## ABSTRACT

This study presents a comprehensive approach to optimizing hydrogen supply chain network (HSCN), focusing initially on Texas, with potential scalability to national and global regions. Utilizing mixed-integer nonlinear programming (MINLP), the research decomposes into two distinct modeling stages: broad supply chain modeling and detailed hub-specific analysis. The first stage identifies optimal hydrogen hub locations, considering county-level hydrogen demand, renewable energy availability, and grid capacity. It determines the number and placement of hubs, county participation within these hubs, and the optimal sites for hydrogen production plants. The second stage delves into each selected hub, analyzing energy mixes under variable solar, wind, and grid profiles, sizing specific production and storage facilities, and scheduling to match energy availability. Iterative refinement incorporates detailed insights back into the broader model, updating costs and configurations to converge upon an optimal supply chain design. This design encapsulates macro-level network configurations, including centralization versus decentralization strategies, transportation cost analysis, and carbon footprint assessment, as well as micro-level operational specifics like renewable energy contributions, facility scale, and energy portfolio management. The methodology's robustness allows for strategic insights into hydrogen production facility siting, aligning with local energy resources and supply chain economics. This adaptable, multi-scale approach contributes to informed decision-making in the evolution of sustainable hydrogen-based energy systems, offering a roadmap for policy reforms and strategic supply chain development in diverse energy landscapes.

## INTRODUCTION

The global energy landscape is undergoing a paradigm shift towards sustainable and clean energy sources, with hydrogen emerging as a pivotal player in this transition. Hydrogen, particularly green hydrogen produced from renewable energy sources, offers a promising solution to decarbonize various sectors, including transportation, industrial processes, and energy storage [1, 2]. The U.S. Department of Energy's (DOE) investment in hydrogen hubs underscores their pivotal role in advancing the nation's clean energy agenda. With a commitment of \$7 billion towards establishing H2Hubs, alongside \$1 billion to boost clean hydrogen demand and \$1.5 billion to enhance electrolysis technologies, the DOE aims to

significantly reduce the cost of clean hydrogen to \$1 per kilogram within a decade [3]. This initiative is not just an investment in sustainable energy but also a substantial job creator, promising to generate tens of thousands of well-paying jobs across the country. Moreover, the H2Hubs are expected to play a crucial role in environmental conservation by eliminating approximately 25 million metric tons of carbon dioxide emissions annually, equating to the emissions of about 5.5 million gasoline-powered cars [4]. This strategic move marks a significant step towards realizing a more sustainable, low-carbon future, positioning hydrogen hubs as a cornerstone in the transition to cleaner energy sources.

However, establishing an efficient hydrogen supply chain network (HSCN) poses significant challenges due to its complexity and the need for a multi-scale optimization approach encompassing production, storage, transportation, and distribution [5, 6]. The complexity stems from several key aspects: the geographical dispersion of supply and demand centers, the integration of diverse and intermittent renewable energy sources, and the need to align production with fluctuating energy availability. Additionally, the network comprises various interconnected components, including production sites, storage facilities, and distribution hubs, each with its own set of operational constraints and dependencies (see Fig. 1). The variability in renewable energy output, such as solar and wind, adds another layer of complexity, necessitating advanced planning and forecasting methods. This complexity is further amplified by the dynamic nature of market demands, technological advancements, and regulatory landscapes. Solving this multifaceted problem requires not only sophisticated computational models and optimization algorithms but also a deep understanding of the interplay between various elements of the hydrogen supply chain.

Pertinent literature reveals various approaches to modeling and optimizing Hydrogen Supply Chain Networks (HSCNs). Study such as by Vijayakumar et al. [7] have focused on geographic and economic aspects of hub placement. They highlight the importance of long-term planning in mitigating system costs and retail prices, but their deterministic approach overlooks uncertainties in demand and feedstock prices which are crucial for accurate forecasting. In contrast, Li et al. [8] provide an optimization-oriented review of hydrogen supply chain network design, noting gaps such as the treatment of uncertainty. Alkatheri et al. [9] address the intermittency challenges of renewable energies with a multiscale stochastic

programming approach for energy hub design, despite the computational complexity. Moran et al. [10] offer a flexible tool for analyzing regional hydrogen hubs, as exemplified by their Irish case study, but do not fully consider the implications of using grid electricity from non-renewable sources and the variability of the renewable integration. Additionally, Marouani et al. [11] delved into the integration of renewable energy sources into the supply chain. However, the dynamic and variable nature of renewable energy availability, particularly solar and wind, and its impact on hydrogen production and storage scheduling and sizing remains under-addressed.

To address these challenges, this study proposes a novel two-stage mixed-integer nonlinear programming (MINLP) approach. The first stage involves broad supply chain modeling to identify optimal hydrogen hub locations and configurations, considering county-level demand, renewable energy availability, and grid capabilities. The second stage focuses on detailed hub-specific modeling, specifying energy mixes, production and storage capacities, and schedules in alignment with variable energy inputs.

The results of this approach include the identification of optimal hub locations and configurations, tailored energy mixes for each hub, and detailed operational schedules that maximize efficiency and minimize costs. Moreover, the iterative refinement process employed in this study allows for the continuous updating of model parameters, leading to increasingly accurate and optimal solutions. This study not only contributes to the existing body of knowledge on HSCN optimization but also provides a practical and scalable framework for policymakers and industry stakeholders.

## PROBLEM STATEMENT

The central hypothesis of our study posits that by

addressing key research questions within Texas' hydrogen supply chain, the findings could be extrapolated to national or even international scales. McKinsey & Company's sustainability report projects that Texas' demand for clean hydrogen may increase to 21 million tonnes (MT) by 2050, up from the current 3.6 MT produced conventionally [12]. Our assumption is that all 254 counties in Texas will contribute to this demand based on factors such as local energy requirements, population, available land, and the variability of energy sources including the grid, wind, and solar. The target is to answer the following key research questions:

- What are the strategic locations for the hydrogen production plants?
- What constitutes the optimal energy mix for electrolytic hydrogen production, given variable electricity pricing, wind availability, and solar irradiance?
- What are the optimal size of H<sub>2</sub> production facilities, renewable farms, energy storage, considering the temporal variations in renewable energy availability?
- What is the comprehensive cost of the hydrogen supply chain, including production, storage, and transportation?
- What will be the optimal scheduling of the hydrogen production process to match energy availability?

## METHODOLOGICAL APPROACH

We adopt a multi-scale optimization framework that integrates both supply chain optimization (level 1) and process design and energy scheduling (level 2), ensuring convergence towards an optimal supply chain design that encapsulates macro-level network configuration and micro-level operational details.

### Level 1: Supply Chain Optimization

At the macro-level, the network configuration is informed by the optimization of strategic decisions such as site selection, facility sizing, hydrogen distribution, transportation costs to/from other counties, energy portfolio mix and management cost, guided by county-specific roles and requirements. In our supply chain optimization, we employ piecewise linearization to address the economies of scale inherent in hydrogen production. This mathematical technique allows us to model the cost benefits of scaling production facilities accurately. By breaking down the nonlinear cost structure into linear segments, we can analyze scenarios where a single large production facility or multiple smaller ones are more economically viable. This is crucial in evaluating the

feasibility of a hub approach to hydrogen production. Furthermore, this linearization facilitates the use of linear programming techniques, which significantly expedite the optimization process, ensuring a swift and efficient path to finding the optimal supply chain configuration.

$$\min \sum_i \sum_j c_{ij}^{trans,H_2} x_{ij}^{H_2} r_{ij} + \left(\frac{\varphi}{\beta}\right) \sum_i \sum_j c_{ij}^{trans,E} x_{ij}^E r_{ij} + \sum_p c_{i,p}^{prodH_2} \Delta x_{i,p}^{H_2} + \sum_i \sum_{sor} c_{i,sor}^{prodE} x_{i,sor}^E$$

Subject to

$$\begin{aligned} D_i &\leq \sum_j x_{ji}^{H_2} \\ e_i^{intensity} \sum_j x_{ij}^{H_2} &= \sum_{sor} \sum_j x_{j,i,sor}^E \\ \sum_j x_{j,i,sor}^E &\leq e_{i,sor}^{max} \\ \sum_p \lambda_{ip} &= 1 \\ x_{p-1}^L \lambda_{ip} &\leq \Delta x_{ip} \leq x_p^U \lambda_{ip} \\ \sum_j x_{ij}^{H_2} &= \sum_p \Delta x_{ip} \end{aligned}$$

### Level 2: Process Design and Energy Scheduling

The micro-level details focus on operational intricacies within individual counties. This includes determining the roles counties play within the network, scaling production and storage facilities, configuring the energy portfolio, aligning production timing with renewable energy availability, devising energy storage solutions, sizing renewable energy farms for grid independence, and formulating strategies to meet emissions reduction goals.

$$\min TC = C^{iv,tot} + C^{of,tot} + C^{ov,tot} + C^{ov,um}$$

Subject to,

$$\begin{aligned} LCOH &= \frac{C^{iv,tot} + C^{of,tot} + C^{ov,tot}}{\sum_t m_t^{out}} \\ P_t^g + \sum_{ren} P_{ren,t}^{sor} + \sum_i P_{i,t}^S &= P_t^{el} + P_t^{comp} \\ m_t^{dem} &= m_t^{out} + m_t^{um} - m_t^{excess} \\ C^{ov,grid} &= \sum_t \pi_t P_t^g \Delta t \\ C^{ov,um} &= \sum_t \lambda m_t^{um} \Delta t \\ C^{ov,co2} &= \sum_t P_t^g \gamma \varphi \Delta t \\ C^{iv,tot} &= C_{ren}^{iv,sor} + C^{iv,el} + C^{iv,comp} + C^{iv,tank} \\ &\quad + \sum_i C_i^{iv,stor} \\ C^{of,tot} &= C^{of,el} + C^{of,comp} + C^{of,tank} + \sum_i C_i^{of,stor} \\ C^{ov,tot} &= C^{ov,grid} + C^{ov,um} + C^{ov,co2} + \sum_i C_i^{ov,stortot} \end{aligned}$$

Renewable farm constraints,

 C_i^{ov,stor,tot} &= \sum_t C_{i,t}^{ov,stor}
 \end{aligned}$$

At its core, the model seeks to balance energy production and hydrogen generation across temporal and spatial dimensions, taking into account the variable nature of renewable energy sources and grid electricity prices. The model incorporates decision variables for energy management, renewable energy farms, energy storage, and hydrogen production and storage. These variables are optimized within a system of constraints that ensure energy balance, hydrogen balance, and operational feasibility (see Fig. 2). For example, the power purchased from the electricity grid at any given time is matched against the power consumed by electrolyzers and compressors, ensuring an overall energy balance. The constraints also enforce the physical and operational limitations of the system, such as the maximum hydrogen storage capacity and the power output limits of storage technologies. This detailed formulation allows for the examination of the economic and environmental implications of the supply chain, with the ultimate goal of minimizing costs and emissions while meeting the hydrogen demand.

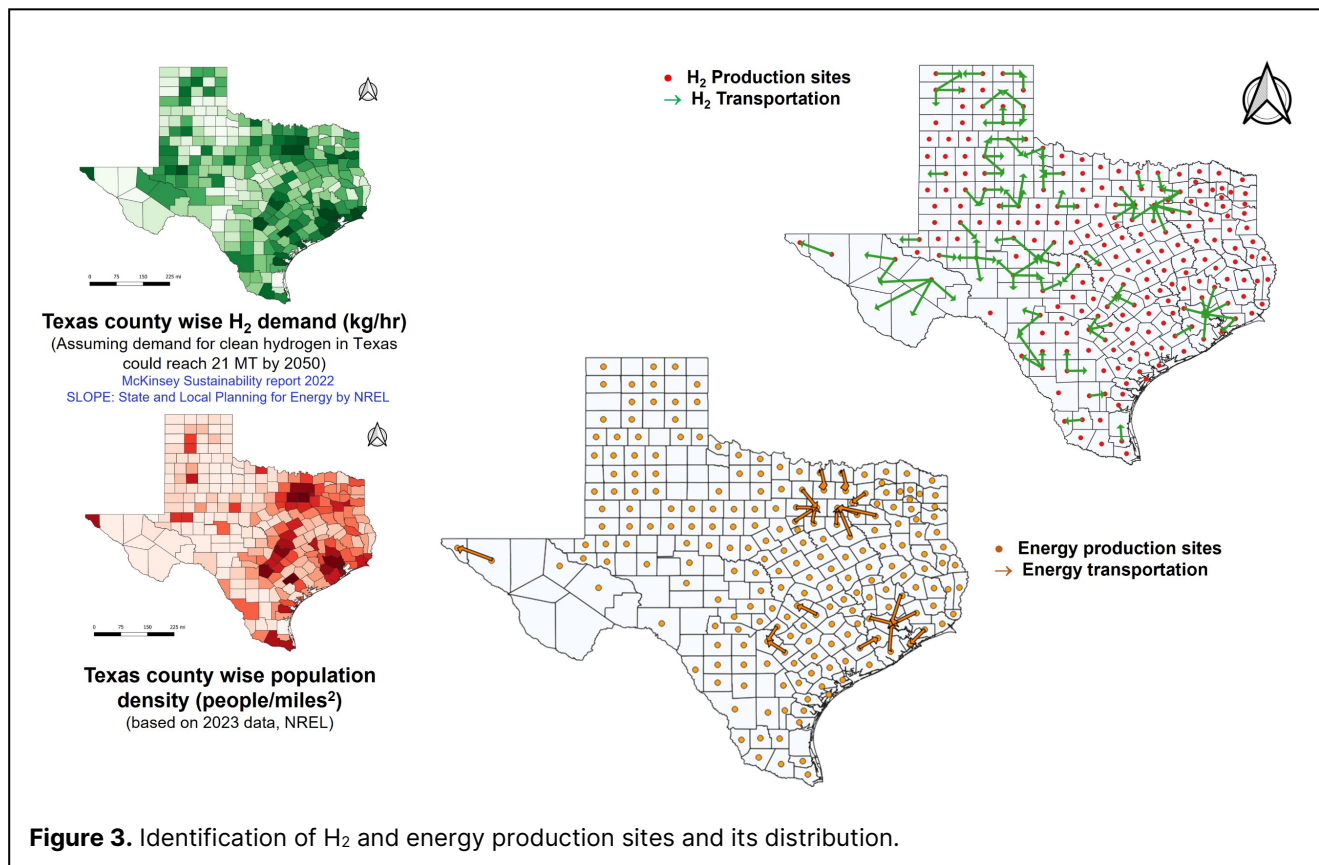

Figure 2. Green hydrogen production system.

This decomposition into two optimization levels allows for a structured breakdown of the complex supply chain problem. The output of level 1, which encapsulates

county-wise energy and hydrogen demand forecasts, informs level 2 decisions. This includes detailed cost assessments for hydrogen production at the county level, which are then fed back into level 1. The iterative feedback loop between the two levels propels the optimization process toward convergence, refining the network configuration with each iteration.

Recognizing the variable nature of energy availability across counties, our model incorporates a robust mechanism for inter-county energy flow. This mechanism dynamically channels surplus energy from counties with excess to those with deficits, thereby maintaining the balance necessary to meet each county's hydrogen production demands. This energy management strategy is integral to our comprehensive approach, affirming that all counties can achieve their hydrogen demand targets through cooperative energy sharing and sophisticated scheduling.

## RESULTS AND DISCUSSION

The broader supply chain optimization achieves strategic positioning of hydrogen production facilities across Texas, with significant concentrations in energy-rich counties. For instance, the production capacities ranged from 0.21 to 21 MT per year, aligning with the variable solar and wind profiles. In Fig. 3, we can see the location of the hydrogen production sites and the

distribution of produced hydrogen to other counties based on the given projected energy demand and population density of each county. We can observe that not every county is producing their H<sub>2</sub> rather few counties are taking the leverage of economics of scale by collaborating with the neighbouring counties. This also gives us the indication that if management or policy makers decided to build up the specific number of hubs for the hydrogen for Texas. Our supply chain optimization can find those locations with some additional constraints. The optimal energy mix was achieved with 35.46% wind, 34.3% solar, and 30.23% grid energy, illustrating a significant reliance on renewable sources.

The simulation results, derived from a year-long variability profile for solar irradiance and wind speed, indicate a consistent alignment between the overall power flow and the hydrogen production profile, which is crucial for maintaining a sustainable energy supply for hydrogen production (see Fig. 4). The hydrogen profile, compared with the demand, reveals that the production from electrolyzers is well-aligned with the demand pattern, suggesting an efficient design of the electrolyzer capacity and operational scheduling. Notably, peak production periods do not always coincide with peak demand times, indicating the necessity for robust storage solutions within the supply chain to balance the temporal discrepancies. In terms of energy supply, the integration of solar and wind energy contributes significantly to the overall

**Table 1:** Selected information on hydrogen production process design.

County	Max installed wind capacity (MW)	Max installed solar capacity (MW)	Installed electrolyzer capacity (MW)	LCOH (\$/kg)	Penalty on unmet H <sub>2</sub> demand (\$)	Total system cost (MM \$)	Emission penalty on grid bought electricity (MM \$)
Austin	528.831	2563.51	1602.3	4.58	-	992	218
Angelina	1.93	286.06	159.73	4.40	-	92	21.2
Archer	194.43	0	68.86	3.39	-	31.5	0.5
Austin	168.38	4.01	61.28	3.51	-	28.8	0.69
Bailey	0	26.38	14.54	4.10	-	6.32	1.18
Bastrop	0	182.41	105.68	4.40	-	61	14.7
Bee	788.58	24.35	290.05	3.73	-	145	8.17
Bell	915.15	55.73	351.74	3.84	-	181	12.4
Blanco	57.03	0	20	3.27	-	8.91	0.02
Borden	0	0	1.80	5.46	-	0.86	0.36

**Figure 4:** Simultaneous design and scheduling model.

power flow, with grid energy supplementing the shortfall. However, the reliance on grid energy varies throughout the day, suggesting potential areas for further optimization of renewable energy sources or storage solutions to minimize grid dependence and enhance sustainability. Furthermore, our optimization model has successfully identified strategic locations for hydrogen production,

factoring in county-specific variables such as land area and energy profiles. This strategic placement, alongside an optimized energy mix, effectively minimizes transport costs and maximizes the use of local renewable energy, supporting the overarching goal of a resilient and sustainable hydrogen economy. Numerical insights obtained from the optimization highlight the potential for a

reduction in carbon footprint through optimized renewable energy use and strategic site placement. The proposed supply chain configuration promises to meet the projected 21 MT hydrogen demand by 2050, with a comprehensive cost analysis indicating a favorable comparison to current conventional hydrogen production costs.

The selective overview of Texas counties reveals a diversified approach to hydrogen production process design (see Table 1). For instance, Austin County showcases a substantial investment in renewable energy sources with impressive wind and solar capacities, facilitating a large-scale electrolyzer capacity that could cater to future hydrogen demands. However, the associated LCOH of \$4.58/kg suggests a higher production cost, potentially due to the scale of installed capacities and emission penalties. Conversely, counties like Archer, with a focus on wind energy, and Blanco, with a conservative renewable approach, indicate a more cost-effective production with their lower LCOH. Borden County's minimal figures might reflect an opportunity for growth or a strategic decision to maintain a small-scale operation. These data points indicate that while some counties are positioning themselves as potential leaders in hydrogen production, others may opt for a scaled approach or are in the early stages of infrastructure development. The diverse strategies underscore the need for a multifaceted, tailored approach in optimizing hydrogen production that balances cost, demand, and environmental impact.

## CONCLUSION

In our study, the placement of strategic hydrogen production sites was pivotal, with locations selected to align local demand with the availability of energy resources. The design of the network integrated insights from county-level contributions and renewable sources, setting a robust foundation for the configuration and scale of these production sites. Our analysis into the energy mix probed the feasibility of utilizing solar, wind, and grid sources to create a flexible energy portfolio for hydrogen production. By adopting an iterative, two-level optimization approach, we enhanced the supply chain model, ensuring economic feasibility and environmental sustainability. Our findings point to a future-adapted hydrogen supply network, resilient and scalable to meet the burgeoning demand and shifts in the energy sector. This synthesis of theoretical insights and numerical analysis underscores the viability of the proposed supply chain configuration, offering a viable pathway to achieving the DOE's goal of \$1 per kilogram of clean hydrogen within a decade.

## ABSTRACT

This research is dedicated to designing and economically evaluating the green ammonia supply chain, considering the fluctuating nature of renewable energy sources and energy demand across both hourly and seasonal variations. It also explores the impact of economies of scale and the delays associated with long-distance shipping to meet energy demands in a timely manner. These considerations require the formulation of a Mixed-Integer Nonlinear Programming model, further complicated by the necessity for a two-stage stochastic programming approach. We introduce a hierarchical optimization framework that utilizes a decomposition method to differentiate between one-time design decisions and subsequent operational choices. At the upper level, potential design solutions are identified through the Bayesian Optimization and Hyperband algorithm, which effectively navigates the non-linear challenges posed by economies of scale. The lower level then addresses a Mixed-Integer Linear Programming problem to independently assess the feasibility of each scenario. Our empirical analysis includes case studies of three potential international routes for transporting green ammonia to Korea. We contrasted our methodology with a hypothetical scenario that presupposes a constant supply of power and a stable demand for energy. Additionally, techno-economic analyses were conducted to evaluate the implications of the minimum operational limits for electrolyzers.

**Keywords:** Green ammonia supply chain, Multi-timescale decision-making, Integrated temporal approach, MINLP, Decomposition approach

## INTRODUCTION

Amidst the escalating global demand for the sustainable energy solutions, the quest for efficient energy transport materials has taken center stage in research and development. Hydrogen and ammonia have emerged as particularly promising candidates, with ammonia gaining traction in international supply chains due to its advantages in long-distance transportation and storage [1].

Nevertheless, the deployment of ammonia as an energy carrier faces challenges associated with the traditional Harbor-Bosch approach, which exhibits limited flexibility and imposes constraints on ramp-up and ramp-down rates [2]. This lack of adaptability poses a major

obstacle to planning a green ammonia supply chain capable of adeptly responding to dynamic renewable energy fluctuations and ensuring timely transport to meet demand. Furthermore, the seasonality and inherent uncertainty in energy production and demand [3], combined with the extended duration of vessel transportation, mandate operational decisions that span multiple time zones.

In the face of these challenges, existing research lacks a comprehensive integrated temporal approach that considers both hourly profiles and weekly shipping schedules, hindering the determination of reliable and economic capacity design. Addressing this deficiency in the literature, our study introduces an innovative meth-

odology for bi-level decision-making, combining Bayesian optimization and hyperband (BOHB) with mathematical programming. The primary objective of this study is to analyze the impact of incorporating uncertainty and intermittency in the environment, as along with techno-economic parameters related to hourly operations, on the economic viability and design of a green ammonia supply chain. By adopting this integrated approach, we significantly lower the complexities associated with energy management and ship scheduling under multi-timescale uncertainties. This, in turn, provides valuable insights into fostering efficient decision-making within the burgeoning field of green ammonia project.

## PROBLEM DESCRIPTION

As depicted in Figure 1, the focal problem addressed in this paper is to minimize the levelized cost of green ammonia (LCOA) by optimizing the capacity sizes of various components, including turbines, PV panels, batteries, PEM water electrolyzers, Harbor-Bosch plants, hydrogen tanks, ammonia tanks, and ammonia ships. The optimization process takes into account operations spanning multiple timescales. Specifically, ship scheduling is determined on a weekly basis, while operational decisions for the energy management of a green ammonia production facility are made on an hourly basis. The model accommodates time delays arising from long-distance shipping, and it incorporates uncertainty on both the demand and supply sides.

Weather and demand uncertainties are modeled through various scenarios generated based on historical weather patterns and energy consumption data. Given that capacity decisions must be made independently of these scenarios, operational decisions are tailored to respond to specific scenarios, serving as recourse decisions. Thus, the problem is formulated as a two-stage stochastic optimization problem, as illustrated in Figure 2. The first-stage decisions revolve around capacity decisions, while the second-stage decisions focus on operational decisions. The distinct timescales associated with the first- and second-stage decisions contribute to the complexity of solving this problem. Furthermore, the difficulty of solving the problem is compounded by the fact that large-scale capacity design necessitates the consideration of economies of scale. Additionally, shipping-related variables and facility sizes, being discrete entities, introduces integer variables into the mix. Consequently, the mathematical programming is formulated as mixed-integer nonlinear programming (MINLP). To address this complexity, we introduce a novel bi-level decision-making framework, described in the method section.

## SYSTEM DESCRIPTION

As shown in Figure 3, energy is harnessed from both wind turbines and PV panels. Batteries play a role in mitigating the inherent volatility of renewable energy, with 'curtailment' denoting the direct release of excess energy

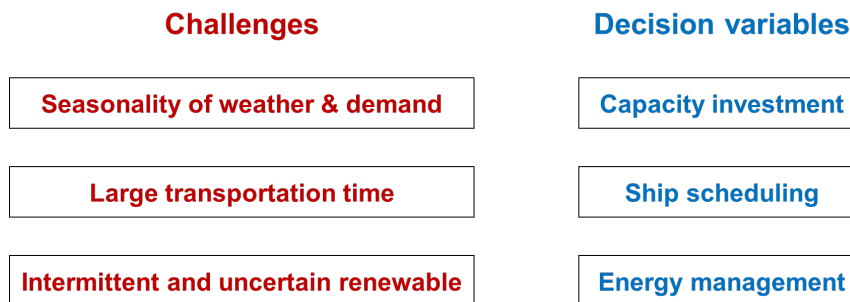

Figure 1. Challenges and multi-timescale decision variables.

### MINLP & stochastic programming

Figure 2. Illustration of two-stage stochastic programming for the problem of this study.

and the management of operations such as idling turbines. Gaseous hydrogen is produced through a water electrolyzer, a process integral to synthesizing ammonia. Any surplus hydrogen generated is stored in a dedicated hydrogen tank. To achieve the minimum load of electrolyzer, the system occasionally relies on the reconversion of hydrogen via a fuel cell. The synthesized ammonia is then stored in tanks before being transported from the exporting country to the importing country via shipping.

For efficient regulation of various current types generated and required by diverse equipment, appropriate converters and current buses are needed. Given the prevalence of DC-type equipment, this study employs a DC bus topology to effectively accommodate the distinctive electrical characteristics.

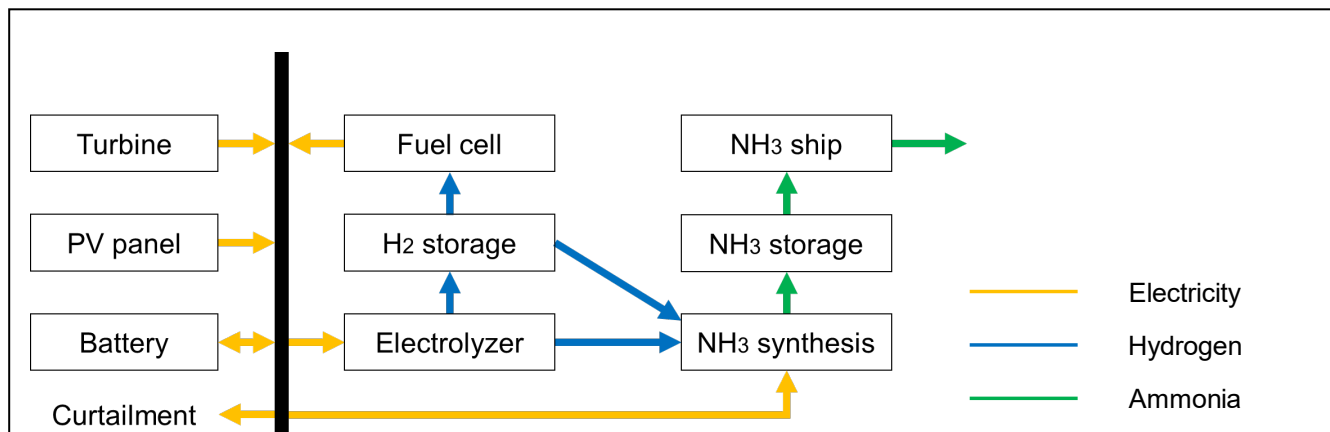

## METHOD

A bi-level decision-making framework is introduced, as illustrated in Figure 4. The initial design decision, facilitated by the BOHB, transforms the remaining optimization into mixed-integer linear programming (MILP). Thus, system operation is addressed through a set of independently manageable sub-problems, markedly lowering

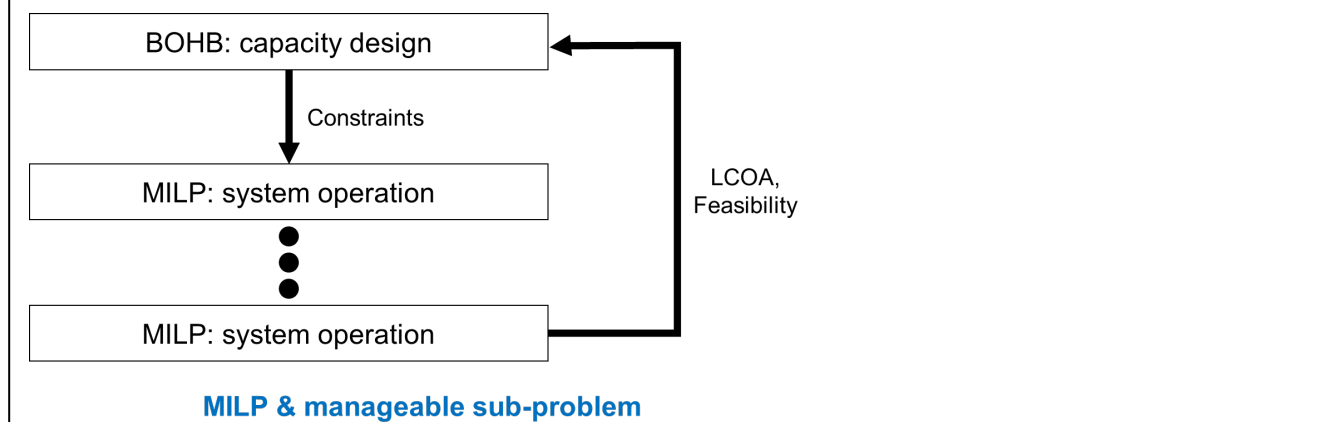

the complexity of the original two-stage stochastic programming.

BOHB, an advanced hyperparameter optimization algorithm, blends the strengths of Bayesian optimization (BO) and hyperband [4]. Known for its ability to achieve both robust and efficient performance in finding the optimal configuration, BOHB overcomes the limitations of traditional methods. While hyperband excels at smaller sampling budgets, it struggles with larger budgets due to its reliance on random sampling. In contrast, BO initially progresses slowly but, given enough time, outperforms hyperband. Combining these approaches, BOHB delivers superior performance and rapid convergence across varying timeframes.

In BO, a surrogate model, often based on Gaussian processes, approximates the distribution of the objective function across decision variables. However, the complexity of Gaussian models grows with increasing samples. BOHB addresses this by using a tree-structured Parzen Estimator (TPE) surrogate model. Leveraging kernel density estimation (KDE), TPE models good and bad hyperparameters separately, providing probability density estimates that account for observed performance [5].

**Figure 3.** Supply system description.

**Figure 4.** Bi-level decision-making framework

Within BO, the acquisition function entails a trade-off between exploration and exploitation, commonly addressed by the expected improvement (EI) function. In TPE, EI relies on estimated probability densities of good and bad performance. Poor-performing configurations are actively avoided in favor of those with high probabilities of good performance. BOHB's TPE model employs a multivariate KDE for probability density estimation, defined by a smoothing function and bandwidth matrix controlling the smoothness of the resulting density curve [6]. BOHB efficiently allocates resources to promising configurations and discards insufficient ones early in the process. Hyperband divides the configuration space into brackets, utilizing consecutive halves within each bracket. BOHB extends hyperband by incorporating model-based search using KDE, guiding searches toward promising regions while retaining hyperband's adaptive resource allocation.

The objective function of the MILP is modified from the original nonlinear form into a linear term involving slack variables, as expressed in the following equation:

$$\sum_t [AP_t^E + AP_t^H + AP_t^A + AC_t^{AIT} + AC_t^{AET}] \quad (1)$$

Here,  $AP_t^E$  represents additional electricity power,  $AP_t^H$  indicates additional hydrogen,  $AP_t^A$  signifies additional ammonia,  $AC_t^{AIT}$  indicates additional capacity of ammonia import tank, and  $AC_t^{AET}$  represents additional capacity of ammonia export tank.

It's important to note that a non-zero objective value from the Mixed-Integer Linear Programming (MILP) analysis indicates that the proposed capacity design is not viable. In instances of unviable capacity designs, the Bayesian Optimization and Hyperband (BOHB) algorithm is informed through the integration of the levelized cost of ammonia (LCOA) with a substantial penalty cost, denoted as  $M$ , to direct the search away from such infeasible design areas. This mechanism is encapsulated in the equation below:

$$receive \begin{cases} LCOA & \text{for feasible design} \\ LCOA + M & \text{for infeasible design} \end{cases} \quad (2)$$

The IBM CPLEX solver is employed to address the MILP problem, which encompasses 122,529 variables and 61,311 constraints.

## RESULT

Three countries—Saudi Arabia, Australia, and Chile—were selected as potential international green ammonia promising trading partners with Korea. A comparative analysis of their economic outcomes are presented in Figures 5-7, and their optimal configurations are presented in Tables 1-3.

In first case (the idealistic case), supply and demand are assumed to remain constant throughout the year (an

assumption often made in prior studies). Figure 5 reveals an overall LCOA ranging between 0.39 and 0.43 \$/Ammonia, with storage costs below 0.01 \$/Ammonia. Australia emerges as the most economically option, boasting the shortest transportation time.

In Figure 6, considering seasonality and uncertain supply and demand (the base case), the overall LCOA fluctuates between 0.59 and 0.68 \$/Ammonia, while storage costs exceed 0.1 \$/Ammonia. Furthermore, the conversion cost couples compared to the first case, suggesting an average operating rate of conversion devices around 50%, not 100%. Saudi Arabia stands out as the most economically promising partner due to its consistent ammonia production capability.

Lastly, Figure 7 examines the design and economics of a scenario where the minimum load constraint of the water electrolyzer is relaxed to 3% (considered an optimistic case, compared to 5% for the base case). The overall LCOA decreases from the base case, as accompanied by a reduction in storage costs. This reduction is attributed to the decrease in battery devices required to meet the minimum load of the water electrolyzer. This highlights the intricate interaction between various factors in the supply chain, aspects often overlooked in many prior studies.

## CONCLUSION

This paper presents a bi-level optimization framework that integrates BOHB with MILP to streamline temporal planning in the design and management of an international green ammonia supply chain. This method effectively simplifies the complexities found in the original MILP and stochastic programming approaches. The research delves into the impacts of uncertainty and techno-economic parameters via three case studies, highlighting the significance of incorporating fast-time-scale operations for the development of a reliable and cost-efficient supply chain strategy. Additionally, it investigates the influence of the minimum operating load of water electrolyzers on the green ammonia supply chain's efficiency and feasibility.

This study bridges a crucial knowledge gap by revealing the interactions between various supply chain components through an integrated temporal planning approach. It underscores the necessity of considering real-time operations, which involve making decisions without future insights, as crucial for achieving a realistic and practical supply chain implementation. This acknowledgment points toward the importance of adaptability and responsiveness in managing the intricacies of the green ammonia supply chain in the face of operational and market uncertainties.

## ABSTRACT

A novel process system which integrates an isopropanol-based chemical heat pump with a post-combustion carbon capture unit was proposed, designed, and analyzed. The system uses low-quality waste heat ( $\sim 80^\circ\text{C}$ ) produced through the  $\text{CO}_2$  adsorption step of a carbon capture process and upgrades that heat to a higher temperature ( $\sim 150^\circ\text{C}$ ) using the chemical heat pump. The chemical heat pump is powered mostly by the waste heat and requires only a small amount of electricity. The higher temperature heat produced can be used in the desorption stage of the  $\text{CO}_2$  capture process, displacing a portion of the existing fossil energy required. The energy and exergy performance characteristics of the chemical heat pump were computed using the results of a steady state simulation in a systems analysis. Using exergy cost correlations, the profitability of the chemical heat pump concept was estimated. It was found that for this particular configuration, the fossil energy load of desorption could be reduced by roughly 2.7% with very little parasitic electric load.

## 1. INTRODUCTION

Chemical heat pumps convert low temperature waste heat into high temperature heat through reversible chemical reactions. Compared to conventional compression-based heat pumps, chemical heat pumps consume far less electricity. One widely researched organic chemical heat pump is the isopropanol acetone system, mainly due to its wide and useful temperature range:

Isopropanol dehydrogenation (Equation 1) is an endothermic reaction operating in the temperature range  $80^\circ\text{C}$ – $90^\circ\text{C}$ . The reverse (acetone hydrogenation, Equation 2) is exothermic and between  $150^\circ\text{C}$ – $210^\circ\text{C}$  [1]. The heat of endothermic reaction is  $100.4 \text{ kJ/mol}$  of isopropanol reacted whereas the heat of exothermic reaction is  $55 \text{ kJ/mol}$  of isopropanol formed [1]. Additional heat is needed for the endothermic reaction since it involves vaporising the isopropanol to the gas phase for the reaction. Previous isopropanol acetone system studies looked at individual aspects, such as catalyst

nuances or the effects of reactor design parameters on performance/efficiency. However there have been very few studies which look at the integration of isopropanol chemical heat pumps with other processes.

**Figure 1.** Chemical heat pump integration with adsorption based  $\text{CO}_2$  capture.

Post-combustion carbon capture involves removing carbon dioxide from flue gas generated during combustion of fuel. The most common technology used for this type of carbon capture is amine absorption. Sorption techniques employing solids materials are in the research & development phase. These materials include polyethyleneimine and dry sorbents. We chose a potassium-based dry sorbent carbon capture processes for this study because the temperature of its waste heat produced and its high-quality heat consumed matches very well with an isopropanol based chemical heat pump.

The carbonation process of the potassium-based sorbent is given the following equation.

The reverse reaction is the regeneration process. In the real system, the heat required for regeneration is more than the heat released during the carbonation process. The regeneration heat comprises of the reaction heat of regeneration as well as the sensible heat which is required to heat the sorbent to the regeneration temperature [5].

Park *et al.* [6] carried out post combustion carbon capture using a potassium-based dry sorbent in a 0.5MW pilot plant. In their work, flue gas from the coal fired power plant was around 80°C, so the carbonation temperature was also maintained the same. The regeneration temperature was in the range 150°C – 200°C. Yi *et al.* [7] carried out carbon capture using a potassium-based sorbent in a bench scale fluidized bed reactor. They have also maintained the carbonation temperature of 80°C and regeneration temperature of 150°C – 230°C.

Here we propose a novel integration of an isopropanol heat pump with a post-combustion sorption-based carbon capture process. In this work we designed the chemical heat pump system, simulated it in Aspen Plus, and analyzed its performance and suitability for this particular application.

## 2. SYSTEM DESCRIPTION

The integrated system is shown in Figure 1. In the carbon capture process, CO<sub>2</sub> from flue gas gets chemisorbed by the sorbent, which is a mild exothermic process (less than 100°C). The regeneration of the sorbent is an endothermic process (less than 200°C) [3].

The sorption energy is generally considered waste as this is low grade heat and is difficult to recover. In the proposed integrated system, the low grade waste heat from the adsorber is upgraded to high temperature heat used for the desorber. Thus, the chemical heat pump can partly supply the energy required for the sorbent regeneration.

There is some literature which reports the simulation of isopropanol chemical heat pumps. There are two

different configurations explored in the literature. The first configuration involves an exothermic reactor, a distillation column, and an endothermic reactor. Here the products (mixture of isopropanol, acetone, and hydrogen) from the exothermic reactor gets separated in the distillation column. The distillate (acetone and hydrogen) goes to the exothermic reactor. The bottoms product (majorly isopropanol) goes back to the endothermic reactor. The second configuration involves the reboiler acting as an endothermic reactor. In this case there is no separate endothermic reactor. Both are represented in Figures 2 and 3.

Configuration 1 requires a greater amount of heat consumption per exothermic heat produced compared to configuration 2. Configuration 2 takes the advantage of the fact that the endothermic reaction temperature and the boiling temperature of isopropanol can be very similar. By synerizing both into the same unit, the total heat load of the system is reduced, because it avoids “boiling the isopropanol twice.”

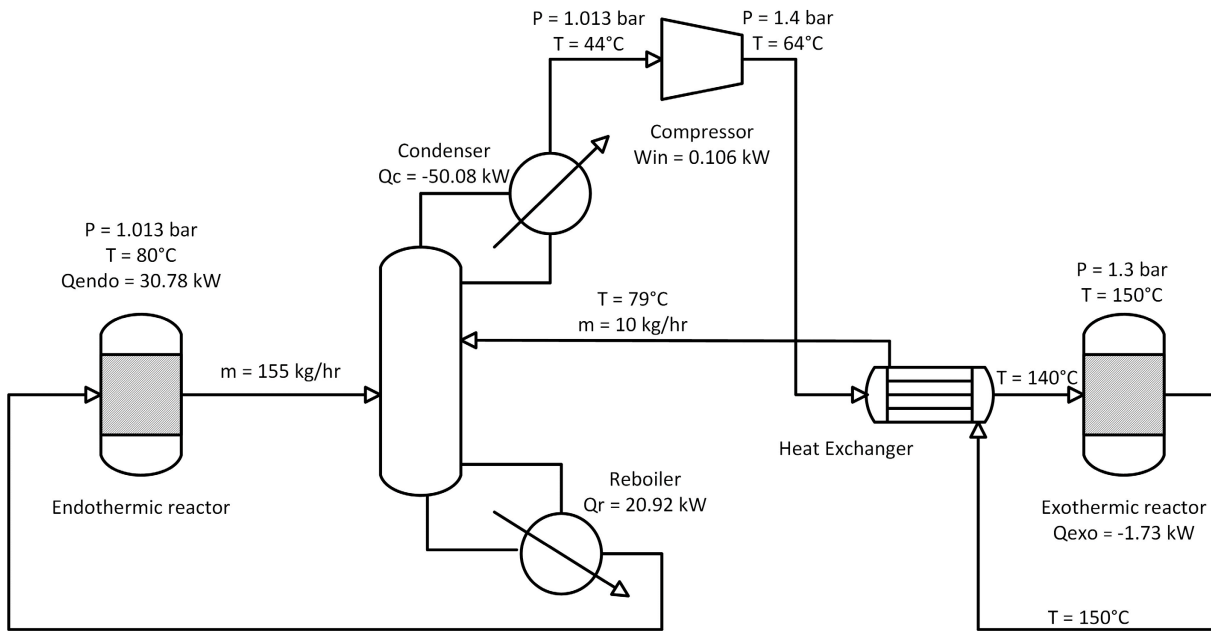

In both designs, the pressure of the exothermic reactor is a little bit higher (1.3 bar) than that of the distillation column (atmospheric). This is because the exothermic reaction equilibrium is more favourable at higher pressure. The optimal pressure, however, is uncertain because of the parasitic electric load of the compressor required. For chemical heat pumps, very low electricity consumption is desirable, as the low-electricity quality is an intentional feature. Related to this, the pressure of the distillation column is atmospheric because the boiling point of isopropanol at atmospheric pressure closely matches the available waste heat temperature.

## 3. METHODOLOGY

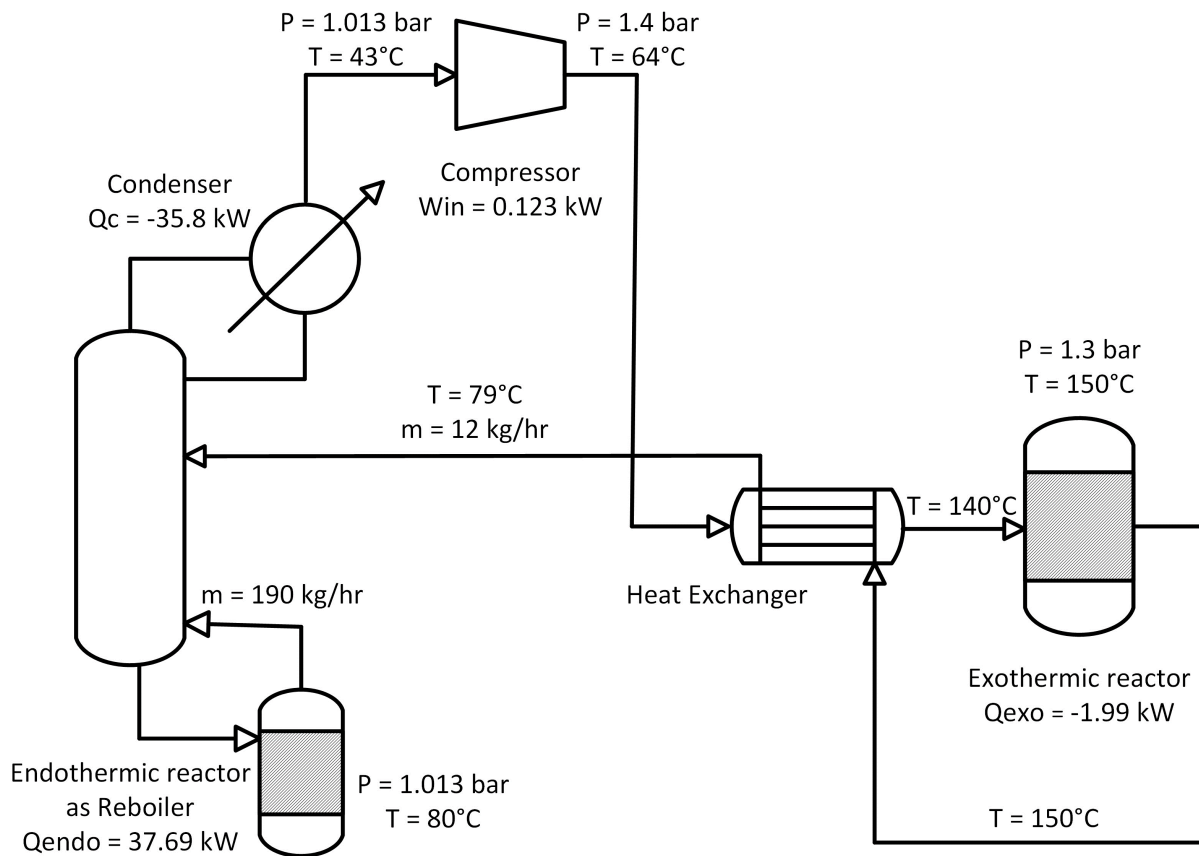

A steady state simulation was created for both configurations using the software Aspen Plus. Configuration 1 was based on the design of [8] but was modified to match the temperature ranges of our particular carbon capture application. The results were similar to those reported in the previous works. Configuration 2 was based on the design of [3] but modified to meet our application-specific requirements. One particularly important change is that we used an equilibrium-based model for the reaction that as will be noted later, results in more conservative reaction yields than those predicted in the reference paper.

### 3.1 Modelling Details

The RADFRAC equilibrium-based model was used for the distillation column. The column design parameters were chosen using the methodology for pre-economic binary distillation column design described in [9]. In this

**Figure 2:** Configuration 1 of isopropanol chemical heat pump

**Figure 3:** Configuration 2 of isopropanol chemical heat pump

methodology, the reflux ratio is adjusted to match distillate purity specifications, and for Configuration 1 the distillate-to-feed ratio is fixed based on obvious desired

recoveries. The initial number of stages above and below the feed was chosen based on the results of the prior work, and then adjusted upward or downward based on

the separate efficiency of each stage such that unnecessary or low-impact stages were eliminated. Finally, the distillate purity specification, which is a degree of freedom, was modified in a sensitivity analysis to understand the impact on the performance of the overall system, repeating the above procedure with each modification. The trade-offs are that high distillate purities yield higher exothermic reaction yields, but at a higher cost of reboiler duty, with diminishing returns. The final selected values were chosen heuristically to balance the distillation heat load with the resulting Coefficient of Performance (COP) of the system as a whole. This method gives very good results and is appropriate for this scope of conceptual design and analysis. A more rigorous optimization approach could be taken in the future given more detailed economic criteria, but the results are not expected to deviate much.

**Table 1:** Specification of the simulation for configuration 1 and 2

Description	Value
Distillation column pressure	Atmospheric pressure
No of stages	7
Feed location	4
Isopropanol mol fraction in distillate (by varying reflux ratio)	0.08
Exothermic reactor temperature	150°C
Exothermic reactor pressure	1.3 bar
Endothermic reactor pressure for configuration 1	Atmospheric pressure
Endothermic reactor temperature for configuration 1	80°C
Distillate to feed ratio for configuration 1	0.11
Compressor discharge pressure	1.4 bar
Heat exchanger: Hot inlet – cold outlet temperature difference	10°C

The *RGIBBS* reactor model was chosen for the exothermic reactor in both configurations and the endothermic reactor in Configuration 1. For Configuration 2, the *RGIBBS* model was used for the reboiler, and the *RADFRAC* model used no reboiler. All *RGIBBS* models used assumed isothermal (at a specified temperatures matching the integrated carbon capture absorber and desorber) and isobaric (no pressure drop) conditions.

The compressors used the *COMP* model, assumed default isentropic efficiencies of 0.72, and required only a single stage. The compressor discharge pressure was chosen such that after upstream pressure drop, the

exothermic reactor pressure was the value recommended in [10] of 1.3 bar.

The *HEATX* model was used for the heat exchanger, with the specification that the cold outlet / hot inlet temperature difference is 10°C, a common specification for pre/post reactor economizers.

Because this study does not consider economics, and all distillation and reaction models are based on equilibrium assumptions, the scale of the simulation is arbitrary, and performance criteria such as efficiency or coefficient of performance does not change with scale. Therefore, all system analysis results are reported on a normalized basis. Furthermore, because phase and reaction equilibrium is assumed, these results are the “best” possible outcome for the reported configuration. A summary of the main specifications are given in Table 1.

## 4. RESULTS

The key results of both simulations are shown in Figures 2 and 3.

### 4.1 Performance Analysis

The COP and exergy efficiency are used to evaluate the performance of the isopropanol chemical heat pump. The COP of this chemical heat pump is calculated according to the formula:

$$COP = \frac{Q_{exo}}{Q_{endo}} \quad (4)$$

where  $Q_{exo}$  is the rate of high temperature heat produced (the exothermic reactor heat duty) in kW and  $Q_{endo}$  is the rate of low temperature heat consumed (the sum of the reboiler and if it exists, the endothermic reactor heat duty) in kW. To compare the COP of the chemical heat pump with a conventional electric heat pump, the COP of the heat pump based on electrical work input is defined:

$$COP_W = \frac{Q_{exo}}{W_{in}} \quad (5)$$

where  $W_{in}$  is the electrical work input in kW. For the isopropanol chemical heat pump this is the compressor power input.

The COP considers only the quantity of heat. Exergy includes both the quantity and the quality of the heat. System exergy input is defined by the below formula:

$$Exergy_{in} = Q_{endo} \left(1 - \frac{T_{ref}}{T_{endo}}\right) + W_{in} \quad (6)$$

where  $T_{ref}$  is the reference temperature in K and  $T_{endo}$  is the endothermic reaction temperature in K. System exergy output is defined by the below formula:

$$Exergy_{out} = Q_{exo} \left(1 - \frac{T_{ref}}{T_{exo}}\right) \quad (7)$$

where  $T_{exo}$  is the exothermic reaction temperature in K. System exergy efficiency is given by the formula:

$$\eta = \frac{Exergy_{out}}{Exergy_{in}} \quad (8)$$

The input values required for COP and exergy calculations are taken from the simulation. The results are presented in Table 2:

**Table 2:** Performance parameters

Description	Config. 1	Config. 2
COP	0.033	0.0525
COP <sub>w</sub>	16.26	16.08
Exergy in (ref temp 25°C)	8.16	6.00
Exergy out (ref temp 25°C)	0.51	0.58
Exergy efficiency	0.063	0.0975
Net profit, \$ per GJ low temp. heat	0.11	0.18

The calculated COP of Configuration 2 is less than what is reported in the literature for a similar case [2] since the equilibrium conversion of the endothermic reaction in our simulation is around 4%, whereas in the literature it is around 7%. Unfortunately, it is unclear whether how that number was obtained or if it was assumed as a parameter in that work. Both works used very similar temperature, pressure, and reagent stoichiometric ratio conditions in the exothermic reactor, so this difference cannot be explained by differences in feed conditions. It should be noted that our model uses an equilibrium assumption that in theory should result in the upper bound on reactor conversion in a real situation without reactor modifications, such as a membrane to remove reaction products in-situ as the reaction progresses.

Increasing the isopropanol purity in the distillate or changing the distillation column pressure beyond the final case reported in Table 1 did not have much effect on COP. The main parameter that governs the COP and the exergy efficiency of the isopropanol chemical pump is the endothermic reaction conversion. The COP<sub>w</sub> of this chemical heat pump is around 16 whereas it is typically around 2 for traditional electric heat pumps. The main advantage of the chemical heat pump is that it utilises significantly less electrical power to produce the temperature lift. Thus chemical heat pumps can play an important role for a future low carbon economy.

## 4.2 Economic Approximation Using Exergy

Exergy is used as a key metric to estimate the profitability of the isopropanol chemical heat pump. A recent analysis has shown that the price of heating utilities is linearly correlated to the exergy of that utility when the reference temperature chosen is "plant ambient" conditions, or about 78°C. In other words, in a typical chemical plant, the value of waste heat at 78°C is on average zero, and above that is valued at \$29.9 (USD<sub>2022</sub>) per GJ of exergy

of heat relative to 78°C [4]. Therefore, we can estimate the net profit from this chemical heat pump by the below formula.

$$net\ profit = value\ of\ product - electrical\ cost \quad (9)$$

where net profit is expressed as \$/GJ of low temperature heat, value of product is \$/GJ of low temperature heat and electrical cost is \$/GJ of low temperature heat. The net profit does not include the value of low temperature waste heat input as it is currently not recovered at all. The value of the high temperature heat product is estimated [4]:

$$value\ of\ product = \frac{Exergy_{out}}{Q_{endo}} \times 29.9 \quad (10)$$

where the constant 29.9 is in \$/GJ of exergy.  $Exergy_{out}$  is calculated using the reference temperature 78°C. The cost associated with the electrical input is calculated as:

$$electrical\ cost = \frac{W_{in}}{Q_{endo}} \times 27.77 \quad (11)$$

where the constant 27.77 is in \$/GJ of electricity. Substituting the simulation results in the above equations, we get the net profit of this chemical heat pump as shown in Table 2.

## 4.3 Economic assessment of the integrated system

As illustrated in the system description section, the endothermic energy required for the isopropanol chemical heat pump is given by the carbon capture carbonation process. The heat required for the carbon capture regeneration process is given by the exothermic heat of the isopropanol chemical heat pump.

Heat generated by the carbonation process of potassium based sorbent is,  $H_{carb} = 141.16$  kJ/mol [5]. The exothermic heat generated by the isopropanol chemical heat pump is given by the below formula.

$$Q_{exo} = H_{carb} \times COP \times F \quad (12)$$

where  $F$  is the carbon capture flow rate in mol/s. The endothermic heat required for carbon capture regeneration is given by the following formula.

$$Q_{regen} = (H_{carb} \times F) + (T_{regen} - T_{carb}) \times \frac{C_p}{1000} \times \frac{F}{A} \quad (13)$$

where  $Q_{regen}$  is the heat required for regeneration of sorbent in kW,  $T_{regen}$  is the sorbent regeneration temperature in °C,  $T_{carb}$  is the sorbent carbonation temperature in °C,  $C_p$  is the specific heat capacity of sorbent with a value of 830 J/kg K [11],  $A$  is the absorption capacity of sorbent with a value of 0.43 mol CO<sub>2</sub>/kg sorbent [5]. The purpose of this integration is to supply part of the regeneration energy for the carbon capture process. The percentage energy savings resulting from this integration is given by the following formula.

$$\% \text{ energy savings} = \frac{Q_{\text{exo}}}{Q_{\text{regen}}} \times 100 \quad (14)$$

When  $T_{\text{carb}} = T_{\text{endo}} = 80^\circ\text{C}$  and  $T_{\text{regen}} = T_{\text{exo}} = 150^\circ\text{C}$ ,  $\% \text{ energy savings} = 2.68\%$ . Here the temperature difference between the chemical heat pump and the carbon capture is kept zero and the resulting energy savings is the theoretical maximum. Altering the chemical heat pump's endothermic and exothermic temperature to maintain some temperature difference would result in reduction of energy savings. The estimation of the carbon capture rate of the potassium-based sorbent at  $80^\circ\text{C}$  and the regeneration efficiency at  $150^\circ\text{C}$  is beyond the scope of this work.

## 5 CONCLUSIONS

The performance of a thermochemical heat pump and its integration with potassium-sorbent-based post-combustion carbon capture was studied. The limiting step in the isopropanol chemical heat pump is the isopropanol dehydrogenation to acetone and hydrogen. Any process improvements to increase the isopropanol conversion to acetone and hydrogen would increase the COP and exergy efficiency. Potassium-sorbent-based carbon capture was selected for integration with this chemical heat pump due to the matching operating temperature. Around 2.7% of thermal regeneration energy savings is possible when both the systems are operated in the temperature range  $80^\circ\text{C} - 150^\circ\text{C}$ . Ultimately, we can recover about 10% of the value (exergy) of the low temperature heat as high temperature heat. The dollar savings would increase when the capacity of the carbon capture unit increases and hence this integration could be economical for large scale systems.

## DIGITAL SUPPLEMENTARY MATERIAL

The Aspen Plus simulation files of the isopropanol chemical heat pump is available in LAPSE at <http://PSEcommunity.org/LAPSE:2023.36832>.

## ABSTRACT

Modern power grids coordinate electricity production and consumption via multi-scale wholesale energy markets. Historically, levelized cost metrics were the *de facto* standard for techno-economic analyses of energy systems and comparison of technology options. However, these metrics neglect the complexity of energy infrastructure including the time-varying value of electricity. An emerging alternative is multi-period optimization, which considers the locational marginal price of electricity as input data (parameters). In this work, we present a general interface for multi-period optimization with time-varying energy prices to facilitate rapid analysis and comparison of potential energy systems models. The PriceTakerModel class is written in the IDAES®-PSE platform and allows users to generate a multi-period, price-taker model instance, as well as automatically generate common operational constraints for their model, such as start-up and shutdown. We show this interface successfully generates multi-period price-taker models, facilitates model discrimination, and aids in analyzing various technologies for deployment in unique energy markets.

**Keywords:** Integrated Energy Systems, Software Design, Optimization, Process Operations, Process Design, Electricity Markets

## INTRODUCTION

Modern power grids coordinate electricity production and consumption via multi-scale wholesale energy markets. These multi-faceted markets set the time-varying value of electricity and other products. Mathematical programming has been used to varying degrees of success depending on model complexity and considerations to maximize the profitability of new and existing energy systems. Complexity is garnered by a few factors:

1. the extent to which the grid is impacted by energy systems behavior,
2. the flexibility of the energy system to respond to grid/market signals, and
3. the extent to which the energy system considers grid behavior in design and operation, e.g., production cost models to capture energy system/grid interactions

This short paper begins by comparing modeling approaches to optimize integrated energy systems in the context of energy markets. Next, we present a generalized interface, the PriceTakerModel class, to streamline these analyses in the IDAES-PSE platform.

### Levelized Cost of Electricity

Levelized cost analysis is the predominant strategy for techno-economic analysis (TEA) [1]. In this method, levelized cost of electricity (LCOE) is used as a market model when determining optimal energy system design and operation. Design decisions consider the size of the equipment needed to construct a new energy system or retrofit an existing one. Operational decisions consider the day-to-day production of electricity and other products provided to the grid. Below is the general mathematical model for TEA using LCOE that simultaneously considers design and operating decisions:

$$\min_{d,u} \text{LCOE} = f_{\text{LCOE}}(d,u) \quad (1)$$

$$\text{s. t. } h_j^{\text{des}}(d) = 0, \quad \forall j \in \mathcal{J}^{\text{des}} \quad (2)$$

$$g_k^{\text{des}}(d) \leq 0, \quad \forall k \in \mathcal{K}^{\text{des}} \quad (3)$$

$$h_j^{\text{op}}(d,u) = 0, \quad \forall j \in \mathcal{J}^{\text{op}} \quad (4)$$

$$g_k^{\text{op}}(d,u) \leq 0, \quad \forall k \in \mathcal{K}^{\text{op}} \quad (5)$$

Where  $f_{\text{LCOE}}$  is the mathematical expression for leveled cost of electricity based on design decisions,  $d$ , and operational decisions,  $u$ . Equation sets  $h_j^{\text{des}}$  and  $h_j^{\text{op}}$  represent model equations of design and operational systems, respectively. Here  $j$  is the index of equations in set  $\mathcal{J}^{\text{des}}$  and  $\mathcal{J}^{\text{op}}$  for design and operational equations, respectively. Inequality constraints  $g_k^{\text{des}}$  and  $g_k^{\text{op}}$  represent model and system inequalities for design and operational systems, respectively. Similarly,  $k$  is the index of inequality constraints for design and operational systems in sets  $\mathcal{K}^{\text{des}}$  and  $\mathcal{K}^{\text{op}}$ , respectively.

The major drawback of this formulation is that LCOE does not consider the time-varying nature of the electricity market. As a result, such analyses often lead to incorrect or misleading comparisons of potential energy systems technologies [2].

### Price-taker

Moving beyond LCOE, state-of-the-art TEA uses multi-period optimization to determine the best design and operating policies while considering dynamic market signals (e.g., prices). Multi-period optimization using the pseudo steady-state, price-taker, and self-schedule assumptions is the most popular approach [2-6]. First, time is discretized based on the market, e.g., 1-hour timesteps to match prices from a day-ahead market. During each time period, the energy system is modeled as operating at steady state with constraints for ramping and energy storage, as shown below:

$$\max_{d,u_t,y_t} \text{NPV} = f_{\text{NPV}}(d,u_t,y_t) \quad (6)$$

$$\text{s. t. } h_j^{\text{des}}(d) = 0, \quad \forall j \in \mathcal{J}^{\text{des}} \quad (7)$$

$$g_k^{\text{des}}(d) \leq 0, \quad \forall k \in \mathcal{K}^{\text{des}} \quad (8)$$

$$h_j^{\text{op}}(d,u_t,y_t) = 0, \quad \forall j \in \mathcal{J}^{\text{op}}, t \in \mathcal{T} \quad (9)$$

$$g_k^{\text{op}}(d,u_t,y_t) \leq 0, \quad \forall k \in \mathcal{K}^{\text{op}}, t \in \mathcal{T} \quad (10)$$

$$r_t(u_t, u_{t-1}) \leq 0, \quad \forall t \in \mathcal{T} \quad (11)$$

$$s_t(y_t, y_{t-1}) \leq 0, \quad \forall t \in \mathcal{T} \quad (12)$$

$$y_t \in \{0, 1\} \quad (13)$$

Where operational variables,  $u_t$ , have now been indexed by time along the entire time horizon,  $t \in \mathcal{T}$ , to account for operational decisions that take advantage of the time-varying market. Note that design and

operational equations and inequalities (Eqs. (7) through (10)) are the same functional form as in the leveled cost analysis with the adjustment for time-varying inputs. Accompanying these dynamic decisions are binary variables  $y_t$  which dictate startup, shutdown, and technological decisions. Since the system is now dynamic, constraints  $r_t$  enforce ramping rate limitations and constraints  $s_t$  enforce startup and shutdown of units. Also, more sophisticated metrics such as net present value (NPV) are used to evaluate the economic viability of an optimal design and operating strategy. For example, Dowling and colleagues [2] discuss revenue opportunities from real-time market and ancillary service products.

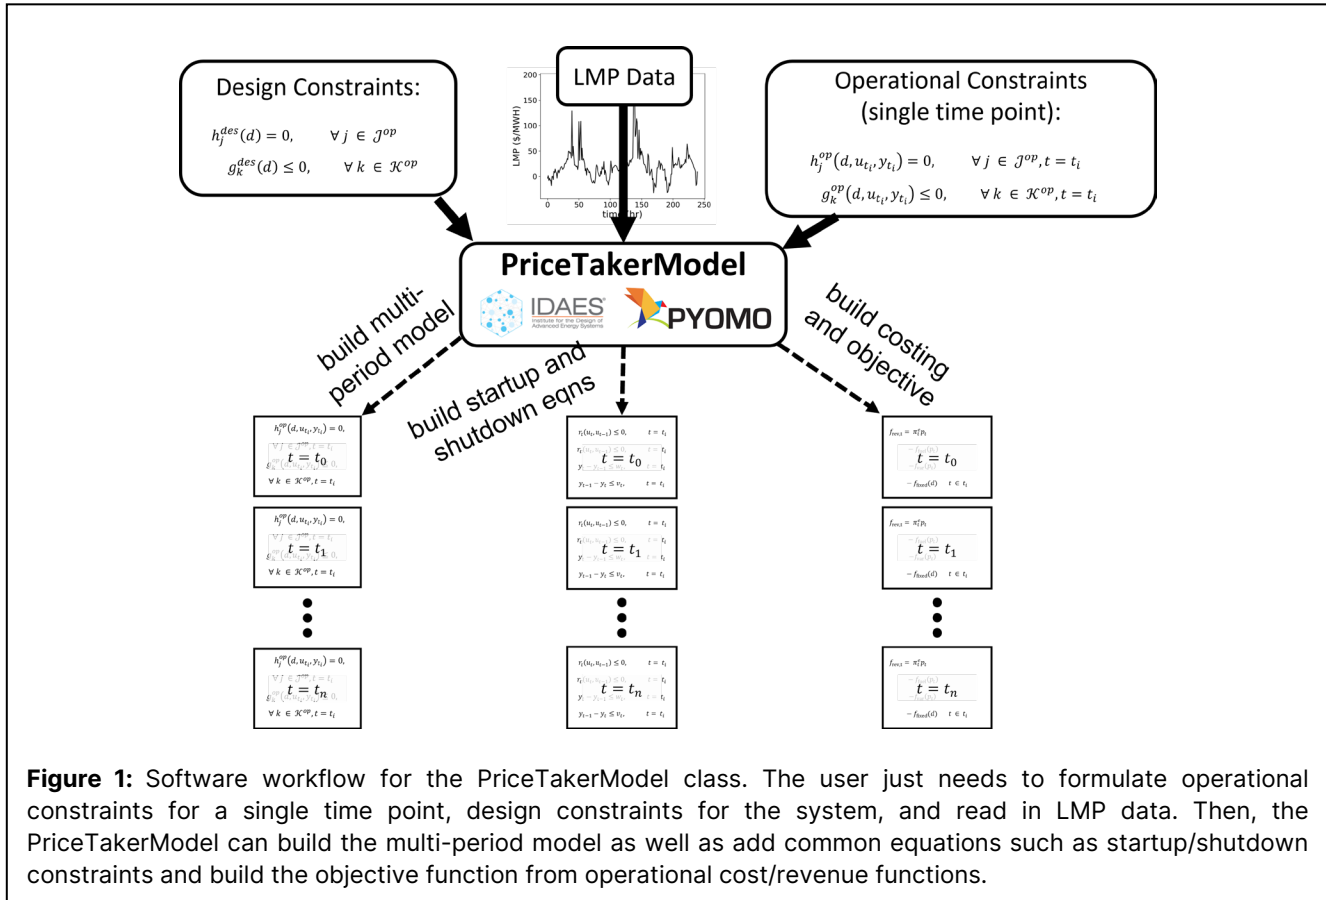

The price taker assumption treats the time-varying energy prices obtained from historical data or forecasts as constant. Likewise, the self-schedule approach ignores the market-clearing processes. Although the price-taker approach is much more informed than leveled cost analysis, the ignorance of the market-clearing processes (e.g., scheduling, dispatching, price settling) can lead to misleading comparisons and incorrect conclusions.

### Beyond Price-taker

Recent multiscale optimization frameworks have emerged to refine these assumptions. Specifically, Gao et al. [7] couple detailed energy system (process) models and grid production cost models (PCMs) to simulate resource bidding (instead of self-schedule), market clearing (instead of price-taker), and tracking (which generalizes beyond steady-state). They demonstrate how the price-taker and self-schedule assumptions break down. This process requires solving multiple optimization problems sequentially. Recent work has highlighted the drawbacks of naïve price-taker approaches through methods using PCM models for solar power plants [8], analyzing IES value in coproduction systems [9], and using PCM for wind energy and storage systems [10]. More information on utilizing PCMs can be found in references [7-10], where methods beyond price taker are shown to perform better.

In the absence of detailed models or to include PCMs in an algebraic formulation, market surrogates can be used to include market behavior without solving market clearing problems [11]. To this end, Jalving et al. [12] propose incorporating market interactions directly into the energy system design and operation co-optimization problem. Jalving et al. [12] use a simple thermal generator case study to illustrate the limitations of the price taker assumption. Nevertheless, the price taker assumption is convenient and has significant advantages over LCOE. It is an excellent starting-point for optimization-based TEA.

### Need Faster Analysis Workflows

**Figure 1:** Software workflow for the PriceTakerModel class. The user just needs to formulate operational constraints for a single time point, design constraints for the system, and read in LMP data. Then, the PriceTakerModel can build the multi-period model as well as add common equations such as startup/shutdown constraints and build the objective function from operational cost/revenue functions.

Unfortunately, most of the optimization-based energy system TEA studies are one-off implementations. This work presents new generalized capabilities in the IDAES®-PSE platform [13] to simplify and standardize optimizing energy systems and market interactions. Specifically, a PriceTakerModel class, which utilizes the Multi-PeriodModel class in IDAES-PSE, facilitates rapid price-taker and self-schedule analyses using either rigorous equation-oriented (EO) process models or surrogates trained for data. Also, the price taker model generally can be solved quickly to provide quick analysis. A generalized interface between process models and a PCM enables rigorous verification by modeling energy system and market interactions.

This work generalizes previous analyses in the IDAES-PSE ecosystem into a software interface for the multi-period price-taker model. Thus, the rest of this work is organized to describe: (i) the software interface using an example to demonstrate the workflow, and (ii) a case study using the software interface and example given in a self-name section.

## SOFTWARE INTERFACE

Typical multi-period price taker models derive complexity from their consideration of time-varying markets.

For instance, let us consider a simple scenario that requires a power plant to operate at a minimum load without shutting down.

$$\max_{p_t} \text{Revenue} = \sum_{t \in \mathcal{T}} f_{rev,t} \quad (14)$$

$$\text{s. t. } f_{rev,t} = \pi_t^e p_t - f_{fuel}(p_t) - f_{var}(p_t) - f_{fixed}(d) \quad \forall t \in \mathcal{T} \quad (15)$$

$$p_t \in [p_{min}, p_{max}] \quad (16)$$

Here,  $p_t$  is the net power generation at time  $t$ . Total revenue is computed using the locational marginal price data (LMP) at time  $t$ ,  $\pi_t^e$ , with net power generation at that time less the fuel costs, variable costs, and fixed costs of the system, or  $f_{fuel}$ ,  $f_{var}$ , and  $f_{fixed}$ , respectively. Since the plant is always on, net power generation must be between  $p_{min}$  and  $p_{max}$ , or the minimum and maximum load of the plant, at all times.

In the IDAES®-PSE platform, new implementations for grid integration have been developed to facilitate multiperiod, price-taker models using the PriceTakerModel class, which makes use of the MultiPeriodModel class for time-varying models. The MultiPeriodModel class is used to extend steady state models to dynamic models by adding time-varying constraints with appropriate model superstructure (defined as Pyomo blocks of the steady-state model at each time interval). The

**Figure 2:** On the left, power generation from both the simple scenario (plant is always operating) and shutdown scenario (plant is allowed to shut down if profitable). On the right, the baseline operating cost in \$/MWH versus real-time, hourly LMP data for the ERCOT West, 2022 energy market.

PriceTakerModel class encapsulates either a steady state model, or a dynamic model as an instance of the MultiPeriodModel class, to facilitate price-taker analysis of an IES. The PriceTakerModel class also allows automated conversion of steady state models to time-varying multi-period models.

As shown in Figure 1, the modeler only needs to provide a function that defines the single time-point models to build the time-varying model. Also, the user can easily specify the LMP data by providing a .csv, .xls data file, or similar data format. As shown, methods for building the multi-period model, generating start-up and shutdown constraints, and building costing functions to aid in objective function development are all core functionalities of the new software interface. Not all features are required to be used for each model. For instance, the model shown in Eqs. (14) through (16) has no start-up or shutdown constraints, so the user can skip the development of those constraints and other parts of the interface as needed.

Also, more complex objective formulations such as evaluation net present value (NPV) with carbon tax, general corporate tax, and other common process design economic evaluators are readily available while building an objective function. Also, algebraic surrogate models can easily be implemented in this framework, as will be shown in the case study in the following section.

## CASE STUDY

A case study similar to that shown in Eqs. (14) through (16) was analyzed with and without start-up/shutdown constraints to demonstrate the utility of the new software interface. These values are based on a

solid oxide fuel cell (SOFC) power generation process, as described in Eslick et al. [14]. As such, the formulation with start-up and shutdown constraints is given below.

$$\max_{p_t, y_t, v_t, w_t} \text{Revenue} = \sum_{t \in \mathcal{T}} f_{\text{rev},t} - \sum_{t \in \mathcal{T}} (\theta_d w_t - \theta_u v_t) \quad (17)$$

$$\text{s. t. } f_{\text{rev},t} = \pi_t^e p_t - f_{\text{fuel}}(p_t) - f_{\text{var}}(p_t) - f_{\text{fixed}}(d) \quad \forall t \in \mathcal{T} \quad (18)$$

$$f_{\text{fuel}}(p_t) + f_{\text{var}}(p_t) = 23.29 p_t + 49.22, \quad \forall t \in \mathcal{T} \quad (19)$$

$$f_{\text{fixed}}(d) = 13500, \quad \forall t \in \mathcal{T} \quad (20)$$

$$y_{t-1} - y_t \leq w_t, \quad \forall t \in \mathcal{T} \quad (21)$$

$$y_t - y_{t-1} \leq v_t, \quad \forall t \in \mathcal{T} \quad (22)$$

$$\sum_{j=t-\tau_d+1}^t w_j \leq 1 - y_t, \quad \forall (t > \tau_d) \in \mathcal{T} \quad (23)$$

$$\sum_{j=t-\tau_u+1}^t v_j \leq y_t, \quad \forall (t > \tau_u) \in \mathcal{T} \quad (24)$$

$$y_t \in \{0, 1\} \quad (25)$$

$$w_t \in \{0, 1\} \quad (26)$$

$$v_t \in \{0, 1\} \quad (27)$$

$$p_t \in [200, 650] \quad (28)$$

The objective function has an additional term to account for the cost of shutting down and starting up the unit,  $\theta_d$  and  $\theta_u$ , respectively. Here, fuel and variable costs are represented linearly by a surrogate model, as shown in Eq. (19). Whether the process is on or off is dictated by binary variable  $y_t$ . Binary variables  $v_t$  and  $w_t$  represent start-up and shutdown indicators, respectively. Subsequently, start-up (Eq. (21)) and shutdown (Eq. (22)) constraints have been added. Similarly, minimum uptime and downtime variables,  $\tau_u$  and  $\tau_d$ , have been added, as well as minimum uptime (Eq. (24)), and minimum downtime

constraints (Eq. (23)) [15]. All cost values are in U.S. dollars per hour. The surrogate model for fuel and variable cost to run the SOFC unit are the truncated linear version of those given in Elick et al. [14]. LMP values,  $\pi_t^e$ , for an entire year were taken from the ERCOT West, 2022 hourly price data. Thus, the dimension of time set  $\mathcal{T}$  is 8760 for an entire year of hourly data.

Since the surrogate for cost is linear, the problem is a mixed-integer, linear programming formulation. Subsequently, these problems were solved using GUROBI [16]. Two scenarios were analyzed in the ERCOT West, 2022 market: (i) a simple scenario where the SOFC unit must remain on for all times (Eqs. (17) through (20) and Eq. (28)), and (ii) a scenario where the SOFC unit is allowed to shut down if it is more profitable (Eqs. (17) through (28)). Each MIP instance solves in less than 10 seconds on a standard workstation.

Results indicated that the SOFC in both scenarios remains on for almost the entire operating year. However, near the end of the year, the second system takes advantage of low prices that close out the year. Figure 2 shows that both scenarios follow power generation trends until scenario two shuts the SOFC unit off around hour 8650. Initially, the cost is large due to the upfront shutdown cost, but the system's low and sometimes negative LMP late in the year (also shown in Figure 2) results in a higher negative revenue stream than the shutdown cost. It should be noted that since the system never turned back on, the second scenario never withstood the large startup cost. The total profit difference due to this shutdown is about \$130,000. Still, the startup cost for this scenario was \$162,015, indicating that if the system must be turned on again after the start of the next year, it may not have been economically feasible if the time horizon did not end. This may indicate a desire to ensure the starting state of the system must match the ending state of the system (creating a continuous loop of yearly operation) with an additional integer constraint:

$$y_1 = y_{8760} \quad (29)$$

To verify this hypothesis, the system was optimized again with Eq. (29) included. The solutions were identical except that system that included Eq. (29) indeed did not turn off because the states need to match at either end of operation. Other analyses are possible, comparing various LMP networks to see which markets are profitable or not for certain technologies. For instance, ERCOT West 2022 indicates a significant profit for operating whereas other regions are less profitable.

## CONCLUSIONS

In this work, we presented a software interface developed in the IDAES®-PSE platform to facilitate implementation of the multi-period, price-taker model for

integrated energy systems. The interface utilizes Pyomo and existing IDAES infrastructure to streamline the creation of time-varying functions. Notably, the interface utilizes a single time point model to build a collection of blocks that elicit time-varying functionality. If the user desires a comparison between methods that are not time-varying, for instance LCOE analysis, the model for this single time point is sufficient for the operating constraints of the system.

Also, rapid comparison of different modeling paradigms is facilitated by the interface. For instance, utilizing other tools in the IDAES platform in conjunction with the interface presented in this work can lead to conclusions beyond power systems, such as multi-systems analysis including water treatment systems [17, 18], co-optimization of electricity and H<sub>2</sub> coproduction, as well as optimizing flexible carbon capture systems.

We showed how the inclusion of start-up/shutdown constraints had little to no impact on the adoption of SOFC in the ERCOT West 2022 market. This is a proof-of-concept comparison but shows modelers can utilize this framework to understand the required model fidelity to adequately capture the behavior of the system. In the future, we plan to integrate more user features that allow reformulations or relaxations of revenue terms and more formats for revenue inclusion in the objective function. We also plan to extend these tools to support beyond price taker approaches, such as surrogate models, to predict how price distributions change as a function of energy system design and operating decisions. This code will be released in the following year within the IDAES®-PSE platform.

## ACKNOWLEDGEMENTS

This work was conducted as part of the Design Integration and Synthesis Platform to Advance Tightly Coupled Hybrid Energy Systems (DISPATCHES) project through the Grid Modernization Lab Consortium with funding from the U.S. Department of Energy's Office of Fossil Energy and Carbon Management, Office of Nuclear Energy, and Hydrogen and Fuel Cell Technologies Office. Additional work was conducted as part of the Institute for the Design of Advanced Energy Systems (IDAES) with support from the U.S. Department of Energy's Office of Fossil Energy and Carbon Management (FECM) through the Simulation-based Engineering Research Program.

## ABSTRACT

As the United States continues efforts to decarbonize the power and transportation sectors, significant challenges associated with the reliance of clean energy technologies on rare earth elements (REEs) will have to be overcome. One potential approach for increasing the supply of these elements is to extract REEs from end-of-life (EOL) hard disk drives (HDDs). HDDs contain neodymium and praseodymium, which are among the most important REEs for the clean energy transition, as they are crucial to producing the permanent magnets needed for wind turbines and electric vehicles. Here, we propose a superstructure-based approach to find the optimal pathway for recovering REEs from EOL HDDs. The superstructure was optimized by maximizing the net present value (NPV) over 15 years. Projected prices for commercial rare earth oxides and the projected amount of EOL HDDs in the U.S. were estimated and used in the model. These projections were used to establish the base case optimal result, assuming that the plant recycles 60% of personal computers EOL HDDs in the U.S. each year. The model was then expanded to consider the recycling of EOL HDDs generated before the beginning of plant production. Next, a sensitivity analysis was conducted to evaluate the impact of different parameters on the venture's profitability and the optimal processing pathway. Combined, these results offer both valuable insights into the economic viability of REE recycling extraction and a method for performing similar analyses in the future.

## INTRODUCTION

The climate crisis presents one of the most significant challenges facing humanity in the twenty-first century, as the Earth has already exceeded pre-industrial temperatures by 1.1°C [1]. It is imperative to take immediate action to prevent further temperature increases, with a preference for staying within 1.5°C above pre-industrial levels [1]. This requires giving priority to the decarbonization of energy and our economy, including a transition to clean energy technologies such as solar panels, wind turbines, and electric vehicles to reduce emissions in the power and transportation sectors. Notably, in the United States, substantial legislative efforts, such as the "Bipartisan Infrastructure Law," entail an unprecedented investment of more than \$430 billion by 2031, aimed at decarbonizing energy among other initiatives [2].

Electrification initiatives are heavily dependent on

rare earth elements (REEs). Presently, the United States mines approximately 15% of the world's REEs but exports all raw materials for separation and refinement, primarily to China, which is responsible for mining around 60% of the world's REEs and maintains near-monopoly control over the entire supply chain [3]. This dependency represents a risk to domestic decarbonization efforts, primarily in terms of establishing domestic supply chains to produce clean energy technologies. Therefore, it is vital for the United States to strengthen its domestic rare earth supply chain as it embarks on the journey toward decarbonization.

The objective of this work is to create an optimization-based framework for designing the most efficient processing pathway for recovering rare earth elements from end-of-life hard disk drives (EOL HDDs). HDDs have received increasing attention in the U.S. as a potential source for REEs as evidenced by the work of agencies and

national laboratories (see for example NREL, EPA, and CMI webpages) [4-6]. The paper is organized as follows; first, an estimation was made regarding the projected quantity of REEs available for recycling from EOL HDDs over a period ranging from 2014 through 2038 [7-13], along with a projection of rare earth oxide (REO) prices over the plant's operational lifetime [14]. Next, a superstructure was formulated containing all potential processing pathways for recovering rare earth elements as rare earth oxides from the incoming HDD-based feedstock. Finally, optimization techniques were employed to find the processing pathway that maximizes the net present value over a 15-year period.

## MODEL ASSUMPTIONS

Rare earth elements (REEs), which encompass the lanthanide elements, scandium, and yttrium, are categorized into two groups based on their atomic weight: light rare earths (LREs) and heavy rare earths (HREs). LREs comprise Ce, La, Pr, Nd, and Sm, while HREs encompass Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lt. These elements serve various purposes, with magnets (Nd, Pr, Dy, Sm) constituting 29% of their usage, catalysts (La, Ce) contributing to 20%, and polishing agents (La, Ce) making up 13% across the top three global end-use sectors [15]. The varying abundance of individual REEs within deposits results in some elements being in surplus globally while others face shortages. Consequently, their prices exhibit significant discrepancies, with Nd/Pr being almost 100 times more valuable than La and Ce [15, 16]. HDDs contain relatively large amounts of Nd/Pr.

Two scenarios were examined in this paper. For the first scenario, only EOL HDDs generated during the plant's operational phase were considered. In this scenario, we assumed that 60% of all available EOL HDDs in the U.S. each year would be recycled and available to the plant [8]. In the second scenario, the model was expanded to consider the EOL HDDs generated in the U.S. prior to the start of production. In this scenario, it was assumed that 25% of all EOL HDDs generated in the U.S. over the period ranging from 2014 to 2024 would be recycled by the plant in addition to recycling 60% of all EOL HDDs available in the U.S. each year. For both scenarios, it was assumed that the plant's construction would begin in 2024 and be completed by 2025, after which production would start and continue for 14 years through 2038.

Several sources were used to estimate and quantify the amount of feedstock available for recycling as detailed in the subsequent section [7-13]. To estimate the price of the neodymium oxide, the rare earth oxide (REO) product of this process, over the operational lifetime of the plant, projections were taken from [14] and extrapolated through 2038.

We assumed HDDs to have a lifetime of 8 years [8].

The composition by wt. % of the average HDD rare earth permanent magnets (REPM) is 30 wt. % Nd/Pr, 66 wt. % Fe, and 4 wt. % other (Tb, Dy, Fe, B, Co, or Al) [7]. However, in this analysis, the 'other' category was ignored, and the composition of the REPM was assumed to be 30 wt. % Nd/Pr and 70 wt. % Fe. Note that following currently available data, Nd and Pr were considered together; in what follows Nd should be read as Nd/Pr.

## QUANTIFICATION OF FEEDSTOCK AND PRODUCTS

To estimate the amount of REPM available for recycling, the number of EOL HDDs in the U.S. was estimated based on historic and projected sales of laptop and desktop computers in the U.S. and other factors such as HDD type. Although the plant is to run from 2024 through 2038, we wanted to account for all the previously generated EOL HDDs, which we hypothesized some percent of which would still be available for recycling. Thus, the sales of desktops and laptops in the U.S. were estimated over a period of 2006 through 2030.

Sales data for laptops and desktops in the U.S. from 2018 through 2022 was taken from [9, 13]. Additionally, these sources contained projected sales for notebooks and desktops from 2023 through 2028. To estimate sales through 2030, a linear model was fit to the projected sales from 2023 through 2038 and extrapolated through 2038. Estimating sales for years before 2018 proved more difficult due to a lack of data. Thus, the following methodology was employed: First, data for the worldwide sales of personal computers (PCs) and the worldwide sales of laptops from 2006 through 2022 was taken from [10, 11]. Then, the worldwide sales for desktops were calculated by subtracting the sales of notebooks from the sales of PCs. Next, the average percentage of global sales the U.S. accounts for from 2018 through 2022 was calculated. This percentage was assumed to hold from 2006 through 2018. Finally, the annual sales of laptops and desktops in the U.S. from 2006 through 2018 were calculated by multiplying the global sales of desktops and laptops by this percentage.

