widely used and validated for particle distributions which do not have a fixed shape or size [14]. This is due to the simplicity of contact detection algorithms for spheres. However, in this study, a polyhedral particle shape, standard round concave shape [15], was used since tablets in pharmaceutical industries generally include sharp edges that are difficult to capture with spheres. Consequently, the contact detection algorithm needs to be modified to accommodate such polyhedral shapes.

## Governing Equations

This study employs DEM using the software product Altair® EDEM™. The default contact model in EDEM is based on the Hertzian theory of contact mechanics [16]. However, for polyhedron-shaped particles, the force equations are modified to account for non-spherical shapes, according to Nassaeur and Kuna [17]. Additionally, a spinning friction model was also introduced to account for the friction that would occur if a particle face were rotating against another particle or geometry.

Contact forces between two particles in the normal direction are given by the following equation:

$$F_n = \left( \frac{0.62}{0.752} \right) \left( \frac{4}{3\sqrt{\pi}} \right) E^* \sqrt{V d_n}$$

where

$V$  = overlap volume between two particles during contact

$d_n$  = indentation depth which is the extension of the overlapping region in the direction of force

$E^*$  = equivalent Young's modulus, defined as

$$\frac{1}{E^*} = \frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2}$$

Dissipative effects were also taken into account by modelling a damping force in the normal direction. The equation for the damping force is given by the following:

$$F_{n,d} = 2 \sqrt{\frac{5}{6} \left( \frac{-\log e}{\log^2 e + \pi^2} \right)} \sqrt{2E^* m^*} \sqrt{\frac{V}{\pi d_n}} v^{rel}_n$$

where

$e$  = coefficient of restitution between two particles

$v^{rel}_n$  = magnitude of relative velocity between both particles in the direction of normal force

$m^*$  = equivalent mass, defined as

$$\frac{1}{m^*} = \frac{1}{m_1} + \frac{1}{m_2}$$

The tangential force between two particles during contact is given by the following equation which is also limited by the Coulomb friction model  $\mu F_n$  where  $\mu$  is the coefficient of friction.

$$F_t = -8G^* \sqrt{\frac{V}{\pi d_n}} d_t$$

where

$d_t$  = extension of the overlapping region in the direction normal to the force

$G^*$  = equivalent shear modulus, defined as

$$\frac{1}{G^*} = \frac{2 - \nu_1}{G_1} + \frac{2 - \nu_2}{G_2}$$

Dissipative effects in the tangential direction were also considered, and are given by the following equation:

$$F_{t,d} = -2 \sqrt{\frac{5}{6} \left( \frac{-\log e}{\log^2 e + \pi^2} \right)} \sqrt{8G^* m^*} \sqrt{\frac{V}{\pi d_n}} v^{rel}_t$$

where

$v^{rel}_t$  = magnitude of relative velocity in the tangential direction

The terms  $E$ ,  $\nu$ ,  $m$ , and  $G$  with subscripts 1 and 2 correspond to the Young's modulus, Poisson's ratio, mass, and Shear modulus of both particles in contact, respectively.

The introduction of spinning friction [18] was essential in this model to account for the friction between two particles whose faces are rotating against each other. This involves calculating the contact area and then applying the torque in the opposite direction to the normal component of the relative angular velocity. The equation for torque on the particle is given as follows:

$$M = \frac{2}{3} \mu F_n \sqrt{\frac{A}{\pi}}$$

where

$\mu$  = coefficient of friction

$A$  = normal area of the overlap region

This torque is limited to avoid numerical instability and any oscillating behavior when the angular velocity is

small. This was done by calculating the torque required to damp the angular velocity in one timestep.

$$M = \frac{0.125\omega_n^{rel} \min(I_1, I_2)}{\Delta t}$$

where

$\omega_n^{rel}$  = normal component of the relative angular velocity

$\Delta t$  = timestep used in the model

$\min(I_1, I_2)$  = minimum value of the moment of inertia of the two contacting particles

## Material model calibration

Material model calibration is a fundamental component of the Discrete Element Modelling methodology. Material model calibration typically consists of replicating a rheological measurement in the model, so that there is confidence in the model behaving in a physically accurate manner. Bulk density is a rheological measurement that needs to be replicated for any DEM model to capture the inertial effects. The other test done for this study to ensure the tablet-tablet interactions are modelled correctly, is the angle of repose test. Since a coating process is modelled for this study, both the bulk density and the angle of repose measurements were done for both core and coated tablets. The average value for both measurements were computed, and the average value was replicated within the DEM model.

For the bulk density measurement, tablets were filled in a known cylindrical volume, and was weighed. The mass of the bulk of the tablets was then divided by the known volume to calculate the bulk density. This process was done for both core and coated tablets. The average value of 601.9 kg/m<sup>3</sup> was replicated within a similar virtual cylinder within the DEM model. This involved a trial-and-error method with running multiple simulations with different parameters on the same setup, until the target bulk density was achieved.

Similarly, for the angle of repose measurement, the tablets were allowed to form a pile on the horizontal after lifting a hollow cylinder filled with these tablets. The angle that this pile makes with the horizontal was measured, for both core and coated tablets respectively. Again, the average value of 35 degrees was replicated within a similar setup in the DEM model. The angle of repose is sensitive to the coefficient of friction values along with other parameters like the individual particle density and the coefficient of restitution, and therefore, these parameters were changed using a trial-and-error method until the DEM model reproduced the same pile with the same angle in the virtual setup.

## Process Modelling

The calibrated interaction parameters are used for the modelling of the industrial scale tablet coater operation. As mentioned earlier, the tablets are polyhedron-

shaped with 78 faces and approximately 10 mm in size, which is a very close estimation of the physical particle shape. The particle shape is shown in Figure 3.

A singular batch in the coater consists of approximately 200,000 tablets, therefore, the simulation was also done for the same load of tablet cores. The simulation was split into two stages – the filling stage and the process modelling stage. To introduce realistic settling of the tablets within the coater before the operation, the tablets were introduced into the coating pan from an opening on the side and allowed to settle under gravity. The coating pan was then rotated at 7 rpm, for 30 seconds of operation. The model was run on an NVIDIA Tesla V100 GPU card which took an approximate of 225 hours of clock time for the whole 30 seconds of operation.

**Figure 3:** Tablet shape used in DEM (left); EDEM simulation of the industrial tablet coating process (right).

All the forces during each contact of the tablet core, with another tablet core or with the coating pan itself, were calculated using the governing equations. However, data was saved at every 0.1 seconds interval due to practical hardware limitations. This data includes position and orientation of the tablets, their velocities, their contact forces and the location of the contact on both interacting bodies. In total, about 98 million contacts were recorded, for these 200,000 tablets at these 0.1 seconds interval during the whole 30 second operation, and analyzed. The force values on each vertex of the polyhedron during each of these contacts are then compared to determine the region of the polyhedron-shaped tablet with maximum propensity for breakage or defect formation.

## RESULTS

In a DEM simulation, for every collision, the impact force increases until it reaches a peak value, and then it decreases with the particles separating from each other. The value of the forces acting on each of the tablets, in this case, and their location of impact for each contact, or collision, was recorded at every 0.1 seconds. Due to this frequency of data recording, it is possible that the peak forces may not be recorded if the peak occurs between data save periods. However, since steady state is achieved relatively early in the process, at about

5 seconds, the simulation consists of random sampling of contacts during twenty-five seconds of steady state operation. This study assumes that the highest recorded forces are indicative of the impact events that lead to tablet defects. Hence, the magnitude of the force itself is insignificant, but the relative distribution of forces is bound to give more insight into the results.

### Force Analysis

In this coating pan simulation, there is a huge number of contacts, and forces are evaluated at each of these contacts. However, a large number of these contacts are weak, primarily in the small movements of the tablets in the avalanche region. There are a few contacts which are stronger, and it is assumed that these stronger contacts are the reason for tablet defects. Considering this, the ten contacts with highest force values were analyzed in Figure 4.

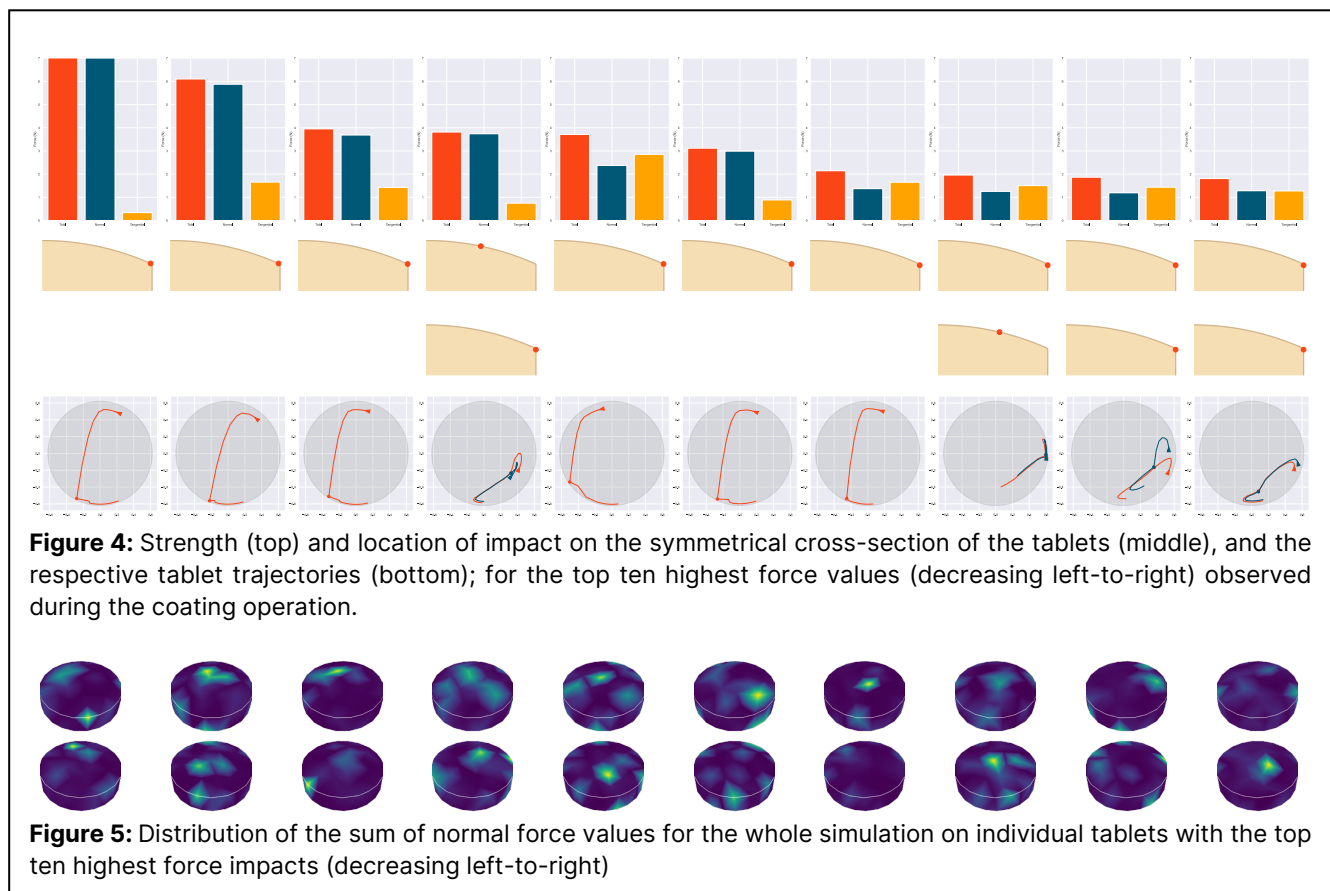

On the top, the orange bar represents the total force magnitude, and the blue and yellow bars represent the normal and tangential force components respectively. This shows the strength of the contact relative to the other contacts in the system. In the first column, since the tangential force is very insignificant, it is almost entirely a normal contact, with an impact on the edge of the tablet. The streamline plot at the bottom also shows that this was caused due to the lifting the tablet by the coater

baffle and dropping it on the coater itself. Figure 4 reveals that although there are some impacts from tablets colliding with other tablets, it is less significant than the tablets impacting the coater pan itself.

The force values at each vertex were summed for all the contacts in the simulation, and a heat map of the force distribution was plotted in Figure 5. This figure gives a pictorial representation of the locations on the tablet that have the highest propensity for defect formation.

### Grouped Statistics

For practical purposes, the defects were classified into two groups – edge defects and face defects. The force distribution on every individual tablet was used to group them. The force value at each vertex were summed up for each of the 200,000 tablets in the system, for every contact that was experienced during the twenty-five seconds of steady-state operation. Out of these summed up force values at every vertex, if the highest force value on an individual tablet was present near the edge of the tablet, that tablet was classified to incur an edge defect, or chipping defect. Consequently, if the highest force value was on the face of the tablet, it was classified as a face defect, or picking defect. Figure 6 shows the regions on the tablet based on which the groups were classified.

The simulation found that 72.12% of the particles are prone to have a chipping defect or an edge defect, while only 27.88% of the particles are prone to have a face defect. Although the highest force values on an individual contact was from lifting of the coater baffles, the highest sum of forces across all contacts is caused in the avalanche region of the coater.

**Figure 6.** Regions on the tablet classified for edge defects (left) and face defects (right)

## CONCLUSIONS

The simulation estimated ~70/30 split between edge defects and face defects. The end-of-batch statistical inspection for visual defects confirmed that physical damage to the tablet edges constituted a far greater percentage of tablet defects than those observed on the face of the tablets. Electronic inspection of the batches also confirmed the simulation results, again showing that the majority of the physically damaged tablets experienced edge damage, with little physical damage being observed on the face of the tablets. During process scale up, when coating conditions fell on the wetter side of the thermodynamic design space, picking defects were observed mainly on the face of the tablets, Figure 2. This would not be unexpected due to the number of tablet-to-tablet interactions that occur during the coating process while the tablets are avalanching in the spray zone of the coating pan. The result of this DEM analysis was used by the manufacturing and development teams to investigate potential modifications. The tablet core robustness was modified to prevent damage to the tablet edges. To prevent picking damage, the coating operation was moved towards the drier thermodynamic space, since reducing the number of tablet-to-tablet interactions would have required altering the production batch size, which was not an option.

The use of the Discrete Element Method to look at the forces that the tablets were experiencing during the coating operation was one part of an investigation that was critically reviewing the drug product formulation and process to establish causal factors associated with tablet edge and face defects. The evaluation looked at the drug production formulation, raw material attribute and variability within a given attribute for the excipients and drug substance. The processing evaluation included the production of the tablet cores, the tablet core robustness to

downstream processing conditions and environment, review of the coating process and the thermodynamic space for which processing was being performed. Additionally, the evaluation also included identifying the location within processing time of the coating operation that the tablet damage was occurring, i.e. beginning middle or end of the coating operation. Since the edge and face defects did not result in exposed cores, the investigation concentrated to the loading of core tablet to the coating pan, the start up of the coating process though the middle of the coating operation. No review of the post coating operation was evaluated for the investigation for causal factors again supported by the defects present did not show any signs of exposed cores.

This present study can also inform population balance models to predict breakage of the tablet cores. This DEM model can provide micromechanical data which can be used in conjunction with a breakage criterion resulting in an analytical breakage model. An approach similar to Ketterhagen et al [11] can be taken to utilize the material strength parameter and the impact energy to characterize a stochastic breakage model using the Vogel and Peukert [12][13] model to quantitatively predict breakage.

## ABSTRACT

In this work, we present a follow-up work of reinforcement learning (RL)-driven process design using the Institute for Design of Advanced Energy Systems Process Systems Engineering (IDAES-PSE) Framework. Herein, process designs are generated as stream inlet-outlet matrices and optimized using the IDAES platform, the objective function value of which is the reward to RL agent. Deep Q-Network is employed as the RL agent including a series of convolutional neural network layers and fully connected layers to compute the actions of adding or removing any stream connections, thus creating a new process design. The process design is then informed back to the RL agent to refine its learning. The iteration continues until the maximum number of steps is reached with feasible process designs generated. To further expedite the RL search of the design space which can comprise the selection of any candidate unit(s) with arbitrary stream connections, we investigate the role of RL reward function and their impacts on exploring more complicated versus intensified process configurations. A sub-space search strategy is also developed to branch the combinatorial design space to accelerate the discovery of feasible process design solutions particularly when a large pool of candidate process units is selected by the user. The potential of the enhanced RL-assisted process design strategy is showcased via a hydrodealkylation example.

## 1. INTRODUCTION

Process synthesis aims to determine the optimal selection of unit operations and their flowsheet interconnections at the optimal operating conditions [1]. However, it is not a trivial task to select the optimal process design considering the plethora of plausible unit operations and flowsheet configurations which have been investigated in chemical process industry.

Optimization-based approaches [2-3] offer a systematic strategy utilizing mathematical programming to synthesize the overall flowsheet based on a superstructure which contains all the possible flowsheet structural alternatives of interest. The representation of chemical processes also plays a key role to ensure fit-for-purpose design creativity and sufficient modeling accuracy with

tractable computational formulations (e.g., state-task-network [4], unit-port-conditioning streams representation [5], phenomena-based representation [6-7]). Although the efficacy of optimization-based process synthesis has been well demonstrated in many chemical and energy systems, major challenges remain on: (i) the request of a user-specified superstructure which heavily relies on engineering expertise to ensure the quality of optimal design solutions, and (ii) algorithmic complexity to solve the resulting large-scale mathematical optimization problems, etc.

To address these challenges, recent research efforts have been made to drive process synthesis using reinforcement learning (RL) in place of optimization algorithms [8-9]. RL-driven process design typically starts from a maximum pool of unit operations without

requesting any superstructure pre-specification. The intelligent RL agent will select among the available unit operations and generate arbitrary process design structures. The objective function value of the derived process design serves as the reward to keep training RL agent to generate better process designs. Despite the advantages, key open research questions lie in the search efficiency and algorithmic scalability as the number of available unit operations increases.

In this paper, we present a follow-up work to the RL-driven process design approach introduced by Wang et al. [8] integrated with the Institute for Design of Advanced Energy Systems Process Systems Engineering (IDAES-PSE) Framework [10]. To enhance the efficiency of RL-driven design, we will discuss the role of reward functions and the implementation of a sub-space branch and search strategy. Section 2 provides a brief overview of the methodology workflow and highlights the interactions between IDAES-PSE and reinforcement learning. Section 3 introduces the hydrodealkylation case study and the process design analyses. Section 4 presents concluding remarks and ongoing work.

## 2. RL-DRIVEN PROCESS DESIGN WITH IDAES-PSE FRAMEWORK

### 2.1. Overview of the Methodology

The methodology workflow is summarized in Fig. 1 with stepwise procedure detailed in what follows [8].

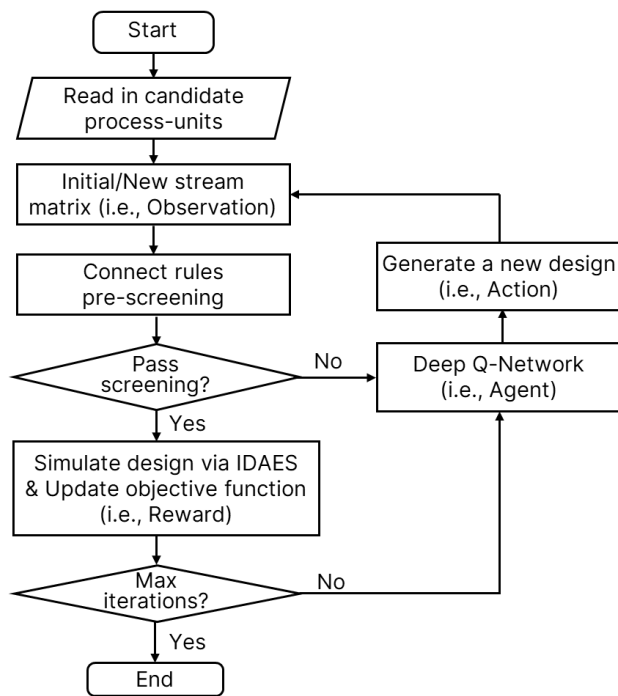

Figure 1. The methodology workflow.

#### 2.1.1. Step 1 – Candidate process-units pool

The design process starts with the users selecting a maximum set of candidate process units which can be used for process design in the next steps. An indicative list of the process unit models, which are supported in the IDAES model library, includes feed (coupled with mixer), product (coupled with flash), flash drum, mixer/splitter, heat/cooler, heat exchanger, stoichiometric reactor, etc. Users are required to specify the types and the maximum number of units available (e.g., maximum of 3 flash drums), while no pre-postulation of flowsheet connections or superstructures is needed.

#### 2.1.2. Step 2 – Flowsheet representation

After defining the candidate process units, an initial process design will be generated via random initializations in the form of inlet-outlet stream matrix. Table. 1 presents an example of the stream matrix representation if the current process flowsheet comprises a heater followed by a stoichiometric reactor. Lists of unit inlets and outlets are first generated to describe the flowsheet connections. The stream matrix then maps the inlet-outlet relationships using 0-1 variables, which serves as the observations to the reinforcement learning algorithm.

Table 1: Stream matrix representation.

	Feed. outlet	Heater. outlet	Reactor. outlet	Flash. outlet
Product.inlet	0	0	1	0
Heater.inlet	1	0	0	0
Reactor.inlet	0	1	0	0
Flash.inlet	0	0	0	0

#### 2.1.3. Step 3 – Connect rules pre-screening

As the flowsheet structure is generated via random initialization (at the first iteration) or via RL (at the successive iterations), it is essential to pre-screen if the structure satisfies general connectivity rules before proceeding with rigorous simulation. Some examples of such rules include:

- At least one unit operation must be selected.
- The outlet of a unit operation cannot be connected with its own inlet.
- Liquid outlet streams cannot connect to compressors or expanders.
- Heaters cannot directly connect to coolers, and compressors cannot directly connect to expanders (turbines).
- There must be a reactor between an outlet product or flash and an inlet feed.

#### 2.1.4. Step 4 – Simulate and optimize process design using IDAES platform

If the structural screening is passed, the flowsheet

is to be simulated and optimized using the IDAES platform with its built-in process-units modeling library, property packages, and mathematical solvers [10]. It is worth noting that the RL reward function is defined as a function of the key process design objectives (e.g., product flow and purity). In this way, the reinforcement learning is continually rewarded to identify better design solutions.

### 2.1.5. Step 5 – RL agent to generate new design alternatives

This step aims to intelligently learn from the observations (step 2) and reward (step 4), thus making a decision on the next action (i.e., generate a new design). Herein, the RL agent adapts the Deep Q-Network (DQN) as illustrated in Fig. 2. DQN utilizes a series of convolutional neural network layers to extract key features from the 2D stream matrices followed by successive fully connected layers to compute the  $Q$  value as per Eq. 1. The  $Q$  value will dictate the value of each action, i.e. adding or removing any unit operation to or from a certain location of the current flowsheet structure. The  $\max(Q_{next})$  term selects the best action in the future  $Q$  values.

$$Q = reward + \gamma \cdot \max(Q_{next}) \quad (1)$$

where *reward* is calculated in step 4 as a function of the objective function,  $\gamma$  is the decay factor,  $Q_{next}$  is the set of future  $Q$  values by taking each possible action.

Figure 2. RL agent using Deep Q-Network.

Therefore, a new process design will be generated by the DQN agent which will be sent to Step 3 for connectivity rule pre-screening and IDAES optimization, etc. until a maximum number of iterations is reached. The outcome of this RL-driven process design strategy is a number of feasible process designs with improved quality against the objective function.

This RL-driven process design method can be applied for grassroots chemical process design, as will be showcased in Section 3. It can also significantly contribute to: (i) Retrofitting to improve existing flowsheet designs, and (ii) Integrating new process technologies (e.g., fuel cell, novel intensified reactors) to existing flowsheet infrastructure. In the latter cases, this method may demonstrate more superior computational efficiency as the design space is smaller.

## 2.2. Integration of RL and IDAES

This integrated tool can be accessed via the open-source IDAES platform. The information flow between IDAES and RL interactions is summarized in Fig. 3 from software perspective. An interactive user interface has also been developed as a Jupyter Notebook (i.e., Notebook Interface.ipynb) which allows the users to select candidate process units, adjust RL algorithm parameters (e.g., learning rate), execute RL-driven design, and report the results. The RL algorithm provides new process designs to the IDAES platform for optimization, and the IDAES platform supplies RL with the rewards based on optimization results. The flowsheets are represented respectively using unit list arrays in IDAES and stream matrices in RL, the conversion of which is performed by the obs2list file to enable mutual communication.

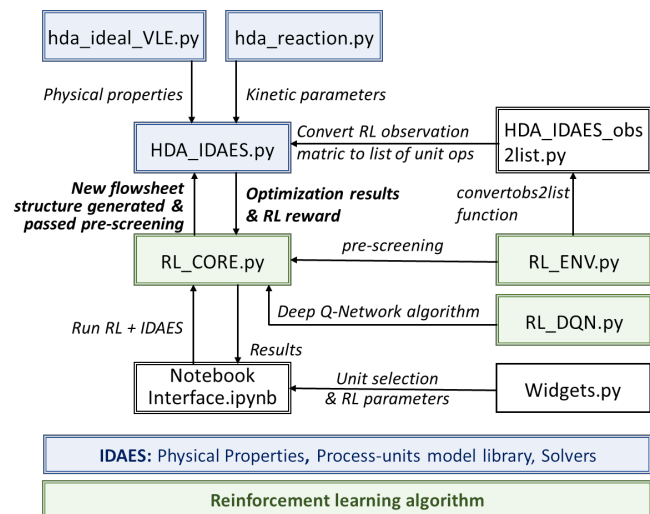

Figure 3. Integrated IDAES and RL information flow.

## 3. CASE STUDY: HYDRODEALKYLATION PROCESS DESIGN

In this section, we apply the afore-introduced methodology to design a hydrodealkylation (HDA) process. Based on the scenario analyses, we discuss several implementations to further improve the RL-driven design efficacy by refining reward function and performing sub-space branching.

### 3.1. Problem Statement

An HDA process is to be designed to produce benzene ( $C_6H_6$ ) from toluene ( $C_6H_5CH_3$ ) and hydrogen ( $H_2$ ) at elevated temperatures. The reaction scheme is shown in Eq. 2, which takes place in the vapor phase. The undesired side reactions are not considered in this case study (e.g., diphenyl production). Ideal vapor-liquid equilibrium can be used to describe the mixture separation behavior.

The feed streams are given in Table 2, consisting of a vapor stream of hydrogen and methane and a liquid stream of toluene. Available process units include feed (coupled with mixer), product (coupled with flash operation), heater, cooler, stoichiometric reactor, mixer, flash, splitter, and compressor. The operating constraints of each type of units are also given, such as heat outlet temperature between 500–600 K. Product specification is set to obtain a vapor product with benzene purity higher than 0.55. The design objective is to determine process solution(s) with optimal vapor product benzene flowrate.

**Table 2:** HDA feed conditions.

	Vapor feed	Liquid feed
Temperature (K)	303.2	303.2
Pressure (kPa)	350	350
Flowrate (mol/s)		
Benzene	0	0
Toluene	0	0.30
Hydrogen	0.30	0
Methane	0.02	0

### 3.2. Scenario Analysis

We first investigate a series of scenarios with different candidate process units selected by user, i.e. different maximum unit sets that can be used for HDA design.

#### 3.2.1. Scenario 1

In this scenario, at most 1 heater and at most 1 reactor can be used to design the HDA process (Table 3). Feed and product are regarded as defaults to be included in process design. Applying the RL-driven approach, the first design solution obtained is shown in Fig. 4. This design solution is referred as Design 1-1, which represents Scenario 1, Solution 1. It is identified at the 63<sup>rd</sup> episode.

The flowsheet comprises a heater with an outlet temperature of 536.9 K followed by a reactor with an outlet temperature of 897.8 K. The flash coupled with outlet product only produces a vapor product stream at 705.7K around 1 atm. The objective value is 0.225 mol/s benzene flowrate, with benzene purity at 0.75 and revenue at  $\$7.65 \times 10^5$ /year.

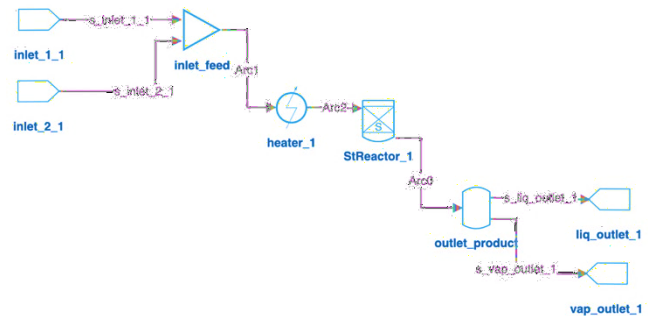

To run a total of 300,500 episodes for this scenario, the total computational time is 2.9 minutes. A substantial portion of the time is spent on RL learning to generate process structures which can pass the pre-screening rules. Only around 4 seconds are consumed by IDAES simulation and optimization. From the aspect of conceptual design, Design 1-1 is actually the best solution of all plausible designs with the maximum benzene flowrate and revenue as well as a most simplified flowsheet.

**Figure 4:** Design 1-1 (and Design 3-1).

#### 3.2.2. Scenario 2

The pool of candidate process units is increased in this scenario, allowing the use of at most 1 unit of each type as defined in Table 4. The first flowsheet design solution (Design 2-1, representing Design Scenario 2, Solution 1) is identified at the 151,507<sup>th</sup> episode, as depicted in Fig. 5. The objective value is 0.180 mol/s benzene flowrate, with benzene purity at 0.75 and revenue at  $\$2.49 \times 10^5$ /year. The inlet feed streams are first heated to 537.6K before entering the reactor. The reactor effluent is cooled down from 898.4K to 325.0K giving a liquid-vapor mixture. The outlet product flash operation then reheats the product temperature to 595 K and reduces the pressure to around 1 atm. A total of 0.18 mol/s benzene flowrate is obtained from the outlet product vapor stream, while no liquid stream is obtained. Another 0.045 mol/s benzene flowrate exists in the outlet exhaust (or purge) stream. While this flowsheet is feasible, it is not a good design. The cooler decreases the energy efficiency and results in the loss of benzene product in the vapor phase via the outlet exhaust.

Another flowsheet design solution (Design 2-2) is generated at the 284,253<sup>rd</sup> episode, as shown in Fig. 6. The objective value is 0.225 mol/s benzene flowrate, with benzene purity at 0.75 and revenue at  $\$5.08 \times 10^5$ /year. To run a total of 300,500 episodes for this scenario, the total computational time is 12.0 minutes.

Several observations can be made for Design 2-2: (i) Similar to Design 2-1, the cooler decreases the energy efficiency, (ii) Compressor is redundant as pressure change is not an essential requirement, (iii) Despite the

fact that the splitter is not completely connected to mixer (one of the pre-screening constraints), the loop of mixer, compressor, and splitter is redundant.

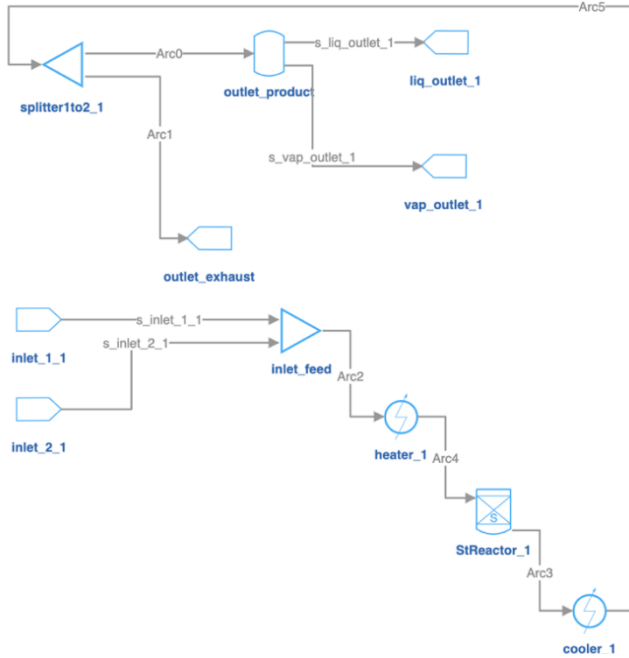

Figure 5: Design 2-1.

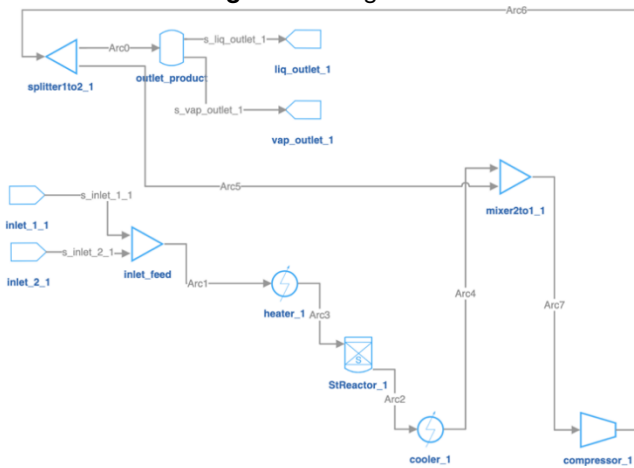

Figure 6: Design 2-2.

### 3.2.3. Scenario 3

The pool of candidate process units is further increased to allow the use of at most 2 units of each type (Table 5). To run 300,500 episodes for this scenario, the total computational time is 24.6 minutes. A flowsheet design solution (Design 3-1) is found at the 788,161<sup>st</sup> episode, which is identical with Design 1-1. No more design solutions are found up to 4,150,000 episodes.

Table 5: User specified candidate units – Scenario 3.

Heater	Cooler	Reactor	Mixer
2	2	2	2

### 3.2.4. Summary of Observations

As the design space increases (i.e., user selects more unit operations to use), the following can be observed based on the above scenario analyses:

- More computational efforts are required to identify any feasible flowsheet design solution. For example, to generate the first feasible design, Scenario 1 at 63<sup>rd</sup> episode, Scenario 2 at 151,507<sup>th</sup> episode, Scenario 3 at 788,161<sup>st</sup> episode.
- The RL algorithm tends to explore the use of more unit operations, despite the possible use of redundant units and/or stream loops (e.g., cooler, compressor, recycle loop).
- The solutions generated from larger combinatorial design space may not recover that from smaller design space. For example, Scenario 2 cannot recover Design 1-1, which is the best design solution.

### 3.3. Impact of Reward Function

To drive the RL algorithm automatically toward a more refined design space with a minimum essential number of unit operations, changing the reward function can be of potential help. The current reward function is given in Eq. 1 which accounts for benzene purity and flowrate. This renders the reward values independent of the number of units. Or in other words, RL does not obtain higher rewards by generating more simplified flowsheet designs. In this context, we propose to incorporate the number of unit operations as part of the reward consideration as defined in Eq. 2.

$$Reward = 1000 + \frac{flow-0.10}{0.05} \times \delta_{scoreA} + \frac{purity-0.55}{0.10} \times \delta_{scoreB} \quad (1)$$

$$Reward = 1000 + \frac{flow-0.10}{0.05} \times \delta_{scoreA} + \frac{purity-0.55}{0.10} \times \delta_{scoreB} + 50 \times (max\_number\_units - actual\_number\_units) \quad (2)$$

Testing again on Scenario 2, the modified reward function leads to the identification of a second flowsheet design at the 242,654<sup>th</sup> episode, which is identical to Design 1-1. This is a faster identification compared to the previous 284,253<sup>th</sup> episode using Eq. 1 while featuring a reduced number of unit operations to identify the best design solution. This reward function is also tested on Scenario 3, in which the user selects maximum 2 units of each type. The first feasible flowsheet design is still

reported at the 788,161<sup>st</sup> episode. Compared to the reward function of Eq. 1 which cannot generate a second flowsheet design within 4,150,000 episodes, the modified function of Eq. 2 reports a second design at the

3,069,993<sup>rd</sup> episode. The flowsheet design comprises a heater, a reactor, a splitter, the outlet exhaust, and the outlet product.

The modified reward function has been

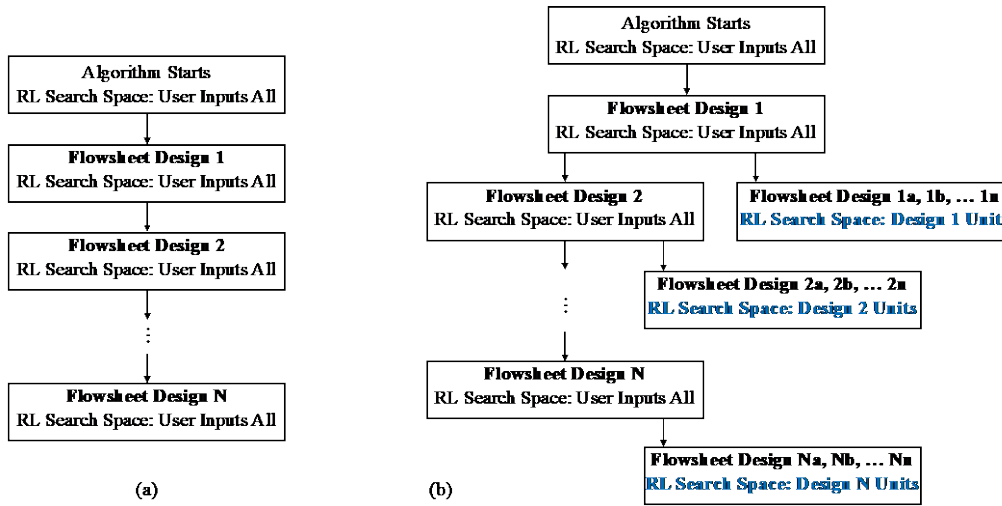

Figure 7: Search strategy for RL-driven design.

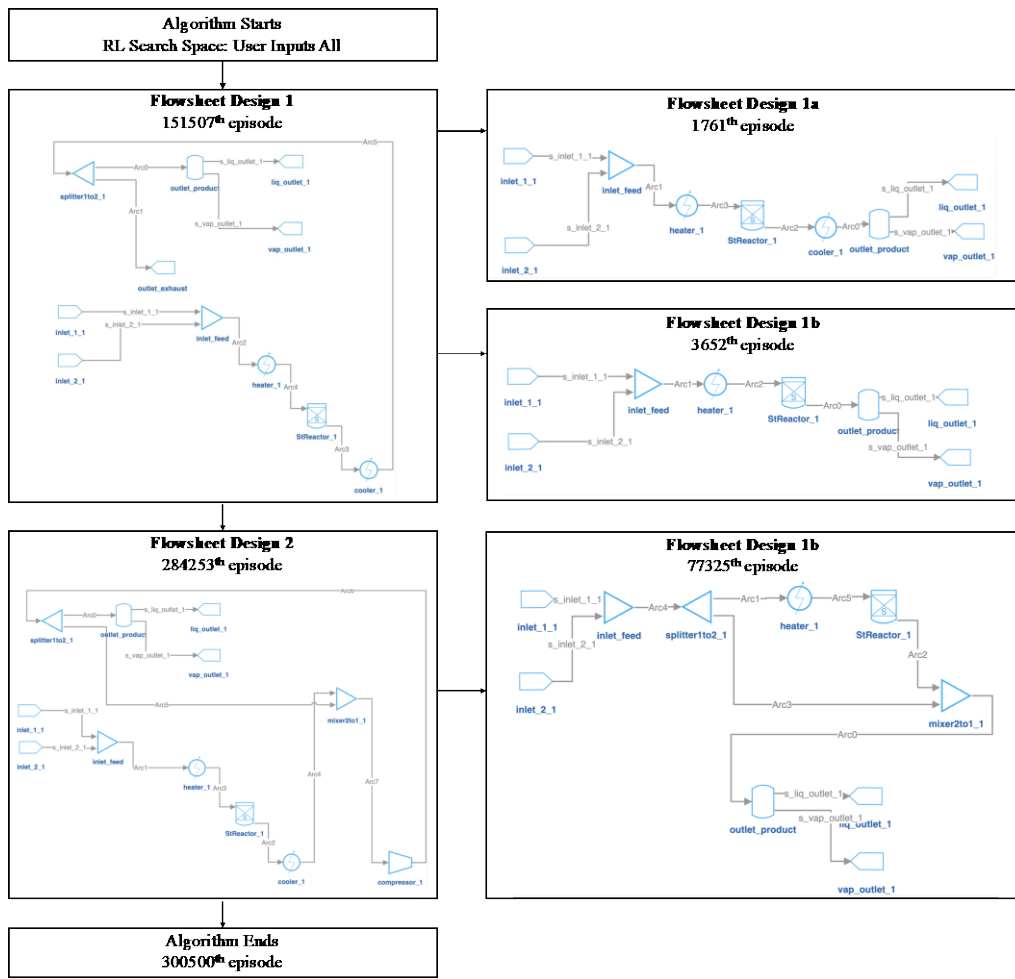

Figure 8: Sub-space search illustration for Scenario 2.

demonstrated to drive the RL search to prioritize the use of fewer unit operations and, thus, to accelerate the search of flowsheet designs after the first design is identified. However, this formulation cannot contribute to accelerate or improve the identification of the first feasible flowsheet design.

### 3.4. Sub-Design Space Branch and Search

As shown in Fig. 7a, the current RL-driven design is set to always explore the entire design space of all candidate process units specified by the user. Arguably, the infeasible flowsheet design space for the arbitrary selections and combinations of these units can be significantly larger than the feasible space. In this way, with a larger number of available unit operations, the RL-driven design may spend the most time learning the infeasible space while directed away from the feasible space. As such, we propose a parallel sub-space search as illustrated in Fig. 7b. Namely, for each of the feasible flowsheet design generated from learning the entire design space, a quick RL search is performed using the list of units in this design as candidate process units (ignoring the specific inlet and outlet connections in this design). Thus, the sub-space search aims to identify, using a reduced pool of unit operations that can construct a feasible flowsheet design, if better design solutions can be generated. This branch and search strategy is implemented for Scenario 2 and the reported results are given in Fig. 8. Better design options are efficiently identified in the sub-space search.

## 4. CONCLUDING REMARKS

In this paper, we have introduced a reinforcement learning-driven process design approach with application to HDA production. Two improvements are implemented to enhance the RL efficiency to search the combinatorial design space, respectively by refining the reward function and branching the search space. Ongoing work is applying superstructure optimization to expedite the sub-design space search. In other words, RL will identify a minimum essential set of unit operations based on which superstructure optimization will screen this sub-design space to find the optimal design solution. The integrated strategy aims to augment RL exploration ability in large combinatorial design space and superstructure optimization rapid screening in smaller design space when mixed-integer nonlinear optimization becomes tractable.

## ABSTRACT

Water-gas shift membrane reactors (WGS-MRs) offer a pathway to affordable blue H<sub>2</sub> generation/purification from gasified feedstock or reformed fuels. To exploit their cost benefits for blue hydrogen production, WGS-MRs' performance needs to be optimized, which includes navigating the multidimensional design space (e.g., temperature, feed pressures, space velocity, membrane permeance and selectivity, catalytic performance). This work describes an equation-oriented modeling framework for WGS-MRs in the Pyomo ecosystem, with an emphasis on model scaling and multi-start initialization strategies to facilitate reliable convergence with nonlinear optimization solvers. We demonstrate, through sensitivity analysis, that our model converges rapidly (< 1 CPU second on a laptop computer) under a wide range of operating parameters (e.g., feed pressures of 1-3 MPa, reactor temperatures of 624-824 K, sweep-to-feed ratios of 0-0.5, and steam/carbon ratios of 1-5). Ongoing work includes (1) validation and calibration of the WGS-MR model using benchtop laboratory data and (2) design, intensification, and optimization of blue H<sub>2</sub> processes using the WGS-MR model.

**Keywords:** Modelling, Membranes, Hydrogen, Process Design, Water-Gas Shift, Model Initialization

## INTRODUCTION

The water-gas shift (WGS) reaction is essential for converting CO into CO<sub>2</sub> and producing additional hydrogen from syngas generated from reforming or gasification [1-2]. WGS is especially critical in blue H<sub>2</sub> production technologies, where the produced CO<sub>2</sub> is captured and sequestered downstream [3].

WGS is an established industrial reaction that has been broadly studied [4]. Ebrahimi et al. [5] provide a comprehensive overview of the WGS reaction, including the CO conversion, H<sub>2</sub> selectivity, and structural properties of transition and noble metal catalysts on oxide and carbon-based supports. The state-of-the-art design for WGS reactors includes a two-staged packed bed reactor: a high-temperature shift (643 K to 673 K) stage followed by inter-stage cooling and then a low-temperature shift (450 K to 553 K) [6]. One prevailing challenge with WGS is that it is a reversible and exothermic reaction ( $\Delta H_{298}^0 = -41$  kJ/mol), which imposes thermodynamic limitations on the attainable conversion.

Incorporating a membrane within a water gas shift reactor enhances H<sub>2</sub> production [2, 6-7]. H<sub>2</sub>-selective membranes (e.g., dense metallic membranes, polymer membranes, and other inorganic membranes) have been previously used for this purpose [7-8]. Particularly, Pd-based membranes are promising for H<sub>2</sub> separation due to their ultra-high H<sub>2</sub>-selectivity [2, 9]. One major challenge with Pd-based membranes is inadequate thermal stability/chemical tolerance in these harsh operating conditions, which can be mitigated by alloying Pd with other elements [2, 10]. Pd-based membranes are used for H<sub>2</sub> production in the form of membrane separators [7, 10] or membrane reactors, i.e., membrane reformers or water-gas shift membrane reactors (WGS-MR) [9, 11].

WGS-MRs offer the added benefit of combining separation and reaction in one unit, providing process intensification opportunities. The continuous separation of H<sub>2</sub> from the reactor through Pd-based membranes provides three distinct advantages:

1. The thermodynamic equilibrium continuously shifts in favor of the forward reaction, leading to

- improved CO conversion [2, 12, 13].
- The continuous production of H<sub>2</sub> from the reaction boosts the H<sub>2</sub> partial pressure on the retentate side, enhancing the recovery of H<sub>2</sub> through separation.
  - The retentate is a high-pressure CO<sub>2</sub>-concentrated stream, making carbon capture less energy intensive [14].

Mathematical modeling and numerical simulation are needed to elucidate the design of WGS-MRs for maximizing technical and economic benefits [7, 9, 12]. Membrane modules have been widely modeled in flow sheet simulators such as Aspen Plus to support process-scale optimization and techno-economic analysis [13, 15]. Our approach, based on equation-oriented (EO) design, supports the simultaneous solution of the various model equations, making it easier to embed them directly into large-scale optimization models [16-18]. However, EO models require careful equation and variable scaling and initialization to ensure reliable solver convergence [19]. Additionally, the literature on EO modeling of WGS-MR is notably sparse, with significant contributions from Gosieswki et al. [14].

This brief paper introduces an EO modeling framework of WGS-MRs. We focus on model scaling analysis and multi-start initialization strategies to promote fast and reliable convergence in the solution of the nonlinear model. Finally, we show the model's capabilities for the rapid study of the WGS-MR system through sensitivity analysis.

**Figure 1.** Schematic of a WGS-MR module. The syngas feed flows on the shell side, which is packed with a catalyst for the WGS reaction; the tube is made of a Pd-based membrane that is selectively permeable to H<sub>2</sub>; permeated H<sub>2</sub> and an optional sweep gas flow on the tube side in a counter-current flow direction. Based on similar schematics in Brunetti et al. [9].

## METHODS

### WGS-MR model

We consider a cylindrical, tube-in-shell reactor module with the reaction occurring on the shell side in a packed catalyst bed, as shown in **Figure 1**. The tube

comprises a Pd-based membrane that selectively supports H<sub>2</sub> permeation, which flows on the tube side in a counter-current direction.

### Mass Balance:

The retentate side mass balance for this reactor configuration is given as:

$$\frac{dF_{ret,i}}{dz} = -J_i \frac{A_{mem}}{l} + v_i(-r_{CO}) \frac{V_{rxn}}{l}. \quad (1)$$

Similarly, the permeate side mass balance is given as:

$$\frac{dF_{perm,i}}{dz} = -J_i \frac{A_{mem}}{l}, \quad (2)$$

where  $F_{ret,i}$  (mol s<sup>-1</sup>) and  $F_{perm,i}$  (mol s<sup>-1</sup>) are the retentate and permeate side flowrates of species  $i$  respectively;  $z$  (m) is the axial distance along the WGS-MR module;  $A_{mem}$  (m<sup>2</sup>) is the membrane area;  $l$  (m) is the total length of the module;  $v_i$  (unitless) is the stoichiometric coefficient of species  $i$  in the WGS reaction;  $r_{CO}$  (mol m<sup>-3</sup> s<sup>-1</sup>) is the reaction rate of CO in the WGS reaction;  $V_{rxn}$  (m<sup>3</sup>) is the retentate side volume of the WGS-MR available for the reaction.  $J_i$  (mol m<sup>-2</sup> s<sup>-1</sup>) is the flux of species  $i$  through the Pd-based membrane.

The flux,  $J_i$  is defined by the Sievert-type expression [9, 20]:

$$J_i = \begin{cases} Q(T) [(P_{ret} y_{ret,i} + \varepsilon)^n - (P_{perm} y_{perm,i} + \varepsilon)^n], & i = H_2 \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

Here,  $Q(T)$  (mol m<sup>-2</sup> Pa<sup>-0.5</sup> s<sup>-1</sup>) is the permeance of the membrane, which correlates with the reactor temperature as given in **Eq. (4)**.  $P_{ret}$  (Pa) and  $P_{perm}$  (Pa) are the retentate and permeate side pressures, respectively.  $y_{ret,i}$  and  $y_{perm,i}$  are the retentate and permeate side compositions of gas species  $i$ , respectively, as defined in **Eq. (5)**. The Sievert's law pressure exponent,  $n$ , ranges from 0 to 1 and takes a value of 0.5 for the ideal Sievert behavior where the diffusion of H atoms in the bulk Pd metal forms the rate-limiting step for H<sub>2</sub> permeation in the Pd-based membrane, and the Pd-H system is infinitely diluted [20].  $\varepsilon$  is a small number (e.g., 10<sup>-8</sup>) that prevents computing the  $n < 1$  exponent of near zero when the partial pressure is very small.

$$Q(T) = Q_0 \exp\left(-\frac{E_a}{RT}\right), \quad (4)$$

$$y_{ret,i} = \frac{F_{ret,i}}{\sum_j F_{ret,j}}, \quad y_{perm,i} = \frac{F_{perm,i}}{\sum_j F_{perm,j}}. \quad (5)$$

In **Eq. (4)**,  $Q_0$  (mol m<sup>-2</sup> Pa<sup>-0.5</sup> s<sup>-1</sup>) is the pre-exponential factor;  $E_a$  (J mol<sup>-1</sup>) is the activation energy of permeation; and  $R$  is the universal gas constant (8.314 J mol<sup>-1</sup> K<sup>-1</sup>).

WGS is a reversible exothermic reaction given in **Eq. (6)** [9]. In this work, we use the reaction rate expression, **Eq. (7)**, proposed by Amadeo and Laborde [21] for WGS catalyzed by copper/zinc oxide/alumina.

$$-r_{\text{CO}} = \frac{0.92 e^{\left(\frac{-454.3}{T}\right)} P_{\text{CO}} P_{\text{H}_2\text{O}} \left(1 - \frac{P_{\text{CO}_2} P_{\text{H}_2}}{P_{\text{CO}} P_{\text{H}_2\text{O}} K_{\text{eq}}}\right) \left(\frac{1}{K_{\text{eq}}}\right)}{\left(1 + 2.2 e^{\left(\frac{101.5}{T}\right)} P_{\text{CO}} + 0.4 e^{\left(\frac{158.3}{T}\right)} P_{\text{H}_2\text{O}} + 0.0047 e^{\left(\frac{2737.9}{T}\right)} P_{\text{CO}_2} + 0.05 e^{\left(\frac{1596.1}{T}\right)} P_{\text{H}_2}\right)^2} \times 16.6667 \rho_{\text{catalyst}} \quad (7)$$

where  $P_{\text{CO}}$ ,  $P_{\text{H}_2\text{O}}$ ,  $P_{\text{CO}_2}$ , and  $P_{\text{H}_2}$  denote the partial pressures in Pa of gas species, CO, H<sub>2</sub>O, CO<sub>2</sub>, and H<sub>2</sub>, respectively,  $\rho_{\text{catalyst}}$  (kg m<sup>-3</sup>) is the density of the WGS catalyst, and  $T$  (K) is the reactor temperature. The 16.6667 multiplier enforces unit conversion from mol g<sup>-1</sup> min<sup>-1</sup> to mol kg<sup>-1</sup> s<sup>-1</sup> units.  $K_{\text{eq}}$  is the equilibrium constant, given by [22]:

$$K_{\text{eq}} = 1.2 \times 10^{-2} e^{\left(\frac{4639}{T}\right)}. \quad (8)$$

### Momentum Balance:

Assuming constant pressure drop on both sides of the Pd-based membrane, the momentum balances in the WGS-MR are as follows:

$$\frac{dP_{\text{ret}}}{dz} = \text{constant}, \quad \frac{dP_{\text{perm}}}{dz} = \text{constant}. \quad (9)$$

A total pressure drop of 35 kPa was used on the retentate side and 0 kPa on the permeate side.

The boundary conditions for the WGS-MR module are:

$$z = 0: F_{\text{ret},i} = y_{\text{feed},i} F_0, \quad P_{\text{ret}} = P_{\text{feed}}, \quad (10)$$

$$z = l: F_{\text{perm},i} = y_{\text{sweep},i} F_{\text{sweep}}, \quad P_{\text{perm}} = P_{\text{sweep}}, \quad (11)$$

where  $F_0$  (mol s<sup>-1</sup>) is the total feed flowrate and  $F_{\text{sweep}}$  (mol s<sup>-1</sup>) is the total sweep flowrate.

### Model scaling

The material balances in **Eqs. (1) & (2)** result in poor solver convergence when the component flowrates,  $J_i$ , are near minimal values ( $\leq 10^{-4}$ ). To circumvent this, we apply dimensionless analysis to scale the flowrates and axial distance using the characteristic parameters  $F_0$  and  $l$ :

$$\bar{F} = \frac{F}{F_0} \leftrightarrow dF = F_0 d\bar{F} \quad (12)$$

$$\bar{z} = \frac{z}{l} \leftrightarrow dz = l d\bar{z}. \quad (13)$$

The material balances in **Eqs. (1) & (2)** become:

$$\frac{d\bar{F}_{\text{ret},i}}{d\bar{z}} = -J_i \frac{A_{\text{mem}}}{F_0} + v_i (-r_{\text{CO}}) \frac{V_{\text{rxn}}}{F_0} \quad (14)$$

$$\frac{d\bar{F}_{\text{perm},i}}{d\bar{z}} = -J_i \frac{A_{\text{mem}}}{F_0} \quad (15)$$

The boundary conditions in **Eqs. (10) and (11)** are updated accordingly by dividing the component flowrates ( $y_{\text{feed},i} F_0$  and  $y_{\text{sweep},i} F_{\text{sweep}}$ ) by  $F_0$ .

**Table 1** reports the model parameters used in this study.

**Table 1.** WGS-MR model parameters. These parameters are based on the work of Brunetti et al. [9]. \*Estimated from property data.

Parameter	Value	Description
$A_{\text{mem}}$ (m <sup>2</sup> )	1.57 $\times 10^{-2}$	Membrane area
$V_{\text{rxn}}$ (m <sup>3</sup> )	3.93 $\times 10^{-5}$	Reaction volume
$Q_0$ (mol m <sup>-2</sup> s <sup>-1</sup> Pa <sup>-0.5</sup> )	1.62 $\times 10^{-2}$	Permeance pre-exponential factor
$\frac{E_a}{R}$ (K)	3.10 $\times 10^3$	Activation energy of permeation per gas constant
$\rho_{\text{catalyst}}$ (kg m <sup>-3</sup> )	1.38 $\times 10^3$	Catalyst density
$n$ (unitless)	0.5	H <sub>2</sub> partial pressure exponent
$F_0$ (mol s <sup>-1</sup> )	1.26 $\times 10^{-3}$ *	Feed flowrate
$T$ (K)	553	Reactor temperature
$P_{\text{feed}}$ (MPa)	1	Feed pressure
$P_{\text{sweep}}$ (MPa)	0.1	Sweep-side pressure
$y_{\text{feed,CO}}$ (vol%)	20	Molar composition of gas species in the feed
$y_{\text{feed,H}_2\text{O}}$ (vol%)	20	
$y_{\text{feed,CO}_2}$ (vol%)	10	
$y_{\text{feed,H}_2}$ (vol%)	50	

### Numerical solution and computational environment

The WGS-MR model represented by the differential-algebraic system in **Eqs. (3) to (11) and (14) to (15)** was discretized using 20 finite volumes, resulting in 520 equations with 520 variables. The model was implemented in Pyomo v6.4.0 [23] and solved using Ipopt v3.13.2 [24] with linear solver ma27 [25], distributed as part of the Institute for the Design of Advanced Energy Systems Process Systems Engineering Framework (IDAES PSE) [26]. The model reliably converged in less than 0.1 CPU seconds on a laptop computer running Windows 11 with Intel® Core™ i5-8250U processor and 8GB of RAM.

### Performance criteria

CO conversion is the percentage of CO in the WGS reactor feed that is reacted to produce H<sub>2</sub> and CO<sub>2</sub> as expressed below [9]:

$$\text{CO Conversion} = \left(1 - \frac{\bar{F}_{\text{ret,CO}}^{\text{out}}}{\bar{F}_{\text{ret,CO}}^{\text{in}}}\right) \times 100\%. \quad (16)$$

H<sub>2</sub> recovery is the percentage of available H<sub>2</sub> in the reactor that is recovered in the permeate outlet [9, 14]:

$$\text{H}_2 \text{ Recovery} = \left( \frac{\bar{F}_{\text{perm,H}_2}^{\text{out}}}{\bar{F}_{\text{perm,H}_2}^{\text{out}} + \bar{F}_{\text{ret,H}_2}^{\text{out}}} \right) \times 100\%. \quad (17)$$

## Model initialization procedure

In the sensitivity analysis, we solved the WGS-MR model in three steps using a multi-start initialization strategy to improve solver convergence:

**Step 1:** Toggle off the reaction by fixing the reaction rate variable  $-r_{\text{CO}}$  to zero and deactivating **Eq. (7)**. Then, solve the resulting model. This reduces model complexity by eliminating the nonlinear reaction rate from the material balances in **Eq. (14)**.

**Step 2:** Activate the reaction rate expression in **Eq. (7)**, unfix and initialize the reaction rate,  $-r_{\text{CO}}$ , using partial pressure and temperature values from the solution from the previous step. Solve the entire model.

**Step 3:** Iteratively update the perturbed parameter (e.g., sweep ratio or steam/carbon ratio), defined as a mutable parameter in Pyomo, and re-solve the model for each point in the sensitivity analysis.

## RESULTS

### WGS-MR model reproduces the expected concentration profiles

**Figure 2.** The retentate side concentration profiles of gas species shows that the WGS-MR model captures the relevant physics (i.e., species production/consumption by WGS reaction and  $\text{H}_2$  depletion due to transmembrane permeation).

**Figure 2** shows the retentate side composition of gas species along the dimensionless length of the reactor. As expected, the concentration of the reactants, CO and  $\text{H}_2\text{O}$ , decreases along the reactor length due to their consumption in the WGS reaction. The concentration of  $\text{CO}_2$ , on the other hand, increases along the length of the reactor. The concentration of  $\text{H}_2$ , which is the only gas permeating through the Pd-based membrane, increases and then decreases with a peak near  $\bar{z} = 0.2$ . The

increasing  $\text{H}_2$  concentration corresponds to the reaction-dominated regime, whereas the decreasing  $\text{H}_2$  concentration corresponds to the transport-dominated regime. This concentration profile conforms to other WGS-MR concentration profiles reported in the literature [14, 27].

### Sweep gas increases $\text{H}_2$ production

Using an inert sweep gas on the permeate side promotes  $\text{H}_2$  recovery and CO conversion in the WGS-MR by increasing the driving force for  $\text{H}_2$  permeation [9, 12].  $\text{N}_2$  was used as the sweep in this study. The sweep-to-feed ratio (i.e., the ratio of sweep gas flowrate to feed gas flowrate) was systematically varied to investigate the influence of sweep gas on CO conversion and  $\text{H}_2$  recovery in the WGS-MR (**Figure 3**).

**Figure 3(a)  $\text{H}_2$  recovery:** Using a  $\text{N}_2$  sweep-to-feed ratio of 0.1 resulted in a 4% increase in  $\text{H}_2$  recovery in the WGS-MR compared to baseline WGS-MR with no sweep. The sweep gas increases the  $\text{H}_2$  recovery by diluting the  $\text{H}_2$  in the permeate, which lowers its partial pressure and increases the transmembrane partial pressure difference in **Eq. (3)**, which is the driving force for  $\text{H}_2$  flux across the membrane. For reaction temperatures of 724 K and higher, the gain in  $\text{H}_2$  recovery plateaus at a sweep ratio of 0.1 as it approaches the theoretical maximum of 100%. Although sweep gas flow shows the potential for improving  $\text{H}_2$  recovery in the reactor, it also dilutes the recovered  $\text{H}_2$  which may necessitate additional purification based on the application.

**Figure 3(b) CO conversion:** At 724 K, a sweep-to-feed ratio of 0.5 raises CO conversion from 86% to 98%. This improvement in CO conversion is explained by the gain in  $\text{H}_2$  recovery, which translates to increased withdrawal of a reaction product, prompting the reversible WGS reaction to be favored in the forward direction.

Generally, improved performance is observed at higher temperatures. This is the expected behavior for  $\text{H}_2$  recovery because increasing the temperature boosts the  $\text{H}_2$  permeance of the membrane as shown in **Eq. (4)**. However, the increased CO conversion at higher temperatures is intriguing because WGS is an exothermic reaction. We expect lower conversions at higher temperatures. We hypothesize the trends in **Figure 3(b)** are an interplay between temperature effects on the equilibrium constant and  $\text{H}_2$  flux. Specifically, increasing the temperature enhances the flux of  $\text{H}_2$  across the membrane, according to **Eqs. (3)** and **(4)**, shifting the equilibrium to increase CO conversion. Concurrently, the elevated temperature diminishes the equilibrium constant according to **Eq. (8)**, thereby reducing the CO conversion. **Figure 4** shows additional sensitivity analysis for varying either **(a)** reactor temperature or **(b)** membrane temperature while the other is fixed at 624 K. **Figure 4** confirms the increase in CO conversion from the increased  $\text{H}_2$  flux outweighs the temperature shift in the reaction equilibrium.

**Figure 3.** Increasing the sweep-to-feed ratio produces considerable gains in (a) H<sub>2</sub> recovery and (b) CO conversion in a WGS-MR.

### CO conversion sensitive to steam/carbon ratio in a WGS-MR

Next, we vary the steam/carbon ratio in the feed (**Figure 5**). The total feed flowrate (and, by extension, the gas hourly space velocity) is fixed as reported in **Table 1**; only the relative proportions of steam and carbon in the feed changed.

**Figure 5** shows that excess steam (greater than the stoichiometric ratio) promotes CO conversion in the WGS-MR. We observe that for a given feed pressure, CO conversion increases monotonically with the steam/carbon ratio up to 98 to 99% conversions at a steam/carbon ratio of 5.0. This observation is consistent with the experimental results of Bang et al. [28] for a Pd-Cu WGS-MR. Increasing the steam/carbon ratio increases reactant concentration, which triggers the forward reaction to nullify the disturbance in the equilibrium state as prescribed by La Chatelier's principle [28]. Increasing the steam/carbon ratio beyond 3.0 yields

modest improvements in CO conversion as it approaches the theoretical maximum of 100%. The optimal choice of steam/carbon ratio would maximize CO conversion while constraining steam consumption in the reactor.

**Figure 4.** CO conversion as a function of sweep-to-feed ratio in a WGS-MR for two hypothetical conditions: (a) The reactor temperature is fixed at 624 K, and the membrane temperature varies. (b) The membrane temperature is fixed at 624 K and the reactor temperature varies.

### Model convergence with Ipopt solver

The WGS-MR model demonstrates good solver convergence over a wide range of input parameters (e.g., feed pressures of 1 to 3 MPa, reactor temperatures of 624 to 824 K, sweep-to-feed ratios of 0 to 0.5, and steam/carbon ratios of 1 to 5). For instance, the CPU time corresponding to the sensitivity analysis results in **Figure 3** for  $T = 624$  K is 0.26 CPU seconds for **Step 1**, 0.080 CPU seconds for **Step 2**, and 0.010 to 0.64 CPU seconds (average 0.074 CPU seconds) for **Step 3**.

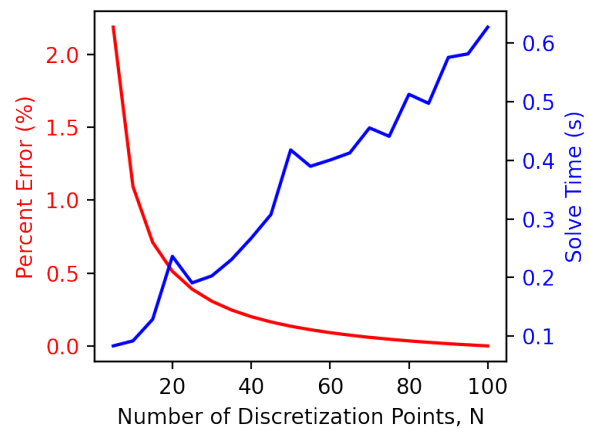

**Figure 5.** CO conversion in the WGS-MR increases with the steam/carbon ratio. Higher conversions are observed at higher feed pressures due to increased H<sub>2</sub> recovery at elevated pressures.

**Table 2** compares the solver convergence performance (i.e., number of iterations and CPU seconds) of the WGS-MR model before and after rescaling the model using the initialization procedure described above. These data correspond to the sensitivity analysis in **Figure 3** and show that the scaled model converges in about 50% of the CPU seconds for the unscaled model, emphasizing the role of proper model scaling in improving numerical performance. A similar trend is observed for other temperatures and sweep-to-feed ratios in **Figure 3**, which are omitted for brevity. We found the scaled model is more robust to a naive initialization, although we recommend the procedure described above.

**Table 2:** Solver convergence of WGS-MR model.

		624 K		824 K	
		scaled	un-scaled	scaled	un-scaled
Sweep ratio = 0.0	# of iterations	4	4	6	7
	CPU secs	0.019	0.036	0.043	0.111
Sweep ratio = 0.2	# of iterations	4	5	5	6
	CPU secs	0.028	0.058	0.034	0.046

**Figure 6** investigates the impact of the number of discretization points on the solve time and percent error. Here, percent error is defined relative to the numeric solution with  $N = 100$  discretization points. As expected, the solve time increases approximately linearly with the number of discretization points, whereas the percent error decays nearly exponentially as  $N$  increases. Based on these results, we conclude that  $N = 20$  is likely sufficient for process design and optimization.

**Figure 6.** Sensitivity analysis quantifies the impact of the number of discretization points on the solve time and percent error. The percent error was calculated for the flowrate of H<sub>2</sub> in the permeate relative to the numerical solution with  $N = 100$ .

## CONCLUSIONS

We present an EO modeling framework for WGS-MR and propose a scaling analysis and multi-start initialization procedure that promotes solver convergence. Through sensitivity studies with this model, we show that sweep gas on the permeate side could drive up conversion to over 95% and H<sub>2</sub> recovery to ~99% for temperatures 674 K and above. We also show that excess steam could promote CO conversions in the WGS-MR up to a steam/carbon ratio of 3.0 for the dataset considered in this study. This EO model converges rapidly (<1 CPU sec) and serves as a tool for the design and optimization of WGS-MRs.

Ongoing work utilizes this model to optimize the techno-economic benefits of WGS-MRs for blue H<sub>2</sub> production from gasified biomass. The EO modeling approach adopted in this work motivates further work into integrating the design of WGS-MR membrane modules into large-scale, EO-based flow sheets for process-wide optimization of H<sub>2</sub> production technologies.

## ABSTRACT

Direct air capture (DAC) of carbon dioxide is a promising technology to enable climate change mitigation. The liquid solvent DAC (LSDAC) process is one of the leading technologies being piloted. However, LSDAC uses a high-temperature regeneration process which requires a lot of thermal energy. Although current LSDAC designs incorporate pre-heat cyclones and a heat recovery steam generator to enable heat recovery, these do not maximize the use of the heat in the products of calcination. In this paper, a linear optimization model is developed to minimize energy cost in a LSDAC that is powered by renewable energy and natural gas. First, the material flow network is modified to include a heat exchanger (HX) and water supply to a proton exchange membrane (PEM) electrolyser. Mass and energy balance constraints are then developed to include the water flow as well as the energy balance at the PEM and the HX. Results show that about 911 tonnes of hydrogen could be produced over 336 hours of operation using a 136MW PEM. Further analysis reveals that hydrogen production is only prioritized if the value is higher than the cost of natural gas.