After estimating the sales of laptops and desktops in the U.S., the next step was to evaluate how many contained HDDs. To accomplish this, we first took data for the global sales of HDDs and SSDs from 2015 through 2022 from [12]. Next, a linear model was fit to the sales data and used to extrapolate sales back to 2006 and up to 2030. In the case of SSDs, this linear model began predicting negative sales in 2012. Thus, the sales of SSDs were assumed to be zero from 2006 through 2012. Using this sales data, the ratio of HDDs to SSDs sold each year was estimated. It was then assumed that this ratio was the same in the U.S. as globally. Additionally, it was assumed to hold for laptops and desktops sold. Thus, the number of HDD-

containing laptops and desktops in the U.S. was estimated by multiplying the sales of laptops and desktops by the percentage of total HDD and SSD sales that HDDs make up. These estimates can be seen in Figure 1.

Finally, using this information, the amount of REPM available for recycling was estimated. HDDs have two sizes: 2.5" and 3.5". We assumed all desktops used 3.5" HDDs and all laptops used 2.5" HDDs. It was also assumed that each 2.5" HDD contains 2.5g of REPM [7]. To estimate the amount of REPM per 3.5" HDD in grams, a linear model taken from [7] was used and shown in Equation 1.

$$17.87 - 0.35t \quad (t = 0 @ 1990) \quad (1)$$

Further, it was assumed that the amount of REPM contained within a 3.5" HDD would stop decreasing once it equaled the mass of REPM contained within a 2.5" HDD (2.5g). The annual amount of REPM and Nd available for recycling from EOL HDDs in the U.S. is in Figure 2.

## PROCESSES FOR RECOVERING REES FROM EOL HDDS

Rare earth recycling comprises four primary processing stages: disassembly, demagnetization, leaching, and extraction. Each stage contains several potential

processes, represented as nodes in Figure 3. The naming convention for the nodes is  $\langle \text{stage number}, \text{node number} \rangle$ , where 1 represents the disassembly stage, 2 the demagnetization stage, 3 the leaching stage, and 4 the extraction stage. The superstructure containing all potential processing pathways can be seen in Figure 3.

For the disassembly stage, three processes were considered: Manual Disassembly  $\langle 1,1 \rangle$ , where REPM is removed from EOL HDDs manually [17]; Automatic Disassembly  $\langle 1,2 \rangle$ , which automates the process with robots [18]; and Shredding  $\langle 1,3 \rangle$ , which involves first heating the HDDs to high temperatures to demagnetize them, after which they are shredded using an industrial shredder. The final node is blank and represents skipping the disassembly stage.

In the demagnetization stage, three processes were explored: Hydrogen Decrepitation  $\langle 2,1 \rangle$ , which involves the reaction of the REPM with hydrogen gas at 170°C for 3 hours to produce a demagnetized, friable material [19]; Heating  $\langle 2,2 \rangle$ , which involves heating the magnets to 350°C for 30 minutes followed by milling [20]; and Extreme Heating  $\langle 2,3 \rangle$ , which involves heating the magnets to 950° C for 15 hours to demagnetize and oxidize them [21] followed by milling. This extreme heating results in

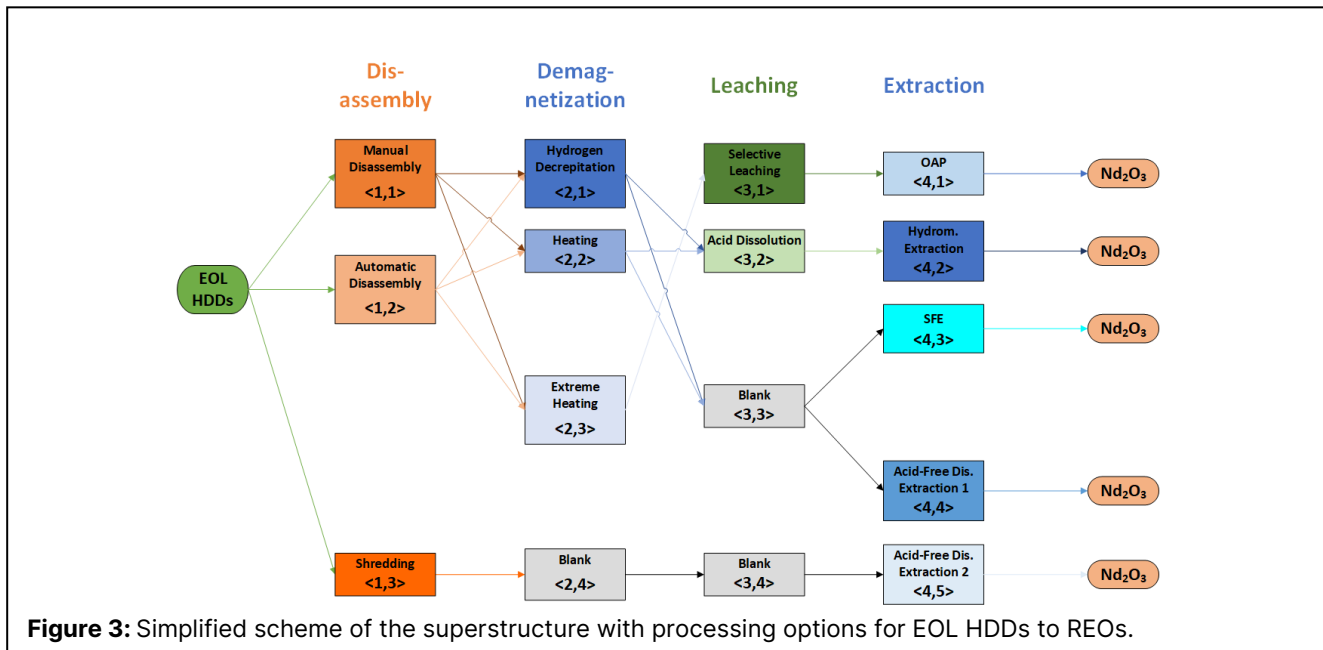

**Figure 1:** Annual estimated sales, sales from data, and projected sales of desktops and laptops containing HDDs in the U.S. from 2006 through 2030.

**Figure 2:** REPM and Nd available for recycling from HDDs in the U.S. from 2014 through 2038.

iron precipitation during the subsequent selective leaching process. The final node  $\langle 2,4 \rangle$  is blank and represents skipping the demagnetization stage.

For the leaching stage, two processes were considered: Selective Leaching  $\langle 3,1 \rangle$  with hydrochloric acid [21], which follows the extreme heating process, and Acid Dissolution  $\langle 3,2 \rangle$  using sulfuric acid [22]. In selective leaching, iron precipitates out of the solution as iron (III) hydroxide. The final two nodes,  $\langle 3,3 \rangle$  and  $\langle 3,4 \rangle$  are blank and represent skipping the leaching stage.

Five processes were examined in the extraction stage. The first process, Oxalic Acid Precipitation (OAP)  $\langle 4,1 \rangle$ , utilizes oxalic acid to directly precipitate neodymium out of solution [23]. The next process, Hydrometallurgical Extraction  $\langle 4,2 \rangle$ , precipitates neodymium as an Nd-sodium double salt to separate it from iron. Subsequent steps involve reactions with oxalic acid and calcination to produce pure  $\text{Nd}_2\text{O}_3$ , with the iron-containing leachate being treated with ammonium sulfate to precipitate it out of solution as iron jarosite [22]. The third potential process, Supercritical Fluid Extraction (SFE)  $\langle 4,3 \rangle$ , utilizes supercritical  $\text{CO}_2$  to separate Nd from iron [24, 25].

In the final two processes, Acid-Free Dissolution Extraction 1  $\langle 4,4 \rangle$  and 2  $\langle 4,5 \rangle$ , REPM powder is dissolved in an aqueous copper(II) nitrate solution [26]. Next, oxalic acid is added to precipitate neodymium out of solution as neodymium oxalate and iron out of solution as iron-ammonium oxalate. The neodymium oxalate precipitate is then filtered from the soluble iron-ammonium oxalate. Finally, the neodymium oxalate is calcined to produce  $\text{Nd}_2\text{O}_3$  [26]. These final two processes are identical, except in their final product yield ( $\text{Nd}_2\text{O}_3$ ). The yield for this process differs depending on whether the incoming feedstock is shredded HDDs or pure REPM. The yield for a pure REPM feedstock is 98.5 wt. %, while the yield for a shredded HDD

feedstock is 73 wt. %. Due to space constraints, details on these processes are not shown in the Figure.

## OPTIMIZATION PROBLEM FORMULATION

Equations (2-8) were formulated to describe the superstructure's configuration. A binary variable  $y_{i,j}$  is introduced to model the selection of node  $\langle i,j \rangle$ . If the node is selected, the binary will equal 1; if not, it will equal 0. Equation (2) enforces that only one node per stage is selected. Equation (3) enforces that if  $\langle 1,1 \rangle$  or  $\langle 1,2 \rangle$  is selected, then either  $\langle 2,1 \rangle$ ,  $\langle 2,2 \rangle$  or  $\langle 2,3 \rangle$  must be chosen. Equation (4) enforces that if  $\langle 1,3 \rangle$  is selected,  $\langle 2,4 \rangle$ ,  $\langle 3,4 \rangle$  and  $\langle 4,5 \rangle$  must all be selected. Equation (5) ensures that if  $\langle 2,1 \rangle$  or  $\langle 2,2 \rangle$  are selected, then either  $\langle 3,2 \rangle$  or  $\langle 3,3 \rangle$  must be selected. Equation (6) ensures that if  $\langle 2,3 \rangle$  is selected, then only  $\langle 3,1 \rangle$  or  $\langle 4,1 \rangle$  can be chosen. Equation (7) ensures that if  $\langle 3,2 \rangle$  is selected then  $\langle 4,2 \rangle$  is also chosen. Equation (8) enforces that either  $\langle 4,3 \rangle$  or  $\langle 4,4 \rangle$  is chosen if  $\langle 3,3 \rangle$  is selected. Finally, big-M constraints were added to relate the flow through a unit to its selection, as shown in Equation (9). Here,  $F_{i,j,c,t}^{in}$  represents the flow of component  $c$  entering node  $\langle i,j \rangle$  in year  $t$ ,  $M^{i,j}$  represents the maximum inlet flow rate for node  $\langle i,j \rangle$ ,  $I$  is the set of all stages in the superstructure,  $J_i$  is the set of all nodes in stage  $i$ ,  $C$  is the set of tracked components, and  $T$  is the set of all years the plant is in operation. The mass balance for a generic node is illustrated in Figure 4.

$$\sum_{j \in J_i} y_{i,j} = 1 \quad \forall i \in I \quad (2)$$

$$\begin{aligned}
y_{1,1} + y_{1,2} &= y_{2,1} + y_{2,2} + y_{2,3} & (3) \\
y_{1,3} &= y_{2,4} = y_{3,4} = y_{4,5} & (4) \\
y_{2,1} + y_{2,2} &= y_{3,2} + y_{3,3} & (5) \\
y_{2,3} &= y_{3,1} = y_{4,1} & (6) \\
y_{3,2} &= y_{4,2} & (7) \\
y_{3,3} &= y_{4,3} + y_{4,4} & (8) \\
F_{i,j,c,t}^{in} &\leq y_{i,j} M^{i,j} \quad i \in I, j \in J_i, c \in C, t \in T & (9)
\end{aligned}$$

Components in the feedstock, intermediates, and products were tracked. The mass balance at each node includes three sequential steps: convergence of the inlet flows from different upstream nodes, processing, and separation of the outlet flows to other downstream nodes. The specific equations are defined in Equations (10-12).

$$\sum_{k=1}^{K^{in}} F_{i,j,k,c,t}^{in} = F_{i,j,c,t}^{in} \quad \forall i \in I, j \in J_i, c \in C, t \in T \quad (10)$$

$$F_{i,j,c,t}^{out} = a_{i,j,c} F_{i,j,c,t}^{in} \quad \forall i \in I, j \in J_i, c \in C, t \in T \quad (11)$$

$$F_{i,j,c,t}^{out} = \sum_{k=1}^{K^{out}} F_{i,j,k,c,t}^{out} \quad \forall i \in I, j \in J_i, c \in C, t \in T \quad (12)$$

Here,  $F_{i,j,c,t}^{in}$  is the flow of component  $c$  entering node  $\langle i, j \rangle$  in time  $t$ ,  $a_{i,j,c}$  is the yield of component  $c$  for node  $\langle i, j \rangle$ ,  $F_{i,j,c,t}^{out}$  is the flow of component  $c$  leaving node  $\langle i, j \rangle$  in time  $t$ , and  $F_{i,j,k,c,t}^{out}$  is the flow of component  $c$  leaving node  $\langle i, j \rangle$  at time  $t$ .

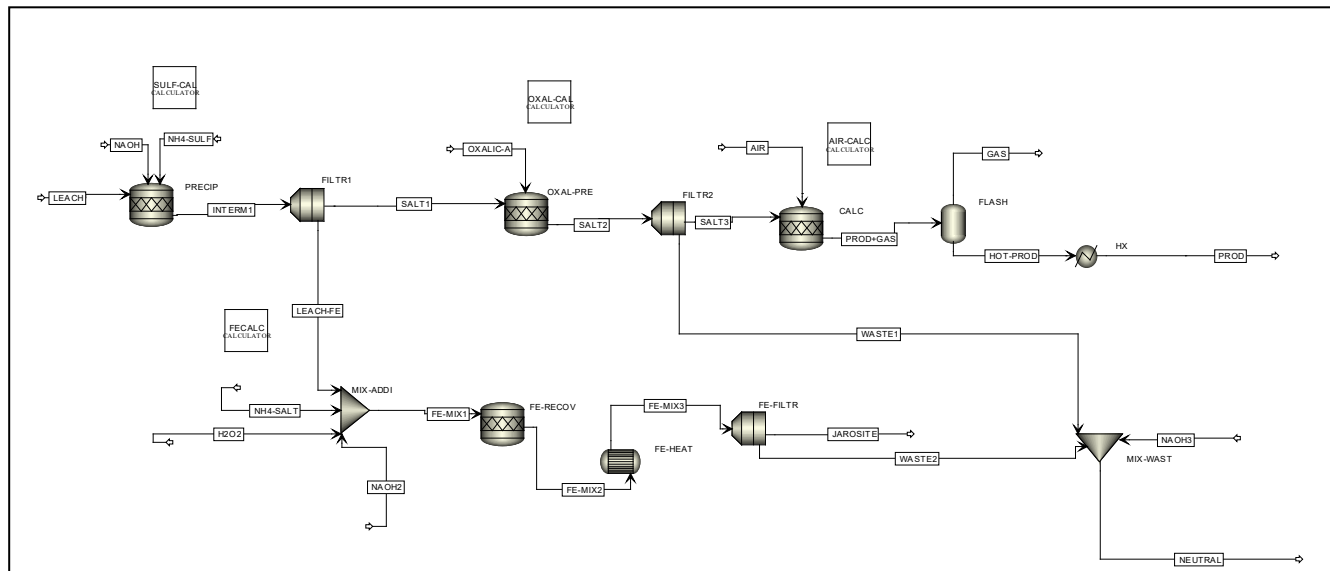

**Figure 4:** Mass balance framework for generic node  $\langle i, j \rangle \forall c \in C, t \in T$ .

## ASPEN FLOWSHEETS AND SIMULATIONS

The study and simulation of REE recycling production pathways is a newer and rapidly evolving area of research. Hence, in several cases, process flowsheets with techno-economic analysis were either not available in the literature or the data were of insufficient detail to effectively leverage for this study. Consequently, process flowsheets for several recycling pathways were designed and simulated in Aspen Plus. These flowsheets included the following unit operations: hydrogen decrepitation, heating/high-temperature heating, acid-free dissolution extraction, selective leaching, hydrometallurgical extraction, solvent extraction, and oxalic acid precipitation.

As an example, Figure 5 depicts the Aspen flowsheet designed for the hydrometallurgical extraction process. In the first step, the incoming leachate from the acid dissolution process is reacted with NaOH and ammonium sulfate at a pH of 1.5 to form Nd-sodium double salt precipitates. In the next step, the precipitate is separated from the iron-containing leachate and is reacted with oxalic acid to form neodymium oxalate. The neodymium oxalate is first filtered and then calcined at 750°C in the presence of oxygen to form Nd<sub>2</sub>O<sub>3</sub>. In the final step, the product is cooled to 100°C using cooling water. However, before the spent leachate can be disposed of, the iron must first be

**Figure 5:** Aspen simulation built for the hydrometallurgical process built using reaction yield data from [24].

precipitated out of solution as jarosite. This is accomplished by heating the leachate to 90°C for 6 hours and reacting it with ammonium sulfate in the presence of an oxidizing agent at a pH of 2 [22]. Finally, the spent leachate is neutralized with NaOH.

The individual operations in these flowsheets were modeled using reaction and separation data from literature. Capital (CAPEX) and operating costs (OPEX) were evaluated using the Aspen Process Economics Analyzer.

## OBJECTIVE FUNCTION

The goal of the optimization problem was to maximize the NPV over the plant's lifetime, as shown in Equations (13-14) [27]. Where  $CF_n$  is the cash flow in year  $n$ ,  $LT$  is the plant's lifetime in years, and  $IR$  is the interest rate.

$$NPV = \sum_{n=1}^{LT} \frac{CF_n}{(1 + IR)^n} \quad (13)$$

$$CF_n = Profit_n - (CAPEX_n + OPEX_n) \quad (14)$$

An interest rate of 10% was used as recommended by [28]. Tax and depreciation were ignored. It was assumed that all capital investments were made in year 1, and that the plant does not begin operation until year 2. Therefore, CAPEX was only considered for year 1, after which only profit and OPEX were considered. The methodology described by [27] was used for each node to calculate the CAPEX and OPEX. For OPEX, only the cost of labor was considered for the disassembly stage, and only the cost of raw materials and utilities were considered for the later stages.

Costing information that was available from the literature was adjusted for capacity using a piecewise-linearized approximation of the six-tenths rule [27]. When not available from the literature, Aspen Plus simulations and the Aspen Process Economic Analyzer were used to estimate CAPEX and OPEX costs for a range of flow rates. A linear regression model was then fit to obtain the CAPEX and OPEX vs incoming flow rates.

## RESULTS

The optimization problem was coded in Pyomo and solved with CPLEX version 22.1.1.0 using the default options. The decision variables consisted of the operations included in the process and their sizing. The formulation for the MILP optimization problem is as follows:

$$\begin{aligned} \max \quad & z = NPV \\ \text{s.t.} \quad & Eq. (2 - 12) \\ & F_{i,j,c,t}^{in} \geq 0, y_{i,j} \in \{0,1\} \forall i \in I, j \in J_i, c \in C, t \in T \end{aligned}$$

The base scenario assumed that the plant recycles

60% of all available EOL HDDs in the U.S. annually [8]. The optimal pathway was found to consist of shredding, followed by acid-free dissolution extraction, and resulted in a negative NPV. The acid-free dissolution extraction processing step was found to be the most significant contributor to CAPEX, accounting for ~90% of the cost. Approximately 162.5 tonnes of  $Nd_2O_3$  were recovered.

Next, we conducted a sensitivity analysis on the percentage of EOL HDDs in the U.S. the plant recycles each year (collection rate, Fig. 6). We found that the plant remained unprofitable even at a 100% collection rate. The NPV breakeven point was found to occur at a collection rate of ~360%, and the optimal process never changed. This suggests that an insufficient number of HDDs are being produced for the plant to leverage economies of scale to be profitable.

**Figure 6:** NPV for a varying collection rate. The base case is a collection rate of 60% and no recycling of EOL HDDs generated prior to plant production. The NPV break-even point was found to occur at ~360%. Numerical values are not reported to preserve confidentiality.

Given the results of our first sensitivity analysis, we hypothesized that the optimal process may prove to be profitable when the recycling of EOL HDDs stockpiled from years prior to the beginning of plant production was considered. Therefore, we expanded our model to recycle 25% of all EOL HDDs generated in the U.S. over the period ranging from 2006 to 2024 (initial collection rate) in addition to recycling 60% of all available EOL HDDs each year of operation. The optimal process was found to be the same as that of the previous scenario, however, the NPV was still found to be negative. We then conducted a sensitivity analysis on the initial collection rate and found the NPV breakeven point to occur at ~148% (Fig. 7). The optimal process never changed.

Finally, we conducted a sensitivity analysis on projected REO prices for the expanded model. To vary the projected REO prices, the new projection was assumed to be some percentage of the initial estimate. This percentage was then varied. The NPV breakeven point was found to occur at ~168% of the initial estimate (Fig. 8). Once

again, the optimal process never changed.

**Figure 7:** NPV for a varying initial collection rate. The base case has a collection rate of 60% and an initial collection rate of 25%. The NPV break-even point was found to occur at ~148%. Numerical values are not reported to preserve confidentiality.

**Figure 8:** NPV for varying percentages of the initial REO price projection estimate. The NPV break-even point was found to occur at ~168%. Numerical values are not reported to preserve confidentiality.

## CONCLUSION

Superstructure optimization was utilized to design a process for the recycling of rare earth elements from EOL HDDs, with the objective of maximizing the NPV. The study determined that the optimal process for both the base case and expanded model consists of shredding, followed by acid-free dissolution extraction. Our results show that the venture considering HDDs from PCs is likely not profitable as a stand-alone plant due to the total amount of REPM available for recycling from EOL HDDs being insufficient given the projected REO prices. However, we hypothesize that by expanding the plant to process multiple feedstocks, or by introducing multiple agents to handle the different processing steps, the optimal pathway may become profitable. Future work will investigate these options.

## ABSTRACT

Solid oxide cells (SOCs) are a promising dual-mode technology that generates hydrogen through high-temperature water electrolysis and generates power through a fuel cell reaction that consumes hydrogen. Reversible operation of SOC requires a transition between these two modes for hydrogen production setpoints as the demand and price of electricity fluctuate. Moreover, a well-functioning control system is important to avoid cell degradation during mode-switching operation. In this work, we apply nonlinear model predictive control (NMPC) to an SOC module and supporting equipment and compare NMPC performance to classical proportional integral (PI) control strategies, while ramping between the modes of hydrogen and power production. While both control methods provide similar performance in many metrics, NMPC significantly reduces cell thermal gradients and curvatures (mixed spatial-temporal partial derivatives) during mode switching. A dynamic process flowsheet of the reversible SOC system was developed in the open-source, equation-based IDAES modeling framework. Our IDAES dynamic simulation results show that NMPC can ramp the SOC system between hydrogen and power production targets within short mode-switching times. Moreover, NMPC can comply with operating limits in the SOC system more effectively than PI, and only NMPC can directly enforce user-specified limits for mixed spatial-temporal partial derivatives of temperature. This allows for management of the trade-off between operating efficiency and cell degradation, which is dependent on these temperature curvatures.

## INTRODUCTION

In recent years, a growing share of variable renewable energy generation and ambitious decarbonization targets have spurred a notable shift away from fossil fuels, with hydrogen poised to play a crucial role in this energy transition. By combining hydrogen production and electricity generation, integrated energy systems based on reversible SOC technology (rSOC) can be optimized to provide the operational flexibility required to meet the varying load demand of the modern grid. Hydrogen can function as a valuable energy storage medium and as a

versatile feedstock for other purposes. While most industrial hydrogen today is produced through steam methane reforming, which uses a fossil fuel feedstock, water electrolysis is a promising replacement, producing no direct greenhouse gas emissions when renewable energy is used.

For hydrogen production through water electrolysis, Nernst potential, the minimum potential difference at which electrolysis occurs, decreases with increasing reaction temperature. Because solid oxide electrolysis cells (SOECs) and solid oxide fuel cells (SOFCs) operate at 600°C to 1000°C, much higher temperatures than those

of other electrolysis technologies, they are good candidates for efficient water electrolysis. In power production mode, high temperature operation allows various fuels, including hydrogen, to rapidly undergo oxidation reaction on the fuel electrode. However, high temperature operation comes with significant drawbacks. Besides additional heat exchange equipment and good thermal insulation requirements, transitions between operating points must be carefully controlled to minimize power requirements and avoid thermal stress.

Many SOC systems are reversible and can operate as hydrogen fuel cells when grid demand becomes high. This flexible operation is necessary to stabilize the grid and operate profitably with intermittent renewable energy. Switching between SOEC and SOFC modes while considering both operating performance and equipment longevity can be challenging. Ferrari [1] coupled PI controllers with feed-forward approaches to reduce thermal gradients and limit the peak anode-cathode differential pressure for a tubular SOFC/GT hybrid system. However, modeling of the SOFC was based on "lumped volume" OD models, and the chemical reactions were assumed to be at equilibrium. Abbaker et al. [2] used a discrete-time adaptive terminal sliding-mode control strategy for voltage setpoint tracking for an SOFC. A pseudo-partial derivative technique was used to model the SOFC. Botta et al. [3] considered an rSOFC system and applied a PI controller to prevent dangerous operating conditions at the stack level. They analyzed individual SOFC and SOEC modes, as well as switching between these modes during reversible operation of the stack. Spivey and Edgar [4] developed a dynamic model for a tubular SOFC to capture the dynamics of critical thermal stress drivers and applied it to a MIMO predictive controller. Schotman [5] applied an output feedback adaptive NMPC approach to an rSOC system to control cell temperature and temperature gradients while maintaining desired level of power output. Xing et al. [6] designed a model predictive control (MPC) strategy based on a linear parameter varying model to improve short-term tracking performance and long-term operating efficiency for an rSOC plant. The process model for rSOC was a linear state-space model of the plant.

SOC systems are good candidates for nonlinear MPC (NMPC) since many manipulated variables (MVs) are highly interactive. As mentioned earlier, NMPC [7-8] uses a system model to predict system response to a sequence of MVs and optimizes it with respect to performance metrics. Because the controller can manipulate several degrees of freedom, it affords a quicker response than that of classical control.

In this work, NMPC is applied to an SOC module and supporting equipment, with its performance compared to that of classical PI control strategies for switching between the modes of hydrogen and power production.

Switching from maximum hydrogen production to power generation and back to hydrogen production is demonstrated for the SOC system. Performance is judged based on the speed of production rate transition, total power usage, and whether unsafe thermal levels occur in the SOC.

## PROCESS MODELING

The SOC system flowsheet is built in the IDAES modeling framework [9]. The SOC model is publicly available in the IDAES GitHub repository [10], and a preliminary version is available in the literature [11]. There is ambiguity in denoting the cell "anode" and "cathode" in a reversible SOC, because the anode in fuel cell mode is the cathode in electrolysis mode and vice-versa. Hence, we refer to the electrode where hydrogen is produced or consumed as the fuel electrode and the electrode where oxygen is produced or consumed as the oxygen electrode. Model parameters were fit to data from the two-cell fuel electrode supported short stack shown in Figure 1 for the SOC system described in Figure 2.

The SOC model shown in Figure 1 is one dimensional in channels and (potentially) two dimensional in the fuel electrode, electrolyte, oxygen electrode, and interconnect. However, because the thickness of the positive electrode-electrolyte-negative electrode (PEN) assembly is only approximately one millimeter (with almost all of that in the fuel electrode), only one finite element is used in the x direction for the fuel electrode, while the electrolyte and oxygen electrode are approximated as thin-film resistors. The interconnect, which is 5 mm thick, also uses one finite element. The length of the cell in the z direction is 23.5 cm and ten finite elements are used in that direction for all subcomponents. The cell is run in a countercurrent configuration. The interconnect is represented by a periodic boundary condition, with one end attached to the top of the fuel channel and one to the bottom of the oxygen channel, to represent a cell in the center of a large stack. The cell model does not consider losses to the environment.

**Figure 1.** SOC configuration. Note that this diagram is not

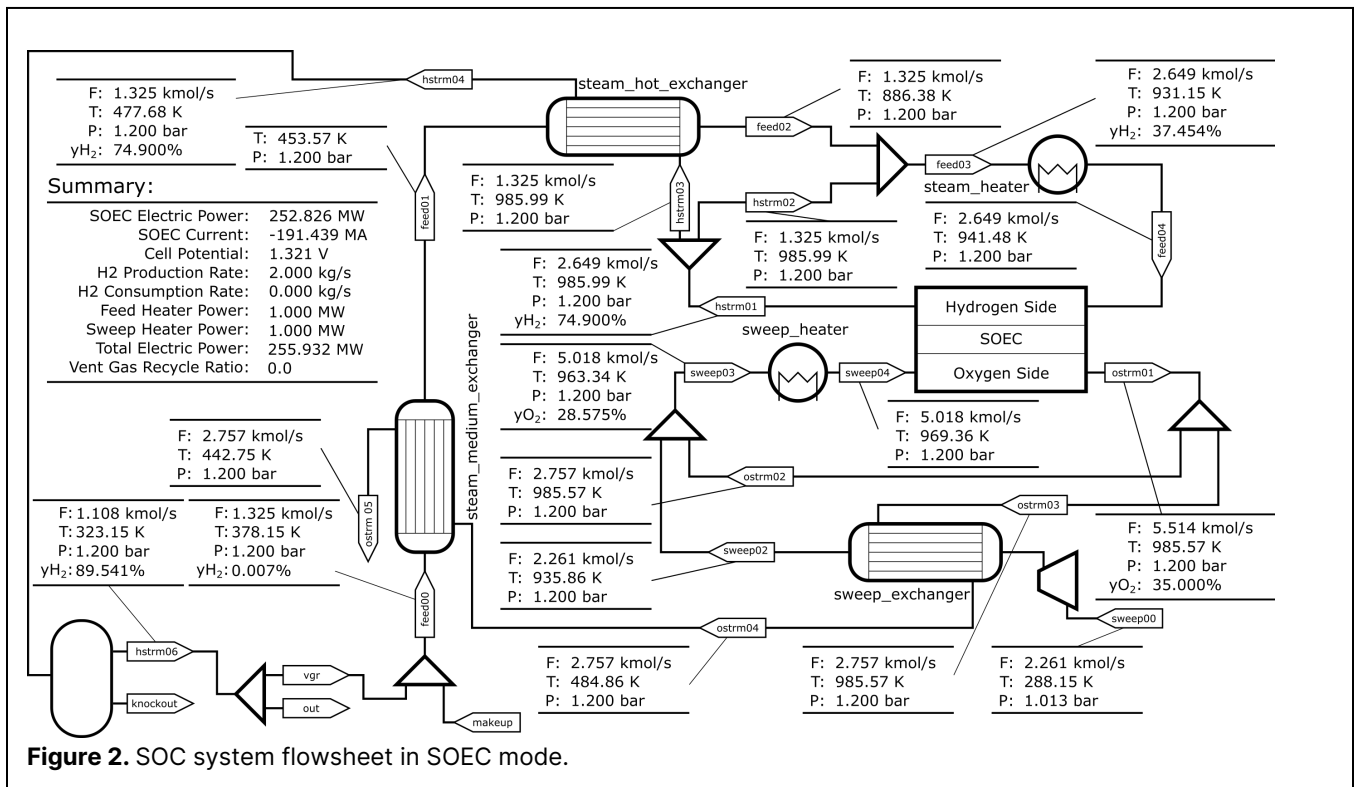

Figure 2. SOC system flowsheet in SOEC mode.

to scale—the cell is millimeters thick, and the electrolyte and oxygen electrode are hundreds of micrometers thick.

The SOC system flowsheet in Figure 2 consists of supporting equipment for the SOC module. Three cross-flow heat exchangers heat incoming air and water/hydrogen up to the cell’s operating temperature of approximately 975 K (in electrolysis mode). Two resistive trim heaters provide additional heat as well as control the temperature of the inlet streams to the stack. The oxygen stream is vented to the atmosphere, while the fuel stream goes to a condenser. Water is knocked out in a flash vessel. The hydrogen-rich gas exiting the flash is either mixed with the fresh fuel inlet to return to the SOC (in fuel-cell mode) or is taken out of the system for compression and further purification (in electrolysis mode). The heat exchangers and trim heaters use 1D models, whereas the other supporting equipment units use 0D models. Because of the short gas phase residence time in the system (about four seconds for the fuel side in electrolysis mode), gas phase holdups are turned off in all units, leaving thermal holdups as the primary source of dynamic behavior. For every discretized time step within the dynamic model, the SOC system flowsheet consists of 900 differential equations, 6955 algebraic equations, and 4311 inequalities.

In electrolysis mode, the hydrogen production rate is fixed at 2 kg/s, with the system aiming to minimize total power usage. The split fraction to the vent gas recycle stream is set to 0.0001 to avoid zero flows, and the cell

is sized to produce 2 kg/s with an average current density of  $-10,000 \text{ A/m}^2$ , allowing for a maximum current overshoot of 30%. Water conversion is constrained between 60% and 75% to optimize steam usage. In fuel cell mode, the cell operates at an average current density of  $4,000 \text{ A/m}^2$ , with an upper bound of  $5,200 \text{ A/m}^2$ . Hydrogen conversion has no specific bound due to recycling unconsumed hydrogen. Trim heaters provide 10 kW each to prevent issues with controller setpoints.

### CLASSICAL PROCESS CONTROL

The SOC control system must enforce a variety of process constraints. The fuel-side inlet stream must have at least 5% (mole-basis) of hydrogen to avoid oxidation of the electrode or interconnect. The fuel-side outlet must also have at least 25% hydrogen in fuel cell mode or water in electrolysis mode to avoid cell degradation from reactant starvation. The oxygen outlet stream can have at most 35% oxygen to avoid oxidation of process equipment. The cell voltage is limited between 0.7 and 1.4 V to avoid oxidation or reduction of the cell. The maximum temperature in the cell must be kept below 1023.15 K (750 °C) to avoid degradation, and the temperature difference between the ends of the cell must be kept below 75 K to avoid thermal stress on the cell. To accomplish these goals, the following manipulated variables are used: cell potential, makeup steam/hydrogen feed rate, steam/hydrogen ratio in makeup stream, sweep feed rate, fuel trim heater duty, sweep gas trim heater duty,

fuel stream recycle ratio, sweep stream recycle ratio, and vent gas recycle ratio. Classical control uses many P and PI control loops, detailed in Table 1. Derivative action was not used, because its benefits are severely degraded by measurement noise, which cannot be added to the PETSc TS integrator used in this study for dynamic simulations with classical PI control. The PI controller model in IDAES supports both variable bounds and anti-windup, both of which were used in these simulations.

**Table 1.** Variable pairings for classical control.

Controller Type	Manipulated Variable (MV)	Controlled Variable (CV)
PI	Cell potential	SOC fuel outlet H <sub>2</sub> mole fraction
P	Makeup feed rate	Hydrogen production rate
P	Sweep feed rate	SOC stack core temperature
PI (C11)	Steam heater duty	Steam heater outlet temperature
PI (C21)	Sweep heater duty	Sweep heater outlet temperature
P (C10)	Steam heater outlet temperature setpoint	SOC feed outlet temperature
P (C20)	Sweep heater outlet temperature setpoint	SOC sweep outlet temperature
None	Feed & sweep recycle ratios, makeup H <sub>2</sub> & H <sub>2</sub> O mole fractions, vent gas recycle ratio (used by NMPC, not PI)	

The cell potential has an immediate effect on the hydrogen composition of the fuel outlet stream; therefore, these two variables are paired. The makeup feed rate is then paired with the net hydrogen production/consumption rate (which can be calculated from the total current flowing through the cell, which is easily measurable). The trim heaters have an immediate impact on the stack inlet temperatures of their respective streams and are thus paired. However, it is desirable that the trim heaters also help adjust the SOC module's temperatures as needed. Therefore, a cascade arrangement is used, with another controller adjusting the inlet stream's setpoint based on the outlet stream's temperature. Typically, in cascade control, the inner controller is P and the outer controller is PI; however, an arrangement with the inner controller

PI and the outer controller P was chosen to avoid controller conflicts. Finally, because the trim heaters are not engaged in SOFC mode, the sweep blower flow rate is paired with stack core temperature (measured via a thermocouple embedded in the stack) to cool the cell as needed.

## NONLINEAR MODEL PREDICTIVE CONTROL

To compare the performance of classical control and advanced control strategies, an NMPC framework was developed for setpoint tracking using eight non-artificial MVs in Table 1: cell potential, makeup and sweep feed rates, feed and sweep recycle ratios, makeup H<sub>2</sub> and H<sub>2</sub>O mole fractions, and vent gas recirculation (VGR) ratio. Trim heater duties are not directly tracked to enable more freedom of adjustment.

Because makeup mole fractions are tracked instead of being fixed along a linear trajectory as in the classical control case, an equality constraint pinning their sum at 0.999 is introduced to the NMPC formulation. The remainder consisted of inert gases, with fixed mole fractions of 0.0008 N<sub>2</sub> and 0.0002 Ar. Feed heater duty is bounded between 0 MW and 2 MW and sweep heater duty between 0 MW and 4 MW for reasonable capital equipment sizing. Condenser vapor outlet temperature is fixed at 323.15 K under the ideal condenser assumption and thus is not an MV.

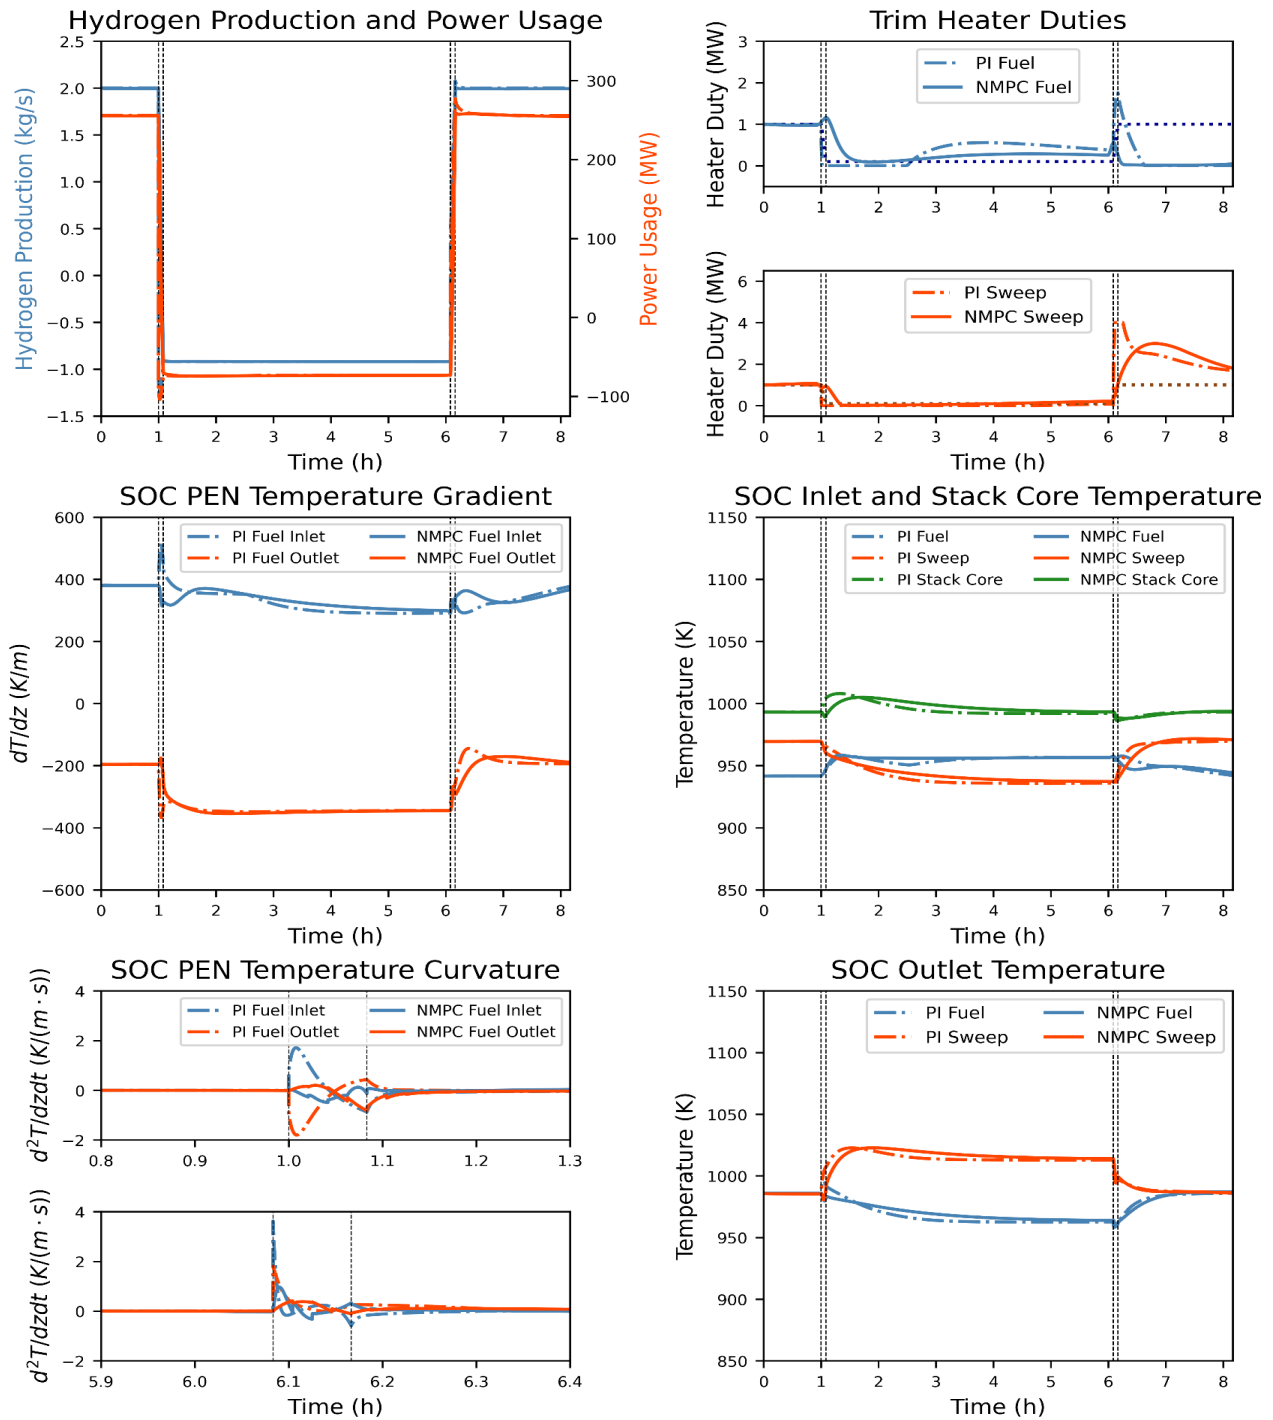

$$\begin{aligned}
 f_{obj} = & \sum_{i=0}^N \rho_{H_2} (y_i - y_i^R)^2 + \sum_{i=0}^N \sum_{j \in J} \rho_j (u_{ij} - u_{ij}^R)^2 \\
 & + \sum_{i=0}^N \sum_{k \in K} \rho'_k (x_{ik} - x_{ik}^R)^2 + \sum_{i=1}^N \rho' (v_i - v_{i-1})^2 \\
 & + \sum_{i=0}^N \sum_{z=1}^{z_L} \rho_M \left( \frac{\partial T_{iz}}{\partial z \partial t} \right)^2 \quad (1)
 \end{aligned}$$

As shown above, the objective function (eqn. 1) contains weighted sum of squared errors (SSE) of the trajectory-tracking of H<sub>2</sub> production rate as well as deviations of MVs and CVs from their reference values. A rate-of-change penalty on trim heater duties is added to attenuate oscillatory trajectories. In addition, to limit cell thermal degradation over time, the magnitude of PEN temperature curvature along the cell length (z-direction), is penalized. The first term in the objective function is the SSE of H<sub>2</sub> production rate,  $y_i$ , from its tracking target,  $y_i^R$ , at time  $t_i$ . The penalty on the H<sub>2</sub> rate tracking term,  $\rho_{H_2}$ , is selected to be 1. The second term involves penalties on SSEs of the tracked MVs,  $u_{ij}$ , from their references,  $u_{ij}^R$ ;  $J$  represents the set of tracked MVs. Similarly, the third term penalizes deviation of the CVs (represented by set  $K$ ) from their reference trajectories. The fourth term

is the rate of change penalty on trim heater duties, represented by  $v$ . Setpoint tracking and rate of change penalty terms are scaled to be  $O(1)$ , and 0.01 is selected for their penalties,  $\rho_i$ ,  $\rho_{k_i}$  and  $\rho'$ , to prioritize H<sub>2</sub> production rate tracking. The final term has a penalty of  $\rho_M$  on the sum of squares of PEN temperature curvatures in the z-direction.  $N$  is the number of steps in the prediction

horizon.

For this work, it is assumed that system dynamics is unambiguously captured in the controller model; in real-world application, potential plant-model mismatch can be addressed using moving horizon estimation (MHE) with an integrating disturbance model. The controller predicts

**Figure 3.** Comparison of classical control with NMPC in mode-switching operation.

system response for a given MV trajectory over the controller horizon with the system model and optimizes the MV trajectory for minimum objective function value. The first element of the solved trajectory is injected into the system, and the MV trajectory is re-optimized at the next sampling time over a shifted horizon. The actual decision variables in the NMPC problem are time derivatives of the MVs so that piecewise linear control profiles (first-order hold), instead of step inputs (zero-order hold), can be injected into the system. Placing a first-order hold on MVs, as opposed to a zero-order hold, smooths out the transition of control actions from the previous time step to the next and thus reduces spikiness in system response.

## SIMULATION RESULTS

For performance comparison of classical control and NMPC, the SOC system was linearly ramped from maximum hydrogen production (SOEC mode) to power production (SOFC mode) and back to maximum hydrogen production in simulation. A parametric sweep on  $\rho_M$  was conducted to investigate the trade-off between operating efficiency and cell degradation, which is dependent on PEN temperature curvatures. The ramps were carried out over 5 min, with the hydrogen-power ramp followed by 5 h settling at the new operating point and the power-hydrogen ramp followed by 2 h settling. Dynamic simulations using classical process control were conducted via the IDAES interface to the PETSc [12] suite of differential algebraic equation (DAE) solvers. Because this DAE system is stiff, a variable time step implicit Euler method was used. The time step was initialized at 0.1 s, after which it typically grew to 5 s to 10 s during the initial transient after ramping started or stopped, and then to 5 min to 10 min by the end of the integration interval. When anti-reset windup was turned on or off in the PI controllers, the time step decreased to 0.5 s to 1.0 s due to the steep transition, between error integrating and not. The fully discretized control problem for NMPC had approximately 47000 equations and variables. The studies were performed on an AMD Ryzen™ 9 processor @ 3.7 GHz with 16 GB memory. On average, the solution time was 2.4 CPU s for a prediction horizon of 375 s; the problem was solved well within the sampling time of 75 s.

Figure 3 compares the performance of the two control strategies, with  $\rho_M$  set to  $10^{-2}$  in the NMPC objective formulation;  $10^{-2}$  offers a good balance between settling speed of hydrogen production rate, the primary output variable, and addressing thermal degradation considerations. Both classical control and NMPC reach the SOFC mode production rate of  $-0.92$  kg/s from the SOEC mode production rate of  $2.00$  kg/s by the end of the five-minute ramp, with a considerable amount of overshoot observed in classical control. In the SOFC-SOEC ramp, both classical control and NMPC afford similar hydrogen production

rate tracking performance, with a small amount of overshoot in the former.

Curbing temperature gradient is critical to long-term operating performance of the cell. While PEN temperature gradients are not explicitly accounted for in either classical control or NMPC, both cases are well within the safety limit of  $1000$  K/m, and NMPC has advantages due to smoother trajectories and lower peak magnitudes at fuel inlet and outlet.

Moreover, the time derivative of SOC PEN temperature gradient describes the trend in the gradient's temporal variation. Here, NMPC affords lower peaks in the temperature curvatures at fuel inlet and outlet, as the final term in the NMPC objective (eqn. 1) imposes squeezing action on curvatures across all z-nodes. Cell temperatures in both control strategies generally take over 2 h to settle after the ramps finish. A slightly greater overshoot is observed in sweep channel inlet temperature for NMPC after the SOFC-SOEC ramp, and the same holds for classical control stack core temperature after the SOEC-SOFC ramp. While classical control temperatures mostly settle faster than the NMPC ones, this difference is less pronounced after the SOFC-SOEC ramp. Sweep heater duty in classical control saturates at the upper bound during the SOEC-SOFC switch, whereas NMPC produces smoother profiles well within design limits. Visible deviation of trim heater duties from setpoints reveals that the system has not reached steady state even by the time of the switch back from SOFC mode to SOEC mode. Despite the different heater duty profiles by classical control and NMPC, total power usage in both strategies is similar.

## CONCLUSIONS

In this work, a dynamic system flowsheet of an rSOC module and supporting auxiliary equipment was developed in the open-source, equation-based IDAES modeling framework. Control of this system for switching between maximum hydrogen production (SOEC mode) and power production (SOFC mode) was conducted with both classical control and NMPC. Dynamic simulation results show that although both control methods attain similar performance in many areas, a sophisticated classical control system involving non-intuitive cascade control arrangement was required to match the performance of NMPC in mode switching. Moreover, NMPC goes a step further by mitigating PEN temperature gradients and PEN temperature spatial-temporal derivatives along cell length more effectively than classical control does.

While classical control and NMPC attain similar total power usage in mode-switching operation, NMPC formulation in this work does not optimize for efficiency. Future work on economic MPC would allow the use of non-tracking objectives like efficiency optimization. Such

a scheme would be well suited to this rSOC system, since the system response time is slow compared to the rate at which electricity prices change. System performance while tracking more frequently alternating setpoint trajectories from fluctuating locational marginal prices (LMPs) is also critical in system economics evaluation. Another challenge is managing the trade-off between capital cost (cell degradation) and operating cost (setpoint tracking performance) over long-term operations. Finally, although the average CPU time in NMPC simulations already occupies only a small fraction of the sampling time, both advanced-step NMPC (asNMPC) and a distributed framework consisting of subsystem NMPCs can help drive down online computation delay; latency-free NMPC is a topic for further study.

## ACKNOWLEDGEMENTS

## ABSTRACT

Increasing wind and solar electricity generation in power systems increases temporal variability in electricity prices which incentivizes the development of flexible processes for electricity generation and electricity-based fuels/chemicals production. Here, we develop a computational framework for the integrated design and optimization of multi-product processes interacting with the grid under time-varying electricity prices. Our analysis focuses on the case study of nuclear-based hydrogen (H<sub>2</sub>) and electricity generation, involving nuclear power plants (NPP) producing high temperature heat and electricity coupled with a high temperature steam electrolyzers (HTSE) for H<sub>2</sub> production. The ability to co-produce H<sub>2</sub> along with nuclear is widely seen as critical to improving the economics of nuclear energy technologies. To that end, our model focuses on evaluating the least-cost design and operations of the NPP-HTSE system while accounting for: a) power consumption variation with current density for the HTSE and the associated capital and operating cost trade-off, b) heat integration between NPP and HTSE and c) temporal variability in electricity prices and their impact on plant operations to meet a baseload hydrogen demand. Instead of formulating a monolithic optimization model, which would be computationally expensive, we propose a decomposition approach that reformulates the original problem into three sub-problems solved in an iterative manner to find near-optimal solutions. Through a numerical case study, we demonstrate the potential synergies of NPP and HTSE integration under alternative electricity price scenarios. This synergy is measured via the metric of relative breakeven H<sub>2</sub> selling price that accounts for the opportunity cost of reduced electricity sales from H<sub>2</sub> co-production.

## INTRODUCTION

Despite its significant share of generation today and importance for climate change mitigation, nuclear power faces economic hurdles in many U.S. and other regions primarily due to depressed wholesale electricity prices stemming from increasing electricity generation from natural gas and variable renewable energy (VRE). For instance, between 2013 and 2021, 9.4 GW of existing nuclear power plants (NPP) have retired in the U.S. with an additional 7.2 GW scheduled to retire by 2025, mostly in regions with restructured electricity markets [1]. This economic outlook for existing U.S. NPPs also makes investments in new NPPs, based on next-gen small

modular reactor (SMR) concepts, challenging. However, despite their higher capital costs per kW relative to VRE generation sources, these NPP designs represent a type of low-carbon, dispatchable generation resource which has been shown to be critical to minimizing the cost of achieving deeply decarbonized power systems [2]. NPPs are not fully compensated for this benefit in current markets, so there is a need for alternative business models and revenue streams to support deployment of new NPPs to support economy-wide decarbonization goals.

In this context, the ability to deploy NPPs for simultaneously co-producing low-carbon hydrogen (H<sub>2</sub>) via water electrolysis that can be used for industrial applications is appealing for several reasons. First, industrial H<sub>2</sub>

demand, amounting to ~10 million tonnes per year in the U.S. in 2015 [3], tends to be centralized and constant in its consumption, both of which match well with least-cost NPP designs that tend to favor continuous operation and large-scale deployment. Second, H<sub>2</sub> demand is anticipated to grow, by up to 7X per one estimate [3], as part of efforts to decarbonize difficult to electrify end-uses. Third, high temperature heat available from next-generation nuclear reactors can be used to improve the electrical efficiency of H<sub>2</sub> production (and by extension, other industrial processes) by carrying it out at higher-than-ambient temperatures, such as high temperature steam electrolysis (HTSE) [4].

The design of integrated NPP-HTSE systems to co-produce H<sub>2</sub> and electricity needs to consider: a) the temporal dynamics in the economic value of electricity and its impact on co-product hydrogen price, b) the heterogeneity in design of new NPPs, particularly in terms of the maximum temperature of heat supply, c) the design of heat integration schemes between NPP and HTSE systems and d) the operating performance of the HTSE system, particularly the current density-dependent efficiency and heat management.

Previous NPP-HTSE system analyses have generally focused on light-water or pressurized water NPPs with lower temperatures of heat generation supply [5-7]. These analyses address detailed assessment of plant-level dynamics operations [5] as well as overall economic optimization using less-detailed plant-level models and soft-linking plant and grid-centric models [6-7].

Here, we develop an integrated design and scheduling optimization framework to address co-production of electricity and H<sub>2</sub> under time-varying electricity prices. For a given NPP design, electricity price series and exogenous H<sub>2</sub> demand, the model can evaluate the cost-effective sizing of HTSE, on-site H<sub>2</sub> storage and other auxiliary units (e.g. heat exchangers) as well as operation over a representative year, while adhering to a range of operational constraints. Crucially, we account for energetic and economic impacts of HTSE operation across a range of current densities & NPP-HTSE heat integrations.

Solving the proposed model in its original form takes several hours, even for representative periods as short as 12 hours. To include much longer representative periods, up to a year at hourly resolution, we accelerate solution of the proposed model by applying a decomposition strategy. This involves iteratively solving an upper-level investment problem sizing the HTSE using a line search algorithm, mid-level problem to size the heat exchanger network, and a lower-level operational model with fixed HTSE and heat exchangers which is formulated as a mixed integer linear program (MILP) and solved via Gurobi [19]. In addition, we utilize a Taylor expansion-based approximation of bilinear terms to speed up computation of the middle and lower-level operational model.

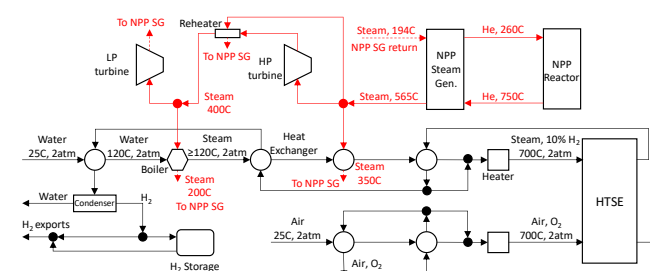

Finally, we propose a new metric of relative break-even price for H<sub>2</sub> production, which as opposed to the leveled cost of hydrogen (LCOH), accounts for the opportunity costs of forgoing electricity outputs in favor of H<sub>2</sub>. While the analytical framework has been developed for NPP-HTSE systems, it can be applied to other processes involving multiple co-products and dynamic interaction with the grid (e.g. electrified chemical production).

As a case study, we evaluate the integration of a high-temperature gas cooled reactor (HTGR) based NPP (750 °C) with an HTSE operating at 750 °C, where we quantify the value of heat integration between HTSE and NPP on the cost of hydrogen produced. We test the economics of the proposed system under current-day and future electricity prices and show how the relative break-even price as opposed to the LCOH is the appropriate metric for such multi-product systems.

## METHODOLOGY

### Process description

Figure 1 shows the schematic for the process where the HTGR is the primary heat source for the power generation and electrolysis processes. The HTGR produces hot gas leaving the reactor at 750 °C that is fed to steam generator producing steam at 565 °C and 16.5 MPa, that is used for power generation via a Rankine cycle [8]. A similar concept was chosen for a pilot project to provide heat and power for a U.S. petrochemical facility [9]. Part of the heat available from the HTGR can be used to improve the energy efficiency of HTSE H<sub>2</sub> production through feed heating. As seen in Figure 1, we allow for reactor to provide high temperature heat for steam superheating and low temperature heat for steam generation.

**Figure 1.** Overview of a high-temperature gas cooled reactor (HTGR) NPP integrated with HTSE operating at 750 °C. The black arrows relate to the HTSE flows and the red lines the nuclear power plant (NPP) flows. For simplicity, we have not shown the return of some steam flows back to the NPP steam generator (SG). All of the temperature and mass flow rates are free variables unless a value is given. The HTSE operating temperature is assumed constant and equal to the feed. Temperature of exhaust streams from HTSE are model variables but

must be within 100 °C of the inlet temperature to avoid thermal gradients [14].

## HTSE modeling

A key goal of our analysis was to understand how NPP and HTSEs might vary their electricity and H<sub>2</sub> outputs in response to electricity prices to maximize their profit. Therefore, it was important that we accurately model the dynamic operation of HTSE and how the efficiency varies as a function of the current density.

We developed a 0-D HTSE model based off the generic electrolyzer model produced by Orella [10] along with overpotential calculations from Buttler et al. [11]. The HTSE potential ( $V$ ) as function of current density ( $j$ ) at each time-step is calculated as sum of thermodynamic potential ( $V_{th}$ , Eq. 2), ohmic overpotential ( $V_{ohm}$ , Eq. 3), concentration overpotential ( $V_{conc}$ , Eq. 4-5), and activation overpotential for each electrode ( $V_{act,k}$ , Eq. 6). Each of these terms are related to SOEC system parameters, such as cell temperature ( $T$ ), exchange current density ( $j_{exchange,k}$ ), and partial pressures of components. Full details of the terms are given in [11].

$$V = V_{th} + V_{ohm} + V_{conc} + V_{act,c} + V_{act,a} \quad (1)$$

$$V_{th} = V_0 + \frac{RT}{2F} \ln \left( \frac{p_{O_2}^{0.5} p_{H_2}}{p_{steam}} \right) \quad (2)$$

$$V_{ohm} = -2.99 \times 10^{-5} j \delta e^{-\frac{10300}{T}} \quad (3)$$

$$c = -\frac{100\sqrt{2}jRT_{cath}}{2FPD_{steam}} \quad (4)$$

$$V_{conc} = \frac{RT}{2F} \ln \left( \frac{1 + \frac{c}{j_{H_2}}}{1 - \frac{c}{j_{steam}}} \right) \quad (5)$$

$$V_{act,k} = \frac{RT}{F} \sinh^{-1} \left( \frac{j}{2j_{exchange,k}} \right) \quad \forall k = a, c \quad (6)$$

Given the HTSE stack area ( $A$ ) and time-dependent current density  $j_t$  (which is linearly proportional to the H<sub>2</sub> production rate for a given HTSE area by Faraday's Law), the power required to operate the HTSE at each time step  $t$  is given by Eq. 7, where the cell voltage ( $V$ ) is calculated as per Eq. 1-6 for the given current density.

$$P(j, A, t) = j_t A V_t(j_t) \quad (7)$$

As shown in Fig. 2A, the power consumption per unit HTSE area varies quadratically with the current density, meaning that the electrolyzer energy efficiency decreases with increasing current density owing to greater overpotentials. This creates an incentive to oversize the electrolyzer relative to demand, increasing the electrolyzer area ( $A$ ) and CAPEX to reduce the current density and hence power consumption required to achieve a given hydrogen production rate. Our modelling results exhibit this CAPEX - OPEX trade-off as we include a piece-wise approximation of the power vs. H<sub>2</sub> production curve for a fixed HTSE area.

The energy balance around the HTSE system is modeled with the constraint that feed stream and HTSE

operating temperature are fixed at 750 °C, and the ratio of hydrogen to steam at the cathode is held constant. At each time step, the heat balance of the HTSE is determined by the difference between its electric power demand and the enthalpy of the water splitting reaction, with high (low) current density operation generally leading to greater (less) overpotentials and heat generation. The HTSE is endothermic when operated below the thermoneutral potential ( $V_{th}$ ). The deficit or excess heat in the HTSE is balanced by either cooling or heating, respectively, the outlet streams. Outlet stream temperatures are model operational variables along with the HTSE stack current density. In this way, the HTSE dynamic operation is coupled with the operation of the heat exchanger network associated with feed preheating and product cooling shown in Fig. 1.

**Figure 2.** A: example piecewise power – current density relationship used in the model, for a 100m<sup>2</sup> HTSE producing up to 0.36 tonne H<sub>2</sub> per hour. We used 5 elements in our piecewise approximation. B: Overview of the three-part solution strategy used to optimize our model. MIQCP= Mixed integer quadratically constrained programme. MILP = Mixed integer linear programme.

## Model description and solution strategy

As shown in Eq. 8, the overall problem can be defined as a single mixed integer nonlinear program (MINLP). The objective function of this model is to minimize the total system cost while meeting a constant hourly hydrogen demand and several other operational and capacity constraints associated with units in Fig. 1.

$$\begin{aligned} \min_{x,y,z} & c_1 x + c_2^T y + c_3^T z \\ \text{s.t.} & f(x, y, z) = 0 \\ & h(x, y, z) \leq 0 \\ & g(x, y) \leq 0 \\ & x, y, z \geq 0 \end{aligned} \quad (8)$$

In Eq. 8,  $x$  is the stack area of the HTSE,  $y$  represents the vector of variables corresponding to the areas of the heat exchangers and boilers in the heat exchanger

network, and  $\mathbf{z}$  is the vector of variables corresponding to the capacity of the electricity and H<sub>2</sub> storage as well as the scheduling decisions for the entire system. Note that  $\mathbf{z}$  includes both continuous and binary variables, where the latter are associated with NPP start-up/shutdown [8].

Since we are interested in accounting for plant operational dynamics subject to hourly changes in electricity price over the year, solving the monolithic model of Eq. 8 becomes computationally challenging for representative periods longer than 12 hours. Therefore, we decomposed the original problem into three sub-problems that are iteratively solved to find the optimal solution. Fig. 2B shows the sequence of operations, where: a) the upper-level problem sizes the HTSE area, b) the middle-level problem sizes the heat exchanger network for a given HTSE area and maximum H<sub>2</sub> output for HTSE and c) lower-level operational problem evaluates cost-optimal plant operation over the entire year and sizes on-site H<sub>2</sub> storage capacity for a given HTSE area and heat exchanger network (via part a and b).

The upper-level investment problem is solved using Brent's method [12] to search for the HTSE area which minimizes the total system cost (capex + opex, Eq. 8). Brent's method is a gradient-free 1D minima-finding algorithm which combines the inverse quadratic interpolation, secant method, and bisection method. At each iteration, the ordering and value of function evaluations of the previous iterates, i.e. the results of solving the intermediate the lower problems, are compared to select the best methods to calculate the next iterate.

The middle-level problem optimizes the design of the heat exchanger network for a given HTSE area and several operating state of the system, corresponding to zero H<sub>2</sub> output, the mean output, and the maximum H<sub>2</sub> output. The only non-quadratic nonlinear constraints in the model pertain to the logarithmic mean temperature difference ( $\Delta T_{LMTD}$ ) in the heat exchanger sizing constraint. We approximate this by its first order Taylor expansion around initial guesses of the temperature differences ( $\Delta_{a,0}, \Delta_{b,0}$ ) for the various streams, as shown in Eq. 9. We set upper and lower bounds on each stream temperature based on the known temperatures (e.g. the HTSE operating temperature) and used the mid-point of these ranges as the initial temperature guesses.

$$\Delta_a = (T_{h,in} - T_{c,out}), \Delta_b = (T_{h,out} - T_{c,in}) \quad (9)$$

$$\Delta T_{LMTD} = \frac{\Delta_a - \Delta_b}{\ln(\Delta_a/\Delta_b)} \quad (10)$$

$$\Delta T_{LMTD} \approx \frac{\Delta_{a,0} - \Delta_{b,0}}{\ln(\Delta_{a,0}/\Delta_{b,0})} + \sum_{q \in [(h,in),(c,in)]} \frac{(T_q - T_{q,0})}{\ln(\Delta_{a,0}/\Delta_{b,0})^2} \left( \frac{\Delta_{b,0} - \Delta_{a,0}}{\Delta_{a,0}} \pm \ln \frac{\Delta_{a,0}}{\Delta_{b,0}} \right) + \sum_{q \in [(h,out),(c,out)]} \frac{(T_q - T_{q,0})}{\ln(\Delta_{a,0}/\Delta_{b,0})^2} \left( \frac{\Delta_{a,0} - \Delta_{b,0}}{\Delta_{b,0}} \pm \ln \frac{\Delta_{a,0}}{\Delta_{b,0}} \right) \quad (11)$$

This approximation is correct to within a few percent for the temperature ranges in our problem and is more accurate than using the arithmetic mean of the temperature differences when calculating heat fluxes. We

determined the heat exchanger areas by solving this middle-level problem for one hour of operation assuming the HTSE is operating at its mean hydrogen output for the given HTSE area. This problem is small, consisting of approximately 100 variables and 100 constraints with 27 quadratic constraints, and thus can be solved in under a second using Gurobi 10.0.

The lower-level problem is a mixed-integer quadratically constrained program (MIQCP) which optimizes the capacities of the battery and H<sub>2</sub> storage as well as the operating decisions of all the components for each of the 8760 hours of the year. The role of the H<sub>2</sub> storage is to allow for flexible operation of HTSE while meeting base-load H<sub>2</sub> demand. The battery storage could allow for enhancing flexibility of NPP by storing electricity at times of low electricity prices and discharging to operate HTSE or export to grid during high price periods.

To speed up solution of lower-level problem, we make two further approximations to convert it to a mixed-integer linear program (MILP): a) we approximate the HTSE power demand as a 1D piece-wise linear function of the current density using SOS2 constraints (Fig. 2A). b) the remaining quadratic constraints are related to the energy and mass balances in the heat exchanger network and splitters/mixers, respectively. For the bilinear terms, we employed a Taylor expansion-based linearization approach per Eq. 12, similar to the approach undertaken to approximate the LMTD in the middle-level problem.

$$xy \approx x_0 y_0 + (x - x_0) y_0 + (y - y_0) x_0 \quad (12)$$

We use the temperatures and mass flow rates from the intermediate problem solution to set  $x_0$  and  $y_0$ . The resulting MILP for a full year at hourly resolution has approximately 400,000 constraints and 400,000 variables and 1.5M non-zero terms after presolve. The solution time typically requires less than 30 seconds to solve the root relaxation followed by about three hours for branch and bound using 16 cores and Gurobi 10.0. The overall solution procedure of Fig. 2B typically requires 8-10 iterations to converge to the cost-optimal investment and operation so the total run time for the overall optimization is approximately 24 hours.

Our decomposition method can be improved in several ways. The upper problem could be solved using a gradient-based solver, making use of the duals of the lower problem. We could also solve more states of the system in the intermediate problem to both find Taylor expansion values for each time step, improving the accuracy of the linearization of the lower problem, and creating a warm start for the lower problem. This would reduce the time required for the branch and bound step.

## Case study

We model the co-production of electricity and H<sub>2</sub> via the process in Figure 1 with a NPP with thermal capacity

200 MW<sub>t</sub> (80 MW<sub>e</sub>), located in Waterford, LA, USA. This location has an existing NPP and is close to many existing H<sub>2</sub> consumers (e.g. petrochemical plants). We assume the plant being optimized must supply a constant H<sub>2</sub> demand of 20 tonne/day, simulating H<sub>2</sub> demand from an industrial user. This means our optimization does not depend on the price of hydrogen. We do not consider cases where a facility can maximize revenue by freely choosing between selling electricity and hydrogen as this would require hourly timeseries of hydrogen prices.

### Electricity price scenarios

We evaluate the model outcomes for current grid conditions, represented by 2018 wholesale electricity prices at the Waterford site, as well as future grid scenarios for 2030 and 2050 by NREL for the same region [13]. Figure 3 shows the hourly electricity price distribution of the three price timeseries. The median 2030 price is greater than in 2018 but the distribution has shorter high and low tails. The mean and median 2050 prices are lower than both 2018 and 2030 and there are around 250 hours where electricity is priced at \$0/MWh.

**Figure 3.** Hourly electricity price distribution for the 3 scenarios evaluated in the study. 2018 prices are realized prices at the Waterford, LA node, while 2030 and 2050 scenarios are sourced from NREL ReEDS capacity expansion model outcomes [13]. Median prices for 2018, 2030 and 2050 are 29, 30, and 25 \$/MWh [13,24].

### Technology cost and performance assumptions

The major cost and performance assumptions used in the study are summarized in Table 1. We trial cases with and without a \$10/MWh transmission charges applied to imports. This charge reflects the difference in wholesale and industrial electricity prices [18].

### Relative breakeven price

We evaluated the cost benefits of co-producing electricity and H<sub>2</sub> by comparing the minimum selling price of H<sub>2</sub> produced by a NPP-HTSE co-production facility with the minimum selling price for a standalone HTSE

using grid electricity. The minimum H<sub>2</sub> selling price for a standalone HTSE is the price at which the project net present value is zero, i.e. annualized costs are equal to annualized revenues. This is the LCOH of the facility. However, computing the minimum H<sub>2</sub> selling price for a facility selling electricity and H<sub>2</sub> is more complicated since producing H<sub>2</sub> entails not selling the electricity used to produce the H<sub>2</sub>. This creates an opportunity cost which must also be recovered in the minimum selling price of the H<sub>2</sub>. We call this the relative breakeven price for H<sub>2</sub> associated with a co-production facility.

**Table 1.** Key cost and performance assumptions

Property	Value	Property	Value
<b>System</b>		<b>HTSE [10, 11,15, 16]</b>	
Hourly demand (tonne/hour)	0.83	Fixed costs (\$/m <sup>2</sup> /yr)	3,770
Discount rate	10%	Temperature (C)	750
<b>NPP [8, 17, 20, 21]</b>		Pressure (atm)	2
Reactor capacity (MWt)	200	Max. current density (A/cm <sup>2</sup> )	1
Turbine capacity (MWe)	80	H <sub>2</sub> mole fraction	0.1
CAPEX (\$/MWe/yr)	300,000	O <sub>2</sub> mole fraction	0.21
Fixed costs (\$/MWe/yr)	71,000	Cathode thickness (μm)	12.5
Variable Cost (\$/MWe)	15	Anode thickness (μm)	17.5
Minimum load	50%	Cell gap (μm)	12.5
Shutdown period (hours)	24	Diffusion coefficient (cm <sup>-2</sup> s <sup>-1</sup> )	5x10 <sup>-9</sup>
<b>H<sub>2</sub> storage [22]</b>		<b>Battery [23]</b>	
Fixed costs (\$/MWe/yr)	44,987	Fixed costs (\$/MWe/yr)	258,277
Compression energy (kWhe/kg)	0.4	Duration (hours)	4

The relative breakeven price is calculated by finding the H<sub>2</sub> price which ensures a co-production facility earns at least as much profit as the NPP would make if operating independently and only sold electricity. This is done by solving the model in Eq. 8 twice: once as described for the full co-production facility and a second time where x = 0 (i.e. without a HTSE) and the exogenous hydrogen demand is set to zero. In the latter case, the NPP will operate independently selling electricity.

## RESULTS

### Base system design and operation results

Figure 4A shows the optimal dispatch of the base case system over two weeks using 2018 electricity prices. Given the high cost of HTSEs (Table 1), it is not

**Figure 4:** Optimal dispatch of NPP and HTSE over two weeks of operation for the 2018 and 2050 electricity price scenario and assumptions summarized in Table 1. Left panel shows reactor thermal balance (left axis) overlaid with electricity price profile (right axis, black line) for 2018 while right panel shows results for 2050. In all cases, system meets 20 tonne/day of baseload H<sub>2</sub> demand while adjusting grid electricity exports depending on electricity prices.

surprising to see that HTSE utilization is quite high despite fluctuating electricity prices. The HTSE output is only reduced during periods of very high electricity prices, when it is more profitable to reduce H<sub>2</sub> production and maximize power exports to the grid. This is enabled by 3 hours of H<sub>2</sub> storage and the HTSE being 8% oversized relative to the minimum HTSE area required to meet the H<sub>2</sub> demand constraint.

It might be expected that the facility would export less power during periods of high prices and use the cheaper electricity generated by the on-site NPP to reduce its average cost of electricity. However, deferring H<sub>2</sub> production till grid prices fall is less expensive overall – as long as storage is cheap enough – because less valuable electricity is used to produce H<sub>2</sub>, reducing the opportunity cost of hydrogen production.

The relative breakeven price of the co-produced H<sub>2</sub> accounts for the opportunity cost of lost electricity sales and should be compared to the LCOH of the independent HTSE. These figures are shown in Table 2. In this instance, an independent NPP will be loss-making so the opportunity cost of lost electricity sales is negative. This makes the relative breakeven price of NPP-HTSE H<sub>2</sub> less than its LCOH. An existing co-production facility should be willing to offer H<sub>2</sub> at the relative breakeven price, even though it will lose money on each kilo of H<sub>2</sub>, because it will lose less money than if it sold the same electricity.

Clearly, more revenue must be found to make the NPP-HTSE facility profitable overall especially for new facilities. One option is to sell H<sub>2</sub> priced at the LCOH of the NPP-HTSE facility. However, the losses being covered are from the electricity-side of the co-production facility. The relative breakeven price is the price required for the H<sub>2</sub>-side of the co-production facility to be profitable. In a

scenario with profitable independent NPPs, the relative breakeven price of NPP-HTSE H<sub>2</sub> is higher than its LCOH as the H<sub>2</sub> revenue must also recover the lost NPP profit.

The technical synergies from using NPP heat in the HTSE system reduces the cost of H<sub>2</sub> by approximately \$1/kg. We know this because the relative breakeven price of an NPP-HTSE which only exchanges electricity and where no import tariffs were in place should equal the LCOH of an independent HTSE in the same scenario. When there is no asymmetry in the price of buying and selling electricity, the cost of electricity from an onsite NPP is the same as that of purchasing grid power if the opportunity costs of lost NPP sales are also accounted for in the H<sub>2</sub> price. The results in Table 2 show that this is not the case. The relative breakeven price of the NPP-HTSE is \$1/kg cheaper than the no-tariff LCOH of the independent electrolyzer, indicating savings from using nuclear heat. This heating is used 5:1 to boil water versus superheat it. This could also be done using low-temperature NPPs, which operate at ~300 C.

H<sub>2</sub> produced by NPP-HTSEs is competitive with that from an independent HTSE, particularly if the grid has import tariffs. However, H<sub>2</sub> produced by both facilities is expensive, especially compared to the \$1/kg target. This is due to the relatively high capex of HTSE vs. state-of-art proton exchange membrane (PEM) electrolyzers. In addition, while HTSEs require less electricity input per kg of H<sub>2</sub> vs. PEM, they have lower current density limits than PEM electrolyzers, typically 1A/cm<sup>2</sup> vs. 2-3A/cm<sup>2</sup>. This means a large HTSE is required for the same H<sub>2</sub> output, compounding the cost difference.

### Impact of varying electricity price scenarios

Fig. 4B shows the optimal dispatch of the co-

production facility over two weeks under 2050 scenarios, for which the average electricity price is \$24/MWhe versus \$34/MWhe in 2018. The overall pattern of operation is similar to that in Fig. 4A. The HTSE is only 4% oversized, so there is little scope to vary its output much from the average H<sub>2</sub> demand. The NPP reduces its output during periods when the wholesale price falls to \$0.01/MWhe. This period only lasts seven hours so the NPP does not shutdown, as then it would have to wait a further 17 hours due to the 24-hour minimum shutdown constraint. The HTSE operates throughout.

The LCOH of the co-production facility is higher in 2050 than in 2018. This is because the price of electricity is lower and the NPP earns less revenue. However, the 2050 relative breakeven price of the NPP-HTSE is lower as this only considers the costs of producing H<sub>2</sub>, which is lower as electricity is cheaper. The reduction in prices also reduces the LCOH of the independent HTSE.

**Table 2.** The levelized cost of hydrogen (LCOH) and relative breakeven price of hydrogen for the independent HTSE and co-production facility in each of the three scenarios. The relative breakeven price of the independent electrolyzer is equal to its LCOH as it never incurs an opportunity cost when it produces H<sub>2</sub>.

	Electricity price timeseries year [13,24]		
	2018	2030	2050
Mean electricity price (\$/MWhe)	34.30	32.00	23.85
Median electricity price (\$/MWhe)	28.95	29.65	24.50
Co-production LCOH (\$/kg)	4.73	4.72	5.14
Co-production Relative breakeven price: (\$/kg)	2.54	2.29	1.95
Independent HTSE, no tariff LCOH (\$/kg)	3.62	3.43	2.90
Independent HTSE, \$10/MWh tariff LCOH (\$/kg)	4.52	3.79	3.38

H<sub>2</sub> produced by the NPP-HTSE facility in 2030 is \$0.3/kg cheaper than in 2018. While the mean price of electricity in the 2018 and 2030 scenarios is almost the same, the median price is higher, and the distribution of prices is shifted to the left and its right-hand tail is gone. This means there are more periods of low prices. By varying its output, both HTSE facilities can reduce their average price of electricity. In these runs, the effective price of electricity was as low as \$10/MWh. This trend continues in 2050, where the price distribution has a bimodal peak at \$0/MWh (see Fig. 3). However, the relatively high cost of H<sub>2</sub> storage limits the extent to which these periods of low prices can be taken advantage of.

## Sensitivity to the HTSE cost and current density limit

The optimized HTSE and NPP-HTSE facilities produce expensive H<sub>2</sub>. This is largely a function of the high cost of HTSEs and their low current density limit. We perform a sensitivity study of these values to see how they would affect the cost of H<sub>2</sub> and see which would be most impactful to improve.

Table 3 shows the results of the sensitivity study for the NPP-HTSE facility. As expected, increasing the current density or reducing the cost of the HTSE cause the biggest reduction in the H<sub>2</sub> LCOH and relative breakeven price. In both cases, it is economic to oversize the NPP-HTSE system significantly and mostly produce H<sub>2</sub> during periods of low prices. Fig. 5 shows an example of this for the 6A/cm<sup>2</sup> NPP-HTSE. The NPP exports and NPP-HTSE energy balance vary very closely with the price of electricity. As before, the NPP reduces its power output during zero-priced periods.

The other two changes had smaller impacts on the cost of H<sub>2</sub>. Reducing the cost of the NPP reduces the LCOH of H<sub>2</sub> as the NPP fixed costs are less, but has no impact on the relative breakeven price as the cost of electricity is unaffected.

**Table 3.** The LCOH and relative breakeven price of the four sensitivity study cases. Each was evaluated using the 2050 electricity price data.

	2050 Base-case	Low-cost HTSE [16]	900C HTSE	\$35 / MWh NPP [20]	6A/cm <sup>2</sup> HTSE
HTSE oversizing	4%	9%	1%	12%	70%
LCOH (\$/kg)	5.07	3.74	4.67	2.70	3.71
Rel. break. price: (\$/kg)	1.87	0.54	1.47	1.87	0.51

**Figure 5.** Dispatch and energy balance of the NPP over two weeks as part of the NPP-HTSE system for the 2050 system and a 6A/cm<sup>2</sup> HTSE.

## CONCLUSION

In this paper we have developed an integrated design and scheduling optimization model to study grid-interactive processes producing multiple products. To solve the model, a nonconvex MINLP, we proposed a three-level decomposition approach and range of tailored approximations to identify near-optimal solutions. We then demonstrated the approach in a short case study of electricity and hydrogen co-production using a high-temperature nuclear power plant and HTSE. While there are opportunities to improve the numerical stability and runtime of the method, we have shown that it can be used to capture HTSE part load operations and high temporal resolution efficiently.

In our case study, we demonstrated the cost advantage of co-producing electricity and hydrogen using an NPP and HTSE. We have shown that co-production facilities must consider the opportunity cost of not selling electricity when they price their hydrogen. We call this combination of the levelized cost of producing H<sub>2</sub> and the opportunity cost of not selling electricity the relative breakeven price. Through our sensitivity analysis, we highlighted how electricity prices, HTSE capital costs and current density limits, impact the minimum price of H<sub>2</sub>

## ABSTRACT

With growing concern over the effects of green-house gas emissions, there has been an increase in emission-reducing policies by governments around the world, with over 70 countries having set net-zero emission goals by 2050-2060. These are ambitious goals that will require large investments into the expansion of renewable and low-carbon technologies. The decisions about which technologies should be invested in can be difficult to make since they are based on information about the future, which is uncertain. When considering emerging technologies, a source of uncertainty to consider is how the costs will develop over time. Learning curves are used to model the decrease in cost as the total installed capacity of a technology increases. However, the extent to which the cost decreases is uncertain. To address the uncertainty present in multiple aspects of the energy sector, multistage stochastic programming is employed considering both exogenous and endogenous uncertainties. It is observed in scenarios when costs of emerging technologies decrease to competitive prices, decisions to invest in these technologies should be made earlier to allow for the decrease in costs to be taken advantage of in the future. Noticeably, a wider variety of energy and biofuel technologies are invested in when uncertainty is included. Interestingly, it is also seen that there are lower carbon emissions when uncertainty is considered.

---

**Keywords:** Stochastic Optimization, Design Under Uncertainty, Energy Systems

## INTRODUCTION

Due to concerns of global warming, many countries are setting goals to reach net-zero emissions sometime between the years 2050-2060 [1]. These goals will require large investments into low-carbon and renewable technologies, which will allow for emerging and underdeveloped technologies to advance. These technologies will need to be integrated into our current energy system efficiently. Energy system modeling can be used to inform decision makers about possible investment pathways that can help to reach net-zero emissions.

Energy system models are used to analyze how we can expand and operate a given set of technologies to meet specified goals. The model results can be used to inform policy makers of possible energy futures and show guiding decisions on the best investment choices to make today [2]. The results are not meant to be taken as the only way to reach the specified goals, but show

guiding decisions, such as what technologies are often invested in, what technologies are rarely invested in, or what technologies should be built in which regions. Energy system models tend to be over many years and include many sources of uncertainty since it is not known how parameter values are going to change over time.

When considering emerging or underdeveloped technologies, a source of uncertainty to consider is how the costs will develop over time. Learning curves are used to model the decrease in cost as the total installed capacity of a technology increases. The steepness of this curve, or how quickly the cost decrease, is based on a learning rate [3]. These learning rates can be estimated for any given technology, but ultimately are uncertain.

In order to address the uncertainty present in an energy system model, a sensitivity analysis is often completed to test how the outcomes will change as the input parameters are varied [2]. While this method does offer insight into how decisions might change as parameters

change, it does not offer a unique decision that can be made today to address the different parameter levels. The goal of this paper is to develop a multistage stochastic programming (MSSP) model in order to account for uncertainty and is applied to a problem for the United States using real data, allowing for the distinct parameter outcomes to be related today through first-stage decisions.

## METHODS

### Stochastic Programming

Stochastic programming is used to account for uncertainty in model parameters through the use of scenarios. In a two-stage stochastic program, the decision variables are partitioned into two sets: first-stage decisions and second-stage decisions. First-stage decisions are made before any uncertainty is observed and are the same for all scenarios, while second-stage decisions are made after uncertainty is observed and depend on the scenario. In a multistage stochastic program, there are more than two stages of decisions because uncertainty is observed sequentially throughout the time horizon. A multistage stochastic program is shown in equations 1-5 [4]:

$$\min z = c^1 x^1 + E_{s \in S^2} [\min q_s^2 y_s^2] + \dots + E_{s \in S^H} [\min q_s^H y_s^H] \quad (1)$$

$$\text{s.t. } W^1 x^1 = h^1 \quad (2)$$

$$T_s^2 x^1 + W^2 y_s^2 = h_s^2, \forall s \in S \quad (3)$$

...

$$T_s^H x^{H-1} + W^H y_s^H = h_s^H, \forall s \in S \quad (4)$$

$$x^1, y_s^t \geq 0, \quad t = 2, \dots, H; \quad (5)$$

There are H stages that the following vectors and matrices relate to.  $E_{s \in S^H}$  is the expectation of the costs across the scenarios in a given stage,  $c$  is the first-stage cost vector,  $q_s^H$  is the cost vector related to stage H,  $W^H$  is a recourse matrix,  $h_s^H$  is the right-hand side, and  $T_s^H$  is a technology matrix that is used to relate the current and previous stage decisions together. First-stage decisions are shown as  $x^1$  and  $y_s^H$  refer to the decisions at stage H and scenario  $s$ .