**Keywords:** Climate change, Direct air capture, Hydrogen, Negative emission technologies, PEM

## INTRODUCTION

To forestall a possible climate crisis, negative emission technologies (NETs) such as direct air capture (DAC) of  $CO_{2(g)}$  from the atmosphere are considered a necessary addition to other mitigation measures [1]. This is due to its ability to capture the already emitted carbon from the atmosphere independent of the origin of the emission. Also, DAC is likely to reduce the cost of achieving net-zero power grids [2], [3]. DAC has special advantages over other NETs such as traceability, controllability, and modularity. Two crucial DAC technologies are currently being piloted in various parts of the globe: liquid solvent DAC (LSDAC) and solid sorbent DAC. Compared to the solid sorbent technologies, the LSDAC has a slightly lower energy requirement per tonne of  $CO_{2(g)}$ , better scalability and continuity of operation [1]. Further, LSDAC uses mature chemical process technologies such as calcium looping (CL) [4].

Despite the promising features of LSDAC, it faces

several challenges. First, its capture rate is heavily influenced by climate as the liquid solvent may freeze at temperatures below 0 °C [5]. Second, the high-temperature regeneration process is energy intensive requiring a stable power supply necessitating the use of high capacity factor power generation technologies, most of which depend on fossil fuels. DAC energetics is an important research agenda that would enable efficient integration of the technology into the energy system. Among the aspects of improving the energy profile of LSDAC is reducing the energy required for regeneration through electrochemical processes [6]. Another important aspect is making the regeneration process flexible so that it could be powered using renewable energy (RE) sources, which are intermittent by nature [7]. One technique of improving DAC energetics that is missing in the literature is the full utilization of heat recovered from the LSDAC. In [8],  $H_{2(g)}$  is produced using waste heat from an organic Rankine cycle generator. The waste heat is useful in providing the thermal needs of the PEM and raising the temperature of

the inflowing water to the PEM's operating temperature, thereby improving its performance [9], [10].

Keith et al [4] discussed several heat integration techniques that enhanced the use of heat recovered from the calciner and the slaker. In their model, heat is recovered from outgoing  $CO_{2(g)}$  from the calciner to pre-heat the incoming  $CaCO_{3(s)}$  pellets from the pellet reactor to 650 °C through two cyclones. Another cyclone is used to recover heat from  $CaO$  to pre-heat oxygen from the air separation plant (ASP) to 674 °C. Heat is also recovered from these two substances and the steam slaker through a heat recovery steam generator to produce steam which is used to drive a steam turbine to produce electricity for the plant. However, this elaborate heat recovery scheme still leaves a lot of thermal energy wasted. For instance, after all the heat recovery processes,  $CO_{2(g)}$  is still at 325 °C, which has energy that could still power the system if properly integrated. Furthermore, if the system is all electric, there is no need for an ASP, thus freeing the heat from  $CaO$  for reuse in the process.

This paper proposes the use of the recovered heat from the products of calcination to produce  $H_{2(g)}$ . It is an improvement of [7], where a linear programming (LP) model was proposed to lower energy costs in the LSDAC plant by flexibly scheduling regeneration process to maximize the utilization of RE in the plant. First, the process flow is modified to include a heat exchanger (HX) and water supply to a proton exchange membrane (PEM) electrolyser. Additional constraints are then developed to model the additional water flow as well as the energy balance at the PEM and the HX.

## METHODOLOGY

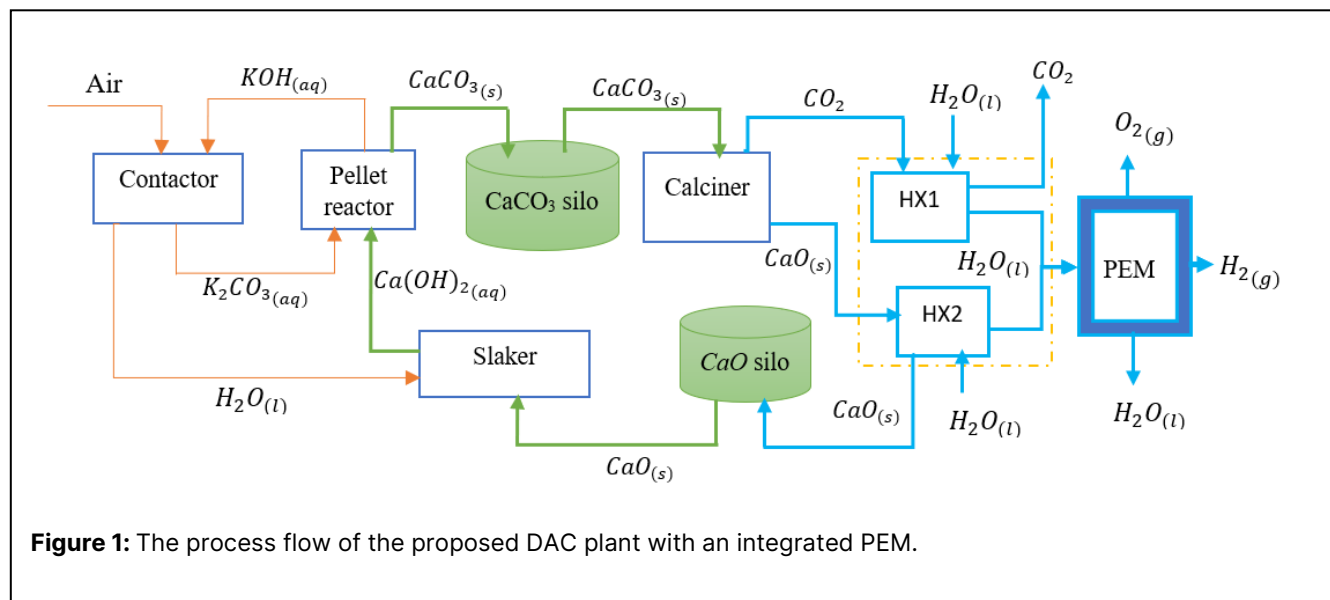

## Process Flow Design of the Proposed DAC Plant

Designed by Keith et al [4], a typical liquid solvent DAC plant has two major loops. The first loop – the potassium cycle – starts at the air contactor where  $KOH_{(aq)}$  reacts with  $CO_{2(g)}$  from the air, producing  $K_2CO_{3(aq)}$ , which is reacted with  $Ca(OH)_{2(aq)}$  in the pellet reactor, thereby regenerating the  $KOH_{(aq)}$  to complete the cycle. The second cycle starts with the thermal decomposition of  $CaCO_{3(s)}$  from the pellet reactor in a calciner to regenerate the captured  $CO_{2(g)}$ . This is followed by slaking of the resultant  $CaO_s$  using steam to produce  $Ca(OH)_{2(aq)}$  for use in the pellet reactor, thus completing the second cycle. In [7], the second loop is remodeled to include solids storage silos to enable flexible scheduling of the calcination process to maximize RE utilization in the energy-intensive process. In this paper, a further modification is proposed to improve the utilization of the energy contained in the  $CO_{2(g)}$  and  $CaO_s$  from the calciner. This is done by including  $H_{2(g)}$  production in the process flow to make use of the waste heat. Pre-heat cyclones included by Keith et al [4] are utilized here except for the one that is associated with the air separation plant, which is not necessary in our electrified calciner. The process flow of the proposed DAC plant with an integrated PEM is shown in Figure 1.

## Optimization Model of the Flexible DAC with Hydrogen Production

A new model is developed to include  $H_{2(g)}$  production constraints. The model is defined as follows:

$$\min F = \sum_{t \in T} (C_{ng} p_t^{ng} \Delta t + C_i C_c p_t^{ng} \Delta t - C_{H_2} m_t^{H_2}) \quad (1)$$

$$p_t^{pem} \geq \alpha m_t^{H_2O,pem}, \quad \forall t \in T \quad (2)$$

$$m_t^{H_2O,out} = m_t^{H_2O,in} - m_t^{H_2O,pem}, \quad \forall t \in T \quad (3)$$

$$m_t^{H_2} = \frac{2}{18} m_t^{H_2O,pem}, \quad \forall t \in T \quad (4)$$

$$m_t^{O_2} = \frac{16}{18} (m_t^{H_2O,pem}), \quad \forall t \in T \quad (5)$$

$$p_t^{pem} + m_t^{H_2O,in} c_{H_2O} (T_{hx}^{H_2O} - T_a) = \beta m_t^{H_2O,pem} + m_t^{H_2} c_{H_2} (T_{pem} - T_a) + m_t^{O_2} c_{O_2} (T_{pem} - T_a) + m_t^{H_2O,out} c_{H_2O} (T_{pem} - T_a), \quad \forall t \in T \quad (6)$$

$$m_t^{H_2O,in} c_{H_2O} (T_{hx}^{H_2O} - T_a) = \eta x_t^c (0.44 c^{O_2} (T_{dac}^{CO_2} - T_{hx}^{CO_2}) + 0.56 c^{CaO} (T_{dac}^{CaO} - T_{hx}^{CaO})), \quad \forall t \in T \quad (7)$$

$$P^{df} + p_t^{dv} + p_t^{pem} = p_t^{ng} + p_t^w + p_t^s, \quad \forall t \in T \quad (8)$$

$$p_t^{dv} = \phi m_t^{CO_2}, \quad \forall t \in T \quad (9)$$

$$0 \leq p_t^w \leq P_{max}^w, \quad \forall t \in T \quad (10)$$

$$0 \leq p_t^s \leq P_{max}^s, \quad \forall t \in T \quad (11)$$

$$0 \leq p_t^{ng} \leq P_{max}^{ng}, \quad \forall t \in T \quad (12)$$

$$m_t^{cc} = m_{t-1}^{cc} + r_t^{cc} \Delta t, \quad \forall t \in T \quad (13)$$

$$-R_{max}^{cc} \leq r_t^{cc} \leq R_{max}^{cc}, \quad \forall t \in T \quad (14)$$

$$0 \leq m_t^{cc} \leq M_{max}^{cc}, \quad \forall t \in T \quad (15)$$

$$m_t^{cc} = 0, \quad t \in \{0, T\} \quad (16)$$

$$m_t^c = m_{t-1}^c + r_t^c \Delta t, \quad \forall t \in T \quad (17)$$

$$-R_{max}^c \leq r_t^c \leq R_{max}^c, \quad \forall t \in T \quad (18)$$

$$0 \leq m_t^c \leq M_{max}^c, \quad \forall t \in T \quad (19)$$

$$m_0^c = m_T^c \quad (20)$$

$$x_t^c \leq X_{max}^c, \quad \forall t \in T \quad (21)$$

$$r_t^{cc} + x_t^c = X^p, \quad \forall t \in T \quad (22)$$

$$0.56 x_t^c = X^s + r_t^c, \quad \forall t \in T \quad (23)$$

$$m_t^{CO_2} = 0.44 x_t^c \Delta t, \quad \forall t \in T \quad (24)$$

The objective of the model is to minimize energy cost as given by equation (1), where the sales of hydrogen is subtracted to encourage heat recovery. Equation (2)-(7) are the PEM plant constraints defined as follows: the PEM electrical energy supply constraint (2); the water flow balance for the PEM (3); the  $H_{2(g)}$  output (4);  $O_{2(g)}$  output (5); power equilibrium at the PEM (6); and the HX thermal energy balance (7). In (2),  $\alpha$  is the Gibb's free energy,  $\Delta G$ , of water at the operating temperature (353K) in MWh/kg. This is obtained from the value of  $\Delta G$  in kJ/mol expressed as [11], [12], [13]:

$$\Delta G = nF (1.229 - 0.0009(\tau - 298)) \quad (25)$$

where  $n = 2$  is the number of electrons transferred in the electrolysis of a molecule of water,  $F = 96485C$  is Faraday's constant and  $\tau$  is the temperature in Kelvin. Equations (8)-(12) and (13)-(26) are the energy supply constraints and mass flow constraints for the flexible DAC plant; the reader is referred to [7] for a detailed description of these constraints. The energy supply constraints are briefly defined as follows: power equilibrium at the supply bus (8), variable calciner and compressor demand (9), wind power generator boundary (10), solar generation constraint (11), and NGG capacity constraint (12). The mass flow constraints for the DAC plant are defined as follows:  $CaCO_3$  storage silo mass flow dynamics (13), silo flowrate (14) and capacity limits (15); capture rate enforcement constraint for the  $CaCO_3$  silo (16), which ensures all the captured  $CO_{2(g)}$  is regenerated;  $CaO$  silo mass flow dynamics (17), flowrate (18) and capacity limits (19); capture rate enforcement constraint for the  $CaO$  silo (20); calciner throughput limit (21); coupling constraint between the calciner and the  $CaCO_3$  silo (22); coupling constraint between the calciner and the  $CaO$  silo (23) and a constraint to compute the mass of  $CO_{2(g)}$  regenerated. Table 2 shows the model decision variables that are optimized.

## Data

The parameters of the model are shown in Table 1. Details of the RE profiles and the DAC parameters have been provided in [7].

## RESULTS AND DISCUSSION

This paper models  $H_{2(g)}$  production from waste heat from a liquid solvent DAC plant using a PEM. The PEM is assumed to be able to make use of all the heat recovered to produce the  $H_{2(g)}$ , thus, the PEM size is not limiting. In this section, PEM output and the impact of this modification on the overall energy cost of the plant are discussed.

### PEM Performance and Energy Consumption

Over the 336 hours modeled, which represent variation in renewable energy supply, a total of about 910,890 kg of  $H_{2(g)}$  is produced, which translates to about 2,711 kg/h. This level of production would need a 136 MW PEM, if losses are ignored. Given that the higher heating value (HHV) of  $H_{2(g)}$  is about 0.0394 MWh/kg, the output energy is close to 35,889 MWh of energy produced at an average rate of 106 MW, which is equivalent to 78.4% efficiency. This efficiency value would be lower if all the losses are considered. However, it would still result in a better efficiency compared to using the recovered heat to generate power using an organic Rankine cycle, whose efficiency is less than 30%.

**Table 1:** Model Parameters

Parameter	Description	Value and Units
$C_c$	Carbon tax	37.1 \$/tonne- $CO_2$
$C_i$	NGG carbon intensity	0.3894 tonne- $CO_2$ /MWh
$C_{H_2}$	Price of $H_{2(g)}$	\$/kg
$C_{ng}$	Cost of natural gas	27.77 \$/MWh
$c^{CO_2}$	Specific heat capacity of $CO_2$	1.065 kJ/kg/K
$c^{O_2}$	Specific heat capacity of $O_2$	0.924 kJ/kg/K
$c^{H_2O}$	Specific heat capacity of $H_2O$	4.184 kJ/kg/K
$c^{H_2}$	Specific heat capacity of $H_2$	14.493 kJ/kg/K
$c^{CaO}$	Specific heat capacity of $CaO$	0.945 kJ/kg/K
$M_{max}^c$	$CaO$ silo capacity	370 tonnes
$M_{max}^{cc}$	$CaCO_3$ silo capacity	660 tonnes
$p^{df}$	Fixed DAC demand	20 MW
$p_{max}^{ng}$	NGG capacity	165 MW
$p_{max}^s$	Maximum PV power	110 MW
$p_{max}^w$	Maximum wind power	140 MW
$R_{max}^c$	$CaO$ silo maximum flowrate	134 tonnes/h
$R_{max}^{cc}$	$CaCO_3$ silo maximum flowrate	240 tonnes/h
$T$	Optimization horizon	336h
$T_a$	Ambient temperature	25 °C
$T_{dac}^{CO_2}$	Temperature of $CO_2$ leaving the pre-heat cyclones of DAC.	450 °C
$T_{dac}^{CaO}$	Temperature of $CaO$ leaving the calciner	900 °C
$T_{hx}^{CaO}$	Temperature of $CaO$ leaving the HX	300 °C
$T_{hx}^{H_2O}$	Temperature of $H_2O$ leaving the HX	80 °C
$T_{pem}$	PEM operating temperature	80 °C
$X_{min}^c$	Minimum calciner flowrate	20 tonnes/h
$X_{min}^{cc}$	Minimum calciner flowrate	500 tonnes/h
$X^p$	Pellet reactor flowrate	260 tonnes/h
$X^s$	Slaker flowrate	145.6 tonnes/h
$\alpha$	Gibb's free energy of $H_2O$ at $T_{pem}$	0.00351 MWh/kg
$\beta$	Enthalpy of formation of $H_2O$	0.00441 MWh/kg
$\eta$	HX efficiency	0.8
$\phi$	Calciner and compressor consumption	1.226 MWh/tonne- $CO_2$
$\Delta t$	Timestep size	1h

### Sensitivity Analysis: Factors Affecting the Mass of Hydrogen Produced

The production of  $H_{2(g)}$  requires both thermal and electrical energy. Although the amount of thermal energy recovered from the calciner is constant – provided the

Variable	Description	Units
$m_t^c$	Mass of stored $CaO$ at time, $t$	tonne
$m_t^{cc}$	Mass of stored $CaCO_3$ at time, $t$	tonne
$m_t^{CO_2}$	Mass of $CO_2$ regenerated at time, $t$	tonne
$m_t^{H_2}$	Mass of $H_2$ produced at time, $t$	kg
$m_t^{H_2O,in}$	Mass of $H_2O$ flowing into the PEM at time, $t$	kg
$m_t^{H_2O,out}$	Mass of $H_2O$ flowing out of the PEM at time, $t$	kg
$m_t^{H_2O,pem}$	Mass of $H_2O$ electrolyzed by the PEM at time, $t$	kg
$m_t^{O_2}$	Mass of $O_2$ produced by the PEM at time, $t$	kg
$p_t^{dv}$	Variable demand of the DAC plant at time, $t$	MW
$p_t^{ng}$	Power generated by the NGG at time, $t$	MW
$p_t^{pem}$	Electrical power supplied to the PEM at time, $t$	MW
$p_t^s$	Solar power consumed at time, $t$	MW
$p_t^w$	Wind power consumed at time, $t$	MW
$r_t^c$	Mass flow rate of the $CaO$ silo at time, $t$	tonne/h
$r_t^{cc}$	Mass flow rate of the $CaCO_3$ silo at time, $t$	tonne/h
$x_t^c$	Calciner flowrate at time, $t$	tonne/h

$CO_{2(g)}$  capture rate is enforced – the electrical input is derived from RE and the NGG. The objective function of the optimization model penalizes the use of NGG while encouraging the production of  $H_{2(g)}$ . Therefore, two main factors affect the amount of  $H_{2(g)}$  produced.

First, if the cost of NGG is constant, the price of  $H_{2(g)}$  determines whether  $H_{2(g)}$  is produced. Observing the amount of  $H_{2(g)}$  produced per hour for the value of  $C_{H_2}$  ranging from 0.0 to 3.0 \$/kg, it was established that the  $H_{2(g)}$  production becomes attractive at  $C_{H_2} = 1.67$  \$/kg. Considering that the higher heating value (HHV) of  $H_{2(g)}$  is about 0.0394 MWh/kg, this price coincides with an energy price of about 42.38 \$/MWh, which is very close to but slightly above the cost of NGG power from the NGG, which is 42.22 \$/MWh. Figure 2 shows the impact of the price of  $H_{2(g)}$  on its hourly production rate.

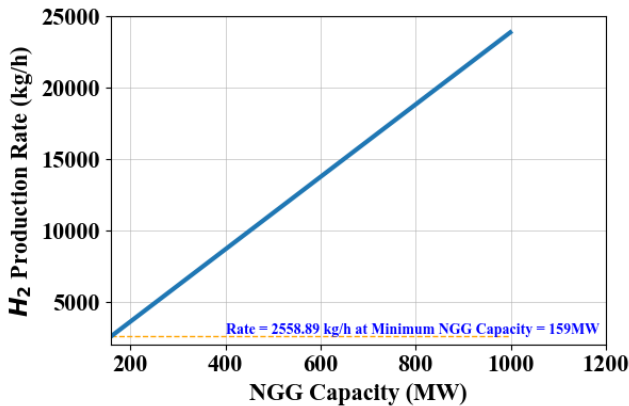

The second important factor affecting the  $H_{2(g)}$  production rate is the NGG capacity. If the price is set at 1.67 \$/kg, increasing the NGG capacity increases the rate of  $H_{2(g)}$  production provided the PEM capacity is not limited. This is because the increase in NGG capacity increases the amount of energy available for  $H_{2(g)}$  production. The production also increases because the price of

**Table 2:** Model Decision Variables

$H_{2(g)}$  is set slightly higher than the cost of energy from the NGG. Figure 3 shows the impact of the NGG capacity on  $H_{2(g)}$  production rate.

**Figure 2.** Impact of  $H_{2(g)}$  price on the production rate.

**Figure 3.** Impact of NGG capacity on  $H_{2(g)}$  production rate.

Though the rate of production of  $H_{2(g)}$  increases with NGG capacity, it also leads to more emission of  $CO_{2(g)}$ , therefore, only the capacity needed to sustain the system is allowed, which is set at 165 MW.

### Implications of Including the PEM on System Energy Use Dynamics

With flexibility in the  $H_{2(g)}$ , the role of the solids storage silos in minimizing curtailment vanishes, provided the PEM size is not a limiting factor. Therefore, the silo size no longer impacts the cost of energy, which departs from the findings in [7] where the silos played a major role in curtailment reduction. This is because the cheap RE facilitates the  $H_{2(g)}$  production so that none of the available renewable energy is curtailed. Furthermore, including the PEM increases the energy demand considerably such that no moments of oversupply exist.

Consequently, the calciner and the NGG operate at full capacity throughout the optimization horizon. This is because there is an incentive in the objective function for increasing hydrogen production. The calciner operates at full capacity to supply the thermal demands of the PEM while the NGG supplies the electrical energy demand.

However, the PEM's output profile coincides with that of the RE. This is because RE provides cheap electrical energy for hydrogen production, which could be used for both the PEM's thermal and electrical needs. Figure 4 shows the mass of  $H_{2(g)}$  produced by the PEM, which aligns with RE availability and use.

**Figure 4.**  $H_{2(g)}$  production profile alongside RE supply (Smoothing was done using Savitzky–Golay filter).

## CONCLUSION

This paper presents a linear programming optimization model which was developed to incorporate a PEM in the process flow design of an LSDAC plant to maximize the use of waste heat for hydrogen production. Novel mass and energy flow constraints are developed to maintain energy and water supply to the PEM electrolyser. Results show that 911 tonnes of hydrogen could be produced over 336 hours of operation by a 136 MW PEM. Sensitivity analyses reveal that hydrogen production is only prioritized if its sale value is higher than the cost of natural gas. Under such market conditions, the production of hydrogen would only be limited by the PEM size and availability of the required electrical energy. The inclusion of the PEM also eliminates the need for solids storage silos, which were previously required to enhance process flexibility and use of variable renewable energy. Future research could develop temperature-dependent models for the PEM hydrogen output profile to enable analysis of the impact of temperature on the amount of hydrogen produced from the recovered heat.

## ABSTRACT

Chemical looping ammonia synthesis (CLAS) is a new ammonia synthesis method capable of efficiently synthesizing ammonia at atmospheric pressure. The low-pressure operation of CLAS systems could decrease the capital and operational costs of ammonia synthesis. Despite its early developmental stage, the use of standard process engineering equipment in CLAS makes it possible to reasonably assess its economic potential. In this study, we evaluated the technoeconomic potential of CLAS systems in comparison to a Haber-Bosch (HB) synthesis process in the context of green ammonia production. CLAS is more compatible with the separate nitrogen and hydrogen feedstocks used in green ammonia production, and cost savings from CLAS could improve the economic viability of green ammonia production. Ammonia synthesis loops were modeled in Aspen Plus and the levelized cost of ammonia (LCOA) of each system was calculated. Three CLAS systems; two high temperature and one low-temperature chemical loop, were compared to a conventional HB system of equivalent size. This study found that CLAS can reduce the synthesis cost by 90% and that the low temperature CLAS is more economically viable than the high temperature CLAS. The need for an external heater in the high temperature CLAS diminished any cost savings that would have been realized due to the low-pressure operation. This work highlights the potential of CLAS to reduce ammonia synthesis costs and emphasizes the need for further development of low-temperature CLAS systems.

## INTRODUCTION

Ammonia is a vital chemical for our modern society. Most of the industrially produced ammonia is used as a fertilizer to feed the global population, and the remainder is used to manufacture pharmaceuticals, chemicals, or used as a refrigerant [1]. The high energy density of ammonia and hydrogen capacity per volume, makes ammonia an attractive solution as a carbon-free energy carrier [1]. Because of this, ammonia is expected to play a pivotal role in decarbonizing notoriously difficult to abate sectors like aviation, and maritime shipping [2-3]. However, ammonia production itself is a carbon-intensive and hard to abate sector. Global ammonia production emits 1.8% of annual CO<sub>2</sub> emissions while consuming 1% of the annual energy demand [1]. As global reliance on ammonia grows with the emergence of new applications, it is crucial to

ensure that the rising demand for ammonia production does not lead to a corresponding increase in CO<sub>2</sub> emissions.

Industrial ammonia synthesis is performed by the Haber-Bosch (HB) process which combines nitrogen and hydrogen to synthesize ammonia via R1:

Although the ammonia synthesis reaction doesn't directly emit carbon dioxide, it results in the emission of 2 tons of CO<sub>2</sub> for every ton of ammonia produced [1]. This significant carbon footprint stems largely from generating hydrogen via steam methane reforming and combusting natural gas to heat the process [1]. Consequently, adopting carbon-free sources for hydrogen and heating is essential to curtail CO<sub>2</sub> emissions associated with ammonia production.

Green ammonia production offers a low-carbon solution for ammonia synthesis. This approach typically involves generating hydrogen through water electrolysis and extracting nitrogen from air using an air separation unit (ASU). These gases are then reacted in a Haber Bosch (HB) reactor to produce ammonia, with the entire process powered by renewable energy, making it environmentally friendly [2]. While technically viable, green ammonia production is not yet economically feasible in most cases [1]. Current efforts to lower production costs have primarily focused on reducing electrolyzer costs, with less emphasis on cost savings within the ammonia synthesis loop. Additionally, the HB reactor's sensitivity to minor fluctuations poses a challenge in integrating with intermittent renewable energy sources, underscoring the need for a more robust synthesis loop [4].

Chemical Looping Ammonia Synthesis (CLAS) is a new ammonia synthesis method that enables efficient ammonia production at atmospheric pressure and mild temperatures (<300°C) [5]. CLAS synthesizes ammonia in two or more steps mediated by a carrier material, typically a metal catalyst. A generalized CLAS process is shown in R2-R3:

where nitrogen is fixed to the metal catalyst in R2 and removed as ammonia in R3 using hydrogen. The primary benefit of CLAS is its ability to circumvent the equilibrium constraints of the traditional HB process (R1) [5]. This allows for ammonia production at reduced pressures and temperatures, which can significantly lower both capital and operational costs by enabling the use of more affordable compressors and reactors than those required for the HB process. Furthermore, CLAS is particularly well-suited for green ammonia production, which generates nitrogen and hydrogen in separate streams – a requirement for CLAS reactors. CLAS systems can vary in their number of steps, carrier materials, operating temperatures, and hydrogen sources making them difficult to assess [5]. Despite ongoing development of more CLAS systems, there's a gap in assessing their techno-economic viability, especially as a direct replacement for the HB synthesis loop in green ammonia production proposals. Currently, CLAS has a low technology readiness level (TRL) of 3. However, its use of established technologies such as compressors, heaters, heat exchangers, and fixed bed reactors allows for a reasonably confident early-stage economic assessment. In this work we aim to assess the techno-economic feasibility of CLAS reactors as a drop-in replacement for a HB synthesis loop in a green ammonia production system.

## METHOD

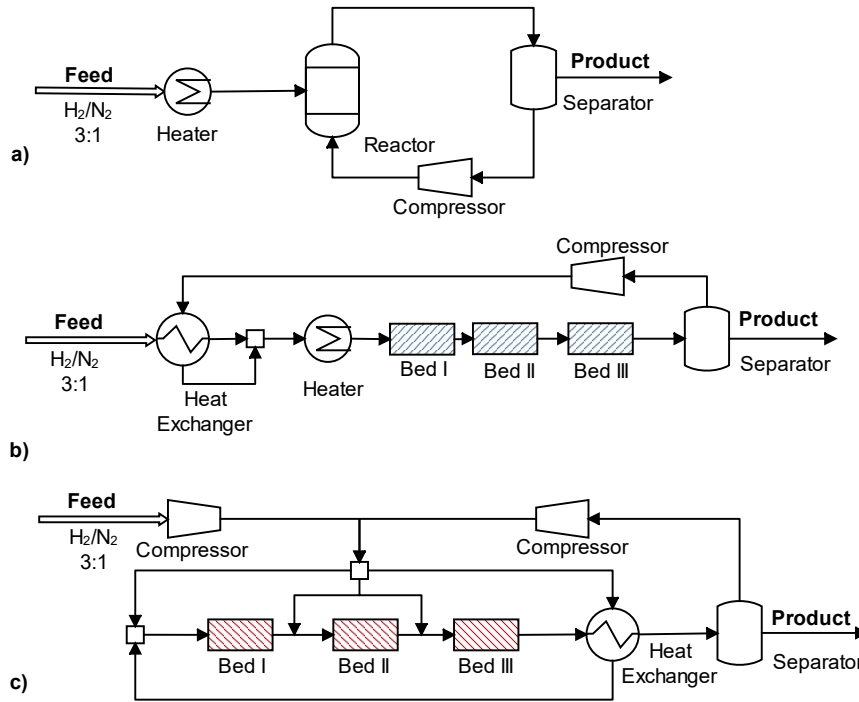

In this study, HB and CLAS systems were simulated in Aspen Plus and their levelized cost of ammonia (LCOA) were compared. For the HB process, we simulated a state-of-the-art loop featuring a three-bed reactor. For the CLAS systems, we examined two high-temperature processes operating at 400°C using data from two preliminary catalysts (Catalyst A & B) studied in-house reported in [6], and a low-temperature process operating at 270°C utilizing Ni-BaH<sub>2</sub> [7]. Each synthesis loop was fed with 2,600 kmol/h of nitrogen and hydrogen in a ratio of 3:1 at a temperature of 80°C and a pressure of 5 atm to replicate the pressure from a PEM electrolyzer [1]. The capital cost of each equipment was calculated using published correlations [8]. The levelized cost of ammonia was calculated using a 20-year period and 5% discount rate. The effect of conversion and CLAS reactor configuration was studied in relation to LCOA. The details of this analysis are described in this section.

### Chemical Looping Reactor Model

The chemical looping reactor models were simulated at cyclical steady state using adiabatic RSTOIC reactors with a fixed fractional conversion of N<sub>2</sub> [9]. In this context, cyclical steady state describes a condition in which the reactor performance is stabilized across multiple chemical looping cycles and reaches a steady state. In this work the single reactor model shown in Figure 1.a, and the three-reactor model shown in Figure 1.b were studied. In the single reactor model, the feed gas is heated to the set point temperature of the chemical loop before being reacted. Ammonia is separated from the reactor outlet using a separator, and the unreacted gases are recycled back to the reactor using a compressor. In the three-reactor setup three CLAS reactors are connected in series and the feed gas is preheated in a heat exchanger, before being sent to the heater that is set to the setpoint of the chemical looping reactor. Again, ammonia is separated from the reactor outlet, and unreacted N<sub>2</sub> and H<sub>2</sub> are recycled, forming the synthesis loop. Three CLAS configurations were examined, using preliminary production rates of 105 μmol/g<sub>cat</sub>·h for Catalyst A, 2 mmol/g<sub>cat</sub>·h for Catalyst B, and 28 mmol/g<sub>cat</sub>·h for Ni-BaH<sub>2</sub> [7].

### Haber-Bosch Reactor Model

The Haber-Bosch synthesis loop shown in Figure 1.c, was simulated as a three-bed reactor system with a preheater and quench splits [10]. The molar flow of the feed, shown in Figure 1.c, was split sending 23%, 13.9% and 12.7% to beds 1, 2, and 3, respectively and the balance sent to the preheater [10]. The catalyst beds were modeled as adiabatic plugged flow reactors with a catalyst void fraction of 0.33 and a density of 2200 kg/m<sup>3</sup>. The iron-based catalyst kinetics are described by Eq. 1 [10]:

**Figure 1:** Diagrams of the ammonia synthesis loops modeled in this work where; a) is the single CLAS reactor model, b) is the three reactor CLAS model, and c) is the three bed Haber Bosch model.

$$r_{Fe} = \frac{9.5}{\rho_{cat}} \left( \frac{k_{Fe} P_{N_2} P_{H_2}^{1.5}}{P_{NH_3}} - \frac{k_{-Fe} P_{NH_3}}{P_{H_2}^{1.5}} \right), \quad (1)$$

where  $\rho_{cat}$  is the catalyst bulk density,  $P_i$  is the partial pressure of component  $i$  in bar, and  $k_{Fe}$  and  $k_{-Fe}$  are the kinetic constants for the forward and reverse reactions of R1 respectively as:

$$k_{Fe} = 1.79 \times 10^4 e^{\left(-\frac{87,090}{RT}\right)}, \quad (2)$$

$$k_{-Fe} = 2.75 \times 10^{16} e^{\left(-\frac{198,464}{RT}\right)}, \quad (3)$$

where  $R$  is the universal gas constant, and  $T$  is the gas temperature in Kelvin.

### Auxiliary Equipment

Auxiliary equipment was simulated to replicate realistic operation of each synthesis loop. A multistage compressor was used to elevate the pressure from 5 atm to 200 atm for the HB synthesis loop. The compressor includes an interstage cooler to reduce the outlet gases temperature to 250°C. The cooler was modeled as a heat exchanger with pumped cooling water as the working fluid. The pumps were modeled to increase the cooling water pressure by 1 atm with a 95% pump and driver efficiency. The cost of cooling water was not considered in this work. Compressors were simulated as isentropic using the ASME method with an efficiency of 95%. The compressors were powered by explosion proof drivers

[8]. Heat exchangers were modeled with a 1 atm pressure drop across each side with a design specification to achieve a 50°C temperature change. The reported area of the heat exchangers was used to size the equipment. Heaters were modeled as electric heaters in Aspen Plus, and the duty of the heater was used to size the equipment. The separator used in each model assumed to be an absorbent based separator with a return stream of 250°C and a pressure drop of 1 atm [11]. The cost of separation was not included in the scope of this work.

### Economic Calculations

The capital cost of each synthesis loop was calculated using Eq 4-6 :

$$C^{cap} = \sum_j^n C_j, \quad (4)$$

$$C_j = C_e \times AF \times P_e \times \frac{CEPCI}{1000}, \quad (5)$$

$$\log_{10} C_e = K_1 + K_2 \log_{10}(A) + K_3 [\log_{10}(A)]^2, \quad (6)$$

where  $C^{cap}$  is the capital cost of the synthesis loop,  $C_j$  is the bare module cost of equipment  $j$ ,  $n$  is the number of equipment in the synthesis loop,  $AF$  is the alloy factor used as 2.7 for stainless steel,  $P_e$  is the pressure adjustment factor for each equipment, and the chemical engineering plant cost index,  $CEPCI$ , was taken as 800 for 2023 [8,12].  $C_e$  is the bare cost of the equipment defined by Eq. 6 where parameters  $K1 - K3$  and  $A$  are described

in Table 1 for each equipment.