Uncertainty is classified into two types: exogenous and endogenous. If the uncertainty is exogenous, it is known when in time the uncertainty will be observed and scenarios will become distinguishable. In the case of endogenous uncertainty, it is not known when uncertainty will be observed and, thus, in a MSSP setting when scenarios will become distinguishable; rather, the timing depends on decisions [5]. For example, a cost reduction for a technology will only be observed if that technology is

chosen to be invested in; otherwise, it will remain unknown. Nonanticipativity constraints are used to group together scenarios that have not yet become distinguishable. For the case of exogenous uncertainty, a variable  $y$  must have the same value across scenario pairs until a certain time period when the uncertainty is observed, seen in equation 6.

$$y_{t,s} = y_{t,s'}, \forall (s, s', t) \in \Omega_t \quad (6)$$

Where  $\Omega_t$  is the set of scenario pairs that are indistinguishable at time period  $t$ .

For endogenous uncertainty, when the uncertainty will be observed depends on which decisions are made. Equation 7 is the nonanticipativity constraint for endogenous uncertainty. The variable  $y$  is now bounded by another variable  $z$ , which is the decision variable that relates to when the observation of uncertainty will occur. The timing of when this decision will be made is unknown.

$$-z_{t,s,s'} \leq y_{t,s} - y_{t,s'} \leq z_{t,s,s'}, \forall (s, s') \in \Psi \quad (7)$$

Where  $\Psi$  is the set of scenario pairs that are indistinguishable until uncertainty is observed.

### Value of the Stochastic Solution

The value of the stochastic solution (VSS) is used to measure the possible benefit of using stochastic programming. The calculation of the VSS is shown in equation 8.

$$VSS = EEV - OBJ\_MSSP \quad (8)$$

Where EEV is the expected result of using the solution of the deterministic model and OBJ\_MSSP is the optimal objective function value of the MSSP model. EEV is calculated by solving the deterministic model along each scenario path of the stochastic model and finding the expected value at the end of the time horizon using the same probabilities as the stochastic model [6]. The EEV is used in calculating the VSS rather than the optimal objective function value of the deterministic model because the deterministic model only considers one outcome of all parameters that is within the range of the scenarios that the stochastic model considers. By calculating the EEV, the deterministic model is exposed to the same uncertainty that the stochastic model is accounting for. This is a fairer comparison between accounting for uncertainty through stochastic programming and using a perfect foresight (deterministic) model when uncertainty is present.

## MODEL FORMULATION

The developed model is an energy system model similar to Rathi et al. with the addition of constraints on transportation and trade between regions and is applied to a problem for the entire United States [7]. The model

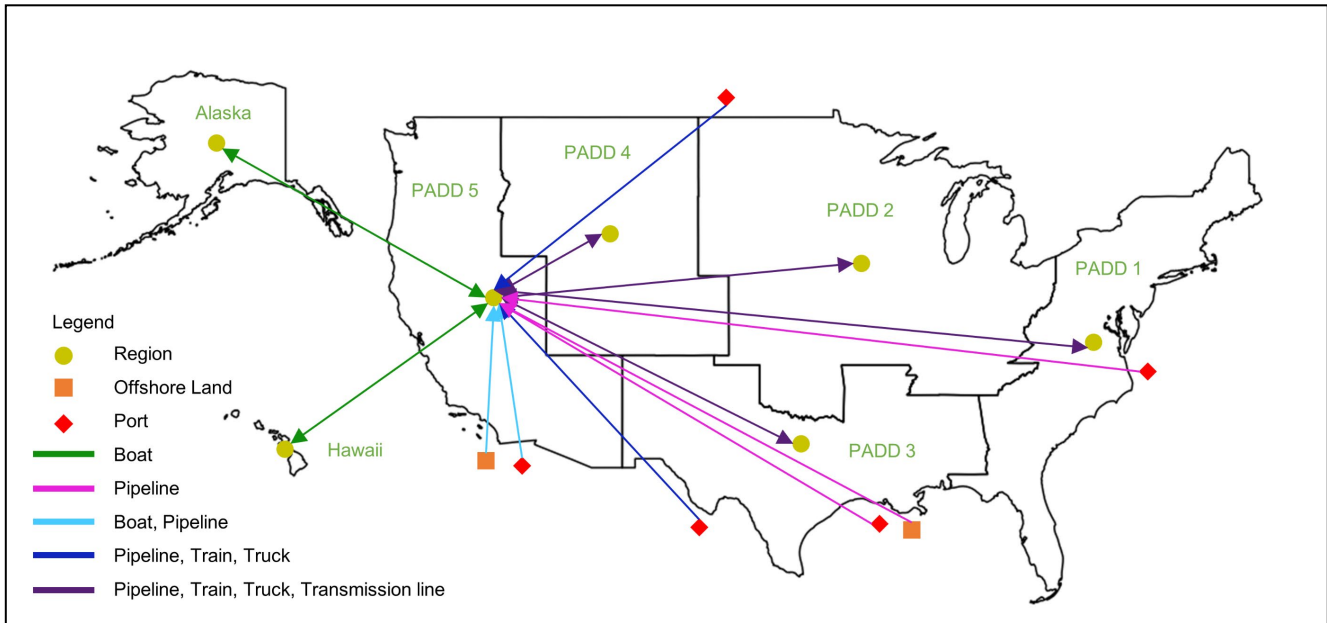

is a capacity expansion model that considers ten liquid fuel producing technologies, nine electricity generating technologies, and two intermediate technologies and must meet the expected demand in the United States over a 30-year time horizon that is divided into six 5-year time periods. For this problem, the United States is represented by 7 regions: Alaska, Hawaii, and 5 regions for the continental United States that follow the Petroleum Administration for Defense Districts (PADDs) as defined by the EIA [8]. Alaska and Hawaii are considered separate regions since they are disconnected from the continental United States. Trade between and within the different regions is also considered. The regions for the United States as well as an example of how one region is connected to the rest of the country is illustrated in Figure 1.

A deterministic and stochastic mixed integer linear model are developed that include constraints on capacity expansion, demand and supply, mass/energy flows through technologies, and conversion of components in

each technology. The models also include constraints on transportation between and within the regions, the material allowed to be transported by different transportation modes, and the direction material is allowed to flow between the regions. The objective function, shown in equation 9 for the deterministic model, is to minimize the cost of the system. The costs considered are the capital costs ( $C^{CAP}$ ), purchasing cost of raw material and final products ( $C^{PUR}$ ), operating costs ( $C^{OP}$ ), transportation costs ( $C^{TRANS}$ ), and a penalty for unmet demand ( $C^{PEN}$ ). The costs can be reduced through credits for carbon capture ( $C^{CAPTURE}$ ) and production of electricity from renewable sources ( $C^{REN}$ ).

$$\min COST = C^{CAP} + C^{PUR} + C^{OP} + C^{TRANS} + C^{PEN} - C^{CAPTURE} - C^{REN} \quad (9)$$

The stochastic model has the same costs in the objective function, but the objective is to minimize the

**Figure 1:** Map of the United States and example of how PADD5 is connected to the rest of the country. The color of the arcs indicate different transportation modes that are allowed between the different regions. Trade can occur in both direction of arcs with double sided arrows, while trade is restricted to one direction along arcs with single sided arrows.

**Figure 2:** Scenario trees for (A) the demand of electricity, (B) the credit for carbon capture, and (C) the learning curve for a corn ethanol plant.

expected cost across all the scenarios.

The system we study includes 24 scenarios representing the observation of two exogenous random parameters (demand and credits related to carbon emission reduction) and one endogenous random parameter (learning rate of biofuel technologies). The scenario trees for some of the random parameters can be seen in Figure 2. The outcome of the demand and credits related to carbon emission reduction are denoted as OD and OI in Figure 2A and 2B respectively. The total energy demand is assumed to be known, but what fraction that will be met by electricity or liquid fuels is unknown. The potential demand for electricity is presented in Figure 2A. There are six possible outcomes that relate to different levels of electrification with the highest electrification denoted as OD1 and the lowest level of electrification (or highest liquid fuel demand) denoted as OD6.

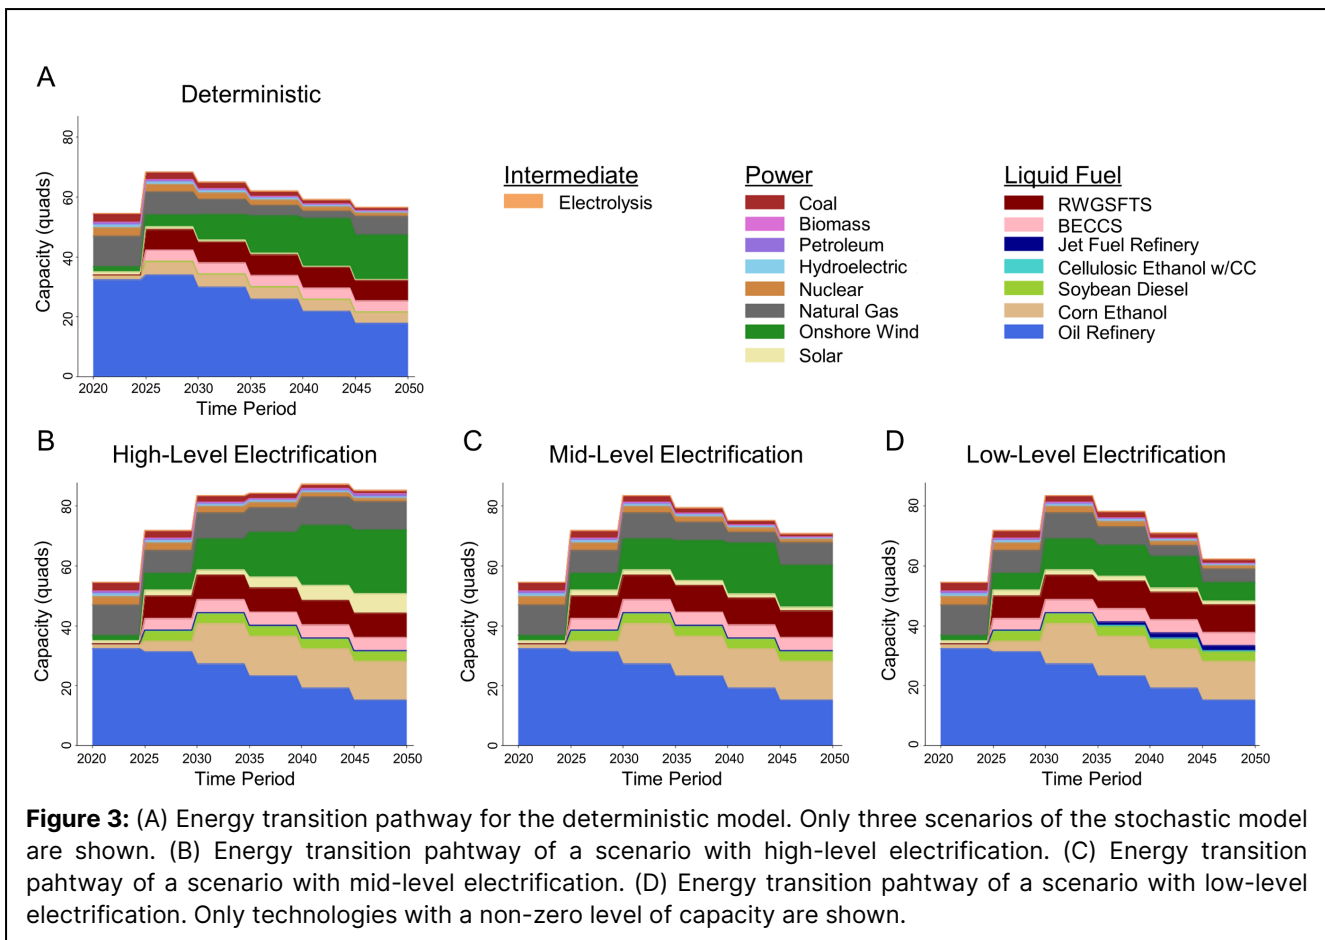

It is assumed that all biofuel technologies will learn together, meaning the capacity that will indicate a decrease in the capital cost along the x-axis of the learning curve, as shown in Figure 2C, will be based on the cumulative capacity of all biofuel technologies. For example, if an investment is made to expand corn ethanol plants, and the total installed capacity is increased from 5 quads to 10 quads, the cost will now decrease for all biofuel

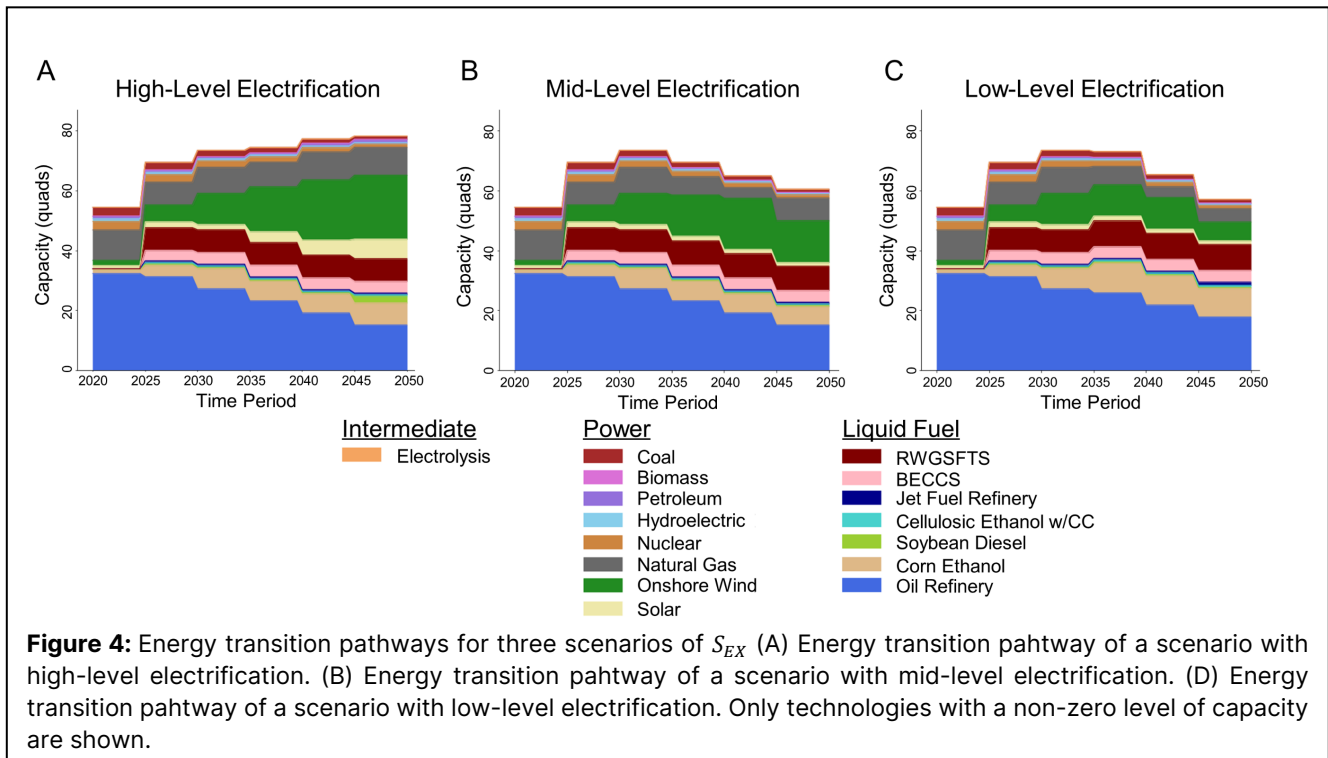

technologies. For instance, bioenergy with carbon capture and storage (BECCS) plants will also have a decrease in cost even though the total capacity of BECCS plants in the system has not changed. The decrease in cost will depend on the learning rate of the individual technology.

## RESULTS

### Energy Transition Pathway of the Deterministic and Stochastic Models

The initial investment decisions of the solution to the stochastic model are different than the initial investment decisions of the solution to the deterministic model. The energy transition pathway for the deterministic model and three scenarios of the stochastic model are presented in Figure 3A and Figure 3B-D respectively. The initial investment decisions of the stochastic model are the first stage decisions, meaning that they are the same across all scenarios. These decisions are seen in the second time period of Figure 3B-D. The capacity is not available until the second time period because we consider a 5-year lag between the time an investment decision is

made and when the capacity is available for use. When the first-stage decisions of the stochastic model are compared with the initial investment decisions of the deterministic model, it is observed that the stochastic model has more investment into onshore wind, solar, reverse water-gas shift combined with Fischer-Tropsch (RWGSFTS), soybean diesel, and cellulosic ethanol with carbon capture. This is because the stochastic model considers scenarios with both higher electricity and liquid fuel demand along with the possibility of lower capital costs in biofuel technologies.

The displayed scenarios have the same level of credits related to carbon emission reduction and learning rate but differ in the outcome of the demand. In the scenario with high and mid electrification there is an increase in electricity generating technologies by the end of the time horizon compared to both the pathway of the deterministic model and the low electrification scenario. The low electrification scenario has more liquid fuel production capacity and less electricity generating capacity by the end of the time horizon compared to the pathway of the deterministic model and the other electrification scenarios.

### Comparison of Accounting for Endogenous and Exogenous Uncertainty

The previous results were for a stochastic model that accounts for endogenous uncertainty. A stochastic model that considers only exogenous uncertainty was also considered. For the remainder of the paper, the stochastic model that accounts for endogenous uncertainty

will be referenced as  $S_{EN}$  and the stochastic model that accounts for exogenous uncertainty will be referenced as  $S_{EX}$ .

In  $S_{EX}$ , there is uncertainty in the fraction of the demand that will be met by liquid fuels or electricity and uncertainty in policy related to the reduction of carbon emissions. The uncertain parameters have the same scenario trees used in the  $S_{EN}$  shown in Figure 2. There is still a learning curve for each biofuel technologies that is based on the cumulative installed capacity of all biofuel technologies, but the learning rate is now assumed to be certain. The energy transition pathway for three scenarios of  $S_{EX}$  are shown in Figure 4. The scenarios shown in Figure 4A-C have the same level of demand and credits related to carbon emission reduction as Figure 3B-D. When only exogenous uncertainty is considered, there is less investment into the different biofuel technologies since there is not an opportunity for higher learning rates to be observed. Notably, there is less investment into corn ethanol and soybean diesel plants. This is because the initial capital cost of these technologies is less than other biofuel technologies; therefore, when endogenous uncertainty is considered through uncertain learning rates based on cumulative installed capacity, there are large investments into corn ethanol and soybean diesel plants in order to reach a cumulative installed capacity that is large enough for the other biofuel technologies to have competitive prices. Also, there is less total installed capacity compared to  $S_{EN}$ . The optimal objective function value of  $S_{EN}$  is less than 1% higher than the optimal objective function value of  $S_{EX}$ . This demonstrates that

while the objective value obtained considering endogenous uncertainty is only slightly higher than considering purely exogenous uncertainty, the investment decisions can be different, which was seen with higher investment into low-carbon technologies in  $S_{EN}$ .

The stochastic models are larger than their deterministic counterparts since there are additional variables and equations, defined for all scenarios, as can be seen in the formulation shown in equations 1-7. All models were implemented in GAMS 42.1.0 and solved using Gurobi 10.0.0 to a 1% optimality gap on 2.6 GHz Intel cluster machines. The deterministic model has 26,637 equations, 108,971 continuous variables, 1,773 binary variables and is solved in 2 seconds.  $S_{EX}$  has 345,277 equations, 1.3 million continuous variables, 21,276 binary variables and is solved in 1.5 hours. Lastly,  $S_{EN}$  has 739,021 equations, 2.6 million continuous variables, 42,552 binary variables and is solved in about 48 hours. Although the stochastic models are significantly more expensive, considering uncertainty can lead to significant cost savings compared to the perfect foresight approach.

### Benefit of Accounting for Uncertainty

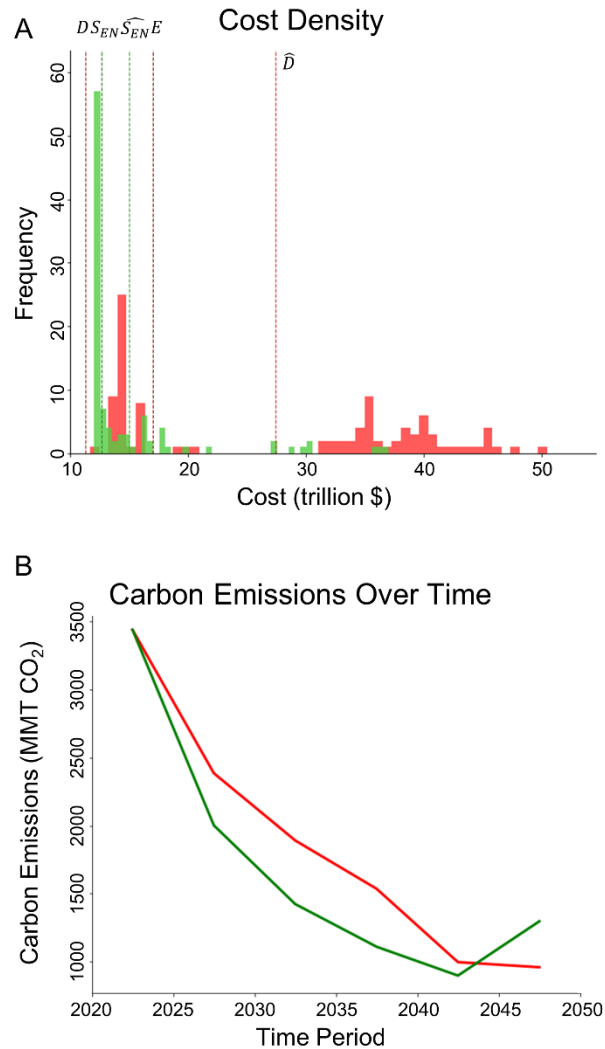

In order to test the benefit of using stochastic programming, the VSS was calculated. The optimal objective function value of the deterministic model is \$11.28 trillion and the optimal objective function value of  $S_{EN}$  is \$12.93 trillion. As explained earlier, the VSS is calculated with the EEV in order to have a fairer comparison between a model that is accounting for uncertainty and a model with perfect foresight. The EEV is \$17.07 trillion. This leads to a VSS of \$4.15 trillion, showing that there is a benefit to accounting for uncertainty through the use of stochastic programming.

It was also desired to test the sensitivity of the investment decisions of the deterministic and stochastic models to varying parameter values. To do this, the investment decisions of the deterministic model found when calculating the EEV and the investment decisions of the stochastic models were used as input parameters and the models were run 100 times with different parameter values. The parameter values that are varied are the random parameters considered in the stochastic models.

### Sensitivity of the results of the deterministic model and the stochastic model that considers endogenous uncertainty

Figure 5 shows the results when the parameter values were varied 100 times for the deterministic model and  $S_{EN}$ . The optimal objective function values (costs) for the deterministic model and  $S_{EN}$  as well as the EEV are shown as D, S, and E respectively along the top of Figure 5A. The average cost for  $S_{EN}$  and the average cost of the deterministic model are denoted as  $\widehat{S}_{EN}$  and  $\widehat{D}$  respectively.  $\widehat{S}_{EN}$  is lower than  $\widehat{D}$ , and the difference is larger

than the VSS calculated earlier. This shows that considering uncertainty with stochastic programming leads to a system that is more robust to changes in the input parameters.

**Figure 5.** (A) Distribution of the cost of the deterministic model (red) and  $S_{EN}$  (green) for 100 varied parameter values. (B) Carbon emissions over time for the deterministic model and  $S_{EN}$ .

Figure 5B shows carbon emissions over time for the deterministic model and  $S_{EN}$ . The carbon emissions of  $S_{EN}$  are lower for most of the time horizon, due to higher investments into renewable and low-carbon technologies. There is an increase in emissions in the last time period because there is a finite horizon. Since there is no information past the last period on demand or credits to reduce carbon emissions, the model will increase emissions in order to meet the highest level of demands at the cheapest cost.

### Sensitivity of the results of the stochastic model that considers endogenous uncertainty the stochastic model that considers exogenous uncertainty

The sensitivity of  $S_{EX}$  and  $S_{EN}$  are shown in Figure 6. The parameter values were varied for 100 simulations with the same values used in the simulations to compare the investment decisions of the deterministic model and  $S_{EN}$ . The results of  $S_{EN}$  are the same in Figure 5 and Figure 6.

**Figure 6.** (A) Distribution of the cost of  $S_{EX}$  (blue) and  $S_{EN}$  (green) for 100 varied parameter values. (B) Carbon emissions over time for  $S_{EX}$  and  $S_{EN}$ .

The costs for  $S_{EN}$  and  $S_{EX}$  are shown along the top of Figure 6A and are similar, where the cost of  $S_{EN}$  is less than 1% higher than the cost of  $S_{EX}$ . The average cost of  $S_{EN}$  and  $S_{EX}$  are denoted as  $\widehat{S}_{EN}$  and  $\widehat{S}_{EX}$  respectively. The average costs are similar but  $\widehat{S}_{EN}$  is slightly higher. The carbon emissions over time (Figure 6B) are also similar,

but  $S_{EN}$  has slightly lower emissions than  $S_{EX}$ . Although the costs are not significantly different, it is important to note that the technology mix can be different, as seen in the differences in capacities of Figure 3B-D and Figure 4A-C.

## CONCLUSIONS

An energy system model that considers capacity expansion of liquid fuel producing technologies and energy generating technologies to meet the energy demand was developed and applied to a problem for the United States using real data. As most literature energy system models, it was assumed that there is a single decision maker for the entire system, which, obviously, is not the case. Nevertheless, the results of the proposed models allow us to better understand the energy sector by identifying what levels and types of investments are necessary to meet certain goals and constraints, such as net zero emissions. A multistage stochastic programming model was developed to consider both exogenous and endogenous uncertainty. The exogenous parameters considered were the demand in electricity and liquid fuels, and credits related to reducing carbon emissions. Endogenous uncertainty was introduced through uncertain learning rates of biofuel technologies. When uncertainty is considered through stochastic programming there are higher initial investments into renewable and low-carbon technologies, which will be required in order to meet net-zero emission goals. With the calculation of the VSS, it was seen that there is a cost benefit when we consider uncertainty rather than assuming perfect foresight. Also, it was shown that the results of the stochastic model led to solution with additional desired characteristics, such as lower carbon emissions and a technology mix that is more robust to varying input parameter values. Lastly, it was seen that introducing endogenous uncertainty does not increase the cost of the system significantly compared to considering only exogenous uncertainty, but there can be a difference in the investment decisions.

## ABSTRACT

Thermal separation processes, such as distillation, play a pivotal role in the chemical and petrochemical sectors, constituting a substantial portion of the industrial energy consumption. Consequently, owing to their huge application scales, these processes contribute significantly to greenhouse gas (GHG) emissions. Decarbonizing distillation units could mitigate carbon emissions substantially. Heat Pumps (HP), that recycle lower quality heat from the condenser to the reboiler by electric work present a unique opportunity to electrify distillation systems. In this research we try to answer the following question in the context of multi-component distillation – Do HPs actually reduce the effective fuel consumption or just merely shift the fuel demand from chemical industry to the power plant? If they do, what strategies consume minimum energy? To address these inquiries, we construct various simplified surrogate and shortcut models designed to effectively encapsulate the fundamental physics of the system. These models are integrated into a superstructure-based Mixed-Integer Nonlinear Programming (MINLP) formulation, which is amenable to global optimization algorithms aimed at minimizing the effective fuel consumption of the system. Moreover, through the examination of a toy 4-component alcohol separation example, we demonstrate how HPs can notably reduce carbon emissions, even when the consumed electricity is generated by burning fossil fuels.

---

**Keywords:** Distillation, Optimization, Energy Efficiency, Process Design

## INTRODUCTION

With more than 40,000 operational columns in the USA alone, distillation accounts for 90-95% of all fluid separations [9]. Distillation is a thermal method that uses differences in component volatilities to achieve separation. In the current economy, thermal energy is generally provided as heat by the combustion of fossil fuels. Given the immense scale at which distillation is deployed, its cumulative energy consumption constitutes a substantial 2.5% of the overall energy consumption within the United States [6]. Consequently, distillation is also responsible for a significant fraction of GHG emissions.

One of the solutions to minimize this significant carbon footprint of distillation systems is to electrify them. Two predominant advantages of electrification are as follows:

1. Even within the current economic framework,

which includes a portion of electricity generation sourced from non-renewables, electrification can potentially curtail fuel consumption.

2. Additionally, it steers the chemical industry toward the imminent shift of energy sources to renewable electricity [2].

In this study, we delve into the application of heat integration (HI) and heat pumps (HP) for electrifying distillation systems. Heat Integration involves the transfer of energy from a heat source with a higher temperature to a lower temperature level where heat is needed [13]. In contrast, heat pumps are devices that can upgrade the heat from a lower temperature source to a higher temperature sink using mechanical work [15]. They are particularly useful in binary and multi-component distillation systems because the condenser's heat at lower temperatures can be upgraded effectively to meet the reboiler

heat demands [3].

**Figure 1.** (a) One of the many possible configurations (b) HI-HPAD version of (a) (The part in yellow represents heat integration, the part in blue represents heat pump)

We demonstrate the synergistic use of the two technologies using an equimolar 4-component feed (Benzene, Toluene, p-Xylene and o-Xylene) separation. For a 100 kmol/hr feed, the configuration in Figure 1 (a) consumes about 130% more energy than the HI-HPAD version of the same configuration in Figure 1 (b).

Figure 1 (a) shows one of the many possible sequences for a 4-component separation. It's important to note that in the first column, the feed 'ABCD' undergoes a sloppy split i.e. one or more of its components are distributed in the distillate and the residue. Considering these splits is crucial during the design of a distillation sequence. By modifying the distribution of components, it becomes possible to influence the temperature of the condenser and reboiler. This, in turn, facilitates the establishment of heat integration links between condensers and reboilers. For example, by altering the split of component 'B', the temperature of the first column's reboiler is brought down such that vapor from the third column can heat the reboiler of the first column (see Figure 1(b)). Further, in this research, we focus on a specific type of heat pump called as – 'Mechanical Vapor Recompression' (MVR) due to its widespread applicability in the literature and industry. In this setup, the vapors from the overhead are compressed to a higher pressure and then condensed against the boiling liquid in the reboiler as in the third column in Figure 1 (b). Note that the reboiler of the third column is partly powered by steam (not shown in the diagram). The potentially high coefficient of performance (COP) and versatile applicability make the technology an appealing option for the electrification process.

The decisions pertaining to the number of configurations, their operating conditions, and HI-HP links for multicomponent separations increase combinatorially, prohibiting industrial practitioners from evaluating every possibility in commercial process simulators [3,17]. This can result in suboptimal configurations being employed and a higher energy penalty. The goal of this research is to develop a method that generates a rank list of configurations exploring all HI-HP possibilities that help

industrial practitioners in decision making.

Towards that goal, in the following section 'Model Development', we propose equations that capture the essential thermodynamics with high fidelity while still being tractable by global optimization solvers like Gurobi and BARON. Further, the developed equations are organized in a superstructure based MINLP formulation that embeds all possible distillation sequences (including sloppy splits), heat integration links and heat pump connections. Subsequently, we validate the proposed model by applying it to a binary alcohol separation system using the commercial process simulator ASPEN Plus V11. Additionally, through a demonstration involving a toy 4-component alcohol separation problem, we showcase the model's efficacy in identifying configurations that significantly reduce effective fuel consumption.

## MODEL DEVELOPMENT

Developing such a framework presents three challenges – determining the energy consumption of a split given the component distribution, estimating temperature of multi-component phase changing streams and the electricity consumption of compressor in the heat pump. We solve the three problems systematically in this section -

### Heat Duty Estimation in Multicomponent Distillation Sequencing

The distillation sequencing problem has received extensive attention in the literature [1,4,5,17,18]. A comparative analysis among different configurations is possible when each configuration operates at its global minimum energy. Hence, we use state of the art superstructure based global optimization model relying on the Underwood's method to compute minimum energy consumption of a given split [7].

State-of-the-art methods directly using Underwood's equations minimize vapor consumption and employ the Constant Molar Overflow (CMO) assumption. We relax this assumption using the CHT (Constant Heat Transport) model [12] which employs a simple variable transformation for the flow variables -

$$F_i^{LH} = F_i \lambda_i$$

$$z_i^{LH} = \frac{z_i \lambda_i}{\sum_{j=1}^n z_j \lambda_j} \quad (1)$$

$F_i^{LH}$  is the latent heat variable defining heat flow,  $F_i$  is the molar flow and  $\lambda_i$  is the molar enthalpy of vaporization of component 'i' in the feed. This straightforward transformation allows the computation of the needed heat duties for the heat pump calculations.

## Multi-component Phase Change Temperature Estimation

In multi-component distillation systems, we frequently encounter streams that undergo non-constant temperature phase changes. To guarantee a positive driving force in the heat exchanger, involving the condensation of compressed vapor and boiling liquid, we have developed an easy-to-use surrogate model [14] –

$$T = \frac{B_{\text{mix}}}{A_{\text{mix}} + \ln(\rho)} - C_{\text{mix}}; \rho = \frac{P^{\text{ref}}}{P} \sum_i \alpha_i X_i \quad (2)$$

The parameters  $A_{\text{mix}}$ ,  $B_{\text{mix}}$  and  $C_{\text{mix}}$  are specific to a mixture and are trained using data from experiments or detailed thermodynamic models. The variable  $\rho$  is called the 'pressure scaled pseudo relative volatility'. It captures the thermodynamic state (liquid fraction) of the stream by changing liquid mole fraction variables. In our recent article [14], the model underwent testing across various non-azeotropic multi-component systems, yielding a high coefficient of determination ( $R^2$ ) of approximately 0.99 for all the cases. An expedient and accurate estimation of the temperatures of fluids involved in heat pumping is essential.

## Heat Pump Electricity Consumption

Similar to the temperature model, the electricity consumption of the compressor is modeled by making a 'reversible heat pump' approximation –

$$W = F^{\text{LH}} \int_0^1 \left( \frac{T(P_2)}{T(P_1)} - 1 \right) dq^{\text{LH}} \quad (3)$$

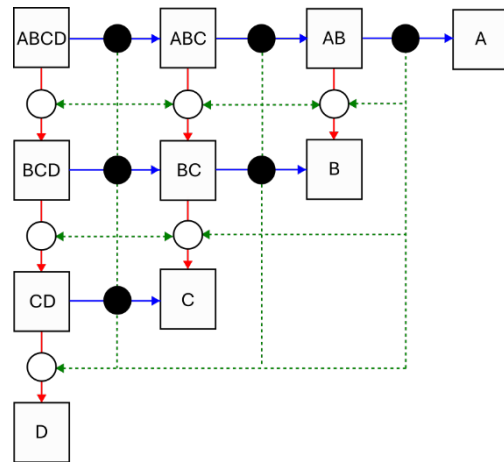

$$q^{\text{LH}} = \frac{L^{\text{LH}}}{F^{\text{LH}}}$$

$P_2$  is the pressure of the compressed overhead vapor in the heat pump while  $P_1$  is the pressure of the column. The integral factorizes the effect of changing temperature as the stream undergoes phase transition.

Leveraging temperature and work consumption models, in the next section, we construct a superstructure atop the MINLP model by Tumbalam Gooty et al. (2022) incorporating heat pump links between various condensing and boiling streams.

## MINLP SUPERSTRUCTURE

The components in the MINLP formulation are represented by alphabets, with their order corresponding to decreasing relative volatility. Each stream is represented by a sequence of alphabets, where each alphabet corresponds to a distinct component present in the stream (see Figure 2).

**Figure 2.** MINLP Superstructure for HI-HP integrated distillation column sequencing. Streams (Squares), Condensers (filled circles), Reboilers (empty circles) for the separation of a 4-component mixture. The dotted green paths represent the heat-work network.

To establish a heat-work network within the existing sequencing superstructure, we connect all condensers to all reboilers and assign a binary variable representing the presence or absence of a connection between each pair. The state of these binary variables, activated or deactivated, is determined by the driving force for heat exchange.

This superstructure accommodates both heat pumps and steam utility to power the reboilers. Our objective is to minimize the effective fuel consumption for generating the required electricity and steam, assuming a boiler efficiency of 85% and a power plant efficiency of 50%.

## MODEL VALIDATION:

The effectiveness of the MINLP model for multi-component heat duty prediction has been thoroughly established through extensive testing on a variety of mixtures [12,16]. Additionally, the temperature model's accuracy has been verified by comparing it to detailed thermodynamic calculations [14]. In this study, we focus solely on validating the performance of the 'reversible heat pump model'.

We validate the model using two test cases – Methanol & Ethanol, Methanol & Propanol. These cases are specifically chosen to evaluate the model performance with increasing boiling point differences in the feed components. The flowsheet simulated in ASPEN Plus V11 is shown in Figure 3.

**Figure 3.** HPAD for binary distillation simulated in ASPEN Plus V11

**Table 1:** Effective fuel consumption for Steam driven and HPAD distillation. The saturated liquid feed mixture is set to be equimolar. The energy consumption values are expressed in the unit MJ/kmol feed.

Binary Mixture	ASPEN Steam Driven		Shortcut Model Steam Driven	
	Steam Driven	HPAD	Steam Driven	HPAD
Methanol - Ethanol	76.1	10.2	74.7	8.9
Methanol-Propanol	39.4	9.7	37.1	9.2

The feed to the distillation column is configured to be equimolar, and the target product purity is set at 99%. As the research primarily centers around a comparative analysis of various strategies, the number of stages' degrees of freedom (DOF) is excluded from the analysis. In ASPEN simulation, a uniform number of stages, specifically 200, is applied for all simulations. Additionally, the minimum approach temperature in the heat pump systems is standardized to be 5°C. Note that the shortcut model performs calculations for a pinched column, therefore, a lower energy demand than the corresponding ASPEN simulation is not unexpected.

The data presented in Table 1 clearly indicates that the shortcut model demonstrates commendable performance for both mixtures. This suggests that the model is proficient in simulating the separation of components with moderate temperature differences. However, based on our experience, as the boiling points of the mixture components diverge significantly, the difference between the calculated energy consumption values from the proposed model and the ASPEN simulation tends to increase. Nevertheless, when comparing different configurations, the model accurately preserves the relative benefits in them.

In the next section, we demonstrate the efficacy of the model using a toy 4-component alcohol separation problem.

## CASE STUDY – ALCOHOL SEPARATION

We proceed to evaluate the framework on a toy multi-component (ABCD) alcohol mixture separation problem. The saturated liquid feed comprises 35% methanol (A), 35% ethanol (B), 20% propanol (C), and 10% butanol (D). The problem is reformulated as a Mixed-Integer Quadratically Constrained Programming (MIQCP) problem and solved using Gurobi 9.1.

Figure 4 illustrates the configuration with the lowest effective fuel consumption, achieved without employing heat integration or a heat pump (HI/HP). This configuration is referred to as a fully thermally coupled system (FTC). The calculated effective fuel consumption using the shortcut model for this configuration is 56.7 MJ/kmol feed.

**Figure 4.** Lowest energy consuming configuration that doesn't involve heat integration or heat pumps. This configuration is the dividing wall column version of fully thermally coupled (FTC) system.

Subsequently, we introduce heat integration (HI) links in the model, allowing for varying column pressures while still utilizing steam as the energy source. Figure 5 depicts the optimal heat-integrated configuration, resulting in a reduced effective fuel consumption of approximately 17.5% to 46.7 MJ/kmol feed. The dividing wall column versions of multi-component configurations can be drawn using the method proposed by Ramapriya et al. [10,11]. Similar to the fully thermally coupled system (FTC), the proposed optimal configuration employs steam at the highest temperature, specifically in reboiler D. The divided wall column beneath operates at a higher pressure, facilitating heat transfer to the column above. It is noteworthy that the condensation of stream AB at a higher pressure provides heat to reboiler C at a lower pressure. Such integrations remain unexplored if column pressure variation is not considered and demonstrates the efficacy of our model.

**Figure 5.** Lowest energy consuming configuration involving heat integration but not heat pumps.

Furthermore, the problem is constrained to include only one heat pump compressor. Figure 6 illustrates one of the top configurations that minimizes effective fuel consumption to 21.4 MJ/kmol feed. The fuel consumption of this is approximately 63% less compared to FTC and 54% lower as compared to the heat integrated configuration. Two notable features of the presented configuration are: (a) The configuration does not rely on any steam utility, and (b) The entire separation unit operates using only a single compressor. Given that compressors contribute significantly to the capital expenditures (CAPEX) of the system, the use of a single compressor results in reduced capital costs.

**Figure 6.** One of the optimal configurations to separate the 4-comp alcohol mixture involving heat integration and heat pumps. The configuration involves a single compressor as the energy input.

## CONCLUSIONS

In the era of decarbonization, it is crucial to evaluate whether the proposed electrification of unit operations genuinely reduces fuel consumption or merely shifts the demand for fuel from the chemical industry to power plants. In this article, we develop a systematic framework to evaluate the aforementioned metric for multi-component distillation systems.

The framework relies on different shortcut and surrogate models which capture the thermodynamics of the system efficiently. Through a couple of binary distillation examples, we establish the accuracy of the model in comparing different alternatives and reduction in fuel consumption. Finally, using a toy multicomponent problem, we demonstrate the efficacy of the proposed framework to identify configurations consuming significantly lower fuel than traditional steam heated distillation units.

For most cases, HP assisted configurations can help mitigate carbon emissions in the current economy. A further reduction in energy consumption can be brought about by using intermediate reboilers/condensers, Multi-effect distillation etc which can be explored in the context of multi-component distillation systems.

## TABLE OF ACRONYMS

Acronym	Full Form
HI	Heat Integration
HP	Heat Pump
HPAD	Heat Pump Assisted Distillation
CAPEX	Capital Expenditure

## ABSTRACT

As a low-carbon fuel, feedstock, and energy source, hydrogen is expected to play a vital role in the decarbonization of high-temperature process heat during the pyroprocessing steps of clinker production in cement manufacturing. However, to accurately assess its potential for reducing CO<sub>2</sub> emissions and the associated costs in clinker production applications, a techno-economic analysis and a study of facility-level CO<sub>2</sub> emissions are necessary. Assuming that up to 20% hydrogen can be blended in clinker fuel mix without significant changes in equipment configuration, this study evaluates the potential reduction in CO<sub>2</sub> emissions (scopes 1 and 2) and cost implications when replacing current carbon-intensive fuels with hydrogen. Using the direct energy substitution method, we developed an Excel-based model of clinker production, considering different hydrogen-blend scenarios. Hydrogen from steam methane reformer (gray) and renewable-based electrolysis (green) are considered as sources of hydrogen fuel for blend scenarios of 5%–20%. Metrics such as the cost of cement production, facility-level CO<sub>2</sub> emissions, and cost of CO<sub>2</sub> avoided were computed. Results show that for hydrogen blends (gray or green) between 5% and 20%, the cost of cement increases by 0.6% to 16%, with only a 0.4% to 6% reduction in CO<sub>2</sub> emissions. When the cost of CO<sub>2</sub> avoided was computed, the extra cost required to reduce CO<sub>2</sub> emissions is \$229 to \$358/metric ton CO<sub>2</sub>. In summary, although green hydrogen shows promise as a low-carbon fuel, its adoption for decarbonizing clinker production is currently impeded by costs.

## INTRODUCTION

In the United States, cement (and lime) production in 2022 is responsible for 31 million metric tons (MMT) CO<sub>2</sub> emissions of the industry sector's total CO<sub>2</sub> emissions [1]. These GHG emissions attributed to the cement sector are directly associated with clinker manufacturing, which constitutes 70%–90% of conventional cement blends. With clinker production volume of 79 MMT in 2022 [2], if the status quo is maintained, reduction of these emissions is vital if we intend to achieve the 1.5°C target.

Because clinker manufacturing involves the breakdown of limestone to lime and the concurrent production of byproduct CO<sub>2</sub> in a high-temperature pyroprocessing

step, the generation of process- and combustion-related CO<sub>2</sub> emissions is currently inevitable. Owing to the chemistry of the reaction, process-related CO<sub>2</sub> emissions account for up to 60% of total clinker production CO<sub>2</sub> emissions with the remaining associated with energy use. Given the twofold sources of CO<sub>2</sub> emissions in cement production, efforts are channeled toward decarbonizing one or both.

To decarbonize the cement industry, implementation of the crosscutting decarbonization pillars—namely energy efficiency; low-carbon fuels, feedstocks, and energy sources (LCFFES); industrial electrification; and carbon capture, utilization, and storage (CCUS)—are necessary conditions to attain a low-carbon cement industry. Hence, over the years, different research efforts have

been focused on these carbon-reducing strategies, technologies, and practices.

For example, Worrell et al. [3] conducted an energy efficiency analysis using 30 energy-efficient technologies and measures in the US cement sector. Results of the analysis showed energy and CO<sub>2</sub> savings of 11% and 5%, respectively. Nevertheless, current typical energy use in the cement sector still revolves between 3.5 and 4.1 GJ/MT [4–6] and with emissions intensity as high as 900 kgCO<sub>2</sub>/MT cement [7]. Advanced waste heat recovery and process intensification are still needed for the contribution of energy efficiency pillars to be significant. For LCFES applications, the use of supplementary cementitious materials such as blast furnace slag, volcanic ash, pozzolans, fly ash, and calcined clay can reduce the clinker-to-cement ratio to about 65%–75% with the innovative limestone calcined clay allowing higher clinker substitution up to 50% [8]—thereby reducing energy use and emissions typically associated with clinker production. However, a drawback to using slag and fly ash is the transition from blast furnace and coal power plants to more sustainable alternatives [9]. Industrial electrification research has focused on the electricity-driven calciner or calciner/kiln system [4–5]—offsetting on-site scope 1 CO<sub>2</sub> emissions emanating from fuel combustion and enabling a CO<sub>2</sub>-rich flue gas (pyroprocessing step), which minimizes the energy requirement for carbon capture (CC). An innovative electrified cement production in progress is the Leilac project designed to indirectly heat raw meal in a shell and tube system, efficiently separating the process CO<sub>2</sub> for direct capture or use [10]. Finally, CCUS is primed as the sole decarbonization pillar that can significantly reduce CO<sub>2</sub> intensity of the cement sector, depending on the technology implemented. However, the most feasible cement CC technologies are still at a low technology readiness level (TRL), and the high TRL technologies are very energy intensive [11], which the current cement facility is not equipped to support.

**Figure 1.** Average cement fuel mix [12].

Among all decarbonization pillars, fuel switching has received little or no attention. Traditionally, US cement

facilities use a range of fuel mix, as depicted in Figure 1. Coal and petroleum coke with high-carbon content account for 65% of this fuel mix, dominating the energy-related emissions. In practice, cement facilities usually combust any cheap fuel in the market or even receive a tipping fee to dispose of industrial wastes in the kiln [13]. To decarbonize the cement sector, broad commitment toward clean or low-carbon fuels is needed.

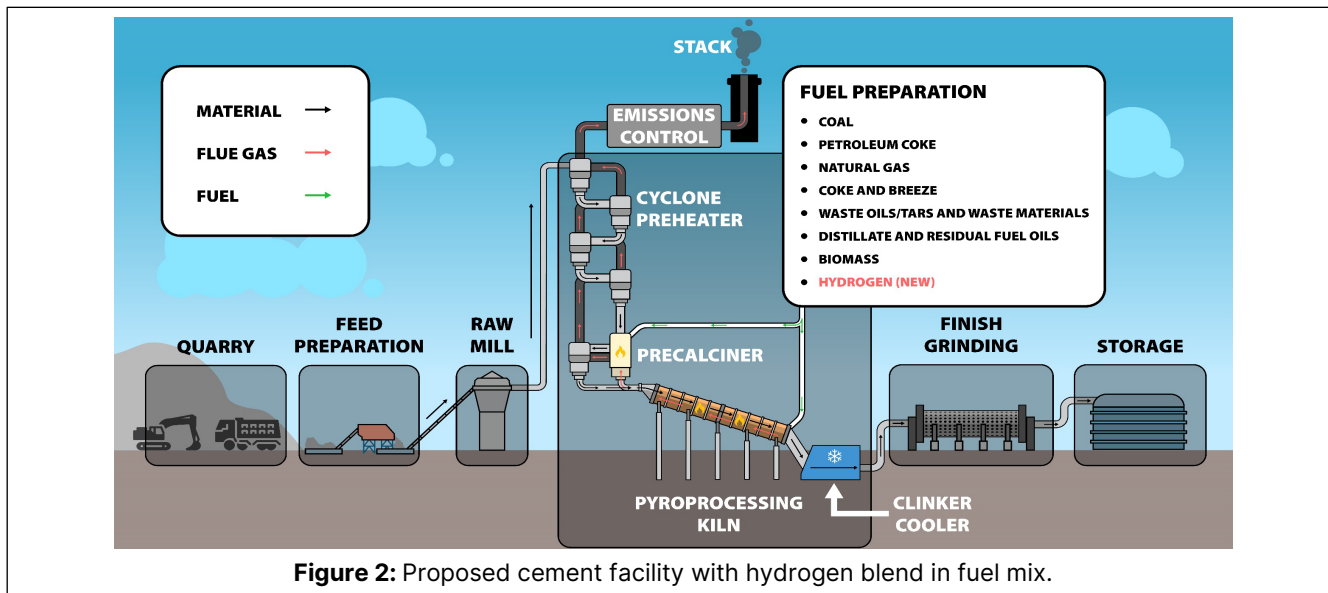

Within the hydrogen economy, hydrogen as a carbon-free energy carrier is being pushed as a fuel that can decarbonize the cement industry sector. For instance, CEMEX has announced the use of hydrogen as a share in cement fuel mix for all cement facilities in Europe to attain zero CO<sub>2</sub> combustion emissions and improve energy efficiency [14]. Nevertheless, whereas hydrogen seems to be a viable means to decarbonize cement production, the technical challenges, costs, and potential emissions reduction that could impede the full adoption of hydrogen as a fuel need to be evaluated.

Hence, in this study, we assessed the cost and potential CO<sub>2</sub> emissions reduction of blending hydrogen as a fuel in cement production. This analysis explored the use of hydrogen from both conventional steam methane reformer (SMR) hydrogen (gray) and renewable-powered electrolysis hydrogen (green). In this context, scope 2 emissions of hydrogen production were considered. In addition, discussions on the near-term technical challenges currently impeding hydrogen use in the industry sector are highlighted. Performance metrics, such as facility-level CO<sub>2</sub> emissions, minimum cement selling price (MCSP), and cost of CO<sub>2</sub> avoided (CCA), were computed. Overall, insights on the current state of hydrogen adoption as a fuel in the cement sector are elucidated.

## METHODOLOGY

### Process modeling and assumptions

This work employs a brown-field cement facility with a five-stage cyclone preheater with precalciner system for dry portland cement manufacturing. Clinker production is sized to be about 1.2 MMT (clinker to cement ratio = 81%) corresponding to an average US cement facility. In this proposed facility, hydrogen is assumed to substitute 5%–20% of the primary energy demand. At the time of this analysis, it is assumed that a hydrogen blend of up to 20% would not necessitate any significant modification of the equipment [24] used in the cement facility. The authors developed an Excel-based model for the energy demand of hydrogen-fired cement production using a direct energy substation method. Hydrogen supply to the cement facility is assumed to be met via SMR hydrogen (gray) and electrolysis hydrogen (green)—with associated scope 2 emissions included. For comparison, the conventional cement (based on traditional fuel mix) was also modeled. Intrinsicly, it is assumed that the cement

**Figure 2:** Proposed cement facility with hydrogen blend in fuel mix.

produced in each scenario meets the portland cement standard. Key parameters and assumptions used in the model are shown in Table 1.

Figure 2 shows the proposed cement production facility. As a decarbonization strategy, different hydrogen blend ratios are designed to substitute carbon-intensive fuels such as coal and petroleum coke while keeping natural gas and biomass fuels constant. Overall, the performance of the cement facility with different hydrogen sources at different blend ratios was assessed in terms of MCSP, facility-level CO<sub>2</sub> emissions (scopes 1 and 2), and CCA.

**Table 1:** Parameters used in the model.

Parameter	Value	Ref
<i>Energy demand (GJ/t)</i>		
Feed preparation	0.13	[6]
Fuel preparation	0.13	[6]
Pyroprocessing (with cooling)	3.61	[6]
Finish grinding	0.21	[6]
Primary thermal energy	3.51	[6]
Electricity (site)	0.19	[6]
Raw meal to clinker ratio	1.6	[15]

### Process description

Portland cement manufacturing involves the general steps of mining or extraction of feedstock, feedstock preparation via crushing and grinding operations, fuels preparation, the pyroprocessing operation (preheater/precaliner), kiln with cooling system, and final grinding with additives, as shown in Figure 2.

Raw materials for cement production such as limestone, clay, shale, marl, and iron ore are mined or extracted at quarries typically located near the cement facility. Additional raw material such as gypsum needed in the finishing grind operation is also sourced. Cement

facilities currently use waste materials such as fly ash and blast furnace slag, etc. as raw materials [16].

To ensure the homogeneity of the mixture and that the appropriate chemical and physical properties are achieved, these raw materials are crushed into smaller particles using hammer or jaw crushers [6]. The crushed particles are further processed by grinding to form raw meal, which is sent to the preheater [6]. This raw material processing takes place in the feed preparation unit which is powered primarily by electricity.

Owing to the diverse nature of fuel mixes (solids, liquids, and gases) used in cement production, fuel preparation is a standard process. Conventional fuels like coal, petroleum coke, and waste tire are crushed, creating fine particles that improve combustion. These fuels are then combusted in the calciner and kiln to drive the calcination and sintering reactions.

Raw meal from the grinder is sent to the pyroprocessing step, where the moisture content is reduced in the cyclone preheater system before the meal is sent to the precaliner. In the precaliner, the initial calcination reaction takes place at about 900°C, driving off CO<sub>2</sub> from the raw meal and improving the overall thermal efficiency of the process. Clinker formation occurs in the rotary kiln, which operates at 1,450°C to produce hot solid clinker products.

The final cement production step involves air cooling and subsequent grinding of the clinker into a fine powder, which is mixed with gypsum and other additives to form cement.

### Facility-level CO<sub>2</sub> emissions assessment

In this analysis, the facility-level CO<sub>2</sub> emissions are based on scopes 1 and 2 emissions emanating from on-site (process and combustion) and upstream (electricity and hydrogen) emissions. Other on-site CO<sub>2</sub> emissions such as mobile equipment use are not considered. The

facility-level CO<sub>2</sub> emissions are computed as:

$$CO_{2t} = CO_{2p} + CO_{2f} + CO_{2e} \quad (1)$$

$$CO_{2f} = \sum_i CO_{2i} \quad (2)$$

where  $CO_{2t}$  is the total facility-level CO<sub>2</sub> emissions,  $CO_{2p}$  is the process-related CO<sub>2</sub> emissions,  $CO_{2f}$  is the fuel combustion CO<sub>2</sub> emissions,  $CO_{2i}$  accounts for the combustion-related CO<sub>2</sub> emissions of  $i^{th}$  fuel, and  $CO_{2e}$  is the electricity CO<sub>2</sub> intensity.

For the fuel-related emissions, the waste biomass used as fuel is assumed to be sustainable; hence, biomass combustion CO<sub>2</sub> equals zero. Whereas the fuel emissions intensity is obtained from EPA's emission factors for GHG inventories [17], we used the following emissions factors: for electricity, 0.4 kg/kWh; for conventional SMR hydrogen, 10 kgCO<sub>2</sub>e/kg H<sub>2</sub>; and for electrolysis green hydrogen, 0.97 kgCO<sub>2</sub>e/kg H<sub>2</sub> [18].

### Cost assessment

Cost performance of the proposed cement manufacturing is conducted to assess the economic viability of this decarbonization strategy when compared with the conventional cement pathway. The direct equipment cost (DEC) of the cement facility is estimated based on [4] using the sixth-tenth rule to adjust for plant capacity.

The equipment cost is presented in \$US2020 using the Chemical Engineering Plant Cost Index [19]. Based on the computed DEC, the total capital investment is calculated using correlations from [20,21]. The operating costs (variable and fixed) were estimated as a function of plant-size consumables (feedstock, fuel, electricity), labor, maintenance, operating overhead, and property insurance costs [4,21]. The MCSP is computed by conducting a discounted cash flow rate of return over the assumed lifetime of the plant using the economic parameters presented in Table 2.

Parameter	Value	Parameter	Value
Plant life (years)	30	Tax rate (%)	40
Plant avail. (%)	75	Rate of return (%)	12
Plant loan (years)	10	Depreciation	MACRS
Loan interest (%)	9.5	Working capital	15%
Debit/equity (%)	50	Operating hours	8,000
<b>Fuel costs (\$/GJ)</b>			
Coal	2.01	Distillate fuel oils	9.70
Petroleum coke	2.69	Biomass	3.34
Natural gas	2.93	SMR H <sub>2</sub>	7.09
Waste oils/tars	0.01	Electrolysis H <sub>2</sub>	31.91
Coke and breeze	2.02		

### Cost of CO<sub>2</sub> avoided

We computed the CCA to ascertain the additional cost incurred to offset a unit amount of CO<sub>2</sub> in cement manufacturing. The CCA formulation is given in Eq. (2) based on [22,23]:

$$CCA = \frac{MCSP_s - MCSP_c}{CO_{2,c} - CO_{2,s}} \quad (2)$$

where  $MCSP_c$  and  $MCSP_s$  are the minimum cement selling price of the conventional and scenario hydrogen fuel fired cement in \$/MT cement, respectively; and  $CO_{2,c}$  and  $CO_{2,s}$  are the CO<sub>2</sub> emissions of both the conventional cement and scenario hydrogen fuel blended cement in kgCO<sub>2</sub>eq/MT cement, respectively.

## RESULTS

### Systems performance: Gray hydrogen blend

Table 3 shows the MCSP, facility-level CO<sub>2</sub> emissions, and CCA for different blends of gray hydrogen ratios when compared with the conventional clinker. The MCSP for conventional cement is \$106.9/MT, whereas a blend of hydrogen between 5% and 20% changes the

**Table 2:** Economic parameters and assumptions.

<b>Table 3:</b> Costs and performance analysis of SMR hydrogen blend ratios with conventional fuels

Process CO <sub>2</sub>	kgCO <sub>2</sub> /MT	518	518	518	518	518
Total CO <sub>2</sub>	kgCO <sub>2</sub> /MT	749	746	743	739	736
Cost of CO <sub>2</sub> avoided	\$/MT CO <sub>2</sub>	-	228.9	246.9	228.9	228.9

**Figure 3:** Percentage change in cost and emissions of cement for SMR hydrogen blends.

**Figure 4:** Percentage change in cost and emissions of cement for green hydrogen blends.

MCSP to \$107.6–\$109.6/MT. This represents an increase of up to \$2.8/MT cement. As can be observed (Table 1), the change in cement cost affects only the fuel cost owing to hydrogen use. Other cost components such as electricity (power), capital, fixed operating & maintenance (O&M), and variable O&M were assumed to remain the same. This assumption is feasible because hydrogen blends up to 20% are currently stipulated as the maximum limit before major infrastructure change is required [24].

In terms of emissions reduction, whereas the process emissions remain unchanged when hydrogen is blended in the fuel mix (Table 1), energy-related CO<sub>2</sub> emissions change depending on the amount of hydrogen blended. Hence, the total scopes 1 and 2 CO<sub>2</sub> emissions for the 5%–20% H<sub>2</sub> blends ranged between 736.4 and 745.5 kgCO<sub>2</sub>/MT cement. If only the energy-related CO<sub>2</sub> emissions are considered, a 5% maximum CO<sub>2</sub> emissions reduction is achieved. This extent of emissions reduction is due to the scope 2 emissions associated with hydrogen production. Hypothetically, only when the scope 2 emissions of SMR hydrogen are zero can a significant reduction (as high as 23%) in energy-related CO<sub>2</sub> emission be achieved.

The CCA—a function of the additional cost incurred

to avoid CO<sub>2</sub> emission—ranged between \$228.9 and \$246.9/MT CO<sub>2</sub>. An interesting observation in the computed CCA is the increase in CCA from \$228.9/MT (for 5% H<sub>2</sub>) to \$246.9/MT (for 10% H<sub>2</sub>), followed by a decrease back to \$228.9/MT (for 15% and 20% H<sub>2</sub> blends, respectively). This phenomenon is linked to the extent of emissions offset when compared with the extra cost incurred to achieve such an extent of reduction.

Figure 3 depicts the comparative emissions savings of an H<sub>2</sub> blend with the corresponding change in MCSP necessary to achieve the CO<sub>2</sub> reduction. Blending 5% H<sub>2</sub> in the clinker fuel mix had only a 0.4% reduction in total facility-level CO<sub>2</sub> emissions while increasing the cost by 0.6%. When 10% H<sub>2</sub> is blended, only 0.8% reduction in CO<sub>2</sub> emissions is achieved—increasing the cost of cement by 1.3%. At 20% H<sub>2</sub> blend, emissions reduction is still below 2%, whereas the clinker cost increases by 2.6%. One might wonder why the emissions reduction is not significant for a zero-carbon fuel like hydrogen. We considered indirect CO<sub>2</sub> emissions (scope 2) associated with hydrogen production, which, on a mass basis, are higher than the fossil fuels for which they substitute.

### Systems performance: Green hydrogen blend

When green hydrogen is considered as the source

**Table 4:** Costs and performance analysis of green hydrogen blend ratios with conventional fuels

Metric	Unit	Conventional	5% H <sub>2</sub>	10% H <sub>2</sub>	15% H <sub>2</sub>	20% H <sub>2</sub>
<i>Cost</i>						
Fuel	M\$/year	7.02	13.8	19.0	24.2	29.4
Electricity	M\$/year	4.03	4.03	4.03	4.03	4.03
Capital	M\$	369.3	369.3	369.3	369.3	369.3
Fixed O&M	M\$/year	36.42	36.42	36.42	36.42	36.42
Variable O&M	M\$/year	7.22	7.22	7.22	7.22	7.22
MCSP	\$/MT	106.9	111.1	115.4	119.6	123.9
<i>Emissions</i>						
Combustion CO <sub>2</sub>	kgCO <sub>2</sub> /MT	230	218	206	194	182
Process CO <sub>2</sub>	kgCO <sub>2</sub> /MT	518	518	518	518	518
Total CO <sub>2</sub>	kgCO <sub>2</sub> /MT	749	736	725	712	700
Cost of CO <sub>2</sub> avoided	\$/MT CO <sub>2</sub>	–	351.7	358.3	351.7	351.7

of hydrogen in the fuel mix, cost and emissions performance differs, as shown in Table 4. In terms of cost, H<sub>2</sub> blends between 5% and 20% yield an MCSP of \$111.1–\$123.9/MT with corresponding CO<sub>2</sub> emissions of 700–736 kgCO<sub>2</sub>/MT cement. Comparing the emission reduction achieved using green hydrogen to that of gray hydrogen, additional 5% and 16% improvements in facility-level and energy-related CO<sub>2</sub> emissions are achieved, respectively. For a 5% reduction in facility-level emissions, up to a 13% increase in MCSP is observed for green hydrogen-fired cement compared with the gray hydrogen counterpart. Clearly, this premium for decarbonized cement might be difficult for cement manufacturers to compete in the market, given the extent of reduction.

It is not surprising that the CCA for the use of green hydrogen ranges between \$351.7 and \$358.3/MT CO<sub>2</sub>. Again, this computed CCA is more expensive than the cost of carbon capture reported for the cement industry (\$50–\$60/MT) [25]. This implies that it is economically and even environmentally competitive to adopt and use CC in cement rather than use hydrogen as a fuel for decarbonization purposes.

Finally, Figure 4 directly compares the emissions reductions achieved and the associated costs for different H<sub>2</sub> blend ratios relative to conventional cement. For a 2% reduction in CO<sub>2</sub> emissions, a 4% increase in MCSP was observed for a 5% H<sub>2</sub> blend. A maximum of 6% reduction in facility-level CO<sub>2</sub> can be achieved when 20% H<sub>2</sub> is blended in a clinker fuel mix—at the expense of a 16% increase in MCSP. Given the minimal reduction in emissions at a high cost, at present it does not make economic sense to use hydrogen as a decarbonization lever in the cement industry.

### Sensitivity analysis

Because green hydrogen blend in cement fuel mix offers more CO<sub>2</sub> emissions reduction when compared with gray hydrogen, the effect of green hydrogen's cost on MSCP is assessed via sensitivity analysis. Figure 5

shows the effect of green hydrogen's cost on MCSP for different hydrogen blend ratios.

**Figure 5:** Sensitivity analysis of the effect of green hydrogen cost on cement price.

At a green hydrogen price of \$1/kg owing to the federal Infrastructure Reduction Act 45 V tax credit that incentivizes green hydrogen products, the MCSP is between \$107.6 and \$109.7/MT for 5%–20% hydrogen blend ratios. Even at \$1/kg for green hydrogen, the selling price of cement is still \$0.70/MT higher than that of conventional cement. The CCA of the cement at this hydrogen price is between \$57.6 and \$58.7/MT CO<sub>2</sub> avoided, which is competitive with that achieved via CCS. To a greater extent, because CCS implementation at a specific cement facility can be impeded by a lack of CO<sub>2</sub> transportation and sequestration sites, use of green hydrogen proves to be more suitable. Nevertheless, on an emissions intensity basis, a CCS-enabled cement facility at 85% capture (112.3 kgCO<sub>2</sub>/MT) outperforms the green hydrogen-fired (700 kgCO<sub>2</sub>/MT) cement facility.

At a \$7/kg green hydrogen price, the cost of cement increases between \$113.7 and \$134/MT with a corresponding CCA of \$562–\$572/kgCO<sub>2</sub>eq avoided. Overall, the high cost of hydrogen when compared with the extent of emissions reduction limits its use as a

decarbonization strategy in cement production.

## DISCUSSIONS

Decarbonizing cement production is vital to attaining US economy-wide GHG reduction goals. With an interest in decarbonizing industrial process heat, cement manufacturers are beginning to propose the adoption of hydrogen as fuel. Argos and CEMEX are pushing toward a hydrogen share in their cement fuel mix for facilities in Honduras [28] and Europe [14], respectively. However, this analysis shows that pursuing this route as a decarbonization strategy is highly limited by cost when compared with the amount of reduction attained. At best, when green hydrogen (with zero emissions) constitutes 100% of fuel used in cement production (not shown in this analysis), only a 29% reduction in scope 1 emissions is achieved. Nevertheless, when scope 2 emissions of hydrogen and electricity are considered, the reduction amount drops to 26%. Therefore, it is evident that hydrogen should be channeled to other industrial applications.

Despite the emissions- and cost-related challenges, supply chain and other technical barriers still impede the widespread adoption of hydrogen as fuel (blend mix or 100% H<sub>2</sub>). At 100% use of hydrogen in the cement sector, the demand for hydrogen per annum will be about 2 MMT (based on 2022 clinker production of 78 MMT). Because the current annual US hydrogen production is about 10 MMT, a supply-demand issue might arise. In addition, significant reconfiguration of existing cement facilities with high CAPEX will be required [26].

Technical challenges associated with hydrogen include storage owing to low volumetric energy density, increasing tendency of fire or explosion because of its wide flammability range in air, burning challenges linked to its burning velocity that will require complex control systems, high NO<sub>x</sub> formation because it has a high adiabatic flame temperature (burner modification required, with associated costs), and low thermal radiative heat transfer owing to the absence of soot exhibited by hydrogen flames [27] that affect clinker quality. Other technical challenges include hydrogen leakage and equipment/pipeline embrittlement, etc. Hydrogen leaks appear to be very detrimental because hydrogen tends to react with hydroxyl radicals, reducing the amount of OH needed to break down methane in the atmosphere [29].

Overall, more research and development are needed in the efforts to adopt hydrogen as fuel in the cement industry and other sectors in which hydrogen has the potential to contribute to decarbonization goals. In addition, government funding and policies will play a key role in reducing the cost of hydrogen (green) for industries to begin this much-needed shift.

## CONCLUSION

Clean hydrogen is a low-carbon fuel, feedstock, and energy source that can play a key role in the decarbonization goals of the US economy. Nevertheless, the use of hydrogen as a fuel has inherent supply chain technical challenges that must be overcome before it can safely and easily be adopted as a fuel mix. Even though these challenges are addressed, the cost implications could prove to be prohibitive for industry—particularly, the cement industry, with low margins—to adopt hydrogen as fuel. At 20% green H<sub>2</sub> blend, a CO<sub>2</sub> emissions reduction of 6% can be achieved at a significant 16% increase in cement cost. Therefore, it might not be economically viable for the cement industry to adopt hydrogen as a fuel in clinker manufacturing.

As observed, the CCA did not change for the hydrogen blend ratios except for 10%. The obvious explanation for this impact is that blending hydrogen as fuel (within this ratio) in clinker production does not really affect carbon emissions reduction, given the significant contribution to the overall emissions by the pyroprocessing step. Because there is an additional 8% increase in CCA for the 10% hydrogen blend, any cement facility considering blending hydrogen in the fuel mix is better off with any of the other blend scenarios because the cost increment is commensurate with the emissions offset.

## ABSTRACT

Hydrogen, as a clean and versatile energy carrier, holds immense promise for addressing the world's growing energy and environmental challenges. However, hydrogen-based energy systems face challenges related to efficient storage methods, energy-intensive production, refueling processes, and overall cost-effectiveness. To solve this problem, a superstructure was developed that integrates overall technologies related to hydrogen energy transportation. This study synthesizes process pathways for hydrogen energy transportation method including energy carrier production, storage, and refueling, based on the developed superstructure. The techno-economic analysis was conducted to evaluate the performance of each transportation pathway and compare it with conventional fossil fuel transportation system. Process performance criteria, including unit production cost (UPC), energy efficiency (EEF), and net CO<sub>2</sub> equivalent emissions (NCE), serve as indicators for process performance. By comparing technological pathways, we can propose the most economically and environmentally optimal energy refueling route. Additionally, sensitivity analyses were performed on various external factors, identifying influential variables in the decision-making process for hydrogen production, storage, and refueling strategies, while also elucidating technological limitations.

**Keywords:** Hydrogen, Process synthesis, Environment, Techno-economic analysis, Energy refueling

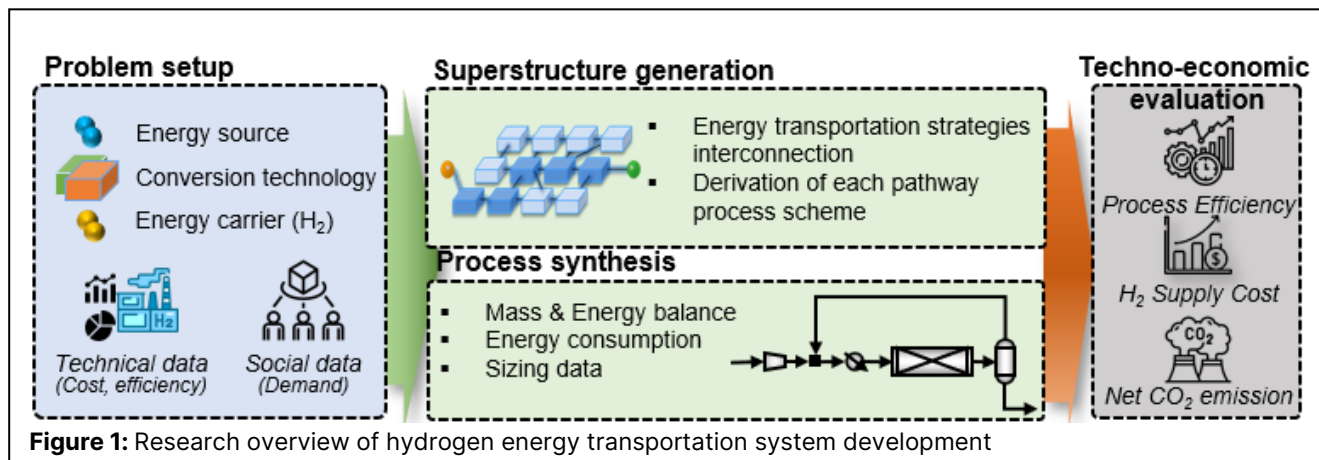

## 1. INTRODUCTION

One of the most important global environmental issues is the depletion of conventional energy sources and the climate change caused by greenhouse gas (GHG) emissions. Hydrogen is flexible energy carrier that can be converted into usable forms of energy and is an environmentally clean energy source. The concept of hydrogen economy, characterized by the production, distribution, and utilization of hydrogen as a primary energy carrier, has gained significant traction. The transformative vision envisions a departure from conventional fossil fuel dependency toward a circular and interconnected energy system where hydrogen acts as a linchpin for integration, storage, and efficient utilization of renewable energy sources.

To establish a hydrogen energy system, various preliminary studies are being conducted on developing hydrogen production, storage, and transportation systems. Li Lin et al. conducted the process development

and cost analysis of an ammonia-based hydrogen refueling station process [1]. A.D. Korberg et al. developed and evaluated a transport process for renewable energy resources [2]. Jack Shepherd et al. developed a green ammonia value chain and proposed the pathway with the highest economic feasibility [3]. Ayodeji Okunlola et al. proposed an optimal hydrogen transportation method through analysis of inter-country hydrogen transportation and supply [4].

In preliminary research, the development of technologies for the production, storage, and transportation of hydrogen is progressing, and research on establishing hydrogen energy system is also being conducted. However, the previous study has not determined and evaluated compared conventional fossil fuel transportation system. We compared and analyzed the energy system, including hydrogen production, storage, and transportation, with the conventional fossil fuel-based energy system to determine the possibility of hydrogen replacing conventional energy resources. This study focused on

various hydrogen storage and transportation method such as high-pressure compression, liquefaction, ammonia, liquid organic hydrogen carriers (LOHC). Each developed hydrogen storage and transportation method is synthesized with a process for production hydrogen from various energy sources.

This study developed the superstructure of the entire energy transfer based on hydrogen and fossil fuels. An energy transport pathway was developed by modeling various unit processes within the superstructure. Then, a techno-economic analysis is performed for each pathway to derive energy efficiency (EEF), levelized cost of energy (LOCE), and net CO<sub>2</sub> equivalent emissions (NCE), which are quantitative indicators of process performance. Through the results of techno-economic analysis, a process pathway with optimal economic or environmental feasibility for hydrogen energy transportation was derived. In addition, we identified technical limitations for establishing a hydrogen energy system and proposed technical and political strategies.

## 2. RESEARCH OVERVIEW AND METHODOLOGY

### Research Overview

The goals of this work are: i) to propose optimal economic or environmental hydrogen energy transportation pathway, ii) to determine technical limitation of hydrogen energy transportation system, iii) to propose technical and political strategies for hydrogen energy system. Figure 1 provides procedures for energy transportation system development. First, we set problem by investigating energy sources, conversion technologies, and energy carriers and making a database of the technical and social data. To identify the overall structure of the hydrogen energy transportation system, a superstructure connecting transportation technologies was developed based on technical data. Then, a unit process model on the energy transportation system superstructure was developed and the mass and energy balance for each energy

transport pathway was derived through process synthesis. Through a techno-economic analysis of each developed process model, process efficiency, cost, and CO<sub>2</sub> emissions are calculated.

Primary energy source considered in this study include conventional fossil fuels such as coal, crude oil, and natural gas, as well as renewable energy sources such as wind energy, solar energy, and biomass. These energy sources can be transported as is or converted into other forms of energy carriers. Table 1 shows information on the energy carriers considered in this study. The energy carriers considered in this study of fossil fuels transported as primary energy sources, hydrogen for transporting renewable energy, and hydrogen carriers for efficient transport of hydrogen. Among them, hydrogen is the most important material and serves as an intermediate for transportation with high energy density. However, hydrogen has a low density, making it difficult to transport. Therefore, convertible materials were considered to facilitate transportation of hydrogen from energy resources: ammonia, methanol, methyl cyclohexane (MCH), perhydro dibenzyl toluene (H<sub>18</sub>-DBT).

**Table 1:** Energy carrier for hydrogen transportation system.

Transportable primary energy source	
Coal	
Crude oil	
Natural gas	
Biomass	
Converted energy carrier	
Converted energy carrier	Description
Hydrogen	H <sub>2</sub>
Methanol	CH <sub>3</sub> OH
Ammonia	NH <sub>3</sub>
Methyl cyclohexane	C <sub>7</sub> H <sub>14</sub>
H <sub>18</sub> -Dibenzyl toluene	C <sub>21</sub> H <sub>38</sub>

### Process Analysis Method

In this study, the techno-economic and environmental feasibility was evaluated using the process

performance indicators such as EEF, LCOE and NCE.

To determine technical aspects of hydrogen energy transportation pathways, EEF serves as an assessment indicator. EEF is expressed as the ratio of transported energy to the total of primary energy and utility consumption for conversion, as shown in Eq (1).

$$EEF = \frac{\text{Transported Energy}}{\text{Primary energy source} + \text{Utilities}} \times 100 (\%) \quad (1)$$

To compare economic performance of the hydrogen energy transportation pathways, the LCOE was used as an indicator. The LCOE is calculated using annualized capital investment (ACI) and total operating cost (TOC) and transported energy as shown in Eq (2).

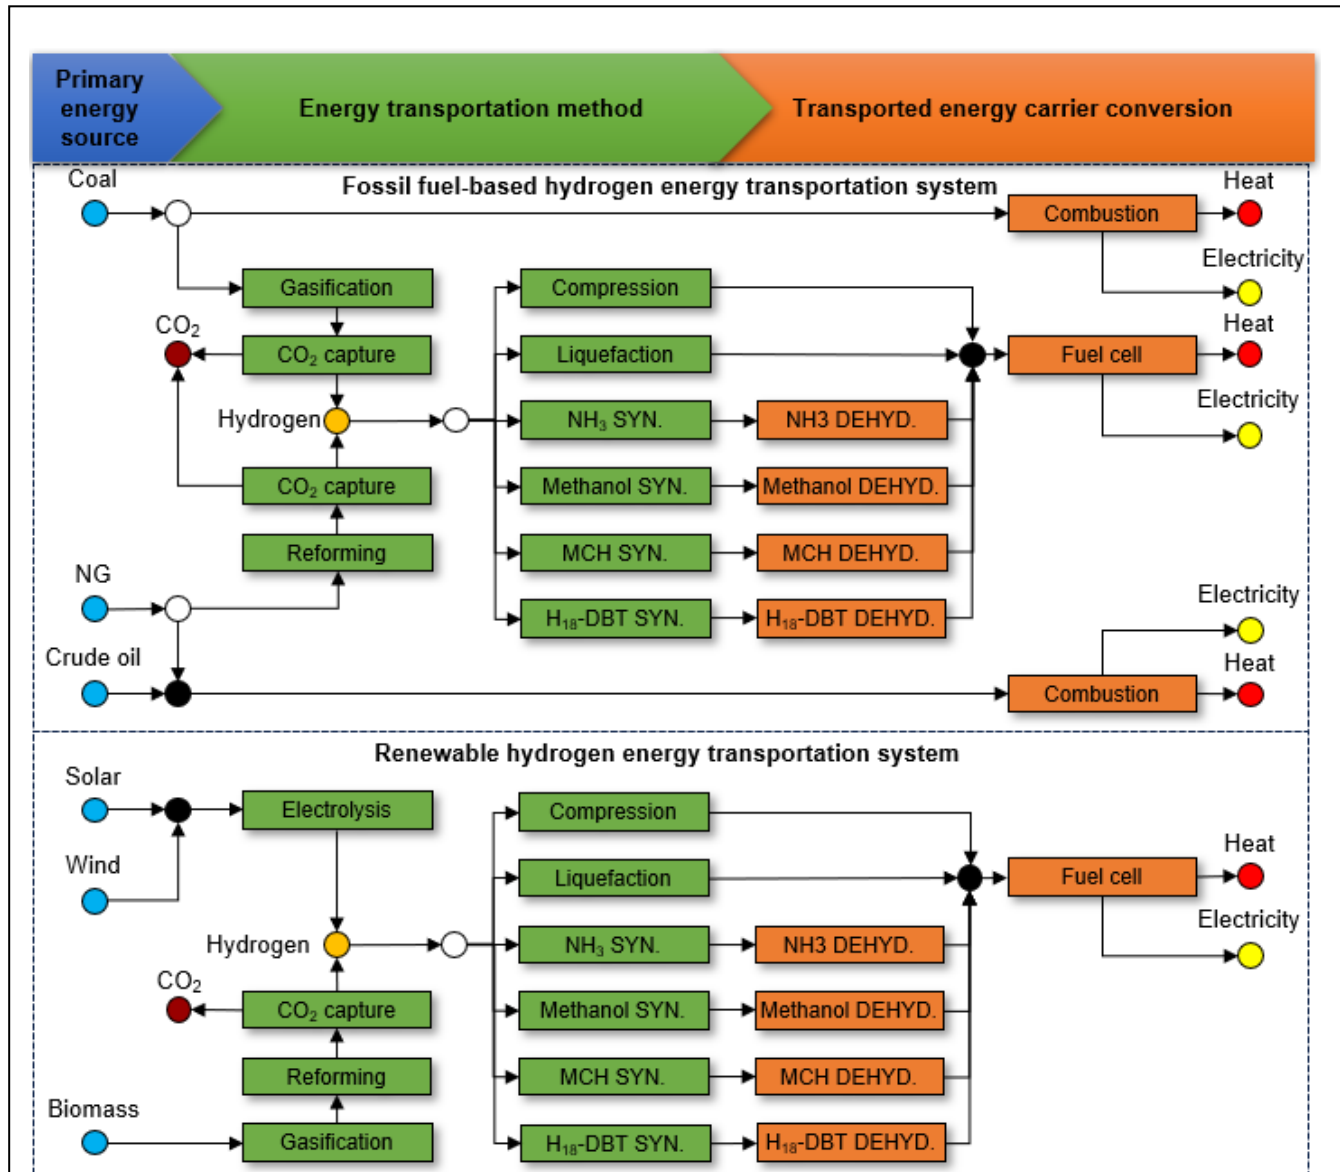

$$LCOE(\frac{\$}{kWh}) = \frac{ACI + TOC}{\text{Transported energy}} \quad (2)$$

ACI is an amortized cost of the capital expenditure (CAPEX), which is specified using a straightforward depreciation method, as shown in Eq. (3). The TOC consists of the primary energy source and utility cost which is specified Eq. (4).

$$ACI = CAPEX \times \frac{\text{interest rate} (1 + \text{interest rate})^{\text{lifetime}}}{(1 + \text{interest rate})^{\text{lifetime}} - 1} \quad (3)$$

$$TOC = \text{Raw material cost} + \text{Utility cost} \quad (4)$$

To assess the environmental performance of the

**Figure 2:** Superstructure of fossil fuel-based and renewable energy transportation system, NG: natural gas, MCH: methyl cyclohexane, H<sub>18</sub>-DBT: perhydro dibenzyl toluene, SYN.: synthesis process, DEHYD.: dehydrogenation process [5-10].

hydrogen energy transportation pathways, the NCE was calculated by including two different indicators to CO<sub>2</sub> emissions. First, the direct emission was GHGs (CO<sub>2</sub>, CH<sub>4</sub>) that are emitted directly through the exhaust and tail gas during process operation. The second is indirect emissions from the usage of utilities, during the process. Thus, the NCE as an environmental indicator is expressed as the total CO<sub>2</sub> emission per transported energy, as shown in Eq. (5).

$$NCE = \frac{\text{Direct emission} + \text{Indirect emission (kg CO}_2\text{-eq)}}{\text{Transported energy}} \quad (5)$$

### 3. RESULT AND DISCUSSION

#### Superstructure Development

As mentioned above, this study developed superstructure for energy transportation method. We developed two hydrogen energy transportation systems, illustrated in Fig 2: fossil fuel-based energy transportation system, renewable energy transportation system. In the case of fossil fuel-based hydrogen transportation systems, both direct transportation primary energy source and transportation via hydrogen are viable options. The pathway that converts fossil fuels into hydrogen and transport will benefit in terms of transport mass due to the high energy density of hydrogen and is expected to have better environmental performance by using the CO<sub>2</sub> capture process. Hydrogen-based energy carriers are essential to transport renewable energy. There are two reasons for this: the form of energy generated from wind or solar energy is electricity, and the low energy density of biomass.

In this study, a technical information investigation was conducted based on the developed superstructure to build a database. It is used for process simulation and techno-economic analysis through investigation of the operating conditions, raw material prices, and energy consumption of each unit process.

#### Process Development

In this study, we developed hydrogen production, storage and refueling process models were developed using Aspen Plus V12.0 according to hydrogen transportation superstructure. The information of each unit process is summarized in Table 2. It was assumed that each pathway feeds the same amount of energy based on the primary energy source.

The hydrogen transport pathway was modeled through synthesis between each unit process, mass and energy balance were derived. In addition, a techno-economic analysis is performed using process equipment sizing and costing data within Aspen Economic Analyzer based on mass and energy balance. In the separation and purification technologies, the pressure swing adsorption (PSA) amine-based CO<sub>2</sub> capture process, distillation

column and air separation unit (ASU) are mainly adopted for efficient each hydrogen transportation pathway.

**Table 2:** Unit process information for hydrogen energy transportation pathways [5-11].

Unit process	Operating conditions (°C, bar)
Coal gasification	700-1200, 30
Natural gas reforming	700-900, 1
Water gas shift	170-350, 1
CO <sub>2</sub> capture process	40, 1
H <sub>2</sub> liquefaction	-253, 20
Liquid H <sub>2</sub> vaporization	40, 30
NH <sub>3</sub> synthesis	300-350, 100-350
NH <sub>3</sub> dehydrogenation	500, 1
Methanol synthesis	220-250, 50
Methanol dehydrogenation	420, 1
MCH synthesis	210-280, 20
MCH dehydrogenation	320, 1
H <sub>18</sub> -DBT synthesis	150-270, 50
H <sub>18</sub> -DBT dehydrogenation	310, 1
Biomass gasification	450-800, 1

#### Comparative Analysis

Based on the technical, economic, and environmental parameters derived from the previous process simulation part, a techno-economic analysis was performed to compare and evaluate each hydrogen transportation pathway. As expected, the conventional system for directly transporting fossil fuels has the best efficiency and economic performance for obtaining electricity and thermal energy. The pathway with the economic feasibility compared to these direct fossil fuel transportation methods is natural gas-based hydrogen production and transportation through MCH (0.15 \$/GJ). Hydrogen production using natural gas is currently a representative method of producing hydrogen at the lowest cost, and the MCH hydrogen storage process also shows the best indicator for cost-effective hydrogen transportation with low energy consumption. Additionally, the pathway from an environmental perspective is to produce hydrogen from solar and wind electricity and then transport the hydrogen using H<sub>18</sub>-DBT. Although this has low economic feasibility due to the price of raw materials, it has the best performance among hydrogen transportation methods in terms of energy consumption, showing the lowest value in terms of NCE due to less use of additional utilities.

### 4. CONCLUSIONS

In this study, we proposed of most economic or environmental pathways in hydrogen energy transportation systems using it for process performance criteria: LCOE and NCE. This was achieved through process synthesis and evaluation based on hydrogen energy transportation superstructure, and the effect on the application of the hydrogen energy system was shown. The major findings from this study as follows:

- To derive the optimal hydrogen energy

transportation pathway according to evaluation standard, process synthesis for energy transport is performed to derive mass and energy balance.

- We conducted techno-economic analysis and derived cost-effective hydrogen transportation method as natural gas-based hydrogen transport to MCH.
- The environmentally best transportation pathway was found to be transporting renewable electricity-based hydrogen as H<sub>18</sub>-DBT.

In summary, we identified the hydrogen transportation pathway using organic compound is promising energy transportation pathways. As future work, we will expand the scope of energy transportation technologically, geographically, and policy-wise. In addition, we will derive major cost drivers of energy transportation through sensitivity analysis after the development of the energy transportation system and propose energy transportation system strategies through various scenario-based analysis.

## ABSTRACT

Post-combustion carbon capture technologies have the potential to contribute significantly to achieving the environmental goals of reducing CO<sub>2</sub> emissions in the short term. However, these technologies are energy and cost-intensive, and the variability of flue gas represents important challenges. The optimal design and optimization of such systems are critical to reaching the net zero and net negative goals, in this context, the use of computer-aided process design can be very effective in overcoming these issues. In this study, we explore the implementation of carbon capture technologies within an industrial complex, by considering the pooling of CO<sub>2</sub> streams. We present an optimization formulation to design carbon capture plants with the goal of enhancing efficiency and minimizing the capture costs. Capital and operating costs are represented via surrogate models (SMs) that are trained using rigorous process models in Aspen Plus, each data point is obtained by solving an optimization problem in Aspen Plus equation-oriented approach. Since selecting the functional form of the surrogate model is crucial for the solution performance; we study different SM approaches (i.e., ALAMO, kriging, radial basis function, polynomials, and artificial neural networks) and analyze their impact on solver performance. Numerical results show the computational advantage of using ALAMO while highlighting the increased complexity of using ANN and kriging to formulate optimization problems. Regarding the pooling of CO<sub>2</sub> streams, the optimal designs for the network are not trivial, thus showing the importance of addressing the problem systematically.

## INTRODUCTION

Climate change and global warming are relevant issues that we need to face as a society. In particular, the mitigation of CO<sub>2</sub> emissions is crucial to reduce its high atmospheric concentration, which exceeds 50% of pre-industrial era levels and has recently reached a historical maximum concentration of 424 ppm [1].

Carbon capture strategies play a crucial role in most decarbonization pathways, which seek a net-zero emission future to limit the global average temperature rise to below 1.5 °C [2]. These approaches allow retrofitting of power generation and industrial plants in the short and

medium term. Therefore, carbon capture plants can be installed in industrial complexes to reduce CO<sub>2</sub> emissions of the existing facilities, with minor structural modifications in the production process. Currently, CO<sub>2</sub> absorption using amine solvents is the most developed and reliable technology and it has been tested at an industrial scale for post-combustion processes [3]. However, industrial complexes can include several CO<sub>2</sub> streams to be captured (with different CO<sub>2</sub> flowrates and concentrations), and the implementation of post-combustion technologies for each point source in an industrial pole is challenging due to investment costs and operational complexity. Moreover, even one production process can

include several CO<sub>2</sub> point sources, where their mass flowrates and CO<sub>2</sub> concentrations can differ significantly.

An alternative approach involves the pooling of CO<sub>2</sub> streams from various point sources to optimize the distribution and mixture of CO<sub>2</sub> streams within a specific industrial complex. In this way, the total capture cost for the industries can be reduced, while the application of carbon capture is promoted. When engineering this approach, the problem of mixing the streams and designing carbon capture plants must be addressed systematically, using current knowledge and advances in optimization techniques [4,5].

In order to assist decision-making in the design of the carbon capture plants for a given set of point sources, pooling optimization problems could be formulated. The main decision variables are associated with capture plant capacities, CO<sub>2</sub> concentrations of their flue gas streams, and their CO<sub>2</sub> recoveries. Regarding the calculation of economic and performance metrics of the plants based on these variables, rigorous models are generally required to obtain accurate estimations [6], but including such rigorous models in the problem formulation represents numerical challenges.

Surrogate models (SMs) can help to overcome the numerical issues. In this case, SMs can be used to estimate capital and operating costs for carbon capture plants from the main decision variables, replacing the need for the rigorous CCS model. SMs are simplified approximations capable of estimating output data from a set of input variables, demanding negligible CPU resources. In addition, the mathematical expressions of relevant SMs are compatible with an equation-oriented optimization environment, which enables the use of advanced optimization solvers.

However, the accuracy of the RMs could affect the quality of the optimal solution, and their algebraic forms influence the efficiency of the solution algorithm.

Each surrogate model class offers unique advantages and may be chosen based on the specific requirements of the problem, such as the available data, computational resources, target accuracy, computational efficiency, and the complexity of the studied system. Polynomials are commonly used as reduced models that provide a straightforward and interpretable approach. Radial Basis Functions (RBFs), characterized by their reliance on distance from a central point, can represent complex nonlinear relationships in data, particularly in systems with localized behavior patterns [7]. Kriging is a geostatistical technique used for spatial interpolation and prediction [8,9]. It stands out as a robust prediction method, estimating system responses while considering spatial correlations in scattered or noisy data. Automated Learning and Advanced Modeling for Optimization (ALAMO) facilitates the creation of surrogate models, relying on techniques like linear regression and decision trees

[10]. Finally, Artificial Neural Networks (ANNs) show efficacy in capturing complex data relationships, making them useful for function approximation and pattern recognition [11].

This study considers the impact of using different SMs for the formulation of the CO<sub>2</sub> stream pooling problem. In particular, we use the IDAES computational platform [5,12] to test: i) ALAMO-based SMs, ii) Kriging SMs (PySMO), iii) Radial basis function SMs (PySMO), iv) Polynomials (PySMO), and artificial neural networks (ANN) SMs (Keras).

We compare the surrogate model performances for prediction and for the formulation of optimization problems. This analysis provides insights into efficient ways of including SMs to formulate optimization problems and to elucidate the advantages and limitations of using specific SMs.

## METHODOLOGY

### Formulation of the pooling problem

In this section, we address the mathematical formulation of CO<sub>2</sub> stream pooling problems for carbon capture plant design in industrial complexes with various CO<sub>2</sub> point sources. This problem can be tackled by formulating a nonlinear programming (NLP) approach, as shown in problem (1). We are given a set of point sources  $s \in S$ , with their respective CO<sub>2</sub> mass flowrates ( $F_s^{in}$ ) and molar fractions ( $x_s^{in,CO_2}$ ), and we can design a set of carbon capture plants  $p \in P$ , to achieve a global CO<sub>2</sub> recovery of 90 %. In this problem, we need to design a network to blend CO<sub>2</sub> streams for further treatment. So, important decision variables for the network are the mass flowrates ( $F_{s,p}$ ) from a CO<sub>2</sub> point source  $s$  to the carbon capture plant  $p$ . The capture plants are designed by considering three key decision variables, which are the plant capacity ( $C_p$ ), the CO<sub>2</sub> molar fraction of their input stream ( $x_p^{CO_2}$ ), and the number of transfer units ( $NTU_p$ ).

The objective is to minimize the cost of capture (1.1), and we calculate this metric from the total annualized capital cost (which is obtained from the product between the total capital cost,  $CAPEX^t$ , and the annualization factor,  $\phi$ ), the total operating cost ( $OPEX^t$ ), and the total captured carbon dioxide ( $CO_2^t$ ). In Eq. (1.2), we set constraints for the maximum amount of CO<sub>2</sub> ( $F_s^{in}$ ) from source  $s$ . In Eq. (1.3), we include mass balances for the streams fed to plant  $p$ . In Eq. (1.4), we calculate the CO<sub>2</sub> molar fraction ( $x_p^{CO_2}$ ) of the input stream to plant  $p$ , from the features of the blended streams. Eqs. (1.5) and (1.6) represent the surrogate model function correlating operating ( $OPEX_p$ ) and capital cost ( $CAPEX_p$ ) for each plant with the control variables, which are the plant capacity, CO<sub>2</sub> molar flow, and number of transfer units. This last variable is directly related to the CO<sub>2</sub> recovery ( $rec_p$ ), and it is shown in Eq.

(1.7). Using this transformation, we reduce the complexity associated with collinearity in parametric surrogate models [13]. In Eq. (1.8) and (1.9), we calculate the total operating ( $OPEX^t$ ) and capital costs ( $CAPEX^t$ ) by the summation of individual plant costs, and the cost related to the gas distribution. In this context, the functions  $f^{Od}$  and  $f^{Cd}$  determine the operating and capital costs associated with the utilization of blowers to send the flue gases from point sources to the capture plants.  $f^{Od}$  and  $f^{Cd}$  are based on unit models for pressure changes, which are described in the literature [14]. In Eq. (1.10), we calculate the total captured carbon dioxide ( $CO_2^t$ ) considering all plants, and we add a constraint to ensure a minimum global  $CO_2$  recovery of 90 % in Eq. (1.11). Finally, Eqs. (1.12)-(1.14) are the bounds on the main decision variables for designing the plants.

$$\min \frac{\phi CAPEX^t + OPEX^t}{CO_2^t} \quad (1.1)$$

$$s. t. F_s^{in} \geq \sum_{p \in P} F_{s,p} \quad s \in S \quad (1.2)$$

$$\sum_{s \in S} F_{s,p} = C_p \quad p \in P \quad (1.3)$$

$$x_p^{CO_2} \sum_s \frac{F_{s,p}}{x_s^{in,CO_2}} = C_p \quad p \in P \quad (1.4)$$

$$OPEX_p = f^O(C_p, x_p^{CO_2}, NTU_p) \quad p \in P \quad (1.5)$$

$$CAPEX_p = f^C(C_p, x_p^{CO_2}, NTU_p) \quad p \in P \quad (1.6)$$

$$rec_p = (1 - e^{-NTU_p}) \quad p \in P \quad (1.7)$$

$$\sum_{p \in P} OPEX_p + \sum_{s,p} f^{Od}(F_{s,p}) = OPEX^t \quad (1.8)$$

$$\sum_{p \in P} CAPEX_p + \sum_{s,p} f^{Cd}(F_{s,p}) = CAPEX^t \quad (1.9)$$

$$CO_2^t = \sum_{p \in P} C_p rec_p \quad (1.10)$$

$$CO_2^t \geq 0.9 \sum_i F_s^{in} \quad (1.11)$$

$$C_p \leq 1 \quad p \in P \quad (1.12)$$

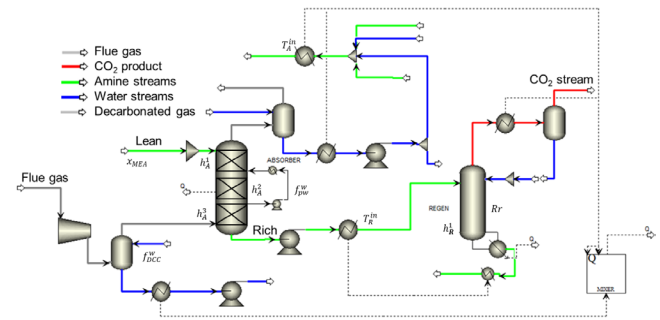

$$0.03 \leq x_p^{CO_2} \leq 0.4 \quad p \in P \quad (1.13)$$

$$0.8 \leq rec_p \leq 0.99 \quad p \in P \quad (1.14)$$

## Carbon capture process

In this study, we consider the conventional absorption-based process with intercooling using mono-ethanolamine (MEA) solvent, which is a well-established technology that serves as a baseline for comparison purposes. We developed a rigorous model for the MEA-based carbon capture process using templates from the Carbon Capture Simulation Initiative (CCSI), as discussed in [6]. The model is implemented in Aspen Plus, employing the electrolyte NRTL thermodynamic framework and incorporating specific interaction parameters derived from experimental data. The process flowsheet, see Figure 1, features a blower and direct contact cooler for flue

gas preconditioning, an absorber with a pump-around system, and a stripping column for solvent regeneration. The “Rich” amine stream from the absorber undergoes heating in a heat exchanger before entering the stripping column, where  $CO_2$  separation from the solvent occurs. The resulting  $CO_2$  product stream and regenerated solvent are obtained from the top and bottom of the stripping column, respectively. The Aspen Plus model is solved using the equation-oriented (EO) mode, in order to leverage the EO optimization features that are available in the software. In this way, the convergence properties of the model improve significantly [6]. Therefore, data generated to train the surrogate models with this method correspond to optimization runs.

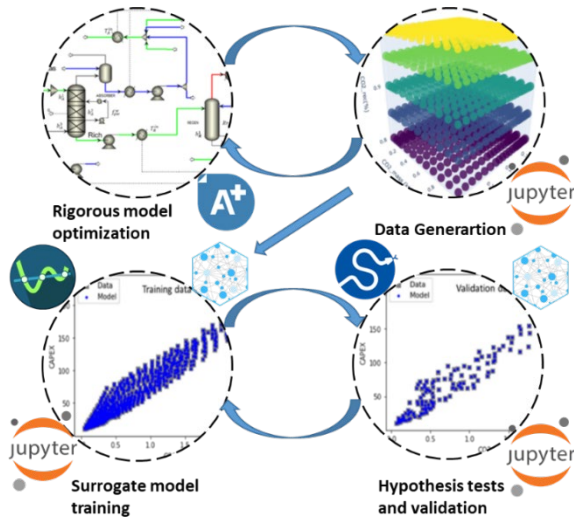

**Figure 1:** Aspen Plus® flowsheet for the carbon capture process

## Surrogate modeling approaches

We build surrogate models generated from optimization runs using the Aspen Plus® rigorous model described earlier. Constructing surrogate models requires a substantial amount of high-quality data points from rigorous models, and running each sample point manually is an inefficient method due to the time-consuming nature of data generation. Therefore, we developed a framework for automated optimization and simulation using the rigorous model [13], and integrating various computational platforms, as shown in Fig. 2. In this work, we employ three input variables (inlet  $CO_2$  mass flowrate in the flue gas, inlet  $CO_2$  mole fraction, and number of transfer units) to generate SMs for the calculation of logarithmic transformations of CAPEX and OPEX. In this case, using log-transformed output variables improves the residual patterns for the parametric SMs [15].

The IDAES computational platform [12] is employed for surrogate model generation, exploiting its capabilities for efficient data splitting (training and validation), different surrogate modeling approaches, and straightforward post-processing analysis (including the generation of 2D scatter plots and calculating fitting metrics).

**Figure 2:** Software workflow between Aspen, Python environments (SciPy, IDAES), and ALAMO in Jupyter Notebook

In order to assess the effect of the functional form of the surrogate model on the solution performance, we examine various surrogate models (SMs) ideas. This work includes surrogate models based on ALAMO (Automatic Learning of Algebraic Models for Optimization), PySMO (Python Surrogate Modeling Toolbox), and Tensorflow Keras.

ALAMO is a powerful tool for surrogate modeling [10]. ALAMO specializes in employing advanced algorithms to select appropriate basis functions and model parameters simultaneously. In this way, it identifies essential features and relationships within datasets. Additionally, ALAMO takes advantage of advanced optimization techniques to perform automated sampling. The AlamoPy application enables the use of this tool through Python code, facilitating post-processing tasks, like generating 2D scatter plots and calculating fitting metrics.

PySMO is a versatile and powerful tool to aid in the creation of surrogate models, offering a range of functionalities for efficient data analysis. The toolbox facilitates the integration of these surrogate models into optimization frameworks, enhancing the overall efficiency of computational processes. It supports the generation of surrogate models using various techniques, including kriging, Radial basis functions (RBF), and polynomials. In this work, we generate kriging and radial basis functions considering the regularization option to handle noise in data and to improve the smoothness of the curve. For RBF, we consider cubic basis transformation. For polynomials, we set a maximum polynomial order of four, including bilinear terms.

Tensorflow Keras is a user-friendly tool designed to simplify the implementation of artificial neural networks (ANNs). As an integral component of the Python ecosystem, Keras provides an intuitive interface for

constructing, training, and deploying neural networks. Its flexibility and modularity make it suitable for various applications, including surrogate modeling. We leverage Keras to develop ANN-based surrogate models, benefiting from its capabilities for efficient data analysis and optimization. We consider one hidden layer and hyperbolic tangent activation functions. The integration of the Keras ANN into the optimization formulation is done by using the toolkit OMLT (Optimization and Machine Learning Toolkit) [16].

## CASE STUDY

In this work, we consider the application of carbon capture to an iron and steel complex, which includes several point sources. The manufacturing process includes three main sectors: iron production, steel production, and a mini mill; producing 5 million tons of steel annually [17].

**Table 1:** CO<sub>2</sub> streams for iron and steel production [17,18]

	Notation	Flowrate of CO <sub>2</sub> (Mt/y)	CO <sub>2</sub> content (mol%)
Iron production			
Power plant stack	S0	3.69	23
Coke ovens gas	S1	1.73	27
Blast furnace	S2	1.94	21
Sinter plant stack	S3	1.67	8
Steel production			
BOF stack	S4	0.28	15
Hot strip mill stack	S5	0.14	7
Plate mill stack	S6	0.60	7
Lime kiln stack	S7	0.05	7
Mini mill			
Electric arc furnace off gas	S8	0.11	40

The blast furnace, fueled by coke from the coke oven, facilitates the reduction of iron ore to molten iron. CO<sub>2</sub> emissions originate from various sources, including coke oven gas generated during coal heating, ore preparation, and the basic oxygen steelmaking unit responsible for reducing carbon in pig iron. The plant is highly integrated, utilizing most blast furnaces and coke oven gases as low-grade fuel for the sinter plant, blast furnace stoves, and lime kiln. Table 1 shows detailed information on CO<sub>2</sub> emission sources within the process.

## OPTIMIZATION RESULTS

In this section, we discuss the results associated with surrogate model fitting and their efficiency within optimization formulation. The problems were implemented in Pyomo [19] and run with IPOPT [20], using the multistart strategy.

**Table 2:** CAPEX surrogate model fitting metrics.

CAPEX	R <sup>2</sup>	Mean squared error	Mean rel. error (%)	Max. rel. error (%)
ALAMO Training data	0.9987	1.02·10 <sup>-3</sup>	0.1411	0.6416
ALAMO Validation data	0.9986	1.13·10 <sup>-3</sup>	0.1442	0.6510
Polynomials Training data	0.9964	2.93·10 <sup>-3</sup>	0.2360	1.2025
Polynomials Validation data	0.9953	3.72·10 <sup>-3</sup>	0.2707	1.2503
RBF Training data	1.0000	1.13·10 <sup>-6</sup>	0.0030	0.0478
RBF Validation data	0.9999	1.10·10 <sup>-4</sup>	0.0357	0.3664
Kriging Training data	1.0000	3.02·10 <sup>-5</sup>	0.0221	0.1750
Kriging Validation data	0.9999	6.52·10 <sup>-5</sup>	0.0274	0.3303
ANN Training data	0.9997	2.56·10 <sup>-4</sup>	0.0684	0.4983
ANN Validation data	0.9996	2.88·10 <sup>-4</sup>	0.0726	0.4499

The computational experiments were performed on an Intel(R) Core(TM) i5-8250U CPU @1.80 GHz and 12 GB RAM. It should be mentioned that the problems were solved using the option "limited-memory" to approximate the Hessian of the Lagrangian using a quasi-Newton method; we observe that this enhances the convergence of the multistart strategy. Approximating the Hessian by this quasi-Newton approach ensures positive definite matrices, thus avoiding potential issues related to the use

of highly nonlinear functions and random initial guesses in the domain.

**Table 3:** OPEX surrogate model fitting metrics

OPEX	R <sup>2</sup>	Mean squared error	Mean rel. error (%)	Max. rel. error (%)
ALAMO Training data	0.9998	1.35·10 <sup>-4</sup>	0.0553	0.2986
ALAMO Validation data	0.9998	1.61·10 <sup>-4</sup>	0.0606	0.3008
Polynomials Training data	0.9979	1.77·10 <sup>-3</sup>	0.2313	0.7236
Polynomials Validation data	0.9975	2.04·10 <sup>-3</sup>	0.2448	0.8448
RBF Training data	1.0000	6.54·10 <sup>-7</sup>	0.0029	0.0479
RBF Validation data	0.9999	9.77·10 <sup>-5</sup>	0.0388	0.2848
Kriging Training data	1.0000	2.89·10 <sup>-5</sup>	0.0239	0.2351
Kriging Validation data	0.9999	4.92·10 <sup>-5</sup>	0.0310	0.2575
ANN Training data	0.9999	9.77·10 <sup>-5</sup>	0.0477	0.3056
ANN Validation data	0.9999	8.89·10 <sup>-5</sup>	0.0463	0.2822

Tables 2 and 3 show key statistical metrics for the CAPEX and OPEX surrogate models, respectively. In particular, the R<sup>2</sup> coefficients surpass 0.995, and the mean squared errors and mean relative errors exhibit consistency between training and validation data, for all surrogate modeling approaches. Only RBF-based SMs show important differences between the training and the validation data, however, the errors for the validation sets are still quite low, as compared to the other approaches. These results show that the selected approaches can fit the target set of data points accurately, to predict the log transformations of CAPEX and OPEX from the main input variables (CO<sub>2</sub> mass flowrate in the flue gas, CO<sub>2</sub> mole fraction, and NTU). It is highlighted that the ALAMO and

Polynomials approaches could present important errors (>50 %) when data is not transformed; in contrast, RBF, kriging, and ANN exhibit superior fitting capacity across diverse datasets. As observed in Tables 2 and 3, polynomial surrogate models yield the highest maximum relative errors (approximately 1.2% and 0.8% for CAPEX and OPEX, respectively). ALAMO and ANN models present relatively similar accuracy, with ANN exhibiting slightly superior indicators compared to ALAMO. In particular, the RBF approach has the best accuracy metrics, closely followed by Kriging surrogate models, indicating the fit capacity of these approaches.

Regarding optimization results using the different surrogate modeling approaches, Table 4 shows the main results. These results correspond to solving the optimization problem by considering 50 different initial guesses to increase the possibility of finding the global optimum.

The problem size of the NLP formulation is the same for the different cases, except when using ANN. We observe that the number of variables increases by 336 % for this case due to the additional variables in the hidden layer. On the other hand, no additional variables are required for the other surrogate model approaches.

CPU times show that ALAMO-based SM formulation is the most efficient strategy, requiring only 47 s to solve the problem with the multistart strategy. Using polynomials is the second most efficient approach, but it increases CPU time by 78 % with respect to the case of using ALAMO. On the other hand, the Kriging-based SM is the one that demands the highest CPU time, indicating the effect of using this highly nonlinear approach. Although the NLP formulation using ANNs has the most equations, it demands 30% lower CPU time, as compared to the use of Kriging.

The objective function values are also shown in Table 4. The lowest objective function is found when using RBF-based SM, and the highest value corresponds to the case of using ALAMO. However, the differences in the objective functions are lower than 3.7 %, suggesting no significant differences in the carbon capture cost obtained when using different surrogate modeling approaches.

In terms of the specific configurations resulting from the optimization process across different approaches, diverse pooling strategies result, based on the surrogate models. It is important to note that the pooling problem exhibits multiple optimal solutions, and in some instances, differences between them may not be substantial. Nevertheless, there are key ideas that are consistent in the solutions, and one of them is the use of a percentage of the point sources to achieve the 90 % target recovery, as detailed in Table 4. Point sources S0-S2, S4, and S8 are fully utilized in all cases due to their high CO<sub>2</sub> concentration. As S3 also presents a relatively high concentration of CO<sub>2</sub>, it is nearly fully employed across all

cases except in the scenario involving polynomial-based SMs, where it is completely used. On the other hand, given the relatively low CO<sub>2</sub> concentration in S5, S6, and S7, they are generally excluded from the CO<sub>2</sub> stream pooling, except when formulating the problem using polynomials, where 50% of S6 is utilized. We note that the constraint of achieving a minimum CO<sub>2</sub> recovery of 90% is active in all cases.

**Table 4:** Main results from the NLP optimization using different surrogate approaches

	Alamo	Polynomials	RBF	Kriging	ANN
N° de vars.	586	586	586	586	2533

### ALAMO solution

Given the efficiency of ALAMO surrogate models, we have selected this approach to present the optimization results. The optimal pooling of CO<sub>2</sub> streams for carbon capture purposes is shown in Fig. 3. We observe that some point sources are higher than the maximum plant capacity (see Eq. (1.12)); therefore, they could be sent to more than one plant. In Fig. 3, we also show the percentage distribution of each point source. In particular, point sources S2 and S3 are fed to 5 and 4 plants, respectively. Although each point source could be treated in two plants, numerical results suggest that these arrangements allow an improved capture cost. These could be associated with avoiding the design of plants operating with low CO<sub>2</sub> concentrations.

We also show the input variables associated with the design of each plant in Fig. 3. It is observed that two kinds of designs are selected to achieve the recovery target. On the one hand, p<sub>0</sub>, p<sub>3</sub>, p<sub>5</sub>, and p<sub>9</sub> operate with CO<sub>2</sub> concentrations of 0.095-0.102, CO<sub>2</sub> mass flowrates of 0.6Mt/y, and recoveries around 94 %. On the other hand, the remaining plants are designed to function with high CO<sub>2</sub> concentrations (0.21-0.28), while the resulting CO<sub>2</sub>

mass flowrate and CO<sub>2</sub> recovery are at their respective upper bounds (1 Mt/y and 99 %).

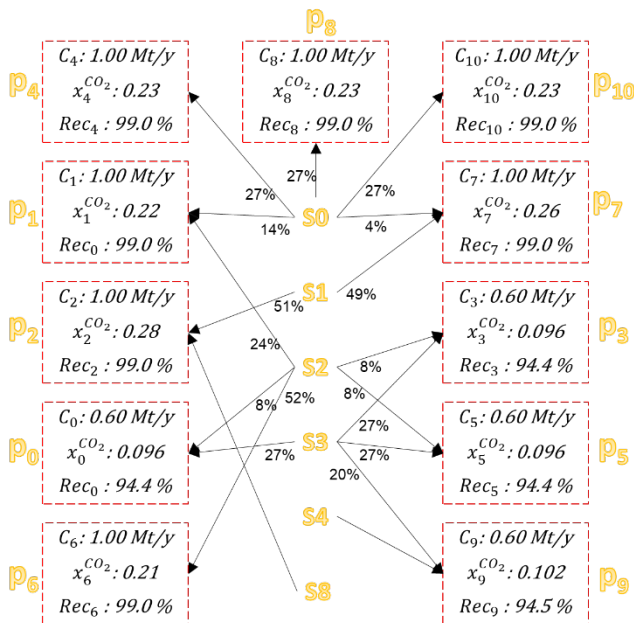

Figure 3: Optimal solution of the CO<sub>2</sub> streams pooling problem using ALAMO-based surrogate models. **p** and **S** correspond to the carbon capture plants and point sources (see references in Table 4), respectively.

## CONCLUSIONS

In this work, we evaluate different surrogate models (SMs) for formulating CO<sub>2</sub> stream pooling problems using the IDAES computational platform. We explore ALAMO-based SMs, Kriging SMs, Radial Basis Function SMs, Polynomials, and Artificial Neural Networks. ALAMO-based SMs prove the most efficient, with significantly lower CPU time. Despite differences in process configurations among the SMs, the impact on capture cost is minimal (below 3.7%). The optimal results associated with pooling configuration change with the surrogate modeling approach, but key ideas, like using high CO<sub>2</sub> concentration sources and maintaining a 90% recovery target, remain consistent across all cases.

## ABSTRACT

An important measure to achieve global reduction in CO<sub>2</sub> emissions is CO<sub>2</sub> capture, transport, and storage. The deployment of CO<sub>2</sub> capture requires the development of a shared CO<sub>2</sub> transport infrastructure, where CO<sub>2</sub> can be transported with different transport modes. Furthermore, the cost of CO<sub>2</sub> transport can be subject to significant economies of scale effects with respect to the amount of CO<sub>2</sub> transported, also mentioned as clustering effects. Therefore, optimizing the shared infrastructure of multiple CO<sub>2</sub> sources can lead to significant reductions in infrastructure costs. This paper presents a novel formulation of the clustered CO<sub>2</sub> transport network. The Markov Decision Process formulation defined here allows for more detailed modeling of non-linear, discrete transport costs and increased geographical resolution. The clustering effects are modeled through cooperative multi-agent interactions. A multi-agent, reinforcement learning-based algorithm is proposed to optimize the shared transportation network, with examples illustrating the results of the method.

## INTRODUCTION

Reducing CO<sub>2</sub> emissions is crucial to limit the temperature increase due to global warming [1]. One important measure for reducing CO<sub>2</sub> emissions is CO<sub>2</sub> capture, transport, and storage (CCS). CCS can be coupled with various individual emission sources [2]. Among the most important considered emissions sources are thermal power generation, industrial facilities (*e.g.* cement plants or iron and steel mills [3]), as well as bioenergy production facilities [4] or direct air capture [5] to achieve net removal of CO<sub>2</sub> from the atmosphere. The rollout of CO<sub>2</sub> capture, independent of the source of the CO<sub>2</sub>, requires the concurrent development of a CO<sub>2</sub> transport infrastructure to the targeted CO<sub>2</sub> storage locations. CO<sub>2</sub> can typically be transported via pipelines, barges, ships, trains, and trucks; or combinations of these. The cost of CO<sub>2</sub> transport can experience significant economies of scale with respect to the amount of transported CO<sub>2</sub> [6]. Hence, developing a common CO<sub>2</sub> infrastructure with clustering of CO<sub>2</sub> from different sources can reduce the cost for each individual actor. This is especially important for industries in which smaller

amounts of CO<sub>2</sub> are captured and/or that are located far from the desired storage location.

The implementation of CCS in the different sectors is frequently analyzed using large-scale (mixed integer) linear optimization problem, both individually [7], focusing on a single sector [8], or combined with the analysis of the decarbonization of the complete energy system [9]. These models face in general however two problems; First, it is difficult to include economies of scale due to the linear description of transport cost. Second, all geographical nodes must be defined before the optimization. The latter is especially important when considering the clustering of individual CO<sub>2</sub> sources to utilize economies of scale. In these models, transport of CO<sub>2</sub> and change of transport mode is only possible in predefined geographical nodes. One approach to solving the problem is utilized by Sunny et al. [8], where a regular grid is superimposed on the investigated region. Correspondingly, the model includes the whole region, allowing for both utilization of economies of scale and change of transport mode. However, the inclusion of a regular grid and binary investments in technologies to include economies of scale complicates the problem, resulting in a

reduced geographic resolution.

This study presents a reinforcement learning approach to determining optimal multi-modal transport networks. The novelty of this work is threefold. First, while most of the literature on CCUS for network deployment focuses on onshore CO<sub>2</sub> pipelines as a mean of transport [10][11], the present work includes tanked-based CO<sub>2</sub> transport options (such as trucks, trains, and barges), which are now expected to play a more significant role in CCUS deployment than a few years ago [12]. Secondly, as the costs of pipeline- and tanked-based transport are significantly non-linear despite most of the literature linearizing it, at least by part, a new methodology is proposed to reduce the computational complexity of the large-scale MINLP transportation problem. Thirdly, as such network developments are unlikely to involve only one agent, the methodology incorporates a multi-agent perspective for cooperative agents that minimizes the overall transportation network costs to account for the economies of scale effects. The method utilizes the concept of regular grids on a geographic region but allows for a higher geographical resolution as it focuses exclusively on the potential CO<sub>2</sub> transport network without considering time. It can be utilized for identifying geographical nodes that should be included in large-scale optimization problems.

## METHOD

### Problem Description

Multi-modality and accommodating for detailed geographical resolution increase the solution space significantly and may affect the numerical tractability of the algorithm. Furthermore, transport costs are, in general, not linear with respect to the transport distance and volume. Therefore, non-linear, and discrete costs should be considered in the method. Finally, CO<sub>2</sub> transported from a capture site to a storage location in limited amounts, while only considering a single source and single sink, will result in a high unit transportation cost. Assuming that there will be a significant amount of CO<sub>2</sub> to be transported from future capture sites, clustering multiple CO<sub>2</sub> sources, and designing a shared infrastructure may reduce transport costs drastically. Table 1 summarizes the CO<sub>2</sub> transport network problem addressed in the methodology proposed.

The multi-modality, the discrete, non-linear costs of the formulated transport problem, and the clustering potential will lead to a large-scale MINLP problem, which may lack numerical tractability and be difficult to solve. This paper proposes a multi-agent reinforcement learning-based approach to determine a minimum-cost CO<sub>2</sub> transportation network to circumvent the problem. Truck-based and pipeline-based transports are considered in this paper, though the method can be extended

to more transport modes. Furthermore, information about the amount and location of the transported CO<sub>2</sub> and the location of storage sites is needed. Detailed knowledge of geographical data on existing road networks and terrain can be easily incorporated into the method.

**Table 1:** CO<sub>2</sub> transport network problem description

Problem	Background	Effect
Multi-modality	Consideration of multiple transport modes	Large solution space
Detailed cost modeling	Non-linear and discrete costs for transport and re-conditioning	Complex objective function
Clustering	Considering multiple capture sites with a shared network to lower transport costs.	Multi-agent approach

### Environment

The environment is modeled as a graph  $G = (N, E)$ , where each node  $n \in N$  represents some geographic location and edges  $e \in E$  connect pairs of distinct nodes in the graph. This formulation allows for extendibility in environment representation, as geographical information can be added to each corresponding edge. When an edge connects two nodes corresponding to two different geographic locations, the edge represents some transport mode between them. The edges have data necessary to infer transportation costs, such as distance between nodes, and can incorporate information about terrain. When nodes connected by an edge are at the same location, however, the edge represents the conditioning of CO<sub>2</sub>. Conditioning of CO<sub>2</sub> is needed when a unit of CO<sub>2</sub> transitions from one transport mode to another. Furthermore, a conditioning cost is also applied to a unit of CO<sub>2</sub> when transitioning from a source node to a transport mode or from a transport mode to a sink node.

The nodes and edges in the graph are ordered in different layers. Each layer represents a single transport mode, and the layers are connected by directed edges for conditioning needed to change the transport mode. However, the used algorithm works for a general graph and is not dependent on a layer-structured environment.

### Optimal CO<sub>2</sub> Transport Network as an MDP

This paper proposes to frame the network optimization problem as a Dynamic Programming (DP) problem. DP refers to both a modeling framework and a solution method for sequential decision-making processes. The fundamental DP problem is a Markov Decision Process (MDP), which is described by discrete state transition

dynamics:

$$x_{k+1} = f_k(x_k, u_k), \quad k = 0, 1, \dots, N-1, \quad (1)$$

for a state  $x_k$  at time step  $k$  to transition to the subsequent state  $x_{k+1}$  given an input  $u_k$ . Each state corresponds to a specific node  $n$  in the network, indicating the agent's current location. The action  $u_k$  corresponds to an edge  $e$  that the agent chooses to traverse, representing either CO<sub>2</sub> transport or conditioning modeled as movement from one node to the other. The general MDP formulation allows for stochastic state transition dynamics. This study, however, neglects state transition stochasticity in the transport investment problem.

For every state transition, the agent incurs a stage cost:

$$g_k(x_k, u_k), \quad k = 0, 1, \dots, N-1, \quad (2)$$

and a terminal cost at the terminal state  $g_N(x_N)$ . The stage cost is given as feedback from the environment. As inputs  $u_k$  are applied and stage costs  $g_k$  are observed, the goal of DP is to minimize the cumulative costs over all time steps. These cumulative costs are expressed in the value function, subject to Bellman's principle of optimality [13]:

$$V = g_N(x_N) + \sum_{k=0}^{N-1} g_k(x_k, u_k). \quad (3)$$

The current problem is solved as steady-state problem. Each agent represents some total annual volume of transported CO<sub>2</sub> moving through the environment describing all possible transport paths from source (capture site) to multiple possible sinks (storage sites), but it is assumed that CO<sub>2</sub> is transported continuously over the year. DP provides a flexible mathematical framework to model sequential decision-making processes under relatively weak assumptions.

While DP algorithms can find the global optimum solution given non-linear and discrete costs, it often struggles with numerical tractability in large state-spaces (so-called "curse of dimensionality"). Approximate Dynamic Programming (ADP) is a family of algorithms derived from DP, which trade off global optimality for numerical tractability. ADP algorithms include reinforcement learning (RL) [14], the A\*-Algorithm [15], Model Predictive Control [16], and Stochastic Programming [17].

Understanding the problem posed in this paper as a DP problem allows for drawing on the rich methodological background to solve such problems. The DP framework can explicitly address modeling a higher geographical resolution, the multi-modality of CO<sub>2</sub> transport, and representing more complex investment costs.

## Multi-agent Approximate Dynamic Programming

The DP framework also offers a solution to model

volume-specific transportation cost decrease when the amount of CO<sub>2</sub> transported increases. These economies of scale effect is often shown in pipeline investments, where building a pipeline with an increased diameter is less costly than building two separate pipelines with smaller diameters to transport the same flow. This effect is also described in minimum concave cost network flow problems which are solved as a network flow optimization [18]. Minimum concave cost network flow problems are shown to be equivalent to the DP problem formulation and can be solved with a DP algorithm known as the send-and-split method [19].

This paper utilizes the MDP formulation and models the economies of scale as multi-agent interactions. The agents are multiple units of CO<sub>2</sub> traversing the graph. When agents invest in pipeline transportation at the same location, the total costs are modelled according to a concave cost function and distributed among the agents contributing to the investment decision. A clustering interaction is therefore defined as multiple agents transitioning over the same transport edge.

Modelling the clustering of CO<sub>2</sub> transport poses another complexity in the transport network investment problem, which increases the computational burden on the solution. The paper explicitly does not consider time-dependency and the rollout of investments. Therefore, agents do not have to traverse the same edge within the same time step.

In an ADP framework, the clustering of agents is incentivized directly through reductions of stage costs to single agents, leading to an overall reduction in system costs (total cost incurred by all agents). The proposed algorithm should be able to utilize discrete and non-linear CO<sub>2</sub> transport network costs and converge to a feasible overall system cost in the transport value chain. We define the pipeline investment problem as a cooperative game with transferable utility, for which the Shapely value [20] is included to distribute the costs fairly among agents [21].

## Algorithm

This paper proposes a modified actor-critic RL algorithm. The critic is formulated as a central evaluator, whose role is to evaluate the current policy followed by the actor [22]. In the multi-agent context, the critic observes the actions of all actors and apply a temporal difference (TD) update [23].

Each actor samples a stochastic policy to determine the next action in a discrete action space, due to the discrete graph structure of the environment. The stochastic policy is a mapping of state-action pair to a real number  $p$  indicating the preference:

$$\Pi(x, u) \rightarrow p. \quad (4)$$

The preference  $p$  is scaled to represent a viable

probability distribution for the stochastic policy with Boltzmann scaling. Each actor will sample a path from their source node to a sink node with their current policy and observe the stage cost feedback from the environment. Because there is no time step dependency defining actor collaboration, the policy update is only applied after each agent completes their path from source to sink.

The centralized critic updates and maintains a value function mapping each state to an expected cost by following the current policy  $V(x)$ . The critic observes the stage costs of a path incurred by all agents and calculates the TD update for the centralized value function.

The actors receive the TD error  $\delta$  to update the actor policy. The TD error is calculated as:

$$\delta(x_k, u_k, x_{k+1}) = g_k(x_k, u_k) + V(x_{k+1}) - V(x_k). \quad (5)$$

The value function is tabular, the actor policy is Boltzmann-sampled. The optimal path of an agent is defined as the trained greedy policy, which maximizes the preference  $p$  over all actions  $u$ .

#### Algorithm 1: Modified Actor-Critic Algorithm

---

```

1. Critic: initialize  $V(x) \leftarrow 0$ , "x
2. For each agent a
3.   Actor: Initialize  $\Pi^a(x, u) \leftarrow 0$ , "x, u
4. For each episode
5.   For each agent a
6.     Initialize  $x \leftarrow x_{source}^a$ 
7.     Initialize path  $p^a$  as empty list
8.     While x is not  $x_{sink}$  do
9.       Actor:  $u \leftarrow \Pi(x)$  get action dictated
           by policy in current state x
10.      Actor: observe state transition  $x \rightarrow x'$ 
11.      Actor: append state-action-state tuple
            $(x, u, x')$  to path
12.      Update state:  $x \leftarrow x'$ 
13. Critic: collect all paths p from agents
14. Critic: determine common state-action-state
           tuples between agents
15. For each agent a
16.   For each step  $(x, u, x')$  in  $p^a$ 
17.     Critic: calculate stage cost g
           considering common state-action-
           state tuples
18.     Critic:  $\delta \leftarrow g + V(x') - V(x)$ 
19.     Critic:  $V(x) \leftarrow V(x) + \alpha\delta$ 
20.     Actor:  $\Pi^a(x, u) \leftarrow V(x) - \alpha\delta$ 

```

---

## EXAMPLES

This paper presents a demonstration of the algorithm methodology in simplified examples. As this paper focuses on presenting the CO<sub>2</sub> transport problem formulation and a methodology, geographical data is not used in the examples presented here; however, the method can be extended to incorporate geographical knowledge in the stage costs observed by the agents. The

environment is represented as an equidistant 6-by-6 grid. The graph has two layers representing the two transport modes in the example, truck-based and pipeline-based transports. Every location on the graph is reachable by either transport mode. In total, the graph has 36 transport nodes with additional source and sink nodes.

The transportation costs are dependent on the transport mode, the distance associated with the edges of the environment, and the total transported volume of CO<sub>2</sub> over the edge. For edges representing conditioning of CO<sub>2</sub>, the cost function only depends on the total volume of CO<sub>2</sub> transported over the edge, and what transport modes are available at each of the nodes connected by the edge.

The annualized transport cost (M€/y), including conditioning, is used as a key performance indicator. In order to use representative costs for both truck- and pipeline-based transports, multiple evaluations were carried out with the iCCS tool, an integrated techno-economic and environmental assessment tool for CCS value chains developed by SINTEF Energy Research [24–26]. Based on these evaluations, cost functions of pipeline- and truck-based transports depending on the annual volume and transport distances were regressed for the ranges relevant to the examples.

The Shapley value is computed for the pipeline costs to incentivize agent cooperation. The costs of both truck transport and pipeline transport are plotted in Figure 1 for a set distance of 100 km. Figure 1 shows that pipelines are cheaper than trucks for volumes above 0.16 Mt of CO<sub>2</sub> transported per year.

**Figure 1:** Transport investment cost per volume of CO<sub>2</sub> for pipeline and truck.

### Example 1

In this example, five agents with relatively large volumes traverse the graph to one sink node located at node (6,4) (shown as a small, light gray circle in the figures, row 6, column 4). The source node locations and volume of each agent are listed in Table 2. The agents are visualized as blue circles with their corresponding numbers in

the figures. Pipeline transport, the preferred transport mode with and without cooperation between the agents, is represented as a solid arrow in the figures.

The example is solved in 23.8 s for 4,000 episodes with a learning rate  $\alpha = 10^{-4}$ . Figure 2 shows the optimal paths of each agent traversing the graph without clustering effects. The algorithm identifies three possible clustering points shown as a larger, grey circle. The total system costs are reduced by 32 % by considering clustering of the agents. Figure 3 shows the results of the calculated path of the agents considering that agents traversing the same pipeline transport edge will reduce costs according to Shapley values.

**Table 2:** Agents in example 1

Agent	Volume	Source node
1	1.5 Mt	(1,2)
2	1.5 Mt	(1,3)
3	1.0 Mt	(2,4)
4	2.0 Mt	(1,5)
5	2.5 Mt	(2,6)

**Figure 2:** Results of the algorithm for agents from Example 1 without agent interactions through clustering. Due to the large volumes being transported in Example 1, pipelines are still preferred compared to trucks.

**Figure 3:** Results of the algorithm for agents from Table 2 traversing the grid when clustering is incentivized with cost reduction. Possible clustering points are identified as dark grey, larger circles. The solid arrows represent pipeline investments. Thicker arrows indicate a larger amount of CO<sub>2</sub> transported through the pipeline.

The example is solved in 23.8 s for 4,000 episodes with a learning rate  $\alpha = 10^{-4}$ . Figure 2 shows the results of the calculated path of the agents considering that agents traversing the same pipeline transport edge will reduce costs according to Shapley values. Figure 3 shows the optimal paths of each agent traversing the graph without clustering effects. The algorithm identifies three possible clustering points shown as a larger, grey circle. The total system costs are reduced by 32% by considering the clustering of the agents.

### Example 2

This example models nine agents traversing the graph to two possible sink nodes located at (6,2) and (6,5). Source location and volume of each agent are listed in Table 3.

**Table 3:** Agents in example 2.

Agent	Volume	Source node
1	0.15 Mt	(4,1)
2	0.15 Mt	(2,2)
3	0.15 Mt	(1,3)
4	0.15 Mt	(3,3)
5	0.15 Mt	(1,4)
6	0.15 Mt	(2,4)
7	0.15 Mt	(5,4)
8	0.15 Mt	(4,5)
9	0.15 Mt	(3,6)

**Figure 4:** Results for Example 2 without clustering effects. Due to the small volume of agents, truck transport, represented in dashed arrows, is preferred.

Example 2 is solved in 57.2 s for 8000 episodes and a learning rate of  $\alpha = 10^{-4}$ . Figure 4 shows that the volume of each agent causes truck transport (represented in dashed arrows) to be preferred if agent interactions, i.e., clustering effects, are not considered.

In Figure 5, the paths for each agent considering clustering effects are shown. All agents choose to forego truck transport, as pipeline transport in larger volumes seems to be preferred. Agents 1 and 9 traverse the graph through pipelines from source to sink without clustering with other agents, even though truck transport would yield lesser costs. Pipeline transport exhibits a high variance in costs. Specifically, in the case of cooperation between agents, these costs are shared, which leads the agents to prefer pipeline transport in the multi-agent scenario even though the greedy policy does not present clustering effects. Nonetheless, total system costs are reduced by 28% with cooperative behavior.

## DISCUSSION

The method proposed in this paper is formulated to be able to incorporate detailed geographical data. The DP framework is chosen as a flexible modelling tool which can be extended for multi-modal and geographical representation.

The drawback of DP is the scalability of the solution methods, as they need to accommodate a large search space. Furthermore, the search space may grow rapidly with the number of agents, the complexity of possible agent policies, and the possible interactions between agents. This is especially exacerbated as not only agent interactions within one time step but across all time steps

in a path are considered. The complexity of the algorithm is also increased due to the tabular representation of policy and value function.

**Figure 5:** Results of the algorithm for agents from Table 3 traversing the grid, where clustering is incentivized with cost reduction. The agents traverse the graph to two possible sinks, represented as small light grey circles. Two possible clustering points are identified.

Investments in the CO<sub>2</sub> transport network are the trained policies of agents corresponding to edges of the environment graph. These edges are defined as a “fixed transportation route”, starting in one node and ending in another. This representation is sufficient for geographically fixed investments such as pipelines, flexible resources in the transport network, such as trucks, are not accurately captured.

While the multi-agent approach allows clustering effects as agent interactions to be captured in the first place, convergence to optimality remains an issue. The multi-agent formulation inherently results in learning a policy in a non-stationary environment, where the behavior of other agents constantly influences the learning goal of one agent. These dynamics between agent behavior lead to unclear convergence to a global optimality [27]. In the method proposed, agents communicate indirectly through the centralized critic and the calculated TD error. However, each agent does not consider other agents’ behavior when sampling their policies. Some multi-agent algorithms, therefore, include either an approximation of other agents’ policies in the decision-making of one agent or a communication term [28].

## CONCLUSION AND FURTHER WORK

This paper presents a formulation of the CO<sub>2</sub>

transport network investment as a MDP. The algorithm is formulated to accommodate incorporating detailed geographical modelling and acknowledging the so-called clustering effects or economies of scale in pipeline investments. The transport network investment problem is formulated as a DP problem. This paper focuses on a description of the proposed methodology while presenting simple examples to illustrate the results of such an algorithm.

DP is known to be inhibited with exponentially growing state-action-space complexity and the resulting computational intractability also known as the curse of dimensionality. A multi-agent reinforcement learning-based algorithm proposed to address the state space complexity of DP. While the multi-agent perspective offers a framework where agents make decisions autonomously and collaborate to achieve lower costs which are in turn distributed fairly onto the agents, multi-agent reinforcement learning is subject to rapidly increasing input complexity as the input space grows in dimension with the number of agents and nonstationarity leading to convergence issues [29] which needs to be addressed in further works.

While the illustrative examples presented in this paper are solved quickly, the computational time is expected to grow rapidly with the number of agents, which may make the application of such an algorithm to truly large-scale systems difficult (infeasible). However, the proposed methodology retains its novelty by considering the economies of scale effects that are commonly neglected in single-agent systems. Further work should, therefore, focus on integrating a sequential rollout approach [30], which would cause the computational time to increase linearly with the number of agents while retaining the fundamental cost improvement property for convergence. One issue in this approach is that the economies of scale effects, which are represented in the interactions between the agents, require the agents to act concurrently to calculate the Shapley values for the cooperating agents. Therefore, the convergence under such system properties needs to be addressed.

## ABSTRACT

As a promising electricity storage system, Liquid Air Energy Storage (LAES) has the main advantage of being geographically unconstrained. LAES has a considerable potential in energy efficiency improvement by utilizing compression heat and integrating with other systems. In this work, the Stirling Engine (SE) is introduced to improve the energy efficiency of the LAES system. Three LAES-SE systems are modelled in Aspen HYSYS and optimized by the Particle Swarm Optimization (PSO) algorithm. The studied systems include (i) the LAES system with 3 compressors and 3 expanders (3C+3E) using an SE to recover the compression heat, (ii) the 3C+3E LAES system with LNG regasification and SE, and (iii) the 3C+3E LAES system with solar energy and SE. The optimization results show that the Round-Trip Efficiencies (*RTEs*) of the LAES-SE system and the LNG-LAES-SE systems are 68.2% and 73.7%, which are 3.2% and 8.7% points higher than the basic 3C+3E LAES-ORC system with an *RTE* of 65.0%. For the Solar-LAES-SE system, a revised *RTE* and the economic performance with solar energy input are optimized. The traditional *RTE* for the Solar-LAES-SE system, which only accounts for power produced and consumed in the discharging and charging sections, is 189% and 173% respectively, when optimized with respect to energy and economic performances. The revised *RTE* accounts for the integrated external sources, avoiding the confusing result that the *RTE* becomes larger than 100%. The energy and economic performances of the Solar-LAES-SE system are proved to be the best compared with the Solar-LAES-ORC and Solar energy directly heated-LAES systems.

## 1 INTRODUCTION

The transition from fossil fuels to renewable energy forms requires substantial investments in energy storage due to the intermittent nature of renewables and fluctuations on the demand side. There is a considerable number of storage technologies, from mature to emerging, all with their inherent advantages and disadvantages. Focusing on storing electricity, the dominating technology is Pumped Hydro Electrical Storage (PHES) with 96% of the world capacity. Another mature, but still developing, technology for storing electricity is different forms of batteries. Emerging energy storage technologies include Compressed Air Energy Storage (CAES) and Liquid Air Energy Storage (LAES).

While PHES and CAES have geographical constraints, standalone LAES can be located wherever it is suitable. When considering integration with external sources of heating and cooling, as the present work will discuss, even LAES has some constraints regarding location. The main disadvantage of LAES has been its relatively low Round-Trip Efficiency (*RTE*). From the first published concepts with an *RTE* of 54.4% [1], recent studies ([2], [3] and [4]) were able to improve the *RTE* for standalone LAES to 68.2% by optimizing the number of compressor and expander stages as well as the cold thermal energy recovery cycles.

In contrast to PHES and CAES, LAES also has substantial improvement potential by utilizing opportunities for integration with external sources of heating and

cooling. Obvious candidates are waste heat streams from neighboring industrial plants and utilization of the cold energy that is released when regasifying LNG. At existing LNG terminals, LNG is regasified using sea water or air; in fact, even combustion of natural gas has been used. This considerable waste of cold energy can easily be converted into power using different types of heat engines such as Organic Rankine Cycle (ORC) and Stirling Engine (SE). In our work, we have even considered solar energy as a heat source for the LAES. These alternatives have been evaluated in the framework of an LAES that operates in three distinct modes: charging, storage and discharging.

Table 1 shows the systems studied and compared in this work. The 3C+3E LAES-ORC system in reference [4] with an  $RTE$  of 65.0% is taken as a base case. In the LAES-SE system, the ORC is replaced by a Stirling engine. In the LNG-LAES-SE system, the heat sink of the LAES-SE system, cooling water, is replaced by the LNG regasification process. In the Solar-LAES-SE system, the heat source and sink of the Stirling engine are solar energy and air in the discharging section, respectively. In this case, all the surplus compression heat is used to drive an ORC.

The energy and economic performances of the Solar-LAES-SE system are compared with the Solar-LAES-ORC system [5] and the Solar directly heated-LAES system [6]. In the first three systems, only the traditional  $RTE$  is studied while in the solar energy integrated systems, both the traditional and the revised  $RTE$  as well as the net income are studied. In the Solar-LAES-SE system and Solar directly heated-LAES system, the charging and discharging sections are decoupled.

The serial numbers for the systems in Table 1 refer to: (1) LAES-ORC system, (2) LAES-SE system, (3) LNG-LAES-SE system, (4) Solar-LAES-SE system, (5) Solar-LAES-ORC system, and (6) Solar directly heated-LAES system.

**Table 1:** Different LAES systems studied.

Sys-tems	Reference	$RTE_{LAES}$	$RTE_{Solar-LAES}$	Net income
1	[4]	✓	×	×
2	This study	✓	×	×

6	[6] and this study	✓	✓	✓

## 2 METHODS

Aspen HYSYS has been used to model the different processes while the Particle Swarm Optimization (PSO) algorithm in MATLAB has been used to find the optimal

$RTE$  for standalone LAES as well as LAES integrated with ORC, SE and Solar energy. The economic performance of the combined Solar-LAES-SE system has also been optimized. Equations (1) and (2) show the traditional and revised  $RTE$ , respectively.

$$RTE_{LAES} = \frac{W_{out}t_{dc}}{W_{in}t_{cc}} = \frac{(W_{AT}-W_{CP})t_{dc}}{W_{AC}t_{ch}} \quad (1)$$

$$RTE_{Solar-LAES} = \frac{W_{el,out}t_{dc}}{(W_{el,in}+\eta Q_{th,in})t_{ch}} \quad (2)$$

In these equations,  $w$  is specific work,  $t$  is time,  $dc$  and  $ch$  are for discharging and charging, respectively,  $\eta$  is the power generation efficiency for converting solar heat into power, and  $Q_{th,in}$  is the solar heat to the system.

## 3 SIMULATION MODEL

### 3.1 Basic LAES System

According to reference [4], the LAES system with 2 compressor stages and 3 expander stages (2C+3E) has the highest  $RTE$ . Their study also revealed that surplus compression heat will only be produced when the number of compressor stages is equal to or larger than the number of expansion stages. Unfortunately, the power produced from such surplus compression heat is not enough to compensate for the reduced power production in the discharging section. In summary, they found that (2C+3E) is better than (3C+3E), (3C+4E) is better than (4C+4E), and (4C+5E) is better than (5C+5E). Of these three systems, (2C+3E) has the highest  $RTE$ . However, when the number of compressor stages in the charging section is only 2, the compression ratio will be 13.11 [4], leading to a high investment cost and some concern about lack of maturity. Taking into consideration both energy efficiency and a more practical compression ratio in the charging section, an LAES system with 3 compressor and 3 expander stages is adopted as the base case for the study in this paper. An Organic Rankine Cycle (ORC) is used to recover the surplus compression heat of the 3C+3E LAES system. The optimized  $RTE$  of the base case is 65.0% according to reference [4]. Based on this, different thermal energy recovery systems and external heat sources and sinks are integrated to improve the  $RTE$  of the LAES system.

### 3.2 LAES-Stirling Engine System

The Stirling engine is an efficient heat recovery technology, whose ideal efficiency is as high as the Carnot cycle, which theoretically has the highest possible thermal efficiency [7]. The Stirling engine is proved to be a promising method to improve the  $RTE$  of the LAES system as an alternative to other compression heat recovery cycles including the ORC, Kalina Cycle and Absorption Refrigeration Cycle. Figure 1 shows the flowsheet of the LAES-SE system simulated in Aspen HYSYS. The heat

sink of the Stirling engine is cooling water at ambient conditions.

The Malmo relation [8] is used to model the Stirling engine in the LAES-SE system because the temperature difference between the heat source (thermal oil from the charging part) and sink (cooling water) of the Stirling engine is low. The Malmo relation is shown by Equations (3)-(4).

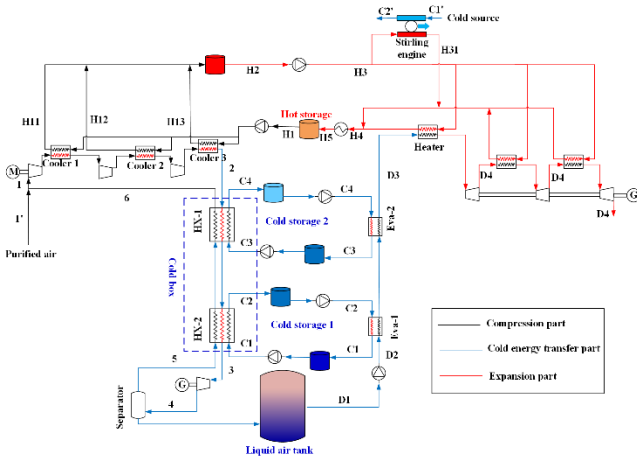

$$P_{\text{Stirling}} = (\eta_H \times \eta_{\text{Mech}} \times \eta_{\text{Thermo}}) \times K_C \times Q_{\text{in}} \quad (3)$$

$$\eta_{\text{Thermo}} = \frac{1-\tau}{1+(1-e) \times (1-\tau) / [(k-1) \times \ln \frac{V_1}{V_2}]} \quad (4)$$

$$\tau = \frac{T_{L,S}}{T_{\text{Heater,wall}}}, T_{L,S} = T_{\text{cooler wall}} + \Delta T_{\text{low}},$$

$$k = \frac{C_P}{C_V}$$

where  $\eta_H$  is the heat source efficiency, which is in the range of 0.85–0.95;  $\eta_{\text{Mech}}$  is the mechanical efficiency, which is in the range of 0.75–0.90;  $K_C$  is the Stirling coefficient, which is in the range of 0.55–0.88; these parameters are taken as 0.9, 0.83 and 0.71 [9].  $e$  refers to the regenerative effectiveness;  $V_1 = V_D + V_P$  is the volume at state 1 and  $V_2 = V_D$  is the volume at state 2 of the compression process;  $V_D$  is displacer swept volume in  $\text{m}^3$  and  $V_P$  is power piston swept volume in  $\text{m}^3$ ;  $\tau$  is the temperature ratio between the heat source and heat sink.  $T_{H,S}$  refers to the high-temperature source and  $T_{L,S}$  refers to the low-temperature source of the Stirling engine.  $k$  is the ratio between specific heat capacity at constant pressure and specific heat capacity at constant volume, and is considered to have a constant value (1.667 for Helium).

**Figure 1.** Flowsheet of the LAES-SE system.

### 3.3 LAES-SE System with LNG regasification

In order to further improve the heat recovery efficiency of the LAES system and thereby improve the  $RTE$  of the entire system, the LNG regasification process is adopted as a heat sink of the Stirling engine with the compression heat as a heat source. Figure 1 is used to

illustrate both the LAES-SE system where cooling water is used as heat sink for the Stirling engine and the LNG-LAES-SE system where LNG regasification replaces cooling water as heat sink.

In the LNG-LAES-SE system, the Pseudo Stirling model [10] is used to simulate the Stirling engine because in this case, the temperature difference between the heat source and heat sink is large. The Pseudo Stirling model is shown in Equations (5)-(10).

$$P_{\text{Stirling}} = \eta_{\text{pcy}}(Q_{\text{high}} - Q_{\text{loss}}) \quad (5)$$

where  $P_{\text{Stirling}}$  refers to the power produced by the Stirling engine,  $\eta_{\text{pcy}}$  refers to the polytropic efficiency as shown in Equation (7),  $Q_{\text{high}}$  is the heat provided by the heat source, and  $Q_{\text{loss}}$  is the heat released to the heat sink by the Stirling engine as shown in Equation (6).

$$Q_{\text{loss}} = Q_{\text{high}}(1 - \eta_{\text{mech}}) \quad (6)$$

where  $\eta_{\text{mech}}$  refers to the mechanical efficiency of the Stirling engine.

$$\eta_{\text{pcy}} = \left[ \frac{(1-RV^{1-k}) - \zeta(RV^{1-k}-1)}{(1-RV^{1-k}) + (1-\zeta)(1-\varepsilon_{ST})} \right] \quad (7)$$

where  $\varepsilon_{ST}$  refers to the efficiency of the Stirling engine regenerator (0.94),  $RV$  refers to the piston compression ratio (1.23), and  $\zeta$  refers to the ratio between minimum and maximum temperature inside the Stirling cycle as shown in Equation (8):

$$\zeta = \frac{T_{L,S}}{T_{H,S}} \quad (8)$$

$$T_{H,S} = T_{\text{heater,wall}} - \Delta T_{\text{high}} \quad (9)$$

$$T_{L,S} = T_{\text{cooler,wall}} + \Delta T_{\text{low}} \quad (10)$$

where  $\Delta T_{\text{high}}$  refers to the temperature change of the heat source and  $\Delta T_{\text{low}}$  refers to the temperature change of the heat sink.

### 3.4 Solar Energy Integrated LAES-SE System

In addition to the case where surplus compression heat is used as a heat source for the Stirling engine, solar energy can also be integrated as a heat source to increase the power generated in the Stirling engine. As shown in Figure 2, solar energy is integrated with the discharging section of the LAES system. The solar heat carried by molten salt is taken as heat source and the air before expanders is taken as heat sink for the Stirling engine. All compression heat from the charging section is used to drive an ORC to generate more electricity. As a result, the charging and discharging sections are decoupled, resulting in improved flexibility and operability of the LAES system compared with previous cases.

The solar energy utilization model is represented by Equations (11)-(13). The efficiency of the collector is defined as the ratio of the energy absorbed by the working fluid in the collector ( $Q_c$ ) to the available energy from the

sun ( $Q_s$ ), as shown by Equation (11). The efficiency of the collector is given by Equation (12), as suggested by Blanco et al. [11]

$$\eta_c \equiv \frac{Q_c}{Q_s} \quad (11)$$

$$\eta_c = 0.75 - 0.000045\Delta T - 0.039 \frac{\Delta T}{G_b} - 0.0003G_b \left(\frac{\Delta T}{G_b}\right)^2 \quad (12)$$

where  $\Delta T$  is the difference between the mean temperature in the solar collector and ambient temperature, as shown by Equation (13).

$$\Delta T = (T_{\text{hot}} + T_{\text{cold}})/2 - T_{\text{amb}} \quad (13)$$

where  $T_{\text{amb}}$  is the ambient temperature, which also has an impact on the system.

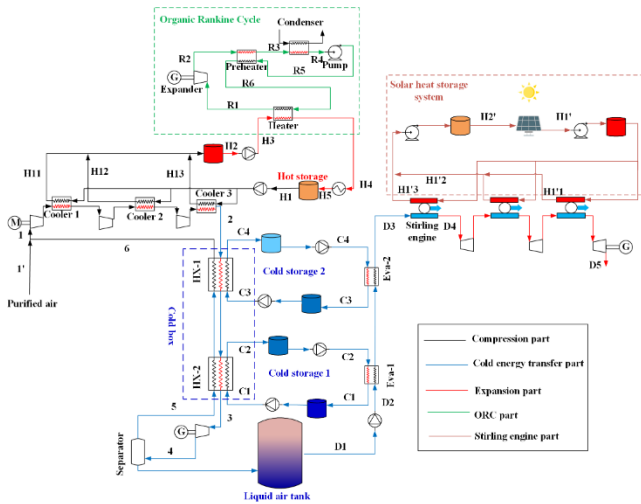

Figure 2. Flowsheet of the Solar-LAES-SE system.

## 4 OPTIMIZATION OF DIFFERENT LAES SYSTEMS

Based on the simulation model of different LAES systems, the Particle Swarm Optimization (PSO) algorithm is used to obtain the optimal  $RTE$  of these systems. The minimum temperature difference of the heat exchangers in the discharging section is fixed as  $10^\circ\text{C}$  while that of the heat exchangers in the charging section is set as a variable changing from  $10^\circ\text{C}$  to  $40^\circ\text{C}$ . The temperature difference of the heat exchangers in the cold box is taken as constraint with a minimum value of  $1^\circ\text{C}$ . Figure 3 shows the framework for the optimization. Besides, for the Solar-LAES-SE system, the  $RTE$  will increase monotonically with the increased input of solar thermal energy, since this heat comes at no expense. Therefore, there is no optimal value for the traditional  $RTE$  given by Equation (1) for the Solar-LAES-SE system. There are two ways to find an optimal condition for this system: (1) consider the solar energy as a heat input in the  $RTE$  calculation, as shown in Equation (2) for the revised  $RTE$ , and (2) consider the economic profit of the solar energy storage

system. Though the energy efficiency could be improved by a large amount of solar energy input, the investment cost of the molten salt and the storage tank would also be increased. Therefore, there will be an optimal value for the investment cost.

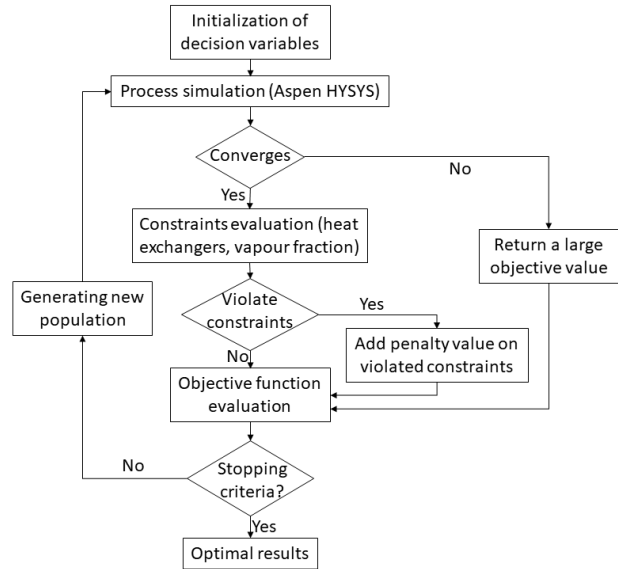

Figure 3. Optimization framework for the LAES systems.

## 5 RESULTS AND DISCUSSION

### 5.1 Energy Efficiency Optimization of the LAES-Stirling Engine System

The optimal  $RTE$  of the LAES-SE system is obtained with compression ratio, expansion ratio, and temperature, pressure and flowrate values for the hot and cold thermal energy recovery sections as decision variables. According to reference [12], the power generation efficiency of the Stirling engine is decreasing with increased outlet temperature of the heat sink. Therefore, the outlet temperature of the heat sink ( $C2'$  in Figure 1) is fixed at  $29^\circ\text{C}$  in order to ensure a reasonable temperature change of the heat sink. The outlet temperature of the heat source ( $H31$  in Figure 1) is fixed at  $30^\circ\text{C}$ , which is the lowest temperature when the minimum temperature difference between the heat source and sink is taken as  $10^\circ\text{C}$ .

For the Stirling engine based compression heat recovery section, the inlet and outlet temperatures of the heat sink and the outlet temperature of the heat source are fixed. Therefore, the power generated in the Stirling engine will mainly be impacted by the inlet temperature and flowrate of the heat source ( $H3$  in Figure 1). These two variables are determined by the compression ratio of the compressors, while the flowrate of the heat source will indirectly be affected by the expansion ratio of the expanders.

The optimization results show that the  $RTE$  of the LAES-SE system will be 68.2%, which is 3.2% points

higher than the LAES-ORC system in reference [4]. This means that the heat recovery efficiency of the Stirling engine is slightly higher than the ORC.

## 5.2 Energy Efficiency Optimization of the LNG-LAES-Stirling Engine System

For the LNG-LAES-SE system, the decision variables are the same as those in the LAES-SE system. For the Stirling engine based compression heat recovery section, the temperature of the heat sink is set to  $-162^{\circ}\text{C}$  since only latent heat from LNG is utilized in this case. The outlet temperature of the heat source is fixed at  $30^{\circ}\text{C}$ . In this case, one part of the thermal oil is used to preheat air before expanders and the other part is used to drive the Stirling engine. Minimum temperature difference of the air preheater is fixed at  $10^{\circ}\text{C}$ . The flowrate of thermal oil to the air preheating part will be determined by (i) the air temperature after evaporation and expansion (D3 and D4 in Figure 1) and (ii) the thermal oil temperature from the charging section. These temperatures depend on (i) the cold storage section and the expansion ratio and (ii) the compression ratio. This means that the flowrate of thermal oil to the Stirling engine also depends on the cold storage section and the expansion and compression ratios, since the total flowrate of thermal oil is fixed by the compression ratio. The optimized *RTE* is 73.7%, which is 8.7% points higher than the basic LAES-ORC system.

## 5.3 Energy Efficiency Optimization of the Solar-LAES-Stirling Engine System

For the Solar-LAES-SE system, as mentioned earlier, there is no optimal *RTE* value for the traditional definition in Equation (1). The *RTE* will be monotonically increasing with the solar energy input since this heat is not included in the traditional *RTE* definition. However, with the solar energy input increasing, the investment cost of the molten salt and the heat storage tank will increase. Therefore, there will be an optimal economic performance for the Solar-LAES-SE system. In addition, when solar energy is included in the *RTE* calculation, there will also be an optimal *RTE* value. Optimal results with respect to economic performance and revised *RTE* value are both studied.

### (1) Optimal revised *RTE* of the Solar-LAES-SE system

In the optimization of the revised *RTE* shown in Equation (2), the power generation efficiency of a Concentrated Solar Power plant (CSP) is taken as  $\eta = 0.214$  [13]. The solar energy input is determined by the cold energy needed in the charging section and the power generation efficiency of the Stirling engine, which is related to the temperature difference between the heat source and sink in the Stirling engine. The revised *RTE* value of the entire LAES-SE system is taken as the optimization objective. The compression and expansion ratios, the

temperature, pressure and flowrate of the hot and cold thermal energy recovery sections, and the molten salt flowrate and outlet temperature from the Stirling engine are taken as decision variables.

The optimization results show that the revised *RTE* will be 76.0% with a molten salt outlet temperature in the Stirling engine of  $500^{\circ}\text{C}$  and the inlet temperature fixed at  $550^{\circ}\text{C}$ . Combined with the density and specific heat capacity of the molten salt represented in Equations (14) and (15) [14], the optimized molten salt mass and volume rates are  $2.83 \times 10^6$  kg/h and  $1160$  m<sup>3</sup>/h. In this optimized condition, the traditional *RTE* is 189%. The optimized condition is related to the power generation efficiency value adopted for the CSP system. A larger power generation efficiency value of CSP will obviously increase the optimal *RTE* value.

$$\rho(\text{kg}/\text{m}^3) = 0.636 \cdot T(^{\circ}\text{C}) + 2089.905 \quad (14)$$

$$cp(\text{kJ}/\text{kg} \cdot \text{K}) = 1.723 \cdot 10^{-4} \cdot T(^{\circ}\text{C}) + 1.443 \quad (15)$$

where  $\rho$  refers to the density of the molten salt,  $cp$  refers to the specific heat capacity of the molten salt, and  $T$  refers to the temperature of the molten salt.

### (2) Optimal economic performance

In this case, the profit of the discharging section is taken as the optimization objective. In addition to the decision variables in the LAES-SE and LNG-LAES-SE systems, the flowrate and temperature of the molten salt are also taken as decision variables. The income from the power generated in the air expanders and Stirling engine and expenses related to the solar heat storage are considered in the profit of the discharging process. The cost of the binary molten salt is 0.8 €/kg and the specific cost of the storage tank is 510 €/m<sup>3</sup> [15]. The price of power is taken as 0.284 €/kWh [16], which was the average electricity price of Europe in 2022. The electricity price will have an obvious impact on the optimization results.

The optimization results show that the traditional and revised *RTE* of the Solar-LAES-SE system will be 173.0% and 72.8% respectively when the economic performance is optimal. In this condition, the outlet temperature of the molten salt in the Stirling engine is  $484^{\circ}\text{C}$  with the inlet temperature fixed at  $550^{\circ}\text{C}$ . The optimal mass and volume flowrates of the molten salt are obtained as  $2.42 \times 10^6$  kg/h and 990 m<sup>3</sup>/h.

### (3) Comparison of optimal revised *RTE* and economic performance

In order to further clarify the difference between the Solar-LAES-SE system under the optimal revised *RTE* and optimal economic performance, the optimal parameters of the corresponding systems are compared, as shown in Table 2. The lower and upper bounds of the air temperature before expanders in the two systems are  $170^{\circ}\text{C}$  and  $270^{\circ}\text{C}$ . The optimization results show that the

optimal air temperature before expanders for the revised  $RTE$  and economic performance is 180.2°C and 180.0°C, respectively. This indicates that a high temperature before the air expanders is not necessary to reach optimal efficiency or economic performance. As the heat sink of the Stirling engine, a higher air temperature before the expander will decrease the power generation efficiency in the Stirling engine due to the reduced temperature difference between the heat source and sink.

Table 2 also shows  $RTE$  values for the Solar-LAES-SE system (both traditional and revised  $RTE$ ). The traditional  $RTE$  ( $RTE_{LAES}$ ) of the entire Solar-LAES-SE system is higher than 100% because the solar energy input is not reflected in the calculation of the traditional  $RTE$ . The optimal revised  $RTE$  ( $RTE_{Solar-LAES}$ ) of the Solar-LAES-SE system is 3.2% points higher than that of the system with optimal economic performance.

**Table 2:** Optimized parameters for the Solar-LAES-SE system.

Items	Optimal economic performance	Optimal revised $RTE$	Units
$W_c$	$1.55 \times 10^4$	$1.31 \times 10^4$	kW
$Q_{solar}$	$1.00 \times 10^5$	$9.04 \times 10^4$	kW
$T_{Air}$	180.2	180.0	°C
$m_{Molten\ salt}$	$2.42 \times 10^6$	$2.83 \times 10^6$	kg/h
$V_{Molten\ salt}$	$9.90 \times 10^2$	$1.16 \times 10^3$	m <sup>3</sup> /h
$T_{Molten\ salt}$	484	500	°C
Molten salt cost	$2.71 \times 10^6$	$3.18 \times 10^6$	\$/h
$P_{LAES}$	$1.02 \times 10^4$	$9.43 \times 10^3$	kW
$P_{Stirling}$	$1.42 \times 10^4$	$1.32 \times 10^4$	kW
$P_{ORC}$ (compression heat)	$2.41 \times 10^3$	$1.98 \times 10^3$	kW
$RTE_{LAES}$	173.0	189.0	%
$RTE_{Solar-LAES}$	72.8	76.0	%
Profits	$3.02 \times 10^7$	$2.77 \times 10^7$	\$/h
Net income	$2.75 \times 10^7$	$2.45 \times 10^7$	\$/h

## 5.4 $RTE$ comparison of Different LAES Systems

Figure 4 shows the  $RTE$  comparison of different LAES systems including (i) stand-alone LAES system with ORC or Stirling engine as the surplus compression heat recovery cycles, (ii) LNG integrated LAES system with compression heat and the LNG regasification process as heat source and sink for the Stirling engine, and (iii) Solar energy integrated LAES system with Solar heat and the air discharging process as heat source and sink for the Stirling engine. For the solar energy based LAES system, there are two optimal  $RTE$  values. One for the optimal revised  $RTE$  and another for economic performance.

For the solar energy integrated systems, the traditional and revised  $RTE$ s provide different points of view to evaluate the energy efficiency. In the traditional  $RTE$ , the solar energy is taken as a free resource. For the revised  $RTE$ , the value of the solar energy is accounted for in the  $RTE$  according to the adopted power generation efficiency of the solar energy. In this way, the  $RTE$  value is adjusted to be lower than 100%. However, the definition of the  $RTE$  should be uniform when comparison with other LAES systems is performed, which is why the traditional  $RTE$  is also taken as a comparison index.

For the traditional  $RTE$ , the Solar-LAES-SE system optimizing on energy efficiency has the highest  $RTE$  value, followed by the Solar-LAES-SE system focusing on optimal economic performance, and the LNG-LAES-SE system focusing on energetic performance. This clearly indicates the high efficiency of the solar energy integrated systems. As shown in Table 2, using an economic objective, the net income (27.5 million \$) is 12.2% higher than when using an energetic objective (24.5 million \$).

**Figure 4.** Comparison of  $RTE$  values in LAES systems.

## 5.5 Comparison between Solar-LAES-ORC and Direct Solar Heating

The performance of the proposed Solar-LAES-SE system is compared with the Solar-LAES-ORC [5] and Solar directly heated-LAES [6] systems (with decoupled charging and discharging sections) shown in Figures 5 and 6. In the Solar-LAES-ORC system, both solar heat and compression heat are used to heat the discharging section and drive ORCs. In the Solar directly heated-LAES system, compression heat is used to drive the ORC while solar heat is used to preheat air in the discharging section.

Table 3 shows the economic and energy efficiency optimization results for the Solar-LAES-ORC system. The revised  $RTE$ s of the Solar-LAES-ORC system with optimal economic and energetic efficiency are 58.0% and 61.3% respectively, which are considerably lower than those of the Solar-LAES-SE system. A similar result (i.e. lower values) is obtained for the net income of the Solar-LAES-ORC system. Therefore, the Solar-LAES-SE system is superior to the Solar-LAES-ORC system in terms of both energy and economy.

**Table 3:** Optimized parameters for the Solar-LAES-ORC system.

Items	Optimal economic performance	Optimal revised RTE	Units
$W_c$	$1.26 \times 10^4$	$1.26 \times 10^4$	kW
$Q_{solar}$	$4.16 \times 10^4$	$2.55 \times 10^4$	kW
$T_{Air}$	183.0	183.0	°C
$M_{Thermal\ oil}$	$1.82 \times 10^5$	$1.12 \times 10^5$	kg/h
$V_{Thermal\ oil}$	$2.01 \times 10^2$	$1.24 \times 10^2$	m <sup>3</sup> /h
Thermal oil cost	$5.66 \times 10^5$	$3.48 \times 10^5$	\$/h
$P_{LAES}$	$8.61 \times 10^3$	$8.58 \times 10^3$	kW
$P_{ORC}$ (solar heat)	$2.71 \times 10^3$	$1.35 \times 10^3$	kW
$P_{ORC}$ (compression heat)	$1.14 \times 10^3$	$1.14 \times 10^3$	kW
$RTE_{LAES}$	98.9	87.9	%
$RTE_{Solar-LAES}$	58.0	61.3	%
Profits	$1.40 \times 10^7$	$1.24 \times 10^7$	\$/h
Net income	$1.34 \times 10^7$	$1.21 \times 10^7$	\$/h

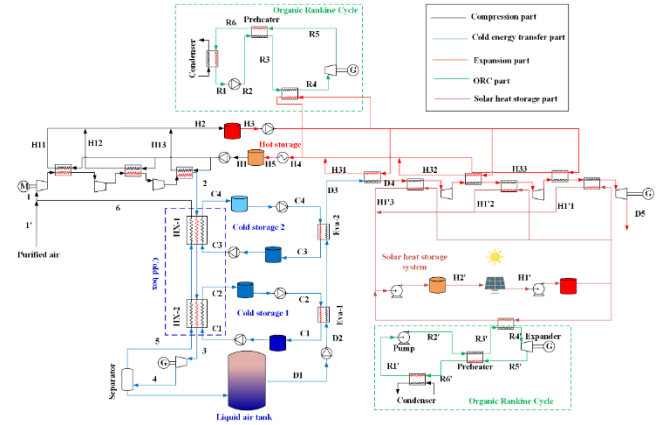

**Table 4:** Optimized parameters for the Solar directly heated ORC system.

Items	Optimal economic performance	Optimal revised RTE	Units
$W_c$	$1.52 \times 10^4$	$1.22 \times 10^4$	kW
$Q_{solar}$	$1.31 \times 10^4$	$1.21 \times 10^4$	kW
$T_{Air}$	183.0	183.0	°C
$M_{Thermal\ oil}$	$5.47 \times 10^4$	$5.06 \times 10^4$	kg/h
$V_{Thermal\ oil}$	60.4	55.8	m <sup>3</sup> /h
Thermal oil cost	$1.70 \times 10^5$	$1.57 \times 10^5$	\$/h
$P_{LAES}$	$9.26 \times 10^3$	$8.39 \times 10^3$	kW
$P_{ORC}$ (compression heat)	$1.72 \times 10^3$	$1.71 \times 10^3$	kW
$RTE_{LAES}$	72.1	82.6	%
$RTE_{Solar-LAES}$	60.9	68.2	%
Profits	$1.23 \times 10^7$	$1.14 \times 10^7$	\$/h
Net income	$1.22 \times 10^7$	$1.12 \times 10^7$	\$/h

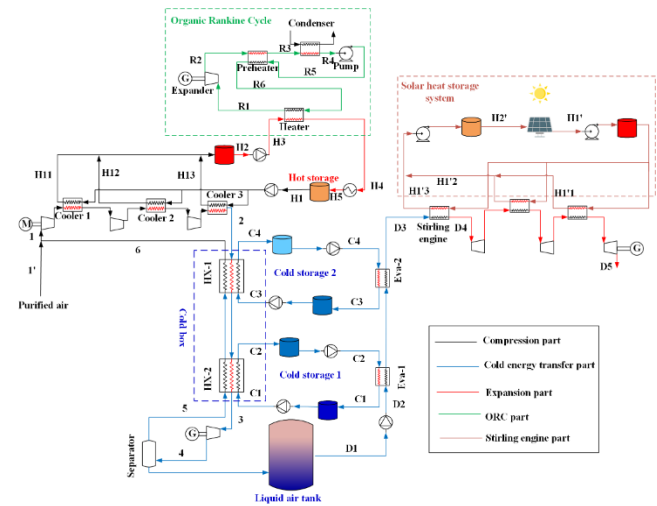

Table 4 shows the optimal results for the solar energy directly heated LAES system. The revised  $RTEs$  of the system with respect to optimal economy and energy efficiency are 60.9% and 68.2%, which are lower than those of the Solar-LAES-SE system but higher than those of the Solar-LAES-ORC system. As for the economic performance, the net income of the Solar energy directly heated-LAES system is the lowest among all solar energy integrated LAES systems.

As a conclusion, for the solar energy integrated

LAES systems, the Solar-LAES-SE system is the best both from the energy efficiency and economic performance point of view. The energy efficiency ranking of the solar energy integrated LAES systems from high to low is Solar-LAES-SE>Solar directly heated LAES>Solar-LAES-ORC, while the economic performance ranking is Solar-LAES-SE>Solar-LAES-ORC>Solar directly heated LAES.

**Figure 5.** Flowsheet of the Solar-LAES-ORC system.

**Figure 6.** Flowsheet of the Solar energy directly heated-LAES system.

## 6 CONCLUSIONS

Different LAES systems integrated with a Stirling engine are modeled and optimized from an energy efficiency and an economic point of view. The following conclusions have been obtained.

- (1) The optimized  $RTE$  of the LAES-SE system is 68.2%, 3.2% points higher than the basic LAES-ORC system. This means that the Stirling engine is more efficient than the ORC in recovering surplus compression heat in the 3C+3E LAES system.

(2) When cooling water is replaced by LNG regasification as a heat sink for the Stirling engine, the optimized *RTE* increases from 68.2% to 73.7%.

(3) For the solar energy integrated system, the traditional *RTE* will be 189% when optimizing with respect to the revised *RTE* and 173% when optimizing with respect to economic performance of the discharging section. Having efficiencies larger than 100% comes as a result of the fact that the basic LAES system (for which the traditional *RTE* is defined) benefits from "free" energy input.

(4) Among the Stirling engine based systems, the Solar-LAES-SE system under the optimal revised *RTE* has the highest energy efficiency, while the LAES-SE system has the lowest energy efficiency. All the studied systems have higher *RTEs* than the basic LAES-ORC system.

(5) For the solar energy integrated LAES systems, Solar-LAES-SE has the highest optimal revised *RTE*, followed by the Solar directly heated LAES-system, while Solar-LAES-ORC has the lowest optimal revised *RTE*. In the case of economic performance, the ranking is Solar-LAES-SE > Solar-LAES-ORC > Solar directly heated LAES.