**Table 1:** Equipment capital cost parameters for Eq. 6 [8].

Unit	Basis (A)	K1	K2	K3
Heater	Duty (kW)	3.068	0.6597	0.0194
Heat Exchanger	Area (m <sup>2</sup> )	2.7652	0.7282	0.0783
Compressor	Duty (kW)	2.2897	1.3604	-0.1027
Driver	Duty (kW)	2.4604	1.4191	-0.1798
Pump	Duty (kW)	3.3892	0.3161	0.1220

The reactor capital costs were calculated using Eq. 7:

$$C_{reactor}^{cap} = C_{fixed}^{cap} + f_p C_{ref}^{cap} \left( \frac{V}{20 \text{ m}^3} \right)^{0.52} + 15.50 w_{cat}, \quad (7)$$

where  $w_{cat}$  is the catalyst weight in kg,  $V$  is the reactor volume in m<sup>3</sup>,  $C_{ref}^{cap}$  is the reference reactor cost of \$268,000,  $C_{fixed}^{cap}$  is the fixed capital cost of the reactor at \$66,800,  $f_p$  is the pressure multiplier that accounts for the increase in vessel wall thickness at higher pressures, calculated as:

$$f_p = 0.125 \left( \frac{P}{10} \right) + 0.875, \quad (8)$$

where  $P$  is in units of bar [11]. To calculate the volume of the RSTOIC reactors, we first established the required weight of the catalyst by dividing the ammonia production rate of each reactor by the catalyst production rate per gram of catalyst. Next, we determined the catalyst's volume using its density. Finally, we increased this volume by 25% to estimate the reactor volume. The HB catalyst cost was assumed to be \$15.5/kg [11] and the CLAS catalyst costs were calculated using the bare metal costs [13-15] plus an 80% markup.

The operating cost of each synthesis loop,  $C^{op}$ , was calculated using Eq. 5:

$$C^{op} = \sum_j^n C_j^{op}, \quad (9)$$

$$C_j^{op} = C_{j,duty} \times e_{cost} \times O_p, \quad (10)$$

where  $C_j^{op}$  is the operating cost of equipment  $j$  in the synthesis loop defined by Eq 10.  $C_{j,duty}$  is the reported duty of equipment  $j$ ,  $n$  is the number of equipment in the synthesis loop,  $e_{cost}$  is the cost of electricity assumed as 7 cents per kWh, and  $O_p$  is the operating period in hours. The levelized cost of ammonia was then calculated using Eq. 11 [16]:

$$LCOA = \frac{\sum_{t=0}^T \frac{C_t^{cap} + C_t^{op}}{(1+r)^t}}{\sum_{t=0}^T \frac{m_{NH_3}}{(1+r)^t}}, \quad (11)$$

where  $T$  is the lifetime of the plant,  $t$  is the year,  $r$  is the discount rate, and  $m_{NH_3}$  is the annual ammonia production in tons. The LCOA was calculated for each synthesis loop using a 5% discount rate over the 20-year lifetime of the plant with an 90% uptime.

## Parameter Analysis

Four studies were conducted to understand how different model parameters affect the levelized cost of ammonia in CLAS systems. The first study varied the reactor conversion rates between 1%, 5%, and 10%. The second study changed the number of reactors in a series, while varying the reactor conversion. The third study involved a sensitivity analysis on the three reactor Ni-BaH<sub>2</sub> CLAS system, where N<sub>2</sub> conversion, electricity cost, catalyst cost, and plant uptime were varied by ±20% individually to determine their impact on the LCOA. Lastly, in the fourth study, a six-reactor CLAS system was studied using the Ni-BaH<sub>2</sub> configuration with a conversion of 10% to determine the marginal cost of adding more reactors.

## RESULTS

Figure 2 shows the levelized cost of ammonia for the single and three-reactor CLAS systems using Catalyst A, B, and Ni-BaH<sub>2</sub>. The figure identifies a "cost-effective" zone where CLAS systems are more economical than the HB synthesis loop, which costs \$63.9/ton. Catalyst A has the lowest production rate of the CLAS systems studied (105 μmol/g<sub>cat</sub>·h), and due to this it is the least economical option. The low production rate requires more catalyst resulting in larger more expensive reactors and a higher LCOA. Increasing the number of reactors with Catalyst A did not make the system more economical than the HB process as shown in Figure 2. Catalyst B has a higher production rate (2 mmol/g<sub>cat</sub>·h) than Catalyst A; however, it was only economically competitive in a three-reactor setup sized for a 10% conversion. In this case, the addition of more reactors reduced the LCOA of the configuration, to where it could be cost competitive with the HB process. The CLAS with Ni-BaH<sub>2</sub> is the only CLAS system that have economical configurations with the single reactor and the three-reactor setup. The Ni-BaH<sub>2</sub> configuration is less expensive overall due to its high production rate (28 mmol/g<sub>cat</sub>·h) and low temperature operation. The high production rate reduces the amount of catalyst needed which in-turn reduces the reactor size and cost. Additionally, the low temperature operation eliminates

**Figure 3:** The capital contribution of each equipment in the synthesis loops studied where R represents the number of reactors and the percentage represents the N<sub>2</sub> conversion of the reactors.

the need for large external heaters. As a result, its single reactor configuration can achieve a LCOA lower than the HB process. A six-reactor configuration with Ni-BaH<sub>2</sub> was studied and shown to achieve a \$9.73/ton LCOA, which represents an 84.8% reduction over the HB loop. The capital cost of the six-reactor synthesis loop is compared to the HB process in Table 2, showing an 82% reduction in capital costs. Table 2 shows that the compressor costs, inclusive of the driver costs, are the main differences between the two systems.

compressor. In the CLAS systems, the major cost contributor varied significantly which each configuration. In the high temperature chemical loops, the need for an external heater drove up the capital cost making it a major cost contributor. In configurations with Catalyst A, the low production rate of the catalyst resulted in the reactor being the major cost driver in most configurations.

**Table 2:** Synthesis loop capital cost (\$Millions USD), comparing the six-reactor Ni-BaH<sub>2</sub> system to the HB.

Stream	Haber-Bosch	Chemical Loop
Compressor	29.1	4.2
Reactor + Catalyst	0.98	1.10
Heat Exchanger	0.21	0.06
Pump	0.04	0.04
Total	30.33	5.4

**Figure 2:** LCOA for each system, highlighting the “cost-effective zone” where systems outperform the HB loop.

The capital contribution of each equipment in the synthesis loop is shown in Figure 3. In the HB synthesis loop, over 95% of the capital expense is attributed to the

A sensitivity analysis was performed on the three-reactor Ni-BaH<sub>2</sub> CLAS system at 5% conversion. The reactor conversion, electricity cost, catalyst cost, and plant uptime were varied  $\pm 20\%$  and the effects on the LCOA were recorded. Figure 4 presents the change in LCOA as a result of the sensitivity analysis showing that the LCOA is most sensitive to changes in the reactor conversion. A 20% decrease in conversion increased the LCOA by 47%, while a 20% increase in conversion decreased LCOA by 25.5%. A  $\pm 20\%$  change in electricity costs resulted in a proportional  $\pm 11\%$  change in LCOA. Finally, a  $\pm 20\%$  change in catalyst cost and uptime had little effect on the LCOA.

**Figure 4:** Percent change in Levelized Cost of Ammonia (LCOA) in response to a  $\pm 20\%$  change in various model parameters: Tornado Diagram Analysis.

Figure 5 shows the energy demand of the Ni-BaH<sub>2</sub> CLAS configurations compared to the HB system. Figure 5 shows that the CLAS systems can reduce energy demand by 86% compared to the HB process, when a six-reactor configuration is used. However, CLAS systems with low conversion (< 1%) can consume more energy than the HB process. Low conversion systems have a higher recycling rate which requires more energy to operate their compressors. On the other hand, CLAS systems with higher conversion have reduced recycling needs and consequently lower energy demands. Nevertheless, CLAS is a more energy-efficient method for ammonia synthesis as the majority of configurations studied are more energy efficient than the HB system.

**Figure 5.** Energy required to produce 585 tons NH<sub>3</sub> per day from the Ni-BaH<sub>2</sub> CLAS systems compared to the HB system.

## DISCUSSION

This study demonstrates the significant potential of chemical looping ammonia synthesis reactors in reducing ammonia production costs. By operating at a lower pressure (5 atm) compared to the Haber Bosch (HB) reactor (200 atm), CLAS can decrease the synthesis loop cost from \$63.9/ton to \$9.95/ton at a scale of 585 tNH<sub>3</sub>/day. This study shows that the cost reduction in CLAS systems is largely due to lower compressor costs, a major cost factor in the HB synthesis loop. However, these savings are not just due to reduced pressure but also because CLAS operates at lower temperatures, eliminating the need for costly external heating. In contrast to the adiabatic HB reactor, CLAS requires active temperature control. Therefore, focusing on mild temperature ( $T < 300^{\circ}\text{C}$ ), low-pressure CLAS systems could significantly lower ammonia production costs compared to the HB process. This reduction in synthesis cost is achievable today using a Ni-BaH<sub>2</sub> CLAS with reported production values. Among the studied systems, the Ni-BaH<sub>2</sub> CLAS had the lowest LCOA due to its high production rate (28 mmol/g<sub>cat</sub>-h) and low temperature and pressure operation. A three-reactor system using Ni-BaH<sub>2</sub> had a LCOA of \$9.95/ton while the six-reactor system had a LCOA of \$9.73/ton. The additional reactors did not significantly improve the LCOA beyond the three-reactor system.

Despite its low TRL, the equipment similarities between CLAS and HB systems enable early economic evaluations of CLAS. This research highlights contrasting cost dynamics between the equipment in a HB system and a CLAS system. While the HB system has low catalyst costs and high reactor vessel costs, the CLAS system has low reactor vessel costs and high catalyst costs. These cost differences effectively balance each other out when the total reactor costs are considered. In the HB system, the compressor costs are high because of the elevated pressure, whereas the compressor costs in the CLAS system is driven by the high recycle rate. Notably, if reactor conversion in CLAS is too low ( $\leq 1\%$ ), its compressor costs can surpass those of the HB system. CLAS need an external heater, which is an important consideration to factor into future CLAS developments. In this work external heat was provided by an electrically driven heater, alternative renewable heating sources could be studied to reduce the heating costs.

This early economic evaluation sheds light on the economic potential of CLAS systems in development. However, there are three limitations in this work. Firstly, the catalyst production rate at 1 atm is assumed to be the same at 5 atm. CLAS production rates have not been extensively studied at elevated pressures therefore the reported production rate at 1 atm is used. Presumably, elevated pressures would increase the production rate of the CLAS improving the performance of the CLAS studied

and reducing their LCOA. Secondly, the analysis assumes the catalyst can last for the lifetime of the plant. There's a lack of long-term data on catalyst longevity and methods for their regeneration in CLAS systems. Shorter regeneration cycles and rising catalyst costs could significantly impact the levelized cost of ammonia by necessitating frequent expensive catalyst replacement. Lastly, the equipment sizing assumes that nitrogen and hydrogen are present in each equipment simultaneously. This is not accurate because CLAS alternate gas flows, which results in the CLAS equipment being oversized. While this is not optimal, it does provide a margin of contingency in relation to the CLAS cost estimates.

Future research into CLAS should focus on two key areas: the development of low-temperature CLAS systems and the exploration of strategies to maintain catalyst activity. The emphasis on low-temperature CLAS is crucial due to the economic challenges posed by high-temperature systems, which require substantial external heating. On the other hand, given the significant impact of catalyst costs on CLAS economics, finding ways to prolong catalyst life is essential. This involves conducting long-term tests to establish replacement timelines and understand degradation processes. Additionally, it is important to develop environmentally friendly methods for catalyst regeneration.

## CONCLUSION

This study evaluated the technoeconomic potential of chemical looping ammonia synthesis (CLAS) reactors compared to a state-of-the-art Haber Bosch loop using Aspen Plus simulations. Three CLAS configurations were studied, two high temperature CLAS using preliminary catalyst performance data and one low-temperature CLAS using Ni-BaH<sub>2</sub> as a catalyst. Studies were performed focusing on the number of reactors in series, their conversion, and a sensitivity analysis on operating variables. The chemical loop with the lowest LCOA was the low temperature Ni-BaH<sub>2</sub> chemical loop, due to its efficient operation at low temperature and pressure. The Ni-BaH<sub>2</sub> chemical loop could reduce the LCOA by 90% when compared to the HB process, when 6 reactors were simulated in series. The study emphasizes the significance of operating CLAS at moderate temperatures to maximize cost savings because the need for an external heater can diminish the cost benefits of low-pressure operation, as was seen in the high temperature chemical loops. Despite CLAS's low TRL, its integration of existing technologies like compressors, heat exchangers, heaters, and fixed bed reactors make it possible to evaluate their economic viability even at this early stage. Future research should focus on the long-term catalyst degradation and regeneration, and performance at varied pressures to optimize CLAS further. This study underscores the need for

ongoing research to make ammonia synthesis more cost-effective and sustainable.

## ABSTRACT

The growing electrification of buildings and vehicles, while a natural step towards achieving global decarbonization, poses some challenges for the electric grid in terms of power consumption. One way of addressing them is by deploying onsite, behind-the-meter resources (BTMR), such as battery energy storage and solar PV generation. The optimal design of these systems, however, is a demanding task that depends on the integration of multiple complex subsystems. In this work, the optimal integrated design and dispatch of BTMR systems for retail buildings with electric vehicle fast charging stations is addressed. A framework is proposed, combining high-fidelity simulation (of buildings, electric vehicle fast charging stations, and BTMR), predictive control strategies with closed-loop implementation, and a derivative-free design method that explores parallelization and high-performance computing. Focus is given to the design layer, highlighting the effect of parallelization on the choice of the method, computational effort, and types of results. A case study of a big-box grocery store with an EV fast charging station is presented, and its optimal BTMR system is identified in terms of equipment sizes, costs (capital, utility, lifecycle, and levelized) and resiliency against outages, demonstrating great potential for real-world applications.

**Keywords:** Battery Energy Storage, Distributed Generation, Electric Vehicle Fast Charging, Model Predictive Control, Derivative-free Optimization.

## INTRODUCTION

Electrification is held as one of the fundamental pillars for achieving widespread decarbonization, especially for historically fuel-dominated sectors such as transportation (now the largest contributor to greenhouse gas emissions in the United States [1]). This trend, however, comes with its own challenges. Widespread electrification will generate loads not seen in the past – a single electric vehicle (EV) fast charger can have a comparable load to an entire commercial building or hundreds of single-home residences, while a fast charging station can overshadow its building counterpart [2]. These loads, if not addressed adequately, will incur hefty penalties in the form of utility charges and power distribution upgrades.

One way of reducing the peak demand and overall energy consumption of these systems is by employing onsite, distributed, behind-the-meter (BTM) resources (BTMR), such as energy storage and generation – battery storage and solar PV generation being the most notable

examples – as shown in Figure 1. This allows the system to generate renewable solar energy during the day and store it for later when either demand or prices are high (reducing both energy and demand charges), as well as to reduce the peak demand by charging the battery in advance and using it instead of the grid to meet the system's demand (reducing demand charges).

The design of BTMR systems, however, is a challenging task integrating multiple time scales, complex subsystems and application-specific parameters (e.g., expected building and EV charging loads, climate data, utility tariff, and power distribution capacity). The most cost-effective design of such systems also depends on their day-to-day operation in response to all these factors over long time periods. Moreover, the high variability of loads such as for EV fast charging requires a high-resolution time step to accurately predict system sizes.

Several tools and works have addressed this problem in the past. REopt [4], DER-CAM [5], and DER-VET [6] are examples of free software tools, while HOMER and

Energy Toolbase are examples of commercial software. The majority of these tools employ a structured, mixed-integer linear programming (MILP) optimization framework that solves an integrated design and dispatch problem. This allows the representation of a large variety of technologies [4], buildings and microgrid configurations [5, 6], but hinder accuracy. The building (and EV charging) loads are typically treated as exogeneous inputs, obtained from historical records or pre-computed hypothetical profiles. Detailed simulation models, essential for capturing equipment performance and financial mechanisms and validating the solutions generated by the simplified dispatching models, are not supported. The closed-loop implementation of the control solutions is also a critical missing component, overlooking forecast errors and their associated limitations (the projection of peak demand charges over the following month being one of the biggest challenges). Lastly, 1 minute time discretization, required to capture EV fast charging dynamics, are difficult to implement (using a year-long horizon, necessary for solar generation) without facing scalability issues.

**Figure 1.** Diagram of behind-the-meter resources. (adapted from [3])

To address these limitations, a novel framework is proposed for simulation-based design of BTMR. This framework is used as the basis for the NREL tool EVI-EDGES (Electric Vehicle Infrastructure - Enabling Distributed Generation and Energy Storage) [7].

## METHODOLOGY

An overview of the methodology framework is presented in Figure 2. Each individual component is described in the following subsections.

<sup>1</sup>Electrical loads can be pre-computed depending on the level of detail required  
<sup>2</sup>Not included in this work

**Figure 2.** Methodology for sizing behind-the-meter resources.

## Simulation

The simulation environment is composed by three main components: building, electric vehicle charging station, and BTMR (battery energy storage, PV, thermal storage). In its simplest form, the first two models can be pre-solved before running the framework (for instance, when solving the base case without BTMR), while the third group of models needs to be solved in real-time with the control layer. When thermal storage (either active or passive) is present (in other words, when the operation of building cooling and heating equipment can be shifted in time), the building load depends on the BTMR dispatch and can no longer be detached and pre-simulated [8]. Thus, ideally, all the models would be integrated and solved simultaneously, allowing the consideration of interaction effects between them (e.g., battery thermal gain affecting the building indoor temperature, or EV charging schedule affected by the buildings loads).

## Building

The building thermal and electrical loads are generated using EnergyPlus (U.S. Department of Energy, 2023), a whole building energy simulation program with a rich database of construction material properties that allows the accurate representation of interactions between building zones and environment, and its resulting energy consumption (e.g., heating, cooling, ventilation, lighting, and plug loads). In its most general form, the framework allows passing operating setpoints from the control block to the building simulation, scheduling the operation of electrically-driven HVAC equipment such as chiller or heat pumps, in turn affecting the building's electrical load. The battery is placed inside of one of the building's zones with temperature control, modeling thermal interaction that determines zone cooling loads as well as battery thermal degradation and effects.

## Electric Vehicle Charging Station

The EV fast charging station is simulated using an

agent-based model (NREL's EVI-EnSite [9]). Input data includes probability distributions of vehicle arrival time and arrival state-of-charge (SOC), the number of vehicle arrivals per day or week, as well as general vehicle type-related characteristics, such as battery size and charge acceptance curves (power x SOC). The vehicle charging process is simulated by assigning arriving vehicles to unoccupied charging ports following a certain metric (usually either first-in-first-out, or a managed-charging schedule based on cost minimization). In case all charging ports are occupied, the arriving vehicles are queued and must wait in order to charge. Typically, the charging station design (i.e., number of charging ports and charging port power level) is performed to minimize the queuing time distribution (mean or a certain percentile), the latter constructed empirically by repeatedly sampling the input distributions in a Monte-Carlo fashion.

### BTMR: Battery Energy Storage and PV

A detailed technoeconomic BTM battery storage model from NREL's System Advisor Model (SAM) [10] is employed to simulate the real system's performance (as opposed to the simplified battery model inside of the MPC formulation). This model is able to represent different battery types (lithium-ion, lead-acid, redox flow) and multiple chemistries of lithium-ion batteries (LMO, LTO, LCO, LFP, NMC, NCA) with associated typical voltage curves, thermal behavior, and lifetime degradation profiles.

The solar PV panels are modeled using NREL's PVWatts model [11, 12], which considers a grid-connected photovoltaic system with modules/panels composed by crystalline silicon or thin film photovoltaic cells. Inputs related to the system's physical characteristics include power capacity, module and array types, losses, array orientation (angles) and mounting type, as well as a few built-in module and inverter characteristics.

### Optimal Dispatch/Control

The battery dispatch/control problem is formulated as a Linear Programming (LP) model (Nonlinear Programming depending on the type of battery degradation considered [13], or Mixed-Integer Nonlinear Programming if thermal storage is included [8]). This problem optimizes the adjusted cost of operation of the system (utility costs and battery degradation). A condensed formulation of the LP problem is presented next:

$$\min \phi = C^E + C^D + C^R \quad (1)$$

subject to

$$C^E = \Delta t \sum_t \phi_t^E (P_t^{purch} - \gamma^{nm} P_t^{sold}) \quad (2)$$

$$C^D = \sum_d \phi_d^D \bar{P}_d^{max} \quad (3)$$

$$C^R = (E^{max} - E_{t=t_f}^h) (RCP * EPR + RCE) \quad (4)$$

$$-P_t^{load} + P_t^{pv} + (P_t^{purch} - P_t^{sold}) + (P_t^{out} - P_t^{in}) = 0 \quad (5)$$

$$E_t - E_{t-1} = \Delta t (\eta^{in} P_t^{in} - \eta^{out} P_t^{out}) \quad (6)$$

$$E_{t=t_0}^h S^{min} \leq E_t \leq E_{t=t_0}^h S^{max} \quad (7)$$

$$E_{t=t_f}^h = E^{max} - D E_{t=t_f}^{tp} \quad (8)$$

$$E_{t=t_f}^{tp} = E_{t=t_i}^{tp} + \frac{\Delta t}{2} \sum_t (P_t^{in} + P_t^{out}) \quad (9)$$

$$\bar{P}_{\bar{t}}^{purch} = \frac{\Delta t}{\Delta \bar{t}} \sum_{t \in T_{\bar{t}}} P_t^{purch} \quad (10)$$

$$\bar{P}_d^{max} \geq \bar{P}_{\bar{t} \in \bar{T}_d}^{purch}, \bar{P}_d^{max} \geq \bar{P}_d^{max,i} \quad (11)$$

where **indices** include the time step  $t \in T$  (initial and final time steps  $t_i$  and  $t_f$ ); 15-min average time step  $\bar{t} \in \bar{T}$ ; and demand charge periods  $d \in D$ . **Special sets** include  $T_{\bar{t}}$  (all time steps  $t$  inside of each 15-min average time step  $\bar{t}$ ); and  $\bar{T}_d$  (all average time steps  $\bar{t}$  inside of each demand period  $d$ ).

**Parameters** include the difference between time steps  $\Delta t$  and  $\Delta \bar{t}$  (hours); battery installed cost per power  $ICP$  (\$/kW) and per energy  $ICE$  (\$/kWh); battery replacement cost per power  $RCP$  (\$/kW) and per energy  $RCE$  (\$/kWh); time-of-use energy prices  $\phi_t^E$  and demand prices  $\phi_d^D$ ; net-metering factor (representing the lesser value of selling power to the grid as opposed to purchasing it)  $\gamma^{nm}$  (decimal); battery charging and discharging efficiencies  $\eta^{in}$  and  $\eta^{out}$  (decimal), battery degradation per energy throughput  $D$  (decimal/kWh); energy to power ratio  $EPR$  (kWh/kW) (from design layer); minimum and maximum state-of-charge  $S^{min}$  and  $S^{max}$  (decimal); and the 15-min peak power demand from the previous day for each demand charge period  $\bar{P}_d^{max,i}$  (kW). **Forecasted parameters** include the system electrical load (sum of building and EV charging)  $P_t^{load}$  (kW), and PV generation  $P_t^{pv}$  (kW).

**Variables** include the battery power charged and discharged  $P_t^{in}$  and  $P_t^{out}$  (kW); the battery energy  $E_t$  (kWh), throughput  $E_t^{tp}$  (kWh), and health  $E_t^h$  (decimal); power purchased from and sold to the grid,  $P_t^{purch}$  and  $P_t^{sold}$  (kW); 15-min average purchased power  $\bar{P}_{\bar{t}}^{purch}$  and maximum purchased power in each demand period  $\bar{P}_d^{max}$  (for demand charge calculations). All variables are non-negative reals.

The **objective function** (1) minimizes energy cost  $C^E$  (\$), demand cost  $C^D$  (\$), and battery replacement cost  $C^R$  (\$). **Constraints** include cost calculations (2-4); power balance (5); battery energy storage difference equation (6); battery energy bounds based on its health (7); battery health at the end of the control window as a function of its energy throughput (8); battery energy throughput definition (9); 15-min averaging of power purchased from the grid (10); and 15-min peak demand power calculation (11).

A control horizon of 1 day is used (typical for short-duration energy storage problems with diurnal patterns), with a recalculation frequency of 1 day and a time step discretization of 1 minute to accurately capture the high variability from EV charging loads (battery and power distribution must be sized with the instantaneous load instead of averages). After each horizon is solved, a time series of control setpoints is provided to the simulation for evaluating the response of the subsystems and updating the stationary battery health. Then the final system state from the simulation is set as initial point of the successive control problem.

## Optimal Design

Under the formulation described above, the overall design problem can be posed as a nested optimization problem, in which each evaluation of the design layer depends on the solution of a lower-level layer consisting of several coupled control optimization subproblems, further complicated by their closed-loop implementation in the simulation environment. The objective function (system lifecycle cost) is also time-consuming to evaluate (in the order of hours), which makes approximating the derivatives via finite-difference methods an ineffective approach. For these reasons, only derivative-free (black-box) optimization methods were considered [14, 15].

These methods are generally classified according to the properties of the black-box oracle function [15], which in the present case is assumed to be deterministic, generally nonconvex and non-smooth, multimodal (although empirically observed to be unimodal), unconstrained, with bounded feasible region (decision variables are typically nonnegative real variables, with upper bounds determined from space and weight constraints or heuristics), and time-consuming evaluation (hours). The latter is a key characteristic that prohibits or hinders the application of direct-search methods such as Nelder-Mead (with a low number of simplex vertices) or trust-region methods, which require several iterations to converge.

The ability to parallelize (concurrent) function evaluations is considered as a critical feature to determine the choice of method. Most optimization methods tend to minimize the total number of function evaluations over the entire algorithm, as opposed to minimizing the time required to solve the problem (typically proportional to each other). When each function evaluation is time consuming, however, it is more efficient to parallelize as many concurrent evaluations as possible, then use the ensemble information to perform the search.

## Sequential Grid Search Method

A sequential grid search method is employed, which samples the decision space using symmetric hypercubes that begin by covering the whole feasible space and shrink around the observed optimum after each iteration.

In other words, after each iteration, the optimum point is identified between two (if the solution lies at the bounds) or three (if it falls in the middle) grid points in each direction, which are set as the new bounds for the reduced grid at the next iteration (previously evaluated points are reused for the new grid to reduce effort). The number of function evaluations for each iteration depends on the number of discrete points in each of the grid's independent coordinates (variables). For a problem with three decision variables, the number of evaluations will then be equal to the number of points to the power of three. This points out the major deficiency of this approach, which is its scalability with the number of decision variables. While it is efficient for this problem setup, it becomes more challenging when including other design variables (e.g., TES or charging station). The method is illustrated in Figure 3, showing the evolution of the grid and optimal point throughout subsequent iterations.

After each iteration, a surrogate model can be fitted and the next-iteration grid can be generated around the surrogate optimum instead of the sampled one. However, the benefit of this approach is not guaranteed, as it depends on how well the surrogate represents the real underlying function. If the surrogate model does not capture the function appropriately, it can mislead the search and affect it negatively, adding iterations and increasing the runtime. It was empirically observed that low order polynomial models do not add a significant value in predicting the true optimum location and were thus not employed.

**Figure 3.** Illustration of a 3-dimensional sequential grid search with 5 points in each direction and 3 iterations. used to interpolate the optimum location.

## Accuracy and Computational Effort

The upper bound on the final accuracy level  $\delta x_{n_i}$  (difference between two evaluated points) after  $n_i$

iterations, using  $n_p$  points in each direction (assuming the same number of points for all directions), and starting with an initial range  $\Delta x_0$ , is given in (12). Solutions obtained at the grid boundaries at any iteration will have a better accuracy due to its one-sided shrinkage (as opposed to two-sided shrinkage necessary for non-boundary solutions).

$$\delta x_{n_i} = \frac{(2^{n_i-1} \Delta x_0)}{(n_p-1)^{n_i}} \quad (12)$$

Two ways of refining the solution accuracy consist in increasing the number of evaluation points ( $n_p$ ) or number of iterations ( $n_i$ ). To guide the parameter tuning decision, the final solution accuracy (relative to the initial range  $\Delta x_0$ ) and computational effort (in terms of core-hours, a typical measure for HPC systems) are presented in Table 1. It is assumed that each design evaluation point (one year simulation with closed-loop optimal control) has a runtime of approximately 2 hours, and that the number of cores equals the number of evaluated design points. Cells with final solution accuracy under 1% of the initial range are highlighted in bold in both tables.

**Table 1:** Solution accuracy and computational effort over varying number of grid points (cols) and iterations (rows).

$n_p$	4	5	6	7	8	9	10	$h$

8	1024	2000	3456	5488	8192	11664	16000	16
9	1152	2250	3888	6174	9216	13122	18000	18
10	<b>1280</b>	2500	4320	6860	10240	14580	20000	20

For the presented setup, the number of grid points should be equal or greater to 5 (using 4 points requires at least 10 iterations, which would entail 20 hours of runtime), while the appropriate number of iterations varies between 3 and 6 (runtime of 6 and 12 hours). The bottom table shows that computational effort increases more rapidly with the number of grid points (total number of evaluations/cores per iteration is given by  $n_p^3$ ) than iterations, although the latter increases runtime linearly by 2 hours. The final setup (grid coarseness and number of iterations) should thus be a function of several factors, including required solution time, number of parallel cores

available, and acceptable solution accuracy.

In summary, a few conditions that encourage the application of this method include time-consuming objective function evaluation (in the order of hours); small number of design variables (up to 3 or 4); high parallelization (100s of concurrent function evaluations); bounded feasible region; and an acceptable final solution accuracy within 1% of initial range.

## CASE STUDY

### Building Model

A big-box grocery store building energy model, developed and validated in [2], was employed in this work. This represents a common type of commercial building in the United States, at which EV fast charging stations are expected to be increasingly deployed in the near future – fast charging stations in retail buildings will attract customers and bring additional revenue, increasing business competitiveness, while also providing charging access to disadvantaged areas with lacking access to home charging. The building model has 18 thermal zones, 136 surfaces, and 263 sub-surfaces (e.g., windows, doors), and an area of approximately 20,000 m<sup>2</sup>. Figure 4 presents the 3D model of the building, with different zones roughly separated by solid roof lines, while the electrical load generated by the building (from HVAC and plug loads) is presented in Figure 5.

**Figure 4.** 3D model of the generic big-box grocery store from OpenStudio.

### Electric Vehicle Charging Loads

A fast charging station with two 150 kW charging ports and 6 events per port per day was simulated. The load profile is presented in Figure 6. Default inputs for commonly used EVs were employed (vehicle battery size, charge acceptance curves), while the probability distributions (vehicle arrival time and SOC) were correlated to the building occupation patterns. The load has a high variability (spikiness), which may not significantly increase the total energy consumption, but will likely result in a higher peak demand, affecting the sizes of both the power distribution system and energy storage, as well as utility demand charges.

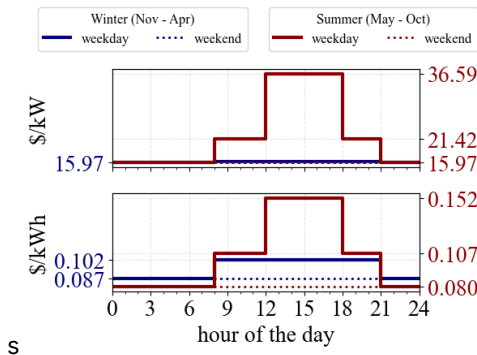

**Figure 5.** Building electrical load over a week for all weeks in a year.

**Figure 6.** Violin plot (left) and weekly profile (right) of EV fast charging electrical load (one week shown as the dark line, remaining weeks in the background).

### Utility Rate Structure

A utility rate tariff structure based on a high-price region (PG&E in Northern California) is used. The demand and energy prices are shown in Figure 7.

**Figure 7.** Utility rate tariff: demand (top) and energy (bottom) prices.

### Location/Weather Inputs

The most relevant location-dependent weather parameters are presented in Figure 8, namely, ambient temperature (which drives the building energy consumption and equipment efficiency) and solar irradiance (which drives building heat gains and solar PV power generation). The city of Tucson, AZ, was chosen as the location for the study.

**Figure 8.** Weather inputs.

### Remaining Inputs

A summary of the remaining inputs and settings is presented in Table 2.

**Table 2:** Remaining inputs.

Input	Value
Life-cycle Analysis Horizon	20 years
Discount Rate	8.3%
Battery Installed Cost	\$540/kW + \$120/kWh
PV Installed Cost	\$1600/kW
PV initial range	0 – 2,000 kW
Battery initial range	0 – 5,000 kW 0 – 10,000 kWh
Forecast Method	Perfect
PV annual degradation	0.5%
Battery usable SOC range	10 – 90%
Battery Chemistry	LMO-LTO
Battery cost de-escalation rate for replacement	6%/year
Battery replacement capacity threshold	60%
MPC time horizon	24 h
MPC time step	1 min
MPC demand charge time averaging	15 min

## RESULTS

The problem was solved using NREL's high-performance computing system Kestrel with dual socket Intel Xeon Sapphire Rapids (52-core) processors, 104 cores per CPU node, and 256 GB DDR5 memory. The sequential grid method was applied with 5 points and 6 iterations, achieving an accuracy upper bound of 0.8% of the initial range (or lower).

## Design Solution: System Sizes and Costs

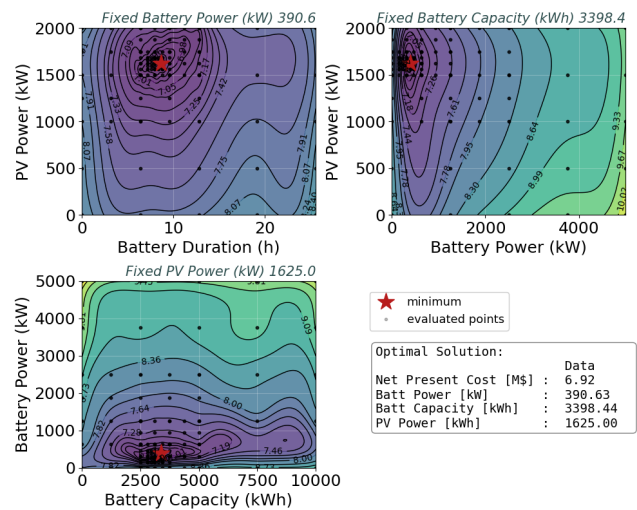

The main results of the analysis are presented in Table 3 for the base case (without BTMR), and the BTMR case (both cases with the EV charging station). The identified BTMR system consists of a battery with 390.6 kW capacity and 8.7 hours of duration, and a PV capacity of 1625 kW, highlighting the potential for PV deployment in locations with high solar incidence. Their associated capital costs follow a similar trend, being dominated by the large PV deployment and its higher unit cost. In this setting, the EV supply equipment (EVSE) capital cost is only a fraction of the BTMR system (which is not always the case, specially for commercial fleets). The benefits of BTMR deployment are shown in the metrics associated with electricity consumption and utility costs. Annual energy and peak demand are significantly reduced (by over half), in turn reducing their associated utility-related charges. The Levelized Cost of Charging (LCOC) (as defined in [13]) demonstrates the positive impact that BTMR systems can have on fast charging station deployment, decreasing from \$0.33/kWh (a typical value in the US) to -\$0.96/kWh (negative value representing the fact that the BTMR system reduces the total operating cost more than the EVSE increases it). Finally, the lifecycle net-present cost (adjusted capital and operating cost) indicates that the BTMR system increases profit gains by \$1.41 million over the system's lifetime.

## Sensitivity Analysis

One of the benefits of evaluating a grid of points (as opposed to a narrow search employed by most derivative-based methods) is that the sensitivity of the objective with respect to the decision variables can be evaluated. This allows the decision maker to identify design solutions with low sensitivity (in which adjusting a design variable does not significantly affect the objective function), adding more flexibility and confidence to the final design solution. Figure 9 shows contour plots of net-present cost with respect to two decision variables at a time (fixing the remaining one at its optimal value). Black dots represent points evaluated during the design procedure, while contour lines are generated performing interpolation using cubic radial-basis functions (RBF). The top-left plot shows a balanced effect between the two variables, with nonconvexities arising for large battery duration values. The top-right plot indicates that the battery power affects the design solution more significantly than PV size (contour lines are closer to each other). A similar trend is observed in the bottom-left plot, where battery power seems to affect the objective more significantly than battery capacity/duration. The ripples and non-convexities shown in the contour lines (more pronounced in the top-left plot) indicate a possibly low quality of the interpolation fit. One way of improving it would be to use a larger number of grid points in the design method.

**Table 3:** Overview of results: system sizes and costs.

Variable	Base Case	BTMR
<i>System Sizes</i>		
Battery Power	--	390.6 kW
Battery Storage (Duration)	--	3398.44 kWh (8.7 h)
PV Power	--	1625.0 kW
<i>Capital Costs</i>		
Battery Capital Cost	--	\$618,750
PV Capital Cost	--	\$2,600,000
EVSE Capital Cost	\$308,400	\$308,400
<i>Electricity Consumption</i>		
Energy from Grid	5,392 MWh/year	2,280 MWh/year
Monthly Peak Demand	1031.81 kW max 891.65 kW mean	695.39 kW max 579.62 kW mean
<i>Utility Costs</i>		
Energy charges	\$527,449/year	\$193,558/year
Demand charges	\$321,538/year	\$147,930/year
<i>Levelized Costs</i>		
EV Charging	\$0.33/kWh	-\$0.96/kWh
Energy (Electricity)	\$0.16/kWh	\$0.13/kWh
<i>Lifecycle Costs</i>		
Net Present Cost	\$8.33 M	\$6.92 M
Net Present Value	--	\$1.41 M

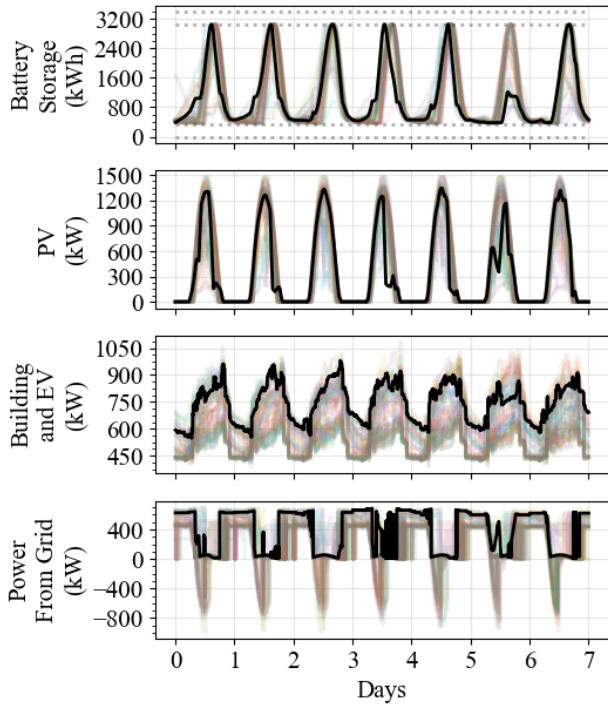

**Figure 9.** Contour plots of net present cost with respect to system design variables.

## Dispatch and Load Profiles

The storage dispatch and load profiles (PV generation, building and EV loads, and power purchased from or sold to the grid) are presented in Figure 10. The first two subplots highlight the synergistic effect between battery

storage and PV generation, the former being discharged soon after the latter starts to decrease. The timing between PV generation and the building and EV charging loads also works in favor of BTMR, allowing most of the solar electricity generated onsite to be directly used to address the load. Finally, the power purchased from the grid shows a significant reduction in peak power demand (as well as energy consumption), inverting the time in which it happens from day to night, and the utilization of the net-metering mechanism to sell electricity back to the grid (despite its price being substantially lower than the purchase) during periods with solar generation surplus.

**Figure 10.** Dispatch and load profiles over all weeks in a year (week 26 highlighted as the dark solid line).

### Resiliency against power outages

The cost-optimal BTMR system sized in the previous section also has the added benefit of providing resiliency against grid interruptions. That is, whenever there is an interruption in the power grid service (average of 4 hours, 1.4 times per year in the United States [16]), the battery storage (and PV generation) can be used to meet the system's electrical load. However, since the battery operates according to a cost-optimal dispatch, there is no guarantee that it will be able to meet that load. To assess this, the battery's SOC at all time steps in the simulated year was used to estimate its resiliency potential (how many time steps into the future it would be able to meet the system's load). The result is a probability distribution of resiliency hours, presented in Figure 11. The bar plots show the resiliency histogram with two levels of

time step granularity (hourly and 15-min intervals). This graph represents the probability that the provided resiliency will be inside of each time interval (e.g., 29% between 0 and 1 hours, or 21% between 45 and 60 minutes). The solid line represents the inverse cumulative distribution function (with 15-min intervals), or the probability that the BTMR will provide over  $n$  hours of resiliency (e.g., 75% of the time the system provides over 1 hour of resiliency). The BTMR system provides over 30 minutes of resiliency 100% of the time, meaning that it can naturally address small outages without having to change its dispatching priorities, and can potentially meet up to 23 hours of future load.

**Figure 11.** Resiliency provided by the cost-optimally-sized BTMR (battery + PV).

## CONCLUSIONS

In this work, the optimal integrated design and dispatch of Behind-the-Meter Resources (BTMR) (i.e., battery energy store and PV generation) for retail commercial buildings with EV fast charging stations was addressed. A novel modeling framework was proposed, integrating detailed simulation models (of building, electric vehicle fast charging station, and BTMR equipment), model predictive control (MPC) strategies for equipment dispatch with closed-loop implementation, and a derivative-free design layer that leverages parallelization and high-performance computing. A sequential grid search method was employed to solve the design problem, balancing accuracy and computational effort. Results from a case study involving a big-box grocery store retail building model highlight the benefits of BTMR in reducing energy and peak demand charges, by generating clean electricity onsite, and shifting power purchases from the electric grid. Contour plots of lifecycle cost, generated by leveraging the parallel evaluations from the design method, indicate the design variables that have the biggest impact on the objective. Finally, the system's resiliency under grid outages was also evaluated, demonstrating a good potential for replacing fuel-based alternatives.

Ideas for future work include expanding the case

study to assess the potential of BTMR for retail buildings across multiple locations and utility rates; including a resiliency-based cost in the dispatch objective; considering the effect of forecast errors of future electrical load (from both building and EV charging station) in the control problem; and including carbon emissions in the design and dispatch optimization objectives.

## ABSTRACT

The chemical industry is actively pursuing energy transition and decarbonization through renewables and other decarbonization initiatives. However, navigating this transition is challenging due to uncertainties in capital investments, electricity costs, and carbon taxes. Adapting to decarbonization standards while preserving existing valuable infrastructure presents a dilemma. Early transitions may lead to inefficiencies, while delays increase the carbon footprint. This research proposes a framework to find an optimal retrofit decarbonization strategy for existing oil refineries. We start with a generic process flowsheet representing the refinery's current configuration and operations, and consider various decarbonization alternatives. Through superstructure optimization, we identify the most cost-effective retrofit strategy over the next three decades to achieve decarbonization goals. We develop a Mixed-Integer Linear Programming (MILP) model, integrating simplified process equations and logical constraints to identify the most economical retrofit decarbonization strategy. The paper presents numerical results from the MILP model. Furthermore, the trends exhibited by the outcomes across various scenarios considering distinct electricity costs and carbon tax levels are presented. These results provide valuable insights into the economic feasibility of retrofit electrification strategies for decision-makers in the chemical industry.

## INTRODUCTION

The 2021 UN Climate Change Conference (COP26) stressed the urgent need to reduce global greenhouse gas emissions to limit global warming to 1.5°C [25]. This goal coupled with a global increase in energy consumption has urged nations to accelerate the adoption of low-emission energy systems. There is a pressure for the chemical industry to embrace emerging low-carbon technologies [16] [8].

Decarbonization of oil refineries is challenging due to their diverse configurations and high operational efficiencies. One potential pathway for decarbonization involves incorporating low-carbon feed into refinery operations. Retrofitting a fossil-based refinery to use a biomass-based feed over a time horizon of 10 years has been studied in [30] using a Mixed-Integer Linear Programming (MILP) model. Currently, significant effort is directed towards reducing scope 1 [32] emissions by electrification of process heat & hydrogen and the use of

carbon capture and storage techniques. Other possible pathways involve the use of carbon capture technologies and/or electrification of hydrogen production and steam generation integrated within existing refinery infrastructure (see Fig. 1 (a)) which are described below.

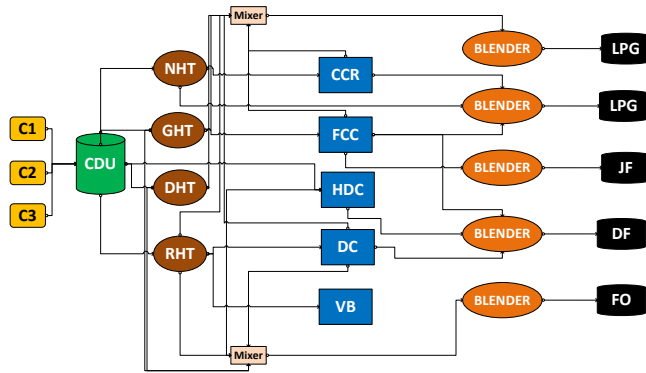

### Carbon capture (CC) Techniques

Post-combustion, pre-combustion, and oxy-combustion are the primary techniques for carbon capture (CC) [18]. Post-combustion capture suits low CO<sub>2</sub> concentration flue gas, while pre-combustion applies to gasification plants. Oxy-combustion involves burning fuel in an oxygen-rich environment. This study exclusively focuses on pre- and post-combustion capture due to their ease of retrofitting existing operations. [22, 24, 28, 12]

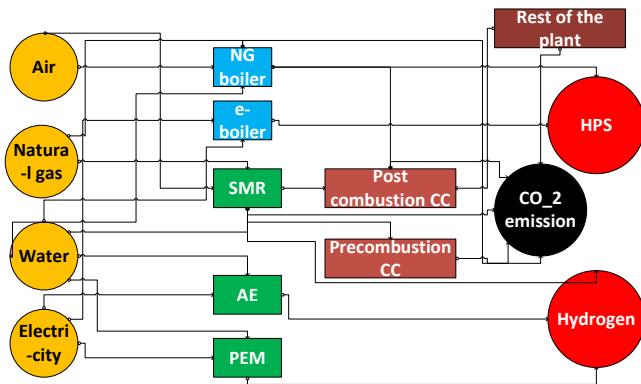

### H<sub>2</sub> production

One approach for decarbonizing H<sub>2</sub> production is through blue H<sub>2</sub> production, where SMR (Steam Methane Reforming) and WGS (Water Gas Shift) reactors are augmented with pre-combustion CC [9]. Alternatively, the flue gas

from these reactors, after extracting hydrogen through adsorption-based separation, can be mixed with flue gas from other plant sources. This mixture allows for absorption-based post-combustion CC. Another method for decarbonizing H<sub>2</sub> production involves using renewable electricity for the electrolysis of water, producing green hydrogen [21, 20, 15, 27]. We focus on the use of low-temperature electrolyzers, such as Alkaline Electrolyzers (AE) and Proton Exchange Membrane Electrolyzer (PEME), due to their level of maturity (AE), efficiency, and adaptability to handling variable operational conditions (PEME) [7].

**Fig 1(a)** : Generic Flowsheet for an oil refinery; CT denotes different types of crude oil fed to Hydrotreating units—NHT (Naphtha Hydrotreater), DHT (Distillate Hydrotreater), GHT (Gas Oil Hydrotreater), and RHT (Residue Hydrotreater)—further treated in processing Units: CCR (Continuous Catalytic Reformer), HDC (Hydrocracking), FCC (Fluid Catalytic Cracking), DC (Delayed Coking), and VB (Visbreaking); Output streams are blended in desired proportions to produce LPG (liquified petroleum gas), JF (Jet Fuel), DF (Diesel Fuel), FO (Fuel Oil); adopted from [29]

**Fig 1(b)**: Superstructure with possible pathways for hydrogen and HPS (high-pressure steam) production: considered routes for H<sub>2</sub> production include Gray H<sub>2</sub>, Blue H<sub>2</sub>, and Green H<sub>2</sub> (using PEME or AE); HPS generation alternatives encompass utilization of Natural Gas (NG) Boilers or e-boilers; Blue hydrogen can be synthesized employing either pre-combustion or post-combustion

techniques; the flue gas released from the rest of the plant is captured by post-combustion CC.

## Process heat

In the refinery, most of the heating demands are met using steam. Boilers in Fig 1 (b) generate only HPS. MPS and LPS are obtained from HPS by reducing the pressure with let-down valves. Other heating needs are fulfilled by furnaces tailored to individual unit operations in the refinery. To simplify the analysis, we assume that flue gas from these sources can be collected and treated by post-combustion CC units. Currently, steam production relies on gas boilers that burn natural gas. Electric boilers (e-boilers) are a possible greener replacement for gas boilers due to their easy installation, control, and maintenance, as well as higher thermal efficiency. e-boilers can also be easily retrofitted with renewable power sources, offering a more sustainable option for steam generation [26].

## The gap: Electrification from a systems perspective

While market-ready technologies exist and techno-economic analysis are available for individual decarbonization initiatives, there is a lack of literature on how these initiatives can be optimally combined to retrofit existing units cost-effectively. As emphasized in [33] since the heat and mass flow between units are interconnected in a chemical industry it is extremely critical to perform a systems level analysis to perform for decarbonization or electrification planning. This work develops a tool for planning a transition towards such a retrofit solution, which can cater to each specific oil refinery at a given location.

## PROBLEM STATEMENT

Existing literature discusses some market-ready technologies for alternative decarbonized technologies [17] but lacks a clear framework for understanding which ones should be chosen, when these alternative technologies should be implemented, and how they could be optimally integrated. This paper aims to fill this gap by developing a comprehensive decarbonization plan that is applied to a given oil refinery operating over 29 years (2022-2050). The plan involves strategic selection and timely implementation of the best set of initiatives for retrofitting the supply of HPS and hydrogen to the given refinery (by addition and removal of units and interconnections), considering operating data for a typical crude-based refinery with a distillation capacity of 100 kbbbl crude oil per day. The objective is to minimize the Present Value of the cost for decarbonization retrofit design, while meeting predefined environmental commitments.

## METHODOLOGY

Fig. 1 (b) shows a superstructure representing potential pathways for High-Pressure Steam (HPS) generation, hydrogen production, and CC.

The variables used in the model are,  $F_{i,j,k,yr}$ , a positive continuous variable representing the amount of component  $k$  present in a stream flowing from unit  $i$  to unit  $j$  in year  $yr$ .  $y_{i,yr}$  ( $m_{i,yr}$ ), a binary variable indicating whether the installation of a specific unit of technology  $i$  (e.g. PEME, AE) is initiated (completed) in year  $yr$ .  $z_{i,yr}$  ( $p_{i,yr}$ ), a non-negative integer variable indicating the number of initiated (completed) installations in year less than or equal to  $yr$  for units of technology  $i$ .  $Q_{i,yr}$ ; ( $QE_{i,yr}$ ), a continuous variable indicating the total (expansion in) installed capacity of a technology  $i$  in a given year  $yr$ .

### Logic Timing constraints

Eqs. (1) and (2) capture the relationships between the described binary variables.

$$\sum_{yr=1}^l y_{i,yr} = z_{i,l} \quad \forall i, l \quad (1)$$

$$\sum_{yr=1}^l m_{i,yr} = p_{i,l} \quad \forall i, l \quad (2)$$

These Eqs. are valid for all years in the range 1-29 unless specified otherwise. Furthermore, additional logical constraints are added to specify that  $z$  and  $p$  are time-lagged copies of  $y$  and  $m$  respectively depending on the duration of installation of each equipment. Flow to units of technology  $i$  is non-zero if the installation of any unit of  $i$  has been completed by a given year. This relationship can be expressed as an upper bound constraint, shown in Eq. (3):

$$F_{i,j,k,yr} \leq UB * p_{i,yr} \quad (3)$$

### Mass Balance constraints

The proposed formulation requires specifying that flow can take place only when the units are connected in the superstructure.

$$F_{i,j,k,yr} = 0 \quad \forall j \notin \text{Out}(i), \forall k, \forall yr$$

Additionally, equations specify that air, natural gas, water, and electricity are obtained from their respective supply nodes.

Mass Balance constraints given by Eqs. (4) and (5) relate the amount of components present in inlet and outlet streams to reactors and separators through simplified yield-based models. In Eq. (6),  $\mu_{in,j,k}$  represents the amount of reactant  $k$  reacting with a certain amount of reactant  $k'$  in unit  $j$ , denoted as  $\mu_{in,j,k'}$ . Similarly, in Eq. (5),  $\mu_{out,j,k}$  denotes the amount of product  $k$  in the outlet stream of unit  $j$ , given a certain amount of reactant  $k'$  in the inlet stream.

$$\sum_{i \in \text{In}(j)} F_{i,j,k,yr} = \frac{\mu_{in,j,k}}{\mu_{in,j,k'}} \sum_{i \in \text{In}(j)} F_{i,j,k',yr} \quad (4)$$

$$\sum_{i \in \text{Out}(j)} F_{j,i,k,yr} = \frac{\mu_{out,j,k}}{\mu_{in,j,k'}} \sum_{i \in \text{In}(j)} F_{i,j,k',yr} \quad (5)$$

$$k \in \{\text{Relevant Components, Electricity}\} \\ \forall i \in \{\text{Reactors, electrolyzers, boilers}\}$$

Here, the notations  $\text{In}(j)$  and  $\text{Out}(j)$  represent the set of nodes connected at the inlet and outlet of node  $j$  respectively.

For the CC units, a component-wise mass balance constraint is applied, as no reactions occur. The constraint is represented by Eq. (6)

$$\sum_{i \in \text{Out}(j)} F_{j,i,k,yr} = \sum_{i \in \text{In}(j)} F_{i,j,k,yr} \quad \forall j \in \text{CC units} \quad (6)$$

Additional constraints are imposed to guarantee the specified purity of the final streams.

### Energy Balance Constraints

Energy balances for Natural Gas (NG) boiler, e-boiler, and electrolyzers are given by Eqs. (7), (8) and (9) respectively.

$$F_{\text{NG Supply, NG Boiler, NG, yr}} LHV_{\text{NG Boiler}} \eta_{\text{NG boiler}} = F_{\text{Water Supply, NG Boiler, NG, yr}} \Delta H_{\text{vap}} \quad (7)$$

$$F_{\text{Grid, e-boiler, electricity, yr}} \eta_{\text{e-boiler}} = \Delta H_{\text{vap}} F_{\text{H}_2\text{O supply, e-boiler, H}_2\text{O, yr}} \quad (8)$$

$$F_{\text{electrolyzer, H}_2\text{ requirement, Hydrogen, yr}} \Delta H_{\text{electrolysis}} = F_{\text{grid, electrolyzer, Electricity, yr}} \eta_{\text{electrolyzer}} \quad (9)$$

$\eta$  denotes the energy efficiency of equipment and LHV is the Lower Heating Value of natural gas.

### Design Constraints

The values of the total HPS and hydrogen produced by all the different pathways must match the total hydrogen and HPS requirements of the refinery. The amount of CO<sub>2</sub> captured and emitted after passing through CC units are linearly related by a constant factor given by the efficiency of the respective CC equipment. Similarly, the steam produced and the losses through the purge stream (blowdown) from the boilers are linearly related by a constant factor.

The amount of CO<sub>2</sub> and other gases present in the flue-gas released from the rest of the operations in the refinery are specified by constraints. Decarbonization goals of the refinery impose an upper limit on the emissions as shown in Eq. (10)

$$\sum_{i \in \text{In}(\text{CO}_2 \text{ emission})} F_{i, \text{CO}_2 \text{ emission, CO}_2, yr} \leq \text{CO}_2 \text{ cap}_{yr} \quad (10)$$

Eq. (11) imposes a logical constraint on the capacity expansion in any year  $\forall i \in \text{PEM, AE, e-boiler, CC units}$ .

$$LB_1 m_{i,yr} \leq QE_{yr} \leq UB_1 m_{i,yr} \quad (11)$$

Eq. (12) evaluates the total capacity at the end of any year  $yr$ . [23, 19]

$$QE_{i,yr} + Q_{i,yr-1} = Q_{i,yr} \quad (12)$$

Eqs. (13) and (14) state that the operating flowrate or power is less than the installed capacity.

$$F_{grid,i,electricity,yr} \leq Q_{i,yr} \quad (13)$$

$$\forall i \in e - boiler, electrolyzer$$

$$F_{CC unit,CO_2 captured,CO_2,yr} \leq Q_{CC unit,yr} \quad (14)$$

We consider that the capacity expansion for e-boiler and CC facilities can take any value within a continuous range, whereas the expansion of electrolyzer capacity can only take discrete values based on available standard sizes. To handle this, we introduce binary variables  $w_{i,h,s,yr}$  which denote whether, in year  $yr$ , the  $h^{th}$  electrolyzer ( $h \in \{1, \dots, H\}$ ) of type  $i \in \{PEM, AE\}$  is of the  $s^{th}$  size  $s \in \{Available\ discrete\ sizes\}$ , with  $d_{i,s}$  denoting the available sizes for each type of electrolyzer.

Eq. (15) adds the size of all installed electrolyzers to calculate the total capacity expansion in any given year [10]. Eq. (16) ensures that at most one size is chosen for every electrolyzer. Eq. (17) is added in order to avoid degenerate solutions.[6]

$$\sum_{h=1}^H \sum_{s=d_{1,s}}^{d_{1,s}} w_{i,h,s,yr} d_{i,s} = QE_{i,yr} \forall i \in PEM, AE \quad (15)$$

$$\sum_s w_{i,h,s,yr} \leq 1 \forall i \in PEM, AE \quad (16)$$

$$\sum_s w_{i,h,s,yr} d_{i,s} \geq \sum_s w_{i,h+1,s,yr} d_{i,s} \quad (17)$$

## Cost Constraints and Objective function

Eq. (18) & (19) incorporate an upper limit on the annual capital expenditure (CAPEX) that can be allocated.

Eq. (18) shows that the total CAPEX for an expansion is denoted by  $\alpha + \beta QE$ , where  $\alpha$  represents the fixed cost and  $\beta QE$  represents the variable cost.

$$CAPEX_{yr} = \sum_i \frac{\alpha_{i,yr}(z_{i,yr} - p_{i,yr})}{dur(i)} + \sum_{p=1}^{dur(i)} \frac{\beta_{i,yr} QE_{i,yr+p}}{dur(i)} \quad (18)$$

$$CAPEX_{yr} \leq CAPEX_{CAP} \quad (19)$$

Here  $dur(i)$  is the time taken to install the unit  $i$ . The OPEX incurred for pursuing the decarbonization initiatives each year is given by Eq. (20). The OPEX consists of two primary components: the first pertains to the consumption of natural gas and electricity from their respective sources, while the second, linked to the CC units, is directly proportional to emission reductions.

$$OPEX_{yr} = \left( \sum_{j \in Out(NG\ Supply)} F_{NG\ Supply, j, NG, yr} \frac{\$}{unit\ mass} + \sum_{j \in Out(NG\ Supply)} F_{Grid, j, Electricity, yr} \frac{\$}{unit\ energy} + \sum_{i \in CCS\ Units} F_{i, Captured\ CO_2, CO_2, yr} OPEX_i \right) time\ units$$

(20)

Finally, we formulate the objective function as the Present Value of the Cost of the decarbonization project in Eq. (21) which is subject to Eqs. (1) to (20), the constraints of the optimization problem.

$$Minimize \sum_{yr=1}^{29} (CAPEX_{yr} + OPEX_{yr}) / (1+i)^{yr} \quad (21)$$

## RESULTS

The formulated retrofit MILP model was implemented in Pyomo Pyomo 6.6.1 with the Gurobi 10.0.1 solver [11], for a 29-year horizon containing 204,700 constraints and 102,918 variables (97,233 continuous, 5,684 integer). Discounting for the inequality constraints and dependent equations, there are ~3,900 degrees of freedom

### Base Case

As shown in Fig. 2 (a) for the base case when pre-defined targets for reduction in CO2 emissions. (i.e. 50% reduction by year 10 and reduction to the minimum attainable value using the given superstructure by year 28) are implemented, carbon capture technology is favored over electrified options. Electrified technologies are not chosen due to the high operating costs associated with them [2, 1, 14, 3, 13, 31, 4]. Due to space constraints details regarding the data used for natural gas and electricity prices and capital costs for e-boilers, electrolyzers and CC technologies shall be disseminated in a full-length journal publication which is under preparation. Among the CC technologies, post-combustion capture is preferred for both SMR and other combustion-related flue gases, as the additional CAPEX for pre-combustion technology outweighs operational cost savings.

Transition to electrified technologies for both steam and H<sub>2</sub> production occurs in 2049 when stringent restrictions are enforced (as shown in Fig. 2 (a) and (c)) that limits the emissions to the minimum attainable value. For electrification of H<sub>2</sub>, PEM electrolyzers are preferred at given electricity price forecasts due to the associated savings in OPEX.

As shown in Fig. 2 (b) the capital expenditure for CC alternatives was very high compared to electrified technologies and reached the upper limit. Fig. 2 (c) shows that carbon neutrality was not achieved in the final years as the current superstructure only allows post-combustion CC of the flue gas from the rest of the plant, which is not 100% efficient. Fig 2(c) also shows that the emission cap constraint is always active at the optima.

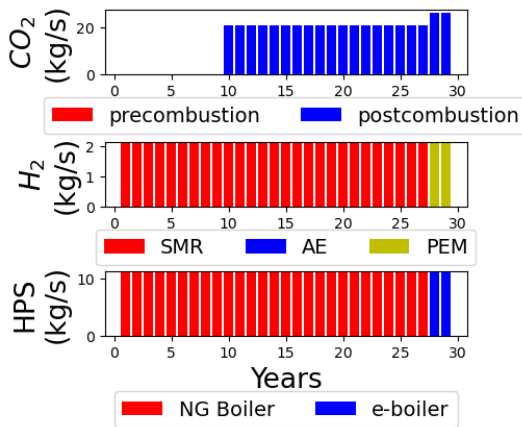

We can see in Fig. 2 (d) that lowering the maximum allowed CAPEX spending per year leads to a preference for installation and use of e-boilers until the CAPEX intensive capture facility is built. Hence, enterprise specific economic policies can alter the optimal solution.

However, adding a penalty for unused capital could alter the optima away from the presented solution.

To gain insight on scenarios that could lead to adoption of electrified options, we studied how the optimal solution varied when (i) Carbon taxes are applied, and (ii) Electricity prices are reduced by different percentages.

### Case 2: Introduction of Carbon taxes

Given carbon tax implementation at specified rates as shown in Figure 3 (b), (mimicking Canadian rates) it was observed that transitioning to CC based decarbonization technologies relatively earlier is economically beneficial as shown in Fig 3(a), decreasing the overall CO<sub>2</sub> emissions. Fig 3(b) also shows that economically optimal emission levels are below the maximum allowed levels. However, C-taxes do not expedite the adoption of carbon-neutral electrified technologies at the optimal design as can be seen in Fig. 3 (a). Additional case studies have also shown us that the results remain qualitatively similar if carbon credits are introduced instead of carbon taxes.

**Fig 2 (a)** The panels from top to down show the contribution of each technology in carbon capture; Hydrogen production and HPS production. Postcombustion CC is preferred over years 10-27; e-boilers and PEMS operated in years 28-29

**Fig 2 (b)** Upper panel shows the actual CAPEX spending and the maximum CAPEX spending limit; along with the total cash outflow associated with hydrogen and HPS

production. The panel below shows the rate at which the electrified alternatives should be installed in KW capacity. It also shows the optimal rate of CC capacity installation in kg/s. CAPEX spending reaches maximum limit when CC infrastructure is built; CAPEX for electrified alternatives is relatively cheaper; large cash outflow after adoption of electrified alternatives

**Fig 2(c)** The total carbon-di-oxide emissions as compared to the maximum allowed emissions over the years. The emissions avoided as a result of the decarbonization initiatives are also shown. Emissions are restricted to 50% of current values from years 10-27; Emissions are capped at the minimum attainable value in years 28-29. Emission cap constraint is always active.

**Fig 2(d)** With \$100,000,000 cap in annual capital expenditure e-boiler is operated until CC technology is built

### Case 3: With reduction in electricity prices

Examining the impact of reductions in electricity costs, it was observed that with 25-70% reduction in electricity costs, the overall solution remained qualitatively similar to the base case. However, a mix of PEME and AE was chosen in the final solution due to the trade-off in CAPEX and OPEX as shown in fig 4(a). Fig 4 (b) shows that upon further reducing electricity costs to 80% below the forecasted levels, e-boiler technology is selected earlier. Nevertheless, the adoption of electrolyzer technology is delayed due to high energy requirements for electrolysis. Fig 4(c) shows that when electricity costs are reduced by 90%, a partial shift from SMR-based

hydrogen production to electrolysis-based hydrogen production is observed, suggesting the use of a mix of both types of electrolyzers. A higher capacity of AEs (Alkaline Electrolyzers) is chosen in the final mix due to the cheap electricity prices in this scenario.

### Case 4: Electricity price reduction and carbon taxes

With reduction in electricity prices and carbon taxes implemented, we further analyze three sub-cases where the electricity prices are reduced by 85%, 90%, and 95% compared to the currently forecasted prices. In all the scenarios, the introduction of carbon capture units is accelerated due to carbon tax introduction as shown in figures 4(d)-4(f). Simultaneously, electrified technologies were also chosen earlier as compared to the base case. In other words, the trends observed are a superposition of the effects obtained in the 2 previous cases. In summary, while carbon taxes Encourage early transition to CC-based technologies, substantial electricity cost reductions or stringent environmental norms are needed for favoring electrified technologies.

### CONCLUSION

This paper has proposed a MILP-based superstructure optimization model to minimize the Present Value of the Cost for retrofit decarbonization of an oil refinery. Higher electricity prices relative to natural gas favor CC over electrification alternatives. Lowering electricity costs by up to 70% has little impact, but further reductions significantly affect the optimal solution. Carbon taxes accelerate adoption of carbon capture technologies. Substantial electricity cost reductions make e-boilers financially attractive.

It should be noted that for the two different carbon capture technologies we have assumed MEA based absorption operating at different conditions and with different costs for dilute (post-combustion) and concentrated (pre-combustion) CO<sub>2</sub> concentrations of the flue gas. For each technology, the cost per unit of captured CO<sub>2</sub> was assumed to remain constant. Future work will enhance the tool by taking into account the differential pricing for carbon capture technologies as a function of the CO<sub>2</sub> concentration of the flue gas stream using piecewise linear approximations. In addition, future work may include the carbon intensity of the fuel and electricity as they are expected to change over time and affect the optimal retrofit plan.

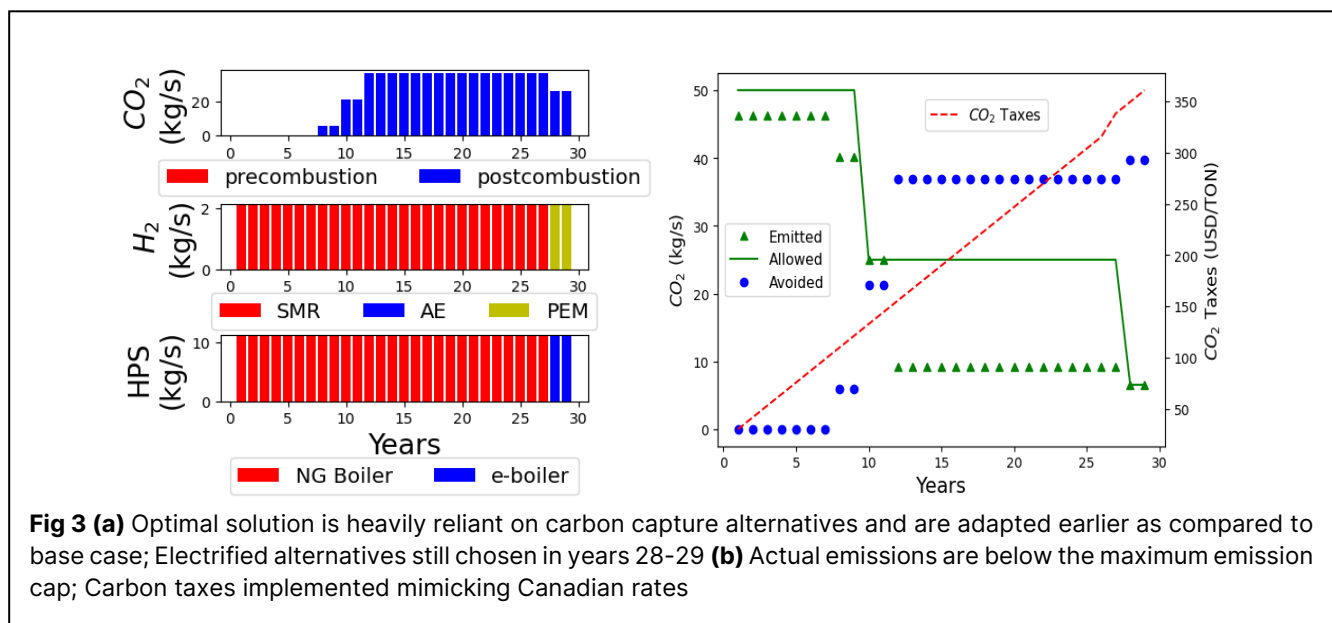

Finally, obtaining accurate cost forecasts are challenging due to energy and carbon market uncertainties. Hence, an enhancement of the solution's robustness is needed. For this, we plan to explore stochastic programming techniques to account for uncertainties in the MILP model [5].