## ABSTRACT

We study the impact of switching from combustion heating to electric heating in processes comprising high temperature reaction/separation sequences, where the heat supporting the reaction(s) is substantially provided by combusting a reaction byproduct (fuel gas). A canonical process structure is defined. It is shown that the conventional combustion-based process presents significant interactions. An asymptotic analysis is utilized to investigate and compare the dynamic responses of the conventional and electric process configurations. It is demonstrated that the dynamic behavior of the two processes exhibits two timescales, with the faster corresponding to the evolution of the temperatures of the units with high heat duty, and the slow time scale capturing the variables involved in the material balance. A simplified ethylene cracking process example is used to demonstrate these findings.

Keywords: Energy Systems, Process Design, Process Electrification

## INTRODUCTION

Process electrification using electricity generated by renewable sources has emerged as one of the routes for decarbonizing manufacturing processes [1,2]. Electrification may involve a complete change of processing technology (e.g., utilizing electrochemical reactions) [3] or upgrades and modifications of existing technology. Of particular interest in the latter area is the electrification of process heating, whereby existing combustion heaters are replaced with electric heating technologies [1,2].

Electrification can in principle eliminate combustion-heating-related CO<sub>2</sub> emissions and has the potential co-benefits of affording more precise/localized heating and providing additional degrees of freedom for operation and control [4]. Nevertheless, it presents several challenges. From a design perspective, electric heating may disrupt existing process integration structures, which rely on, e.g., combusting process-generated waste streams ("tail gas" or "fuel gas") to generate heat [5]. From an operation and control perspective, electric heating must account for the availability of renewable electricity, which

may fluctuate during the day [6]. Motivated by the above, in this work, we provide a rigorous analysis of the design and process dynamics implications of electrified process heating in the context of integrated process systems. We note that there are other sources of CO<sub>2</sub> emissions in chemical/petrochemical processing (including scope 2) emissions, that are not accounted for in this work.

A prototype process structure with reaction, separation, and recycle is defined. It is shown that the conventional combustion-based process presents significant interactions due to the impact of the downstream units (via the heating value of the fuel gas) on the upstream units. An asymptotic analysis is utilized to investigate and compare the dynamic responses of the two process configurations. It is demonstrated that the dynamic behavior of the two processes exhibits two time scales, with the faster corresponding to the evolution of the temperatures of the units with high heat duty, and the slow time scale capturing the variables involved in the material balance. A simplified ethylene cracking process example is used to demonstrate these findings.

**Figure 2:** Structure of process with electric heating.

## PROTOTYPE PROCESS

A system of  $N$  process units, each with mass holdup  $M$ , mass fraction  $x$ , and mass specific enthalpy  $H$ , connected in series is considered. The feed stream, of mass flow rate  $F_0$  has mass specific enthalpy  $H_0$  and contains a reactant with mass fraction  $x_0$ . The reactant undergoes a high-temperature, endothermic transformation in the first unit. Processing units  $2, \dots, i-1$  follow, and heat is eventually removed/recovered from the resulting process stream in unit  $i$ . Finally, the product stream is obtained in unit  $N$ , along with a waste stream of flow rate  $F_R$ . The waste (“off gas”, “tail gas” or “fuel gas”) stream can be used as a fuel but does not have any economic value. Two process configurations are considered:

- A conventional, integrated design (Figure 1), whereby the majority of the heat required for the endothermic transformation occurring in Unit 1 is provided by combusting the fuel stream (possibly combined with a fresh fuel stream of mass flow rate  $F_f$ ). The rate of heat generation by combustion is given by

$$Q_{comb} = \lambda_f F_f + \lambda_R F_R \quad (1)$$

where  $\lambda_f$  and  $\lambda_R$  refer to the heating values of the fresh fuel and the fuel gas, respectively. Combustion of fuel gas occurs in air, and a flue gas stream is generated (not shown in the figure).

- An electrified process configuration (Figure 2), whereby the heat required for the endothermic transformation in Unit 1 is provided by electric

heating. In this case, other means to process the waste gas stream must be identified.

The structure of the two process configurations shown in Figures 1 and 2 is the same as far as material processing is concerned. From a steady state design point of view, it is important to ensure that the product streams resulting from the two configurations are the same (in terms of composition  $x$  and enthalpy  $H$ ), and that the amount of heat recovered  $Q_{out}$  is the same. To this end, the rates of energy input to both processes must be the same, and the following condition must be met:

$$\bar{Q}_{comb} = \bar{Q}_{elec} \quad (2)$$

where the overbar denotes steady-state values. Note that the above condition assumes that heating is 100% efficient, that is, all the heat generated by combustion (as defined in equation (1)) or by electricity is transferred to the process. Heat transfer efficiency is lower in practice.

## DYNAMIC ANALYSIS AND TIME SCALE DECOMPOSITION

The dynamic model of the process is based on the following assumptions: each unit is well-mixed, has constant holdups, constant physical properties, and has no heat loss. With these assumptions, the model of the conventional process shown in Figure 1 can be written as:

Unit 1 :

$$\frac{dx_1}{dt} = \frac{1}{M_1} [F_0 x_0 - F_1 x_1 + f_1(x_1, H_1)]$$

$$\frac{dH_1}{dt} = \frac{1}{M_1} [F_0 H_0 - F_1 H_1 + \lambda_f F_f + \lambda_R F_R + g_1(x_1, H_1)]$$

Unit 2 :

$$\frac{dx_2}{dt} = \frac{1}{M_2} [F_1 x_1 - F_2 x_2 + f_2(x_2, H_2)]$$

$$\frac{dH_2}{dt} = \frac{1}{M_2} [F_1 H_1 - F_2 H_2 + g_2(x_2, H_2)]$$

⋮ (3)

Unit  $i$  :

$$\frac{dx_i}{dt} = \frac{1}{M_i} [F_{i-1} x_{i-1} - F_i x_i + f_i(x_i, H_i)]$$

$$\frac{dH_i}{dt} = \frac{1}{M_i} [F_{i-1} H_{i-1} - F_i H_i - Q_{out} + g_i(x_i, H_i)]$$

Unit  $N$  :

$$\frac{dx_N}{dt} = \frac{1}{M_N} [F_{N-1} x_{N-1} - F_N x_N - F_R x_R + f_N(x_N, H_N)]$$

$$\frac{dH_N}{dt} = \frac{1}{M_N} [F_{N-1} H_{N-1} - F_N H_N - F_R H_R + g_N(x_N, H_N)]$$

The model of the electrified process in Figure 2 can be written in a similar fashion, replacing the sum  $\lambda_f F_f + \lambda_R F_R$  (which represents  $Q_{comb}$ ) in the energy balance of Unit 1 in equation (3) with  $Q_{elec}$ .

In order to proceed with the analysis, the following scaled entities are defined:  $u_j = \frac{F_j H_j}{F_j \bar{H}_j}$ ,  $j = 1, \dots, N$ ,  $u_r = \frac{F_R H_R}{F_R \bar{H}_R}$ ,  $u_q = \frac{Q_{out}}{Q_{out}}$ .

Then, the following assumptions are made, that pertain to steady state operation (the overbar denotes again steady state values):

- Let  $k_1 = \frac{F_1 \bar{H}_1}{F_R \bar{\lambda}_R}$ , and assume that  $k_1 = \mathcal{O}(1)$ , meaning that the amount of energy leaving unit 1 via flow is of comparable magnitude to the energy provided by combusting the waste gas.
- Let  $k_0 = \frac{\bar{F}_f \bar{\lambda}_f}{\bar{F}_0 \bar{H}_0}$ , and assume that  $k_0 = \mathcal{O}(1)$ , meaning that the amount of heat provided by combusting fresh fuel is small and comparable with the amount of heat provided by convection by the feed stream.
- Let  $\varepsilon = \frac{F_0 \bar{H}_0}{\bar{F}_R \bar{\lambda}_R} \ll 1$ , meaning that the energy input from the feed stream is small compared with the amount of energy provided by combusting the fuel gas.
- Let  $k_j = \frac{F_j \bar{H}_j}{F_R \bar{\lambda}_R}$ ,  $j = 1, \dots, i-1$ , and assume that  $k_j = \mathcal{O}(1)$ , meaning that the amount energy leaving unit  $j = 1, \dots, i-1$  via flow is of comparable magnitude to the energy provided by combusting the waste gas stream.
- Let  $I_j = \frac{F_j \bar{H}_j}{\bar{F}_f \bar{\lambda}_f}$ ,  $j = i, \dots, N$ , and assume that  $I_j = \mathcal{O}(1)$ , meaning that the amount energy leaving unit  $j = i, \dots, N$  via flow is of comparable magnitude to the

energy provided by combusting fresh fuel feed.

- Let  $I_p = \frac{\bar{F}_R \bar{H}_N}{\bar{F}_f \bar{\lambda}_f}$ , and assume that  $I_p = \mathcal{O}(1)$ , meaning that the amount of energy contained in the waste stream is of comparable magnitude to the amount of heat provided by combusting fresh fuel feed.

With these definitions and assumptions, the model becomes:

Unit 1 :

$$\frac{dx_1}{dt} = \frac{1}{M_1} [F_0 x_0 - F_1 x_1 + f_1(x_1, H_1)]$$

$$\frac{M_1}{\bar{F}_0 \bar{H}_0} \frac{dH_1}{dt} = u_0 + u_r k_0 + \frac{g_1(x_1, H_1)}{\bar{F}_0 \bar{H}_0} + \frac{1}{\varepsilon} (u_r - k_1 u_1)$$

Unit 2 :

$$\frac{dx_2}{dt} = \frac{1}{M_2} [F_1 x_1 - F_2 x_2 + f_2(x_2, H_2)]$$

$$\frac{M_2}{\bar{F}_0 \bar{H}_0} \frac{dH_2}{dt} = \frac{g_2(x_2, H_2)}{\bar{F}_0 \bar{H}_0} + \frac{1}{\varepsilon} (k_1 u_1 - k_2 u_2)$$

⋮ (4)

Unit  $i$  :

$$\frac{dx_i}{dt} = \frac{1}{M_i} [F_{i-1} x_{i-1} - F_i x_i + f_i(x_i, H_i)]$$

$$\frac{M_i}{\bar{F}_0 \bar{H}_0} \frac{dH_i}{dt} = -I_i k_0 u_i + \frac{g_i(x_i, H_i)}{\bar{F}_0 \bar{H}_0} + \frac{1}{\varepsilon} (k_{i-1} u_{i-1} - k_i u_i)$$

Unit  $N$  :

$$\frac{dx_N}{dt} = \frac{1}{M_N} [F_{N-1} x_{N-1} - F_N x_N - F_R x_R + f_N(x_N, H_N)]$$

$$\frac{M_N}{\bar{F}_0 \bar{H}_0} \frac{dH_N}{dt} = I_{N-1} k_0 u_{N-1} - I_N k_0 u_N - I_p k_0 u_p + \frac{g_N(x_N, H_N)}{\bar{F}_0 \bar{H}_0}$$

This model is a singularly perturbed system of ordinary differential equations in standard form, and it is expected to have a dynamic behavior featuring two time-scales<sup>7</sup>. The framework presented by Baldea and Daoutidis [7] is employed to study the dynamic behavior via an asymptotic analysis using singular perturbation arguments.

Its dynamic behavior is analyzed below, starting from the fast timescale. To this end, a new "stretched" time variable is defined as:

$$\tau = \frac{1}{\varepsilon} \quad (5)$$

With this, the model (4) becomes:

Unit 1 :

$$\frac{dx_1}{d\tau} = \varepsilon \frac{1}{M_1} [F_0 x_0 - F_1 x_1 + f_1(x_1, H_1)]$$

$$\frac{M_1}{\bar{F}_0 \bar{H}_0} \frac{dH_1}{d\tau} = \varepsilon [u_0 + u_r k_0 + \frac{g_1(x_1, H_1)}{\bar{F}_0 \bar{H}_0}] + u_r - k_1 u_1$$

Unit 2 :

$$\frac{dx_2}{d\tau} = \varepsilon \frac{1}{M_2} [F_1 x_1 - F_2 x_2 + f_2(x_2, H_2)]$$

$$\begin{aligned} \frac{M_2}{F_0 \bar{H}_0} \frac{dH_2}{d\tau} &= \varepsilon \frac{g_2(x_2, H_2)}{F_0 \bar{H}_0} + k_1 u_1 - k_2 u_2 \\ &\vdots \end{aligned} \quad (6)$$

Unit  $i$  :

$$\begin{aligned} \frac{dx_i}{d\tau} &= \varepsilon \frac{1}{M_i} [F_{i-1} x_{i-1} - F_i x_i + f_i(x_i, H_i)] \\ \frac{M_i}{F_0 \bar{H}_0} \frac{dH_i}{d\tau} &= \varepsilon [-I_i k_0 u_i + \frac{g_i(x_i, H_i)}{F_0 \bar{H}_0}] + k_{i-1} u_{i-1} - k_q u_q \end{aligned}$$

Unit  $N$  :

$$\begin{aligned} \frac{dx_N}{dt} &= \varepsilon \frac{1}{M_N} [F_{N-1} x_{N-1} - F_N x_N - F_R x_R + f_N(x_N, H_N)] \\ \frac{M_N}{F_0 \bar{H}_0} \frac{dH_N}{dt} &= \varepsilon [I_{N-1} k_0 u_{N-1} - I_N k_0 u_N - I_\rho k_0 u_\rho + \frac{g_N(x_N, H_N)}{F_0 \bar{H}_0}] \end{aligned}$$

An expression of the dynamics in the fast time scale can be obtained by considering the limit case  $\varepsilon \rightarrow 0$ , which corresponds to the limit where the amount of heat obtained from combusting the tail gas is infinitely higher than the amount of heat derived from the combustion of fresh fuel. The fast dynamics thus take the form:

$$\begin{aligned} \text{Unit 1 :} \quad \frac{dx_1}{d\tau} &= 0 \\ \frac{M_1}{F_0 \bar{H}_0} \frac{dH_1}{d\tau} &= u_r - k_1 u_1 \\ \text{Unit 2 :} \quad \frac{dx_2}{d\tau} &= 0 \\ \frac{M_2}{F_0 \bar{H}_0} \frac{dH_2}{d\tau} &= k_1 u_1 - k_2 u_2 \\ &\vdots \end{aligned} \quad (7)$$

$$\begin{aligned} \text{Unit } i : \quad \frac{dx_i}{d\tau} &= 0 \\ \frac{M_i}{F_0 \bar{H}_0} \frac{dH_i}{d\tau} &= k_{i-1} u_{i-1} - k_q u_q \\ \text{Unit } N : \quad \frac{dx_N}{d\tau} &= 0 \\ \frac{M_N}{F_0 \bar{H}_0} \frac{dH_N}{d\tau} &= 0 \end{aligned}$$

The system of equations in (7) suggests that the variables whose dynamic response exhibits a fast component are the mass specific enthalpies (equivalently, temperatures)  $H_1, \dots, H_i$  of units  $1, \dots, i$ . Based on the assumptions made above, Unit 1 has a significant rate of heat input (via either combustion or electric heating). Heat is then conveyed to units  $2, \dots, i$  until it is removed from Unit  $i$  at a rate  $Q_{out}$ . Thus, units  $1, \dots, i$  represent a high energy throughput path through the process (Figure 3) [8].

**Figure 3** The fast component of the dynamics captures the energy balance of the units located in the high energy

throughput pathway of the process.  $Q_{in}$  represents either  $Q_{comb}$  or  $Q_{elec}$

The above arguments suggest that  $\bar{Q}_{out}$  is of comparable magnitude to  $\bar{Q}_{in}$ ; in the case where endothermic reactions occur in units  $1, \dots, i$ , the overall energy balance of the process suggests that the two quantities would differ by the heat consumed by the reactions (as reflected in the terms  $g_i(x_i, H_i)$ ).

The dynamics in the fast time scale are influenced by the rate of energy input to the process (as reflected by the term  $u_r$  in equation (7)), the rate of energy removal (term  $k_q u_q$  in equation (7)), and are not influenced by the rate of raw material input, the production rate and the rate at which fuel is provided from external sources.

It is of note that, even though the dynamics of the variables in the energy balance of units  $1, \dots, i$  are fast, the dynamic response of the individual units may be different; in other words, the time constants  $\frac{M_j}{F_0 \bar{H}_0}$ ,  $j = 1, \dots, i$  in equations (7) may be quite different.

The slow component of the dynamics evolves in time scale  $t$ . Considering the same limit  $\varepsilon \rightarrow 0$  in the original (slow) time scale  $t$  gives rise to the following constraints:

$$0 = u_r - k_1 u_1 \quad (8a)$$

$$0 = k_1 u_1 - k_2 u_2 \quad (8b)$$

$\vdots$

$$0 = k_{i-1} u_{i-1} - k_q u_q \quad (8c)$$

These constraints correspond to a quasi-steady state of the fast dynamics and describe a manifold/subspace where the slow dynamics of the process evolve. By considering these constraints and substituting (8) in equation (6), the slow component of the dynamics can be described as:

Unit 1 :

$$\frac{dx_1}{dt} = \frac{1}{M_1} [F_0 x_0 - F_1 x_1 + f_1(x_1, H_1)]$$

$$\frac{M_1}{F_0 \bar{H}_0} \frac{dH_1}{dt} = u_0 + u_r k_0 + \frac{g_1(x_1, H_1)}{F_0 \bar{H}_0}$$

Unit 2 :

$$\frac{dx_2}{dt} = \frac{1}{M_2} [F_1 x_1 - F_2 x_2 + f_2(x_2, H_2)]$$

$$\frac{M_2}{F_0 \bar{H}_0} \frac{dH_2}{dt} = \frac{g_2(x_2, H_2)}{F_0 \bar{H}_0}$$

$\vdots$

(9)

Unit  $i$  :

$$\frac{dx_i}{dt} = \frac{1}{M_i} [F_{i-1} x_{i-1} - F_i x_i + f_i(x_i, H_i)]$$

$$\frac{M_i}{F_0 \bar{H}_0} \frac{dH_i}{dt} = -I_i k_0 u_i + \frac{g_i(x_i, H_i)}{F_0 \bar{H}_0}$$

Unit  $N$  :

$$\frac{dx_N}{dt} = \frac{1}{M_N} [F_{N-1}x_{N-1} - F_Nx_N - F_Rx_N + f_N(x_N, H_N)]$$

$$\frac{M_N}{\bar{F}_0\bar{H}_0} \frac{dH_N}{dt} = I_{N-1}k_0u_{N-1} - I_Nk_0u_N - I_\rho k_0u_\rho + \frac{g_N(x_N, H_N)}{\bar{F}_0\bar{H}_0}$$

The model of the slow dynamics describes the evolution of the variables in the material balance (notably the product composition  $x_N$ , influenced by the product flow rate  $F_0$ ), as well as the evolution of the slow component of the energy balance of the process.

**Figure 4** Directed graph of the dynamic model of the prototype process. Nodes and edges specific to the integrated process using combustion of fuel gas as the heat source are shown in blue. Nodes and edges specific to electric heating are shown in red. The green and black nodes/edges are common to the two digraphs.

## OPERATIONAL IMPLICATIONS OF ELECTRIFICATION

The implications of the analysis presented earlier are discussed in this section. The presence of a two time scale behavior suggests that these processes lend themselves quite naturally to a two-tiered control and operational decision-making structure.<sup>7</sup> The management of energy use (including temperature control of Units 1, ...,  $i$ ) should be pursued in the fast time scale, while the control and management of production (in terms of production rate, product purity) should be pursued in the slow time scale [7]. The latter can also involve production scheduling.

The fast dynamics (7) of Units 1, ...,  $i$  means that changes in the rate of heat input to Unit 1 will be quickly reflected in the temperatures and compositions of units 2, ...,  $i$ . The impact on units  $i + 1, \dots, N$  will be apparent more slowly. In addition to deliberate operator (or control intervention), changes in the heat rate to Unit 1 can be caused by disturbances and constraints. The origin of these may be exogenous (from outside the process) or endogenous (from within).

To further investigate the impact of these disturbances and constraints on the heat rate, the structure of the two prototype processes is considered. Figure 4

shows the directed graph (digraph) of the system model (3). The fundamental difference between the conventional and electrified processes lies in the presence of a cycle in the graph of the conventional process, reflecting the fact that the heat rate provided to the Unit 1 depends on the composition  $x_N$  of the waste stream. Consider equation (7), and specifically the term  $u_r$ , that reflects the energy input due to combustion of the tail gas. The definition of  $u_r$ , i.e.,  $u_r = \frac{F_R H_R}{F_R \lambda_R}$ , indicates that rate of energy input is a function of  $\lambda_R$ , the lower heating value of the waste gas. The lower heating value is a function of the composition of the waste gas, and hence of the variable  $x_R$ .  $x_R$  is, in turn, affected by (effectively any and all) disturbances affecting the process, from Unit 1 to Unit  $N$ . Thus, a feedback effect is present, whereby variables in the *downstream* sections of the process impact the *upstream* units. Additionally, the dynamics of  $x_R$  evolve exclusively in the slow time scale, meaning that this feedback effect will occur over a long-time horizon.

In the process with electric heating, the heat rate to Unit 1 is completely independent of the downstream units of the process and constitutes an additional degree of freedom for controlling/optimizing the process operation. On the other hand, given the goal of using *renewable* electricity for process heating implies that the rate of heat input may be subject to upper bounds that are lower than the nominal steady state value.

## CASE STUDY: ETHYLENE CRACKER

Thermal cracking of hydrocarbon feedstock to obtain ethylene is one of the most energy-intensive chemical processes and one of the largest carbon emitters in the chemical industry. Its decarbonization potential lies in replacing the conventional combustion-based furnace with an electric furnace [9]. Relevant research efforts are underway in both industry and academia [10,11].

Ethylene crackers are highly integrated, and the by-products of the cracking reactions (methane, hydrogen) constitute an important fraction of the fuel used to heat the cracking reactor (which operates at high temperatures, of around 900°C) [5,12], and the heating value of the fuel gas stream depends on its composition (and ultimately on the operation of the reactor, as argued above).

Ethylene plants are complex and comprise extensive separation sections. We use a simplified representation for the purpose of investigating the dynamic implications of electrified process heating. The model consists of three units: reactor, intermediate unit, and separator, with the latter two serving as a proxy for the separation section. The dynamics of each unit are represented by the material and energy balances, under similar assumptions as listed in developing the model (3), with the exception that holdups are not constant.

The reactor unit is fed with pure ethane. The complex reactions occurring in industrial furnaces are approximated using a simplified two reaction scheme, a reversible reaction emulating the cracking transformation, and the degradation of product ethylene; we utilize methane as a proxy of the hydrocarbon degradation products:

with  $r_m$  referring to reaction  $m = 1, 2$  and  $-1$ .

**Figure 5.** Structure of the ethylene cracker prototype model

The product stream consists of unreacted ethane, product ethylene, and by-products methane and hydrogen. The reactor is modeled as a CSTR with the appropriate material and energy balances.

The intermediate units (I.U.) are intended to capture the (largely physical) transformations occurring post cracking, including the product quench step (represented as heat exiting the block  $Q_{cool}$ ). The material and energy balances follow first order dynamics. A significantly larger holdup is used in the unit compared to that of the reactor, to reflect the large time constant of the separation section of an ethylene plant.

In the separation block, by-products hydrogen and methane are separated from the product (in this case, ethane and ethylene) and recovered to use as fuel. The unit is modeled as a rate-based separation with vapor and liquid holdups, with by-product fuel gas exiting as the vapor stream and ethylene and unreacted ethane exiting as the liquid product stream.

In the conventional system, the fuel gas is recycled to be combusted in the furnace, providing heat for the

cracking reaction. The fuel gas composition, which determines the lower heating value (computed as a linear combination of individual heat values multiplied by their compositions in the fuel gas,  $LHV = \sum_j X_{vap,j} LHV_j$ ), and the corresponding energy input to the reactor, depends on the performance of the reactor and separator. On the other hand, in the electrified system case, the energy is supplied to the reactor from a source outside the process and thus independent of the performance of the process itself.

Structure of matrix A for the integrated process

Structure of matrix A for the electrified process

**Figure 6.** Structure of system matrix A of the linearized process model

Holdup and temperature controllers were implemented in each unit to stabilize holdups and temperatures. Simple P controllers that manipulate outlet flowrates were implemented for holdup control. For temperature control, PI controllers were implemented to manipulate the heat supply to the units. An additional purity controller is implemented in the liquid phase of the

separator to control the mass fraction of the product ethylene in the product stream by manipulating the temperature setpoint in the intermediate units.

An initial analysis focused on model structure; the two models (for the conventional and electrified processes) were linearized around their nominal steady states. The structure of the system matrices  $A$  in both cases is shown in Figures 6. As shown in Figure 6a, the matrix for the linearized model of the integrated process features additional non-zero entries that correspond to the impact of the states related to the composition of the fuel gas on the heat input rate to the reactor, as discussed above and confirming the findings of the graph-theoretical analysis and the structure of the graph in Figure 4.

Subsequent simulations focused on process dynamics. As an example, a  $5^{\circ}\text{C}$  increase in the reactor temperature setpoint, imposed at  $t = 1$  h is shown and discussed.

Figure 7 shows the behavior of reactor temperature in the two systems. In both systems, the controller settings and the tuning parameters are identical, and the difference in the behaviors would arise solely due to the process structure. The reactor corresponds to Unit 1 in the theoretical analysis and is therefore a unit in the high energy-throughput path. Two-time scale behavior is expected in the integrated model with high energy recycle throughput via combustion of by-product fuel gas. In the electrified case, the setpoint is tracked accurately and quickly, corresponding to the fast dynamics of the temperature variable. On the other hand, in the conventional case, the dynamic behavior is more complex, with the fast dynamics being followed by a slower evolution of the temperature towards the set-point, which, as explained earlier, is due to the (slow) feedback effect linking the composition changes in the reactor and separator to the heating value of the fuel gas.

**Figure 7.** Reactor temperature profile subject to reactor temperature setpoint increase of  $5^{\circ}\text{C}$ .

## CONCLUSIONS

In conclusion, the effects of electric heating on process structures and dynamics were studied theoretically and were demonstrated using simulation results. Through singular perturbation analysis, the multiple time-scale behavior was predicted in conventional systems with mass- energy recycling via combustion of waste products, whereas such behavior was expected to disappear in new electrified heating systems. The theoretical results were proven via simulations depicting a conventional ethylene cracker model with tail gas recycle and an electric cracker model.

# Biogas Valorization from a Process Synthesis Perspective: Heat and Work Integration to Maximize CO<sub>2</sub> Conversion

Baraka C. Sempuga\*, Selusiwe Ncube

University of South Africa, Institute for Catalysis and Energy Solutions, Johannesburg, Gauteng, South Africa.

\* Corresponding Author: sempubc@unisa.ac.za

## ABSTRACT

Biogas is often considered as a source of renewable energy, for heat and power production. However, biogas has greater promise as a source of concentrated CO<sub>2</sub> in addition to methane, making it a rich supply of carbon and hydrogen for the generation of fuel and chemicals. In this work, we use the concept of attainable region in the enthalpy-Gibbs free energy space to identify opportunities for effective biogas valorization that maximizes the conversion of CO<sub>2</sub>. The AR concept allows us to study a chemical process without knowing the exact reaction mechanism that the species in the process use. Deriving Material Balance equations that relate a reactive process's output species to its input species is sufficient to identify process limits and explore opportunities to optimize its performance in terms of material, energy, and work. The conversion of biogas to valuable products is currently done in two steps; the high temperature and endothermic reformer step, followed by the low temperature exothermic synthesis step. We demonstrate, using Aspen Simulation, that energy integration, both heat and work, between the two steps is crucial to achieving a substantial amount of CO<sub>2</sub> conversion. We also show how a heat pump configuration can be utilized to integrate energy between the reformer and synthesis steps against the temperature gradient by integrating external renewable energy.

## INTRODUCTION

Biogas is not only a source of green energy [1] but also a source of concentrated green CO<sub>2</sub>. The composition of CO<sub>2</sub> in biogas typically ranges between 25-50% by volume, with the balance primarily consisting of methane, varying depending on the feedstock [2,3]. This characteristic makes biogas a suitable feed for CO<sub>2</sub> conversion processes. Several authors have shown different ways of upgrading and valorizing biogas by either extracting the energy by direct combustion or converting it to chemicals such as methanol [1,4-6]. Several authors have also demonstrated different techniques to converting the CO<sub>2</sub> in biogas along with methane to chemicals, including dry reforming where CO<sub>2</sub> and CH<sub>4</sub> are converted to synthesis gas followed by methanol synthesis [4]. Another technique starts by removing the CO<sub>2</sub> from CH<sub>4</sub> before converting to hydrogen via steam reforming and water gas shift reaction followed by CO<sub>2</sub> hydrogenation to methanol

[6]. While these studies have shown these conversion techniques to be feasible, one major drawback is the intense energy demand of the reforming step which could result in substantially lower net CO<sub>2</sub> conversion depending on where the energy is sourced from. For instance, if the energy is supplied by burning a carbon-based fuel, which is commonly practiced, then one needs to consider the CO<sub>2</sub> emitted during the combustion of the fuel. Ideally, the energy for reforming should come from a renewable source in the form of electricity to achieve a net negative CO<sub>2</sub> emission. Another drawback is the inability to integrate the energy between the synthesis and reformer sections due to temperature gradients. Ncube et. al. (2023) [7] have shown that heat integration between the reformer and synthesis section is essential to achieving higher energy efficiency and increased CO<sub>2</sub> conversion and they suggested that this can be done by integrating a heat pump that runs on renewable energy to the system. In this work, we use the attainable region concept

to identify more effective ways for converting biogas from a material, energy, and work balance perspective. To optimize the conversion of CO<sub>2</sub>, we place a strong emphasis on the product selection and energy integration.

## THE APPROACH

In this section we would like to determine the attainable region for biogas conversion into various products. The attainable region will provide information on the performance limits of the process from the material and energy perspectives. The limits of performance can be understood as the extreme points that any biogas conversion process can achieve for a given feed composition. Thus, for the given feed composition and a given set of species involved in the process, we can determine the attainable region of the process by finding all possible composition states that can result from the chemical conversion of the biogas into the specified species. We will explore how this is done by using the notation and terminology found in Smith & Missen (1982) [8].

For a *chemical system* containing  $N$  species and  $M$  elements, denoted as:  $\{(A_1, A_2, \dots, A_i, \dots, A_N), (E_1, E_2, \dots, E_k, \dots, E_M)\}$  where  $A_i$  is the elemental formula of species  $i$  and  $E_k$  is the  $k$ th element in the system. The order in which the species and elements are presented in the system is not important for the attainable region, however, once decided upon, it must be kept consistent during the derivation as most the equations are written in matrix form. Thus for the biogas conversion chemical system with 9 species ( $N = 9$ ) and 3 elements ( $M = 3$ ) we have

$\{(CH_4, CO_2, H_2O, O_2, H_2, CO, CH_2, CH_3OH, C), (C, H, O)\}$ .

The *element-abundance* constraint is one of the constraints that must always be satisfied as it constitutes the basis for the material conservation within the system.

$$\mathbf{A}\mathbf{n} = \mathbf{b} \quad (1)$$

-  $\mathbf{A}$  is the *formula matrix* an  $M \times N$  matrix containing the amount of each element in each species where  $M$  is the number of elements and  $N$  is the number of species in the system.

-  $\mathbf{n}$  is the *species-abundance* vector ( $N \times 1$ ) containing the number of moles of each species in the system.

-  $\mathbf{b}$  is the *element-abundance* vector containing the total amount of each element available in the system. Thus  $\mathbf{b}$  is fixed for a given feed composition.

Given the initial number of moles of all the species (or the initial species-abundance vector)  $\mathbf{n}^0$ , the element-abundance vector  $\mathbf{b}$  is fixed and is given by  $\mathbf{b} = \mathbf{A}\mathbf{n}^0$ . Therefore, the element-abundance constraint can also be written as follows:

$$\mathbf{A}\mathbf{n} = \mathbf{A}\mathbf{n}^0 \quad (2)$$

The compositional state  $\mathbf{n}$  of a system can be

expressed in terms of an initial compositional state  $\mathbf{n}^0$  as follows:

$$\mathbf{n} = \mathbf{n}^0 + \sum_{j=1}^R \mathbf{v}_j \xi_j \quad (3)$$

where  $\mathbf{v}_j$  is the stoichiometric vector such that:

$$\mathbf{A}\mathbf{v}_j = \mathbf{0}; (\mathbf{v}_j \neq \mathbf{0}); \quad j = 1, 2, \dots, R \quad (4)$$

Thus  $\mathbf{v}_j$  is any set of  $R$  independent solutions that satisfies eq.4. Therefore,  $R$  is the maximum number of linearly independent solutions for eq.4. It is given by:

$$R = N - C \quad (5)$$

$$C = \text{rank}(\mathbf{A}) \quad (6)$$

For the biogas system the formula matrix  $\mathbf{A}$  is derived from the elemental composition of the species as shown in the table below

**Table 1:** Derivation of the formula matrix from the elemental composition of the species

$N \setminus M$	$C$	$H$	$O$
$CH_4$	1	4	0
$CO_2$	1	0	2
$H_2O$	0	2	1
$O_2$	0	0	2
$H_2$	0	2	0
$CO$	1	0	1
$C_8H_{18}$	8	18	0
$CH_3OH$	1	4	1
$C$	1	0	0

Therefore  $\mathbf{A}(M \times N)$  is:

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 1 & 8 & 1 & 1 \\ 4 & 0 & 2 & 0 & 2 & 0 & 18 & 4 & 0 \\ 0 & 2 & 1 & 2 & 0 & 1 & 0 & 1 & 0 \end{pmatrix} \quad (7)$$

It follows that  $C = \text{rank}(\mathbf{A}) = 3$ ; therefore  $R = N - C = 9 - 3 = 6$ , where  $R$  is the maximum number of independent chemical equations that can be derived from the system.

We therefore define the matrix  $\mathbf{N}$ , an  $N \times R$  matrix, as the *complete stoichiometric matrix* whose  $R$  columns are linearly independent vectors  $\mathbf{v}_j$ . And therefore eq. 4 can be written as a single matrix as follows:

$$\mathbf{A}\mathbf{N} = \mathbf{0} \quad (8)$$

where  $\mathbf{N} = (\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_R)$ .

The vector  $\mathbf{v}_j$  contains the stoichiometric coefficients of the  $j$ th chemical equation. Therefore, for any chemical system there are only  $R$  independent chemical equations that represents all possible compositional states of the system.

For the biogas conversion process, we adopt the method described in Smith & Missen (1982) [8] and use Matlab® to derive the stoichiometric matrix  $\mathbf{N}(N \times R)$ . In this case we derive a set of the 6 non-unique independent chemical equations for this system, where negative

values stand for the coefficient on the left side (reactant) and positive are those on the right side (product) of the equation.

$$\mathbf{N} = \begin{pmatrix} 0.50 & -0.25 & -0.25 & -6.25 & -0.75 & -0.5 \\ -0.50 & 0.25 & -0.75 & -1.75 & -0.25 & -0.5 \\ -1.00 & -0.50 & 0.50 & 3.50 & -0.5 & 1 \\ 1.00 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1.00 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.00 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1.00 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1.00 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

From eq.4, a complete set of  $\mathbf{v}_j$  (also written as  $\mathbf{N}$ ) is not unique but can be any set that satisfies eq.4 (or eq.8). Therefore, the set of independent chemical equations derived from the stoichiometric vectors do not represent any *chemical reactions* occurring in the system but are simply algebraic solutions of all possible composition states that any chemical reactions path can achieve. Thus, to distinguish a *chemical equation* from a *chemical reaction*, we use the equal sign (=) instead of an arrow ( $\rightarrow$ ).

The quantities  $\xi_j$  in eq.3 are a set of parameters, which determine the linear combination of the coefficient vectors  $\mathbf{v}_j$  required to achieve a particular compositional state  $\mathbf{n}$ . Thus, the number of moles of each species at a compositional state is given by:

$$n_i = n_i^o + \sum_{j=1}^R v_{ij} \xi_j \quad (9)$$

where  $v_{ij}$  is the *stoichiometric coefficient* of  $i$ th species in the  $j$ th stoichiometric vector, and  $\xi_j$  is the parameter for the  $j$ th stoichiometric vector.

The *Attainable Region* (AR) for the chemical system is defined by the sets of  $\xi_j$ 's for which the number of moles of each species is positive. Thus, the AR is obtained by using eq 9 as an additional constraint when written as an inequality equation as follows:

$$n_i = n_i^o + \sum_{j=1}^R v_{ij} \xi_j \geq 0 \quad (10)$$

One can also formulate a linear programming problem to determine the attainable region as follows:

$$\text{find all } \xi_j, \text{ subject to } \begin{cases} \mathbf{n} = \mathbf{n}^o + \sum_{j=1}^R \mathbf{v}_j \xi_j \geq 0 \\ \mathbf{A}\mathbf{n} = \mathbf{A}\mathbf{n}^o \end{cases} \quad (11)$$

Eq.11 is a linear programming problem whose vertices constitute a convex connected region in the  $\xi$  space of dimension  $R$ . It can also be transformed into the  $n_i$  space of dimension  $N$ .

If there are  $K$  extreme points in the attainable region, we can denote the set of these vertices in the  $\xi$  space as  $\xi_V$  ( $\xi_{V_1}, \xi_{V_2}, \dots, \xi_{V_K}$ ), where  $\xi_{V_k}$  is the parameter vector at the  $k$ th vertex. Similarly, in the  $n_i$  space as we denote  $\mathbf{n}_V$  ( $\mathbf{n}_{V_1}, \mathbf{n}_{V_2}, \dots, \mathbf{n}_{V_K}$ ), where  $\mathbf{n}_{V_k}$  is the composition vector at the  $k$ th vertex of the AR.

Another way of visualizing the AR is to transform its vertices into a two-dimensional space of Gibbs Free Energy and enthalpy as follows:

$$\left. \begin{aligned} \Delta G_{V_k} &= \sum_{j=1}^R \xi_{jV_k} \mathbf{v}_j \hat{\mathbf{G}}^T \\ \Delta H_{V_k} &= \sum_{j=1}^R \xi_{jV_k} \mathbf{v}_j \hat{\mathbf{H}}^T \end{aligned} \right\} \quad (12)$$

Where  $\hat{\mathbf{G}}$  and  $\hat{\mathbf{H}}$  are the molar Gibbs free energy and molar enthalpy vector for the species.

Figure 1 is the attainable region of biogas conversion in the Gibbs Free Energy and enthalpy space (GH-AR) with a feed composition of  $\text{CH}_4$ ,  $\text{CO}_2$  and  $\text{H}_2\text{O}$  at a ratio of 4:4:1. It shows the theoretical limits of all possible product compositions that can be obtained from the given feed composition, while simultaneously showing the minimum energy requirement ( $\Delta H$ ) and minimum work (or energy quality) requirement ( $\Delta G$ ), both taken at reference temperature  $T_o = 25^\circ$  and reference pressure  $P_o = 1\text{bar}$ , associated with the conversion of the given feed to products. Each point of the GH-AR can be considered as an *overall process* target for energy, exergy (here represented by  $\Delta G$  since the change in exergy at  $T_o$  and  $P_o$  is equal to  $\Delta G$  at  $T_o$  and  $P_o$ ), and material conversion, and as such can serve as a benchmark for real processes. A more elaborate discussion on the GH-AR can be found in Fernandez-Torres et al. (2023) [9], however, we will discuss a few important insights into the process. Using the GH-AR in Figure 1. The vertices in the GH-AR represent the points where one or more of the species is zero thus represent the limits for biogas conversion. Thus, points of complete and incomplete overall conversion of  $\text{CH}_4$  and  $\text{CO}_2$  can be seen on GH-AR where either  $s_1$  or  $s_2$ , representing  $\text{CH}_4$  and  $\text{CO}_2$  respectively, or both appear. Some of the points contain undesirable products such as carbon C ( $s_9$ ), CO ( $s_6$ ) and  $\text{H}_2$  ( $s_5$ ) as final products.

Another important insight from the GH-AR is regarding biogas conversion to methanol. The observation in Figure 1 is that every point in the GH-AR representing methanol ( $s_8$ ) as a product is accompanied by other less desirable products. An example of such a point is point M ( $s_2, s_8, s_9$ ) representing a process target that produces methanol and the less desirable products  $\text{CO}_2$  and C. Since  $\text{CO}_2$  is one of the feed components, the production of  $\text{CO}_2$  at M can be thought of as incomplete overall conversion of  $\text{CO}_2$ . Another example is at point N ( $s_4, s_6, s_8$ ) representing  $\text{O}_2$ , CO and methanol as final product. While  $\text{O}_2$  is not necessarily an undesirable product but CO is less desirable as a final product. This observation suggests that undesirable by-products may be inevitable when converting biogas to methanol. Thus, the process seems to be less optimal although it receives increasing interest among several authors [4-6].

On the other hand, Fisher Tropsch fuels (FT-fuels) production can be more effective in the conversion of  $\text{CO}_2$  without producing undesired by-products. This can be seen at point F ( $s_4, s_8$ ) in Figure 1 representing a

process target to produce octane (s8) and oxygen (s4) only as final products. Furthermore, point F represents a 100% carbon and hydrogen conversion efficiency where all the carbon and hydrogen in the feed report to the desired product, octane. As such, this point must be considered the ultimate target for biogas conversion for the given feed composition. We will explore with the aid of an Aspen Plus simulation how the target at F can be achieved by integrating both the material and energy within the process.

The GH-AR not only provides information regarding the material conversion limit but also the energy ( $\Delta H$ ) and the work ( $\Delta G$ ) requirements to achieve a specific product composition [8]. One important observation is that for biogas conversion almost all targets are in the Region A and B with positive  $\Delta H$  and  $\Delta G$ , which shows that external energy supply is necessary to achieve the targets where  $\text{CO}_2$  is consumed. Points located at the bottom section of the GH-AR have less  $\text{CO}_2$  conversion thus need less energy compared to those in the upper part where more  $\text{CO}_2$  is consumed and therefore need more energy at higher quality as  $\Delta G$  is higher.

Furthermore, the  $45^\circ$  line represents processes that require the highest energy quality (pure work, or electricity). The processes in Region A, below the  $45^\circ$  line, are relatively easy to achieve in one step by utilizing a source of thermal energy at an appropriate temperature. However, those in region B, above the  $45^\circ$  line, are not feasible if done in one step from feed to final product but require several intermediate steps that are fully integrated in terms of energy and materials and would require a supply of high-quality energy. This is the case to produce FT-fuels, with its ultimate target located in region B. Thus, to achieve this target, one must run the process in at least 2 steps, notably, the reforming step where biogas is converted to synthesis gas followed by the FT synthesis section where syngas is converted to liquid fuels.

One of the major challenges in achieving this target is the inability to integrate energy between the reforming section, an endothermic process that runs at higher temperatures, and the synthesis section, an exothermic section that runs at lower temperature. Ncube et. al. (2023) [7] have also shown that a heat pump is needed to integrate the energy between these two sections. In this work we explore how a heat engine configuration can be used to achieve both the material and energy integration within the system, by means of water electrolysis as shown in the Aspen Plus simulation in Figure 2.

The feed to the process flowsheet denoted as Biogas enters the process at a ratio of 4:4:1 of  $\text{CH}_4$ :  $\text{CO}_2$ :  $\text{H}_2\text{O}$ . The feed is preheated before entering the reformer where the feed is converted to syngas, a mixture of mainly  $\text{CO}$  and  $\text{H}_2$ . The reformer is modelled using a Gibbs reactor block (RGibbs), which uses Gibbs free energy minimization to determine the equilibrium composition of specified

components in the reactor at given conditions of temperature and pressure. The components that were considered are  $\text{CH}_4$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{O}_2$ ,  $\text{H}_2$ ,  $\text{CO}$ , and  $\text{C}$  (as pure solid). A temperature of  $950^\circ\text{C}$  in the reformer was used to achieve a high conversion of  $\text{CH}_4$  and  $\text{CO}_2$  at 1 bar. The syngas from the reformer is cooled down using the incoming stream to the reformer, and then goes to the Fischer Tropsch (FT) synthesis reactor (FT-RCT) where  $\text{CO}$  and  $\text{H}_2$  are converted FT-fuels (represented by  $\text{C}_8\text{H}_{18}$ ) and  $\text{H}_2\text{O}$ . The FT-synthesis reactor is modelled using a stoichiometric reactor block (RStoic) which is used when the reactions and conversions are known. In this simulation we consider only one reaction in the FT-RCT to model the production of FT-fuels and we assume complete conversion of  $\text{CO}$  to  $\text{C}_8\text{H}_{18}$  via the reaction;  $8\text{CO} + 17\text{H}_2 \rightarrow 8\text{H}_2\text{O} + \text{C}_8\text{H}_{18}$  at  $250^\circ\text{C}$  and 1 bar. The product stream from the FT-RCT is cooled down and separated using a Sep block (PR-SEP1) which assumes perfect separation based on split fractions or mole flows of pure components. The PR-SEP1 produces a pure stream of FT-fuel, water and a gas stream containing unreacted  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{CH}_4$ . The water is sent to the electrolyzer reactor (ELECT-RC) modelled using the RStoic block to produce  $\text{H}_2$  and  $\text{O}_2$  at  $250^\circ\text{C}$ . The temperature of the electrolyzer was chosen to allow heat integration with the FT-RCT. The product from the electrolyzer is separated using the Sep block to achieve a perfect separation of  $\text{H}_2$  and  $\text{O}_2$ . Part of the  $\text{H}_2$  produced is used to supply the energy needed at the reformer using a portion of the  $\text{O}_2$  produced from the electrolyser, and the remaining  $\text{H}_2$  is fed to the reformer to enhance the conversion of  $\text{CO}_2$ . On the hand the remaining  $\text{O}_2$  from the electrolyser is taken out of the process as a product. The combustion of  $\text{H}_2$  with  $\text{O}_2$  is modelled using the RStoic block with the combustion temperature set at  $955^\circ\text{C}$  to allow for at least a temperature approach of  $5^\circ\text{C}$  for heat exchanged between the combustion unit at the reformer.

## SIMULATION RESULTS

The electrolyzer and  $\text{H}_2$  combustion configuration enables achieving three main goals:

- 1) Heat transfer from the synthesis reactor at  $250^\circ\text{C}$  to the reformer at  $950^\circ\text{C}$  is achieved by using the energy released from the FT-synthesis to provide heat to the electrolyzer and thus lowering the electrical requirements of the electrolyzer. This energy is chemically stored in  $\text{H}_2$  part of which is converted to high temperature heat required by the reformer.

2) The recycled hydrogen to the reformer provides a hydrogen rich environment that enhances the conversion of CO<sub>2</sub> via the reverse water gas shift reaction to produce CO and H<sub>2</sub>O, carbon formation is also eliminated at temperatures above 750°C. The reformer temperature is set at 950°C leading to a CO<sub>2</sub> conversion across the reactor of approximately 94% and a CH<sub>4</sub> conversion of 99% (See Table 2). Similar results were also obtained by Rosha et.al. (2021) with slight deviations due to the differences in CH<sub>4</sub> and CO<sub>2</sub> ratios in the feed and in the operating pressure. The ratio H<sub>2</sub>/CO obtained in approximately 2.16.

3) The overall hydrogen and carbon efficiency ( $\eta_{H_2}$  and  $\eta_C$ ) in Eq. 13,

$$\eta_i = \frac{\text{moles of atoms of } i \text{ coming into the process}}{\text{moles of atoms of } i \text{ in the desired product}} \times 100 \quad (13)$$

is the fraction of the total hydrogen and carbon atoms in the feed that reports to the desired product. Assuming a high CO conversion in the FT-reactor, a 97% hydrogen efficiency and a 99% carbon efficiency were obtained. This results in almost no tail gas, leading to FT-fuels and O<sub>2</sub> as the main products across the process.

4) The energy efficiency is evaluated in terms thermal efficiency expressed as

$$\eta_{thermal} = \frac{m_{FT-fuels} HHV_{FT-fuels}}{m_{Biogas} HHV_{Biogas} + W_{electricity}} \quad (14)$$

where *HHV* is the higher heating value, *m* is the molar flowrate and *W<sub>electricity</sub>* is the electrical power input to the process. The electrical power supplied to the electrolyzer is the only point of entry of high-quality energy across the process. This meets the target set out in the attainable region as needed by the overall process as discussed in the previous section. The process requires 135kW of electrical energy. This translates to a thermal efficiency of 96%, a significant improvement compared to other reported results such as those by Guares et al. (2021) [10] who reported 41-46% thermal efficiency in a biogas to power process. Rosha et al. (2021) [4] reported 63.7% thermal efficiency in a biogas to methanol process.

**Table 2:** Material flows in selected major streams of the Aspen Plus simulation in Figure 2.

Kmol/h	Biogas	Syn-gas-1	FT-Fuel	Oxy-gen	Tail Gas
CH <sub>4</sub>	1	0.005	0	0	0.005
CO <sub>2</sub>	1	0.062	0	0	0.062
H <sub>2</sub> O	0.25	0.193	0	0	0
O <sub>2</sub>	0	0	0	1.06	0
H <sub>2</sub>	0	4.174	0	0	0.065
CO	0	1.933	0	0	0
C <sub>8</sub> H <sub>18</sub>	0	0	0.242	0	0
CH <sub>3</sub> OH	0	0	0	0	0
C	0		0	0	0

## CONCLUSION

The efficiency of biogas conversion to valuable products depends on the choice of the products and the efficacy of the material and energy integration within the process. The GH attainable region is a useful tool in identifying the process material balance targets with high CO<sub>2</sub> conversion and with less or no undesirable by products. Conversion of biogas to FT-fuel is one such a process with an ultimate target of 100% CO<sub>2</sub> and CH<sub>4</sub> conversion to produce FT-fuels and oxygen. This, however, requires the supply of high-quality energy, such as electricity or high temperature heat, from an external source, coupled with adequate material and energy integration within the process. We have shown, using an Aspen plus simulation, that electrical power supply to the overall process via water electrolysis not only enables supplying high quality energy to the process but also facilitates the integration of energy from the synthesis section to the reformer section against the temperature gradient hence acting as heat pump. The Aspen Plus simulation shows that with this process configuration 97% carbon and 99% hydrogen conversion is possible.

The present work is based on a specific feed composition. Changing this parameter will change the results observed in the attainable region in Figure 1 which could lead to a different ultimate process target and would require a different process configuration to achieve the target. For instance, a higher ratio of CH<sub>4</sub> to CO<sub>2</sub> in the feed could lead to the production of FT-fuels and Carbon as the ultimate process target rather than the production of FT-fuels and oxygen. To avoid this one may require modifying the amount of water to be fed to the process to ensure that a target for the production of FT-fuels and O<sub>2</sub> is maintained. This suggests that the ratios of carbon, hydrogen and oxygen in the feed is a significant factor that needs to be investigated.

## ABSTRACT

The transition to net-zero greenhouse gas emissions requires a rapid redesign of energy systems. However, the redesign may shift environmental impacts to other categories than climate change. To assess the sustainability of the resulting impacts, the planetary boundaries framework provides absolute limits for environmental sustainability. This study uses the planetary boundaries framework to assess net-zero sector-coupled energy system designs for absolute environmental sustainability. Considering Germany as a case study, we extend the common focus on climate change in sustainable energy system design to seven additional Earth-system processes crucial for maintaining conditions favorable to human well-being. Our assessment reveals that transitioning to net-zero greenhouse gas emissions reduces many environmental impacts but is not equivalent to sustainability, as all net-zero designs transgress at least one planetary boundary. However, the environmental impacts vary substantially between net-zero designs, highlighting that design choices exist to address transgressions of planetary boundaries.

## INTRODUCTION

The energy system needs to be redesigned to reduce greenhouse gas emissions to net-zero. The redesign is commonly guided by energy systems models in optimization studies [1]. A common finding in energy system optimization studies is the rise of sector coupling to integrate low-carbon electricity into sectors such as mobility and heating [2–5]. Combined with environmental life-cycle assessment (LCA) [6], energy system modeling and optimization can account for climate change and additional environmental impacts.

In LCAs of the energy system transition, reducing the climate change impact of energy systems has been shown to result in burden-shifting, i.e., environmental impacts shift from climate change to other categories, such as in land use, resource depletion, toxicity, and ecosystem diversity [7, 2]. However, traditional LCA commonly adopts a comparative approach, where the

environmental impacts of systems are assessed in relation to a reference system [8]. While such traditional LCAs show relative differences in impacts, they do not quantify the severity of shifting environmental impacts.

Recently, metrics were introduced to assess environmental trade-offs and provide critical limits by so-called absolute environmental sustainability assessment [8]. Such methods connect life-cycle assessment with absolute environmental sustainability assessment (for a review, see [8]). A popular example is the application of the planetary boundary framework [9–11] to life-cycle assessment [12, 13]. The planetary boundaries framework defines safe operating spaces for climate change and 8 additional Earth-system processes critical to maintaining an Earth-system state that is beneficial for humans. A recent assessment [11] finds that the planetary boundaries are transgressed for 6 Earth-system processes: climate change, change in biosphere integrity, biogeochemical flows of phosphate and nitrogen, land-system change,

freshwater change, and novel entities. Only 3 processes remain within boundaries: stratospheric ozone depletion, ocean acidification, and atmospheric aerosol loading. Hence, it is crucial to consider planetary boundaries in the sustainable design of future energy systems.

In pioneering work, absolute environmental sustainability assessments going beyond climate change have been applied to energy systems [14] but typically consider only one sector, such as power [15–17] or building heat systems [18]. Hence, the impact of sector coupling on absolute sustainability is poorly understood. Here, we conduct an absolute environmental sustainability assessment for net-zero sector-coupled energy systems via the planetary boundaries framework.

## PLANETARY BOUNDARIES IN ENERGY SYSTEM MODELING

Energy system modeling and optimization frameworks vary in model complexity depending on the application. For (inter)national sector-coupled energy system models, linear or mixed-integer linear programming formulations are commonly selected to represent techno-economic constraints [19].

In addition to techno-economic constraints, environmental impacts are included via LCA in models of sector-coupled energy systems from international [3, 4] to national scale [5, 2]. Previous LCA studies [2–5] found environmental burden-shifting resulting from the energy transition, e.g., increasing the use of land, water, and resources.

In previous work, we considered the environmental impacts of the German sector-coupled energy transition to net-zero operational greenhouse gas emissions [20]. Our work revealed increases in up to 7 of 16 impact categories compared to the status quo, e.g., resource depletion of minerals and metals may increase up to four times. However, the degree of burden-shifting can be reduced by design choices: Carbon capture and storage is found to be a lever to steer environmental impacts.

While the identified burden-shifting highlights potential areas of concern, the relative increase in impacts does not reveal if the increase contributes to a transgression of limits of absolute sustainability. Absolute assessments via planetary boundaries aim to overcome this limitation and have been conducted for a single sector of the energy system [14–17]. As these studies are limited to a sector or geographical region and the safe operating space applies to all human activities, downscaling is required, where a share of the safe operating space is allocated to the assessed system [21]. Typically, the safe operating space is allocated by one or a combination of the following principles: egalitarian, utilitarian, or acquired

rights. All of the energy-related studies [15–18] apply downscaling by population to account for the geographical scope, and some further apply downscaling by economic principles or acquired rights.

## METHODS

### Absolute environmental sustainability assessment via planetary boundaries

Here, we assess the absolute sustainability of the net-zero designs for the German sector-coupled energy system identified in previous work [20]. We apply the planetary boundaries framework using the impact assessment method provided in [13]. Note that novel entities are excluded from our assessment, as they are not quantified in [13]. However, in [11], the planetary boundary for novel entities is considered transgressed if any synthetic chemical is released into the environment without adequate safety testing. Hence, the boundary is likely transgressed for the energy system.

As the geographical and sectorial scope is limited in the case study, we allocate a share of the global safe operating space to the German energy system. We first apply downscaling by population based on egalitarian principles to account for the geographical scope. Thus, a share of the total safe operating space is allocated to Germany based on its share of the global population in 2021 [22]. We subsequently apply downscaling by grandfathering to account for the sectorial scope. For the grandfathering, we limit the share of the German safe operating space that the energy system can occupy to the share of environmental impacts caused by the energy system in the reference year (2016). The share of environmental impacts in the reference year is estimated compared to the total German impacts determined using a global input-output database [23]. As an additional reference, we include the share of safe operating space based on gross domestic product in 2021 [24] instead of population. We thus identify environmental impacts exceeding absolute limits for sustainability.

### Energy system model description

The net-zero sector-coupled energy systems are designed via a modeling and optimization framework with integrated LCA<sup>1</sup> [25] based on the life-cycle inventory database ecoinvent 3.5 (APOS) [26].

The system boundary of the energy system includes the electricity sector, the private mobility sector, and the heating sector for buildings and for industry on three temperature levels. In addition, we include CCS technologies and a direct air capture technology to enable CO<sub>2</sub> emission avoidance and CO<sub>2</sub> removal (Table 1).

As the functional unit, we select the supply of all

<sup>1</sup> [git-ce.rwth-aachen.de/secmod](https://git-ce.rwth-aachen.de/secmod)

exogenous end-use demands for electricity, mobility, and heat. Additionally, we constrain operational greenhouse gas emissions to reach net-negative emissions of -29 Mt CO<sub>2</sub>-eq. in 2045, assuming that the energy system contributes to balancing hard-to-abate emissions, e.g., in agriculture. A detailed description is available in [20].

**Table 1:** Technologies considered in the energy system case study based on [2, 20].

<b>electricity</b>	<b>heating</b>
biogas-to-power	<b>building</b>
geothermal	natural gas boiler (district)

The multi-period investment decisions are determined in a rolling-horizon optimization, minimizing total annualized cost with investments every 5 years for a foresight horizon of 10 years. We apply a linear programming formulation for the design problem, assuming linear input-output relationships in energy conversion, continuous equipment sizing, and linear investment and operating costs.

## CASE STUDY RESULTS

Transition pathways depend on key technology options, such as the availability of green electricity imports or DAC as a carbon dioxide removal technology. DAC opens a design space with solutions spanning between the cost-optimal and the minimally-required deployment of CO<sub>2</sub> sequestration that still meets greenhouse gas emission targets.

Here, we assess the absolute environmental sustainability assessment of a conservative scenario from [20] that excludes electricity imports into the energy system. Further, we consider 3 sub-scenarios where CO<sub>2</sub> storage is 1) unconstrained (min-TAC), 2) constrained to a minimum (min-storage), and 3) constrained to an intermediate value (compromise).

The net-zero energy systems outperform the fossil system from the initial year of the transition horizon in at least 6 of 9 impact categories (Figure 1). Only for the nitrogen cycle, impacts increase beyond the level of 2016 in all net-zero designs. Additional burden-shifting occurs only in scenarios with minimal CO<sub>2</sub> sequestration, where the impacts increase in atmospheric aerosol loading and in freshwater use compared to the reference in 2016. However, the absolute sustainability assessment reveals that the burden-shifting for freshwater use does not result in a transgression of the safe operating space.

In the other Earth system processes, the net-zero designs reduce impacts, sometimes substantially, e.g., in ocean acidification (-91 %), climate change (-90 %), the phosphorus cycle (-86 %), change in biosphere integrity (-82 %), and land system change (-57 %).

However, no net-zero energy system stays within all planetary boundaries when downscaling is applied based on population. In particular, all energy systems transgress boundaries for the nitrogen cycle and atmospheric aerosol loading, while some further exceed boundaries for climate change, change of biosphere integrity, and ocean acidification. The designs obtained for the compromise scenario and the scenario with minimal CO<sub>2</sub> sequestration exceed boundaries for climate change despite reaching net-zero operational greenhouse gas emissions due to greater infrastructure intensity with embedded emissions.

The transgression is particularly large for the nitrogen cycle, where the boundaries are exceeded by a factor of 4.2 on average across the three net-zero designs due to massive investments in battery electric vehicles, power-to-methane, and insulation material for energetic rehabilitation.

While all three net-zero designs transgress at least 2 planetary boundaries and are therefore unsustainable, the designs differ substantially in their environmental impact (Figure 1): On average, the energy system occupies 77 % of the safe operating space for the case minimizing

total annualized cost with unconstrained CO<sub>2</sub> sequestration (min-TAC) but by up to 190 % for the case with minimal CO<sub>2</sub> sequestration (min-stor). The results indicate that design choices, such as the availability of flexible negative emission technologies, can reduce transgressions.

The results vary depending on the choice of downscaling methods, which involves distributive justice considerations and introduces subjectivity into the assessment [21]. Therefore, we include downscaling by gross domestic product instead of population as an additional reference.

Downscaling by gross domestic product instead of population quadruples the safe operating space due to Germany's large per-capita gross domestic product. For downscaling by gross domestic product, an energy system design within the modeled planetary boundaries seems possible if CO<sub>2</sub> sequestration is unconstrained (Figure 1, min-TAC). However, downscaling by economic indicators is controversial [21]. In general, the

downscaling method requires careful consideration in the interpretation of results.

## CONCLUSIONS AND OUTLOOK

Global greenhouse gas emissions must decline rapidly to limit human-induced climate change. In addition to climate change, other sustainability challenges must be addressed simultaneously.

The planetary boundaries framework defines a safe operating space for human activities for 8 Earth-system processes in addition to climate change. The planetary boundaries thus impose additional constraints on the design space of sustainable energy systems that are commonly neglected.

Here, we evaluate the environmental impacts of net-zero energy system designs considering the planetary boundaries. In particular, we consider net-zero designs of the sector-coupled energy system of Germany, a representative industrial economy. Our case study reveals a

**Figure 1.** Share of safe operating space occupied by sector-coupled energy system designs with net-zero operational greenhouse gas emissions for the German energy transition in 2045 aiming for minimal cost (min-TAC) or minimal CO<sub>2</sub> sequestered (min-storage), and an intermediate solution (compromise). Downscaling of the global safe operating space to the share of safe operating space allocated to the German energy system is based on 1) the population of Germany in 2021 and 2) on the energy system's share of the total environmental impacts in Germany in the original year of the transition horizon (2016) (population). As a reference, downscaling based on gross domestic product in 2021 instead of population is indicated as well (GDP).

The share of safe operating space occupied by the energy system in the reference year (2016) is marked (♦) for comparison with the energy systems in 2045.

abbreviations: nitrogen cycle (N), atmospheric aerosol loading (AAL), climate change (CC), change in biosphere integrity (BIO), land-system change (LSC), freshwater use (FW), stratospheric ozone depletion (OD), ocean acidification (OA), phosphorous cycle (P)

Novel entities are excluded, as they are not quantified in [13]. However, in [11] the planetary boundary for novel entities is considered transgressed if any synthetic chemical is released to the environment without adequate safety testing. Hence, the boundary is likely transgressed for the energy system.

transgression of at least 2 planetary boundaries for all net-zero designs. At the same time, the transgressions vary substantially across designs, indicating opportunities to address transgressions via design choices.

The present work demonstrates the need to include all planetary boundaries in the design of sustainable energy systems. This perspective leads to multiobjective optimization for design space exploration to determine technological barriers and supply chain contributions to environmental impacts. We thus aim to identify enablers of energy systems within planetary boundaries, which will be presented in future work.

## ABSTRACT

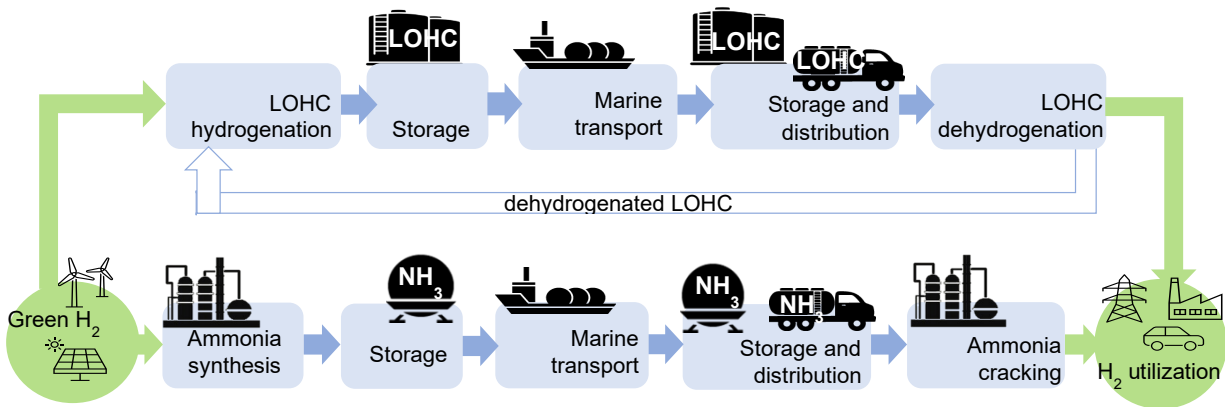

In view of achieving the decarbonization target, green hydrogen is commonly regarded as the alternative capable of reducing the share of fossil fuels. Despite its wide application as a chemical on industrial scale, hydrogen utilization as an energy vector still suffers from unfavorable economics, mainly due to its high cost of production, storage and transportation. To overcome the last two of these issues, different hydrogen carriers have been proposed. Hydrogen storage and transportation through these carriers involve: 1. the carrier hydrogenation, exploiting green hydrogen produced at the loading terminal, where renewable sources are easily accessible, 2. the storage and transportation of the hydrogenated species and 3. its subsequent dehydrogenation at the unloading terminal, to favour H<sub>2</sub> release. Although there is a number of studies in literature on the economic feasibility of hydrogen transport through different H<sub>2</sub> vectors, very few of them delve into the technical evaluation of the hydrogen value chain. From the process design point of view, the hydrogenation and dehydrogenation stages are of paramount importance, considering that they are the cost drivers of the whole system. This work aims to address this gap by presenting a systematic methodology to technically analyse different hydrogen vectors. For the sake of example, ammonia and dibenzyltoluene are considered. Weaknesses of the overall value chain are pointed out, to understand where to focus research efforts for future process intensification.

**Keywords:** H<sub>2</sub> transport, H<sub>2</sub> carriers, sustainable energy, techno-economic assessment, computer-aided process design.

## INTRODUCTION

In the transition towards sustainable energy, green hydrogen has emerged as a promising low-emission alternative. Nonetheless, its transportation is hampered by its low volumetric density. To address this problem, different H<sub>2</sub> carriers have been proposed as a reliable solution. The typical H<sub>2</sub> value chain is depicted in Figure 1, considering ammonia (NH<sub>3</sub>) and liquid organic hydrogen carriers (LOHCs) as hydrogen vectors. NH<sub>3</sub> and LOHCs are commonly perceived as the most encouraging choices, due to the easiness adaptability to the existing infrastructures. These hydrogen-bearing molecules can be hydrogenated at the loading terminal, exploiting green hydrogen produced through renewable sources, more easily stored, transported and, upon arrival, dehydrogenated for H<sub>2</sub> release. The released hydrogen can serve either the mobility or the industrial sectors [1].

NH<sub>3</sub> is a global commodity, already produced in large scale facilities and distributed worldwide. On the other hand, a variety of LOHCs have been considered in literature [2-3]. While some chemical structures are more susceptible to hydrogenation/dehydrogenation than others, certain rules have been identified for selecting favourable compounds. The optimal LOHC has to show low melting point and high boiling point, to avoid solidification and volatilization issues; high H<sub>2</sub> storage capacity; low

**Figure 1:** Hydrogen value chain exploiting LOHCs and  $\text{NH}_3$  as  $\text{H}_2$  carriers.

dehydrogenation enthalpy; low toxicity and low cost [2]. Selected the best candidate as hydrogen carrier, the essential starting point for the feasibility study of the hydrogen value chain is the identification of the basis of the design, including:

1. production rate of green  $\text{H}_2$ , to be fed to the system. Specifically, tuning the plant size according to the land footprint of renewables is crucial for the assessment of realistic scenarios. Renewable sources are characterized by a power density several orders of magnitude lower than fossil fuels. The transition pathways towards sustainability must consider both the limitations of available land and the specific geophysical conditions [4]. Understanding the extent of land needs can put the feasible scale of green hydrogen production into perspective [5]. In this analysis, flat  $\text{H}_2$  production of  $20000 \text{ Nm}^3/\text{h}$  is supposed via 100 MW alkaline electrolyzers, available at 20 bar and  $25^\circ\text{C}$ .
2. Loading and unloading terminal location and, consequently, distance to be covered for  $\text{H}_2$  transport. Different scenarios can be inferred, as the long-distance harbour-to-harbour hydrogen transport, which involves the  $\text{H}_2$  seaborne transport or the short distance hydrogen transport, that implies the road or pipeline hydrogen transport. In the hydrogen value chain of Figure 1, the seaborne  $\text{H}_2$  transport is considered.
3.  $\text{H}_2$  utilization and its centralized or decentralized application. According to the centralized scenario, the  $\text{H}_2$  produced is conveyed into a power plant for green electricity production. In this case, less stringent specifications on  $\text{H}_2$  purity are needed, likely. On the other hand, for the decentralized  $\text{H}_2$  utilization,  $\text{H}_2$  has to be distributed to several hydrogen refuelling stations, to serve the mobility

sector. Thus, high  $\text{H}_2$  purity is necessary. The selection of the centralized/decentralized scenario also affects the process design of the whole value chain and, consequently, the operating conditions of the delivered hydrogen (*i.e.*, temperature and pressure of discharge at the end user, together with required purity). In the present study,  $\text{H}_2$  centralized application at a  $\text{H}_2$  valley is considered, such that the hydrogen product is released at 30 bar and with a purity of 99.9 mol%.

Defined the basis of design, both technical and economic assessments can be carried out. However, it is worth noticing that the economic evaluations are, generally, strongly dependent on the hypotheses introduced and on the methodology adopted. Variable results can be obtained, such that it is difficult to draw general conclusions. For this reason, from the process engineering point of view, it is more relevant to focus on the design of the whole value chain and its technical assessment, with a particular attention to the cost-driving stages, rather than demonstrating the economic viability of hydrogen transport. In this respect, this work aims at presenting a systematic methodology to analyse different hydrogen value chains. Ammonia and dibenzyltoluene (H0-DBT) are selected as the representative carriers, due to their promising features. Hydrogenation and dehydrogenation stages have been designed in Aspen Plus V11<sup>®</sup>. Based on the simulations presented, a detailed technical analysis is discussed, to pave the way for future process intensification.

## SIMULATION OF THE COST-DRIVING PROCESSES

### Ammonia ( $\text{NH}_3$ )

Ammonia is a global commodity, already distributed worldwide and used in the chemical industry. Recently, it

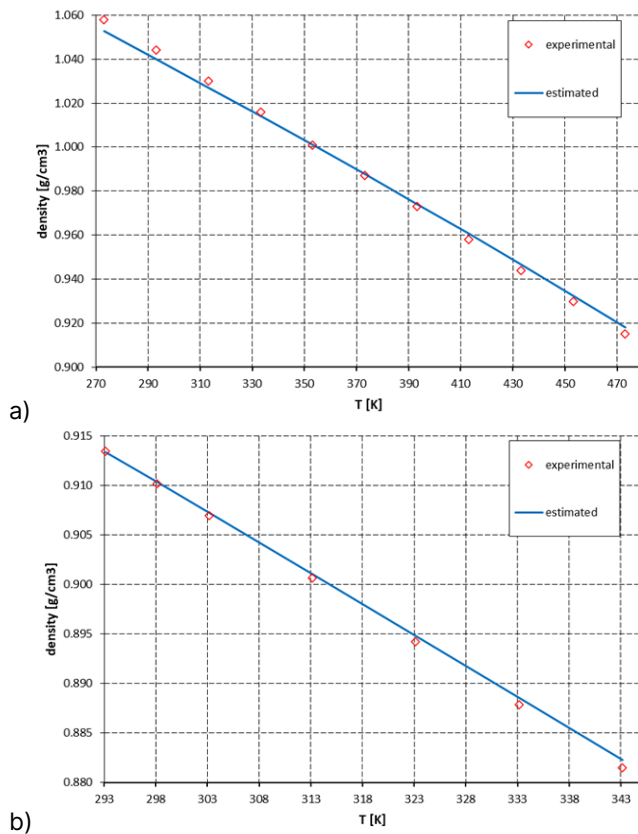

including the new pseudo-components in Aspen Plus simulation software. Once these properties are introduced, the compounds physical-chemical characterization occurs in Aspen Plus® with the aid of NIST TDE (ThermoData Engine) tool and the Aspen property estimation system.

**Table 1:** Dibenzyltoluene (DBT) and perhydrodibenzyltoluene (H18-DBT) properties [10].

Property	Value	
	DBT	H18-DBT
TB [°C]	390	371
MW [kg/kmol]	272.4	290.4
SG* @ 60°F [-]	1.047	0.916
$\Delta H_{\text{form}}$ [kJ/kmol]	225700	-387400

\*SG: Specific Gravity.

**Figure 3:** Comparison between experimental and predicted density values for: a) H0-DBT and b) H18-DBT.

In addition to what provided in Table 1, supplying experimental molar volume and ideal gas heat capacity can enable the development of a more robust model. Implemented all the available experimental datasets, in view

of assessing the reliability of the models, the predicted physical properties can be compared with the experimental ones. Results are reported in Figure 3 considering the density of the hydrogenated and dehydrogenated species for the sake of example. A satisfactory agreement is obtained between the experimental and calculated values.

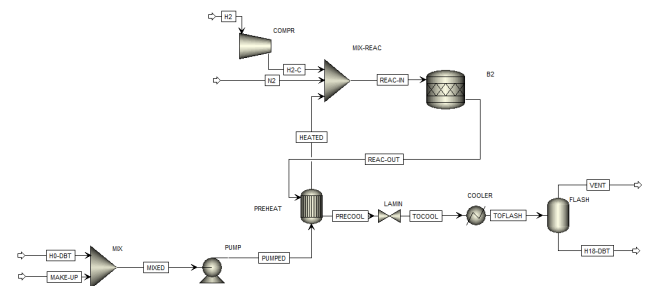

### H0/H18 DBT hydrogenation and dehydrogenation

Once the process simulator has been set up, both hydrogenation and dehydrogenation stages have been designed in Aspen Plus V11®.

The hydrogenation section is represented in Figure 4. The process receives at its battery limits the hydrogen produced via the alkaline electrolyzers, at 50°C and 20 bar. This stream undergoes compression up to 35 bar and is fed to the reactor (*B2* in Figure 4), together with a nitrogen stream that acts as a thermal diluent. Also dibenzyltoluene coming both from the make up stream and the dehydrogenation process is fed to the hydrogenation reactor, after preheating in a process-process heat exchanger (*PREHEAT* in Figure 4). The reactor operates at a pressure of 35 bara and a temperature of 210°C for the catalytic hydrogenation reaction (2) to occur. While the exothermic nature of the hydrogenation reaction would suggest lower temperatures for enhanced reaction equilibrium, the operating temperature also considers the catalytic activity requirements [11]. Based on what available in literature [12], the reactor is simulated through the *RStoic* module of Aspen Plus at quantitative conversion and selectivity.

Downstream the reaction section, the outlet stream, which contains the perhydro-dibenzyltoluene along with unreacted hydrogen and nitrogen, is cooled and expanded to favour the separation of light gases from the heavier H18-DBT, which can be sent for storage and then transported to the spot of hydrogen delivery.

**Figure 4:** H0-DBT hydrogenation section. Simulation in Aspen Plus V11®.

As for the pair H0-DBT/H18-DBT, the process simulation suffers from the not detailed reactor modeling, such that fundamental research is needed to identify a well-established kinetic expression to be included in the Aspen Plus scheme. Despite the drawback of low maturity, the dibenzyltoluene shows the intrinsic advantage of a reduced volatility, which allows the production of high purity hydrogen after dehydrogenation, facilitating the H<sub>2</sub> separation from unconverted gases downstream the reaction section.

The hydrogenation section electricity consumption amounts to 615.96 kW, for the compression and pumping of reactants at the battery limits, while only cooling water is needed as external utility, to provide a cooling duty of 482.3 kW. The high endothermicity of the hydrogenation reaction (16462.3 kW) could represent a plus point in the overall energy balance. When designing the whole value chain, strategies for heat integration have to be figured out to understand how to maximise revenues.

Concerning the dehydrogenation section, 3758.97 kW of electricity consumption are registered for the H18-DBT dehydrogenation process. Despite this number could seem high at a first glance, most of the electric energy required by the process is due to the hydrogen compression up to the delivery pressure, which cannot be reduced. Thermal energy consumption of the process is related to the cooling duty by means of cooling water, which accounts for a total of 4822 kW, together with the heat necessary for the hydrogenation reaction to occur. Despite no external utility is required, the high reaction endothermicity (19887.3 kW) is responsible for a dramatic reduction of the hydrogen flow rate exiting the battery limits. For 103.83 kmol/h of H18-DBT entering the process, 575.65 kmol/h of hydrogen are produced. The choice of coping the reaction endothermicity by burning part of the hydrogen produced is for sustainability purposes. It is true that H<sub>2</sub> is a high value-added product, probably too valuable to be burnt in a combustion chamber, but, on the other hand, the utilization of any fossil-based fuels does not make sense environmentally, if CO<sub>2</sub> is emitted upon combustion. Research efforts for process intensification should focus, primarily, on the identification of a suitable organic molecule to be used as H<sub>2</sub> vector, to reduce the heat requirements of the dehydrogenation section as much as possible. Selected the best candidate as LOHC, heat integration in the whole hydrogen value chain, together with the selection of a suitable clean burning fuel, compliant with plant location and needs, could be strategies for energy savings and, ultimately, operating cost reduction.

## CONCLUSIONS

Green hydrogen transport through different H<sub>2</sub> carriers still suffers from unfavourable economics. With the

aim of understanding where to focus research efforts for process intensification, this work offers a systematic methodology for the analysis of the value chain cost drivers, *i.e.*, hydrogenation and dehydrogenation stages. Ammonia and the pair dibenzyltoluene/perhydrodibenzyltoluene are selected as representative carriers.

For ammonia value chain, focal points of research to be investigated for cost reductions are:

- the NH<sub>3</sub> synthesis process intensification on small scale, to enable green ammonia production at milder operating conditions;
- the NH<sub>3</sub> thermocatalytic cracking process intensification, to enable the reaction to occur at milder operating conditions and to optimize the N<sub>2</sub>-H<sub>2</sub> separation downstream the reactor as much as possible.

For LOHC value chain, active and fundamental research is still needed to identify the most promising candidate to be used as the hydrogen carrier, to assess its physical-chemical properties and to investigate the hydrogenation and dehydrogenation reaction kinetics at the laboratory scale. Furthermore, points to be investigated are:

- for the hydrogenation section, the maximisation of the heat integration, taking into account the reaction exothermicity;
- for the dehydrogenation section, the identification of alternative methods for heat supply to cope the reaction endothermicity.

## ABSTRACT

The placement of wind turbines is a crucial design element in wind farms, given the energy losses resulting from the wake effect. Despite numerous studies addressing the Wind Farm Layout Optimization (WFLO) problem, considering multiple directions to determine wind turbine spacing and layout remains limited. However, relying solely on one predominant direction may lead to overestimating energy production, and loss of energy generation. This work introduces a novel mathematical programming optimization framework to solve the WFLO problem, emphasizing the wind energy's nonlinear characteristics and wake effect losses. Comparisons with traditional layout approaches demonstrate the importance of optimizing wind farm layouts during the design phase. By providing valuable insights into the renewable energy sector, this research aims to guide future wind farm projects towards layouts that balance economic considerations with maximizing energy production.

---

**Keywords:** Wind, Turbines, Energy Systems, Renewable and Sustainable Energy, Optimization

## INTRODUCTION

Due to the escalating energy crisis, there has been a growing inclination towards generating more energy from renewable sources. Consequently, aside from constructing new power generation facilities such as wind or solar plants, studying how to optimize these installations is crucial [1]. Among the various renewable energy options available, wind energy stands out due to its efficient power generation capacity and the ability to produce energy on a large scale, making it an attractive option for expanding electricity generation capacity [2-5].

Wind power is produced by converting the kinetic energy of air in motion using a turbine. Usually, wind turbines are arranged in groups known as wind farms to increase power production and minimize costs. Several factors influence the energy production of a wind farm, including wind speed and direction, and various meteorological conditions. Specifically, energy losses occur due to the wake effect. As wind turbines extract energy from the wind, a wake forms downstream, reducing the wind speed. Consequently, the placement of wind turbines

significantly impacts the efficiency of a wind farm [6].

Traditionally, wind farms have followed a rule of thumb of placing wind turbines in rows with 8–12 rotor diameters of spacing parallel to the prevailing wind direction and columns spaced 3–5 rotor diameters apart perpendicular to the wind direction [7]. More recently, several studies have been conducted to determine the optimal positioning of wind turbines within a designated land area [8-11]. The primary objective of these studies has been to minimize wake effects and, consequently, maximize expected power production. These studies consider dividing the domain into a grid that defines possible turbine locations. However, only a limited number of studies have extended their focus to include determining the optimal inter-turbine distance. This problem, known as the wind farm layout optimization (WFLO) problem, has garnered substantial research interest.

Given the nonlinearity inherent in wind energy's characteristics, addressing this issue poses a noteworthy difficulty. Proposed approaches to tackle the WFLO problem predominantly involve using data-driven or metaheuristic algorithms such as genetic algorithms,

random search, and particle swarm optimization. While these algorithms are practical for providing near-optimal solutions, they often do not supply guarantees of optimality [12]. Furthermore, to our knowledge, none of the studies have considered more than one dominant wind direction to determine the spacing and layout of wind turbines, even though promising locations for wind farm installations, such as the Texas Panhandle, have at least two dominant wind directions, and some studies have suggested that ignoring wind direction could lead to an overestimation of the wind energy production [13].

This study introduces a novel mathematical programming optimization framework designed to determine the optimal position and spacing of wind turbines. It explores various design objective criteria, including costs and energy production. The study considers the intrinsic nonlinear attributes of wind energy, incorporates modeling of wake effect losses, and, for the first time, considers both single and multiple dominant wind directions. To illustrate its efficacy, the proposed model is applied in a case study focusing on the energy transition of the University of Wisconsin-Madison campus.

## PROBLEM FORMULATION

### Wake effect model

The wind losses due to the wake effect are model using the Jensen model, which is one of the most widely used wake model [14-15]. It assumes that the diameter of the wake increases linearly in proportion to the downstream distance,  $z$ . The speed downstream can be calculated as

$$v(z) = v^0 \cdot [1 - (1 - \sqrt{1 - Ct}) \left( \frac{Di}{Di + 2kz} \right)^2] \quad (1)$$

, where  $v^0$  is the undisturbed incoming velocity,  $k$  is the rate of the wake expansion and have a value of 0.075 for onshore wind,  $Di$  is the diameter of the rotor of the wind turbine and  $Ct$  is the trust coefficient, which as a value of 0.8 [16-17].

In this study, the wake effect model was adapted to consider multiple wind directions. For each wind direction  $wd_j$  the velocity is calculated considering in characteristic distance  $z_j$ . The calculation of the wind velocity for the two directions  $wd_1$  and  $wd_2$  is presented below, while an illustration of the two chosen directions is presented in Figure 1. The main assumption is that the wind velocity reaching the turbines ( $v_{wd_j,r,c,t,d}$ ) that are in the same row ( $r$ ) or column ( $c$ ) are not affected by each other. The

losses due to the wake effect will be denoted as  $WL$ , rewriting equation (1) as the following:

$$v(z) = v^0 \cdot [1 - WL(z)] \quad (2)$$

For wind direction  $wd_1$ , the velocity at each position at time  $t$  of day  $d$  ( $v_{wd_1,r,c,t,d}$ ) can be calculated as:

- For the first row ( $r = 1$ )

$$v_{wd_1,1,c,t,d} = v_{t,d}^0 \quad \forall c, t, d \quad (3)$$

- For any other row ( $\forall r \neq 1, c, t, d$ )

$$v_{wd_1,r,c,t,d} = v_{wd_1,r,c-1,t,d} \cdot [1 - y_{r,c}^b \cdot WL(y)] \quad (4)$$

Similarly, for wind direction  $wd_2$ , the velocity ( $v_{wd_2,r,c,t,d}$ ) is calculated as:

- For the first column ( $c = 1$ )

$$v_{wd_2,r,1,t,d} = v_{t,d}^0 \quad \forall r, t, d \quad (5)$$

- For any other column ( $\forall r, c \neq 1, t, d$ )

$$v_{wd_2,r,c,t,d} = v_{wd_2,r,c-1,t,d} \cdot [1 - y_{r,c}^b \cdot WL(x)] \quad (6)$$

The binary variable  $y_{r,c}^b$  denotes if the turbine in row  $r$ , and column  $c$  is installed (1 if it is installed, 0 if not). Lastly, it is assumed that the wind only blows in one direction at each time step, given by equation (6). We denote the parameter  $w_{wd,t,d}$  which has a value of 1 if the wind blows in direction  $wd$  at time  $t$  of day  $d$ , and 0 if not.

$$v_{r,c,t,d}^{curve} = \sum_{wd} v_{wd,r,c,t,d} \cdot w_{wd,t,d} \quad (7)$$

**Figure 1.** Wind farm layout and turbine spacing.

## Wind farm layout optimization model

The power output of the wind turbines ( $P_{r,c,t,d}$ ) was calculated using piecewise linear approximation of the power curve of a wind turbine Vestas V112-3.08, selected considering the average size of wind turbine used in the market [18]. Figure 2 shows the results of the linearization done. Regarding the operation of the wind farm, the turbines only produce energy if they are installed.

$$P_{r,c,t,d} \leq M \cdot y_{r,c}^b \quad \forall r, c, t, d \quad (8)$$

$$P_{r,c,t,d} \leq P_{r,c,t,d}^{curve}(v_{r,c,t,d}^{curve}) \quad \forall r, c, t, d \quad (9)$$

The area used by each turbine is considered to be a rectangle corresponding to the shaded area in Figure 1, and the total area available is limited (Equation 10 and 11).

$$A = N_{tot} \cdot x \cdot y \quad (10)$$

$$A \leq A_{max} \quad (11)$$

Two objective functions are considered in this study: minimization of annual costs, and maximization of the annual energy produced. The annual costs ( $AC$ ) include the annual investment costs ( $C_{inv}$ ) and the annual operation and maintenance costs ( $C_{OM}$ ), as expressed by equations (12).

$$AC = C_{inv} + C_{OM} \quad (12)$$

The initial investment costs ( $C_{inv}^{cap}$ ) are converted into annual investment cost per capacity using the Capital Recovery Factor (CRF) [19], defined as

$$CRF = \frac{i}{1 - (1+i)^{-L}} \quad (13)$$

, where  $i$  is the interest rate and  $L$  the lifetime of the wind turbines. In this study, an interest rate of 7% and a lifetime of 30 years were assumed [20]. The annual investment and operation and maintenance costs can be expressed by equations (14) and (15), respectively.

$$C_{inv} = N_{tot} \cdot P_{nom} \cdot C_{inv}^{cap} \cdot CRF \quad (14)$$

$$C_{OM} = N_{tot} \cdot P_{nom} \cdot C_{OM}^{cap} \quad (15)$$

The annual energy produced ( $AEP$ ) is calculated as the sum of the energy produced at each hour and day represented by equation (16).

$$AEP = \sum_{r,c,t,d} P_{r,c,t,d} \cdot f_d \quad (16)$$

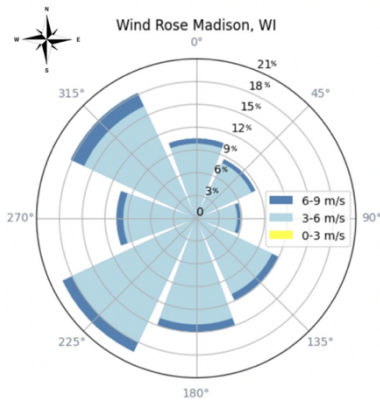

, where  $f_d$  is the frequency of the representative day  $d$ .

**Figure 2.** Power curve of the turbine Vestas V112-3.08 [21].

## CASE OF STUDY

To demonstrate the applicability of the developed model formulation and framework, a case study was conducted to design a wind farm in Madison, Wisconsin as an option for energy transition in the University of Wisconsin-Madison. The wind data used were obtained from the AOSS Tower located at the University of Wisconsin-Madison [22]. A typical meteorological year was constructed using data from 2013 to 2023. The annual wind source distribution can be observed in Figure 3. There are two predominant wind directions: SW and NW, with an average wind speed of 4.8 m/s at 30 m (altimeter height). It is noteworthy that the wind speed is below 3 m/s only 1% of the year (yellow label), indicating an area with potential for the installation of a wind farm.

**Figure 3.** Wind speed and direction distribution in Madison, Wisconsin.

The proposed model is classified as a mixed integer nonlinear problem (MINLP) problem, where the nonlinear terms are associated with the wake effect. To account for the variability and intermittency of the wind resource, and at the same time make the problem tractable, the year wind data was reduced to three representative days using hierarchical clustering. Hierarchical clustering is a machine learning algorithm that groups similar data points into nested clusters based on their proximity, forming a tree-like structure [23]. The three representative days selected are presented in Figure 4. Before using the data in the model, the wind speed inputs were adjusted from the measured height ( $H_i$ ) to the hub height of the turbine ( $H$ ) using equation (17) and considering a shift coefficient ( $\alpha$ ) of 0.14 [21]. The model was implemented in GAMS [24] and solved using the BARON solver [25].

$$v_{t,d}^0 = v_{t,d}^m \cdot \left(\frac{H}{H_i}\right)^\alpha \quad \forall t, d \quad (17)$$

**Figure 4.** Representative days for wind speed using hierarchical clustering.

## RESULTS & DISCUSSION

In this study, we approached the problem by examining one and two wind directions ( $wd_1$  and  $wd_2$ ) for up to nine wind turbines. Figure 5 presents the results for minimizing annual costs and maximizing yearly energy production. Utilizing costs as the primary design criterion for a wind farm may not be ideal, as it does not optimize turbine placement and overall area utilization, consequently reducing the energy output. The findings reveal a potential reduction in energy production of up to 13% for identical-capacity wind farms when costs are minimized compared to the maximization of energy production. Maximizing energy output appears more effective in optimizing the wind farm layout, as it reduces energy losses. However, it is essential to evaluate the land area used. The model tends to position turbines further apart to maximize energy, which might require a more extensive area. Figure 6 illustrates different arrangements leading to varying energy production for the installation of six turbines for reference. In both cases, the annual costs are the same, but the configurations differ. Minimizing costs results in layouts with more closely spaced rows and a higher number of rows, increasing wake effect energy losses. On the other hand, maximizing energy production leads to a larger distance between turbines, utilizing more land.

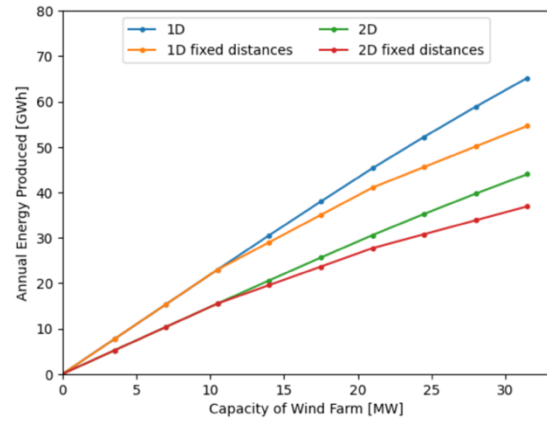

**Figure 5.** Annual energy produced considering the minimization of annual costs and maximization of energy produced.

**Figure 6.** Layout of installing 6 wind turbines considering a) minimization of annual costs b) maximization of annual energy production.

Figure 7 compares energy production when considering the model with one or two wind directions and using Patel's rule of thumb. The findings indicate that adhering to the rule of thumb for turbine placement could lead to lower energy production; therefore, optimizing the layout is a crucial aspect of wind farms and should be evaluated during design. Considering only the predominant wind direction, i.e., one direction, could lead to overestimating energy production, which can affect the project's financial aspects. Taking into consideration multiple wind directions represents the system more accurately, as the wind blows in multiple directions in many locations.

A sensitivity analysis was conducted regarding the land area available. The results, depicted in Figure 8, indicate that the model is sensitive to this value. It is important to note, that in practical scenarios, the land availability will be either already bought or modifying the existing land may involve associated costs or logistical constraints, imposing limitation for its modification. Considering an unlimited area can lead to an overestimated energy production by up to 15%, according to the model developed. Moreover, assuming an unlimited or vast area suggests a linear relationship between capacity and energy produced, neglecting wake effects and energy losses. As the number of turbines increases, so does the wake effect, resulting in a nonlinear increase in energy production.

**Figure 7.** Annual energy production considering different number of wind speed directions and distances between turbines.

**Figure 8.** Annual energy produced considering different values for land area available.

## CONCLUSION

This study introduced a comprehensive optimization framework to design an optimal layout for a wind farm, accounting for the wake effect in various directions. The energy system was formulated as a MINLP problem with two objective functions: minimizing annual costs and maximizing energy production, showing a difference of up to 13% in the energy produced between both criteria. The results indicate that considering only the predominant wind direction could lead to an overestimation of the energy produced. The model was solved using up to two wind directions, but future work should extend this to evaluate the ideal number of wind directions to consider when designing wind farms in different locations, considering solving time and model accuracy. Additionally, coping with the uncertainties associated with wind farm parameters is an important area for future work. The following steps for this work will also focus on extending the analysis to higher wind farm capacities and evaluate extreme weather scenarios to refine the model's accuracy and applicability.

## ABSTRACT

The synthesis of energy systems necessitates simultaneous optimization of both design and operation across all components within the energy system. In real-world applications, this synthesis poses a mixed-integer nonlinear programming (MINLP) problem, considering nonlinear behaviours such as investment cost curves and part-load performance. The complexity increases further when seasonal energy storage is involved, as it requires temporal coupling of the full time series. Although numerous solution approaches exist to solve the synthesis problems simplified by linearization, methods for solving a full-scale problem are currently missing. In this work, we introduce a rigorous method, RiNSES<sup>4</sup>, to manage the nonlinear aspects of energy system synthesis, particularly focusing on long-term time-coupling constraints. RiNSES<sup>4</sup> calculates the upper and lower bounds of the initial synthesis problem in two separate branches. The proposed method yields feasible solutions through upper bounds, while evaluating the solution quality via lower bounds. The solution quality is iteratively enhanced by increasing the resolution for calculating upper bounds and tightening the relaxations for computing lower bounds. Both branches work simultaneously and independently, with their outcomes compared after each iteration within each branch. The iterations continue until a predefined optimality gap is reached. We apply RiNSES<sup>4</sup> to design a photovoltaic and battery energy system, considering the seasonality of both energy supply and demand sides. In comparison with a state-of-the-art commercial solver, RiNSES<sup>4</sup> enables to solve the MINLP synthesis problem with great temporal detail and shows high potential.

**Keywords:** Mixed-integer nonlinear programming, time series aggregation, linearization, decomposition, relaxation

## 1. INTRODUCTION

Mathematical modeling and optimization can aid in identifying the optimal design and operation of energy systems, spanning from industrial to international scale. The synthesis problem of an energy system necessitates simultaneous optimization of both design and operation, across all components within the energy system [1]. At the design level, the types and sizes of energy system components are determined. At the operation level, decisions are made regarding the on/off status and load allocations for each time step. In general, the synthesis poses a mixed-integer nonlinear programming (MINLP) problem, taking into account nonlinear behaviors such as investment cost curves at the design level and part-load

performance at the operation level [2]. However, solving an MINLP problem is generally challenging due to its intrinsic complexity. The complexity increases further when incorporating seasonal energy supply and storage, as it requires extensive temporal data input as well as temporal coupling of the full time series [3].

In the literature, energy system modelers adopt various approaches to address synthesis problems, aiming to achieve computationally tractable results. Kotzur et al. [4] applied time series aggregation methods to efficiently reduce the size of synthesis problems. Gabrielli et al. [5] and Kotzur et al. [6] further proposed alternative modeling approaches to reduce the complexity of synthesis problems from the temporal coupling aspects. However, such approaches only yield solutions for a simplified

version of the synthesis problem.

To tackle the synthesis problem employing the full time series, Baumgärtner et al. [7] developed the RiSES<sup>4</sup> method. The method is designed to solve the linear synthesis of energy systems with seasonal storage, ensuring a solution with known quality. RiSES<sup>4</sup> integrates time series aggregation [8] with superposition seasonal storage modeling [6] in the synthesis problem, and subsequently solve an operational optimization problem with full time series directly through commercial solvers. RiSES<sup>4</sup> employs a rigorous method [9] for measuring the quality of the resulting solutions. In cases where the resulting operational optimization problems remain computationally challenging, a decomposition-based method, DeLoop, proposed by Baumgärtner et al. [10], could be potentially incorporated to more effectively address the long-term operational optimization of energy systems. RiSES<sup>4</sup> has been applied to design an industrial energy system using a mixed-integer linear programming (MILP) formulation, as well as a national energy system using a linear programming (LP) formulation, demonstrating promising performance [7].

Nevertheless, the application of RiSES<sup>4</sup> is limited to linear synthesis problems. The nonlinear nature of an energy system's synthesis is neglected in advance. As a result, the solution obtained for the linearized problem might be infeasible for the initial nonlinear synthesis problem.

### 1.1. Contribution of this work

In this work, we propose the RiNSES<sup>4</sup> method, an extension of the RiSES<sup>4</sup> method, specifically designed to address the nonlinear aspects of energy system synthesis.

Similar to the RiSES<sup>4</sup> method, RiNSES<sup>4</sup> independently computes the upper and lower bounds of a synthesis problem, but with an MINLP formulation. For calculating the upper bounds, building upon RiSES<sup>4</sup>, we use a linearized problem with aggregated time series to find design candidates. These design candidates are then fixed, and the initial MINLP problem is solved as an operational optimization problem to obtain a feasible solution, thereby establishing an upper bound for the initial problem. For computing the lower bounds, we relax various constraints within the synthesis problem to accelerate computation. We iteratively improve the solution quality by increasing the resolution for calculating upper bounds and tightening the relaxation for computing lower bounds. To assess the performance of the proposed method, we apply RiNSES<sup>4</sup> to design an energy system including photovoltaic panels and a battery for seasonal energy supply and storage.

The structure of this paper is as follows: Section 2 explicates the problem statement and the RiNSES<sup>4</sup> method. In Section 3, the proposed method is applied to a case study. Section 4 concludes the work.

## 2. METHOD

### 2.1. General MINLP formulation

$$\begin{aligned}
 & \min_{\dot{E}_k^N, E_k^N, \dot{E}_{e,t}^{\text{buy}}, \dot{E}_{e,t}^{\text{sell}}, \dot{E}_{k,e,t}^{\text{in}}, \dot{E}_{k,e,t}^{\text{out}}, E_{k,e,t}, \mathbf{y}, \mathbf{z}} TAC = \frac{1}{APVF} CAPEX + OPEX & (1a) \\

 & \quad \forall k \in \mathcal{K}, \forall e \in \mathcal{E}, \forall t \in \mathcal{T}
 \end{aligned}$$

Problem 1

In Problem 1, we state the generic synthesis problem of an energy system using an MINLP formulation. To start with, we assign all components inside the energy system ( $k \in \mathcal{K}$ ) to two categories: storage components ( $k \in \mathcal{K}^{\text{sto}}$ ) and conversion components ( $k \in \mathcal{K} \setminus \mathcal{K}^{\text{stor}}$ ). Storage components transport products ( $e \in \mathcal{E}$ ) from one time step to other time steps ( $t \in \mathcal{T}$ ), while conversion components convert one product to any other product(s). Additionally, the category “exogenous inputs” indicates that the energy system is connected with exogenous energy supply ( $\tilde{e} \in \mathcal{E}^{\text{ext}} \subseteq \mathcal{E}$ ) and demand ( $\dot{E}_{e,t}^{\text{D}}$ ).

We minimize the total annualized costs  $TAC$  that consists of the capital and operational expenditures,  $CAPEX$  and  $OPEX$  (Equation (1a)). The annualized present value factor is defined as  $APVF = \frac{(1+i)^n - 1}{(1+i)^n \cdot i}$  with the interest rate  $i$  and the number of periods  $n$ .  $CAPEX$  is the sum of the investment costs of all energy system components, which follow the capacity power law (Equation (1b)). The investment costs  $I_k$  of the component  $k$  are defined as the reference cost  $I_k^{\text{ref}}$  multiplied by the ratio of the nominal size  $\dot{E}_k^{\text{N}}$  or  $E_k^{\text{N}}$  and a reference value  $\dot{E}_k^{\text{N,ref}}$  or  $E_k^{\text{N,ref}}$  to the power of  $M_k \leq 1$ . Please note that the indicators for conversion and storage components differ in their respective units.  $OPEX$  are defined as the sum of maintenance costs and external energy costs of each time step, where  $c_k^m$ ,  $c_{e,t}^{\text{buy}}$  and  $c_{e,t}^{\text{sell}}$  indicate a maintenance factor, and external energy buying and selling prices, respectively (Equation (1c)).  $\Delta t_t$  represents the length of time step  $t$ .

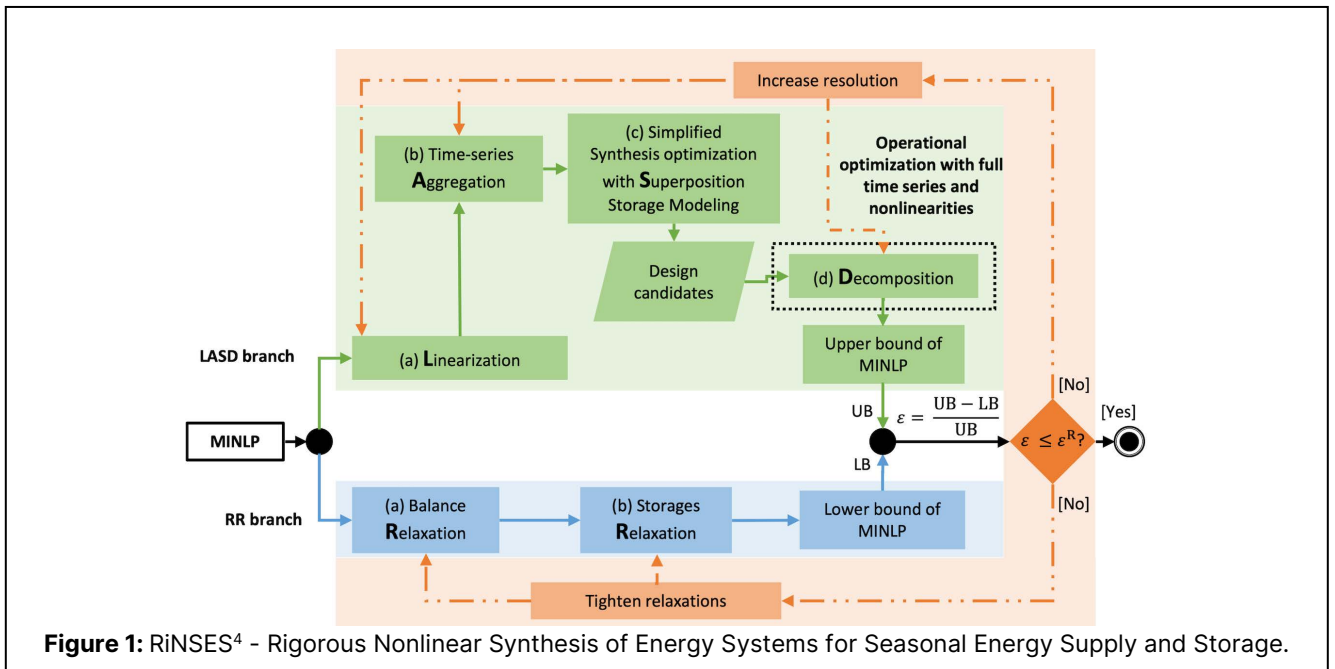

Given the input time series, the designed energy system needs to fulfill the energy demands for each time step through energy conversion or by purchasing energy from external energy supplies (Equation (1d)). Here,  $\dot{E}_{k,e,t}^{\text{in}}$

and  $\dot{E}_{k,e,t}^{\text{out}}$  denote the input and output flows, respectively, of product  $e$  at time step  $t$  for component  $k$ . The state of charge  $E_{k,e,t+1}$  of a storage component  $k$  at the time step  $t + 1$  depends on its' state of charge  $E_{k,e,t}$  at time step  $t$  and the product input and output flow at the time step  $t$ , considering the efficiencies of self-discharge  $\eta_{k,e}^{\text{self}}$ , charging  $\eta_{k,e}^{\text{in}}$  and discharging  $\eta_{k,e}^{\text{out}}$  (Equation (1e)). The so-called cycling constraint ensures that the product is conserved (Equation (1f)). All other constraints are concisely encapsulated in Equations (1g) and (1h), including the part-load performance of each conversion component. All decision variables and their respective bounds are summarized in Equations (1i) and (1j). The surrogate vectors  $\mathbf{y}$  and  $\mathbf{z}$  represent other decision variables that are not specified here, encompassing investment decisions and on/off decisions for each energy system component.

In addressing both the design and operation levels of an energy system synthesis problem, we utilize the index  $t$  to differentiate between design variables (without the index  $t$ ) and operation variables (with the index  $t$ ). This distinction also extends to constraints: design constraints, which are independent of the number of time steps, and operation constraints, which recur at each time step. This distinction is crucial for the method we propose in the following section.

## 2.2. RiNSES<sup>4</sup> Method

The proposed RiNSES<sup>4</sup> method solves Problem 1 with the full time series. As depicted in Figure 1, RiNSES<sup>4</sup> handles the initial MINLP problem in two separate branches to compute the upper (illustrated as the green segment in Figure 1) and lower bounds (shown as the blue segment in Figure 1) of the MINLP problem,

**Figure 1:** RiNSES<sup>4</sup> - Rigorous Nonlinear Synthesis of Energy Systems for Seasonal Energy Supply and Storage.

respectively. Both branches incorporate independent iterations (represented by the red segment in Figure 1) to improve the solution quality.

The upper bounds (UBs) are feasible solutions to the MINLP Problem. To calculate an upper bound for Problem 1, we use four distinct techniques: linearization (L), time-series aggregation (A), superposition storage modeling (S) and decomposition (D). The tetrad of techniques is collectively referred to as the LASD branch. A detailed description of the LASD branch is provided in Section 2.2.1. The quality of the optimal solution derived from the LASD branch is evaluated using lower bounds (LBs). The lower bounds for Problem 1 are computed via a two-stage relaxation (R) process, named as the RR branch. A detailed discussion of the RR branch is provided in Section 2.2.2. After each iteration, RiNSEs<sup>4</sup> compares the current UB and LB to calculate the current optimality gap  $\varepsilon$ , as described in detail in Section 2.2.3. We iteratively improve the solution quality by increasing the resolution for calculating UBs and tightening the relaxations for computing LBs. The two branches work simultaneously and individually from each other. The RiNSEs<sup>4</sup> method terminates if a predefined optimality gap  $\varepsilon^R$  is reached.

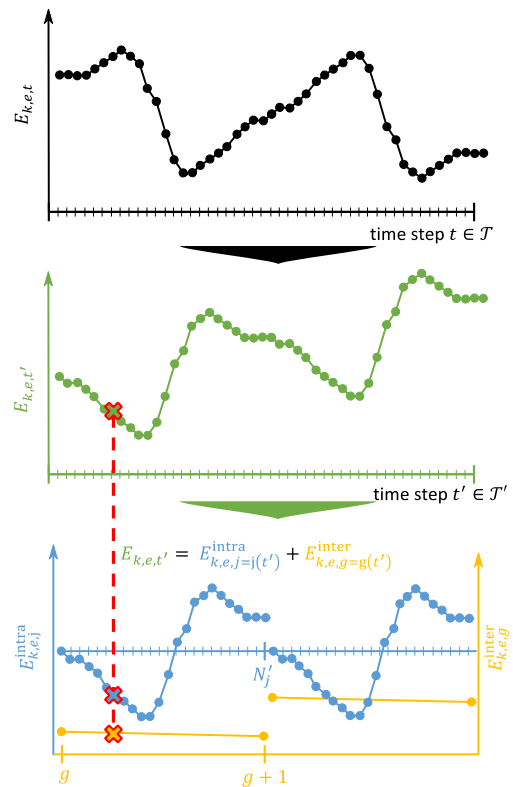

### 2.2.1. Calculating the upper bounds in LASD branch

In the LASD branch, feasible solutions (upper bounds) of the initial synthesis, Problem 1, are calculated based on four steps, as represented in the green segment in Figure 1: We first simplify the synthesis problem in steps (a) and (b) to obtain values for the design variables in step (c). Then, we validate the feasibility of the design variables in an operational optimization problem with the full time series and all nonlinearities in step (d). To efficiently solve the resulting MINLP operational problem, a decomposition approach can be applied in step (d). If there is a feasible solution to the operational optimization problem, the solution is also a feasible solution to Problem 1 and, thus, an upper bound (UB) for Problem 1.

In step (a), we first linearize nonlinearities of the initial MINLP problem to obtain an MILP formulation. The nonlinearities include investment cost curves, as shown in Equation (1b), and nonlinear part-load performance, as outlined in Equation (1h). The linearization is based on the non-separable piecewise-linear optimization approach proposed by Vielma et al. [11], which can be readily integrated using a Python package [12]. Through linearization, we simplify the complexity of the nonlinear constraints. However, the linearization results in an increase in the number of the binary decision variables in the resulting MILP problem, potentially leading to longer computing time.

Therefore, in step (b), we further simplify the synthesis problem through time series aggregation to reduce the size of *exogenous inputs*. As explained in [8] and in

[9], the initial input time series  $\mathcal{T}$ , consisting of  $N_t$  time steps, is divided into  $N_k$  periods  $\mathcal{P}$  with  $N_j$  time steps in each period, where  $N_k = N_t/N_j$ . Through time series aggregation,  $N_k$  and  $N_j$  are aggregated to  $N'_k$  typical periods  $\mathcal{P}'$  with  $N'_j$  segments in each typical period, i.e., the number of time steps is reduced to  $N'_k \times N'_j$ , which is significantly smaller than  $N_t$ . In this work, we employ the tsam Python package [13] for aggregating time-series data, taking advantage of its various available aggregation approaches. Kotzur et. al [4] analyzed the impact of various aggregation approaches on their optimization results, revealing that the choice of the aggregation approach had only minor impacts. In our study, we hence adopt the k-mean aggregation, a prevalent approach in energy system optimization, for time series aggregation.

**Figure 2:** Overview of the superposition storage modeling. The figure is adapted from Kotzur et al. [6].

Upon completing steps (a) and (b), we derive a simplified synthesis problem in step (c). Here, to consider product transport on a seasonal scale, we adopt the superposition storage modeling approach, initially introduced by Kotzur et al. [6] and also implemented in RiSES<sup>4</sup> [7]. In our work, we extend the model by incorporating typical segments. Figure 2 illustrates the basic principles of this superposition modeling approach.

In step (c), the state of charge associated with the initial input time series  $E_{k,e,t}$  ( $t \in \mathcal{T}$ ), illustrated in the top

part of Figure 2, is replaced with the state of charge for the aggregated time series  $E_{k,e,t'}$  ( $t' \in \mathcal{T}'$ ), shown in the middle part of Figure 2. The superposition modeling approach decomposes  $E_{k,e,t'}$  (in green) into two parts: the intra-period state of charge  $E_{k,e,j}^{\text{intra}}$  ( $j \in \{1, \dots, N'_j\}$ , colored in blue) and inter-period state of charge  $E_{k,e,g}^{\text{inter}}$  ( $g \in \{1, \dots, N'_g\}$ , colored in orange), depicted in the bottom part of Figure 2.  $E_{k,e,j}^{\text{intra}}$  describes the storage behavior within the typical periods, whereas  $E_{k,e,g}^{\text{inter}}$  represents the storage behavior between these periods. The relationships  $j = j(t')$  and  $g = g(t')$  denote the corresponding values of  $j$  and  $g$  associated with the time step  $t'$ .

Please note that in superposition storage modeling, the sequence of time steps is of paramount importance. Therefore, we use the symbol  $N'_g$  to denote the typical periods, rather than  $N'_k$  mentioned earlier. The key difference between  $N'_g$  and  $N'_k$  is that  $N'_g$  encompasses the sequence of occurrence of typical periods, and, thus, has the same size as the periods  $\mathcal{P}$  previously described. For an in-depth explanation of superposition storage modeling approach, please refer to references [6, 7].

As a consequence, for the *exogenous inputs*, the initial full time series  $\mathcal{T}$  with  $N_t$  time steps is reduced to the aggregated time series  $\mathcal{T}'$  with  $N'_g \times N'_j$  time steps. In the following, we refer to the linearized and aggregated synthesis problem with superposition storage modeling as Problem 2. In Problem 2, Equations (2a) to (2d) are applied as operation constraints for all storage components, replacing the constraints (1e) and (1f).

$$\frac{E_{k,e,j+1}^{\text{intra}} - E_{k,e,j}^{\text{intra}}}{\Delta t_j} = -\eta_{k,e}^{\text{self}} E_{k,e,j}^{\text{intra}} \quad (2a)$$

$$+ \Delta t_j \left( \eta_{k,e}^{\text{in}} \hat{E}_{k,e,j}^{\text{in}} - \frac{E_{k,e,j}^{\text{out}}}{\eta_{k,e}^{\text{out}}} \right)$$

$$E_{k,e,g+1}^{\text{inter}} = E_{k,e,g}^{\text{inter}} (1 - \eta_{k,e}^{\text{self}} \Delta t_t)^{N'_j} + E_{k,e,N'_j+1}^{\text{intra}} \quad (2b)$$

$$E_{k,e,1}^{\text{inter}} = E_{k,e,N'_g+1}^{\text{inter}} \quad (2c)$$

$$E_{k,e,t'} = E_{k,e,j=j(t')}^{\text{intra}} + E_{k,e,g=g(t')}^{\text{inter}} \quad (2d)$$

Problem 2, formulated as an MILP problem with a small-scale input time series  $\mathcal{T}'$ , facilitates an efficient solution process in step (c). Based on the results of Problem 2, we fix the design variables of the original MINLP synthesis problem to the solution of Problem 2, receiving an MINLP operational optimization problem. The resulting operational optimization problem with the full time series is a large-scale MINLP problem (Problem 3).

In step (d), we solve the resulting Problem 3. Depending on its size, we first try to solve Problem 3 using a commercial MINLP solver. If Problem 3 cannot be solved within a predetermined computing time frame, we employ the DeLoop method, developed by Baumgärtner et al. [10]. DeLoop handles time-coupled long-term operational optimization problems via decomposition and parallel computing, and it systematically reduces the number

of decomposed subproblems in an iterative manner. In the worst-case scenario, the original MINLP operational problem is tackled.

If Problem 2 provides feasible design decisions for Problem 3, where the full time series and nonlinearities at the operation level is addressed, we yield an upper bound (UB) to the initial synthesis problem by combining the design decisions of Problem 2 and the operation decisions of Problem 3. However, we cannot guarantee that the design decisions identified in Problem 2 allows feasible operation in Problem 3. If an infeasibility occurs, we iteratively repeat steps (b)-(d) with enhanced time series resolutions, until a feasible solution is found, or the original size of the input time series is applied in step (b). If no feasible solution could be found during aggregation, the resulting superposition storage modeling in step (c) are equivalent to Equations 1(e) and 1(f) in the original synthesis problem. If all attempted steps still result in infeasibility, the final move is to increase the number of breakpoints during linearization. As the number of breakpoints increases, so does the accuracy of the linearization. In the case of infinitely many breakpoints, the linearized problem closely approximates the original MINLP synthesis problem. Should this scenario arise, the LASD branch addresses the original MINLP synthesis problem.

With increasing time series resolution and accuracy of linearization, the whole LASD branch converges to the original MINLP synthesis problem in the worst-case scenario. In practice, we observed that the iterative approach consistently identified a feasible solution before necessitating the use of the full-scale time series in Problem 2. Thus, this work has not yet explored the aspect of infinite number of breakpoints. During implementation, we define a maximum number of breakpoints, for example, four. When the LASD branch reaches this maximum, it forcibly transitions to tackling the original MINLP synthesis problem.

### 2.2.2. Computing the lower bounds in RR branch

In the RR branch, we underestimate Problem 1 using two-stage relaxations and obtain a relaxed synthesis problem. Solving the relaxed synthesis problem provides a lower bound, which serves as the lower bound for Problem 1, as visually represented by the blue segment in Figure 1.

In stage (a), we employ the same time series aggregation methods as those in the LASD branch, which leads to typical periods  $P'$  with aggregated segments  $S$  within each typical period. In each segment, we identify the maximal and minimal external energy demands  $\hat{E}_{e,t}^{\text{D,max}}$  and  $\hat{E}_{e,t}^{\text{D,min}}$  for each energy form ( $\forall e \in \mathcal{E}$ ). Subsequently, we relax the constraints by replacing Equation (1d) with Equations (3a) and (3b). Please note that, unlike the LASD branch, we maintain the initial size and sequence of the input time series  $\mathcal{T}$  in this stage. The number of

decision variables of the synthesis problem therefore remains unchanged, only the solution space is larger.

$$\sum_{k \in \mathcal{K}} (\dot{E}_{k,e,t}^{\text{out}} - \dot{E}_{k,e,t}^{\text{in}}) + \dot{E}_{e,t}^{\text{buy}} - \dot{E}_{e,t}^{\text{sell}} \leq \dot{E}_{e,t}^{\text{D,max}} \quad (3a)$$

$$\sum_{k \in \mathcal{K}} (\dot{E}_{k,e,t}^{\text{out}} - \dot{E}_{k,e,t}^{\text{in}}) + \dot{E}_{e,t}^{\text{buy}} - \dot{E}_{e,t}^{\text{sell}} \geq \dot{E}_{e,t}^{\text{D,min}} \quad (3b)$$

In stage (b), we further underestimate Problem 1 by relaxing the constraints associated with the storage components. We replace Equations (1e) and (1f) with Equations (4a) and (4b) for each time step ( $\forall t \in \mathcal{T}$ ), which effectively decouples the constraints between two adjacent time steps. We refer to the resulting large-scale MINLP problem as Problem 4, which we solve directly using an MINLP solver. Upon solving Problem 4, its lower bound is a lower bound to the initial synthesis problem (Problem 1).

$$E_{k,e,t} (1 - \eta_{k,e}^{\text{self}} \Delta t_t) + \Delta t_t \left( \eta_{k,e}^{\text{in}} \dot{E}_{k,e,t}^{\text{in}} - \frac{\dot{E}_{k,e,t}^{\text{out}}}{\eta_{k,e}^{\text{out}}} \right) \geq 0 \quad (4a)$$

$$E_{k,e,t} (1 - \eta_{k,e}^{\text{self}} \Delta t_t) + \Delta t_t \left( \eta_{k,e}^{\text{in}} \dot{E}_{k,e,t}^{\text{in}} - \frac{\dot{E}_{k,e,t}^{\text{out}}}{\eta_{k,e}^{\text{out}}} \right) \leq E_k^N \quad (4b)$$

In the RR branch, we expand the solution space by relaxing different constraints of Problem 1, potentially resulting in an increased computing time for Problem 4. Consequently, we employ computing time as an additional termination criterion, and adopt the lower bound of Problem 4 as the lower bound for Problem 1. If Problem 4 is infeasible, the RR branch proceeds to the next iteration.

For new iterations, we gradually revert the relaxations: starting with step (b) for each storage component, followed by step (a) for each energy balance equation. This sequential tightening of underestimation continues until, in the worst-case scenario, the original synthesis problem is fully addressed.

### 2.2.3. Optimality gap and Iteration

Finally, as marked by the red segment in Figure 1, we compare the best resulting lower and upper bounds obtained using Equation (5) and verify whether the pre-defined optimality gap  $\varepsilon^R$  is satisfied:

$$\varepsilon = \frac{TAC^{\text{UB}} - TAC^{\text{LB}}}{TAC^{\text{UB}}} \leq \varepsilon^R \quad (5)$$

RiNSES<sup>4</sup> identifies global optimal solutions for the initial MINLP synthesis problem (Problem 1),  $TAC^{\text{UB}}$ , with a known quality  $TAC^{\text{LB}}$ . It assesses the progress by comparing the current optimality gap  $\varepsilon$  against the required optimality gap  $\varepsilon^R$ . RiNSES<sup>4</sup> solves Problem 1 in the LASD

branch and the RR branch with different levels of simplification. If the achieved optimality gap  $\varepsilon$  fails to meet the required optimality gap  $\varepsilon^R$ , new iterations are triggered in both branches.

In the LASD branch, we enhance the time step resolution for time series aggregation in step (b) and, potentially, the number of breakpoints for linearization in step (a). Should Problem 2 or Problem 3 exhibit infeasibility, the computing process proceeds directly to the next iteration. In the RR branch, we undo the relaxations gradually, first for storage components in step (b), then for energy balance equations in step (a). Should Problem 4 encounter infeasibility, the computing process proceeds directly to the next iteration.

The iterations stop as soon as the required optimality gap  $\varepsilon^R$  is reached. The current best upper bound is a feasible solution to the initial nonlinear synthesis problem, Problem 1, with known quality. Since both the LASD and RR branches converge to the original MINLP problem in the worst-case scenario, the RiNSES<sup>4</sup> method guarantees the convergence to the initial MINLP synthesis problem (Problem 1).

## 3. CASE STUDY

### 3.1. Set-up

Figure 3: Structure of a PV-BAT energy system.

To evaluate the effectiveness of the proposed method, we apply RiNSES<sup>4</sup> to design a small energy system for seasonal energy supply and storage. We compare the method to an MINLP commercial solver. Thus, we choose a system small enough to be solvable by the MINLP commercial solver as well. As depicted in Figure 3, the energy system includes a conversion component (photovoltaic panels, PV), a storage component (battery, BAT), and three exogenous data inputs (weather, electricity selling price and demand). The renewable electricity generated by photovoltaic panels can be directly used

**Table 1:** Model parameters of the case study for the energy system components at the design level. The energy system components include photovoltaic panels (PVs) and a battery (BAT).

$k \in \mathcal{K}$	$I_k^{\text{ref}}$	$\dot{E}_k^{\text{N,ref}}$	$M_k$	$c_k^m$	$\dot{E}_k^{\text{N}}$
PVs	4264.3	1 $kW_{el}$	0.9592	0.01	[100, 20000] in $kW_{el}$
BAT	$I_k^{\text{ref}}$	$\dot{E}_k^{\text{N,ref}}$	0.8382	0.025	$\dot{E}_k^{\text{N}}$
	2116.1	1 $kWh_{el}$			[40, 600000] in $kWh_{el}$

to fulfill the electricity demand, stored in a battery, or fed into the electricity grid.

In the case study, we assume an interest rate  $i = 8\%$  and an investment period  $n$  of 10 years to calculate the annualized present value factor. The model parameters and the nominal size bounds at the design level are from the literature [14] and summarized in Table 1. For details on the model at the operation level and input time series, please refer to our previous work [15]. Please note that this work adopts a 4-hour resolution, representing the average values derived from every four time steps of the input time series used in our previous research [15]. Additionally, electricity selling prices here are based on the electricity buying prices cited in literature [15].

We set the predefined optimality gap  $\varepsilon^R$  to 5%. All resulting MILP problems are solved by the commercial solver Gurobi [16] with an optimality gap of 1%, whereas all MINLP problems are handled using the commercial solver BARON 22.11.3 [17] with an optimality gap of 0.2%. We model the energy system on the COMANDO platform [12] using Python 3.8. All computational tasks are carried out on Intel® Xeon® W-2155 processors with 3.3GHz and 128 GB RAM.

### 3.2. Results and discussion

The initial synthesis problem of the energy system contains 26,284 constraints and 17,524 decision variables. We address this synthesis problem with two solution approaches:

- Using the state-of-the-art MINLP global solver, BARON 22.11.3 [17], and
- Implementing our proposed method RiNSES<sup>4</sup>.

Figure 4 shows the results, illustrating the computing times for the upper and lower bounds of both, RiNSES<sup>4</sup> (blue lines) and BARON (green lines). The black dotted line represents the global optimal solution to the MINLP problem. Additionally, as explained in Section 2, the RiNSES<sup>4</sup> method independently calculates the upper and lower bounds, resulting in varying computing times for each.

In our case study, RiNSES<sup>4</sup> finds the first feasible solution within 150 seconds, which is nearly 20 times faster than BARON (2844 seconds). In addition, the initial feasible solution of RiNSES<sup>4</sup> is of high quality, closely approaching the optimal solution, in contrast to that of BARON. When comparing the upper bounds with the optimal solution, the relative error of the first feasible solution of RiNSES<sup>4</sup> is already within the predefined optimality gap  $\varepsilon^R$  5%.

In terms of the lower bounds, RiNSES<sup>4</sup> calculates the initial lower bound in 1444 seconds, which is twice as fast as BARON (2844 seconds). However, the initial lower bounds of both methods are significantly distant from the optimal solution. While BARON improves its lower bound in 2885 seconds, RiNSES<sup>4</sup> requires considerably more

time, achieving a better lower bound in 6649 seconds.

The solver BARON achieves the predefined solution quality in 6518s, with an optimality gap of 2.59%, whereas RiNSES<sup>4</sup> needs a slightly longer computing time of 6649s to reach an optimality gap of 4.97%. This is due to the slower improvement of lower bounds in the RR branch. All in all, RiNSES<sup>4</sup> can find good feasible solutions to MINLP energy system synthesis problems faster than the state-of-the-art solver BARON, even if the proof of optimality takes longer for the regarded case study.

**Figure 4:** Lower and upper bounds of RiNSES<sup>4</sup> and BARON as function of the computing time for designing a PV-BAT energy system.

### 4. CONCLUSION

The synthesis of energy systems for seasonal energy supply and storage initially results in large-scale MINLP problems, which are computationally challenging and often simplified and reformulated as (MI)LP problems to enhance computational tractability.

This work introduces the RiNSES<sup>4</sup> method, specifically designed to address nonlinearity in energy system synthesis. RiNSES<sup>4</sup> features two separate branches to under- and overestimate the initial MINLP problem simultaneously and independently. The method provides feasible solutions by upper bounds, which involve linearization, aggregation, superposition storage modeling and decomposition. For computing lower bounds, which are crucial for assessing solution quality, two-stage relaxations are utilized.

RiNSES<sup>4</sup> is applied to design a photovoltaic and battery energy system, with the results evaluated in computational studies. In comparison to the commercial solver BARON, the proposed RiNSES<sup>4</sup> method finds the initial optimal solution very quickly, albeit with a higher optimality gap.

The RiNSES<sup>4</sup> method is generally applicable to two-stage, time-dependent synthesis problems with coupling decision variables and constraints in complex energy systems. However, the method's approach for computing lower bounds, which relies on two-stage relaxations,

requires further enhancement. One potential enhancement could involve integrating nonlinear relaxation into the RR branch. This integration could help to effectively underestimate the nonlinear constraints and reduce computing time by solving MILP formulations within the RR branch. Overall, the foundational design and adaptability of RiNSES<sup>4</sup> render it a promising tool for advancing the field of nonlinear synthesis of energy systems for seasonal energy supply and storage.

## ABSTRACT

This study delves into the development and examination of various mathematical models for conventional steam-methane reforming (SMR) reactors, establishing a foundational basis for an electrified SMR reactor design. Distinct mathematical models with different scales and dimensions are derived. A basic 1D-fluid, 0D-catalyst (1D-0D) pseudo-homogeneous model is validated with plant data, and progressively advanced to a 2D-0D model considering radial transfer, then further extended to a rigorous 2D-1D model considering transfer phenomena between catalyst particle and fluid. Simulation cases are conducted under uniform design parameters, heat source and operation conditions. Comparative analyses focus on several key performance aspects, including temperature, reaction rate distribution, and outlet characteristics such as temperature, pressure, flow rate, composition and CH<sub>4</sub> conversion. The models effectively describe the industrial SMR reactor behavior. Influences of scale and dimension of mathematical model on reactor performance are highlighted. The rigorous 2D-1D model is identified as the most suitable model for adapting to electrified reactor configurations due to its precise capture of transfer phenomena and detailed illustration of both fluid and catalyst behaviors.

## 1 INTRODUCTION

Hydrogen (H<sub>2</sub>) is a crucial industrial chemical with a reported demand of approximately 90 million tonnes in the year 2020 and a projected increase in demand ranging from 28% to 45% by 2030 [1]. H<sub>2</sub> plays a vital role in various sectors including oil refining, and ammonia production among others [2]. About 62% of H<sub>2</sub> is produced from natural gas especially through steam-methane reforming (SMR) [1]. However, conventional SMR has disadvantages including: consumption of fossil fuels, emissions of carbon dioxide, heat transfer limitation of tube-furnace design. Electrification through induction heating as a substitute of heat source presents a noteworthy alternative [3]. To numerically assess an electrically-heated SMR (E-SMR), an electromagnetic model for induction heating is required. Concurrently, a comprehensive SMR model that can correlate the heat generation at

catalyst sites with the overall behavior of the reactor is essential.

There has been abundant research about modeling of SMR reactor. Latham *et al.* [4] developed a mathematical model of the reformer by segments which were discretized axially. Constant effectiveness factors were implemented with intrinsic kinetic model for reaction rate calculation. The model can predict temperature profiles for the outer-tube wall, inner-tube wall, furnace gas and process gas. Kuncharam, B. V. R *et al.* [5] employed a multi-scale modeling approach, integrating a steady state two-dimensional model for fluid-phase with a one-dimensional model for the pellet-phase. The effectiveness factor assumption was avoided. Their findings assert that the application of the Ergun equation to calculate the pressure drop in SMR reformer yields satisfactory results. Furthermore, the incorporation of molar change is necessary. Tacchino *et al.* [6] presented a validated

steady state multi-scale model of an industrial SMR reactor comprised of the furnace and reformer. A significant variability in effectiveness factor was observed, indicating the necessity of including catalyst particle simulation. The model proved its robustness by showing no sensitive reliance on adjustable parameter, the flame length.

Current advances in SMR modeling reveal a notable discrepancy in the approaches across different scales and dimensions. Models have been developed based on distinct parameters, operating conditions, and empirical expressions. Key factors such as fluid mechanics, heat input, temperature and reaction rate distributions, showing significant influence on the overall behavior including outlet condition, CH<sub>4</sub> conversion and efficiency of the reformer, have dependencies on scale and dimensionality. There lacks a comprehensive comparative analysis rooted in a uniform basis. In order to lay a foundation for E-SMR model development, and to quantify the key factors and the influence of varied-scale and varied-dimension on reactor behavior, numerical simulation of different models and analysis are required [7].

In this paper, for fluid-catalyst dimensions, 1D-0D, 2D-0D, 2D-1D mathematical models of conventional SMR are developed based on the same design parameters and operation conditions. Temperature and reaction rate distributions corresponding to different scenarios are illustrated. SMR reactor properties are recognized. Outlet behaviors, including temperature, pressure, flow rate, composition and CH<sub>4</sub> conversion are observed. Sensitivity analysis is conducted for the radial conductivity. Differences of the modeling schemes are recognized and analyzed.

## 2 MODEL DEVELOPMENT

**Table 1:** Characteristics of reactor tube and catalyst particles.

Parameters	Value	Unit
Length of tube	12.5	m
Radius of tube	0.063	m
Diameter of catalyst	0.0035	m
Conductivity of catalyst	33	W/m/K
Density of catalyst	3690	kg/m <sup>3</sup>
Heat capacity of catalyst	880	J/kg/K

Industrial SMR reactors contain parallel tubes arranged in rows and columns inside the furnace, each packed with catalyst. This paper sets up a mathematical model of an industrial-scale single tube to observe the overall behavior of the reactor. Ni/MgAl<sub>2</sub>O<sub>4</sub> catalyzes the reaction. Characteristics of reactor tube and catalyst particles are listed in Table.1.

The following assumptions have been made for establishing the models:

## 2.1 Assumptions

1. Operational conditions and performance data can be linearly extrapolated from a single tube to the overall reactor;

2. The fluid phase follows ideal gas behaviors;

3. Spherical catalyst particle and cylindrical tube have constant porosity respectively;

4. 3 main reactions occur:

5. Inner tube wall temperature is a polynomial function of axial space position fitted from industrial data.

**Figure 1.** Abbreviated diagram of industrial SMR reactor (reproduced from Ref. [4]) and illustration of three models regarding scale and dimension.

Three models covering different scales and dimensions are shown in Figure 1, along with industrial SMR reactor diagram. Tube expressions are derived in cylindrical coordinate, while catalyst particle expressions in spherical coordinate. Considering geometric symmetry, the most rigorous scenario is a multi-scale model considering multi-dimension including axial and radial domains for the fluid phase in tube, and radial domain for catalyst particle (2D-1D). Additional assumptions may be included owing to the distinct characteristics in each model. In the 2D-0D model, reactor tube is assumed to be pseudo-homogeneous simplifying the heterogeneity. For 1D-0D model, plug flow behavior is additionally assumed.

**Table 2:** Nomenclature.

Symbol	Unit	Name
C	mol/m <sup>3</sup>	concentration
u	m/s	Interstitial velocity
U	m/s	Superficial velocity
D	m <sup>2</sup> /s	diffusivity
y		Composition
f	Hz	Frequency of alternating magnetic field
a <sub>p</sub>	m <sup>2</sup> /m <sup>3</sup>	surface area per unit volume of catalyst
d <sub>p</sub>	m	diameter of catalyst
R <sub>tube</sub>	m	Radius of reactor tube
k <sub>m</sub>	m/s	solid-fluid mass transfer coefficient
k <sub>h</sub>	W/m <sup>2</sup> /K	solid-fluid heat transfer coefficient
ρ <sub>f</sub>	kg/m <sup>3</sup>	density of fluid
ρ <sub>p</sub>	kg/m <sup>3</sup>	density of catalyst particle
c <sub>p</sub>	J/kg/K	heat capacity
T	K	temperature
λ	W/m/K	conductivity
R	mol/kgcat/s	reaction rate
L	m	length of reactor tube
ΔH	J/mol	reaction enthalpy
ε		porosity
v		stoichiometry of reactions
h	W/m <sup>2</sup> /K	Tube-fluid heat transfer coefficient

## 2.2 Mathematical Expressions

The mathematical models encompass mass, heat

and momentum conservations under steady state for fluid mechanics description, and kinetic model for reaction description. Mass diffusion and convection, and heat conduction and convection, are considered for transfers. Pressure drop expression is derived from momentum conservation with friction factor calculated by the Ergun equation.

For the purpose of elucidating the expressions, the rigorous 2D-1D model is shown below as a representative example since it is the most detailed.

### 2.2.3 Fluid Phase

#### 2.2.3.1 Mass Conservation

$$\frac{\partial C_i}{\partial z} u_z + C_i \frac{\partial u_z}{\partial z} = \frac{1}{r} D_{i,r}^e \frac{\partial C_i}{\partial r} + \frac{\partial D_{i,r}^e}{\partial r} \frac{\partial C_i}{\partial r} + D_{i,r}^e \frac{\partial^2 C_i}{\partial r^2} + \frac{\partial D_{i,z}^e}{\partial z} \frac{\partial C_i}{\partial z} + D_{i,z}^e \frac{\partial^2 C_i}{\partial z^2} + \frac{(1-\varepsilon_b)}{\varepsilon_b} a_p k_{i,m} (C_{i,s} - C_i) \quad (1)$$

Boundary conditions:

$$C_i|_{z=0} = c_{i0}; \quad \frac{\partial C_i}{\partial z}|_{z=L} = 0; \\ \frac{\partial C_i}{\partial r}|_{r=0} = 0; \quad \frac{\partial C_i}{\partial r}|_{r=R_{tube}} = 0 \quad (2)$$

#### 2.2.3.2 Heat Conservation

$$\varepsilon_b \rho_f u_z c_p \frac{\partial T}{\partial z} = \frac{1}{r} \lambda_r^e \frac{\partial T}{\partial r} + \frac{\partial \lambda_r^e}{\partial r} \frac{\partial T}{\partial r} + \lambda_r^e \frac{\partial^2 T}{\partial r^2} + \frac{\partial \lambda_z^e}{\partial z} \frac{\partial T}{\partial z} + \lambda_z^e \frac{\partial^2 T}{\partial z^2} + (1 - \varepsilon_b) a_p k_h (T_s - T) \quad (3)$$

Boundary conditions:

$$-\lambda_r^e \frac{\partial T}{\partial r}|_{r=R_{tube}} = h(T_w - T); \quad \frac{\partial T}{\partial r}|_{r=0} = 0; \\ T|_{z=0} = T_0; \quad \frac{\partial T}{\partial z}|_{z=L} = 0 \quad (4)$$

### 2.2.4 Catalyst Phase

#### 2.2.4.1 Mass Conservation

$$0 = \frac{2}{\rho} D_{i,p,\rho} \frac{\partial C_{i,p}}{\partial \rho} + \frac{\partial D_{i,p,\rho}}{\partial \rho} \frac{\partial C_{i,p}}{\partial \rho} + D_{i,p,\rho} \frac{\partial^2 C_{i,p}}{\partial \rho^2} + \frac{1}{\varepsilon_p} \rho_p \sum_{j=1}^3 \nu_{ij} R_j \quad (5)$$

Boundary conditions:

$$\frac{\partial C_{i,p}}{\partial \rho}|_{\rho=0} = 0; \quad -\varepsilon_p D_{i,p,\rho} \frac{\partial C_{i,p}}{\partial \rho}|_{\rho=R_p} = k_{i,m} (C_{i,s} - C_i) \quad (6)$$

#### 2.2.4.2 Heat Conservation

$$[(1 - \varepsilon_p) \rho_p c_{p,p} + \varepsilon_p \rho_f c_{p,f}] \frac{\partial T_p}{\partial t} = \frac{2}{\rho} \lambda_{p,\rho}^e \frac{\partial T_p}{\partial \rho} + \frac{\partial \lambda_{p,\rho}^e}{\partial \rho} \frac{\partial T_p}{\partial \rho} + \lambda_{p,\rho}^e \frac{\partial^2 T_p}{\partial \rho^2} - (1 - \varepsilon_p) \rho_p \sum_{j=1}^3 R_j \Delta H_j \quad (7)$$

Boundary conditions:

$$\frac{\partial T_p}{\partial \rho}|_{\rho=0} = 0; \quad -\lambda_{p,\rho}^e \frac{\partial T_p}{\partial \rho}|_{\rho=R_p} = k_h (T_s - T) \quad (8)$$

### 2.2.5 Coefficients

### 2.2.5.1 Diffusivity

Axial and radial effective diffusivity are expressed as following:

$$\frac{1}{Pe_z} = \frac{0.72}{Re_p Sc} + \frac{0.52}{\left(1 + \frac{9.0}{Re_p Sc}\right)} \quad (9)$$

$$\frac{1}{Pe_r} = \frac{0.34}{(Re_o Sc)^{0.80}} + \frac{0.08}{\left(1 + \frac{10.8}{Re_o Sc}\right)} \quad (10)$$

### 2.2.5.2 Conductivity

$$\frac{\Delta_f^e}{\lambda_f} = \frac{\lambda^{eo}}{\lambda_f} + 0.1PrRe \quad (11)$$

$$\frac{\lambda_z^e}{\lambda_f} = \frac{\lambda^{eo}}{\lambda_f} + 0.5PrRe \quad (12)$$

### 2.2.5.3 Solid-fluid transfer coefficient

$$Sh = \frac{k_{i,m} d_p}{D_{i,m}} = 2 + 1.1Sc^{1/3} Re_o^{0.6} \quad (13)$$

$$Nu = \frac{k_h d_p}{\lambda_m} = 2 + 1.1Pr^{1/3} Re_o^{0.6} \quad (14)$$

### 2.2.5.4 Tube-fluid heat transfer coefficient

$$H = \alpha \frac{\lambda}{d_p} \left( 2.58 Re_p^{1/3} Pr^{1/3} + 0.094 Re^{0.8} Pr^{0.4} \right) \quad (15)$$

### 2.2.6 Kinetics

An intrinsic Langmuir-Hinshelwood-Hougen-Watson kinetic model developed by Xu and Froment [8] is applied.

## 3 RESULTS

The equation-based mathematical models composed of PDEs are coded in FORTRAN and solved in Aspen Custom Modeler V12.1. Physical properties are calculated by calling Aspen properties bank. Finite difference methods are used for discretization. Newton Method solves the system of nonlinear equations.

### 3.1 1D-0D Model Validation

This model describes homogeneous reactor tube with only axial domain transfer. The simulation has 9,887 equations after decomposition. Operating conditions of the three cases implemented are listed in Table 3.

The model validation focuses on temperature profile along the tube, CH<sub>4</sub> conversion of methane and outlet pressure. Root mean standard error (RMSE) and Pearson correlation Coefficient (PCC) defined in Equation 16 are calculated to measure deviation and correspondence of change tendency of profile. The smaller RMSE is, and the closer CF is to 1, the better consistency the simulated profile shows to industrial case. Relative error (RE) is calculated for evaluating CH<sub>4</sub> conversion and pressure. Figure 2 shows comparative results between temperature profile derived from our model and those documented in

literature under Case 3 operation conditions as an example. Modeled composition profiles are plotted in Figure 3, along with industrial outlet values. Table 4 shows the evaluation coefficients quantifying the comparison of temperature profile. The developed 1D-0D model has lowest PCC of 0.9979, highest RE of 3.61%, highest RMSE of 14.28 compared with 800-1150K range, showing a consistency with literature reported. The outlet behaviors are listed in Table 5. The results are aligned with plant data.

$$CF = \frac{\sum(x-\bar{x})(y-\bar{y})}{\sqrt{\sum(x-\bar{x})^2 \sum(y-\bar{y})^2}} \quad (16)$$

Heat is input into a discretized plug flow segment for 1D-0D model. The profile is plotted in Figure 4 along with reaction rate. The maximum heat input is reached at about L=3-5m, which is the length of a combustion flame. The majority of reactions happen near the entrance of the tube length area, leading to a temperature drop to minimum at about L=0.625m.

**Table 3:** Inlet operation conditions of 3 industrial cases [4].

	Case1	Case2	Case3
T [K]	884.55	887.05	879.85
P [bar]	30.060	29.440	28.085
Velocity [m/s]	1.279	1.147	0.925
y <sub>CH4</sub>	0.2421	0.2487	0.2401
y <sub>H2O</sub>	0.7461	0.7377	0.7437
y <sub>CO</sub>	0.0036	0.0042	0.0060
y <sub>CO2</sub>	0.0047	0.0053	0.0042
y <sub>H2</sub>	0.0036	0.0042	0.0060

**Table 4:** Evaluation coefficients of 3 cases compared with literature documented [4].

	Case1	Case2	Case3
RMSE	14.28	12.58	10.46
PCC	0.9979	0.9981	0.9979

**Figure 2.** Simulated (solid), literature (dashed) temperature profile along the tube of Case 3 with RMSE of 10.4.

**Figure 3.** Simulated industrial composition profile along the tube, and CH<sub>4</sub> conversion of case 3.

**Figure 4.** Simulated reaction heat (solid) and input heat (dashed) profile along the tube.

### 3.2 2D-0D Model

Radial transfer is introduced in 2D-0D homogenous model based on 1D-0D model. The simulation has 43,035

equations after decomposition. Case 3 is implemented for comparison.

Figure 5 shows simulated temperature distribution. Axially lowest temperature appeared at  $L=0.3125-0.625m$ , which is at similar position compared with 1D-0D. Radial temperature difference is observed, with a highest of 126.31K at  $L=4.0625m$ , which is slightly delayed compared with the maximum heat input at  $L=3.75m$ . Radial temperature difference follows the same trend as heat input as shown in Figure 6 (top). Radial temperature difference indicating heat loss is inevitable considering the relatively low radial heat transfer efficiency. However, the average temperature along axial direction still shares a similar trend compared with 1D-0D. 2D-0D case has a lower average temperature of 49.4K, leading to a CH<sub>4</sub> conversion decrease from 75% to 64%.

**Figure 5.** Simulated temperature distribution in 2D-0D case.

Figure 7 illustrates the distribution of the reaction rate, using Reaction 3 as a representative case. 99.5% of the overall reaction occurs with the length  $L=0.9375m$ . For the rest of the tube length, 69%-83% of the reaction occurs near the reactor tube wall where temperature is highest radially, indicating the reactor being heat transfer limited.

The different behaviors between 2D-0D and 1D-0D are resulted from with or without plug-flow assumption. Radial transfer coefficient is assumed to be infinitely large to reach uniform distribution. This tendency is illustrated in Figure 8 that the larger the radial conductivity is, the closer the average outlet temperature is to 1D-0D model.

**Table 5:** Modelled outlet behaviors compared with industrial data [4].

	Case 1	Plant 1	Case 2	Plant 2	Case 3	Plant 3
Temperature [K]	1107.51	1105.55	1108.77	1107.15	1108.25	1108.95
Pressure [bar]	28.461	28.189	28.040	27.990	27.234	27.155
Flow Rate [mol/s]	8.935	8.970	7.797	8.082	6.136	6.024
CH <sub>4</sub> Conversion [%]	73.79	71.30	73.11	70.70	74.77	72.16
y <sub>CH4</sub>	0.0461	0.0505	0.0484	0.0526	0.0482	0.0440
y <sub>H2O</sub>	0.3614	0.3507	0.3517	0.3417	0.3430	0.3580
y <sub>H2</sub>	0.4544	0.4583	0.4593	0.4631	0.4655	0.4580
y <sub>CO</sub>	0.0790	0.0820	0.0820	0.0845	0.0850	0.0808
y <sub>CO2</sub>	0.0591	0.0582	0.0587	0.0575	0.0574	0.0592

**Figure 6.** (top) Heat input profile (left) and radial temperature difference (right) profile along the reactor tube; (bottom) 1D-0D temperature profile, untuned and tuned 2D-0D average temperature profile.

**Figure 7.** Reaction rate distribution in reactor tube with as a function of a specific length.

**Figure 8.** 2D-0D average outlet temperature versus radial conductivity.

To ensure that the 2D model has better accordance with industrial data regarding the  $\text{CH}_4$  conversion, the amount of heat input is recalculated by parameter tuning of the tube-fluid heat transfer coefficient  $\alpha$ . The tuned-conversion reaches less than  $5e-4\%$  RE compared with industrial data. Heat input after tuning has an average of  $1.7e5 \text{ W/m}^3$  more in amount compared with untuned case. Outlet average temperature has 1.03% RE, while pressure has 0.15% RE. The tuned temperature distribution has an average temperature of 14.3K lower than 1D-0D due to the radial temperature distribution, but 35.1K higher than untuned 2D-0D shown in Figure 6 (bottom). The outlet behaviors are listed in Table 6. The tuned case approaches the plant data more than untuned case.

**Table 6.** Comparison of tuned, untuned 2D-0D cases and industrial case.

Outlet	Tuned	Untuned	Plant
Temperature [K]	1096.86	1064.77	1108.95
Pressure [bar]	27.19	27.25	27.23
Flow Rate [mol/s]	6.133	6.015	6.024
$\text{CH}_4$ Conversion [%]	72.16	64.32	72.16
$y_{\text{CH}_4}$	0.0496	0.0560	0.0482

$y_{\text{H}_2}$	0.4480	0.4364	0.4655
$y_{\text{CO}_2}$	0.0605	0.0619	0.0573
$y_{\text{CO}}$	0.0757	0.0702	0.0850

### 3.3 2D-1D Model

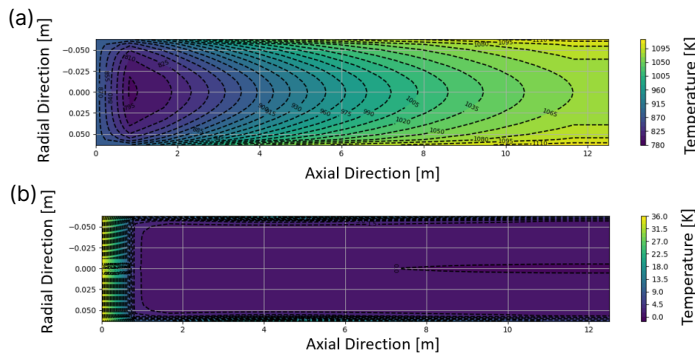

Solid catalyst particle phase is taken into consideration for 2D-1D heterogenous model. External transfer between catalyst surface and fluid phase, and internal transfer in catalyst particle are introduced. The simulation has 205,389 equations after decomposition. Case 3 is implemented for comparison.

Temperature difference exists between the fluid, the catalyst surface, and catalyst center, leading to

additional heat loss. Figure 9 (a) shows the temperature distribution of fluid. Temperature differences from catalyst center to catalyst surface is less than 0.5 K. Temperature difference from catalyst surface to fluid distribution is shown in Figure 9 (b), the average is 3.69 K. The maximum difference axially is at entrance, while radially is at tube wall, where the majority of reactions occur, which is consistent with 2D-0D observation. A drop in CH<sub>4</sub> conversion of 24% is observed under the same condition as 2D-0D.

Reaction rate distributions of catalyst particle at specific positions are shown in Figure 10. The majority of reactions occur near the surface, which indicates that the catalytic reactions are diffusion-limited.

The outlet behaviors are shown in Table 7. The 2D-1D outlet behaviors show good consistency with 2D-0D case, except temperature and CH<sub>4</sub> conversion.

**Figure 9.** (a) Temperature distribution of 2D-1D fluid phase; (b) Temperature difference between fluid and catalyst surface distribution of 2D-1D.

**Figure 10.** Reaction rate distribution of catalyst particle at position (a) L/L<sub>tube</sub>=0; (b) L/L<sub>tube</sub>=0.20; (c) L/L<sub>tube</sub>=0.47; (d) L/L<sub>tube</sub>=0.73; (e) L/L<sub>tube</sub>=1.

**Table 7.** Comparison of 2D-1D with tuned 2D-0D cases.

Outlet	2D-1D	2D-0D
Temperature [K]	1080.09	1096.86
Pressure [bar]	27.19	27.19
Flow Rate [mol/s]	6.083	6.133
CH <sub>4</sub> Conversion [%]	47.99	72.16
Y <sub>CH4</sub>	0.0498	0.0496
Y <sub>H2O</sub>	0.3665	0.3661
Y <sub>H2</sub>	0.4481	0.4480
Y <sub>CO2</sub>	0.0606	0.0605
Y <sub>CO</sub>	0.0750	0.0757

### 3.4 E-SMR Model

The development of conventional SMR model lays foundation for heat electrification that E-SMR model is developed by incorporation of induction heat model. Hysteresis heat is regarded as dominant induction heat source, which is estimated by the following expression:

$$P_{hys} = A_{hys} f \rho \quad (17)$$

where hysteresis area  $A_{hys}$  is dependent on material electromagnetic property, magnetic field strength and temperature.

In conventional SMR reactors, the heat flux source is introduced as a boundary condition for the fluid phase boundary at tube layer. While for induction-heated E-SMR reactor which utilizes dual-function catalysts, heat is directly generated at the catalyst sites. The heat flux is introduced internally from the catalyst phase in the way that the  $P_{hys}$  term is included as a source term in the energy conservation equation of the catalyst/fluid phase.

## 4 CONCLUSIONS

Mathematical models covering varied scales and dimensions of SMR Reactor tube have been developed. Comparative analyses have been carried out focusing on

temperature, reaction rate distribution and outlet behaviors, including temperature, pressure, flow rate, composition and CH<sub>4</sub> conversion.

Validation with industrial data shows that the 1D-0D numerical simulation can precisely describe the SMR reactor behavior. When developed on the same basis, the 2D-0D shows a radial temperature distribution. When resistance of radial transfer is set to infinitely small, the behavior of 2D-0D is approaching 1D-0D, which is a validation of the developed 2D-0D model. Higher reaction rates are mainly distributed near entrance and near tube wall positions, indicating a heat transfer limited property. 2D-0D shows a lower CH<sub>4</sub> conversion than 1D-0D considering the heat resistance behavior in the way of radial temperature distribution. A heat transfer coefficient corresponding to industrial plant CH<sub>4</sub> conversion can be obtained by parameter fitting. The fitted 2D-0D case shows a high correlation with plant data. 2D-1D model was further developed with the results showing additional heat resistance in the way of temperature difference between the fluid, catalyst surface, and catalyst center. A further decrease of CH<sub>4</sub> conversion compared with 2D-0D is observed. On catalyst sites, the majority of reactions occur at position close to the catalyst surface, indicating the diffusion-limited property.

Simplification of model in terms of scale and dimension neglects some of the heat resistances. Due to the fixed tube wall assumption for all three cases, and same initial conditions, the neglected heat resistance manifests in the way of decreased CH<sub>4</sub> conversion. However, distinct models are suitable for different tasks. When an estimation of effectiveness factor is unavailable and catalyst behaviors are required, rigorous 2D-1D is more suitable.

## ABSTRACT

Initial design stages are inherently complex and often lack comprehensive information, posing challenges in evaluating sustainability metrics. Machine Learning (ML) emerges as a valuable solution to address these challenges. ML algorithms, particularly effective in predicting environmental impacts of new chemicals with limited data, enable more informed decisions in sustainable design. This study focuses on employing ML for predicting the environmental impacts related to human health, ecosystem quality, climate change, and resource utilization to aid in early-stage environmental impact assessment of chemical processes. The effectiveness of the ML algorithm, eXtreme Gradient Boosting (XGBoost) tested using a dataset of 350 points, divided into training, testing, and validation sets. The study also includes a practical application of the model in a cradle-to-cradle LCA of N-Methylpyrrolidone (NMP), demonstrating its utility in sustainable chemical process design. This approach signifies a significant advancement in the early stages of process design, highlighting the potential of ML in enhancing environmental sustainability in the chemical industry.

**Keywords:** Machine Learning, Life Cycle Analysis, Process Design, Modelling, Process Synthesis

## INTRODUCTION

Amidst growing climate change concerns and heightened environmental awareness, industries are increasingly scrutinized for their environmental impact [1]. This scenario underscores the importance of environmental impact assessment at early-stage process synthesis [2], [3], where operational processes are initially formulated and assessed. Decisions made at this stage have significant implications for the environmental footprint of the entire operation. In this context, Machine Learning (ML) [4], [5] presents a transformative solution. By integrating ML in the early stages, industries can efficiently utilize its potential for rapid, accurate, and comprehensive assessments of sustainability.

ML offers a significant advantage in systems with non-obvious relationships in that, once trained, ML models can be used to predict such environmental metrics, facilitating prompt design modifications and improvements. Its adaptability also allows for easy integration with optimization strategies, aiding industries in

developing processes during early-stages that balance environmental and economic factors. Financially, ML is invaluable; addressing sustainability issues early on helps industries avoid costly later-stage modifications, leading to substantial cost savings. In essence, incorporating ML into early-stage process synthesis represents a forward-thinking move for industries striving towards sustainability.

Thermodynamic properties such as enthalpy, entropy, Gibbs free energy [6], [7], among others provide crucial insights into the energy requirements of a process, operational efficiency, and overall feasibility. These attributes significantly influence the energy consumption of the process, impacting essential sustainability metrics such as GWP and total carbon footprint. On the other hand, molecular characteristics [8], [9], including molecular weight, bond energies, and functional groups, among others offer valuable information about the inherent qualities of chemical substances such as reactivity [10], potential toxicity [11], and environmental impacts [12], [13]. Often times, data on both thermodynamic and molecular

properties are available during the initial stages of process design. Therefore, by developing a ML model that incorporates thermodynamic and molecular descriptors as input and sustainability metrics as outputs, it is possible to predict sustainability metrics for both new and existing chemicals that lack established sustainability data. This approach enables a more holistic and informed evaluation of sustainability at the early stages of chemical process synthesis.

Previous research has shown that ML can be utilized to effectively enhance energy efficiency [14] and forecast corporate carbon footprints [15], among others [16], [17]. Building on this, the current study applies ML, specifically, eXtreme Gradient Boosting (XGBoost) [18], [19], to predict endpoint impact metrics for chemicals, particularly new molecules. This approach can lead to the development of safer and more sustainable chemical alternatives and circular process designs. Subsequently, the developed ML model is used together with other methods to predict the entire cradle-to-cradle environmental impact of NMP.

## METHODOLOGY

In this section, we discuss the data gathering process, preprocessing, ML model building, and evaluation metrics.

### Data Acquisition

A comprehensive dataset of 350 common solvents, including alcohols, esters, hydrocarbons, and ethers, was compiled for this study. The dataset is divided into two parts: the feature set and the label set. The feature set consists of thermodynamic and molecular descriptor data, encompassing the chemical properties used for model training. The label set, on the other hand, represents the data that the model aims to predict. For each chemical, 15 thermodynamic properties are gathered, such as critical temperature, pressure, volume, heat capacity, boiling point, and standard Gibbs-free energy. The data collection process begins with extracting the SMILES string [20] and chemical formula for each solvent.

These SMILES strings are used to extract the corresponding thermodynamic properties. This is achieved through two Python libraries: "chemicals" [21] and "thermo", which host extensive databases of pure and calculated chemical properties. The local databank in these libraries includes over 20,000 chemicals and their properties, compiled from sources like the National Institute of Standards and Technology (NIST), Design Institute for Physical Properties (DIPPR), PubChem, CRC Handbook, Perry's Chemical Engineers' Handbook, and various scientific papers and publications.

The molecular descriptor properties for each

chemical were obtained using RDKit [22] (version 2023.3.3), an open-source Python library renowned in cheminformatics. For this study, RDKit was employed to acquire 200 molecular descriptors for each chemical, covering various properties. These include molecular weight, carbon count, maximum partial charge, functional group, number of heterogeneous atoms, number of radical atoms, and the number of aliphatic rings, among others.

For the label data, SimaPro® [23] (version 9.4.0.2) is used to gather the cradle-to-gate metrics for each chemical. The metrics include human health impact (HHI), ecosystem quality impact (EQI), global warming potential (GWP), and resource utilization impact (RUI). These four endpoint metrics are chosen due to decision-making relevance, ease of communication, and depth of analysis.

### Data Preprocessing

The initial step is to address the issue of missing data in the label set. While removing rows with missing data is a typical solution, ML models benefit from larger datasets. Therefore, the k-Nearest Neighbors (kNN) method, a well-established technique in data imputation, was employed for this analysis. Upon completion, the feature dataset was scaled to be in a range of 0 and 5.

Given the large number of features available in the dataset, it was necessary to identify and select those features that contribute most significantly to the model. This process of feature selection not only reduces computational time but also eliminates redundant features, thereby enhancing model accuracy. A balanced approach was adopted, choosing a total of 10 features with an equal number (5) from both the thermodynamic and molecular feature sets. This equal representation ensures that each feature set contributes fairly to the model. The streamlined selection of just 10 features also adds practical value for users, simplifying the prediction process for specific chemicals by requiring only a limited set of properties. Additionally, the model was tailored to each of the four metrics it predicts, with a unique set of features for each metric. This customization ensures that only the most relevant and impactful features are used for predictions in each specific case, optimizing the effectiveness and precision of the model. The Sequential Backward Feature Selection (SBFS) methodology, with linear regression and Mean-Squared-Error (MSE) criterion, was used to achieve this aim.

### Model Training and Hyperparameter Tuning

Once the feature set for each label is finalized, the next step is to build the ML model for the prediction. Two models were developed, XGBoost and Artificial Neural Network (ANN), but in this paper, we present the XGBoost model.

XGBoost, an advanced ensemble ML model, is an

efficient implementation of the gradient boosting framework, particularly suitable for optimizing large-scale ML problems. It functions by iteratively building and refining models, each new model correcting the inaccuracies of its predecessors. This refinement is guided by the gradient descent method, which addresses the weaknesses in the existing ensemble by adding new decision trees, continuing until a predetermined error limit is reached or a specified number of trees is included.

In this study, the data was divided into training, validation, and testing sets. This split was not fixed but was determined based on the label being predicted. To enhance the performance of the model, key hyperparameters of XGBoost (version 1.7.6) were optimized. This optimization involved selecting and tuning four to six hyperparameters that most significantly affect the model. This process was facilitated by the "hyperopt" [24] (version 0.2.7) library, which employs a Bayesian optimization framework [25]. The hyperparameters adjusted include the maximum depth of a tree, learning rate, number of trees, minimum child weight in a node, subsample fraction for growing trees, and the fraction of features chosen for tree development. The optimal hyperparameters were determined using the validation set, with an objective function designed to minimize the MSE between the actual and predicted values after training on the training set. The test set, crucially, was reserved exclusively for evaluating the generalizability and overall performance of the model.

For model evaluation, two key metrics were used: R-squared ( $R^2$ ) value and the Root-Mean-Squared-Error (RMSE). The  $R^2$ , also known as the coefficient of determination, indicates the proportion of the variance in the dependent variable that the independent variables in the model can explain. On the other hand, the RMSE measures the average magnitude of the errors between the predicted and actual outcomes, providing a direct assessment of the accuracy of the model. This metric gives an absolute measure of the fit of the model, quantifying the average deviation in the predictions.

## RESULTS AND DISCUSSION

In this section we discuss the results from the feature selection, the developed XGboost model and an NMP case study.

### Feature Selection Result

Table 1 outlines the chosen features for evaluating various sustainability metrics, following the application of SBFS. The selected features underscore the importance of both thermodynamic properties and molecular descriptors in providing a comprehensive assessment of sustainability. Notably, critical temperature and heat capacity emerge as common thermodynamic features

across all metrics, highlighting their universal applicability in sustainability evaluations. These properties are fundamental in understanding the energy dynamics and efficiency of chemical processes. Furthermore, the inclusion of XLogP and boiling point in three out of the four metrics signifies their relevance in assessing different environmental impacts. Molecular descriptors, particularly HallKierAlpha, have been selected for their ability to represent the three-dimensionality of molecules, a factor crucial in understanding the environmental behavior and impact of chemicals. HallKierAlpha, selected for three of the four metrics, specifically captures shape representation and molecular branching, aspects essential for evaluating the environmental compatibility of chemical substances.

**Table 1:** Selected features for each endpoint metric

Metric	Thermodynamic Feature	Molecular Descriptor Feature
HHI	heat of vaporization, heat capacity, XLogP, acentric factor, critical temperature	Chi0, HallKierAlpha, SMR_VSA7, VSA_EState6, NumValenceElectrons
EQI	heat capacity, standard formation enthalpy (gas), boiling Point, critical temperature, critical volume	Chi2v, BertzCT, HallKierAlpha, qed, fr_halogen
GWP	heat capacity, boiling point, XLogP, critical temperature, critical molar volume	BertzCT, ExactMolWt, HallKierAlpha, PEOE_VSA6, NOCount
RUI	heat capacity, boiling point, XLogP, critical pressure, critical temperature	ExactMolWt, MaxAbsPartialCharge, MaxPartialCharge, NumRotatableBonds, SMR_VSA2

### Model Result

Figure 1 presents a parity plot of the predictive accuracy of the XGBoost model across the various environmental metrics. This parity plot offers a comprehensive view of the model's performance, highlighting its strengths and areas for further improvement.

Starting with the Human Health Impact (HHI) metric, as depicted in Figure 1 (a), the model demonstrates remarkable accuracy. The test set notably outperforms both the training and validation sets, achieving an  $R^2$  of 0.997. This high score indicates a strong correlation

between the predicted and actual values, signifying the efficacy of the model in predicting HHI metric. Additionally, the RMSE values across the train-validation-test sets are closely aligned, further underscoring the reliability of the predictions. The range of HHI predictions, spanning 0.63 – 12 ( $\times 10^{-6}$ ) DALY/kg<sub>chem</sub> with a 95% confidence interval, reflects the model's comprehensive coverage of potential human health impacts.

The Ecosystem Quality Impact (EQI) metric, illustrated in Figure 1 (b), presents a slightly different picture. Although the RMSE values remain within acceptable limits, suggesting general reliability, the model exhibits a significant discrepancy in the  $R^2$  value for train-validation sets but performs well on the test set. This variance indicates a need for refinement in the model to achieve a more dependable  $R^2$  value for EQI predictions. The predictions for EQI range from 0.022 – 3.0 PDF.m<sup>2</sup>.yr/ kg<sub>chem</sub>.

In the case of the Global Warming Potential (GWP) metric, the model shows good predictive performance, though it is not without its challenges. The GWP model displays a tendency to generalize to a good degree on the validation set but performs less efficiently on the testing set based on the  $R^2$  however, the RMSE for both validation and training set are similar in magnitude and order. The predicted values for GWP, ranging from 0.81 to 9.0 kgCO<sub>2</sub>-eq/kg<sub>chem</sub> within a 95% confidence interval, demonstrate capability of the model in this domain.

Lastly, the Resource Utilization Impact (RUI) metric, which can be interpreted as the Cumulative Energy Demand (CED) for chemical production, performs less in terms of prediction on the test set. The predictions for RUI, ranging from 4.5 to 15 ( $\times 10^1$ ) MJ-primary/kg<sub>chem</sub> with a 95% confidence interval, indicate a high degree of accuracy and reliability, showcasing the model's strengths in this area. In this study, the 95% confidence intervals were derived through a bootstrapping technique. This resampling approach enables us to assess the variability in the predictions made by our models. Specifically, for each model (HHI, EQI, GWP, RUI), we generated 1,000 bootstrap samples. This was achieved by randomly selecting 50% of the dataset with replacement in each iteration. Subsequently, we utilized the models to make predictions for each bootstrap sample. The construction of the 95% confidence intervals involved determining the 2.5th and 97.5th percentiles from the distribution of these bootstrap predictions. It is important to note that these intervals reflect the variability associated with the model predictions themselves, rather than the uncertainty in the hyperparameters of the XGBoost model or the variability inherent in the dataset. Table 2 also shows the comparison of the 95% confidence intervals for the actual data and the developed XGBoost model indicating a good agreement with the original data.

**Table 2:** Comparison of confidence interval for actual data and XGBoost model

Metric	Actual Data	XGBoost Model
HHI ( $\times 10^{-6}$ )	0.55 – 12	0.63 – 12
EQI	0.022 – 3.1	0.022 – 3.0
GWP	0.68 – 9.8	0.81 – 9.0
RUI ( $\times 10$ )	3.5 – 17	4.5 – 15

### Case Study: Cradle-to-cradle Life Cycle Assessment (LCA) of N-Methylpyrrolidone (NMP)

(NMP) is a polar aprotic solvent, notable for its high boiling point, and is widely used in the chemical industry, particularly in the production of polymers. Its role in polymer manufacturing is significant, but it also raises environmental concerns. The issue with NMP lies in its non-consumptive use in synthesis and processing, leading to its release as waste, a common occurrence in the fine and specialty chemical industries. The environmental and health risks associated with the disposal of NMP are well-recognized. However, the lack of suitable and safer alternatives to NMP and similar dipolar aprotic solvents has resulted in its continued widespread use in specialty chemical applications. Given these circumstances, the importance of solvent recovery after its usage becomes paramount. Recovering NMP not only mitigates the environmental and health risks but also addresses waste management concerns in the chemical industry, emphasizing the need for sustainable and responsible solvent usage practices.

#### Process Description

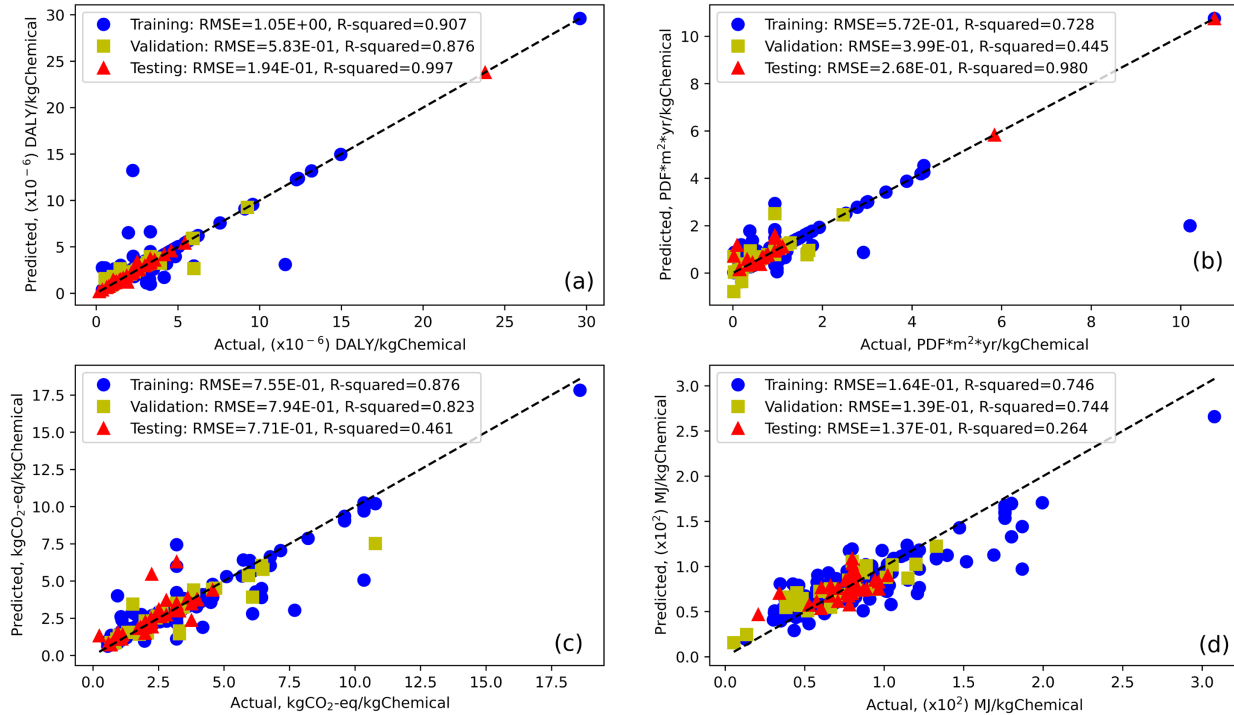

We consider a specific case where fresh solvents (n-methyl-2-pyrrolidone (NMP)) and reagents (trifluoroacetic acid (TFA), hydroxyethyl methacrylate (HEMA), hydrochloric acid (HCl)) are initially sent to a reactor together with monomers (oxydianiline (ODA), pyromellitic dianhydride (PMDA)) for making a resin (polyimide (PI)) precursor. The role of the NMP is to dissolve the ODA while the reagents are added to the reaction medium to improve the photosensitivity of the PI produced. Once the reaction is complete, the product stream flows to the washing stage where ultrapure water is used to wash the produced resin resulting in three main streams: 1) the resin precursor stream which is sent to a filter press for further processing, 2) a hazardous waste stream containing NMP, and 3) a wastewater stream. We look at three main stages in the impact assessment: 1) the cradle-to-gate (production phase) impact which entails the feed stream containing the solvents, reagents and monomers, 2) gate-to-gate (usage phase) impact which entails the energy and water usage from the reaction and washing stages, and 3) gate-to-cradle (end-of-life phase) which entails the recovery of NMP from the hazardous waste

stream. Here, the XGboost model is used to predict the cradle-to-gate impact metrics, which represent the production phase. Additionally, we use the predicted values in the gate-to-cradle phase which represent the end-of-life phase of the waste solvent. Table 3 highlights the specifications for the case study.