## ABSTRACT

Most integrated energy system (IES) optimization frameworks employ the price-taker approximation, which ignores important interactions with the market and can result in overestimated economic values. In this work, we propose a machine learning surrogate-assisted optimization framework to quantify IES/market interactions and thus go beyond price-taker. We use time series clustering to generate representative IES operation profiles for the optimization problem and use machine learning surrogate models to predict the IES/market interaction. We quantify the accuracy of the time series clustering and surrogate models in a case study to optimally retrofit a nuclear power plant with a polymer electrolyte membrane electrolyzer to co-produce electricity and hydrogen.

**Keywords:** Integrated Energy System, Surrogate Models, Machine Learning, Optimization, Time Series Clustering

## INTRODUCTION

Integrated energy systems (IES) exploit synergies between different technologies and energy carriers [1] such as fossil, nuclear, renewable (e.g., solar, wind), and storage to produce multiple products such as electricity, heat, and chemicals while increasing energy efficiency and supporting greater renewable integration into the grid. Moreover, IES can provide more flexibility to the grid, which is critical for increasing the integration of non-dispatchable renewable energy sources and meeting decarbonization goals.

The price-taker approximation is a widely used approach to incorporate dynamic market signals into the optimization of IES. The price-taker approximation treats the electricity grid as an “infinite bus” that can receive any amount of electricity produced by each generator or IES at any time without affecting the location marginal price (LMP) of electricity. Price-taker allows for co-optimizing IES design and operating decisions using historical or forecasted time-series LMPs. Lakey et al. [2]

proposed a framework that allows users to generate a multi-period, price-taker model instance and automatically generate common operational constraints for their model in the IDAES-PSE platform [3].

Recent papers [2-5] highlight the inaccuracies of the price-taker approximation compared to more rigorous production cost models (PCM) for analyzing IES. Specifically, Martinek et al. [4] compare the revenue, dispatch, and scheduling of concentrating solar power plants using the PCM and price-taker models. They show the price-taker approximation can over-aggressively respond to short-duration peaks in LMP. Likewise, Frew et al. [5] show the price-taker approximation can overestimate the value of IES that co-produces electricity and hydrogen. Sousa et al. [6] evaluate the integration of wind energy and pump storage systems and find that in the PCM, storage operation will decrease the electricity price and dispatch less wind power than the price-taker. Finally, Xian et al. [7] propose a multiscale simulation framework that combines rigorous process (IES) and grid (PCM) models to quantify IES-grid interactions across

hourly to annual timescales. They find that optimizing the design, operation, and control of a single IES impacts the prices and dispatch of generators across the electric grid.

We recently proposed a machine learning surrogate-assisted optimization framework [8] to integrate the process-centric model (price-taker) and grid-centric model (PCM) into the IES conceptual design optimization. Specifically, we contemplate how to size a replacement generator while considering market impacts. We compare algebraic and neural network surrogate models to predict market revenue, annual capacity factor distribution, and the number of shutdowns as a function of the characteristics of the replacement generator. We embed these surrogates into a nonlinear optimization problem and show more accurate results versus the price-taker approximation compared to PCM simulations (ground truth). While promising, this approach only considers steady-state models and surrogates.

In this short conference paper, we extend our prior work [8] by using time series clustering to generate time series representative dispatch scenarios. Then, we train a frequency surrogate model that predicts the frequency of each scenario according to the different IES designs. Together, these surrogate models provide dynamic operation profiles that may be embedded in multiscale IES optimization problems. We develop the surrogate models and clustering methods using a baseload nuclear power plant (NPP) with a polymer electrolyte membrane (PEM) electrolyzer that produces hydrogen ( $H_2$ ) as a case study.

**Figure 1.** The nuclear + PEM IES can divert the power to co-produce hydrogen when the LMP is low to increase its profitability and flexibility.

## Nuclear and $H_2$ IES

We consider retrofitting an existing nuclear power plant with a polymer electrolyte membrane (PEM) electrolyzer to co-produce electricity and hydrogen, as shown in Figure 1. The NPP has a nameplate capacity of 400MW and operates strictly as a baseload generator. After retrofitting, the IES (i.e., NPP + PEM) operates as a hybrid baseload and peaking generator when power from the NPP can be diverted to the PEM to produce hydrogen. Thus, from the perspective of the electric grid, the PEM provides flexibility. Hydrogen is an important resource for the future energy industry and is essential to the decarbonization of many industries [9]. The retrofit thus increases and diversifies the NPP's revenue.

## Production Cost Models

A PCM simulates the operation of an electricity system by scheduling generators and clearing the market (i.e., setting time-varying prices). In summary, each generator communicates its (time-varying) production costs and operational constraints (e.g., minimum up and down times, startup costs) to the market. This includes a bid curve (see Figure 2 for an example), which communicates the cost of producing electricity as a function of the market price. Using this information, the market operator solves unit commitment and economic dispatch optimization problems, which seek to minimize the total system-wide generation costs subject to the costs and constraints of each generator and forecasted demand and renewables production. Most regions schedule most electricity generation in the day-ahead market (DAM). The real-time market (RTM) operates (sub)hourly to correct for forecasting errors and unplanned events. The PCM simulates the rolling horizon operation of the DAM and RTM. See [10] for details.

In this work, all PCM simulations were performed using the open-source production cost model Prescient [11] and the RTS-GMLC [12] dataset. RTS-GMLC is an open-source test network that approximates the characteristics of the southwest United States [7]. We consider retrofitting the 121\_NUCLAER-1 nuclear generator in RTS-GMLC region 1 with a PEM.

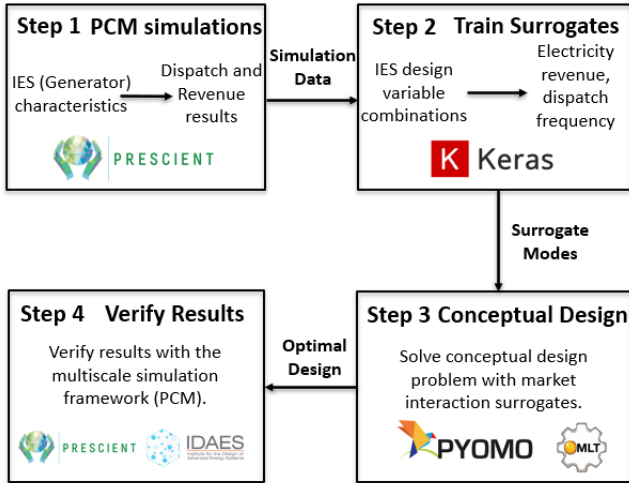

## METHODS

**Figure 2.** Bid curve of the NPP-PEM IES. The IES will dispatch all power to the grid when the electricity price exceeds  $\pi^*$ . Otherwise, the IES will divert  $P_{max}^{NPP} - P_{max}^{PEM}$  power to co-produce  $H_2$ .

### Surrogate-Assisted Optimization Workflow

Figure 3 illustrates the four-step surrogate-assisted optimization workflow.

**Figure 3.** Surrogate-assisted IES conceptual design workflow, adapted from [6].

**Step 1: Perform PCM simulations to generate training data for surrogate models.** We consider two IES design variables: (1) the ratio of maximum PEM power ( $P_{max}^{PEM}$ ) to the maximum power plant power ( $P_{max}^{NPP}$ ), and (2) the threshold LMP price ( $\pi^*$ ) that the IES diverts from the electricity production mode to the hydrogen co-production mode. In PCM simulations, we use different bidding curves [13] (production-cost pairs, see Figure 2) to communicate the IES's flexibility and economics to the

market. We discretize the continuous IES design space and simulate all combinations in the PCM. We performed 192 annual IES PCM simulations in the NPP-PEM IES case study. PCM simulation results give detailed hourly LMP and dispatch profiles within the simulation horizon (366 days).

**Step 2: Train IES-market surrogate models.** Using the LMP and dispatch profile, we calculate the total electricity revenue of each IES design combination. Then, we train a neural network revenue surrogate model (2 hidden layers, 25 nodes each layer and activated by hyperbolic tangent) to predict the annual electricity revenue according to the IES design. We subdivide the annual hourly time series IES dispatch profile into 366 daily dispatch profiles. Next, we use time series clustering [14] to identify 24-hour representative dispatch profiles for the IES conceptual design optimization problem. A neural network dispatch frequency surrogate model (3 hidden layers, 75 nodes each layer and activated by sigmoid) is trained to predict the occurrence probability of each representative day. Inputs of surrogate models are two design variables mentioned in Step 1, plus PCM simulation reserve factor and load shed price. Both surrogate models are trained by Keras [15], and we use 80% of the data for training and 20% for validation.

**Step 3: Solve conceptual design optimization of IES with surrogate models.** We then formulate and solve a stochastic optimization problem, Equations (1) to (5), with IES-market surrogate models to obtain the optimal IES design and operation decisions:

$$\max \varphi[R(x) + \sum_s \omega_s(x) \sum_t R_{H2}(x, u_{s,t}, \delta_{s,t}) - C(x, u_{s,t}, \delta_{s,t})] - CAPEX(x) \quad (1)$$

$$\text{s. t.} \quad h(x, u_{s,t}, \delta_{s,t}) \leq 0, s \in S, t \in T \quad (2)$$

$$g(x, u_{s,t}, \delta_{s,t}) = 0, s \in S, t \in T \quad (3)$$

$$R(x) = f_{rev}(x) \quad (4)$$

$$\omega_s(x) = f_{dis}(x), s \in S \quad (5)$$

The objective function is the 30-year NPV value of the IES retrofit. The two-stage stochastic optimization problem aims to optimize the IES design and operation together under the operation uncertainty. Table 1 summarizes the nomenclature.

For brevity, we do not report optimization results for (1) – (5) in this short conference paper. We recommend using OMLT [16] to embed neural network surrogate models in Pyomo [17]. Because the neural network uses nonlinear activation functions, we recommend using IPOPT [18] with HSL linear algebra [19] distributed as part of the IDAES platform [3].

**Step 4: Verify the optimal IES design with PCM.** Perform PCM simulation of the optimal design IES and compare the result obtained from Step 3. If the verification result varies dramatically from the optimization

results, the training data can be expanded and Steps 2 to 4 repeated.

This conference paper focuses on the time-series clustering in Steps 1 and 2.

Symbol	Meaning
$s, S$	Scenario (Set)
$t, T$	Time step (Set)
$R()$	Revenue surrogate model
$\omega_s()$	Frequency surrogate model
$C()$	Operation cost
$CAPEX()$	Capital cost
$h()$	Inequality constraints
$g()$	Equality constraints
$x$	Surrogate input variables
$u$	Operation variables
$\delta$	Representative dispatch profiles
$\varphi$	NPV multiplier

### Time Series Clustering of PCM Data

Time series clustering is employed to generate representative IES operation profiles. In Step 1, we perform PCM simulation of different IES designs and obtain an annual IES operation profile. We slice the dispatch profile into 24-hr daily time series and use the K-means clustering algorithm to minimize the within-cluster sum of squares Euclidean distance to get the representative days.

In the NPP-PEM model, due to the different PEM

max capacity, the minimum power of the IES will be different. To increase the clustering accuracy and avoid the potential infeasibility in the conceptual design model, we scale the capacity factor of NE/PEM IES between 0 and 1, given in Equation (6). The 0 corresponds to the minimum power output to the grid, i.e., when the PEM is operating at the maximum power.

$$cf_t^{NPP} = \frac{p_t^{NPP} - p_{min}^{NPP}}{p_{max}^{NPP} - p_{min}^{NPP}} \quad (6)$$

Before applying K-means clustering, we filter the time series with capacity factors equal to 0 (minimum dispatch at  $p_{max}^{NPP} - p_{max}^{PEM}$ ) or 1 (max dispatch at  $p_{max}^{NPP}$ ) at every time step. These time series are placed into two clusters labeled “min” and “max” in Figure 4. We find this filtering improves the accuracy of K-means clustering and reduces the size of the clustering dataset by 43.5%.

## RESULTS AND DISCUSSION

### Time Series Clustering Centers Reliably Represent the Entire Dispatch Dataset

In Figure 4, we use a box plot to sort the daily capacity factor of all clusters from “min” to “max” calculated via:

$$cf_{daily}^{NPP} = \frac{\sum_{t=1}^T cf_t^{NPP}}{T} \quad (7)$$

Figure 4 shows that cluster centers accurately represent the data in the cluster, and each cluster center has a substantial amount of data. As we can see there, except for the “min” and “max,” all other clusters hold the time

**Figure 4.** Daily capacity factors of clustering centers. Green lines are median capacity factors, and red lines are representative capacity factors. The clusters are sorted by the capacity factor from low to high. In the horizontal, we show the index of each cluster and the amount of data that falls in the cluster.

series from 1.2% to 6.7%, and there is no single cluster with a significant large or small amount of data. None of the clusters have a significant number of outliers.

As shown in Figure 2, the NPP-PEM IES offers power between  $P_{max}^{NPP} - P_{max}^{PEM}$  (min) and  $P_{max}^{NPP}$  (max). Moreover, because the PEM model is linear (constant efficiency assumption), the bid curve is piecewise constant with two segments. This means the NPP-PEM is almost always dispatched at min or max (unless it is the marginal generator). However, the K-means clustering algorithm gives the average of the time series data within the cluster, whose values may deviate from the true NPP-PEM IES operation. To avoid this, we can choose the time series data with the median capacity factor in each cluster to replace the representative time series generated by the K-means algorithm. Figure 4 shows that the median and mean capacity factors are very similar.

Figure 5 shows the training data and results for cluster 13. The median and representative time series have similar patterns and capacity factors. However, all values in the median time series are either 0 or 1, which mimics the NPP-PEM IES dispatch from the PCM simulations.

Figure 6 compares the cumulative density of the NPP capacity for the entire dataset and representative days. Using a large number of representative days ( $N = 22$ ) helps ensure the capacity factors of the representative days match the entire dataset, as all red dots are distributed closely around the blue line.

**Figure 5.** Clustering results of cluster 13. Black lines are the time series data in this cluster. The red and green lines are the representative time series calculated by K-means and the time series data from cluster 13 with the median capacity factor, respectively.

**Figure 6.** Comparison of the cumulative density of the capacity factor. The blue line is the full dataset used as input to the time series clustering algorithm, and the red line and dots are the representative days.

### Surrogate Models are Accurate

Figure 7 compares contour plots of the electricity revenue from PCM simulations and surrogate model predictions. These plots are strikingly similar, with the root-mean-squared error (RMSE) of 0.71 M\$ and  $R^2$  of 0.995, emphasizing the surrogate’s accuracy. Moreover, in both plots, the electricity revenue does not monotonically decrease with the increasing power of the PEM, which highlights the non-trivial IES-market interactions. Diverting power to co-produce hydrogen reduces the supply of electricity in the market, which increases the LMP; the average day-ahead LMP of all PCM simulations (22.43 \$/MWh) is 1.5% higher than the price-taker signal (22.09 \$/MWh).

The output of the frequency surrogate model predicts the weight of each representative day regarding the given IES design. For the different input  $x$ , the frequency surrogate model predicts the frequency of each representative day within a year. Table 2 summarizes the  $R^2$  value of all 22 representative days.

**Table 2:**  $R^2$  of dispatch frequency surrogate models

	Value
Mean $R^2$	0.9362
Standard Deviation	0.0747
Max $R^2$	0.9988
Min $R^2$	0.7631

**Figure 7.** Contour plots of electricity revenue from (a) PCM Simulation and (b) revenue market surrogate model. In (a), electricity revenue is calculated from 48 PCM simulations with different divergency price and capacity ratio combinations. In (b), we use the surrogate model to predict the electricity revenue using divergency price and capacity ratio combinations as inputs.

To further test the accuracy of the frequency model, we calculated the annual NPP-PEM IES capacity factor predicted by the frequency surrogate model. We compared then compare these predictions with the PCM simulation data. The annual capacity factor is calculated by Equation (8):

$$c_{annual}^{NPP} = \sum_s N_{day} \cdot \omega_s \cdot \sum_t \frac{c_t^{NPP}}{T} \quad (8)$$

$\omega_s$  is the weight predicted by the frequency surrogate model.  $c_t^{NPP}$  is the capacity factor of the IES at time  $t$  in each representative day,  $N_{day}$  is the number of days in a year (equal to 366).

Figure 9 shows the parity plot of the predicted versus actual annual IES capacity factors. The predicted annual capacity factors closely agree with the PCM simulation results, with the root-mean-squared error (RMSE) of 0.006.

**Figure 9.** Annual capacity factor parity plot. The green dots correspond to the 192 annual simulations considered in the training dataset. The parity line is shown in blue.

## CONCLUSIONS AND FUTURE WORK

This work develops time-series clustering methods for surrogate-assisted IES design and operation optimization considering IES/market interactions. The result shows that time series clustering identifies accurate representative days. The representative days and frequency surrogate models accurately predict the annual capacity factor. Finally, the neural network surrogate models for revenue accurately capture complex IES/market interactions as revealed by the PCM simulations (ground truth).

In future work, these surrogate models should be compared within the context of the IES optimization problem (Step 3) and compared to PCM verification simulations (Step 4). Moreover, the modeling strategy should be extended to consider energy storage systems [19], uncertainty from renewables, and additional revenues from ancillary services [20]. We also plan to extend the approach to consider price fluctuations in co-products, which is especially important as hydrogen and other renewable-energy-derived chemical markets continue to mature.

## ABSTRACT

Biogas is a promising energy source for sustainable hydrogen production due to its high concentration of CH<sub>4</sub>. However, determining the optimal process configuration is challenging due to the uncertainty of the fed biogas composition and the sensitivity of the operating conditions. This necessitates early-stage evaluation of the biomass-to-hydrogen process's performance, considering economics, energy efficiency, and environmental impacts. A data-driven model was introduced for early-stage assessment of hydrogen production from biogas without whole process simulation and optimization. The model was developed based on various biogas compositions and generated parameters for mass and energy balance. A database of unit processes was created using simulation models. Sensitivity analysis was performed under four techno-economic and environmental evaluation criteria: Unit Production Cost (UPC), Energy Efficiency (EEF), Net CO<sub>2</sub> equivalent Emission (NCE), and Maximum H<sub>2</sub> Production (MHP). The early-stage evaluation of the biogas-to-hydrogen process can guide the establishment of biogas utilization strategies and propose effective biogas enhancement process development solutions to respond to market disturbances.

## 1. INTRODUCTION

Continuous concerns over global warming and the depletion of fossil fuels have spurred research into efficient technologies and sustainable energy generation. Currently, hydrogen is gaining increasing attention as a substantial energy carrier, primarily due to its environmental advantages and high calorific value. Although hydrogen is a potentially valuable material especially for the environment as a fuel, the conventional steam methane reforming plant, responsible for 50% of conventional hydrogen production emits 13.7 kg eq. CO<sub>2</sub> per kg of net H<sub>2</sub> produced [1]. Biogas is a viable alternative raw material for hydrogen production, as the methane within biogas can be utilized to prevent greenhouse gas emissions into the atmosphere [2]. There are various sources from which biogas can be obtained, such as sewage sludge digesters, organic waste digesters, or landfills. The biogas typically comprises 55 – 75% of methane, 25-45% of CO<sub>2</sub>, and trace elements like nitrogen (N<sub>2</sub>), oxygen (O<sub>2</sub>), hydrogen sulfide (H<sub>2</sub>S), siloxanes, and some dust

particles [3]. Before constructing a biogas utilization plant, an early-stage assessment of the biogas-to-hydrogen process is necessary. Zhao X, et al investigated various biogas reforming technologies utilizing different catalysts to convert biogas to syngas. They conducted techno-economic analysis of biogas conversion technologies [4]. However, the previous research has not explored and evaluated the most efficient pathways for biogas utilization.

In this study, we have presented a superstructure-based data-driven model that can provide optimal strategies for biogas-to-hydrogen conversion. We carried out a comprehensive analysis of economic, environmental, and technological aspects by generating mass and energy balance data for every possible pathway and operating conditions from the superstructure. The main operating variables include the types of reformers and each operating conditions for various criteria. The techno-

**Figure 1:** Research overview of biogas utilization process.

economic analysis and sensitivity analyses were conducted prior to optimization to assess the overall process parameters. As a result of the optimization, we can recommend the appropriate technologies with defined operating conditions for the process.

## 2. RESEARCH OVERVIEW AND METHODOLOGY

### Research Overview

The section demonstrates the conceptual framework for hydrogen production through the reforming of biogas. Figure 1 provides an overall view of the research on the utilization of biogas, which comprises five steps: Problem setting, superstructure generation, data-driven modelling, development of optimization models, and optimal strategy formulation. To begin the process, we identify the feedstock, types of reformers, and product. The superstructure for the biogas-to-hydrogen process can be generated via various pathways, each involving different types of reformers and operating conditions for the applied technologies. Afterwards, data generated from the process simulation can be utilised to estimate additional mass and energy balance. This is done using the Excel-based data-driven model and is key to calculating techno-economic and environmental parameters. Prior to recommending optimal strategies, an optimization model was created based on diverse evaluation criteria evaluating the impact of economic and environmental factors. The optimization outcomes enable the recommendation of appropriate strategies for the distinct elements of biogas.

We considered three biogas compositions, comprising 55%, 65%, and 75%  $\text{CH}_4$ . To attain the best pathways for each composition, we evaluated four reformers: Steam Methane Reforming (SMR), Dry Reforming (DR), Auto-Thermal Reforming (ATR), and Tri-Reforming (TRI).

In the case of conventional hydrogen production from natural gas, SMR is typically employed in conjunction with water gas shift reactions to maximize hydrogen production. However, the significant quantity of  $\text{CO}_2$  emissions produced by the conventional process necessitates the assessment of the biogas utilization process on various parameters. Steam methane reforming, which has a 3:1  $\text{H}_2/\text{CO}$  ratio, is highly endothermic, whereas dry reforming reduces  $\text{CO}_2$  by consuming it as a reactant. Nonetheless, DR is also an extremely high endothermic process. To reduce the consumption of the reforming process, the ATR that employs partial oxidation with steam methane reforming has emerged. The TRI, which simultaneously employs partial oxidation and dry reforming with steam methane reforming, is a viable technology for biogas utilization. Both ATR and TRI can minimise energy consumption for the reforming process, although  $\text{H}_2/\text{CO}$  ratio may decrease to less than 3. Prior to constructing a biogas utilization process, it is crucial to assess the advantages and disadvantages of various technologies. Table 1 showcases the operating limits of each reformer under atmospheric pressure.

**Table 1:** Types and operating conditions of biogas reforming technologies at atmospheric pressure [5-8].

Steam reforming (Ni/Mg $\text{Al}_2\text{O}_4$ spinel)	Temperature: 600-900°C $\text{H}_2\text{O}/\text{CH}_4$ : 1-3
Dry reforming (Rh/ $\text{Al}_2\text{O}_3$ )	Temperature: 600-1,000°C $\text{CO}_2/\text{CH}_4$ : 0.4-1
Auto-thermal reforming (Ni/Mg $\text{Al}_2\text{O}_4$ )	Temperature: 600-1,000°C $\text{H}_2\text{O}/\text{CH}_4$ : 1-5 $\text{O}_2/\text{CH}_4$ : 0-0.5
Tri-reforming (Ni/Mg $\text{Al}_2\text{O}_4$ )	Temperature: 600-1,000°C $\text{H}_2\text{O}/\text{CH}_4$ : 1-2 $\text{O}_2/\text{CH}_4$ : 0.1-1

## Process Analysis Method

The process was assessed using multiple criteria, including unit production cost (UPC), Net CO<sub>2</sub>-equivalent emissions (NCE), and energy efficiency (EEF), as demonstrated in Eqs. (1)–(3). In the economic evaluation, capital expenditures (CAPEX) and operating expenses (OPEX) were divided by the quantity of produced hydrogen. The UPC was estimated using an interest rate of 7% over a 25-year plant lifespan.

$$UPC = \frac{CAPEX+OPEX}{Amount\ of\ hydrogen}, (\$/kg_{H_2}) \quad (1)$$

In order to calculate the environmental parameters, we considered the net CO<sub>2</sub>-equivalent emissions (NCE). The term 'direct CO<sub>2eq</sub>' refers to greenhouse gas emissions during process operations, whilst 'indirect CO<sub>2eq</sub>' pertains to the emissions caused by the consumption of utilities for the consumption of electricity and heating sources in the process operation. The 'carbon credit' (CC) represents the decrease in the amount of CO<sub>2</sub> achieved by utilizing CO<sub>2</sub> as a reactant.

$$NCE = \frac{Direct\ CO_{2e}+Indirect\ CO_{2e}-CC}{Amount\ of\ hydrogen}, (kg_{CO_2-eq}/kg_{H_2}) \quad (2)$$

For the assessment of the technical aspects of the biogas-to-hydrogen process, energy efficiency (EEF) serves as an assessment parameter. To determine the EEF of the process, the heat generated by the product (hydrogen) is divided by the energy used by utilities and the heat introduced by the fed feedstock (biogas).

$$EEF = \frac{Heat\ of\ hydrogen}{Heat\ of\ fed\ biogas + E_{utilities}} \times 100\%, (\%) \quad (3)$$

## 3. RESULTS AND DISCUSSION

### Techno-economic analysis

For the purpose of economic evaluation, we analysed the breakdown of overall production cost and operational cost for producing hydrogen.

**Figure 2:** Total production cost analysis of biogas-to-hydrogen processes with different reformers.

To address different strategies, we initially studied the optimal operating conditions for each type of reformers. Figure 2 presents the cost breakdown of hydrogen production, indicating that the total operating cost (TOC) represents more than 80% of the total cost for all technologies. To evaluate the impact of OPEX, which is a significant factor in this research, we analysed the specific breakdown of the total operating cost, which is displayed in Figure 3.

**Figure 3:** Analysis of total operating cost of the biogas-to-hydrogen processes.

The analysis of total operating costs indicates that utility costs (UTC) dominate the process that employs SMR and DMR for reforming, while raw material costs (RMC) are the most influential parameter for the process using ATR and TRI reactions. It has been determined that highly endothermic reforming reactions yield a relatively larger amount of hydrogen than processes utilizing partial oxidation reactions. Furthermore, we have observed that the process which adopts highly endothermic reforming reactions can produce a greater quantity of hydrogen compared to the partial oxidation reaction process. However, the high heat consumption rate has led to an increased proportion of utility costs in the total operating costs.

### Sensitivity analysis

The sensitivity analysis of the hydrogen UPC was conducted by examining the impact of a 20% change in major economic parameters, as displayed in Figure 4. Optimal conditions for every biogas composition and type of reformer were analyzed, with results presented as a range distribution. The bar graph demonstrates the average values obtained across all cases. Technical abbreviations have been explained within the text.

The results of the sensitivity analysis indicate that the price of biogas (feedstock) has the largest impact on the UPC, decreasing and increasing by 20.1% and 18.1%, respectively. The price of fired heat and electricity are

the second and third most sensitive parameters, resulting in UPC changes of around 5% and 3%, respectively.

**Figure 4:** Sensitivity analysis for the unit production cost of total biogas-to-hydrogen processes.

Other factors have a minor impact on UPC, staying below 2%. Accordingly, we scrutinized that the cost of generating hydrogen is significantly linked to OPEX, particularly the expenses concerning raw materials, fired heat, and electricity. Thus, these costs have a trade-off relation with respect to economic and environmental factors.

### Optimization model

To identify the optimal pathways of biogas-to-H<sub>2</sub>, we developed optimization models using a mixed-integer linear programming (MILP) technique. Here, we considered various evaluation criteria as objective functions to identify the viable biogas utilization strategies. Eq. (1) identifies the minimum unit production cost for a fixed capacity of biogas as a feedstock, which represents the most economic strategy.

$$MinUPC = \sum_j \alpha_j + \sum_j \phi_j + \sum_{i \in I^F} \phi_i F_{ij} + \sum_{i \in I^U} \pi_i U_{ij} \quad (1)$$

where  $\alpha_j$  is the total capital investment cost of pathway  $j$ ,  $\phi_j$  is the fixed operating cost factor of pathway  $j$ , and  $\pi_i$  and  $\phi_i$  are the unit costs for utilities and feedstock, respectively.  $F_{ij}$  and  $U_{ij}$  is the amount of feedstock  $i \in I^F$  and utilities  $i \in I^U$ , respectively.

Eq. (2) seeks for the most eco-friendly process, which is minimum net CO<sub>2</sub> emission strategy for the same amount of process capacity.

$$MinNCE = \sum_j \delta_j + \sum_{i \in I^F} \varepsilon_i U_{ij} - \sum_{i \in I^F} \gamma_i F_{ij} \quad (2)$$

where  $\delta_j$  is the amount of directly emitted CO<sub>2</sub> by technology  $j$ .  $\varepsilon_i$  is the amount of indirect CO<sub>2</sub> emission by using utility  $i \in I^U$ , and  $\gamma_i$  is the CO<sub>2</sub> inventory for feedstock  $i \in I^F$ .

Finally, maximum energy efficient process is identified via Eq. (3), which is maximum energy stored in product with a certain input energy to process.

$$MaxEE = \sum_j \rho_i P_{ij} \quad (3)$$

where  $\rho_i$  is the heating value of final product  $i \in I^P$ .  $P_{ij}$  is the amount of product of pathway  $j$ .

The optimization model with proper corresponding constraints is developed as follows.

**Flow conservation:** Eq. (4) is used to balance the amount of flows between the utilized feedstock and the total amount of processed feedstock in pathway  $j$ .

$$\sum_h F_{ij} = \sum_h Q_{ij}^{in} \quad \forall i \in I^F \quad (4)$$

where  $Q_{ij}^{in}$  is the flow rate of the feedstock input to technology  $j$ .

Similarly, the flow rate of the feedstock input to the technology must be identical to the sum of the three output flow rates for the final product, by-product, and waste, as illustrated in Eq. (5)

$$Q_{ij}^{in} = P_{i'j} + B_{i''j} + W_{i'''j} \quad \forall i \in I^F, i' \in I^P, i'' \in I^W, j \in J \quad (5)$$

where  $P_{i'j}$ ,  $B_{i''j}$ , and  $W_{i'''j}$  are the amount of product, byproduct and waste from pathway  $j$ , respectively.

**Feed availability:** The amount of feedstock should be bounded by an upper limit (i.e., availability) and a lower limit (i.e., minimum purchase for realistic technology operation) as shown in Eq. (6)

$$r_i \leq \sum_j F_{ij} \leq \omega_i \quad \forall i \in I^F \quad (6)$$

where  $r_i$  and  $\omega_i$  are the minimum purchase and feed availability, respectively.

**Logistic constraint:** In case an input can be processed by various technologies, only one technology that can satisfy the objective function should be selected using binary variables.

$$\sum_{j_n} X_{j_n} \leq 1 \quad \forall \{j_1, \dots, j_n\} \in J \quad (7)$$

where  $X_{j_n}$  is a binary variable that represents the pathway selection.

**Technology capacity:** The involved technology is limited by its capacity ( $\psi_j$ ).

$$Q_{j_n}^{in} \leq \psi_j X_{j_n} \quad \forall j_n \in J \quad (8)$$

### Optimal strategies of biogas-to-hydrogen process

The most efficient hydrogen production methods from diverse biogas compositions are evaluated using Figure 5, based on three different criteria. The first column of Figure 5, representing the optimization results, takes into account black utility and levelized cost of biogas (LCOB). According to the estimated process cost by UPC, SMR utilization strategies show the most cost-effective pathways for all the examined biogas

Optimization results: Black utility + LCOB					Optimization: Alternative Scenarios

Figure 5: Optimal strategies for different evaluation scenario by considering different biogas compositions.

compositions. The utilization process for low-concentration methane within biogas resulted in an increase in UPC due to the limited production of hydrogen caused by the low levels of methane. By comparing the operating conditions of strategies aimed at minimizing UPC, we can determine that a relatively low-temperature reforming process was utilized for low-concentration methane within biogas. When considering the environmental impact, the TRI utilization strategies exhibit the lowest NCE for all biogas compositions evaluated. The TRI reaction has the potential, in theory, to use CO<sub>2</sub> as a reactant via partial oxidation, thereby supporting the highly endothermic steam methane reforming reaction. The process has the potential to reduce utility consumption through partial oxidation while also reducing CO<sub>2</sub> in the feedstock.

Based on the results of the sensitivity analysis, three parameters that potentially present a trade-off between UPC and NCE when modified can be viewed as constraints for the optimization process. In Case 1, we opted for the use of a green utility with a low CO<sub>2</sub>-eq value despite its higher utilization cost instead of a black utility. Remarkably, the optimal pathway for hydrogen production from biogas has been altered. For all evaluation values (UPC, NCE, and EEF), the utilization of SMR process displays the most viable option for converting biogas-to-hydrogen. The SMR utilization strategy generates significant hydrogen production with minimal CO<sub>2</sub> emissions from the utilities, which is the best pathway for minimizing NCE when the biogas contains 75% concentrated methane. Optimal pathway changes when biogas contains less than 65% methane. The DMR strategies were selected for their eco-friendly nature, reducing significant CO<sub>2</sub> emissions by using CO<sub>2</sub> as a feedstock. Consumption of sustainable, 'green' utilities can reduce the significant CO<sub>2</sub> emissions generated from traditional utilities. In case 2, we assumed a biogas price of 0, which can be obtained

from upcycling waste. There is no significant change in the optimization results, but the utilization processes of ATR and TRI could be more cost-effective pathways compared to the SMR process for biogas with methane concentrations of 55% and 65%, respectively.

Finally, if we consider both assumption that are used in Case 1 and Case 2, the optimization results can be drastically altered. In terms of cost-effectiveness, strategies utilizing partial oxidation reactions to reduce energy consumption are preferred, while SMR and DMR may be the most environmentally friendly processes by reducing CO<sub>2</sub> emissions from utility consumption and utilizing CO<sub>2</sub> as a feedstock. For technology, the SMR-based process remains the most energy-efficient option.