Equations (1) – (3) gives the environmental impacts of each phase of the Life Cycle Assessment (LCA).

$$LCA_{i,production} = \sum_j^n LCA_{i,j,production} \quad (1)$$

$$LCA_{i,use-phase} = \sum_j^m LCA_{i,k,use-phase} + LCA_{i,water,use-phase} \quad (2)$$

**Figure 1:** Parity plot for each metric from the XGBoost model. (a) HHI, (b) EQI, (c) GWP, (d) RUI

**Table 3:** NMP case study specification

Component	Inlet mass flowrate to Reactor (kg/y)	Ultrapure water for washing (kg/y)	Hazardous waste solvent stream composition (%wt)
NMP	183416	-	17
ODA	24055	-	-
PMDA	26202	-	-
HEMA	5448	-	0.5
TFA	5448	-	0.5
HCl	5448	-	0.5
H <sub>2</sub> O	-	4114148	81.5

**Table 4:** Impact metric prediction for each chemical for the production phase from XGboost model

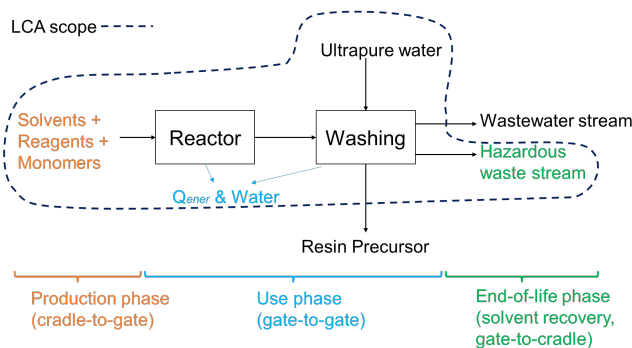

Component	HHI (x10 <sup>-6</sup> , DALY/kg <sub>Chem</sub> )	EQI (PDF.m <sup>2</sup> .yr/kg <sub>Chem</sub> )	GWP (kgCO <sub>2</sub> eq/kg <sub>Chem</sub> )	RUI (x10, MJ/kg <sub>Chem</sub> )
NMP	7.6	1.9	2.7	11.3
ODA	1.7	0.6	2.5	14.1
PMDA	3.9	0.9	2.0	16.5
HEMA	1.8	1.0	2.5	7.3
TFA	1.2	0.9	2.7	5.4
HCl	0.7	0.2	0.7	0.2

$$LCA_{i,EoL} = (1 - R_{rec,NMP})LCA_{i,NMP,EoL} + \sum_{j=1}^n LCA_{i,k,EoL} + \sum_j^m LCA_{i,k,EoL} \quad (3)$$

Here,  $LCA_{i,j,production}$  is the environment impact metric  $i$  for the production of chemical  $j$ , and  $n$  is the total number of chemicals.  $LCA_{i,k,use-phase}$  is the environmental metric  $i$  for the energy demand of technology  $k$ ,  $m$  is the total number of technologies in the process,  $LCA_{i,water,use-phase}$  is the impact metric for the total amount of water used in the process.  $R_{rec,NMP}$  is the amount of NMP recovered for reuse,  $LCA_{i,NMP,EoL}$  is the environmental impact metric for NMP,  $LCA_{i,j,EoL}$  is the environmental impact of the remaining chemicals not being recovered, and is the environmental impact due to the energy demand of the technologies (pervaporation in this case) for the solvent recovery process. The total cradle-to-cradle impact assessment per kg of NMP is given by Equation (4).

$$LCA_{i,cradle-to-cradle} = LCA_{i,production} + LCA_{i,use-phase} + LCA_{i,EoL} \quad (4)$$

Here,  $i$  is the environmental impact indicator (HHI, EQI, GWP, RUI),  $LCA_{i,production}$  is the impact metric for the production phase of the chemicals (cradle-to-gate),  $LCA_{i,use-phase}$  is the impact metric for the use-phase of the chemicals – in this case the energy demand and water usage in the reaction and washing stages (gate-to-gate) and  $LCA_{i,EoL}$  is the impact metric for the EoL phase (gate-to-cradle) for the chemicals in the hazardous waste stream. NMP is the functional unit for the analysis hence the impact metric analysis is per kg of NMP basis. Figure 2 shows the LCA scope and the associated stages of the cradle-to-cradle assessment.

**Figure 2:** LCA scope and the various aspects of the cradle-to-cradle assessment

### Case Study Results & Discussion

Table 4 shows the predictions for each chemical for the production phase assessment from the developed XGBoost model. To give a perspective of how the predictions compare with actual data from the SimaPro® software, the HHI, EQI, GWP, and RUI are  $7.6 \times 10^{-6}$ , 1.93, 7.7,

and 168.9, respectively for NMP. It should be noted that for water, we used SimaPro® values for the analysis since we did not consider it to be a chemical.

Figure 3 shows the comprehensive impact of the NMP lifecycle.

**Figure 3:** Endpoint impacts of NMP across its lifecycle. C2G:Cradle-to-Gate; G2G:Gate-to-Gate; G2C:Gate-to-Cradle

In the HHI, the results indicate a markedly higher impact in the C2G phase, illustrating the significant health-related implications during the initial stages of NMP production. This could be attributed to the extraction and processing of raw materials, underscoring the need for stringent health and safety measures during these processes. The EQI shows similar trend with the highest impact also observed in the C2G phase. However, the G2G is higher in this case signifying a higher impact contribution from the use-phase. For GWP, the difference between the C2G and G2G is 71.5%, while that between the G2G and G2C is 52.7%. Similar trend is observed with the RUI metric.

### CONCLUSION

In this work, an XGBoost model is developed to predict four endpoint impact metrics of chemicals based on thermodynamic properties and molecular descriptors. The developed model was subsequently used in a case study where a cradle-to-cradle life cycle assessment is performed with NMP as the functional unit. The model is used to predict the production phase of the various chemicals used, and subsequently used in solvent recovery which is the considered route for the end-of-life phase. The use-phase is analysed using the utilities from the reaction and washing processes. The model results indicate that the human health impact has the best accuracy. While the remaining three metrics had significant improvements on the validation set, the models could be improved to enhance the predictions on the test set. Regarding the life cycle assessment, it is observed that the

cradle-to-gate stage has the significant impact on the lifecycle followed by gate-to-gate, and finally, gate-to-cradle for all four metrics. Additionally, this case study shows that ML model predictions can be used to substitute unknowns data for cradle-to-gate, and even gate-to-cradle life cycle assessment. Furthermore, the developed model can be incorporated during the early-design stage to provide initial estimates of impact metrics for better decision-making.

# Design and Optimization of Circular Economy Networks: A Case Study of Polyethylene Terephthalate (PET)

Abdulhakeem Ahmed<sup>a</sup>, Ana I. Torres<sup>a\*</sup>

## ABSTRACT

Circular systems design is an emerging approach for promoting sustainable development. Despite its perceived advantages, the characterization of circular systems remains loosely defined and ambiguous. This work proposes a network optimization framework that evaluates three objective functions related to economic and environmental domains and employs a Pareto analysis to illuminate the trade-offs between objectives. The US polyethylene terephthalate (PET) value chain is selected as a case study and represented via a superstructure containing various recycling pathways. The superstructure optimization problems are modeled as a mixed integer linear program (MILP) and linear programs (LPs), implemented in Pyomo, and solved with CPLEX for a one-year assessment horizon. Solutions to the circular economy models are then compared to the corresponding solutions of linear economy models. Preliminary results show that the optimal circular network is advantageous over the optimal linear network for all objectives subject to the current market supply of raw materials and the total cost of production. However, when considering the present chemical processing infrastructure of the US economy and unrestricted biomass feedstock availability, a linear economy is favorable as an outcome of low operating cost and carbon sequestration.

## INTRODUCTION

With the growth of modern societies, waste management and finite resource depletion have become problematic. A primary facilitator of this phenomenon is the extensive employment of linear systems where materials are extracted, used, and discarded. Due to heightened concerns regarding finite resource depletion and the environmental effects of mismanaged waste, there is growing interest in adopting circular economies. A circular economy (CE) strives to eliminate waste and pollution, circulate products and materials at their highest level, and regenerate nature [1]. Applications of a CE have been present, to some extent, at the micro-level of some organizations. However, what remains elusive is effective representation at the macro-level and well-defined metrics and methodologies for achieving and quantifying circularity.

**Figure 1.** High-level superstructure representation.

Each year, plastics constitute roughly 400 million tonnes of generated waste, of which approximately 80% enters landfills or is emitted into the environment [2]. Of all produced plastics, polyethylene terephthalate (PET) is one of the most widely consumed, with applications of PET ranging from consumer packaging to films and textiles (polyester). In the US, historical demands for polyester and bottle-grade PET comprise over 85% of all PET

products [3]. However, recycling rates for bottles and general textiles are approximately 30% and 15%, respectively [4,5]. For these reasons, we consider the PET economy as an application case study for assessment.

A holistic representation of the PET value chain (product life cycle) and potential circular processing pathways is depicted in Figure 1. The analysis is posed as a superstructure optimization problem. The superstructure includes fossil and biomass feedstocks for PET precursors, production routes from these precursors to virgin PET (vPET), manufacturing and use phases for PET-based products, and end-of-life (EoL) processing technologies. EoL processes include traditional and novel processing of the following grouping: landfilling, incineration, mechanical recycling (MR), chemical recycling (CR), and thermochemical recycling.

The application of various recycling processes allows for material retention within the value chain. However, it remains unclear how favorable these processes are over a dominantly linear PET economy. To enhance this understanding, we formulate a mixed integer linear programming problem (MILP) where we assess an economic, environmental, and material utilization objective. The optimization problems are solved to determine the optimal selection of processing technologies and material flows that satisfy demand and are then compared to the optimal solutions of a linear economy reference model. The linear reference model is obtained by imposing flow restriction constraints, which void recycle flows. A Pareto analysis is then performed using the epsilon-constrained method defined in [6] to identify the trade-offs between the objectives.

## METHODS

### Modeling Framework

For modeling purposes, a State Task Network (STN) formulation where processes (tasks) consume and produce materials (states) is followed. Two types of nodes are defined, one constituting key chemical components and the other technologies that convert components. Technology nodes ( $j$ ) accept flows from component nodes, performing composition transformations and acting as the influx to other component nodes. Component nodes ( $i$ ) combine fluxes from different technology nodes and are also connected to the external market, allowing purchases and sales of material. The characterization of the nodes is depicted in Figure 2. A technology matrix ( $A$ ) is defined to contain process conversion information representing transformations across technology nodes. The technology matrix is informed by industrial data and process simulations from the literature.

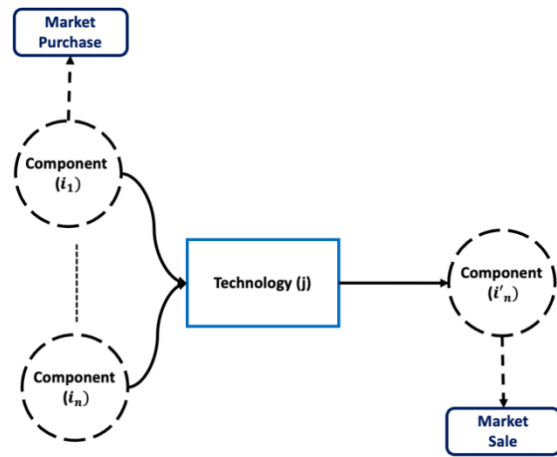

Figure 2. Network node characterization.

The generalized model equations for the given framework are defined by equations (1-7). Eqs. (1) and (2) define the generation and consumption of component  $i$  in technology  $j$ . Where  $\gamma_{ij}$ , a conversion factor, is positive for generative transformations and negative for consumption. Parameter  $\gamma_{ij}$  constitutes the members of matrix ( $A$ ) and is defined by industrial data aggregated by Franklin Associates [7], the US EIA [8], the US EPA [9], and Aspen simulations documented in the literature [10-17]. Variable  $l_j$  represents the total flow through a technology node. Sets  $J^G$  and  $J^C$  designate producing and consuming technology nodes, respectively.

$$g_{ij} = \gamma_{ij} l_j \quad \forall i \in I, \forall j \in J^G \quad (1)$$

$$c_{ij} = -\gamma_{ij} l_j \quad \forall i \in I, \forall j \in J^C \quad (2)$$

$$\sum_{j \in J} \gamma_{ij} l_j + p_i = s_i \quad \forall i \in I \quad (3)$$

Eq. (3) represents the general material balance for all components in the set  $I$ , stating that the purchase plus the total generation and consumption of  $i$  across the set of technologies ( $J$ ) is equal to the market sales or excess of  $i$ . Furthermore, component purchases ( $p_i$ ) are bounded by an upper limit ( $p_i^L$ ), which in this analysis is the five-year historical average supply for all raw materials. Eq. (5) states that the demand for end products must be satisfied for all  $I$  belonging to a subset  $I^D$ . Table 1 represents the annual rate of PET consumption (megaton) in the US in 2018 [3,18].

$$p_i \leq p_i^L \quad \forall i \in I \quad (4)$$

$$\sum_{j \in J^G} g_{ij} \geq d_i \quad \forall i \in I^D \quad (5)$$

$$g_{ij'} \leq \eta_i \sum_{j \in J^G} g_{ij} \quad \forall i \in I^G \quad (6)$$

$$c_{ij'} \leq \eta_i \sum_{j \in J^C} c_{ij} \quad \forall i \in I^C \quad (7)$$

Lastly, Eqs. (6-7) generalizes the process constraints imposed on network flows to satisfy select technical requirements. These equations state that the

production or consumption of component  $i$  by  $j$  is limited by the net generation or consumption of  $i$  multiplied by a scalar  $\eta_i$ . The parameter  $\eta_i$  represents flow ratios and corresponds to current process capabilities detailed in the literature.  $I^G$  and  $I^C$ , are subsets of  $I$ . And  $j'$  is a referenced technology node corresponding to  $\eta_i$ . For example, one such constraint is the allowable composition of mixed virgin PET resin and recycled PET (rPET) resin produced by mechanical recycling that satisfies intrinsic viscosity requirements for processing into new bottles. Here,  $\eta_i$  is 0.35 [19] and  $j'$  is the mechanical recycling of post-use bottles. Additional technical constraints include an upper bound on the fraction of end-of-life textiles (EoL) to be downcycled to satisfy a portion of demand. Secondly, there is an upper bound on the amount of non-bottle/non-polyester EoL materials that can be recycled, which discounts products that generally cannot be recycled, such as food containers.

**Table 1:** Case study demand specification.

Product Type	Demand (Mt/year)
Bottles	2.84
Polyester	7.84
Films/sheets/others	1.17

## Design Objectives

Three design objectives are assessed to explore economic and environmental domains. These include total annualized cost of production, process greenhouse gas emissions (GHGs), total virgin raw material utilization.

### Total Annualized Cost

$$TAC = \sum_{j \in J^E} (opex_j l_j + ACCR \sum_{t \in T} capex_{jt}) \quad (8)$$

The economic dimension is evaluated with Eq. (8) which states that the total annualized cost of production is equal to the sum of operational costs and annualized capital expenses (ACC) for the technologies. Operating cost ( $opex_j$ ) equals the sum of feed, utility, and labor minus the sale of by-products for each  $j$ . We assume a ten-year amortization period and an interest rate of 15%, which correlates to an annual capital charge ratio (ACCR) of 0.199 [20]. Investment costs ( $capex_{jt}$ ) are indexed by plant ( $t$ ) belonging to the set of plants ( $T$ ). Set  $J^E$  is a subset of economically evaluated technologies.

$$\frac{capex_j^{ref}}{(capacity_j^{ref})^{0.6}} \left[ a^{0.6} + \frac{b^{0.6} - a^{0.6}}{b - a} (capacity_{jt} - az_{jt}) \right] \quad (9)$$

$$capacity_{jt} \leq Mz_{jt} \quad \forall j \in J, \forall t \in T \quad (10)$$

$$l_j \leq \sum_{t \in T} capacity_{jt} \quad \forall j \in J \quad (11)$$

To account for economies of scale, the six-tenths rule is applied to estimate  $capex_{jt}$ . This rule leads to a non-linear non-convex equality. Thus, a secant

linearization [21] as presented in Eq. (9) is applied, where  $a$  and  $b$  are lower and upper bounds of the approximating function.  $capex_j^{ref}$  and  $capacity_j^{ref}$  are reference parameters taken from the literature. And the capacity of plant  $t$  for process  $j$  is represented by  $capacity_{jt}$ . Furthermore, the binary variable  $z_{jt}$  indicates whether a plant  $t$  is selected for the process  $j$ . Eq. (10) ensures that capacity is zero if plant  $t$  of process  $j$  is not selected, with  $M$  equal to the maximum plant capacity. Lastly, Eq. (11) bounds net flow through  $j$  by the total capacity of  $j$ .

### GHG Emissions

$$GHG = \sum_{j \in J^E} \phi_j g_{ij} \quad \forall i \in I^R \quad (12)$$

The environmental objective presented by Eq. (12) represents raw material extraction, processing, and manufacturing emissions. It states that the net greenhouse gas (GHG) emissions are equal to the total generation of components  $i$  in the set of reference products  $I^R$  multiplied by the emission factor  $\phi_j$  which measures carbon equivalents ( $CO_2e$ ). Set  $I^R$  is defined such that emission parameters are normalized per reference product belonging to each evaluated technology node. The considered GHGs are carbon dioxide, methane, and nitrous oxide. Parameter  $\phi_j$  is determined with process data available in the literature.

### Virgin Raw Material Utilization

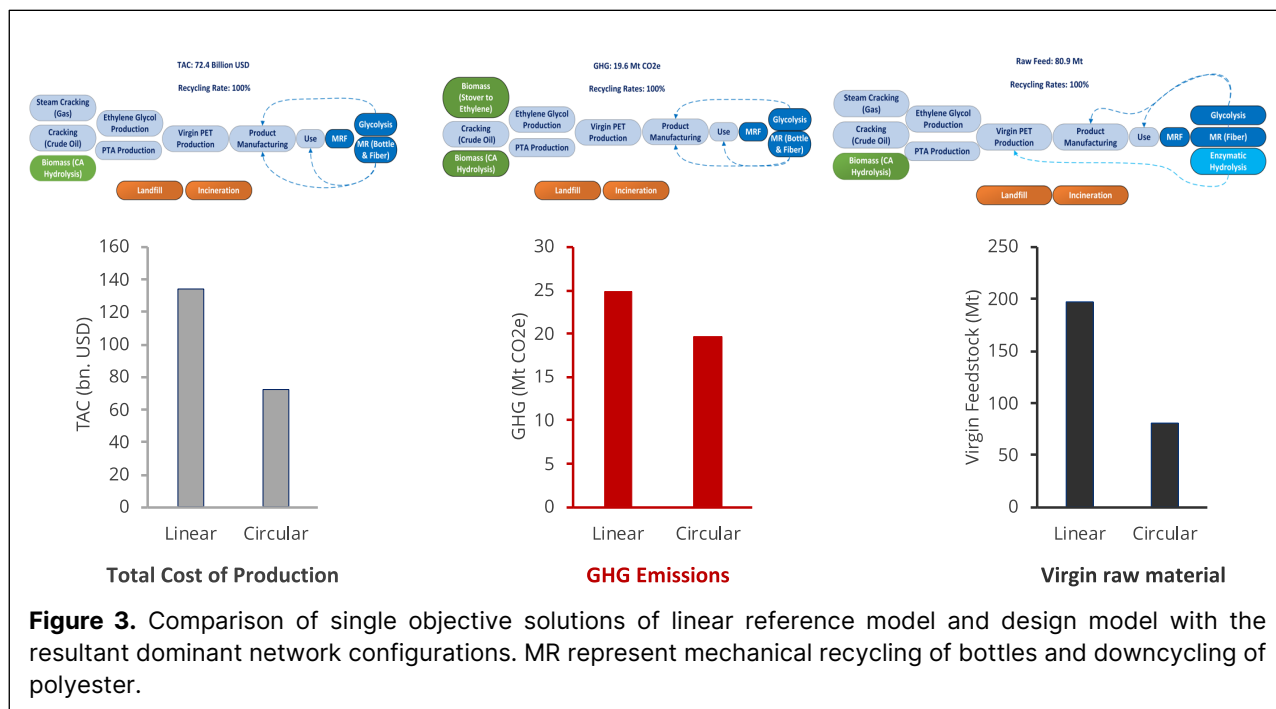

$$VF = \sum_{i \in I^F} p_i \quad (13)$$

The final design goal considers raw material use and measures network material efficiency. This objective serves as a proxy for quantifying circularity. The objective function is defined by Eq. (13) and represents the sum of market purchases of virgin feedstock, where  $I^F$  describes feedstock components.

### Optimization Problem

The analysis involves solving the optimization problem defined in Eq. (14). Here,  $Z$  represents each objective function, where Eq. (14) is a MILP for the annualized cost objective but an LP for both environmental and material use objectives as Eq. (9-11) pertain only to the economic problem.

$$\begin{aligned} & \min Z \\ & s. t. Eq. (1 - 7), Eq(9 - 11) \\ & l_j, s_i, p_i, capex_{jt}, capacity_{jt} \geq 0, z_{jt} \in \{0,1\} \end{aligned} \quad (14)$$

## RESULTS

### Single-Objective Solutions

The optimization problem is solved using CPLEX version 22.1.1 and Pyomo, a Python optimization modeling language [22]. The results and comparisons for the single objective problems are presented in Figure 3. Considering the economic objective, the optimal network configuration of the design model is circular, employing both mechanical recycling and glycolysis. Final products from recycling include rPET that is sent directly to the manufacturing stage to create final PET end products. Comparing this optimal network to the solution of the corresponding linear reference model shows that a circular network offers a 46% cost reduction over the linear counterpart.

Likewise, for the GHG emission objective, the solution of the design model leads to a circular network achieved with mechanical recycling and glycolysis. However, contrary to the network configuration of the economic objective, more biomass feedstock is used over fossil feedstock. Additionally, comparing the solution of the GHG objective to the corresponding linear reference gives a 21% reduction in supply chain process emissions. This reduction is lower relative to that achieved by the economic objective.

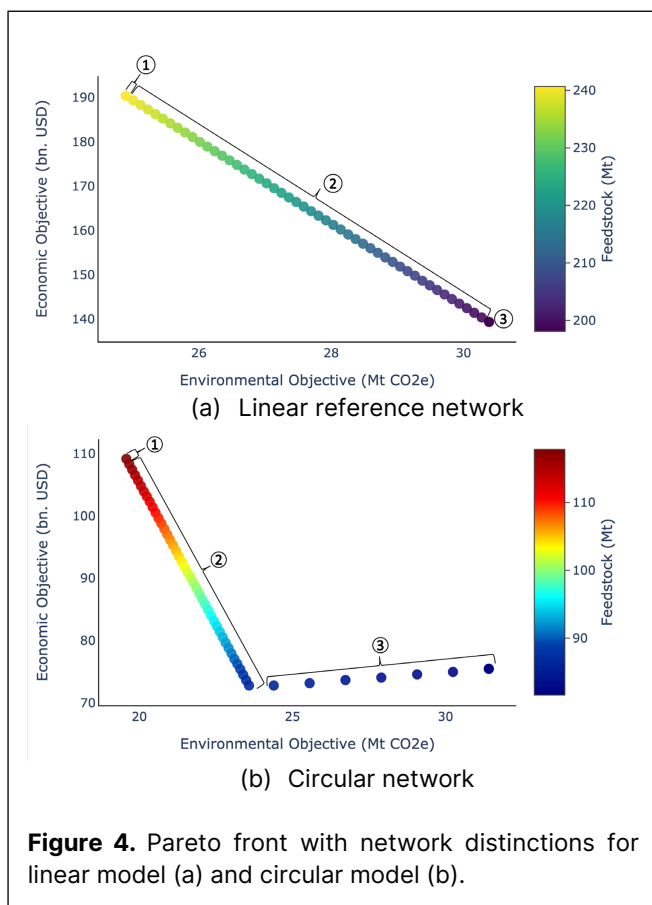

Lastly, the solution of the circular design model for the virgin raw material objective is a circular network with a 59% reduction in raw material consumption. However, compared to the previous design solutions, this network consists of a much higher application of chemical recycling via glycolysis and enzymatic hydrolysis and the rest

of the downcycling of polyester. In addition to rPET production, monomers are produced and sent upstream for polymerization into PET.

In addition to the base cases, additional considerations are evaluated for the economic and environmental objectives. The first assigns zero Capex to developed US processes to account for existing infrastructure. The resultant networks for both linear and circular models converge to an equivalent linear network. The selected network utilizes a purely fossil-based pathway employing steam cracking of natural gas and cracking of crude oil. The second consideration is unrestricted access to all feedstock, where unlimited is defined by altering market bounds to allow one gigatonne for all feed components. Like the first consideration, solving the reference and circular model leads to an equivalent linear network. However, contrary to the previous network, the obtained network follows a purely biomass-based pathway via biomass-to-ethylene conversion and acid hydrolysis of biomass to produce paraxylene.

### Pareto Assessment

The Pareto fronts for the design and linear models are shown in Figure 4. The linear model exhibits a linear trade-off between all objectives, where reducing emissions leads to higher-cost networks that consume more virgin feedstock. This trend occurs as increasing biomass feed consumption leads to reduced emissions. Yet, because process conversions of biomass processes are relatively low compared to fossil processes, higher raw material input is required to satisfy demand. These observations are further validated via the change in configuration of the selected optimal networks numbered in Figure 4.

**Figure 4.** Pareto front with network distinctions for linear model (a) and circular model (b).

In Figure 4(a), network one corresponds to the solution of the GHG emission objective presented in Figure 3 without selections for recycling. Likewise, network three is consistent with the cost objective network in Figure 3, without recycling. Network two corresponds to an intermediary of network one with steam cracking of natural gas without recycling, supporting the observable transition from biomass pathways to better conversion fossil pathways.

For the circular model, the Pareto front is piecewise linear. As shown in Figure 4(a), the leftmost trend line abides by the reasoning discussed for the linear model. However, after some threshold, attaining increased material circularity (lesser virgin feedstock consumption) leads to more emissions and higher annualized costs. The rationale for this behavior is that further reductions in material consumption demand a reasonably material-efficient network. Such a network is achievable by selecting more chemical recycling processes, contributing to increased capital investment and GHG emissions. Like the linear model, these trends are supported by the network configurations spanning the Pareto front. Looking at Figure 4(b), network three corresponds to the solution of the virgin raw material objective presented in Figure 3, plus the mechanical recycling of bottles. Network one corresponds to the GHG emission objective in Figure 3. And network two, an intermediary of network one with steam

cracking of natural gas.

## CONCLUSIONS

This work formulates a superstructure optimization problem for the US polyethylene terephthalate value chain to determine an optimal network selection consisting of processing technologies and material flow pathways satisfying each design goal for a one-year assessment period. The three assessed design goals are total annualized cost, GHG process emissions, and virgin feedstock consumption, which served as a proxy for measuring material circularity. Finally, a multi-objective Pareto assessment was performed to illuminate existing trade-offs between competing objectives for the linear and circular design models.

The results of the single-objective analysis indicate that circular PET supply chains offer lower GHG process emissions, water consumption, and virgin feedstock usage. Additionally, under current market conditions, a circular PET network is a better investment than a linear network when constructed from a zero-infrastructure ground state. Next, the results of the Pareto assessment portray a linear trade-off between objectives for the linear model, with a correlation between total annualized cost and virgin feedstock consumption, which vary inversely with GHG process emissions. The same observation is initially present for the circular model. However, attaining better material circularity increases the carbon intensity and cost for the selected networks, chiefly due to the additional processing technologies required to realize greater network efficiency.

## ABSTRACT

Recent advances in process design for solvent-based, post-combustion capture (PCC) processes, such as the Piperazine/Advanced Flash Stripper (PZ/AFS) process, have led to a reduction in the energy required for capture. Even though PCC processes are progressively improving in Technology Readiness Levels (TRL), with a few commercial installations, incorporating carbon capture adds cost to any operation. Hence, cost reduction will be instrumental for proliferation. The aim of this work is to improve process economics through optimization and to identify the parameters in our economic model that have the greatest impact on total cost to build and operate these systems. To that end, we investigated changes to the optimal solution and the corresponding cost of capture considering changes in the price of utilities and solvent. We found that changes in solvent price had the most effect on the cost of capture. However, re-optimizing the designs in the event of price changes did not lead to significant improvements in the case of piperazine, cooling water and electricity, whereas re-optimizing for changes in steam prices lead to yearly saving of 3.8%. These findings show that the design choices obtained at the nominal optimal solution are insensitive to utility price changes except for the case of steam and that there is a need for altered designs for locations where the steam prices are different.

**Keywords:** post-combustion carbon capture, rate-based model, optimization, nonlinear programming, sensitivity analysis.

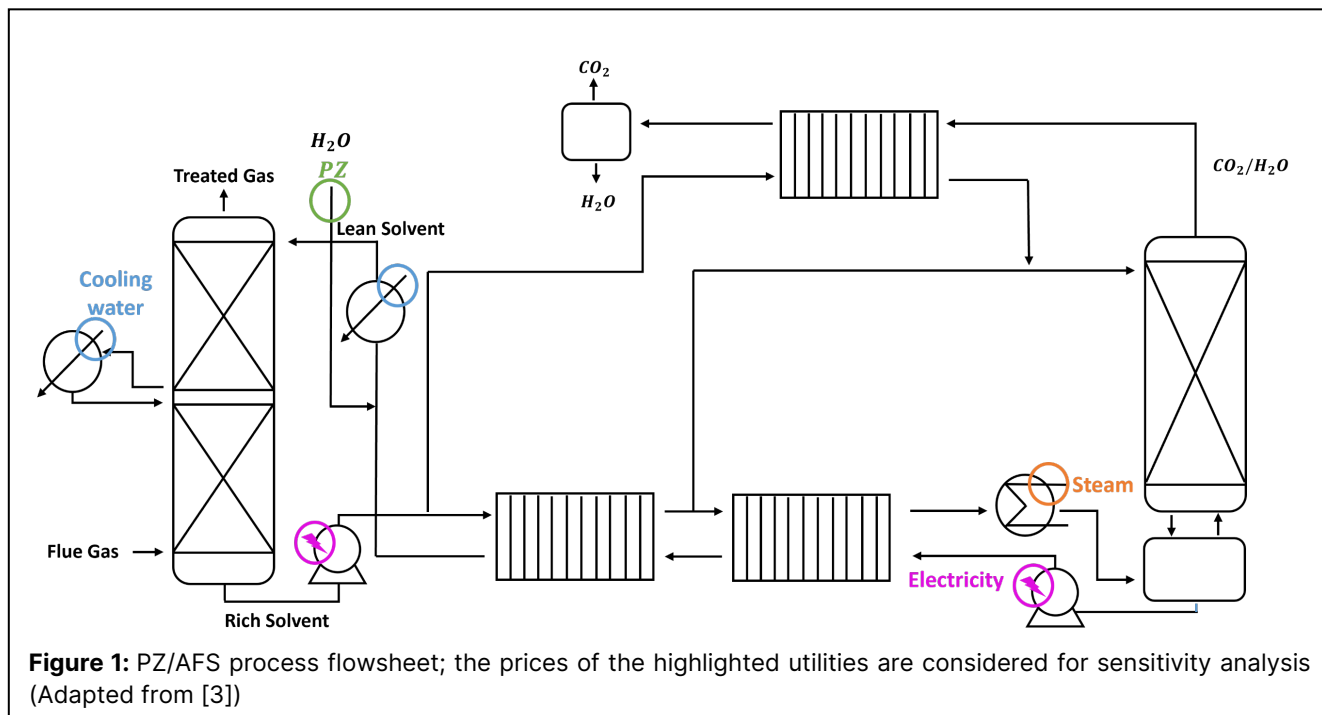

## INTRODUCTION

### Solvent-Based Carbon Capture Process Modeling

Solvent-based post-combustion carbon capture (PCC) processes are the most promising way to mitigate the increasing CO<sub>2</sub> emissions. There has been significant focus on trying to reduce the energy and cost required for capture, one prominent example being the Piperazine/Advanced Flash Stripper (PZ/AFS) process [1], shown in Fig 1. This novel process uses PZ as the solvent and the AFS process design, as shown. Flue gas containing CO<sub>2</sub> is contacted with the CO<sub>2</sub>-lean solvent in a packed absorber column. An intercooler in the middle of the column, as well as a cooler at the top, are used to drive down the solvent temperature to improve absorption. After leaving the absorber, the CO<sub>2</sub>-rich solvent passes through a heat exchanger network that has two

split streams; one of which is pumped directly to the top of a stripper column, while the other is pumped to a steam heater as shown in Fig 1. After the solvent is further heated in a steam heater, it gets flashed inside of a flash tank where the resulting vapor then enters the stripper column. After stripping, a vapor phase containing a CO<sub>2</sub> - water mixture exits the column from the top. It is then cooled down in a heat exchanger and finally separated out in a condenser drum. The lean solvent recovered in the flash tank is pumped back to the absorber column with the addition of make-up PZ and water.

The economics of PCC processes can be improved by optimization, which requires a mathematical model of the process. Hence, a detailed model of the PZ/AFS process was built using an equation-oriented approach in the IDAES framework, an open source, Python-based modeling medium [2]. In addition to the absorber and stripper columns, our model also includes the flash tank, all heat exchangers, and a recycle stream with solvent

make-up. For the columns, a rate-based modeling approach was used (as opposed to equilibrium-based), and a finite-difference scheme was used for discretization of the system of differential algebraic equations (DAE). This led to a highly nonlinear programming (NLP) model with over 8600 variables and constraints. The solution strategy includes a tailored, multi-level initialization cascade for reliable model convergence [3]. Once the model results were validated with pilot plant data [4], economic optimization was performed, which resulted in identifying the design and operating conditions that led to a considerable reduction in the capital and operational costs compared to the baseline, at the pilot scale [3]. To test the robustness of the model and to aid the commercialization of this process, optimization was performed for varying plant capacities (processing up to 1500 times more flue gas than the pilot scale) and for feed gases with different  $\text{CO}_2$  concentrations to represent different flue gas sources that may arise in practice [3].

### Parameter Uncertainty and Variability

In chemical process models, there are many parameters that are uncertain or subject to variability which, if disregarded by the model, lead to solutions that may not be truly optimal or even feasible in real life. Hence, it is crucial to account for these during the design phase. Uncertainty in a parameter stems from a lack of knowledge of its exact value, whereas variability is concerned with a parameter that may take on a different value, for example at a different point in time or at another location [5]. In the context of process models, these parameters can be categorized into three groups: (1) *epistemic parameters*, which are inherent in any process model, and which stem

from the approximating nature of correlations used to evaluate properties (kinetic, thermodynamic, transport) and the overall assumptions made therein; (2) *operational parameters*, which pertain to the upstream conditions and may be subject to temporal variations, e.g., composition, flowrate and/or temperature of the flue gas; and (3) *economic parameters*, such as the applicable prices for utilities and the solvent.

To identify which of the above are most impactful and to quantify the extra costs necessary for designs to insure against them, a series of sensitivity analyses were conducted. More specifically, the aim of this work was to leverage the equation-oriented model that we had previously built to gather insight on the impact of the economic parameters on the optimal process designs. In our previous study it was seen that, at the commercial scale, along with the purchase cost of the absorber column, the operating expenses for cooling water, steam, electricity, and solvent renewal were the dominating costs [3]. Therefore, this study further investigated the sensitivity of the plant design and its total cost to the prices of said utilities and to the piperazine solvent.

### METHODOLOGY

For this study, we chose to perform sensitivity analyses on the commercial scale, natural gas combined cycle (NGCC) flue gas processing plant. The feed gas flowrate was 30,000 mol/s, and the parallel train configuration was used as it was done in the Mustang Station plant, presented in the work of Clossmann et al. [6]. The optimization problem was structured to minimize the total annualized cost (TAC), subject to some performance

constraints, such as a 96% capture target and flooding constraints for the columns [3]. Thirteen degrees of freedom were the packed length and the inner diameter of the absorber and stripper columns, the areas of the three heat exchangers, the two coolers and the steam heater, two bypass ratios, and solvent circulation rate. The first ten were the decision variables related to design, which must be committed before building the plant, whereas the bypass ratios and the solvent amount were operational decisions that can be adjusted.

The parameters that we focused on were the prices of the utilities (e.g., steam, cooling water and electricity) and piperazine, which were nominally assumed to be at the values given in Table 1. Cooling water was used for the two coolers, as shown in Fig 1. It must be noted that the optimal solution for the nominal case for the commercial-scale natural gas combined cycle (NGCC) flue gas processing plant does not use the intercooler. Hence, in the nominal solution, cooling water is only needed for the lean cooler at the top of the absorber column. However, the optimal solution for the cases that consider price variation, the inclusion of intercooler is allowed as a degree of freedom. Steam is used to heat up the rich solvent in a heater before it enters the flash tank. Electricity is needed for pumping the lean and rich solvents between columns. Our economic model considers operational expenses for these utilities as a fixed per unit price. To compensate for any losses, make-up of water and piperazine is needed to close the recycle loop. However, in a real-world plant operation, the lost piperazine is mostly

recovered in a water wash section above the absorber column. Therefore, cost of make-up is not additionally considered in our economic model. Instead, the cost of the solvent initially used in loading up the system is included in the capital costs at the design stage. Thereafter, it is assumed that the entirety of the solvent will be renewed every three years to make up for losses and degradation. This cost is included in the operational costs.

**Table 1:** Fixed prices assumed for utilities and piperazine.

Utility	Price
Piperazine	3750 \$/ton
Steam	14.5 \$/ton
Cooling water	0.0329 \$/ton
Electricity	0.06 \$/kWh

Optimal designs and corresponding operating conditions are obtained for cases for which the prices of selected parameters are changed stepwise up to a range of  $\pm 50$ . CONOPT was used as the solver for solving this nonlinear optimization problem [7]. By reoptimizing the system for each case with respect to all degrees of freedom (both design and operational), we can see how designs change and how the overall cost changes with the utility prices. The insights gained from this study are particularly useful when designing plants for geographies or markets with different applicable utility prices. Additionally, the parameter that has the greatest impact on total

**Figure 2:** Sensitivity of the optimal cost of capture to changes in utility and solvent prices

cost can be identified along with design optimizations that can mitigate the impact of its price change.

## SENSITIVITY OF OPTIMAL DESIGN TO ECONOMIC PARAMETERS

The corresponding changes in the optimal cost of capture with changing utility and solvent prices is shown in Fig 2. It is observed that the change in the price of piperazine has the most significant effect on the cost. This is due to the way solvent renewal is accounted for in our economic model, where it is a part of both capital and operational expenditures. Moreover, while there is flexibility in the usage amounts of utilities, a certain base amount of solvent needs to be used to achieve a given capture target no matter what. It is observed that electricity has the least impact on the cost of capture. This could be because our model does not consider a compressor train, so electricity is only used for running the pumps. The column pressures are not allowed to vary, therefore the only decision variable that would affect the electricity consumption is the amount of solvent circulated. While all cost curves are mostly linear, the curve representing steam becomes non-linear at lower prices, with the cost of capture becoming more sensitive to steam for price decreases beyond 20%.

To further investigate the sensitivities to price changes, the optimal solutions were compared to results from the baseline case, where price changes were implemented on the nominal solutions but without any optimization. For steam, reoptimizing the process design for price changes can lead to savings up to 3.8% (around \$1.6M yearly) compared to the baseline solution. The most significant difference is observed in the case of steam as compared to other parameters. Reoptimizing for different prices of piperazine leads to savings up to 0.2% (around \$100k yearly). However, for cooling water and electricity, reoptimizing did not lead to significant changes. The new solutions did not deviate from the original solution significantly. The nominal optimal solution is therefore robust for the changes in the price of electricity and cooling water. However, it must be noted that these are local optimal solutions, which can be dependent on initialization. Since each problem is initialized from the nominal solution, a better solution further away from the nominal case can not be ruled out.

### Sensitivity to Steam

The effect of changes in steam price on the optimal solution along with the percent reduction in the optimal Total Annualized Cost (TAC) were further investigated. Fig 3 shows the change in the steam consumption with price changes. When the price is increased by 50%, very little steam is used, with a steam heater area that is almost  $1/6^{\text{th}}$  of its original size. When the price is decreased

by 50%, the change in steam consumption is much more pronounced. This also reflects in the reduction of TAC as seen in Fig 3. For price changes between -50% and -30%, we can see a significant reduction in TAC. The steam consumption also changes sharply after the -30% price change point. This is also evident in Fig 2, where the curve representing steam shows nonlinear behavior.

**Figure 3:** Percentage reduction in TAC by redesigning for different steam prices

The change in the values of the other decision variables given the steam price changes are shown in Fig 4. Once again, we observe the jump to a better solution at the -30% price change point. The cooler area and the stripper diameter have a similar trend with the steam consumption where they decrease with increasing steam prices. Using more steam increases the temperature of the lean solvent being pumped back to the absorber. Therefore, a bigger cooler and a higher cooling water consumption is needed when more steam is used as the system would now need more cooling. Usage of more steam also decreases the lean loading since more  $\text{CO}_2$  is flashed from the rich solvent at a higher temperature. Moreover, since more water and  $\text{CO}_2$  are flashed with increased steam usage, the gas flowrate within the stripper column increases, leading to a need for larger diameter. However, its change from the nominal solution is around 10%.

The packed absorber length, solvent flowrate and the total heat exchanger area show an opposite trend with steam consumption. Since more steam and cooling water are used, there is less of a need for the heat exchangers. Thus, at low steam prices, there is a significant (reaching up to 40%) reduction in the total heat exchanger area needed. Cooling improves the absorber performance since absorption is exothermic. As discussed above, using more steam leads to more cooling water consumption therefore, we can use a shorter column when steam prices are low. However, the change in absorber packing height is less significant. Similarly, since increased cooling water improves absorption and more steam improves stripping, less solvent may be used

to achieve the same capture target. Indeed, we can see that 20% less solvent is used for the cheapest steam price case.

## CONCLUSIONS

We leveraged the optimization capabilities of the equation-oriented model of a novel solvent-based PCC process that we had previously developed to find cost-optimal solutions considering variation in economic parameters. This was done through a series of parameter sweeps on the price of cooling water, steam, electricity, and the solvent. The prices were perturbed in steps up to a range of  $\pm 50\%$ . Piperazine had the most significant effect on the change of cost of capture while electricity had the least effect. Upon comparing the nominal solutions obtained for each price change from the baseline with those solutions obtained on re-optimizing for each price change, it was observed that only changes in steam price had a significant impact. Thus, we infer that the optimal solution for the nominal case is robust to changes in the price of cooling water, electricity and piperazine. In contrast, for steam, an optimal value with significant differences from that of the nominal solution was obtained for different prices. This change was significant for cheaper steam prices, where yearly savings of 3.8% were obtained when reoptimizing for 50% cheaper steam. For this case, a bigger cooler and a larger stripper diameter was chosen, while savings were achieved through using a shorter absorber column, lesser solvent amount, and smaller heat exchangers. So, if this plant was to be

implemented at different locations where different steam prices apply, it is worth changing the design accordingly, whereas for the other utilities this may not be a concern.

There are many more parameters in this model that could be considered uncertain. When transitioning into an optimization under uncertainty framework, it is important to pre-screen the parameters with the highest impact through sensitivity analyses as shown in this work. In the future, more parameters relating to epistemic and operational uncertainty should be investigated and the sensitivity of the total cost to said parameters should be ranked in a systematic way. Another future direction could be to assess the flexibility of a design by optimizing solely over the decision variables related to operation.

## ABSTRACT

The overarching goal of limiting the increase in global temperature to  $\leq 2.0^\circ\text{C}$  likely requires both decarbonization and defossilization efforts. Direct air capture (DAC) and CO<sub>2</sub> electrolysis stand out as promising technologies for capturing and utilizing atmospheric CO<sub>2</sub>. In this effort, we explore the details of designing and operating an integrated DAC-electrolysis process by examining some key parameters for economic feasibility. We evaluate the gross profit and net income to find the most appropriate capacity factor, average electricity price, syngas sale price, and CO<sub>2</sub> taxes. Additionally, we study an optimistic scenario of CO<sub>2</sub> electrolysis and perform a sensitivity analysis of the CO<sub>2</sub> capture price to elucidate the impact of design decisions on the economic feasibility. Our findings underscore the necessity of design improvements of the CO<sub>2</sub> electrolysis and DAC processes to achieve reasonable capacity factor and average electricity price limits. Notably, CO<sub>2</sub> taxes and tax credits in the order of \$400 per t-CO<sub>2</sub> or greater are essential for the economic viability of the optimistic DAC-electrolysis route, especially at competitive syngas sale prices. This study serves as a foundation for further work on designing appropriate power system models that integrate well with the presented air-to-syngas route.

## 1. INTRODUCTION

Suppressing the increase in global temperature to  $\leq 2.0^\circ\text{C}$  likely necessitates the combination of decarbonization and defossilization technologies, including point-source CO<sub>2</sub> capture (PSCC), carbon dioxide removal (CDR), CO<sub>2</sub> storage, and CO<sub>2</sub> utilization [1–7]. The path to carbon neutrality implies using defossilized carbon sources, such as biomass, sea/oceanwater, and air. There has been a significant effort on using biomass as a nature-based carbon source [8–10]. However, concerns have been raised about the effects of biomass-based technologies on crop prices, human rights, and their

competition with food lands [3,11–15].

Alternatively, one could leverage sea/oceanwater and air as defossilized carbon sources. Indeed, a key CDR method that has been gaining significant attention in the recent years is direct ocean capture (DOC) [16–20], which benefits from the CO<sub>2</sub> equilibrium between the atmosphere and the ocean as a capture step and focuses on the extraction of CO<sub>2</sub> from carbonized oceanwater. Although this technology can be promising, it is still nascent and further research is underway to understand its potential in the broader scope of defossilization efforts.

Another key CDR technology is direct air capture (DAC), which captures CO<sub>2</sub> from the atmosphere using a

chemical or a physical sorbent/solvent. DAC offers several advantages including smaller land requirements compared to nature-based CDR technologies, modular contactors, and almost no competition with food crop lands [7,21–23]. One of the advanced DAC designs utilizes a two-cycle process to capture CO<sub>2</sub> using a hydroxide-based solvent (generally, KOH) in the form of (bi)carbonates [24–27]. This technology is currently being developed and commercialized by a collaboration between Carbon Engineering and Oxy companies. However, one of the major challenges of hydroxide-based DAC is its high cost, with estimates ranging from \$94 to \$1,000 per t-CO<sub>2</sub>, and high energy consumption, which ranges from 5.50 to 8.81 GJ per t-CO<sub>2</sub> [21,24,28–30]. Most of this high energy cost originates from the elevated temperature needed (900° C) to regenerate the captured CO<sub>2</sub> via calcination [30]. Nevertheless, hydroxide-based DAC is thought to be the most scalable and cost-effective DAC technology today [21,22], making it an attractive option for obtaining defossilized carbon from air.

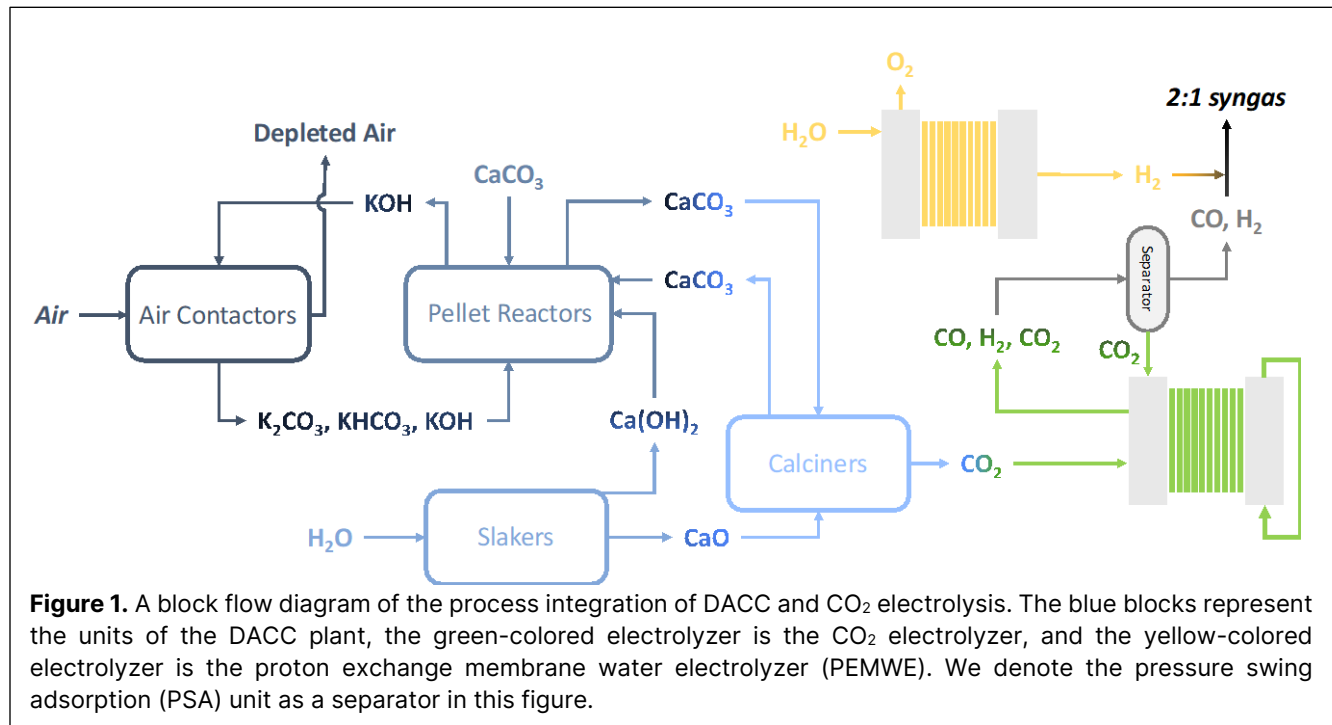

To utilize this captured CO<sub>2</sub> in a way that achieves circularity, both thermochemical and electrochemical methods can be used to convert it to more valuable products such as syngas (i.e., a mixture of H<sub>2</sub> and CO), which is a key intermediate product that can be used in the production of methanol, ethylene, jet fuel, and other high-value products [31,32]. One of the most technologically mature methods for producing syngas from a feed of CO<sub>2</sub> is reverse water gas shift (RWGS), which takes in H<sub>2</sub> as a second reactant and produces syngas at a H<sub>2</sub>:CO molar ratio of 1-2 [33,34]. The main downside of this technology is the high temperature (1,000° C) requirement that

likely necessitates the use of traditional heat sources (e.g., natural gas).

An alternative technology is low-temperature CO<sub>2</sub> electrolysis, which directly utilizes electricity to reduce CO<sub>2</sub> to CO at ambient conditions over a silver electrocatalyst in the cathode of an electrochemical cell. Although still a nascent technology, low-temperature CO<sub>2</sub> electrolysis allows the direct utilization of renewable electrons, enabling the design of a fully renewable CO<sub>2</sub> utilization method. It is worth noting that several start-up and established companies are trying to develop and upscale this technology, including Twelve [35], GIGKarasek [36], Siemens [37], Evonik [37], and Dioxide Materials [38].

The integration of DAC with low-temperature CO<sub>2</sub> electrolysis (DAC-CO<sub>2</sub>ER) can provide a promising defossilized air-to-syngas production pathway. We evaluated the techno-economics of this pathway against that of an integrated DAC-RWGS route in a previous effort [21], in which we found a potential route for DAC-CO<sub>2</sub>ER to be economically competent with more conventional routes in a future scenario. One of the main takeaways was to operate CO<sub>2</sub> electrolysis at a current density of 1,500 mA per cm<sup>2</sup> and a cell voltage of ≤ 2.00 V to enable the competition between DAC-CO<sub>2</sub>ER with DAC-RWGS and conventional methods for 2:1 syngas production.

In this work, we especially focus on the economic feasibility of the DAC-CO<sub>2</sub>ER route that will allow it to be continuously operated at a large scale. We study the influence of capacity factor, average electricity price, syngas sale price, CO<sub>2</sub> taxes, and CO<sub>2</sub> tax credits on the process economics. We first estimate the design and operational limits of a baseline CO<sub>2</sub> electrolysis system by

varying the capacity factor, average electricity price, and syngas sale price. We then look at an optimistic case of CO<sub>2</sub> electrolysis to understand the effect of cell voltage and current density optimization on the design and operational limits. To expand on this, we perform a sensitivity analysis of the CO<sub>2</sub> capture cost on the optimistic-scenario limits to also consider further improvements of the DAC design. We then estimate the natural gas (NG) based market syngas sale price with CO<sub>2</sub> taxes, enabling a comparison with potential future conventional syngas prices. Finally, we add CO<sub>2</sub> tax credits to the DAC-electrolysis system to search for economically feasible regions of this defossilized syngas production pathway for design and operating conditions.

## 2. METHODOLOGY

### 2.1. Process description

Figure 1 envisions a block flow diagram of the presented defossilized syngas production pathway. The DAC technology considered here uses KOH to capture CO<sub>2</sub> from the atmosphere in the form of K<sub>2</sub>CO<sub>3</sub> and KHCO<sub>3</sub> in an air contactor. The captured liquid solution is then sent to a set of pellet reactors along with a Ca(OH)<sub>2</sub> slurry to regenerate the liquid KOH solvent and produce CaCO<sub>3</sub> pellets. The pellets are then sent to calciners where they are dissociated into CaO and CO<sub>2</sub> at a temperature of 900° C. The CaO is then mixed with H<sub>2</sub>O in a set of slakers to re-produce a Ca(OH)<sub>2</sub> slurry, whereas the gaseous product is dehydrated to produce a purified CO<sub>2</sub> stream. This whole process is continuous, allowing for the capture of CO<sub>2</sub> in the form of potassium (bi)carbonates as well as the regeneration of liquid KOH and gaseous CO<sub>2</sub>.

The concentrated gaseous CO<sub>2</sub> can then be sent to a CO<sub>2</sub> electrolyzer where it is electrochemically reduced to CO using two electrons and two protons, Eq. (1). It is worth noting that the local pH near the catalyst surface determines the proton source, which also determines the reaction by-product (i.e., OH<sup>-</sup> for neutral-to-alkaline local pH or H<sub>2</sub>O for acidic local pH) [39]. In this work, we assume a high local pH, which corresponds to H<sub>2</sub>O being used as the proton source. On the other side, the anode electrochemical reaction is assumed to be the oxygen evolution reaction (OER), Eq. (2), which commonly occurs on a Nickel-based or an Iridium-based electrocatalyst.

The CO<sub>2</sub> electrolyzer is not only producing CO, but also H<sub>2</sub> via the competing hydrogen evolution reaction (HER), Eq. (3). However, the CO<sub>2</sub> electrolyzer is generally optimized to increase the CO selectivity and decrease the H<sub>2</sub> selectivity in the product stream. Thus, we supply additional H<sub>2</sub> from a proton exchange membrane water

electrolyzer (PEMWE) that oxidizes H<sub>2</sub>O to produce O<sub>2</sub> and protons (H<sup>+</sup>), Eq. (4). The protons then pass a cation exchange membrane (CEM) as they travel to the cathode side to be electrochemically reduced to H<sub>2</sub> via HER, Eq. (3).

### 2.2. Process models

A hydroxide-based DAC plant was modeled in Aspen Plus based off of Keith et al.'s design [24]. This model provides the mass and energy balances required to estimate the equipment and operational costs of the plant. In addition, we use our own CO<sub>2</sub> electrolysis model that calculates the mass and energy balances of a specified electrolysis system. For further details about the process models, we refer the reader to our previous publication [21].

We design the CO<sub>2</sub> electrolysis system based off of Wen and Ren et al.'s experimental results that achieved 90% Faradaic efficiency of CO (FE<sub>CO</sub>) at 612 mA per cm<sup>2</sup> and 3.3 V (energy efficiency (EE) ≈ 40%) in a 400-cm<sup>2</sup>, 4-cell electrolyzer stack [40]. These performance values are used in our baseline scenario (Table 1). We additionally consider an optimistic scenario in which we assume achievement of a current density and a cell voltage of 1,500 mA per cm<sup>2</sup> and 2.0 V (EE ≈ 67%), respectively. Table 1 summarizes these assumptions.

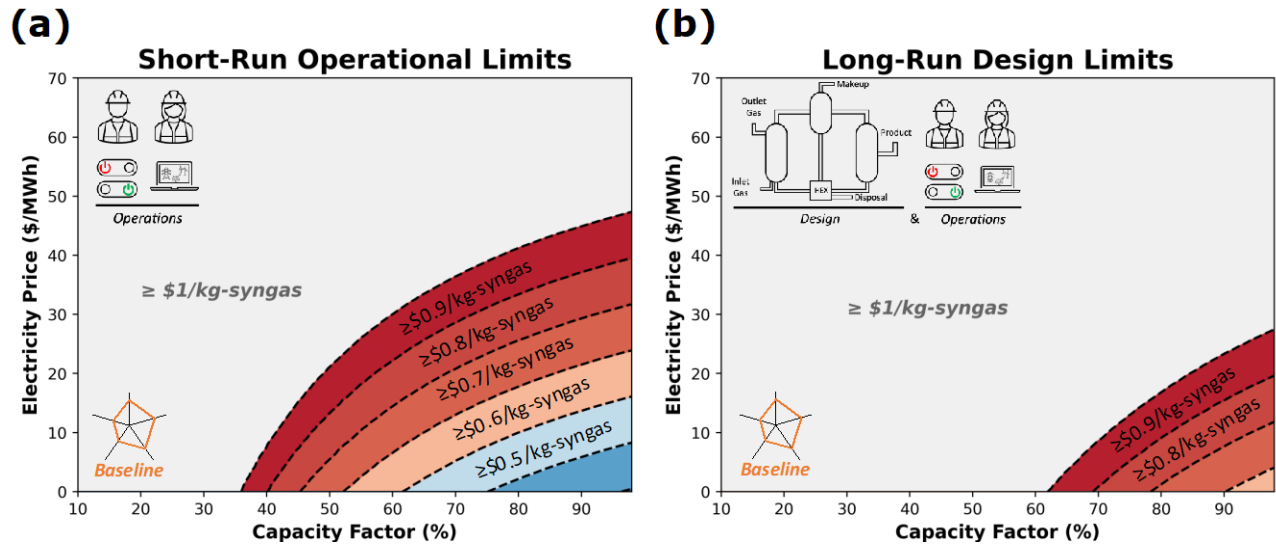

**Table 1.** Key baseline and optimistic assumptions of CO<sub>2</sub> electrolysis.

Metric	Baseline	Optimistic
Symbol		
Total Current Density (mA per cm <sup>2</sup> )	612	1,500
Cell Voltage (V)	3.3	2.0
FE <sub>CO</sub>	90%	90%
Single-Pass Conversion	27%	27%

### 2.3. Techno-economic model

Our techno-economic model was developed to take the results of our process models as inputs and estimate the equipment and operational costs according to Towler and Sinnott's methodology [41]. In addition, we estimate the gross profit, Eq. (5), and the net income, Eq. (6), while varying the capacity factor and average electricity price at a constant syngas price. The gross profit is used as an indicator of the system operations whereas the net income is used as an indicator of both the design and operation of the system. In Eq. (5) and (6), OPEX, CAPEX, and CRF refer to operational cost, capital cost, and capital recovery factor, respectively. The CRF, Eq. (7), is used

**Figure 2.** Capacity factor and average electricity price limits for (a) positive gross profit and (b) positive net income at different syngas prices of the baseline case (cell voltage = 3.3 V, current density = 612 mA per cm<sup>2</sup>, FE<sub>CO</sub> = 90%, CO<sub>2</sub> single-pass conversion = 27%).

to annualize the capital cost of the system, where  $i$  is the interest rate and  $N$  is the plant lifetime. For key assumptions and further details about our techno-economic model, we refer the reader to the SI.

$$\text{Gross Profit} = \text{Revenue} - \text{OPEX} \quad (5)$$

$$\text{Annual Net Income} = \text{Gross Profit} - \text{CAPEX} \cdot \text{CRF} \quad (6)$$

$$\text{CRF} = \frac{i(1+i)^N}{(1+i)^N - 1} \quad (7)$$

We use the techno-economic model outputs to define realistic targets for future renewably powered CO<sub>2</sub> electrolysis designs and techno-economic evaluations, especially in the context of renewably driven defossilized air-to-syngas pathways.

### 3. RESULTS & DISCUSSION

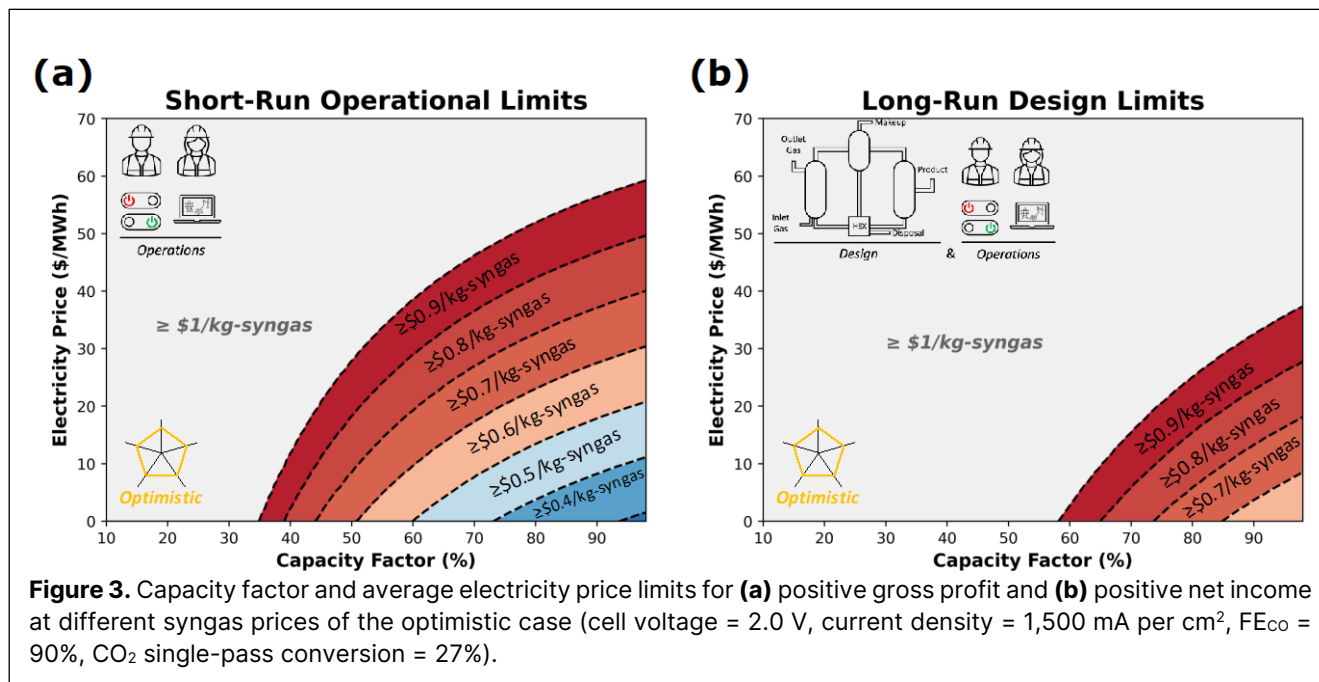

Two of the key assumed parameters in techno-economic assessment (TEA) calculations in electrolysis are the capacity factor and the average electricity price. In the past, a capacity factor of  $\geq 90\%$  and an average electricity price in the range of \$20-60 per MWh have been used in the CO<sub>2</sub> electrolysis field [21,42–47]. Such values are highly optimistic for interactions with a highly renewable decarbonized power system and might unrealistically benefit the economics of CO<sub>2</sub> electrolysis. To provide more realistic assumptions, a more-detailed power system model is needed to fill this gap. However, before this is pursued, it is important to understand the combinations of the capacity factor, average electricity price, syngas sale price, and CO<sub>2</sub> taxes that would allow the whole route to generate positive gross profit and positive net income.

We consider two cases in this effort. In the first

case, we focus on the operational limits of the presented DAC-electrolysis route (Fig. 1) by estimating the gross profit while varying the capacity factor and the average electricity price at syngas sale prices of \$0.3-1.0 per kg-syngas. We then identify the minimum capacity factor and average electricity price at each syngas price that allow the gross profit to stay positive. In the second case, we take the plant's design into consideration as well, meaning that we not only focus on the short-term economic decisions but the long-term ones as well. To accomplish this, we estimate the same parameters that enable the net income to stay positive at the different syngas sale prices. We conduct the same analysis for four scenarios: 1) Baseline without CO<sub>2</sub> tax credits (Fig. 2a and 2b), 2) Optimistic without CO<sub>2</sub> tax credits (Fig. 3a and 3b), 3) Baseline with a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub> (Fig. 5a and 5b), and 4) Optimistic with a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub> (Fig. 5c and 5d).

#### 3.1. Design and operational economic limits of the baseline DAC-CO<sub>2</sub>ER route without CO<sub>2</sub> tax credits

Figures 2a and 2b show the relationship between the capacity factor and the average electricity price at different syngas prices that would allow the gross profit and net income to be positive, respectively. We observe that a positive gross profit (Fig. 2a) at lower syngas prices requires a high-capacity factor and a low average electricity price. As the assumed syngas sale price increases from \$0.3 to \$1.0 per kg-syngas, more flexibility in the capacity factor and the average electricity price can be obtained, while remaining economically viable. For instance, at an assumed syngas sale price of \$0.7 per kg-

syngas, a capacity factor of  $\geq 95\%$  is required at an average electricity price of \$23 per MWh to generate a positive gross profit. However, at a higher assumed syngas sale price of \$1.0 per kg-syngas, more operational flexibility can be provided (e.g., capacity factor of 50%) at the same average electricity price (\$23 per MWh), while still generating a positive gross profit. This finding demonstrates the importance of capacity factor and average electricity price assumptions in determining the short-term operational economic feasibility of the investigated DAC-electrolysis route.

At longer timescales, the cost associated with the design of the plant (e.g., equipment, instrumentations) must be considered. We observe a red shift of the color-map that requires higher syngas prices at higher capacity factors and lower average electricity prices (Fig. 2b). This is caused by the addition of the annualized capital costs, which adds an economic restriction on the design and operations of the plant that must be considered and minimized at an early stage. However, it is worth noting that, in practice, this restriction does not impact the operational decisions but rather the design decisions.

Indeed, reducing the capital cost could significantly help achieve more flexible operations of the electrolysis unit such that the DAC-electrolysis route stays economically feasible throughout the broad range of dynamic electricity prices anticipated in the future [48]. Additionally, benefitting from incentives [49] that partially or fully pay off the capital cost of the plant could significantly hasten the deployment of these defossilized pathways, especially when considering the current average syngas market price (\$0.40 per kg-syngas, see the discussion in section 3.4 and calculation in the SI). However, it is worthwhile to re-iterate that this restriction does not

influence the operational decisions of the plant.

### 3.2. Design and operational economic limits of the optimistic DAC-CO<sub>2</sub>ER route without CO<sub>2</sub> tax credits

Improving the design of CO<sub>2</sub> electrolyzers such that they achieve high current densities ( $\geq 1,500$  mA per cm<sup>2</sup>) at low cell voltages ( $\leq 2.0$  V; EE  $\geq 67\%$ ) is still in progress [21,50]. Defining research targets that consider the economics of such pathways would be helpful to CO<sub>2</sub> electrolysis researchers at this developmental stage. Figure 3 shows the same relationships from Figure 2, however considering an optimistic CO<sub>2</sub> electrolysis performance that achieves 1,500 mA per cm<sup>2</sup> at 2.0 V (EE  $\approx 67\%$ ).

We find the average electricity price to gain more flexibility when considering the optimistic CO<sub>2</sub> electrolysis performance in our gross profit calculations (Fig. 3a). For instance, at an assumed syngas sale price of \$1.0 per kg-syngas, the maximum average electricity prices for the baseline and optimistic scenarios that enable positive gross profits at a capacity factor of 70% are approximately \$37 and \$46 per MWh, respectively. This finding is mainly due to the large influence of electricity costs on the economics of DAC-electrolysis routes, as driven by the cell voltage (or energy efficiency) [21,50].

In addition, we find the capacity factor limits of maintaining a positive gross profit to also change as the cell voltage and current density are optimized (Fig. 3a). At an average electricity price of \$30 per MWh and an assumed syngas sale price of \$1.0 per kg-syngas, the capacity factor limits of the baseline and optimistic scenarios that allow positive gross profits are estimated to be 60% and 52%, respectively. The higher flexibility with operating at lower capacity factors while still generating a

positive gross profit in the optimistic scenario is also driven by the lower electricity costs, which originate from achieving a lower cell voltage of 2.0 V.

Similarly, Figure 3b shows the same general results—i.e., higher flexibility of the average electricity price and the capacity factor limits to generating a positive net income. However, we observe a slightly higher flexibility in the capacity factor, resulting from the reduction of the cell voltage that reduces the power of the electrolyzer; and thus, the electrolyzer's capital cost. Therefore, higher flexibility in the capacity factor can be obtained in the optimistic scenario for operating with a positive net income.

Although assuming an optimistic scenario provides more flexibility in the average electricity price and capacity factor, high syngas prices of  $\geq \$0.6$  per kg-syngas are still needed to generate positive gross profit and net income (Fig. 3). In the following sections, we will explore the effect of CO<sub>2</sub> capture costs, CO<sub>2</sub> taxation on emitting technologies, and CO<sub>2</sub> tax credits for capture technologies in order for the current projections of the integrated process to make economic sense.

### 3.3. Design limits at different CO<sub>2</sub> capture costs without CO<sub>2</sub> tax credits

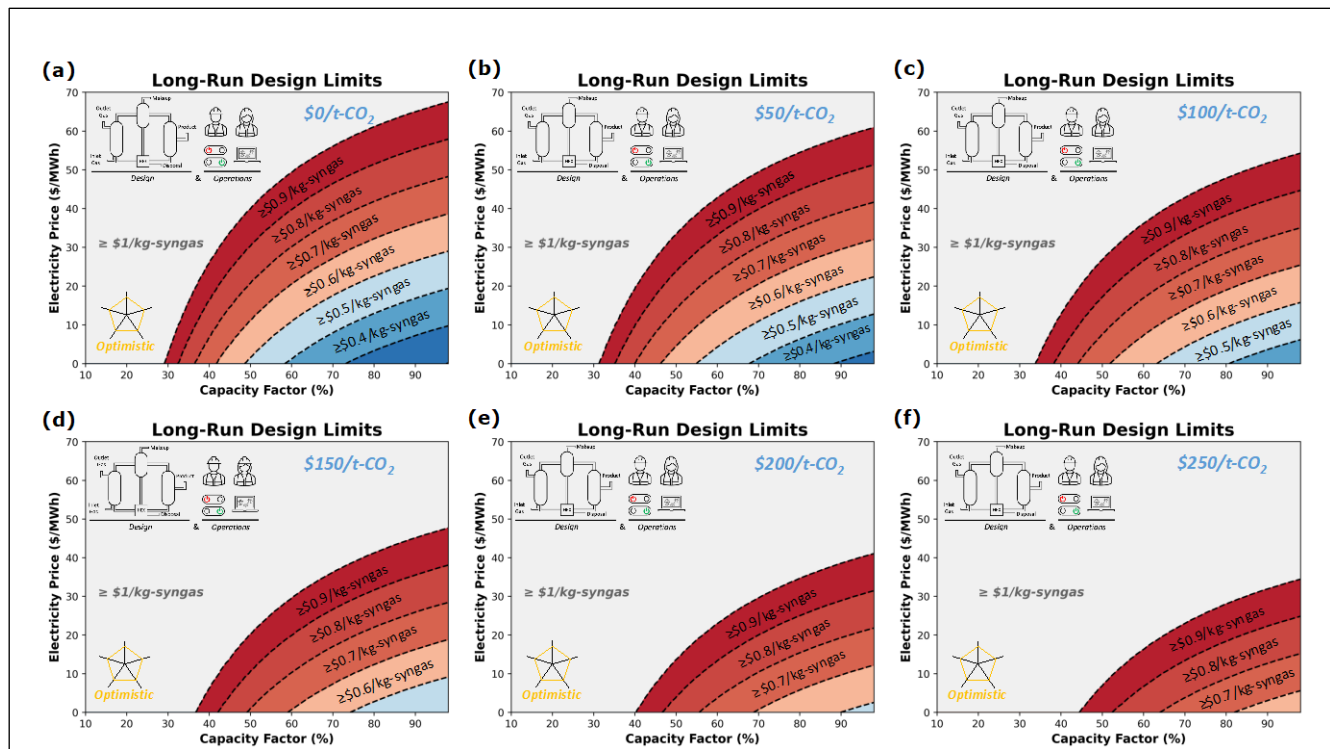

Sourcing the CO<sub>2</sub> from flue gases or from other non-fossil sources could have a significant influence on the

economic feasibility of the presented syngas production route. Thus, we estimated the long-run design limits at different capture costs ranging from \$0 to \$250 per t-CO<sub>2</sub>, as shown in Figure 4.

In general, as the CO<sub>2</sub> capture cost increases, the plot shifts to the red region. At a CO<sub>2</sub> capture cost of \$100 per t-CO<sub>2</sub>, consistent with the U.S. department of energy (DOE) carbon shot goals, we find the average electricity price to be \$19 per MWh at a capacity factor of 80% and a syngas sale price of \$0.7 per kg-syngas. Reducing the CO<sub>2</sub> capture cost to \$50 per t-CO<sub>2</sub>, consistent with sourcing CO<sub>2</sub> from PSCC, allows more flexibility in the average electricity price ( $\leq \$25$  per MWh) at the same capacity factor and syngas sale price. This result demonstrates the importance of reducing the CO<sub>2</sub> capture cost to less than \$100 per t-CO<sub>2</sub> or sourcing the CO<sub>2</sub> from an alternative source that would provide the carbon at a cheaper price. However, herein, we continue to focus on DAC to present an environmental process that allows the production of 2:1 syngas from air.

### 3.4. Conventional syngas market price with CO<sub>2</sub> taxation

The market syngas price is an important metric to compare against when evaluating emerging syngas production pathways. Previous literature have cited or estimated different syngas prices from natural gas (NG) feedstock processes, ranging from \$0.03 to \$0.74 per

**Figure 4. (a-f)** Capacity factor and average electricity price limits for positive net income at different syngas prices of the optimistic case (cell voltage = 2.0 V, current density = 1,500 mA per cm<sup>2</sup>, FE<sub>CO</sub> = 90%, CO<sub>2</sub> single-pass conversion = 27%) and at various CO<sub>2</sub> capture prices ranging from \$0 to \$250 per t-CO<sub>2</sub>.

kg-syngas [21,33,44,51,52]. We use the average NG-based syngas price of these estimates as the market price in our analysis. We assume a NG-based plant that is composed of dry methane reforming (DMR) for 1:1 syngas production and steam methane reforming (SMR) for additional H<sub>2</sub> supply to produce 2:1 H<sub>2</sub>:CO syngas, according to the design of Rezaei and Dzuryk [33]. Figure 5 shows the re-calculated NG-based syngas price with CO<sub>2</sub> taxes of \$0-550 per t-CO<sub>2</sub>. We assume a 90% capacity factor to estimate the process and energy-associated CO<sub>2</sub> emissions from the SMR-DMR pathway. Note that we are not accounting for any emissions outside the scope of the SMR-DMR process (e.g., natural gas processing).

**Figure 5.** NG-based syngas price as a function of CO<sub>2</sub> taxes. The color codes from blue (\$) to orange (\$\$\$\$) correspond to the ranges  $\leq \$0.5$ ,  $\leq \$0.6$ ,  $\leq \$0.7$ , and  $\leq \$0.8$  per kg-syngas cases, respectively. Note that we are not performing a full life-cycle assessment here; we are only accounting for the emissions from the DMR-SMR process, ignoring the emissions associated with raw materials' processing.

The linear relationship shows that the syngas price would increase to \$0.79 per kg-syngas with a CO<sub>2</sub> tax of \$500 per t-CO<sub>2</sub>. Although this would give the DAC-electrolysis pathway more flexibility in the capacity factor and average electricity price choices, it suggests a CO<sub>2</sub> tax that is three times higher than the highest CO<sub>2</sub> tax implemented today (\$155 per t-CO<sub>2</sub> in Uruguay [53]). Thus, it is likely not realistic to consider reaching a CO<sub>2</sub> tax rate of \$500 per t-CO<sub>2</sub> by mid-century.

However, considering a CO<sub>2</sub> tax rate of \$155 per t-CO<sub>2</sub>, the re-calculated NG-based syngas price increases from \$0.40 to approximately \$0.53 per kg-syngas (Fig. 5). At this price, the gross profit of the baseline and optimistic cases can be positive, although at restrictive capacity factor and average electricity price values, whereas the net income can only be negative. The only

exception to this conclusion is if the CO<sub>2</sub> capture costs dropped to  $\leq \$100$  per t-CO<sub>2</sub>, assuming no tax credits are provided to CO<sub>2</sub> capture (note that we will explore CO<sub>2</sub> tax credits in the next section). This finding, along with our previous results [21], suggest that a capital cost reduction of electrolyzers and air contactors would be necessary to make the economics of DAC-electrolysis viable. In addition, deployment incentives that partially or fully pay the capital expenses of building DAC-electrolysis plants could make a difference in deploying such emerging technologies and allowing them to compete with existing NG-based syngas production methods. In parallel, CO<sub>2</sub> tax credits could enormously help the net income to become positive by paying off some of the annual capital cost payments.

### 3.5. Design and operational economic limits of the baseline and optimistic DAC-CO<sub>2</sub>ER route with a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub>

CO<sub>2</sub> tax credits can be paid to CO<sub>2</sub> capture plants whether they capture the gas from point sources or from air. In the U.S., the 45Q tax credit code [49] pays DAC plants a tax credit of \$180 per tonne of captured and geologically stored CO<sub>2</sub>, and \$130 per tonne of captured and used CO<sub>2</sub>. In our analysis, we therefore use a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub> for the captured CO<sub>2</sub> by DAC to be used in the production of 2:1 syngas.

Figure 6 shows the capacity factor and average electricity price limits of the baseline (Fig. 6a and 6b) and optimistic (Fig. 6c and 6d) CO<sub>2</sub> electrolyzer cases with a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub>. The optimistic case enables more flexibility in the capacity factor and average electricity price at all syngas prices. For example, a price of \$0.70 per kg-syngas at a capacity factor of 80% can generate a positive gross profit at average electricity prices of  $\leq \$32$  and  $\leq \$40$  per MWh for the baseline and optimistic cases, respectively. For the same case and same conditions, the maximum average electricity price lowers to \$7 and \$13 per MWh for the two cases, respectively, to generate a positive net income. These results clarify that a CO<sub>2</sub> tax of \$155 per t-CO<sub>2</sub> and a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub> are insufficient for the considered DAC-electrolysis route to be economically feasible, especially when considering annual capital cost payments.

For the optimistic case to generate positive gross profit and net income at a reasonable average electricity price and competitive syngas sale price, two conditions must be met. First, a higher tax rate implemented on NG-based syngas production is necessary. For instance, a CO<sub>2</sub> tax rate of \$383 per t-CO<sub>2</sub> would increase the syngas market sale price to \$0.70 per kg-syngas, as shown in Figure 5. This rate is more than double the highest CO<sub>2</sub> tax rate today—\$155 per t-CO<sub>2</sub>—but is necessary from a business standpoint to strengthen the economic

competition of the presented syngas production pathway.

Second, the CO<sub>2</sub> tax credits must be increased. Assuming an equal CO<sub>2</sub> tax credit of \$383 per t-CO<sub>2</sub>, the average electricity price limit of the optimistic scenario at a syngas price of \$0.70 per kg can increase from \$4 to \$47 per MWh to generate a positive net income, while staying at a 90% capacity factor limit (Fig. S.1b). At this average electricity price and scenario, there will be more freedom in the operational decisions because the gross profit can stay positive even at a low-capacity factor of 60%, albeit at an average electricity price of \$18 per MWh (Fig. S.1a). Although discouraged from a design perspective, this scenario would allow the continued and economic operation of the plant.

To put these results into context, NREL's annual technology baseline (ATB) analysis predicts a levelized cost of energy (LCOE) of utility-scale solar PV with battery storage in the range of \$35-90 per MWh in 2050 [54]. The analysis presented in this section highlights the economic and policy challenges faced by the presented DAC-electrolysis pathway. In other words, it will be difficult for the DAC-electrolysis system to compete with conventional syngas production methods without a CO<sub>2</sub> emission tax rate and a CO<sub>2</sub> capture tax credit on the order of \$400 per t-CO<sub>2</sub>. Even in this scenario, the plant must operate most of the year at a capacity factor of  $\geq 80\%$  and the average electricity price must be in the lower range of the NREL ATB's LCOE predictions (i.e.,  $\leq$  \$40 per MWh). Thus, further design and energy efficiency improvements as well as policy incentives are necessary before this pathway can be commercialized at scale.

#### 4. SUMMARY AND FUTURE TARGETS

In this work, we focused on the capacity factor and average electricity price limits at several syngas prices that enable the gross profit and net income of a DAC-electrolysis route to be positive. We considered hydroxide-based DAC as well as gaseous CO<sub>2</sub> and liquid PEM H<sub>2</sub>O electrolysis systems to produce 2:1 H<sub>2</sub>:CO syngas. We additionally considered an SMR-DMR conventional route to re-calculate the syngas price after the addition of CO<sub>2</sub> taxes. We analyzed baseline and optimistic scenarios of CO<sub>2</sub> electrolysis and accounted for a tax credit payment of \$130 per t-CO<sub>2</sub>.

Our findings suggest that deploying the presented DAC-electrolysis route for syngas production will be economically challenging, even after considering current CO<sub>2</sub> taxes and tax credits. Indeed, our results show that the very best-case scenario—which considers improved CO<sub>2</sub> electrolysis performance, a CO<sub>2</sub> tax rate and tax credit of \$383 per t-CO<sub>2</sub>, and a capacity factor of  $\geq 80\%$ —still requires an average electricity price of \$40 per MWh to generate both positive gross profit and net income. This

price is in the lower range of the 2050 LCOE predicted average electricity prices by NREL's ATB analysis for a utility-scale solar PV with battery storage, and it is about 33% lower than the average 2023 wholesale electricity prices in U.S. markets [55]. Thus, several targets must be pursued before this pathway can be deployed as a defossilized syngas production route.

For CO<sub>2</sub> electrolysis, the main challenge is to achieve high current densities ( $\geq 1,500$  mA per cm<sup>2</sup>) at low cell voltages ( $\leq 2.00$  V) to lower the capital cost while improving the energy efficiency of the process. However, special attention must be paid to the durability and stability of the electrolysis system as achieving the performance metric without stability would not allow industrial deployment at the high capacity factors required for profitability [56]. In addition, flexible operation is still an open problem in the low-temperature CO<sub>2</sub> electrolysis field, requiring experimental tests of interrupted electrolysis operations for long durations.