## 4. CONCLUSIONS

In this study, we analysed the process of converting biogas directly to hydrogen and optimised it for three evaluation criteria: UPC, NCE, and EEF. This was achieved by constructing a superstructure that considered multiple variables and evaluation parameters. We determined the economic, environmental, and technical feasibility and suggested optimal pathways for the process. The major findings and contributions of this research are as follows:

- To solve the problem of multi variables and evaluation parameters, the superstructure based data driven-modeling was conducted.
- Before the optimization process, we conducted techno-economic evaluation and sensitivity analysis that identified major cost drivers (i.e., price of feedstock, price of electricity and fired heat).
- For the case of process which utilizes black utilities and LCOB, the SMR based process is economically and technically optimal while TRI

based process shows the best results for environmental parameters for every biogas compositions.

- The analysis for different assumptions which showed trade-off relationship between economical and environmental parameters were conducted.
- By considering every assumptions for alternative scenarios which was shown in Case 3, we can analyze that ATR and TRI based process is cost-effective process for each biogas compositions while SMR and DMR can be the technically effective and eco-friendly process.

## ABSTRACT

This study focuses on optimizing solid oxide electrolysis cell (SOEC) systems for efficient and durable long-term hydrogen (H<sub>2</sub>) production. While the elevated operating temperatures of SOECs offer advantages in terms of efficiency, they also lead to chemical degradation, which shortens cell lifespan. To address this challenge, dynamic degradation models are coupled with a steady-state, two-dimensional, non-isothermal SOEC model and steady-state auxiliary balance of plant equipment models, within the IDAES modeling and optimization framework. A quasi-steady state approach is presented to reduce model size and computational complexity. Long-term dynamic simulations at constant H<sub>2</sub> production rate illustrate the thermal effects of chemical degradation. Dynamic optimization is used to minimize the lifetime cost of H<sub>2</sub> production, accounting for SOEC replacement, operating, and energy expenses. Several optimized operating profiles are compared by calculating the Levelized Cost of Hydrogen (LCOH).

**Keywords:** Fuel Cells, Dynamic Degradation Modelling, Hydrogen, Optimization, Solid Oxide Cells

## INTRODUCTION

Solid oxide cells (SOCs) are flexible energy conversion and H<sub>2</sub> generation devices that have many benefits including modularity, high theoretical efficiency, and low operating greenhouse gas emissions. They can be operated reversibly in either power generation mode as a solid oxide fuel cell (SOFC) or H<sub>2</sub> production mode as a solid oxide electrolysis cell (SOEC). Steam electrolysis in SOECs has a variety of benefits over a conventional steam-methane reforming process such as no direct emission of CO<sub>2</sub> when renewable sources of electricity are used. High-temperature SOC offer high electrical efficiency especially at high temperatures.

However, the high temperature needed for achieving high efficiency in SOC also leads to chemical degradation of the microstructure in the electrodes and electrolytes. Chemical degradation results in changes in the composition and microstructure of the triple-phase

boundary. The dynamics of these changes are very slow, but the changes can steadily build up during the operating lifetime of a cell. Chemical degradation causes an increase in the voltage losses that reduce the effective voltage utilized for electrolysis.

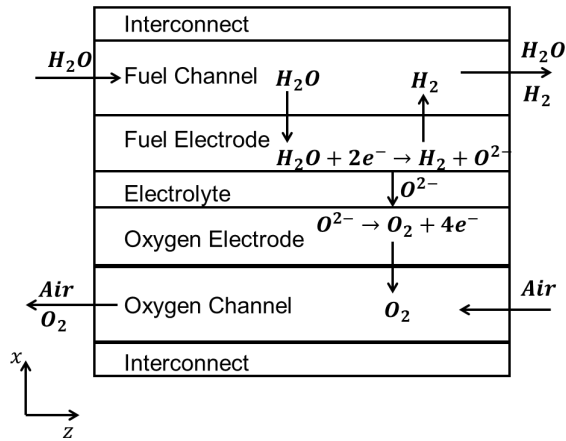

$V_{cell}$ , the cell voltage that contributes to electrolysis, is given by Equation 1. In Equation 1,  $V_{Nernst}$  is the Nernst potential and  $V_{act}$ ,  $V_{Ohmic}$ , and  $V_{conc}$  are the activation, Ohmic, and concentration overpotentials. The magnitudes of these overpotentials depend on the operating conditions of the cell, but these losses are inevitable even in fresh, undegraded cells. The total overpotential due to all long-term chemical degradation mechanisms is given by  $V_{degradation}$ . In a new (i.e., undegraded) cell, the  $V_{degradation}$  term is 0, but this term increases with time.

$$V_{cell} = V_{Nernst} - V_{act} - V_{Ohmic} - V_{degradation} \quad (1)$$

Figure 1 shows a typical SOEC and the reactions

occurring in the fuel and oxygen electrodes. In the oxygen electrode (anode during electrolysis), high partial pressure of oxygen contributes to the oxidation of the active material LSM-YSZ. In the fuel electrode, nickel (Ni) agglomeration occurs due to Ostwald ripening.

**Figure 1.** SOEC Schematic and Reactions

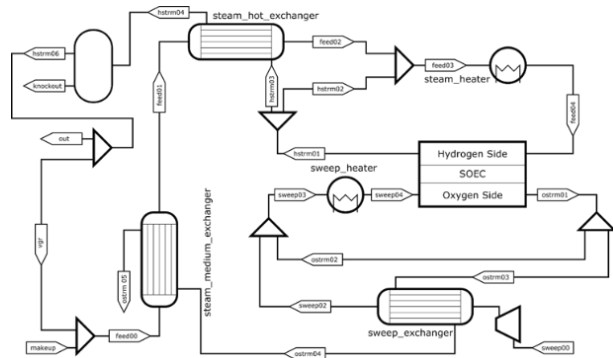

In the literature, many approaches have been proposed to include degradation models for making SOC design and operation decisions. A few relevant optimization studies are reviewed here. For detailed review, we refer readers to [1]. Parhizkar et al. [2] combined microstructure degradation models with a simplified input-output SOFC performance model to perform steady-state optimization to identify operating conditions for minimizing the cost of electricity. Naeini et al. [3] coupled a data-driven model for SOEC degradation with a steady-state model for SOEC operation. In their work, the Levelized Cost of Hydrogen (LCOH) is minimized over a 20-year operating horizon.

In this work, models of key degradation mechanisms are coupled with a first principles two-dimensional (2D) non-isothermal SOEC model. This work seeks to fill two gaps in the existing literature. First, most modeling studies in the literature use isothermal 0D models; therefore, spatial variation and thermal characteristics of a degraded cell are neglected. The 2D non-isothermal SOC model used in this work provides detailed insights into the spatial distribution of degradation in each cell. A second gap, which this work aims to fill, is that most SOC degradation simulation studies do not consider the effects of degradation on the balance of plant. While some studies incorporate simplified heating and compression duties in their calculations for total energy consumption, this work extends this to capture the impact of cell level degradation on the balance of plant by considering a fully modeled SOEC flowsheet. The flowsheet model is used in dynamic optimization to identify optimal operating profiles for system- and cell-level decision variables as a function of time.

## MODELING AND METHODS

### Flowsheet modeling details

As shown in Figure 2, the SOEC hydrogen production system is modeled as a collection of linked unit models in the open-source IDAES, equation-oriented IDEAS (Institute for the Design of Advanced Energy Systems) platform. The system consists of an SOEC stack (modeled as a single cell), and electric heaters for the feed and sweep input streams along with heat exchangers for heat recovery. For a detailed description of SOEC flowsheet modeling details, we refer readers to [4-5]. The models used in this study are available in the open-source IDAES modeling framework [9].

**Figure 2.** SOEC system flowsheet

### Health modeling

Degradation mechanisms in SOCs vary depending on the materials of construction of the cell. For this study, we consider fuel electrode of a Ni-YSZ composite, an oxygen electrode of LSM-YSZ separated by a YSZ electrolyte as a part of a planar fuel electrode supported SOC.

One of the dominant degradation mechanisms that take place in the fuel electrode is the agglomeration of Ni particles due to surface diffusion. The dynamics of the Ni particle growth are described by Equation 2 [6]. Here,  $\bar{d}_{Ni}$  is the average Ni particle diameter,  $m = 0.5$  and  $n = 8$ .

$$\frac{d(\bar{d}_{Ni})}{dt} = \frac{a'}{d_{Ni}^{n-1}} \left( \frac{P_{H_2O}}{P_{H_2}^{0.5}} \right)^m e^{-\frac{E_a}{RT}} \quad (2)$$

The oxygen electrode undergoes degradation due to the growth of oxide scales under high oxygen partial pressure. Under these conditions, Wagner's law for parabolic oxidation is used as a semi-empirical model to describe growth of oxide scale. In LSM-YSZ electrodes, the scales formed are of lanthanum zirconate (LZO) and chromium oxide (COS). The chromium oxide scale is localized to the interface between the oxygen electrode and interconnect. Equation (3) describes the temperature-dependent Wagner's law for a general oxide scale growth length  $l_{sc}$  [7]. Here,  $X_{0,sc}$ ,  $\rho_{sc}$ ,  $K_{sc}$ , and  $E_{sc}$  are the weight fraction, density, weight gain rate, and activation

energies of oxide scale growth, respectively.

$$\frac{dl_{sc}}{dt} = \frac{K_{sc}}{2(X_{0,sc}\rho_{sc})^2} e^{-\frac{E_{sc}}{RT}} \quad \forall sc \in \{COS, LZO\} \quad (3)$$

Other degradation mechanisms that are modeled include coarsening of the LSM-YSZ oxygen electrode and phase transformation of the YSZ electrolyte. Additionally, we make use of property models to relate microstructure parameters to degradation overpotentials [8].

## Solution methodology

Incorporating degradation models into first principles unit models requires solving a differential algebraic equation (DAE) system with multiple timescales. For the SOEC system, these timescales can be broadly divided into two categories: one faster timescale for process operations and SOEC dynamics (minutes to hours) and another slower timescale for degradation (hundreds of hours). To simplify the problem, we assume quasi-steady state for the faster timescale processes. This allows us to discretize and dynamically integrate the slower degradation timescale. With this approach, we can simulate SOEC operation with degradation effects for extended periods, spanning tens of thousands of operational hours, providing insights into long-term performance and design strategies.

We employ the implicit Euler method to discretize the degradation dynamic equations. The discretized system of equations can be solved simultaneously and efficiently using a nonlinear solver such as IPOPT [10]. Because of the quasi-steady state assumption, the only active differential equations in the model are those pertaining to the slow degradation dynamics. The advantage of a simultaneous solution method is the ability to optimize across the entire operational horizon, ensuring a comprehensive assessment of system performance. Additionally, this approach enables the incorporation of constraints spanning multiple time points, thus providing enhanced modeling versatility. In contrast, the sequential time-stepping approach restricts optimization to instantaneous performance metrics like instantaneous efficiency.

## Hydrogen Production Profiles

The discretized SOEC system model is used to assess different long-term operating scenarios by first specifying the nature of the hydrogen production profile.

**Constant H<sub>2</sub> Production:** In this profile, a constant H<sub>2</sub> production rate is maintained throughout the operating lifetime. As shown in Equation 4, an equality constraint indexed over time ensures that the average current density  $J_{avg}$  remains constant. Here,  $j_{t,z}$  is the local current density at a point  $z$  along the length of the cell and  $N_z$  is the number of finite elements. As degradation proceeds,

it is expected that increased degradation losses will result in an increase in operating voltage to sustain the fixed H<sub>2</sub> production rate.

$$\frac{1}{N_z} \sum_z j_{t,z} = J_{avg,0} \quad \forall t \quad (4)$$

**Constant Potential Operation:** In this strategy, a constant cell potential is maintained over time [3]. This keeps cell-level energy consumption constant. However, as degradation progresses, current density decreases. This leads to a gradual reduction in H<sub>2</sub> production at a constant operating temperature. However, by varying the cell operating temperature over time, more complex operating scenarios can be investigated. Cell voltage is held constant by fixing operating voltage for all time points (Equation 5).

$$V_{cell,t} = V_{cell,0} \quad \forall t \quad (5)$$

## Dynamic optimization

Typically, steady-state optimization is used to determine the operational setpoints of a system. In this case, minimization of the system power requirement for a given H<sub>2</sub> production rate [5]. This methodology can be used to determine steady-state optimal operating conditions corresponding to different load conditions. In the absence of degradation, operational efficiency, power consumption, and local cell temperature profile would remain at the steady-state optimal value. In this work, we provide a methodology to optimize the operational profile over 20,000 hours for long-term stability and efficient operation, while accounting for performance degradation.

For long-term dynamic optimization, we propose to maximize the integral average efficiency over the operating lifetime (Equation 6). As a surrogate for system efficiency, we use a simplified version as described in [11]. Under constant H<sub>2</sub> load, the numerator is invariant, and the objective simplifies to the minimization of system power consumption. Obviously, under constant potential operation, the numerator is not constant. Here,  $P_{system}$  is the total electric power consumption of the system, including stack work, electric heater, and blower duties (Equation 7).

$$\max \sum_{t \in \text{time}} \frac{HHV(\dot{m}_{H_2,t})}{P_{system,t}} \quad (6)$$

$$P_{system} = P_{SOEC} + P_{sweep\ heater} + P_{feed\ heater} + P_{blower} \quad (7)$$

A second operational strategy involves minimization of the degradation rate. To include all degradation effects into one combined term, it is desirable to use the degradation overpotential  $V_{degradation}$  in Equation 1. However, since the overpotential at any given point in time

**Table 1:** Summary of Optimization Results

H <sub>2</sub> Production Profile	Objective Function	Avg. H <sub>2</sub> Production Rate (× 10 <sup>7</sup> kg/yr)	Sp. Energy Consumption (kWh/ kg H <sub>2</sub> )	Voltage Degradation Rate (%/ khr)	Replacement Time (years)	LCOH (\$ /kWh)
Constant H <sub>2</sub> Production Rate	Maximize Integral Efficiency	4.74	36.6	4.4	1.5	0.31
	Minimize Degradation Rate	4.74	40.4	1.5	4.0	0.33
Constant Potential Operation	Maximize Integral Efficiency	3.39	35.6	2.7	2.0	0.29
	Minimize Degradation Rate	1.31	41.7	0.7	8.0	0.37
	Maximize H <sub>2</sub> Production	3.93	38.9	5.0	1.5	0.34

depends on the operating temperature and composition following an Arrhenius-type temperature dependence, we consider the voltage at a reference temperature  $\tilde{V}$ . This ensures that the voltage degradation rate for optimization only depends on the operating trajectory. With this we minimize the average voltage degradation rate from  $t=0$  to  $t=t_f$ , the final time point (Equation 8).

$$\min \frac{\tilde{V}_{t_f} - \tilde{V}_0}{\tilde{V}_0} \quad (8)$$

Finally, under constant potential operation, market conditions may require the system to operate at the highest possible H<sub>2</sub> production rate ( $\dot{m}_{H_2}$ ). This can be achieved by maximizing the H<sub>2</sub> production rate (Equation 9).

$$\max \sum_{t \in \text{time}} \dot{m}_{H_2,t} \Delta t \quad (9)$$

The decision variables for optimization include feed and trim heater duties, recycle ratios, blower flowrate, sweep and steam inlet and outlet temperatures. For details on bounds and operational constraints refer to [5].

### Levelized Cost of H<sub>2</sub> (LCOH) Calculation

The different optimized cases are compared based on the resultant LCOH, as shown in Equation 10. We compute the LCOH by modifying the method of [12] to incorporate stack replacement costs. The LCOH includes the capital recovery factor (CRF) and capital costs (CC) for the stack and balance of the plant (BOP).  $OC$ ,  $EC$ , and  $m_{H_2, \text{lifetime}}$  are the operating costs, energy costs, and lifetime H<sub>2</sub> production, respectively. Costing parameters are obtained from [12].

$$LCOH = \frac{CRF_{BOP} CC_{BOP} + \sum_{i=1}^R CRF_{\text{stack},i} CC_{\text{stack}} + OC + EC}{m_{H_2, \text{lifetime}}} \quad (10)$$

The number of stack replacements ( $n_{rep}$ ) over the plant lifetime of 30 years is computed based on the extent of degradation at the end of the 20,000-hour optimization

horizon as per Equations 11 and 12.

$$\text{Replacement time} = \frac{\Delta \tilde{V}_{limit}}{\left(\frac{\Delta \tilde{V}}{\Delta t}\right)_{avg}} \quad (11)$$

$$n_{rep} = \frac{30 \text{ years}}{\text{replacement time}} \quad (12)$$

## RESULTS

Figure 3 compares 20,000 hours of operation, at constant current density and constant potential through simulations. As the degradation overpotential increases over time, we observe that constant current density operation results in a higher voltage degradation rate than constant potential operation. Due to the increase in Ohmic resistance, the thermal characteristics along the length of the cell change with time.

**Figure 3.** Effect of degradation on voltage and current density

As shown in Figure 4, there is a significant increase in the average temperature along the length of the cell for constant current density operation. Here the inlet temperatures were held constant over the 20,000 hours

of operation.

The spatial temperature profile shown is at the center of the cell along the electrolyte layer. During constant current density operation, we observe a large increase in local cell temperature. The increase in degradation over-potential results in an increase in operating potential, which corresponds to operation above the thermoneutral voltage. Furthermore, the larger Ohmic resistance due to degradation also results in higher Ohmic heating. Under constant potential operation, a drop in current density results in lower cell temperatures.

**Figure 4.** Change in temperature profile due to degradation

**Figure 5.** Optimal Constant H<sub>2</sub> Production Operation (Maximize Integral Efficiency)

Table 1 compares key performance measures from the different dynamic optimization case studies. These include the average H<sub>2</sub> production rate, specific energy

consumption, and average degradation rate as calculated in Equation 13.

$$\text{Voltage Degradation Rate} = \frac{1}{t_f} \frac{\bar{V}_t - \bar{V}_0}{\bar{V}_0} \times 100 \quad (13)$$

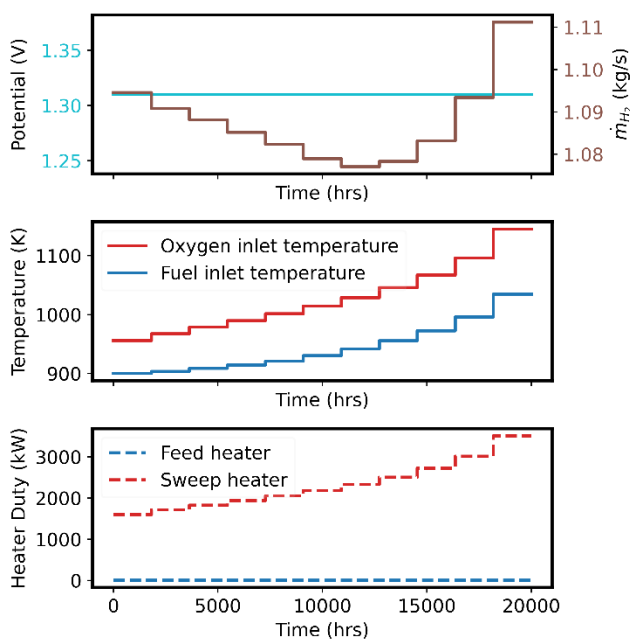

The initial operating point for all cases is identical, and the specific operating conditions were obtained by a steady-state optimization to ensure a H<sub>2</sub> production rate of 1.5 kg/s. This corresponded to an optimal initial voltage of 1.31 V. For more details on the steady-state optimization, refer to [5].

When operating at a constant H<sub>2</sub> production rate, the choice of operating objective can result in significant changes in specific energy consumption and degradation. In this work, we consider the fixed H<sub>2</sub> production rate achieved by constant current density operation to be the upper limit of H<sub>2</sub> production by the system. Based on the costing methods used in this study, a lower LCOH is obtained when integral system efficiency is maximized. Figure 5 describes the temporal profiles of the key decision variables to achieve the maximum integral efficiency. Due to increased voltage losses caused by degradation, operating potential must be increased to maintain the initial H<sub>2</sub> production rate ( $\dot{m}_{H_2}$ ) of 1.5 kg/s. Since inevitable losses depend directly on temperature, the optimal inlet temperatures for both the fuel and oxygen electrodes must be increased to maintain voltage efficiency. Feed and sweep heater duties are kept low due to the presence of recycle streams. Therefore, internal stack resistive heating is used instead of electric heating in the trim heaters. In contrast, degradation rate can be minimized by operating the cell at low temperatures. This results in a significant increase in inevitable losses and, consequently, there is a drop in efficiency as evidenced by the increase in specific energy consumption.

Under a constant potential operating regime (Figure 6), it is observed that the degradation rate depends heavily on the specific operating profile even when operating under constant potential. Under a constant potential over the operating lifetime of the cell, the lowest degradation rate is achieved by operating the cell at low temperatures and, consequently, a very low H<sub>2</sub> production rate (~70% reduction compared to constant H<sub>2</sub> production). Consequently, the specific energy consumption and LCOH when the degradation rate is minimized at constant potential is the highest of all the cases. On the other hand, if operation is optimized for maximum H<sub>2</sub> production under a constant operating potential, we observe a significantly higher degradation rate. At any point in time to maximize H<sub>2</sub> production rate at a constant operating potential, the cell must be operated at the upper bounds of the temperature. Therefore, high temperature ensures a high instantaneous H<sub>2</sub> production rate at all points in time. Consequently, the degradation rate is significantly higher than in all other cases, including those

where  $H_2$  production is held constant.

Figure 6 describes the optimal operating profiles for constant voltage with the objective to maximize integral efficiency. While keeping potential constant, initially it is preferred to operate at a decreasing  $H_2$  production rate to minimize degradation in the early periods of a cell's lifetime. Once degradation in the cell reaches a certain level, it is observed that the  $H_2$  production rate increases again. This is likely because of a phenomenon known as cell break in, resulting from the different rates of degradation of the electrode materials. For example, in Ni-YSZ fuel electrodes, there is a coarsening of Ni particles, while the YSZ particles remain unchanged. The YSZ backbone therefore has a limiting effect on the maximal extent of Ni degradation. Similarly, the parabolic growth rate of oxide scales in the oxygen electrode decreases with the increase in the extent of the oxide scale. To evaluate all optimization formulations and  $H_2$  demand profiles, the LCOH was computed for the five cases. For details on LCOH calculations and costing methodology, refer to [12]. Results presented in the paper correspond to an electricity price of 0.30 \$/kWh. According to this costing methodology, operating at a constant potential and maximizing integral average efficiency leads to the lowest LCOH. The cases with the highest LCOH are those with high energy consumption, where the degradation rate is explicitly minimized. This indicates that system efficiency and  $H_2$  production rate have a higher impact on LCOH than stack replacement costs.

**Figure 6.** Optimal Constant Voltage Operation (Maximize Integral Efficiency)

## CONCLUSION

In this work, we present a dynamic optimization methodology to obtain time dependent operating points for an SOEC system considering the effects of chemical degradation on operating efficiency. The quasi-steady state assumption enables model size reduction to perform dynamic optimization on a fully discretized DAE model.

The 2D non-isothermal SOEC model used in this study captures the thermal implications of chemical degradation. In addition to an increase in electrochemical losses, it is found that chemical degradation results in an overall increase in exothermicity due to an increase in resistive heating. The balance-of-plant model facilitates accurate estimation of SOEC system energy requirements from auxiliary equipment such as heaters and blowers.

Dynamic optimization of long-term operating conditions over 20,000 hours was performed under two  $H_2$  production profiles; namely, constant  $H_2$  production and constant potential operation. This study shows that both operating profiles can result in efficient long-term operation depending on the optimization objective. Strong trade-offs between the integral average operating efficiency and the degradation rate are observed. LCOH is computed for each of the cases and is used to evaluate the different operating trajectories. Operating at a constant potential while maximizing the integral efficiency is found to have the lowest LCOH at 0.29 \$/kWh  $H_2$  with a replacement schedule of 2 years. It must be noted that the LCOH calculation depends on many factors such as the interaction between stack replacement costs and the price of electricity. In a situation where stack replacement costs are higher, it is possible that lower degradation rates would be favorable. Furthermore, this study does not consider the impact of operation on physical degradation. This poses the challenge of incorporating operating profiles from a shorter timescale of daily operation.

## ACKNOWLEDGEMENTS

## ABSTRACT

The decarbonization of the society has a very high effect on the power grids as especially the energy generation will be almost completely shifted to CO<sub>2</sub>-neutral sources such as wind and solar. This implies significant design changes to the power grids and power systems, which lie between the electricity producers and consumers. In this paper, we discuss both the generation and consumer side, including the grid changes and required data exchange to support the transition.

**Keywords:** Electricity & Electrical Devices, Energy Conversion, Renewable and Sustainable Energy, Energy Systems, Power Grid

## INTRODUCTION

Traditionally, power systems have been relatively straightforward: Control a set of electricity generation units balancing the demand and transfer the needed

power to the consumer – one way. This has been a very robust design scheme between the energy providers and consumers, also from the controllability point of view. However, with the introduction of new energy technologies (wind, solar, distributed energy resources,

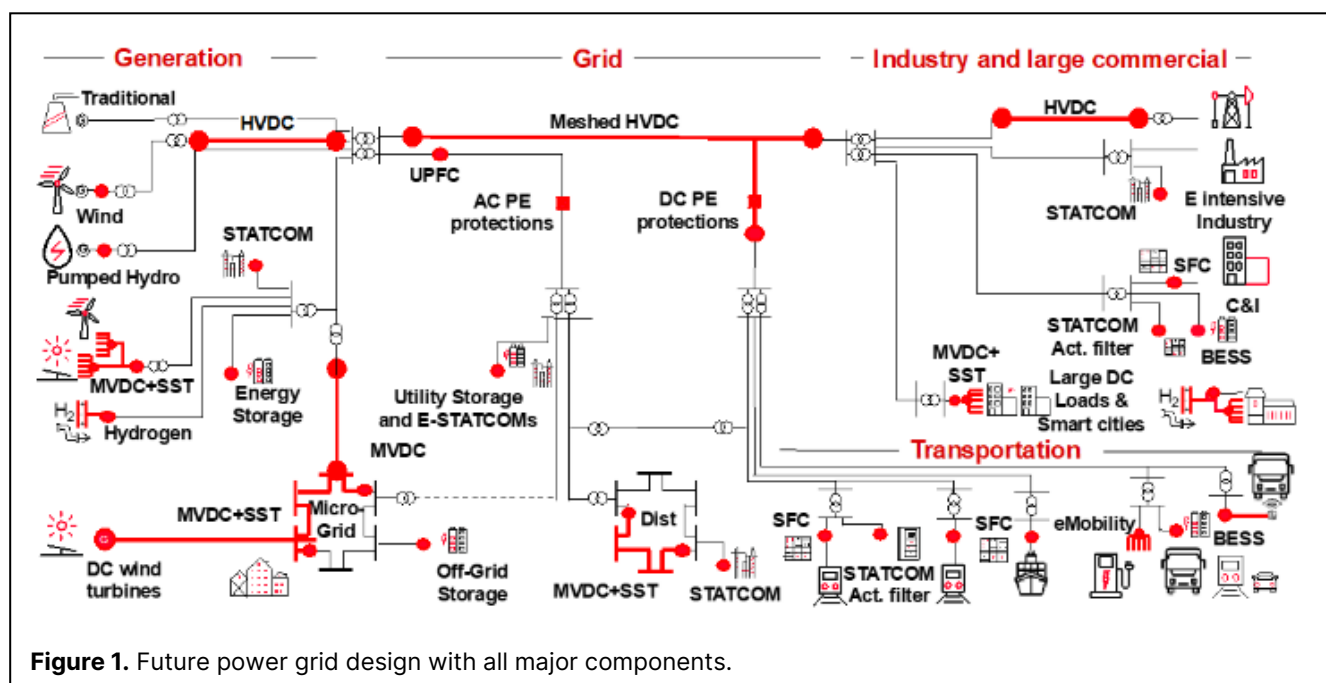

Figure 1. Future power grid design with all major components.

demand-side management, hydrogen, etc.), the traditional design paradigm is no longer sufficient [1][2].

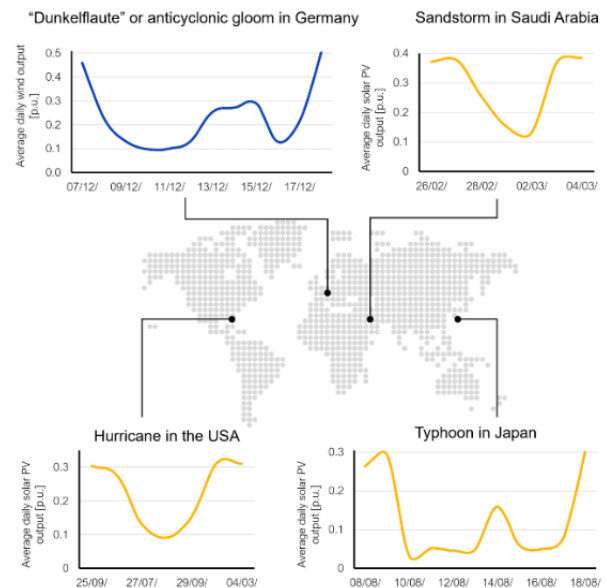

Deregulation of electricity markets and the increased awareness of the climate change have massively increased the share of weather-dependent renewable generation and the need for more flexible power systems. Consequently, due to the volatility of renewable sources, not only are the electricity grids pushed to their boundaries, but there is also a stronger need to create designs where process systems and power systems meet and become strongly integrated. One concrete example is sector coupling, in which various processes are utilized to transfer between electricity and other energy carriers (e.g. ammonia and hydrogen).

**Figure 1** depicts the structure and different components of a future power system. The focus of this paper is on highlighting and discussing potential design changes and challenges involving hardware to enable stronger grids with higher and more intelligent electricity transfer volumes, as well as processes for conversion between electricity and hydrogen. To realize these, the related investments must be both economically and practically feasible to ensure the needed flexibility, and enable secure and sustainable energy supply in all situations, while avoiding stranded infrastructure costs.

In this paper we follow the main structure of **Figure 1** and go into details of the generation and grid aspects. We also discuss the role of industry and large commercial electricity users, as well as the data exchange as an enabler of future collaboration and communication.

## GENERATION SIDE

In short, due to the electrification of industrial processes and transportation sector as well as fast growing share of distributed renewable generation, we can expect that the total global installed electricity generation capacity will increase by a factor of four and the related electricity transfer capacity by a factor of three until 2050. Maybe the most visible changes that have been penetrating the energy landscape in the last decades are on the generation side. To reduce the CO<sub>2</sub>-emissions and due to safety concerns, energy generation has shifted towards variable renewables, mainly utilizing solar and wind power. Many coal-fired and CO<sub>2</sub>-free nuclear power plants have been retired and replaced by significant renewable capacity. In practice, this means going from dispatchable to non-dispatchable energy generation, i.e. we cannot anymore decide and fully control how much and when to generate. The only long-term “traditional” CO<sub>2</sub>-free and flexibly dispatchable electricity generation is hydro power resources, including pump hydro storage. However, as it is both geographically limited and subject to societal constraints,

**Figure 2.** Examples of global weather-dependent disturbances on renewable production.

this “green” transition has already presented significant changes in the electricity supply, mainly observable through significant price changes and spikes during energy scarcity.

The imminent change to the power grid is that maintaining the stability (ensuring and controlling the grid frequency and voltage) becomes more challenging as there is less inertia, dynamic voltage support and sufficient short circuit capacity, e.g., from synchronous rotating machinery present in the system. If, for instance 50% of the electricity generation comes from renewable sources, of which solar power is guaranteed to produce 0 MW in the nighttime and wind power production is highly weather-dependent, it is of great importance to design methodologies for how to deal with times where renewable production is low or even non-existing.

**Figure 2** shows examples across the globe where extreme weather events had an unexpected and significant negative impact on the renewable generation. One approach is to increase the capacity, but this will not solve the root cause of the problem. Another approach is to investigate novel electricity generation technologies such as microreactors, wave power, solar power provided in space and many more recently discussed ideas or solutions at a very early prototype or conceptual phase.

The main target is to be able to deal with the high volatility (worst case is a cold and windless winter night where the energy demand is high) and secure energy supply also through those times where renewable energy is temporarily unavailable [3]. As depicted in **Figure 3**, investing in generation overcapacity is not sufficient

**Figure 3.** Actual use of versus potentially available wind and solar generation (dots represent different regions each with an optimal mix of solar and wind generation). Red numbers show the average penetration percentage based on annual generation and demand match with hourly resolution. Static and dynamic system limits will push the grey zone further down.

since it does not solve the underlying problems of spatial and temporal mismatches between the generation and demand. A possible solution could also lie in process design by making processes more resistant to short- or mid-term energy scarcity. Currently, much research is focused on energy storage options [4], where most alternatives can only provide hours or maximally a few days of capacity. Even the largest electrochemical energy storage (e.g. lithium-ion batteries) can only serve short-term demand and therefore alternatives vary between e.g. gravitation-based energy storage, power electronics, compressed air, molten sand batteries and sector coupling.

Sector coupling, i.e. switching to alternative energy carriers such as hydrogen or ammonia is still in its very early stages. There are still challenges to overcome, e.g. the low round-trip efficiency of 35% for hydrogen and the fact that upfront investment costs are currently quite high. However, this technology is attractive from a few points of view.

1. Alternative energy carriers are relatively stable and can in principle with sufficient capacity help bridging across low renewable power periods.
2. They can also be distributed along the power grids to end consumers, naturally with much slower dynamics (pipelines, ships, trucks). However, a compatible infrastructure is still missing.
3. They can be stored at various sites in small amounts reducing the regional risks of energy scarcity. Larger

storage capacities are geographically constrained.

4. Apart from pure energy storage, many of them can also be used as raw-material or produced as by-product of essential industrial processes.

Especially the last point is worth considering as without re-electrification the losses are much smaller. It is still unclear how the related conversion processes should be designed and embedded into an effectively working energy system. The ongoing overall development also implies that generation will become more local (solar rooftop etc.) and therefore the grid structures must also be adapted to meet the ongoing changes.

## GRID SIDE

As already stated in the introduction, the increased generation also results in roughly three times more energy transmission capacity needed by 2050. Due to this, there are many design changes necessary in the power grids, both on the level of transmission grids that are responsible for the long-distance electricity transfer and connected to large-scale power plants, as well as distribution grids, which operate on a lower voltage level and connect to local consumers and prosumers (e.g. households with solar rooftop and energy storage systems) [5]. The increasing power production within the distribution grid must be supported by stronger local grids. Already today, there are situations where the generation or load must be curtailed in order to avoid grid congestion or voltage issues.

Network switching within a distribution grid, i.e. changing the network topology, can also help in avoiding some congestions. Here, the connection points to the transmission grid may also be changed. Thus, in many situations a closer and faster coordination between the distribution and transmission grids with different voltage levels is required. As much of the energy generation is in fact done in direct current (DC) (e.g. solar power), it must be converted to alternating current (AC) through power converters. Here, many discussions on building pure local DC grids and experimental microgrids for this exist [6]. This could also affect the industry electrification as many processes also utilize direct current.

One of the perhaps largest changes in the transmission grids is caused by the long transmission distance needs between remote renewable generation and the major load centers (often > 1000 km, the longest one of 3300 km built in China). Here a large capacity is transferred and, in order to reduce the power losses and keep the voltage drop within acceptable range, this should take place in high voltage and preferably using high voltage direct current (HVDC) technology, which has significantly lower losses compared to traditional AC-

grids. This also enables the transfer of very high capacities of e.g. 12 GW. Investment costs in HVDC grids and converters are not only very high, but together with other grid improvement measures, including more flexible switching and power converters, also open up new dimensions that require a higher level of automation to work seamlessly. The power network should be continuously monitored and seamlessly adapted to changing situations as well as be able to minimize the impact of local disturbances trying to isolate blackouts to as small areas as possible.

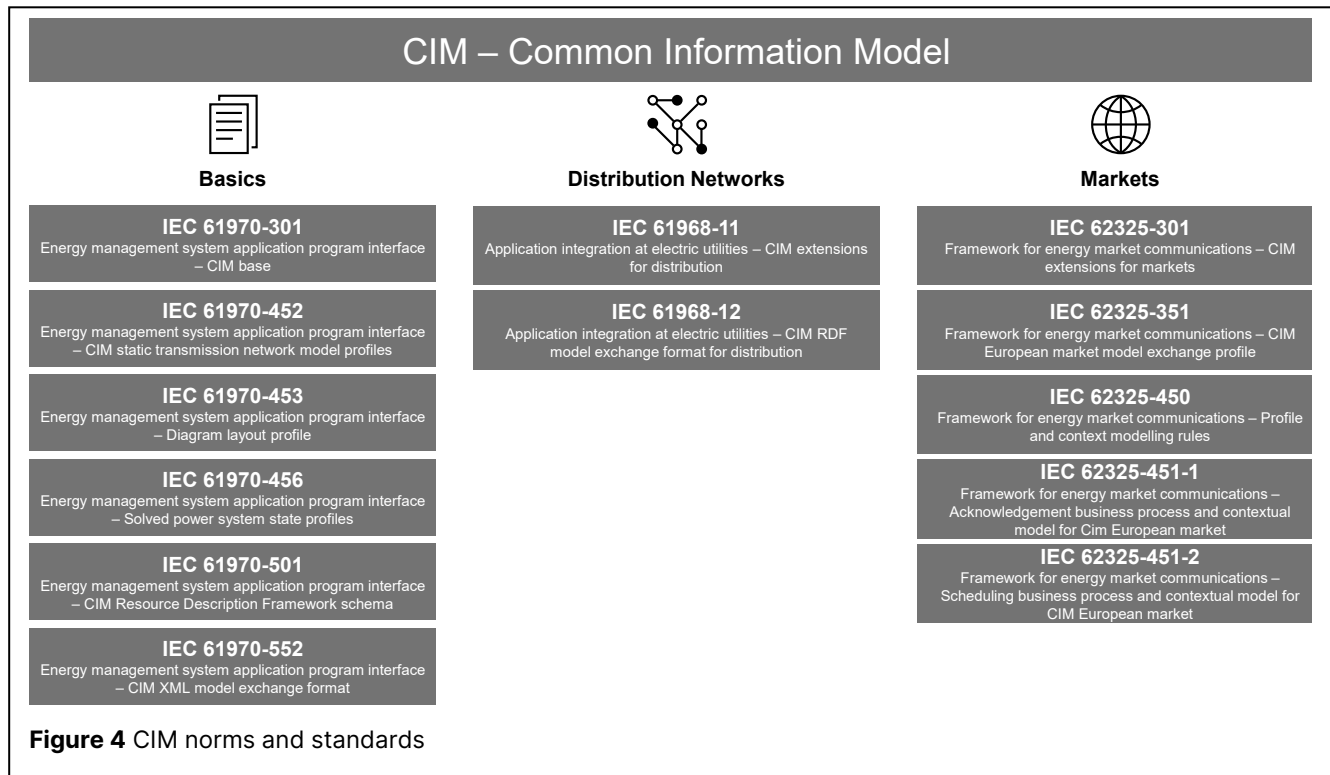

In order to both build more safety buffers for the grid, as well as to maximize the utilization possibility of intermittent renewable generation, we also need energy storage options to support short-term network imbalances and long-term seasonal variations. All of these must naturally also be connected to the power grid (be it transmission or distribution), and may also include sector coupling that calls for simultaneous coordination between multiple energy carriers, e.g. electricity, ammonia, hydrogen and the respective processes managing the conversion.

As the energy supply chain gets increasingly concentrated around electricity, it also becomes a possible target for various threats. Cyber security should be significantly strengthened to ensure a fully functional power grid in all situations – also when the automation systems are under attack.

## INDUSTRY AND LARGE COMMERCIAL

Industry and large commercial are typically consuming around 50% of the total energy (region-dependent) and will play a significant role in the new energy system since we can expect more industrial processes being electrified. With the increasing volatility as well as higher electricity demand, these sectors must provide more flexibility by design, i.e. become prosumers (consumers that can also at least virtually act as producers by temporarily lowering their energy demand). Typically, we refer to this as industrial demand-side management [7]. The main idea is to be able to plan the processes in a way that provides more flexibility towards their electricity need, often with the main objective of reducing the electricity costs. This also gives the power grid operators the opportunity to provide incentives to the market participants through dynamic pricing schemes. Enabling the capability to participate may require significant and expensive changes in process design, as e.g. can be seen in the ongoing electrification of steel industry [8].

Once processes are adapted to provide more flexibility, the next natural step would be to create collaboration opportunities to support large electricity fluctuations with lower impact on the individual processes. Here, we can also expect to see more “isolated” or per need autonomous microgrids that can maintain all critical operations even during a major blackout. These could comprise communities, but also critical functions such as hospitals or industrial sites that

are strongly affected by any power disruptions. There is already much research on how to realize this, e.g. using smart cities concepts with rural areas [9] and university campuses as testing platforms. Nonetheless, it is still an open question how to realize this on a larger scale.

What is unquestionable is that certain autonomy requires local energy generation – even power plants for securing times without renewable generation. To further ensure a CO<sub>2</sub>-free future, these could also be based on sector coupling and various energy storage technologies, either in form of electricity (batteries), hydrogen, ammonia or other chemical forms, as well as number of currently studied technologies, such as gravity batteries [10]. There has been recently also studies looking into either coupled processes with batteries [11] or enabling the process itself being used as energy storage [12][13].

In order to enable and realize these opportunities, there needs to be – apart from novel designs and respective operational updates – also changes to the current power systems market design, which is still not built for enabling sufficient flexibility but rather relies on dispatchable energy generation.

## DATA EXCHANGE

To enable smooth cooperation between various entities in the power system, including system operators, market participants and owners of various assets, standardized data exchange processes are needed. This includes not only standardized data formats to reduce the overhead of data post-processing, but also systematic platforms for data exchange with sufficient cyber-security and ensured data privacy. Information exchange between various entities can be split into three categories based on the time domain:

1. Static data exchange covering general information such as grid topology and installed assets with their characteristics and capabilities.
2. Scheduled data exchange covering information on scheduled functioning of different elements such as day-ahead market bids, generation and load forecasts, planned outages, and information about expected flexibility.
3. Real-time data exchange covering all real-time information such as telemetry measurements, control setpoints, open/close states of switching equipment, node voltages, and any calculated values (line flows, reserves, etc.).

Depending on the nature of data and the role of different entities, data exchange can be either unilateral or bilateral. It is complex to define a unique list of data requirements that are suitable for all entities and all possible cooperation architectures. Still, it is commonly

agreed upon that in addition to the data values themselves, each dataset should be supplemented with metadata including data source, data user, purpose of the data exchange, principles to be applied (e.g. privacy), and KPIs (e.g. data accuracy and latencies) to verify compliance with requirements of different entities.

International Electrotechnical Commission's (IEC) has introduced the Common Information Model (CIM) standards to facilitate data exchange between different entities [14] as shown in **Figure 4**. Despite the great improvement in interoperability that CIM standards provide, they still need to continuously evolve to meet the changing requirements due to the emerging power system landscape. For instance, practical implementation can be challenging since CIM standards do not cover many aspects such as data portability, aggregation and anonymization, data exchange logs and authentication information. How to create working interfaces to other industrial standards and protocols (e.g. OPC UA, ANSI/ISA-95 and S88) is still undefined, as most standards have been created in an isolated business-specific manner. This, however, needs to be done to enable stronger and more straightforward collaboration opportunities and relationships between the power grids and industrial processes.

## CONCLUSIONS

In this paper we have discussed future challenges arising through the energy transition towards zero emission society. This transition has a great impact on the generation and consumption side but also on the often-ignored power grids and -systems. These must be properly expanded w.r.t. capacity and capability to enable a flexible electricity supply and demand. Energy storage and sector coupling play here an important role. The transition will not happen in an isolated way but calls for stronger collaboration as the resulting system will be a co-play between process- and power systems. One of the first steps is to have proper data exchange where the common information models play a central role. Other concrete design-related challenges are:

- Electrification of processes and the related major changes needed in process design.
- Making processes more resilient against short/mid-term electricity scarcity.
- Related to this, evaluating the cost and benefits of microgrid-enabling design alternatives.
- Enabling flexibility by design in order to allow stronger operational collaboration between process and energy markets.
- Optimal designs to support and benefit from sector coupling, using alternative carriers as CO<sub>2</sub>-

free raw-materials, energy storage for trading and to securing own operations.

The next decades will be a golden era for researchers who are interested in focusing on both process and energy aspects – in design, operations and control domains.

## ABSTRACT

The energy transition is driven both by the motivation to decarbonize as well as the decrease in cost of low carbon technology. Net-carbon neutrality over the lifetime of technology use can neither be quantitatively assessed nor realized without accounting for the flows of carbon comprehensively from cradle to grave. Sources of emission are disparate with contributions from resource procurement, process establishment and function, and material refining. The synergies between the constituent value chains are especially apparent in the mobility transition which involves (i) power generation, storage and dispatch, (ii) synthesis of polymeric materials, (iii) manufacturing of vehicles and establishment of infrastructure. Decision-making frameworks that can coordinate these aspects and provide cooperative sustainable solutions are needed. To this end, we present a multiscale modeling and optimization framework for the simultaneous resolution of the material and energy value chains. A case study focusing on the transition of mobility technology towards electric vehicles in Texas is presented. The key contributions of the proposed framework are (i) integrated network design and operational scheduling, (ii) the tracking of disparate emissions, (iii) simultaneous modeling of the material and energy supply chains, (iv) implementation on `energy`, a python package for the multiscale modeling and optimization of energy systems.

**Keywords:** energy transition, material transition, mixed integer programming, multiscale modeling, carbon accounting

## INTRODUCTION

The ongoing energy transition towards net-carbon neutrality has various challenges, not limited to (i) managing the storage for intermittent renewables, (ii) accounting for emissions from disparate sources, (iii) managing the cost to consumers, (iv) coordinating the transition of technologies for different applications such as the generation of power, transportation and production of dense energy carriers (DECs) (v) meeting the material requirements for establishing infrastructure sustainably [1]. Addressing these challenges requires a holistic view of multiple interdependent supply chains and the synergies between them.

Moreover, decarbonization requires both direct and

indirect emissions to be accounted for. Direct emissions occur from the release of pollutants at the operational level by processes, whereas indirect emissions occur due to the refining and procurement of materials and resources as well as the establishment of processes and infrastructure. Further, indirect emissions occur at the onset of establishing infrastructure, while direct emissions can occur over a protracted temporal horizon throughout the lifetime of technology. Decision-makers planning energy systems of the future need to coordinate both aspects to determine optimal transition pathways.

Materials such as minerals, metals, and polymers are required to establish infrastructure. The refining and processing of these is a contributor to emissions. However, polymers can also act as a carbon sink and, in the

context of the circular economy, provide an opportunity for the valorization of the carbon vector.

Given our contemporaneous dependence on carbon-based feedstock for both power generation and production of polymers, the oil & gas (O&G) industry plays a central role in enabling both the energy and material transition. The repurposing of the O&G industry towards the manufacturing of polymeric materials through captured carbon dioxide will also preserve established production infrastructure and capital. Furthermore, polymers offer a durable alternative to metallic materials which have a high energy demand for refining, produce toxic refuse during mining, and have challenges in terms of recycling and reuse in some cases. For example, passenger vehicle designs have evolved to include a larger amount of polymers in their interior while achieving improvements in efficiency and safety due to lower density and higher impact resistance respectively [2].

The use of hydrocarbon feedstock to produce polymers for electric vehicles (EVs) as opposed to transportation fuels for internal combustion engine (ICE) vehicles can also reduce direct carbon emissions as they can act as a sink for carbon that would be otherwise emitted as greenhouse gases (GHGs) [3]. Readily available polymers such as polypropylene (PP), polyamide (PA), polystyrene (PS), polycarbonate (PC), polyurethane (PUR), polyvinyl chloride (PVC), polyethylene (PE), and polyethylene terephthalate (PET) all find use in automobile production. Moreover, polymers are also needed for insulation in grid infrastructure, power conversion systems, and also for ancillary infrastructure in solar and wind farms.

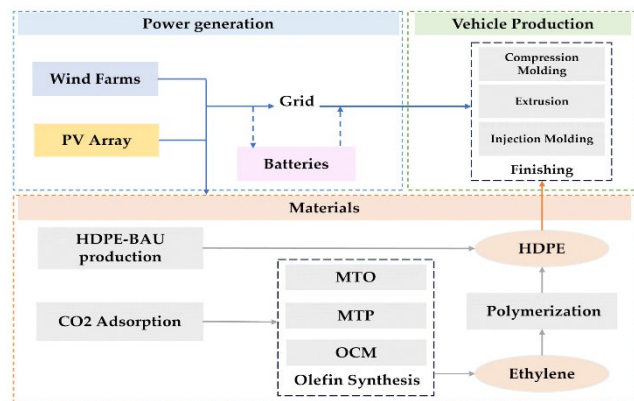

While the modeling and optimization of different aspects of the energy transition has been an active field of research [4,5,6,7], the parallel transition of materials has not received equal attention. In this publication, we introduce a framework for the simultaneous modeling of the material and energy transition, allowing the identification of solutions that reduce emissions across disparate emission scopes. The system is represented through the resource task network (RTN) methodology augmented for the consideration of different material options for process infrastructure. The emissions arising from disparate sources such as material synthesis, resource consumption and utilization post discharge, and production are considered. The mathematical programming framework is modeled as a mixed integer linear program (MILP) with binaries assigned for the establishment of processes and the choice of material modes for said processes. Moreover, the model does simultaneous network design and scheduling which is able to account for renewable intermittency and optimize energy storage.

The publication is organized as follows: first the details of the considered mobility transition supply chain are discussed, next the modeling and solution methodology are elucidated upon and certain aspects of the general

formulation are discussed, followed by the results and ongoing work.

## A MOBILITY TRANSITION SUPPLY CHAIN

The mobility transition with respect to passenger vehicles entails the adoption of EVs to replace ICE vehicles. Using a simple linear forecast to predict EV sales for Texas, more than 900,000 units will be sold in 2050 considering an annual sales growth rate of 16% [8], and about 12 million EVs will be on the road. EVs differ from ICE vehicles in both the energy source for their function, as well as the supply chains involved in making energy available. Fossil fuels utilized in ICE vehicles cause emissions at the point of use. Conversely, EVs have no direct emission but can cause emissions as a result of power generation through fossil fuel-based power generation. Moreover, while power can be generated through renewable means, materials required to establish power generation and distribution infrastructure are still privy to emissions. The transition to EVs will need to be supported by an expansion of the grid and power generation infrastructure.

**Figure 1.** A schematic of the mobility transition supply chain.

The transition of mobility infrastructure requires the transition of technologies for 1) transportation 2) manufacturing, 3) power generation, and 4) polymer production. As a whole, three distinct blocks can be considered as shown in Figure 1, viz. 1) Power generation which include solar photovoltaics (PVs) and wind farms (WFs), 2) Polymer production wherein High Density Polyethylene (HDPE), 3) the production of vehicle parts through a combination of different molding methods. As a whole, we look at two different technology pathways:

1. The business as usual (*BAU*) pathway where in HDPE is produced from fossil feedstock such as natural gas and oil
2. The carbon capture utilization and sequestration (*CCUS*) pathway which necessitates the direct air

capture (DAC) of CO<sub>2</sub> followed by one of three processes for the production of olefins, with polymerization of produced ethylene as the final step

The three pathways for olefin production considered are:

- **Methanol to Olefins (MTO):** In this route, methanol is synthesized from CO<sub>2</sub> hydrogenation and converted into olefins (ethylene and propylene).
- **Methanol to Propylene (MTP):** In this process, the major product is propylene, which is synthesized from CO<sub>2</sub>.
- **Oxidative Coupling of Methane (OCM):** This process produces mainly ethylene through oxidative coupling of methane derived from the hydrogenation of CO<sub>2</sub>

The MTO and MTP processes represent successful initiatives aimed at reducing reliance on petroleum for olefin production. In the MTO process, methanol is transformed into olefins with a carbon selectivity ranging from 78% to 82% at approximately 500 °C and 250 kPa, utilizing a SAPO-34-type zeolite catalyst. The by-products include propylene, C4 fraction, and liquified petroleum gas (LPG).

Similarly, in the MTP process, methanol is converted into propylene with a carbon selectivity of around 71% at temperatures between 400 and 500 °C and a pressure of 150 kPa, employing a zeolite-based catalyst [9]. LPG, propylene, and C5 fraction are by-products.

In the OCM process [10], methane (CH<sub>4</sub>) and oxygen (O<sub>2</sub>) undergo an exothermic reaction on a catalyst bed, resulting in the formation of ethylene (C<sub>2</sub>H<sub>4</sub>), ethane (C<sub>2</sub>H<sub>6</sub>), water (H<sub>2</sub>O), and heat. Traditional reactors, such as packed bed reactors (PBR) and fluidized bed reactors, have been commonly employed for this purpose. However, there is a current exploration of Fluidized Bed Membrane Reactor (FBMR) options to assess the potential improvement in selectivity. The operating conditions for this technology involve temperatures of approximately 800 °C and pressures of 200 kPa. Further, all three processes require the provision of steam, cooling water, oxygen, and hydrogen besides power.

Produced ethylene is converted into HDPE via polymerization through different technologies such as CSTRs, loop slurry, fluidized-bed gas phase, and stirred-bed gas phase reactors. Various processes have been marketed by companies such as LyondellBasell, Mitsui Chemicals, Chevron Phillips Chemicals, Univation, Lummus Novolen, etc. Nevertheless, as data for such processes is not publicly available, the average data from Europe for such processes is considered [11]. Both HDPE production routes, BAU or CCUS, are subject to the finishing processes; a combination of compression molding

(CM) 24.25%, extrusion (EX) 9.25% and injection molding (IM) 66.5% [8].

Currently, the energy demand for EVs and production of resources is met through a mix of fossil fuel (coal and natural gas), and renewable (wind and solar) power generation. In the transition scenario, renewable power will replace fossil fuel-based power generation. Moreover, requisite power generation and management systems can be established through different material alternatives as well. PVs, for example, can be made from monocrystalline or polycrystalline silicon, lithium for lithium-ion batteries can be sourced either through rock or brine lithium, and wind farms can be offshore or land-based each with different material requirements. The other materials required for construction include glass, steel, concrete, aluminum, silicon, copper, and cast iron.

Polymers in EVs account for about 13% of the mass of the vehicle. In the illustrative example, we only consider the need for HDPE which accounts for about 2.7 kg (1.4%) mass of the total amount of polymers used in cars [12], the total car mass considered is 1481 kg. The objective of the considered study is to analyze the network designs of the current HDPE demand for the ~1.3 million passenger vehicles produced annually in Texas through renewable means. Of key interest are 1) the identification of optimal cost and emission technology pathways, 2) the quantitative determination of the trade-offs between cost and emission, 3) identification of optimal material modes for the establishment of infrastructure.

The region of Houston is used as a proxy for the entire state of Texas for the collection of wind and solar data. The GREET model is used to source parameters for natural gas, oil, electricity use, and related process emissions [12], while the Ecoinvent version 3.9.1 database is used to assign a global warming potential (GWP) for every material considered in the study [13].

## METHODOLOGY AND FORMULATION

The framework is multiscale in that it models spatiotemporally disparate phenomena such as renewable intermittency and augmentations in technology costs and efficiency. Moreover, the operational and network planning decisions are modeled simultaneously as well. Emissions are considered from: 1) resource consumption, 2) resource discharge, 3) material procurement for establishing infrastructure. The framework can also consider emissions from construction or manufacturing processes, but this is not modeled in the presented case study given the lack of reliable data. Note, that the framework can also account for different environmental indicators, namely, global warming, ozone depletion, acidification, and eutrophication (marine, terrestrial, freshwater). However, the presented case study only accounts for the global warming aspect of emissions.

For energy technologies, power generation processes are modeled alongside energy storage, and different material modes are considered. The lithium-ion battery (LiI), for example, can use lithium sourced from brine or rock. Each option has different associated emissions due to the process of mining these materials differ significantly. Similarly, different combinations of materials such as steel, cast iron, silicon, concrete, etc. are considered for establishing PVs and WFs.

The system is represented and modeled through an augmentation of the resource task network (RTN) methodology, which considers the materials required to set up processes [14]. This representation is christened the resource task material network (RTMN). Resources, by definition, can be consumed, discharged, stored, transported, or produced. On the other hand, materials are utilized solely for the establishment of infrastructure such as transport linkages and processes. The need for this strict distinction between materials and resources stems from: (i) unlike resources, materials are not converted, (ii) disparate temporal nature of use, wherein resources are used continuously over the scheduling scale and materials are used only in time periods over the network scale when technologies are established, (iii) convenience of reporting emissions in terms of scopes. As a whole, this streamlines the system representation as well as the mathematical modeling. As an example, in the mobility transition supply chain, HDPE is a *resource* produced through the culmination of a set of processes, whereas the concrete required to establish a wind farm is a *material*.

The planning horizon is considered at two distinct discretizations: 1) a scale for network level decisions, 2) a scheduling scale with 8760 discretizations to capture the intermittency of renewables and the flow of resources. Given that a single period is considered for network level decisions, the capital cost or emissions related to material utilization are not annualized. However, the model can be easily expanded to consider multiple network periods along with associated changes in technology costs. Further, while the example presented models a single location, multiple locations along with associated transportation modes between these locations can also be considered.

The framework simultaneously optimizes network design and process scheduling. Mixed integer programming is used with binaries for decisions such as locating processes and determining optimal material modes. Continuous variables capture the mass balance, and monetary aspects. Some important constraints such as the material balance, emission constraints, and network design are discussed here. Network design is achieved through constraints (1 and 2). Material constraints (3-5) allow the model to choose between different available material modes. Each material mode in turn has an

associated consumption of materials ( $\phi$ ) per unit capacity. Notably, emissions can also occur through 1) the consumption or use of produced resources, and 2) direct process emissions as shown in emission constraints (6-9). Inventory balance in every time period in the scheduling horizon is done through constraint 10, wherein each variable is bounded by either a parameter ( $S^{max}$  for S,  $C^{max}$  for C), or by a variable in the network scale ( $Cap^S$  for  $Inv$ ,  $Cap^I$  for  $P$ ).

sets	definition
$l \in L$	location
$i \in I$	process
$r \in R$	resource
$m \in M$	material
$w \in W$	material modes
$e \in E$	emissions
$t \in T^N$ or $t \in T^S$	network or scheduling scale

variables	definition
$Cap_{l,i/r,t}^{I/S}$	process/inventory capacity
$Em_{l,e,r/i/m,t}^{r/i/m}$	resource/process/material emission
$Em_{l,e,t}^{(L)}$	Emission (total at location)
$C_{l,r,t}^{(L)}$	Resource consumption (total at location)
$S_{l,r,t}^{(L)}$	Resource discharge (total at location)
$Mat_{l,i,mt}^I$	Material utilized for process
$Mat_{l,m,t}^L$	Material utilized at location
$Cap_{l,i,m,t}^{I-W}$	Capacity of material mode
$X_{l,i,m,t}^I$	Binary for locating process
$X_{l,i,w,t}^{I-W}$	Binary for choosing process mode
$X_{l,r,t}^S$	Binary for storage facility
$Inv_{l,r,t}$	Inventory level for resource
$P_{l,i,t}$	Production level for process

parameters	definition
$Cap_{l,r/i,t}^{S/I-min/max}$	max/min inventory/process

	capacity
$EP_e^{r/m}$	resource/material emission
$\phi(m, w)$	material consumption
$\eta(r, i)$	conversion

$$Cap_{l,r,t}^{s-min} \cdot X_{l,r,t}^s \leq Cap_{l,r,t}^s \leq Cap_{l,r,t}^{s-max} \cdot X_{l,r,t}^s \quad (1)$$

$$Cap_{l,i,t}^{l-min} \cdot X_{l,i,t}^l \leq Cap_{l,i,t}^l \leq Cap_{l,i,t}^{l-max} \cdot X_{l,i,t}^l \quad (2)$$

$$Mat_{l,i,m,t}^l = \sum_{\forall w \in W} (\phi(m, w) \cdot Cap_{l,i,w,t}^{l-w}) \quad (3)$$

$$Cap_{l,i,t}^{l-min} \cdot X_{l,i,w,t}^{l-w} \leq Cap_{l,i,w,t}^{l-w} \leq Cap_{l,i,t}^{l-max} \cdot X_{l,i,w,t}^{l-w} \quad (4)$$

$$X_{l,i,t}^l = \sum_{\forall w \in W} X_{l,i,w,t}^{l-w} \quad (5)$$

$$Em_{l,e,r,t}^r = EP_e^{r-cons} \cdot C_{l,r,t}^l + EP_e^{r-use} \cdot S_{l,r,t}^l \quad (6)$$

$$Em_{l,e,m,t}^m = EP_e^m \cdot Mat_{l,m,t}^l \quad (7)$$

$$Em_{l,e,i,t}^i = \sum_{\forall i \in I} EP_e^r \cdot \eta(r, i) P_{l,i,t}^l \quad (8)$$

$$Em_{l,e,t}^L = \sum_{\forall r \in R} Em_{l,e,r,t}^r + \sum_{\forall m \in M} Em_{l,e,m,t}^m + \sum_{\forall i \in I} Em_{l,e,i,t}^i \quad (9)$$

$$\sum_{\forall i \in I} \eta(r, i) P_{l,i,t}^l + C_{l,r,t} + Inv_{l,r,t-1} = Inv_{l,r,t} + S_{l,r,t} \quad (10)$$

The implementation in *energiapy* [15] utilizes a component based architecture with temporal horizon, resources, materials, processes, locations, and scenarios serving as modeling components. Various material modes can be declared for each process, wherein the material consumption for the establishment of said infrastructure on a per unit basis is provided as attributes. The associated GWP is declared as an attribute of each material and resource in the object-oriented programming framework. A small example is available in the package documentation to guide users on the application.

## RESULTS AND DISCUSSION

The framework can be optimized to various objectives, the two objectives discussed here are to 1) minimize system costs, and 2) minimize system emissions. First a base case is established wherein the system is optimized only to minimize the system cost while not restricting emissions. The network design for the base case as shown in Figure 2 consists of WF, Lil, HDPE production from the BAU pathway and the molding processes (extrusion, compression, injection). Moreover, the land-based material mode is chosen for establishing WF, and brine lithium is chosen for the Lil. The emissions resulting from the 2.7 kg requirement of HDPE per car is found to be 11.08 kg CO<sub>2</sub>-eq. This includes 3.15 and 0.8 kg CO<sub>2</sub>-eq from the purchase of natural gas and oil respectively, 5.12 from the venting of CO<sub>2</sub>, and 2.00 from the material requirements for establishing the land-based WF and brine lithium based Lil.

**Figure 2.** Low cost pathway for HDPE production.

**Figure 3.** Low carbon pathway for HDPE production.

With the base case established, the network is then optimized towards the reduction of GWP. The maximum possible reduction in emissions is found to be ~9.07%. The cost optimal design for a ~9.07% reduction in emission tilts in favor of the CCUS pathway. The reduction entails a 2.2 factor increase in cost compared to the base case. Even in the minimum emission case, the BAU pathway for the production of HDPE is still utilized. This is due to the energy intense nature of the CCUS pathway which requires larger power generation and energy storage capacities, which are subject to both material emissions and cost. Further, the OCM process is considered. Note that the MTP and MTO processes both have LPG as a by-product which results in emissions at the point of utilization. The WF and Lil capacities are 1.86 and 3.74 times larger than the base case scenario.

The system can then be analyzed for the successive reduction of emissions up to 9.07%. Figure 4 shows

a Pareto front which compares the reduction of emissions to the cost as compared to the base case. Notably, the first 6% reduction in emissions comes at a marginal increase (16.44%) in cost. The network design also evolves with the reduction in emissions, this includes the choice of technologies, the choice of materials to establish said processes, and the process capacities.

**Figure 4.** Trade-off between emission cost and emissions reduction.

The initial 4% reduction in emissions is achieved largely by setting up the energy intensive OCM process (refer to Table 1), and managing the capacity of the WF with a larger Lil. Beyond 4%, larger power systems are needed to accommodate the higher power demand. Given the higher cost of power infrastructure, system costs increase considerably.

Further, the consistent choice of land-based wind farms in both the minimum cost and minimum emissions represents a *win-win* scenario that offers the best solution across multiple objectives. Similarly, some options are never chosen such as the olefin production through the MTP and MTO route which are recognized as being both cost and emission intensive. As a reminder, processes can have different efficiencies based on the choice of materials, as well as different emission potentials based on the sourcing of materials (such as rock or brine lithium). Also, the cost of technologies are expected to reduce along with augmentations in efficiency resulting from adoption and research as the transition progresses.

It is also observed that a production capacity of HDPE from the BAU pathway is established even in the low carbon scenarios. This pathway is utilized on days with low wind availability given the low power requirement. If this pathway is not made available, the required power generation and energy storage capacity is significantly larger. In fact, to achieve a 6% reduction in emissions without the BAU pathway, the WF is sized at 28.98 MW and Lil is sized at 17.7 MW, representing an increase of 315% and 514.5% respectively. Meanwhile the cost of the system increases 388%. This highlights the trade-offs between direct and indirect emissions. The CCUS pathway utilizes significantly higher power which results in larger power generation capacities which in turn cause an increase in the emissions resulting from material utilization.

Figure 5 shows the disparate contribution to emissions. The largest source of emissions is direct CO<sub>2</sub> discharge. The lower emission scenarios have a larger contribution from WF and Lil as they are sized at a larger capacity. Natural gas (NG) and oil consumption decreases with the lower reliance on the BAU pathway and hence the emissions resulting from their sourcing and purchase. It can also be noted that, in the given model, none of the sources of emissions can be entirely eliminated.

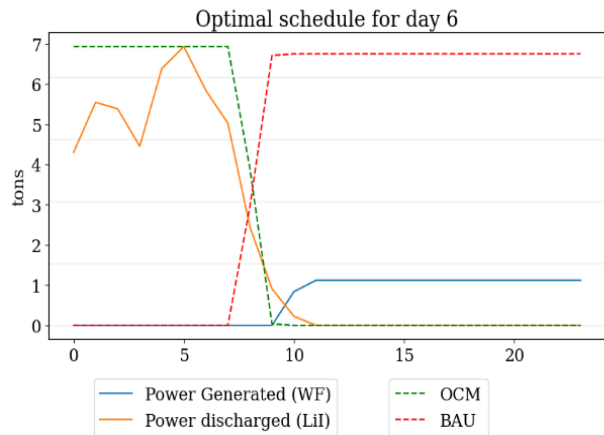

The framework also provides optimal schedules. For example in Figure 6, the schedule for power generation through WF is plotted alongside the power discharged from Lil, and the production through OCM is plotted alongside the production through the BAU pathway for the scenario with a GWP reduction of 6%. It can be seen that the constant demand for HDPE is met either through the OCM or BAU pathway. However, when the wind potential is high the OCM pathway is preferred. During periods of low wind availability, the BAU pathway is preferred with the power demand being met from the discharge of energy stored in the Lil. This is also reflected in the sizing of processes, wherein the BAU process has the same capacity as the OCM process (refer to Table 1).

**Table 1.** Process capacities for different scenarios.

Scenario	DAC (tons)	HDPE-BAU (tons)	HDPE-CCUS (tons)	OCM (tons)	Lil (MW)	WF (MW)
Base	0	0.44	0	0	2.51	8.29
-2%	0.75	0.44	0.1	0.1	2.76	8.03
-4%	2.10	0.44	0.28	0.29	2.75	8.03
-6%	3.23	0.44	0.44	0.45	3.45	9.21
-8%	3.23	0.44	0.44	0.45	6.14	11.98
-9.07%	3.23	0.35	0.44	0.44	9.41	15.45

**Figure 5.** Contribution to GWP from source for each scenario.

**Figure 6.** Schedule for power generation and discharge from energy storage.

Caution should be exercised when interpreting the results due to two limitations: 1) the unavailability of material use data for some processes causing a possible bias in results where values are assumed, and 2) the GWP associated with materials can vary by literature source. Nevertheless, the framework can be interrogated to quantify the sensitivity of the solution to parameter values.

The framework preserves the simultaneous scheduling and network design capability of earlier frameworks in literature [4,5,6,7] while allowing: 1) the estimation of emissions from disparate sources, and 2) identifying optimal material choices for the establishment of processes. Moreover, the framework is applied to a novel case study wherein the material and energy supply chains are modeled simultaneously. This provides a more holistic view of the system, thus enabling decarbonization across the different scopes of emissions. In principle, this framework can be applied towards the optimal

design of systems bearing awareness to life cycle considerations.

## FUTURE WORK

While only GWP is considered in the presented work, other environmental effects such as ozone depletion and acidification potential can also be modeled. The optimization of multiple criteria using multi-objective optimization (MOO) can be reported. In its current form, the emission accounting methodology cannot be considered a comprehensive life cycle assessment (LCA) [7] given the lack of focus on process lifetimes and circularity of materials [16]. A challenge that needs to be addressed in the RTMN methodology is the fact that resources and materials are often not distinct. For example, while HDPE is treated as a resource in the considered mobility example, it may also serve as a material for the establishment of grid infrastructure.

Furthermore, the sensitivity of the model solution to considered parameters can also be assessed. The framework can also be run for longer temporal horizons which will allow the consideration of reductions in technology cost over the temporal horizon. Moreover, only HDPE is analyzed in the presented work, future iterations of the framework will also assess the role of other polymers utilized in the manufacturing of vehicles. Power is also required for charging EVs which can be modeled in tandem. Besides renewable intermittency, the framework can also accommodate variability in the cost of resources such as NG and oil and resource demand. Case studies considering the aforementioned aspects will be presented in future publications.