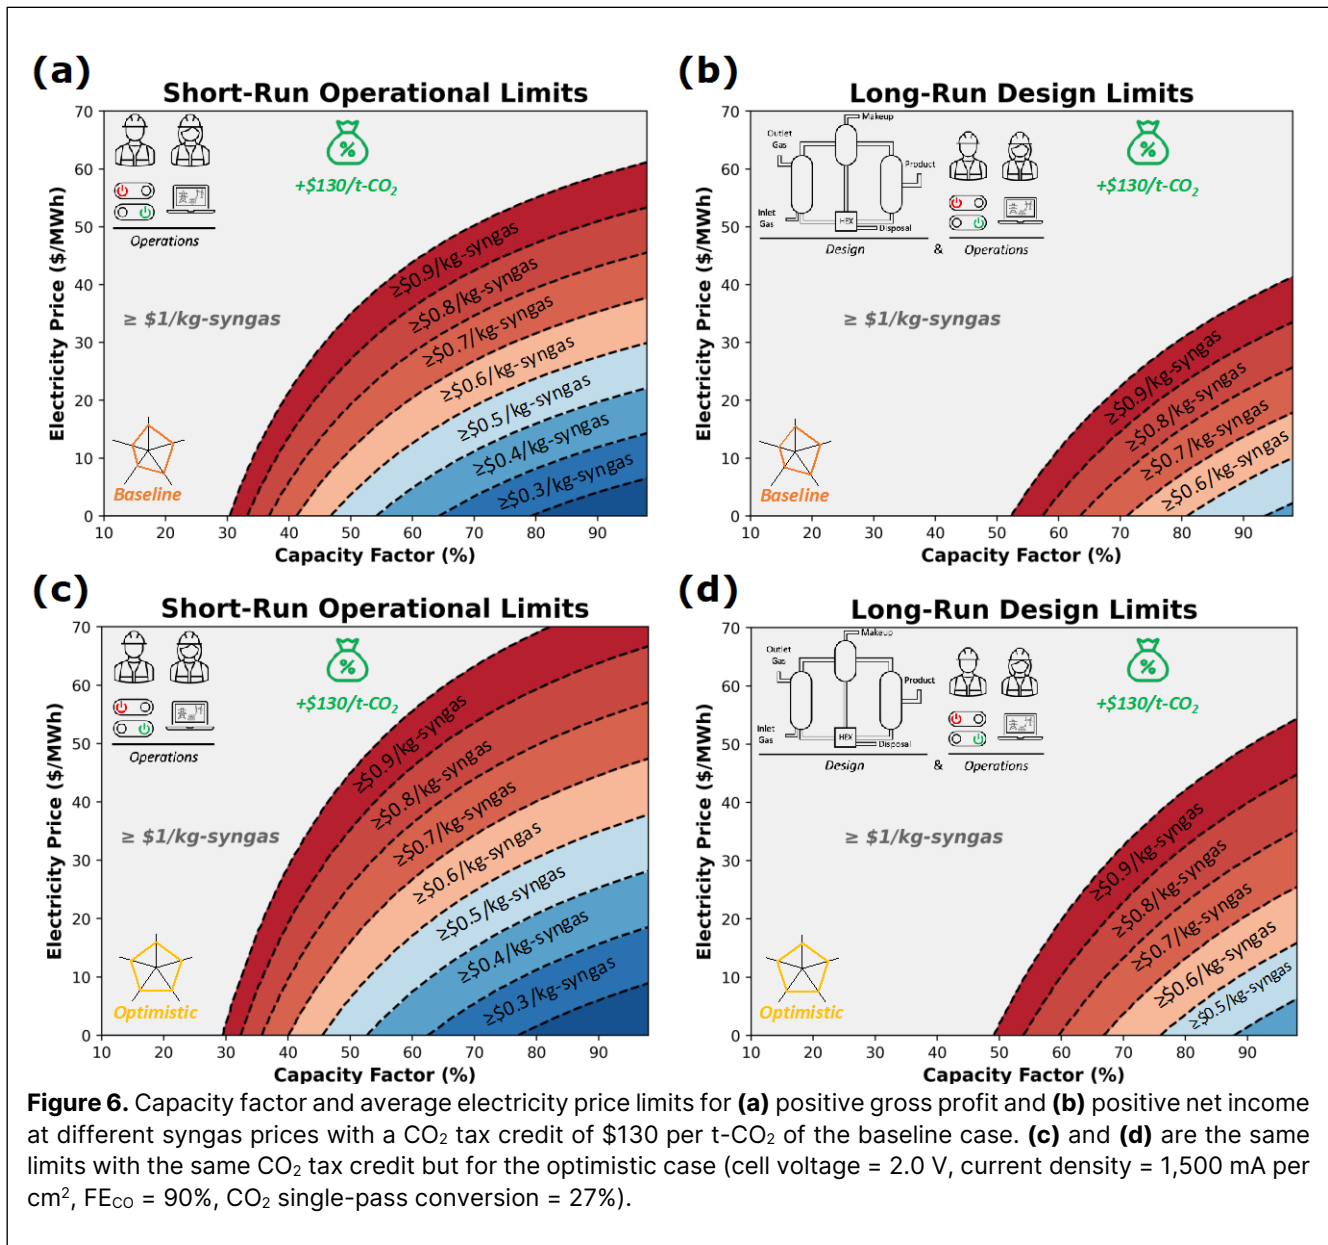

Hydroxide-based DAC plant designs must also be optimized to lower the energy consumption and capital costs. Specifically, the air contactor capital cost needs to be reduced to maximize the net income of the entire integrated route. Alternative low-temperature regeneration methods could help reduce the capital cost as there would not be any need to using heat exchanger networks, which accounts for approximately 21% of the total capital cost of the presented route [21].

Outside of technology development, high carbon taxes on CO<sub>2</sub>-emitting technologies and high carbon tax credits for CO<sub>2</sub>-capturing technologies would likely be necessary. Our results highlighted the importance of these policies in the shift from fossil-based to fossil-free production of syngas. For the defossilized air-to-syngas route presented here to be economically viable, CO<sub>2</sub> taxes and tax credit on the order of \$400 per t-CO<sub>2</sub> are required. These numbers are unquestionably too high. However, early and fast deployment is necessary to enable learning-by-doing and economies-of-scale to help reduce the total cost of these emerging defossilized pathways; and thus, their required CO<sub>2</sub> taxes and tax credits.

Future work should explore several avenues, one of which is the integration of a detailed power system model that considers the dynamics of renewable electricity generation and prices as well as energy storage. In this avenue, a comparison with wholesale electricity supply should be considered to understand the best-case scenario for the DAC-electrolysis route to be economically feasible. In addition, alternative air-to-syngas routes should be explored with a similar methodology as presented here. Indeed, the most feasible integrated air-to-syngas design is still unknown, motivating future works to further explore this research path.

Finally, it is worthwhile to note that the present

**Figure 6.** Capacity factor and average electricity price limits for (a) positive gross profit and (b) positive net income at different syngas prices with a CO<sub>2</sub> tax credit of \$130 per t-CO<sub>2</sub> of the baseline case. (c) and (d) are the same limits with the same CO<sub>2</sub> tax credit but for the optimistic case (cell voltage = 2.0 V, current density = 1,500 mA per cm<sup>2</sup>, FE<sub>CO</sub> = 90%, CO<sub>2</sub> single-pass conversion = 27%).

study particularly considered sourcing CO<sub>2</sub> from air. However, there are other sources of CO<sub>2</sub>, such as the ocean, flue gases, and CO<sub>2</sub> process emissions, which were not explored here. Specifically, the latter two sources are likely to enhance the process economics of the whole integrated pathway, potentially allowing stronger competition with conventional NG-based syngas production methods. However, one should be careful with environmental concerns of upstream processes that generate these point-source gases to assure the design of a sustainable, circular, and environmental process for syngas production.

## ABSTRACT

Sustainable and economically viable plastic recycling methodologies are vital for addressing the increasing environmental consequences of single-use plastics. In this study, we evaluate the plastic waste management value for the state of Georgia, US and investigate the potential of introducing novel depolymerization methods within the network. An equation-based formulation is developed to identify the optimum supply-chain design given the geographic location of existing facilities. Chemical recycling technologies that have received increasing attention are evaluated as candidate technologies to be integrated within the network. The optimum supply-chain design is selected based on environmental and economic objectives. The designed network of pathways uses a mix of different technologies (chemical and mechanical recycling) in a way that are both economically environmentally sound.

**Keywords:** recycling, supply chain, plastics, waste management, optimization

## 1. INTRODUCTION

Plastic materials have revolutionized our daily lives gradually replacing materials used for centuries such as wood, glass, or steel. Unfortunately, a significant amount of the plastics used ends up in landfills or marine environments with a very small percentage of them currently being recycled. For context, 35.7 MT of plastics were generated in the US in 2018 while approximately 26.9 MT ended up to landfill (75.6%) [1]. Consequently, the transition to circular economies (CE) in which waste materials will be effectively re-used stands as one of the most prevalent challenges of our times particularly in context of waste plastics [2].

The plastic waste management routes can be categorized into four categories: pre-consumer, mechanical recycling, chemical recycling, and energy recovery pathways. Currently, mechanical recycling is the primary method for recycling due to its low cost and simplicity, however, the material properties of the plastic degrade during processing (each plastic can be recycled 2-6 times during each lifetime) [3, 4]. As a result, solely depending on mechanical recycling impedes the realization of a closed-loop recycling economy [4, 5].

Chemical recycling of polymers through depolymerization pathways has garnered increased attention in the last decade as a promising alternative strategy. This is because chemical recycling enables the breakdown of polymers to constituent monomers thus, bypassing material degradation issues [3, 6]. A wide variety of methodologies have been proposed to chemically recycle waste plastics that differ considerably in terms of efficiencies, reaction pathways and maturity levels thus, ranking technologies and making decisions is nontrivial [7].

In combination to the already complex network of waste management options (e.g., landfilling, energy recovery, recycling etc.), design of economic and sustainable solutions that would maximize circularity is an open challenge. Previous studies have evaluated how to effectively manage waste systems through integrated supply-chains [8-11]. Ma et al. [4] developed a mixed integer linear program (MILP) approach to study the performance of thermochemical technologies at a regional-scale for low-density polyethylene (LDPE) and polypropylene (PP) waste. Recently, Badejo et al. [12] examined multiple technologies for managing high-density polyethylene (HDPE) waste using an MILP framework focusing on the

United States East Coast.

In this work, we model the supply chain of two types of waste plastics (i.e., polyethylene terephthalate (PET) and HDPE) through an equation-based framework using geospatial data for the state of Georgia, US. Geographic locations of the existing waste processing facilities (e.g., landfilling, mechanical recycling, etc.) are integrated within the network. Subsequently, we assess the potential of integrating novel chemical recycling methodologies into the superstructure for processing PET and HDPE waste. Literature data are incorporated into the formulation, to enable capturing the economic and emissions trade-offs between alternative technologies. Further, we employ multi-objective optimization to identify the Pareto-optimal solutions. In summary, our study presents a computational framework based on a realistic system representation that can be utilized to compare alternative pathways and enable the design of cost-effective supply-chains for PET and HDPE waste plastics.

**Figure 1.** Overview of our analysis including data collection, formulation and optimization of the supply chain model.

## 2. MODEL DESCRIPTION

### 2.1. Model overview and problem statement

An equation-based formulation is established to systematically model the value chain of plastics. The primary objectives are: (a) to determine the most efficient path for plastic waste from various points of collections ultimately to the end-user; and (b) the mix of transformation technologies that would maximize circularity. The model is constructed as a graph where its nodes represent the source, transformation, and demand facilities. Each node is characterized by the geographic coordinates of each facility in Georgia, US (GA). The edges of the graph represent the material flowing between the nodes. This manuscript specifically studies the plastic waste management in the state of Georgia; however, the framework is generalizable and can be adapted for use in other regions that can vary in size.

The supply network in Georgia consists of distinct operations: (a) the plastic waste (HDPE and PET) is collected locally at transfer stations; (b) transported to landfills or recycling facilities; (c) transformed to usable forms through mechanical or chemical recycling; (d) mixed with virgin plastics to meet the market demands; and (e)

transferred to the end-users. A simplistic graph of the route that plastics follows through the designed network is depicted in Figure 2.

Data sourced by the state of Georgia and the Environmental Protection Agency (EPA) [1, 13] are used as inputs to the model. Figure 3 visually presents the geographic locations of the system's nodes. The databases were further refined to include only those locations that process or utilize PET and HDPE. A total of 201 collection sites, 44 landfills, 29 recycling facilities (with 15 processing HDPE and 14 PET), and 30 market sites (11 and 19 sites that demand HDPE and PET, respectively) are considered.

**Figure 2:** Overview of the potential routes for plastic waste upcycling.

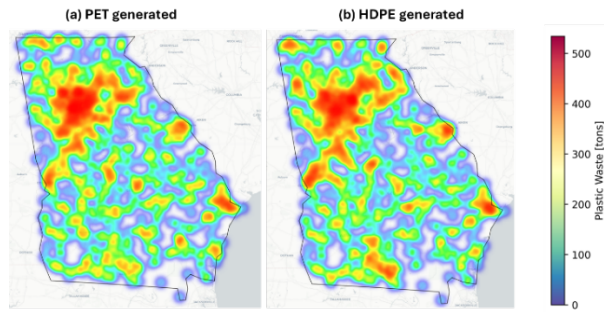

● Transfer Stations ● Landfills ● PET Recycling ● HDPE Recycling ● Market

**Figure 3:** Map of the state of Georgia, US including all nodes of the PET and HDPE supply chain.

Figure 4 (a) and (b) depicts the spatial distribution of plastic waste generation for PET and HDPE in Georgia, respectively sourced from EPA database[1]. The amounts of HDPE and PET waste generated at each zip-code, are assigned as input rates to the closest collection site. It is assumed that the waste is already separated to HDPE and PET at each collection. The demand capacities for the each of the market locations is also assumed to be equal to the required amount of plastic at the closest zip-code [1].

At the existing geographic locations of mechanical recycling nodes, hypothetical chemical recycling facilities are introduced. It is assumed that each recycling node can process plastic waste either chemically or mechanically, provided that the capacity constraints are not exceeded. Various candidate technologies are compared for PET, including dissolution, enzymatic hydrolysis, glycolysis and methanolysis based on literature data [7]. For HDPE the investigation is focused only on dissolution as the primary chemical recycling technology.

**Figure 4:** Heatmap of annual (a) PET (b) HDPE waste generated in Georgia, US as extracted by the EPA database.

## 2.2. Model formulation

As mentioned earlier, the supply chain model adopts a graph network representation. The set of all nodes is denoted as  $N$ . Collection sites ( $T$ ), landfill ( $L$ ), mechanical recycling ( $MR$ ), chemical recycling ( $CR$ ), and market ( $M$ ) sets are introduced to describe the sets of distinct type of facility. Therefore, the entire network is described as  $N = T \cup L \cup MR \cup CR \cup M$ . Furthermore, for each of the sets introduced, a subset for PET and HDPE nodes are also established such that for example  $MR = MR_{PET} \cup MR_{HDPE}$ . The same holds for each of the sets introduced apart from  $L$  that can accept both HDPE and PET waste. Each chemical recycling node is characterized by the candidate depolymerization technology. A binary variable  $y_{i,j,tech}$  is introduced to specify the type of chemical recycling technology implemented at each CR node. Finally, every node is characterized by the material flow  $m_{ij}$ , from the starting node  $i$  to the destination node  $j$ .

The model is formulated as a MILP with the objective of minimizing the economic or environmental impact. The environmental (Equation (1)) and economic (Equation (2)) objectives are defined as follows:

$$E = \sum_{i=1}^N \sum_{j=1}^N d_{ij} m_{ij} E_{mile_{ij}} + \sum_{j=1}^N \sum_{i=1}^N m_{ij} E_{i,j} \quad (1)$$

$$C = \sum_{i=1}^N \sum_{j=1}^N d_{ij} m_{ij} C_{mile_{ij}} + \sum_{j=1}^N \sum_{i=1}^N m_{ij} C_{i,j} \quad (2)$$

Here,  $d_{ij}$  represents the distance between node  $i$  and  $j$ , while  $m_{ij}$  signifies the material flow between the nodes.  $E_{ij}$  and  $C_{ij}$  denote the  $CO_2$ -eq emitted and the cost

of production at the specific node with an input flow of  $m_{ij}$ , while  $C_{mile}$  and  $E_{mile}$  the cost and the emissions of transporting plastic through the edges of the network. The first term in Equations (1) and (2) represents the impact of the transportation to the objectives while the second term the impact of processing the plastic within each node. The material balances of flows entering and exiting each node are given by Equation (3) with  $\alpha_{ij}$  representing the conversion factors. Different conversion factors are assigned based on the technology selected, processing node and material type. Equation (3) should be satisfied for all nodes.

$$\sum_{i=N_{in}} \sum_{j=N_{in}} m_{i,j} \alpha_{ij} = \sum_{i=N_{out}} \sum_{j=N_{out}} m_{ij} \quad (3)$$

Furthermore, demand and source constraints are imposed through Equations (4)-(5). Equation (4) guarantees that the market needs are fulfilled. The demands are satisfied by mixing recycled with virgin, petroleum-derived plastic denoted as  $vPET$  and  $vHDPE$ , respectively. This is included because the current market requirements cannot be exclusively satisfied through recycling, even if all collected plastic is recycled. Equation (5) ensures that all waste gathered is effectively managed either through recycling or disposed at the landfills. Moreover, Equation (6) introduces a capacity constraint within the formulation, to prevent material flows from exceeding the maximum processing capacity of each facility.

$$\sum_{i=CR} \sum_{j=M} m_{i,j} + v_{Plastic} = \sum_{i=M} Demand_i \quad (4)$$

$$\sum_{i=T} \sum_{j=L \cup CR \cup MR} m_{i,j} = \sum_{i=T} Source_i \quad (5)$$

$$\sum_{i=CR \cup MR} \sum_{j=M} m_{i,j} \leq \sum_{i=IM} Capacity_i \quad (6)$$

Equations (7) and (8) set a quality constraint for the final product. This ensures that mechanically recycled plastic can be used in the production of new materials only if blended at a maximum threshold of 50% with virgin or chemically recycled plastic. Finally, Equation (9) guarantees that at each CR node, only one technology can be active.

$$\sum_{i=R} \sum_{j=M} m_{i,j} \leq 0.5 (\sum_{i=CR} \sum_{j=M} m_{ij} + \sum_{i=M} v_{PET_i}) \quad (7)$$

$$\sum_{i=R} \sum_{j=M} m_{i,j} \leq 0.5 (\sum_{i=CR} \sum_{j=M} m_{ij} + \sum_{i=M} v_{HDPE_i}) \quad (8)$$

$$\sum_{tech} \sum_{i=CR} \sum_{j=M} y_{i,j,tech} \leq 1 \quad (9)$$

The emission and cost factors utilized in Equations (1)-(2) are depicted in Table 1. All the environmental factors apart from the chemical recycling steps were obtained from the ecoinvent database v3.10, following the ReCiPe 2016 methodology [14, 15]. The emissions and cost factors for the investigated chemical recycling technologies are taken from a recent study conducted by Uekert et al. [7] in which the authors performed rigorous simulations of various chemical recycling processes. The

cost factors for the rest of the steps are taken from the literature and published industry data [7, 16, 17].

**Table 1:** Emissions and cost factors of processing, feed, and mechanical recycling nodes

Process	Price (\$/kg)	Emissions (kg CO <sub>2</sub> -eq/kg)
Landfill HDPE	0.08	0.138
Landfill PET	0.08	0.095
MR HDPE	0.63	0.737
MR PET	0.54	1.337
Virgin HDPE	0.79	3.277
Virgin PET	1.19	4.086
Transportation	0.04/km	0.196/metric ton km

**Table 2:** Emissions and cost factors for chemical recycling technologies investigated

Process	Price (\$/kg)	Emissions (kg CO <sub>2</sub> -eq/kg)
Dissolution PET	0.87	4.49
Enzymatic Hydrolysis PET	2.01	3.95
Glycolysis PET	0.96	1.32
Methanolysis PET	1.05	4.19
Dissolution HDPE	1.10	2.40

### 2.3. Solution Strategy

The problem defined by Equations (1)-(9) is formulated as an MILP problem. The mathematical problem is solved in Pyomo with CPLEX v22.2. First, the two single-objective problems are solved independently, and the optimal network configurations and technologies of choice are obtained. In the case that the single-objective configurations are different, it indicates a conflict between the two solutions. This implies that there are trade-offs between economically sound and environmentally friendly solutions. Next, to analyze the trade-offs between the two solutions, the multi-objective optimization problem is formulated and solved using the  $\epsilon$ -constraint methodology (Equation 10). The mathematical problem is transformed to a single-objective, bounded by an additional constraint that corresponds to the other objective [18, 19].  $C_{\min}$  and  $C_{\max}$  correspond to the minimum and maximum values of the cost objectives as identified by the single-objective problems.

$$\min E \quad (10a)$$

$$\text{s. t. } C < \epsilon, \text{ where } C_{\min} \leq \epsilon \leq C_{\max} \quad (10b)$$

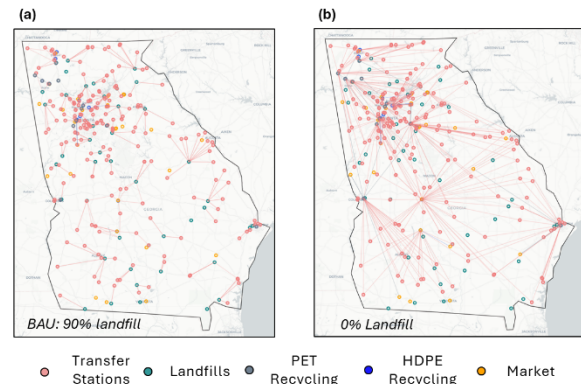

## 3. RESULTS AND DISCUSSION

To evaluate the potential of integrating chemical recycling within the existing network we analyze: (a) the

environmental impacts (Section 3.1), (b) the economic implications (Section 3.2), and (c) both objectives simultaneously (Section 3.3).

### 3.1. Environmental considerations of the GA recycling network

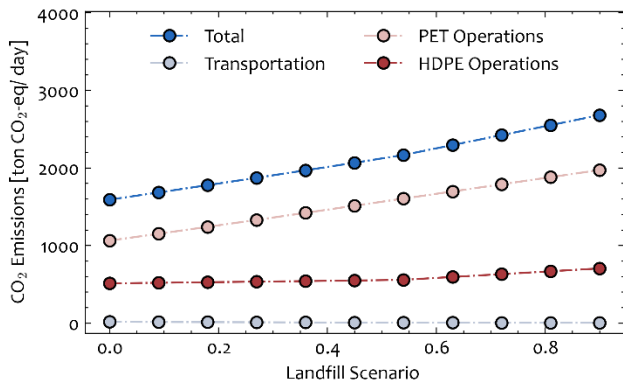

The spatial solution considering the environmental objective is depicted in Figure 5 (a). This solution is representative of the Business-As-Usual (BAU) scenario, where 10% of the plastic waste is recycled. A very small portion of the generated waste plastic are directed to recycling facilities. For PET, mechanical recycling nodes remain inactive and all of plastics are processed through chemical recycling. This is because of the higher conversion rates and relatively similar emissions rates between mechanical recycling and glycolysis (e.g., candidate technology with lower emission factor). Strictly only considering emissions, chemical recycling is favored in the BAU case (e.g., 90% landfill). The opposite is true for HDPE, where all plastics that is not landfilled are mechanically processed. This is attributed to the relatively lower emissions of MR as compared to CR for HDPE. It is worth acknowledging that the emission data for chemical recycling processes are based on experiments and simulations hence, the results may change as closed loop depolymerization recycling methods are further explored and optimized at larger scales.

**Figure 5:** Solution for (a) 90% landfill scenario; (b) 0% landfill scenario under the environmental objective.

To further explore the potential of recycling, sensitivity analyses are carried out to investigate the scenarios in which more plastic waste is recycled. The percentage of waste directed to landfills is changed to represent hypothetical scenarios. As landfilling is increasingly banned across Europe and some US states, those scenarios are important to consider. The network configuration for the zero-waste scenario is depicted in Figure 5 (b). The solution showcases an interconnected network of nodes with both chemical and mechanical recycling facilities activated.

The total CO<sub>2</sub>-eq emissions of the different scenarios are highlighted in Figure 6. It is observed that as landfill is reduced, the total emitted CO<sub>2</sub>-eq are also reduced, even though the emissions of landfilling are minimal. This is outweighed by the fact that plastics diverted from landfills are transformed into usable forms which, consequently, reduces the virgin plastic amount required to satisfy the market demands. Moreover, this is supported by the relatively small emission factors of glycolysis as compared to fossil production. The total emissions reported for HDPE are far lower than those of PET only because the input waste amount of PET is approximately double that of HDPE waste.

**Figure 6:** Emitted CO<sub>2</sub>-eq for different landfilling scenarios categorized by distinct operations

Furthermore, more recycling nodes are activated as landfilling is reduced since more waste needs to be processed while virgin requirements are reduced. The mix of technologies utilized to fulfill the market demands are visually represented in Figure 7 for the BAU and zero-waste scenarios. In the BAU scenario, the demand of new plastic is fulfilled mainly through the production of virgin materials while, in the zero-waste case, mainly through the transformation of waste to useful products. The different solutions can be attributed to quality requirements set by Equations (7) and (8), the capacity constraints set for recycling as well as the amount of plastic diverted from the landfills to processing nodes.

In terms of the investigated technologies, glycolysis outperforms all the other candidate methods and is chosen as the most promising recycling solution in all the investigated scenarios. This is highly correlated with the fact that emissions of glycolysis are considerably lower compared to all others and very similar to those of mechanical recycling. The trade-off is that glycolysis has lower conversion than some of the other candidate technologies, however, this does not outweigh the higher environmental impact. Moreover, the use of plastic sourced from fossil resources is reduced in all those hypothetical cases, as highlighted in Figure 7. As more plastic waste is available for re-processing, the market demands do

not have to be met with virgin quantities and the emissions are reduced. However, even under the zero-waste scenario, some virgin plastic is still required to meet the demands due to material losses occurring at intermediate nodes within the value-chain.

**Figure 7:** Amount of plastic processed through chemical and mechanical recycling compared with virgin requirements for 0% and 90% landfill scenarios.

### 3.2. Economic considerations of the GA recycling network

The spatial solution when considering the economic implications of the network are highlighted for the BAU and the zero-waste cases in Figure 8 (a)-(b). The effect of the same circularity scenarios to the economic objective are depicted in Figure 9.

**Figure 8:** Optimal network configuration under the (a) BAU; and (b) zero-waste scenario considering the economic objective.

It is observed that the evaluated cost objective is relatively constant throughout the different scenarios because of the similar cost factors in the competing scenarios (e.g., fossil production compared to recycling). The use of recycling technologies in the zero-waste scenarios does not reduce the cost relatively to the BAU that needs fossil – derived plastic to meet the market demands. More specifically, the cost of virgin PET is set at

\$1.19/kg compared to \$0.87/kg for the dissolution that has the lowest cost factors amongst the competing technologies, while the cost of landfill is minimal. These two relatively close values in conjunction with the zero-waste constraint, drive the cost of recycling up, and even though recycling is selected, the cost is not substantially reduced. Moreover, the HDPE operation costs increase as the share of landfilling is reduced due to the higher costs of chemical recycling when compared to virgin or MR production. This trend is influenced by the quality constraints set by Equation (8) which enforces a certain amount of HDPE waste to be processed through CR, because otherwise the quality of the final product will be inadequate.

**Figure 9:** Cost objective for different landfilling scenarios as identified for the different technologies.

In terms of the competing technologies for PET, dissolution outperforms all the other options, being different from the environmentally favorable recycling methodology (i.e., glycolysis). This result is attributed to the relatively low-cost factors used for dissolution. In addition, the virgin requirements follow similar trends with the environmentally friendly solution discussed earlier with less fossil-derived plastic required, as landfilling is reduced. All in all, the solution identified for the cost minimization scenario corresponds to a different network with different chemical recycling technologies activated compared to the green-house gas (GHG) minimization scenario, as depicted in Figure 10. This shows that the solutions are in fact in contrast.

### 3.3. Identifying trade-offs between environmentally friendly and cost-effective solutions.

In this section, we investigate the trade-offs between the economically friendly and environmentally sound solutions. The values of the two objectives are depicted in Table 3 for the two distinct landfilling scenarios (0%, 90%). This, along with the recommended technologies (e.g., glycolysis is chosen as the best environmental

case, dissolution for the most economical solution) indicates that the two objectives are in conflict meaning that different value chain networks are optimal. Moreover, the amounts of PET processed through chemical and mechanical recycling are very different for the two single-objective problems as illustrated in Figure 10.

**Figure 10:** vPET required for different landfilling scenarios and technologies to meet the market demands.

The BAU solution is an exception since the identified configuration is very similar for the two problems. This is because very small amounts of plastic waste are recycled and almost all of it is diverted to landfills. The difference between the two cases is how the 10% of waste will be processed. For the zero-waste case studied, the spatial solution and the selected technologies are different, as highlighted in Table (3). Therefore, the trade-offs between the two objectives for this scenario are evaluated by following the procedure outlined in the Solution Strategy section.

**Table 3:** Values of the environmental and economic for the two extreme landfilling scenarios

Objectives	Economics (M\$/day)	Emissions (ton-CO <sub>2</sub> -eq/ day)
<b>90% Landfill</b>		
min Env	0.82	2679
min Ecn	0.79	2682
<b>0% Landfill</b>		
min Env	0.79	1590
min Ecn	0.71	2561

The Pareto front is depicted in Figure 11 for the case of 0% landfilling. Point A represents the optimal configuration corresponding to the minimum cost objective, regardless of the environmental impact. Similarly, point B represents the optimal configuration from an environmental perspective. The exact values of the objectives are presented in Table 3. All other Pareto solutions that lie in between points A and B signify the trade-offs between the two objectives based on the level of

importance between the values.

**Figure 11:** Pareto front and utopia point for the multi-objective optimization problem for the zero-waste case.

Point U, also referred to as Utopia point, reflects an ideal solution, in which the values obtained from the two single-objective problems are plotted. This is a hypothetical scenario that can never be reached for those two conflicting scenarios. The different solutions observed as we move along the Pareto-front stem from changes in the configuration of the optimal waste management network in the studied region and the technology chosen. The most significant difference between the two configurations is that the economically friendly solution only dissolution is chosen as a candidate technology, while in the environmentally sound value chain glycolysis is favored. Glycolysis and dissolution technologies are activated with different quantities processed as we move between points A and C. After point C, the cost objective increases at a different rate than the environmental objective. This is attributed to fact that after this point, only glycolysis is the active CR technology with some amounts processed through MR. As we move between point C to B, waste is diverted from MR to CR which increases the processing costs but has minimal impact to the emissions. This is because the emissions of MR and glycolysis for PET are very similar, while the opposite is true for the cost factors.

#### 4. CONCLUSIONS

In this work, we discuss the design of optimal value chains of plastic recycling for a specific set of collection sites, transformation facilities and market. A superstructure network model was formulated to describe the existing recycling chain in the state of Georgia in the US. Our analysis evaluates the potential of integrating different depolymerization recycling technologies for PET and HDPE waste within the existing network. Different spatial arrangements and technologies are selected and designed for environmentally and economically friendly solutions. This contribution focuses only on the comparison of different depolymerization methods. However, to

holistically evaluate the supply-chain of plastic recycling, it is essential to compare other technologies not solely based on depolymerization, such as energy recovery or feedstock recycling. The landscape of plastic waste management is highly dynamic and as new technologies are advanced and new research is conducted, the emission and cost factors used in this analysis may change. In terms of the HDPE feedstock, this assessment only accounted for the use of dissolution as a chemical recycling technology. Future work will delve deeper into the integration of additional chemical recycling technologies beyond PET and HDPE. We anticipate that this approach will allow for the evaluation and comparison of multiple waste management pathways along with more realistic feedstocks.

## ABSTRACT

2,3 butanediol (BDO) has garnered recent interest due to the high titer concentrations that can be obtained through biochemical routes and its potential for efficient conversion into long-chain hydrocarbons. BDO separation, however, is challenging given its low volatility and high affinity towards water. In this study, two BDO separation pathways were compared, single distillation and combined simulated moving bed (SMB) adsorption with distillation. The separations were incorporated into a 2018 biorefinery design developed by the National Renewable Energy Laboratory (NREL) to produce renewable fuels from corn stover, with BDO as an intermediate and adipic acid as the co-product. The comparison was performed on the basis of sustainability, using lifecycle greenhouse gas (GHG) emissions as the metric. It was found that using a single distillation column gives GHG emissions of 48 g<sub>CO<sub>2e</sub></sub>/MJ for the renewable fuel. This is lower than 93 g<sub>CO<sub>2e</sub></sub>/MJ for petroleum fuel but is higher compared to the SMB-based process which achieves 21 g<sub>CO<sub>2e</sub></sub>/MJ. Additionally, the minimum fuel selling price (MFSP) of each pathway was computed. Single distillation gave a minimum MFSP of \$2.54/GGE (gallon of gasoline equivalent) of fuel, while SMB reached \$2.45/GGE. The SMB's MFSP is lower than the Department of Energy's (DOE) target of \$2.50/GGE, demonstrating this pathway is both an economic and sustainable alternative and a sound separation candidate that can enable the viability of the entire biorefinery. The effect of BDO fermentation titer was also considered through a sensitivity analysis.

**Keywords:** Adsorption, Biofuels, Distillation, Life Cycle Analysis, Technoeconomic Analysis.

## INTRODUCTION

2,3 butanediol (BDO) is a molecule of high interest in the chemical and energy industries that is commonly used as an intermediate for added-value products. BDO is commonly produced by the catalytic conversion of C4 components from hydrocarbon mixtures [1]. Although high conversions can be achieved, these pathways have expensive operating costs and still rely on fossil fuels. This has kept BDO from becoming a sustainable and widespread chemical. Recent advances in the biochemical production of BDO from biomass-derived sugars, and high fermentation titers (50-110g/L), have led to an increased attention to this molecule [2].

BDO is seen as a platform to help decarbonize hard-to-abate sectors, such as heavy transportation (trucking

and aviation). It has a higher heating value and is less volatile than more commonly produced compounds like ethanol or butanol. Thus, at high purity values it can be used as blendstock or even directly as a drop-in fuel. BDO can also be an intermediate to produce renewable hydrocarbons. Its four carbons and two hydroxyl groups allow the dehydration into high carbon alkenes, which could facilitate subsequent oligomerization and hydrotreating steps. Most notably, in 2018 the National Renewable Energy Laboratory (NREL) [2] developed a process design that details the production of a renewable 50/50 diesel+naphtha fuel product from corn stover. BDO obtained from fermentation is the key intermediate of this process and adipic acid is the main co-product. This design will be referred to as the state-of-technology (SOT). **Figure 1** shows a high-level diagram of the SOT. The inside-

battery limit (ISBL) includes alkaline pretreatment, hydrolysis, fermentation, upgrading to fuels and co-product trains. This is an integrated biorefinery, where utilities and other services are provided internally, including combined heat and power (CHP), cooling and wastewater facilities in the outside-battery limit (OSBL).

**Figure 1.** High level diagram of the NREL SOT process. Adapted from Davis et al, 2018 [2]

As seen, the ISBL in the SOT lacks a separation step that recovers BDO post-fermentation. This dilute broth (~100g/L BDO titer) is directly sent to the dehydration reaction. In reality, however, is unlikely for the reactor to efficiently upgrade BDO at dilute conditions, making the separation a required step in the plant. **Figure 2** shows a more detailed diagram of the modified upgrading portion of the SOT, with the proposed separation located between fermentation and dehydration to concentrate BDO.

**Figure 2.** Block diagram based on NREL SOT's [2] main processes downstream of the fermentation

Rejecting water reduces stream size, which directly affects other units. This includes the preheater before dehydration, the dehydration reactor itself and the post-dehydration separation (alkenes/water distillation). The decrease in stream size reduces equipment size, leading to lower capital costs. Most importantly, the BDO pre-heating energy is also reduced, significantly decreasing operating costs and fuel usage. This leads to much smaller CO<sub>2</sub>e emissions that can make the fuel product a sustainable substitute of fossil hydrocarbons.

Nevertheless, BDO separation from a dilute aqueous mixture is challenging. BDO's high boiling point (177°C) and affinity towards water make distillation highly energy

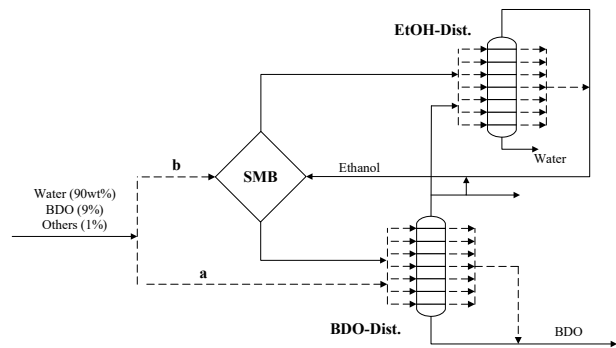

intensive. Simulated moving bed (SMB) adsorption is proposed as an alternative. Adsorption is a material-based separation, and SMB can enrich BDO to the required purity levels, without incurring in large operating expenses.

The main objective of this study is to compare the lifecycle of two pathways that recover BDO from a fermentation broth: 1) simple distillation and 2) SMB + distillation. Greenhouse gas (GHG) emissions was chosen as the sustainability metric, which is minimized for each pathway through deterministic optimization. To ensure the biorefinery is viable, the resulting design is subject to a minimum economic performance.

## PROCESS DESCRIPTION

### Single Column Distillation

**Figure 3** shows the possible separation alternatives to recover BDO. Single distillation bypasses the SMB and sends the broth directly to the column. This process operates under mild vacuum (0.1-0.5 bar) to prevent high temperatures that could lead to side reactions and sugar degradation. A tray efficiency of 80% was assumed and the number of theoretical stages was fixed at 20. This number was found to offer an optimal balance between capital and operating costs through a sensitivity analysis of the total annualized cost.

**Figure 3.** High level process diagram of the proposed BDO separation alternatives: a) single distillation column and b) SMB + distillation

Water primarily exits the condenser as distillate, while BDO is recovered from the bottoms. The broth impurities leave the column through either the distillate or bottoms, depending on the volatility. Organic acids (malic, lactic and acetic) and inorganic ions (Cl<sup>-</sup> and SO<sub>4</sub><sup>2-</sup>) are recovered from the distillate. Acetoin, glycerol, xylitol and residual sugars (arabinose, xylose and maltose) are retrieved from the bottoms. The concentration of these impurities is very small (<1%) in all streams and their presence is not expected to considerably affect the cost.

### Simulated Moving Bed + Distillation

The core of the proposed novel separation is the simulated moving bed (SMB) adsorption unit. SMB adsorption is a technology that mimics movement of solid throughout the bed by fixing the adsorbent and rotating instead the inlet and outlet ports. A 4-4-4-4 SMB is considered, where each column is packed with pure silica MFI-type zeolite, a highly hydrophobic material that is very selective towards BDO. Ethanol was chosen as the SMB desorbent. It has enough affinity with the adsorbent to efficiently displace the adsorbed BDO, and is highly volatile, facilitating its recovery via distillation. Following the SMB are two distillation columns, one to recover BDO from the extract and the other to recover ethanol from the raffinate.

A case study for PAREX [3], a well-known industry-scale SMB process, was used to guide column size (length and diameter), maximum column velocity, Peclet number and other high level operating decisions. Both distillation columns were modelled with the same approach as the single column. A tray efficiency of 50% was assumed for ethanol/water. Through a total annualized cost sensitivity analysis, 30 theoretical stages were found to offer the optimal trade-off between capital and operating costs for both columns.

## METHODOLOGY

### Physical Parameters

Figure 4 shows the stepwise approach that was followed to perform the comparative study. For either case, the first step was obtaining the key physical parameters needed to model either separation unit. For distillation, UNIQUAC was used to compute activity coefficients. The ASPEN Plus V.12. database [4] was used to retrieve the interaction parameters of the binary pairs. These coefficients are based on experimental vapor liquid equilibrium (VLE) data. This database was also used to retrieve the coefficients needed to calculate vapor pressure, heat capacity and reference enthalpy of each component.

For adsorption, a linear driving force (LDF) assumption was used to model the mass transfer from the bulk liquid into the solid adsorbent. The equilibrium in the adsorbent was represented with a Mixed Linear + Langmuir (MLL) isotherm. The relevant parameters are then the apparent mass transfer coefficient,  $K_{app,i}$  Henry's linear constant,  $H_i$  saturation capacity,  $q_{m,i}$ , and Langmuir's affinity,  $K_i$  where  $i$  represents each component. These parameters were obtained by fitting experimental data of a lab-scale SMB pilot plant.

### Mathematical Models

Next, the obtained parameters were used to solve the mathematical equations that represent each system. Distillation was rigorously modeled, meaning mass and energy balances were performed in each stage, while

enforcing phase equilibrium for each component. For adsorption, the mass balance, the convection-diffusion equation was used with axial dispersion values estimates from the Peclet number. It was assumed that the SMB stayed constant at 50°C, as this was the temperature of the pilot-plant experiments. The boundary conditions, flow balances at each node and enforcement of cyclic steady state (CSS) conditions constitute the remainder of the SMB equations.

This led to a system of partial differential algebraic equations (PDAEs) that were modelled as a non-linear programming (NLP) problem. Pyomo.DAE 6.5. [5] was used to discretize the PDAEs and the system was solved using Ipopt 3.12.13 [6].

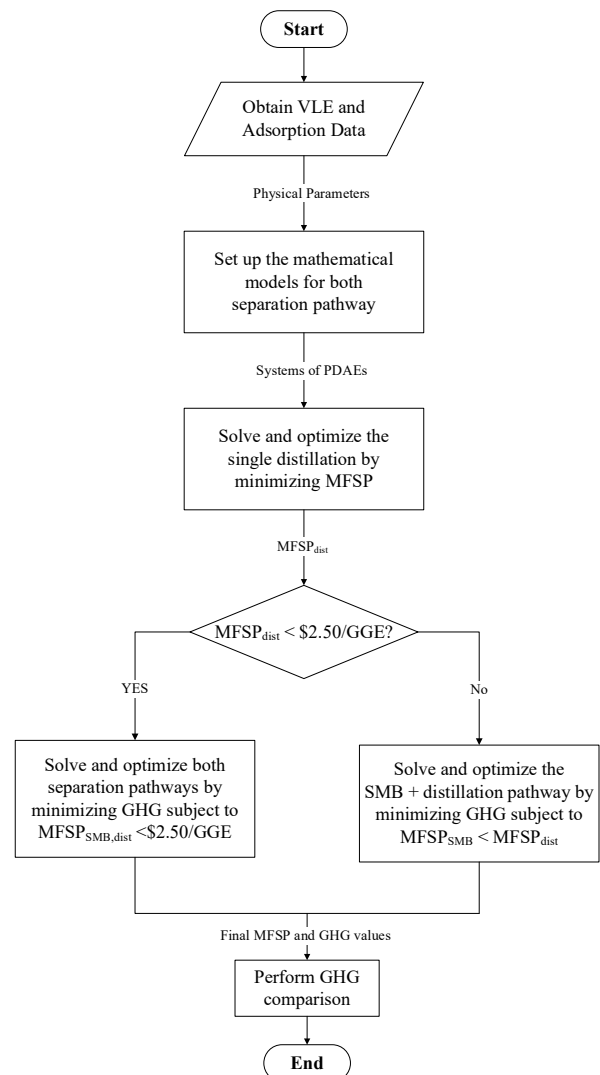

Figure 4. Proposed stepwise approach to develop the comparative study between separation pathways

### Economic Analysis

### Separation Scheme

After solving the PDAEs, the resulting mass and energy balances were used to size the equipment and estimate operating expenses. The distillation columns were sized as tray towers under vacuum conditions. The columns had constant diameter, which was estimated using a correlation based on internal vapor flow. A stage spacing of 1.5 ft was assumed. For SMB, each adsorption column had the same fixed diameter of 4m. This value is in accordance with other large-scale SMB designs found in literature [7,8]. The length of the columns was set as a free variable to be determined from the optimization. After sizing, the columns of distillation and SMB were both costed as empty vertical vessels [9].

The condensers and reboilers were sized as shell-and-tube heat exchangers. The area was estimated assuming counter-current operation and a constant overall heat transfer coefficient. A single stage liquid-ring pump was used to generate vacuum in the distillation columns and centrifugal pumps were used for pressure rise. All aforementioned correlations for purchased and installed costs were obtained from Seider et al. [9], except for the rotary valve, which was obtained from a case study of a large-scale petrochemical plant [10].

Besides utilities, which are mostly satisfied internally, the main operating expenses are related to the purchase of make-up ethanol and adsorbent. The unit cost of adsorbent was based on the cost of its synthesis raw materials. This cost was scaled to the biorefinery level using the six-tenths factor rule. The obtained price was \$20/kg and a replacement time of 5 years was assumed. Given the discrepancy in size between the lab bench and the biorefinery, there is an inherent degree of uncertainty in these values that could be addressed through sensitivity analysis. However, this was considered outside of the scope of this work.

Next, the “Discounted Cash Flow Analysis” model from NREL [11] was implemented in the NLP problem. This model is based on U.S. Department of Energy (DOE) recommendations for renewable energy systems. It includes values for interest rate, equity, depreciation, plant lifetime and taxes. The most important metric from the model is the minimum fuel selling price (MFSP) of the fuel. This is a key metric used to assess the viability of biofuels. DOE has set a MFSP target of \$2.50/GGE (gallon of gasoline equivalent) or less to be reached by 2030. With the current assumptions, the SOT reaches a MFSP value of \$2.47/GGE.

### Utilities of the Biorefinery

As mentioned, the main effect of BDO separation is reducing operating expenses of the biorefinery. Most notably, the broth is raised to 250°C and 60 atm prior to the dehydration reactor, and by removing water and reducing the BDO stream size, the energy load also significantly decreases. This saves around 90% of the high-

pressure steam (HPS) internally produced, which can instead be used to generate additional power in the turbine and reduce imported electricity. Altogether, this leads to a power output of 32.9 MW and a ~50% import reduction from the grid compared to the SOT. This value was corroborated by Liu et al. [12] in a previous study.

Next, heat duties associated with the separation scheme were considered. The distillation reboilers are the main consumers of energy in either pathway. These columns use low-pressure steam (LPS), which requires withdrawal from the turbine system. Without changes to the existing design, this withdrawal would reduce the turbine’s power output. Thus, as a simplification, natural gas is imported in order to generate additional steam needed to meet these duties and still maintain the turbine output of 32.9 MW.

### Greenhouse Gas Emissions System Boundary

The fuel’s lifecycle analysis was then considered, with GHG emissions (in  $g_{CO_2e}/MJ_{fuel}$ ) as the key metric. A technical report in 2020 was developed by the Argonne National Lab (ANL) [13], where the SOT’s well-to-wheel emissions were calculated. The system boundary in this report encompasses all processes between the corn stover collection in the field and the production of fuel and co-product from the biorefinery. The functional unit of the system is a GGE of fuel.

For this study GHGs were estimated using the displacement method. Through this method lifecycle emissions are attributed entirely to the fuel and none to the co-product. The fuel, however, receives credit for the emissions associated with the co-product’s conventional fossil pathway. This remains consistent with the economic model of the SOT, where adipic acid production revenue is credited to the fuel’s MFSP. The ANL 2020 report was used as a guideline and the GREET tool [14] was used to develop expressions for GHG emissions. The reader is encouraged to read this report for more details regarding the lifecycle assumptions.

### Optimization

Below are the expressions of the NLP problem. Pyomo and Ipopt were also used for the optimization.

$$\begin{aligned} \min_{\mathbf{x}} \quad & \mathbf{y} \\ \text{s.t.} \quad & \mathbf{f}(\mathbf{u}, \mathbf{x};) = \mathbf{0} \\ & \mathbf{g}(\mathbf{u}, \mathbf{x};) \geq \mathbf{0} \\ & \mathbf{y} = \mathbf{h}(\mathbf{u}, \mathbf{x}; \theta) \\ & \mathbf{x}_{min} \leq \mathbf{x} \leq \mathbf{x}_{max} \end{aligned}$$

The objective function  $\mathbf{y}$  can be either MFSP or GHG minimization. The equality constraints,  $\mathbf{f}$ , are represented by the system of PDAEs and the discounted cash flow model. The only inequality constraints,  $\mathbf{g}$ , in this problem are the maximum allowable MFSP and minimum BDO purity post-distillation. The main decision variables,  $\mathbf{x}$ , of the SMB are the length of each adsorption column, the

velocity in each zone and step time. For distillation variables are pressure, reflux ratio and reboiler duty. With appropriate initialization, the stage location of each feed stream can also be determined without resorting to MINLP. The state variables are represented by  $u$  and the physical parameters by  $\theta$ .

## RESULTS

### Baseline GHG Emissions

Using GREET and the displacement method, it was found that the lifecycle GHG of the SOT's fuel product is 23.0 g<sub>CO<sub>2e</sub>}/MJ. From this value 121.4 g<sub>CO<sub>2e</sub>}/MJ is attributed to the fuel and 98.4 g<sub>CO<sub>2e</sub>}/MJ is credit from producing adipic acid. This represents a significant decrease from 93.0 g<sub>CO<sub>2e</sub>}/MJ for petroleum-derived diesel [14]. It should be noted that we assumed a carbon footprint of adipic acid (AA) of 4.3 kg<sub>CO<sub>2e</sub>}/kg<sub>AA</sub>. This does not consider GHG-100 emissions from nitrous oxide (N<sub>2</sub>O) and is a more conservative estimate than the ANL 2020 report, which assumed 11.6 kg<sub>CO<sub>2e</sub>}/kg<sub>AA</sub> and led to net emissions of -148 g<sub>CO<sub>2e</sub>}/MJ for the SOT.</sub></sub></sub></sub></sub></sub></sub>

Next, an expression was developed to relate GHG with the relevant mass and energy flows (natural gas import and make-up ethanol). First, GHG emissions were re-calculated based on the updated grid electricity import. As mentioned, turbine output increases from 11.8 MW to 32.9 MW, reducing import from 41.5 MW to 20.4 MW. This resulted in 103.3 g<sub>CO<sub>2e</sub>}/MJ attributed to fuel and after considering adipic acid credit, a net value of 4.9 g<sub>CO<sub>2e</sub>}/MJ was obtained. Then, natural gas (NG) and make-up ethanol (EtOH) import were varied in GREET to estimate how GHG changes, resulting in the following linear expression:</sub></sub>

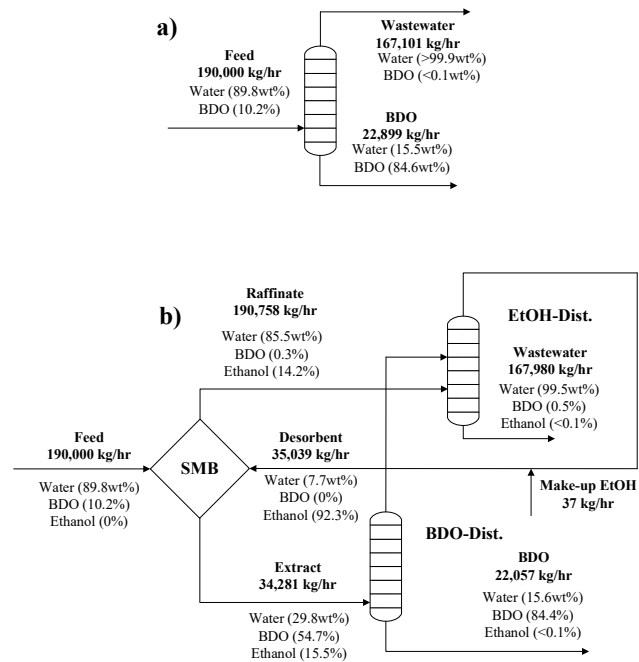

$$GHG = 4.9 \times \frac{1}{R} + 0.1362 \times NG + 0.0023 \times EtOH \quad (1)$$

R represents BDO recovery. This ranges from 0 to 1 and serves as a scaling factor to make-up for BDO lost during separation. GHG is expressed in g<sub>CO<sub>2e</sub>}/MJ, NG in MMBTU/hr and EtOH in kg/hr. This was the expression used in the objective function for minimizing GHG. It should be clarified that NG and EtOH are the added imports that result from incorporating the separation to the biorefinery. Natural gas (58 MMBTU/hr) and ethanol (37 kg/hr) are both imported in the SOT, but those are already accounted in the 4.9 g<sub>CO<sub>2e</sub>}/MJ calculation.</sub></sub>

### Approach Implementation

The proposed approach was implemented and for both pathways, the binary feed is 10wt% BDO (~100g/L titer), while the minimum purity requirement of the exit stream is 85 wt% BDO. **Figure 5a** shows the mass balances of the optimal configuration of the single distillation pathway. This configuration achieved a MFSP<sub>dist</sub> of \$2.54/GGE. **Figure 5b** shows the obtained optimal

configuration for the SMB pathway. This configuration was obtained with a MFSP<sub>SMB</sub> <= \$2.54/GGE constraint.

**Figure 5.** Resulting optimal process designs of: a) the single distillation column and b) SMB + distillation

The optimization problems were solved using the true moving bed (TMB) approximation model for the SMB and an IPOPT convergence tolerance of  $1 \times 10^{-3}$ . It should also be noted that the distillate of the EtOH-dist column is ~92 wt% ethanol. Thus, the ethanol/water azeotrope at this vacuum pressure (~96 wt%) is not expected to be encountered.

### Comparison of the Proposed Pathways

**Table 1** shows the comparison between the distillation columns for both pathways. As seen the most significant difference is the duty of the reboiler and condenser units for each pathway. Most notably, it is shown that the combined reboiler duty from the two columns in the SMB pathway is much lower than single distillation. This further establishes adsorption as a far more effective separation alternative in this context.

In all cases a lower boundary of 0.10 bar was imposed to the column pressure. For single distillation, the optimal pressure was slightly higher at 0.22 bar, since this raises the temperature of the wastewater from the tops, which was used for heat integration with the feed.

**Table 1.** Results operating conditions of the single distillation, and BDO and EtOH recovery columns

Distillation Column	Single Dist.	BDO Dist.	EtOH Dist.
Number of Stages	20	30	30
Feed Stage(s)	19	29	10/18
Pressure (bar)	0.22	0.10	0.30
Reflux Ratio (mole)	0.06	0.02	1.77
Reboiler Duty (MW)	118.2	6.5	24.3
Condenser Duty (MW)	116.2	6.2	26.5

**Table 2** shows the comparison between the alternatives evaluated in this study. The ideal separation represents the SOT with BDO recovery, but without incurring in capital or operating costs yet (i.e., the maximum potential of BDO separation [12]).

**Table 2.** Results operating conditions of the single distillation, and BDO and EtOH recovery columns

Process	SOT	Ideal Sep.	Single Dist.	SMB+ Dist.
Natural Gas Import (MMBTU/hr)	58	58	379	174
Grid Import (MW)	41.5	20.4	20.4	20.4
MFSP (\$/GGE)	2.47	2.11	2.54	2.54
GHG (gCO <sub>2e</sub> /MJ)	23.0	4.9	48.7	20.5

Single distillation, as expected, had poor economic and sustainability performance. Its large MFSP and GHG values render the entire process unfeasible, and thus, simple distillation cannot be considered a viable alternative to recover BDO in this biorefinery. In comparison, SMB+distillation gave lower GHG, demonstrating the effectiveness of the proposed hybrid separation and its potential to be incorporated in the biorefinery.

### Sensitivity Analyses

In the proposed approach, either MFSP or GHG is minimized, but not both simultaneously. This does not provide a complete outlook and Pareto fronts were built to allow a more thorough comparison. **Figure 6** shows the Pareto optimal curves for the single distillation and SMB processes. In the case of single distillation, the leftmost point represents the result from minimizing MFSP without GHG restriction, while the rightmost point is the minimization of GHG without MFSP restrictions.

For the SMB process, the leftmost point is also MFSP minimization without GHG constraint. However, the rightmost end is not bounded, given that the SMB can be as large as needed. This indefinitely increases the quantity of adsorbent, decreasing desorbent use and energy load. Thus, GHG also decrease indefinitely but at the expense of a prohibitive adsorbent purchasing cost.

**Figure 6.** Pareto Fronts of the Separation Alternatives

It should be noted, that for either front, GHG is not very sensitive to the MFSP. The most important observation, however, is that the SMB-process can improve the SOT's economic and sustainability performance. As shown, for any MFSP under \$2.47/GGE, GHG remains below 23 gCO<sub>2e</sub>/MJ, proving again the viability of this separation alternative.

Finally, a sensitivity analysis was developed by varying BDO titer. The fermentation in the SOT is an ongoing research topic and is not clear that a titer of 100g/L is optimal for the overall flowsheet. **Figure 7** shows the effect of BDO titer on GHG and MFSP by applying the proposed approach. As seen, GHG emissions of single distillation considerably increase with decrease in titer. This is an expected result, given that a large and dilute stream leads to a higher energy demand that increases both GHG and MFSP.

**Figure 7.** Effect of BDO titer concentration on the GHG emissions for both separation pathways (the annotated values represent the MFSP at each point in \$/GGE)

Remarkably, however, the change of GHG emissions in SMB is almost negligible. To understand this better we can further explore the 75 g/L titer point. After optimizing the NLP problem with GHG as the objective function, the obtained MFSP is \$2.69/GGE, and the quantity of adsorbent is 1392 tonnes. However, the at this titer level MFSP minimization gives \$2.46/GGE, and a much lower

adsorbent quantity of 342 tonnes. Implementing a very large quantity of adsorbent is clearly a suboptimal economic decision, but it greatly reduces desorbent use and energy duties, all of which help improve GHG. Thus, SMB size is allowed to increase almost indefinitely in order to accommodate varying titers, and only marginal changes in GHG are observed.

## CONCLUSIONS

A comparative study was performed between two separation technologies to recover BDO from a fermentation broth. Single distillation was compared to a novel SMB+distillation separation scheme on the basis of GHG emissions. Both separations were incorporated in a biorefinery design developed by NREL that produces renewable fuels with corn stover as feedstock and dilute (10wt%) BDO as an intermediate.

The comparison was done by following a stepwise optimization approach where GHG is minimized. The resulting design achieved GHG emissions of 20 g<sub>CO<sub>2e</sub></sub>/MJ for SMB+distillation, lower than 48 g<sub>CO<sub>2e</sub></sub>/MJ for single distillation and 93 g<sub>CO<sub>2e</sub></sub>/MJ for petroleum fuel.

The effect of BDO fermentation titer was also considered. As expected, for single distillation, decreasing titer significantly increased energy consumption and, thus, worsened MFSP and GHG emissions. However, for SMB, the GHG emissions were not sensitive to titer.

## ABSTRACT

In this paper, we study the design optimization of methanol production with the goal of minimizing methanol production cost. One challenge of methanol production via carbon dioxide (CO<sub>2</sub>) hydrogenation is the reduction of operating costs. The simulation of methanol production is implemented within the Aspen HYSYS simulator. The feeds are pure hydrogen and captured CO<sub>2</sub>. The process simulation involves a single reactor and incorporates recycling at a ratio of 0.995. The methanol production cost is determined using an economic analysis. The cost includes capital and operating costs, which are determined through the equations and data from the capital equipment-costing program. The decision variables are the pressure and temperature of the reactor contents. The optimization problem is solved using a derivative-free algorithm, pyBOUND, a Python-based black-box model optimization algorithm that uses random forests (RFs) and multivariate adaptive regression splines (MARS). The predicted minimum methanol production cost by pyBOUND is \$1396.56 per tonne of methanol, which corresponds to the pressure of 68.82 bar and temperature of 192.23°C while the actual cost is \$1393.95 per tonne of methanol at these conditions. The cost breakdown of methanol production is 75% hydrogen price, 11% utility cost, 8% capital cost, 5% carbon dioxide price, and 1% operating cost.

## INTRODUCTION

Methanol is utilized as a feedstock for power generation, transportation fuel, and wastewater treatment, as well as for producing various value-added chemicals [1]. Methanol is environmentally friendly, and the use of methanol has lower risks, lower emissions, and higher performance than gasoline [2]. The data from the methanol market indicate that the methanol market is expected to be worth \$38.0 billion by 2028, growing at a compound annual growth rate of 4.2% during the forecast period [3]. Formaldehyde production from methanol is expected to be the largest demand in the forecasted period [3].

Methanol can be produced by two main processes: methanol from syngas and methanol from CO<sub>2</sub> hydrogenation. Traditionally, methanol is produced from syngas. The first commercial methanol plant was established in 1923 by BASF. Conventionally, methanol is produced

from petroleum products via hydrogenation of CO and CO<sub>2</sub> and reverse water gas shift reaction. In the commercial production of methanol from syngas, a catalyst known as CuO/ZnO/Al<sub>2</sub>O<sub>3</sub> is widely employed [4-5]. The choice of copper-based catalysts for converting CO<sub>2</sub> to methanol is primarily driven by their affordability and high catalyst activity [6]. Nowadays, 80% of worldwide methanol is produced from natural gas [7].

Finding new and more sustainable energy sources is crucial to address the environmental crisis caused by the widespread use of fossil fuels. The largest source of CO<sub>2</sub> emissions among human activities that contribute to greenhouse gases (GHGs) is burning fuels for power and heat, accounting for more than 42% of the estimated anthropogenic CO<sub>2</sub> emissions [8]. Carbon capture utilization and storage is the most common technique to reduce anthropogenic CO<sub>2</sub> emissions. Methanol production from CO<sub>2</sub> hydrogenation (using CO<sub>2</sub> captured and pure hydrogen) is considered an important route to reduce CO<sub>2</sub>

emissions [9]. The impact of direct CO<sub>2</sub> hydrogenation to methanol on the environment is lower than production of methanol from syngas [10]. Many studies focus on the optimization of CO<sub>2</sub> hydrogenation process and present various heat integration within the methanol conversion unit [11-12]. Yousaf et al. summarized computational studies on techno-economic analysis of CO<sub>2</sub> hydrogenation [13]. Most studies on the methanol production design using capture CO<sub>2</sub> and pure hydrogen attempt to reduce the production cost due to the high hydrogen price.

We optimize methanol production via CO<sub>2</sub> hydrogenation in this work. The goal is to minimize the methanol production cost by adjusting the pressure and temperature of the reactor contents. The hydrogenation process is in Aspen HYSYS, and the optimization problem is solved using pyBOUND, a Python-based black-box optimization algorithm using random forests [14]. The paper is organized as follows: The next section provides an overview of the general pyBOUND framework. The Case study section provides information on the simulation and economic analysis of the CO<sub>2</sub> hydrogenation process. The optimization formulation section describes an objective function and constraints of the case study. The Results and Discussion section presents the optimum operating conditions and costs. Our concluding remarks and future directions are summarized in the last section.

## A PYTHON-BASED BLACK-BOX OPTIMIZATION USING RANDOM FORESTS, PYBOUND [14]

pyBOUND is a two-stage algorithm. The first stage employs random forests (RFs) and generates better decision variable bounds, shrinking the search space. The second stage refines the solution using multivariate adaptive regression splines (MARS). A general pyBOUND framework is depicted in Figure 1.

### pyBOUND Stage 1: Shrinking the Search space using RFs

For the first stage, the algorithm reduces the size of the original search space by solving a series of global deterministic subproblems using RF models. This stage consists of sampling, construction of an RF model, global optimization of the constrained approximation problem, and collection of new sampling points. The initial data set is generated using a Sobol sequence design. The overall constrained approximation model, which consists of the RFs model objective equation, the RF model constraints, and variable bounds, is solved to optimality using deterministic global optimization methods. The decision variable bounds are generated from the solution of the constrained approximation optimization problem. The constrained approximation models with the RF models are

MILPs, which are solved with CPLEX (version 22.1.1).

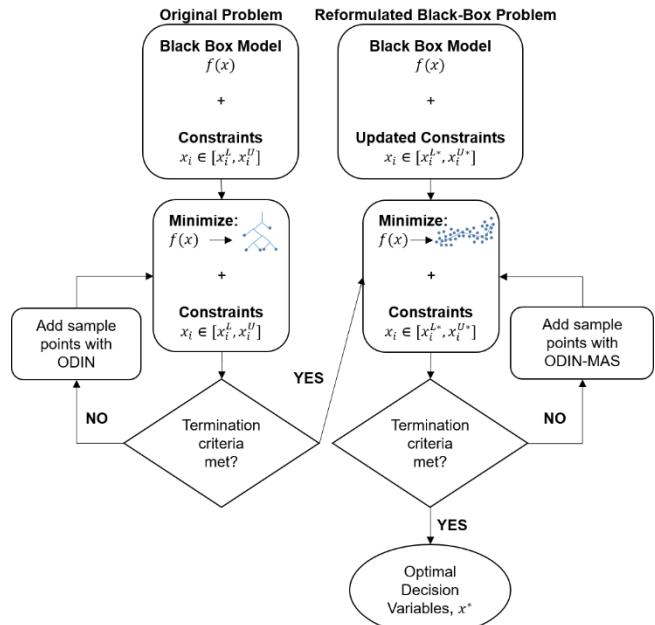

Figure 1. General pyBOUND framework [14].

The algorithm determines a single set of bounds based on the threshold bounds given by every RF tree. The three methods for reducing variable bounds called the cutting methods were studied for bounds reduction. The methods are selecting the widest set of bounds (Wide), selecting the bounds where at least two trees intersect each other (Intersection), and averaging the bounds given by each tree for a single set of bounds (Average). The “Intersection” cutting method is selected for optimization problems with less than ten decision variables, and the “Average” cutting method is selected and implemented for problems with ten or more decision variables.

The ODIN sampling method [15] is selected to update the RF model training set with a termination criterion that depends on the size of the decision variable vector and maximum reduction in the search space.

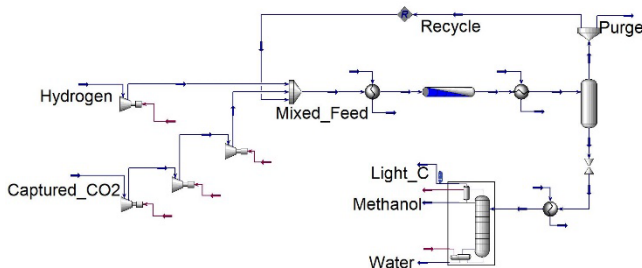

### pyBOUND Stage 2: Refinement of Solution using MARS Models

This stage refines the solution with a local search in the reduced search space, constructs the model, and improves the model with adaptive sampling. Based on the final form of the trained MARS surrogate model, a deterministic optimization problem is formulated and solved to refine the solution. MARS models result in MINLP optimization models, which are solved with ANTIGONE [16]. New sample points are added in the second stage using adaptive sampling on a hybrid of the ODIN sampling method and Mixed Adaptive Sampling (MAS) [17], referred to as ODIN-MAS [15].

## CASE STUDY: METHANOL PRODUCTION

### Process Simulation

The process flow diagram for methanol production implemented within the Aspen HYSYS simulator (version 14) is depicted in Figure 2. The feeds of the process are pure hydrogen and captured CO<sub>2</sub> with a molar flow rate of 3000 kmoles per hour and 1000 kmoles per hour, respectively. Pure hydrogen is fed at 30 bar and 25°C and then compressed to the desired pressure. Captured CO<sub>2</sub> is fed at 2 bar and 28°C through the three-stage compressors to increase pressure before being combined with pure hydrogen. The mixed feed is heated up and enters the reactor, which is modeled as a plug flow reactor and catalytic reaction. The reactions of methanol production via CO<sub>2</sub> hydrogenation follows Equations (1) – (3). The reactor is simulated using a kinetic model [18]. After that, the stream of produced methanol and unreacted feed enters the cooler before it is separated. The vapor stream is recycled and purged with a 0.995 recycle ratio. The liquid phase stream is sent to the distillation column after cooling. The specifications of the distillation column are a 1.52 reflux ratio and 40°C of distillate temperature. The methanol product purity is specified at 99.1% by weight.

**Figure 2.** Methanol production via CO<sub>2</sub> hydrogenation.

### Economic Evaluation

The methanol production cost is determined using an economic analysis. The cost includes both capital and operating costs. These costs are determined through the equations and data from the capital equipment-costing program [19]. The data was adjusted for inflation from the year 2001-2023 by using values of the Chemical Engineering Plant Cost Index, CEPCI. The value of CEPCI in 2001 and 2023 is 297 and 799.1, respectively [20]. The capital cost is calculated using the costing technique. This technique depends on the specific equipment type, the specific system pressure, and the specific material of

construction. In this work, the equipment costs are estimated based on gross root cost ( $C_{GR}$ ), which involves total module cost ( $C_{TM}$ ), Equations (4)-(5), where  $n$  represents the total number of equipment, and bare module cost ( $C_{BM}$ ), Equation (6).  $F_M$  and  $F_p$  are the material factor and pressure factor, respectively.

$$C_{GR} = C_{TM} + 0.50 \sum_{i=1}^n C_{BM,i}^0 \quad (4)$$

$$C_{TM} = \sum_{i=1}^n C_{TM,i} + 1.18 \sum_{i=1}^n C_{BM,i} \quad (5)$$

$$C_{BM} = C_p^0 F_{BM} = C_p^0 [B_1 + B_2 F_p F_M] \quad (6)$$

where  $C_p^0$  is the purchased cost for a base condition which can be calculated following Equation (7).

$$\log_{10} C_p^0 = K_1 + K_2 \log_{10}(A) + C_3 (\log_{10}(A))^2 \quad (7)$$

$A$  is the capacity or size parameter for the equipment. The overall assumptions used for the cost estimation are as follows:

- The plant operates for 8400 hours per year.
- The plant is expected to have 20 years of plant operation and a 10% interest rate.
- Direct supervisory and clerical labor are taken 18% of labor cost.
- Maintenance and repairs are taken 6% of the fixed capital investment.
- Operating supplies are taken 0.9% of the fixed capital investment.
- Laboratory charges are taken 15% of labor cost.
- Local taxes and insurance are taken at 3.2% of the fixed capital investment.
- Plant overhead cost is the summation of 70.8% of labor cost and 3.6% of the fixed capital investment.
- Administration cost is the summation of 17.7% of labor cost and 0.9% of the fixed capital cost.

### OPTIMIZATION FORMULATION

We consider the methanol production via CO<sub>2</sub> hydrogenation as a black-box optimization problem of the form given in Equations (8)-(9),

$$\min_x f(x) \quad (8)$$

$$\text{subject to } x_i \in [x_i^L, x_i^U] \quad \forall i \in \{1,2\} \quad (9)$$

The objective of the optimization problem is to minimize the methanol production cost where  $f(x)$  represents the methanol production cost with the decision

variables of the process with finite bounds  $[x_i^L, x_i^U]$ ,  $x_i$  represents the decision variables:  $x_1$  is the pressure and  $x_2$  is the temperature of the reactor contents. The range of each decision variable is given in Table 1.

**Table 1:** Initial range of decision variables.

Decision variables	Lower bound	Upper bound
Pressure (bar)	50	80
Temperature (°C)	190	210

## RESULTS AND DISCUSSION

The goal is to minimize methanol production cost by applying a derivative-free optimization algorithm, pyBOUND. From the results of the RF stage, the “Intersection” cutting method is used to shrink the search space of the optimization problem. The results at each iteration of the RF stage are shown in Table 2.

**Table 2:** The reduction of search space.

Iteration	1	2	3
Volume of reduction (%)	53.13	72.90	80.13
Number of sample points	20	15	15
Lower bound	50, 190	62.66, 190	62.66, 190
Upper bound	80, 199.38	80, 199.38	80, 196.88

The criterion for the termination of the RF stage is specified as the maximum volume reduction of search space of 0.75. The bound of the pressure is reduced to the range 62.66 – 80 bar and the bound for temperature is reduced to the range 190 – 196.88°C. Eighty percent of the search space is reduced compared to the original search space. The third row of Table 2 shows the number of sample points. Originally, the number of sample points was generated with ten times the number of decision variables (20 sample points). After applying pyBOUND, the final number of sample points in the RF stage is 15, while the number of function evaluations is 30, which is due to some sample points being cut during the RF stage iterations. Fifteen sample points are then used as the initial sample set for the MARS stage.

The results of the MARS stage at each iteration are shown in Table 3. Figure 3 also shows the results of the predicted, actual, and best methanol production cost at each iteration. The best methanol production cost is the lowest cost in the training data set. In the MARS stage, the sample points are added at each iteration using ODIN-MAS algorithm. The pyBOUND algorithm stopped at 144 sample points while the R-squared value of the

model increased after increasing the number of sample points. For the first iteration, the model can not fit well with only twenty sample points. The value of R-squared at the first iteration shows a negative value. At the second iteration, the total number of sample points used to construct the MARS model increased to 37, and the value of R-squared is a positive value.

**Table 3:** MARS model and optimal results

Iteration	Function evaluation	R-squared	Predicted optimum location (bar, °C)
1	20	-0.05	68.84, 192.26
2	37	0.26	68.80, 192.34
3	58	0.50	68.68, 192.24
4	90	0.86	72.51, 192.32
5	144	0.88	68.82, 192.23

**Figure 3.** The values of minimum methanol production cost at each iteration.

The predicted methanol production costs at each iteration are close to the actual methanol production costs. Finally, the pyBOUND algorithm stopped with the criteria of R-squared value more than 0.6 and the Euclidean distance between the best objective values of the last three iterations less than 0.0004. The error between predicted and actual methanol production costs is 0.19%. The optimum methanol production cost is \$1396.56 per tonne of methanol, corresponding to a pressure of 68.82 bar and a temperature of 190.23°C, while the actual methanol production cost at these conditions is \$1393.95 per tonne of methanol. We found that the best objective value is \$1393.80 per tonne of methanol. This value is close to the actual objective value and the best location is similar to the predicted optimal location. The Euclidean distance between the best and actual objective values is 0.02 at the last iteration. The algorithm run time is 458.5 min, which is divided into 79.92 min for the RF stage and 378.58 min for the MARS stage. From the total run time, the time for pyBOUND is 17.32 min, with the remaining

time spent by Aspen HYSYS process simulation.

At the optimum, the contribution of various factors to the cost is illustrated in Figure 4. The contribution of raw materials, including CO<sub>2</sub> and H<sub>2</sub> prices, are 5% and 75%, respectively. The utilities make up 11% of the overall cost. The capital and other operating expenses are 7% and 1%, respectively. The H<sub>2</sub> price is identified to be the major cost of this process.

**Figure 4.** Cost breakdown.

## CONCLUSION AND FUTURE WORK

The pyBOUND algorithm has been successfully applied to the optimization of methanol production via CO<sub>2</sub> hydrogenation process. The minimum cost of methanol production is determined. The algorithm, pyBOUND, demonstrates that the algorithm can estimate the optimum value of the methanol production cost with a small number of sample points. Future work on pyBOUND will focus on applying the algorithm to problems with high number of decision variables and several chemical engineering problems. The optimum value obtained by pyBOUND is comparable to other optimization methods. pyBOUND might exhibit improvements when compared to existing algorithms for both high dimensionality problems and for locating the true optimal decision variable values. We will consider the hyperparameters of the RF stage for consistency of generating variable bounds and investigate the impact of the stopping criteria of the pyBOUND algorithm.

## ABSTRACT

One of the main challenges to support life in space is the development of sustainable, circular processes that reduce the high cost of resupply missions. Space biomanufacturing is an emerging paradigm that aims to reduce the need for resources, enabling on-demand manufacture of products. The cost of installing biomanufacturing systems in space depends on the cost of transporting the system components, which is directly proportional to their mass/weight. From this perspective, the system mass is a critical factor that dictates process design, and this has important implications in how we can approach such design. For instance, mass constraints require circular use of resources and tight process integration (to minimize resupply) and restricts the type of resources and equipment needed. In this work, we evaluate the lactic acid bioproduction design using *Escherichia coli*, *Saccharomyces cerevisiae*, and *Pichia pastoris*. We use the Equivalent System Mass (ESM) metric as a key design measure. ESM allows the quantification of different physical properties of the system in a common mass basis. Our analysis reveals that 97.7 kg/year of lactic acid can be produced using *Saccharomyces cerevisiae* in a 10 L stainless steel fermenter. Furthermore, considering that stainless steel is the design material and quantifying the mass of 1 g/cm<sup>2</sup> of shielding material, the total system mass was 19 kg. This modeling framework also identified the critical system elements responsible for the highest system mass and launch cost. Overall, our analysis reveals how focusing on system mass can bring new design perspectives that can aid the design of traditional manufacturing systems.

## INTRODUCTION

Since 2000, the International Space Station (ISS) has served as a research laboratory in low Earth orbit, supporting several research studies in different scientific fields [1]. During these years, space-based research that study systems under unique, non-terrestrial conditions have produced strong impacts and diverse technological and social benefits. However, the cost of supporting the ISS is still an important factor that influences the development of new projects. The ISS Program's annual budget is about \$3 billion, of which, \$1.8 billion is related to the transportation of crew and cargo services making this the most expensive element of the program [2]. This is mainly because fuel is the dominant cost of space missions [3], and although lower launch costs have been

achieved in recent years, the current price for *delivering one kilogram* of cargo to low Earth orbit *is approximately \$10,000*, which is a high transportation cost [4]. Therefore, one of the main challenges in current space research is to create sustainable, closed-loop (circular) systems for future long-space duration missions to reduce the need for resupply missions.

Water, oxygen, energy, and food are some essential resources to sustain life in space but launch capacity for the ISS is approximately 1 ton of water [5]. Consequently, there is a need for flexible and low-cost space manufacturing processes that enable on-site production of essential chemicals and resources [6]. Over the past few years, research has been carried out to develop advanced technologies that convert human waste and local resources into pure consumables to satisfy the capacity

launch limitations and reduce the high cost of resupply missions. In this regard, in-situ resource utilization has offered new possibilities to develop circular processes that allow for the on-demand production of value-added chemicals and materials for the construction, maintenance, and repair of mission systems [7]. This is crucial in space exploration, because long-duration space missions require circular systems that are capable of manufacturing their essential items [8]. Furthermore, biomanufacturing is a promising approach to support sustainable and circular systems for space exploration [9]. This relies on the use of biological systems that are engineered to produce and manufacture value-added products and objects on demand. Hence, biomanufacturing is a convenient alternative to design systems in remote locations or where supply chains for consumables cannot operate reliably [10].

The use of biomanufacturing in space has diverse applications. Significant research has focused on regenerative medicine applications (e.g., tissue engineering and disease modeling) [11]. Lately, the production of nutrients and food through biomanufacturing has been crucial to support life in space. These studies have focused solely on technical and operational features, without considering transportation cost restrictions (which are critical to implement systems in space).

The traditional paradigm for process design is objective-driven, in the sense that the system is engineered to maximize/minimize specific performance goals. When designing a system in space, however, the mass/size of the system is a critical factor that takes priority due to strict limitations of transportation and resources. As such, the design of space systems is *constraint-driven*. Moreover, space systems are subject to disturbances/externalities (e.g., gravity and cosmic radiation) that pose non-obvious and often unknown constraints. For instance, the fermentation reactor (a key component of a biomanufacturing system), is strongly affected by storage conditions, gravity, and radiation, which can affect the performance and survival of microorganisms employed to produce value-added products.

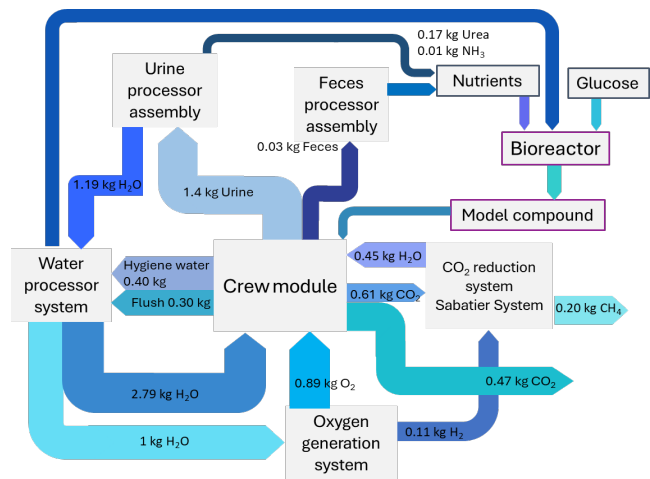

Considering this, new approaches are needed to support the design of biomanufacturing systems that consider both operational restrictions and mass restrictions. One approach to solve this problem involves the use of the Equivalent Systems Mass (ESM) analysis. ESM is a metric that allows the consideration of different physical resources such as power, cooling, and equipment using mass as a common unifying metric [12]. The focus on mass can reveal interesting/hidden aspects of process components; for instance, mass constraints can limit the type of energy vectors used. In this work, we present a computational design framework to evaluate the design of space biomanufacturing systems to produce lactic acid (one of the most valuable platform

chemicals) based on the mass of the system using *Escherichia coli*, *Saccharomyces cerevisiae* and *Pichia pastoris* as microorganisms. Our case study aims to evaluate different configurations for the design of biomanufacturing systems in space to identify the specific components of the system that are responsible for the highest impacts in terms of mass.

## METHODOLOGY

This work evaluates system design scenarios by quantifying system mass using different engineered organisms (*Escherichia coli*, *Saccharomyces cerevisiae*, and *Pichia pastoris*) to produce lactic acid. Lactic acid bioproduction has been widely studied on Earth because it serves as a platform chemical with diverse applications (i.e., chemical, pharmaceutical, food, cosmetics, and plastic industries) [13]. Recently, lactic acid has gained interest due to its capacity to be transformed into polylactic acid (PLA), a biodegradable polymer with applications in the production of packaging and new components through 3D printing, which is very convenient in space missions [14].

Because the performance of the biomanufacturing production may be impacted due to the high radiation levels that exist in the space environment, the addition of a shielding material could be necessary to maintain genetic stability in space fermentation systems. Therefore, these factors are considered to propose different bioprocess designs which can be coupled with the equipment of the life support system of the ISS to take advantage of the in-situ resource utilization.

**Figure 1:** Daily mass balance per crewmember in the ISS.

The life support system involves various chemical and biological processes, allowing the recycling of waste into valuable resources. In this way, the system operates in a closed-loop life support system. However, some waste resources that are not recovered (i.e., urine, fecal

feces) or are commonly vented into space (i.e., CH<sub>4</sub>, CO<sub>2</sub>) can serve as inputs in the bioproduction of lactic acid. For instance, nutrients that are required in the fermentation process can be obtained from human waste and urine. Figure 1 shows the daily mass balance per crewmember in the ISS. Commonly, there are 6 astronauts aboard the ISS, and based on this, the resources required to satisfy their basic living needs and the wastes generated can be quantified from the daily mass balance in the ISS. In this case, the available water that can be supplied to the biomanufacturing system is approximately 5 L per day. Therefore, fermentation volumes less than 5 L can use the available resources in the Life Support System to create a more circular system. Otherwise, for fermentation volumes greater than 5 L, the system will require external resources from resupply missions to be able to carry out the fermentation process. In this work, different fermentation volumes are evaluated to estimate their required mass, which is linked to the launch cost.

### Equivalent System Mass Analysis

The evaluation of a system by means of the ESM allows for the reduction of several physical quantities to a single parameter expressed in the units of mass (kilograms) for direct comparison. ESM has been employed as a transportation cost measure in studies to avoid the technical and political complications of using dollar costs for comparisons. In space missions, the cost of transporting a payload is proportional to the mass of that payload; therefore, a mass-based measure such as ESM is appropriate to quantify the launch cost of the system. In this regard, through ESM analysis, it is possible to identify which of several options can meet all specified requirements and have the lowest launch cost in relation to mass, volume, power, and cooling (Equation 1).

$$ESM = M + (P \times P_{eq}) + (C \times C_{eq}) \quad (1)$$

ESM can be calculated using Equation 1, where  $P_{eq}$  and  $C_{eq}$  are the power and cooling conversion factors (87 kg/kW and 146 kg/KW, respectively) to transform the non-mass quantities to their mass equivalent. These factors were derived by the NASA Life Support Baseline and Assumptions Document (BVAD) [15] and relates the quantity of mass and cost of installation and components per rate of power delivered. The term  $M$  refers to the mass of components that compose the system (e.g., chemicals, glass, stainless steel, polyethylene),  $P$  represents the power consumption (i.e., electrical power demand) and  $C$  is the thermal demand for rejecting from the system (Figure 2).

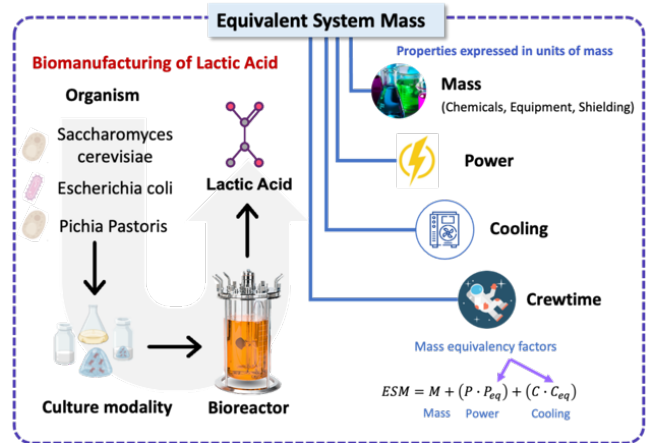

Figure 2: Equivalent System Mass framework.

In this work, the biomanufacturing system design is evaluated to compare the mass of different system designs considering the following assumptions:

- The system is composed of a spherical fermenter for the production of lactic acid.
- The materials employed for the fermenter are glass and stainless steel. The density of the stainless steel and glass are 2500 and 7500 kg/m<sup>3</sup>, respectively.
- The shielding material is polyethylene, which has a density of 930 kg/m<sup>3</sup>.
- The concentration of glucose is 200 g/L.
- In agreement with Rojdev et al. (2009) [16], the typical values for spacecraft structures have areal density thicknesses of approximately 1 to 20 g/cm<sup>2</sup>. In this work, we compared systems with 1 and 5 g/cm<sup>2</sup> areal density thicknesses.

Based on these specifications, the mass of the system involves the mass of the materials or chemicals employed in the lactic acid fermentation, the mass of the equipment and the mass of the shielding needs. The scenarios proposed for the different bioprocess design configurations labeled using the following format:

PX\_A\_B

Where X represents the volume of the fermenter in Liters, A represents the material design, which can be glass or stainless steel (G is used for glass and S represents stainless steel), and B indicates the polyethylene shielding thickness employed in the system. In this sense, some of the scenarios generated are:

- Standard scenario where shielding is not included (P10).
- Scenario with fermentation volume of 10 L using glass as the system design material and including

shielding with 1 cm of thickness (P10\_G\_1).

- Scenario with fermentation volume of 10 L using glass as system design material and including shielding with 5 cm of thickness (P10\_G\_5).
- Scenario with fermentation volume of 10 L using stainless steel as system design material and including shielding with 1 cm of thickness (P10\_S\_1).
- Scenario with a fermentation volume of 10 L using stainless steel as the system design material and including shielding with a 5 cm of thickness (P10\_S\_5).

In this work, fermentation volumes of 5, 10, 15 and 20 L were evaluated for the production of lactic acid. It is worth mentioning that the scenarios evaluated correspond to systems that are not exposed to radiation doses. However, for future work, we will evaluate how the growth of organisms is affected by different radiation doses. This can provide information on how fermentation time is impacted and how this may modify the amount of input resources needed in biomanufacturing processes.

## RESULTS

ESM analysis was performed for the production of lactic acid from glucose using *Escherichia coli*, *Saccharomyces cerevisiae* and *Pichia pastoris*. The analysis was carried out for various design configurations and production capacities.

### Equivalent System Mass

The system mass considers both the mass of the design and protection materials and the production of lactic acid, which in turn is restricted by the fermentation volume. As a result, the system mass among the different organisms is similar. Figure 3 shows the results of ESM analysis using *Escherichia coli* as the host organism for lactic acid production. The results obtained indicate that for a fermentation volume of 10 liters, the system mass is approximately 12.4 kg for a standard scenario (P10). When shielding is added to the system (P10\_G\_1), its mass increases to 14.5 kg. At a shielding of 5 cm thickness, the mass increases further to 22.8 kg (P10\_G\_5). Furthermore, it can be seen that the equipment material design plays an important role in the system mass as a three-fold increase in equipment mass is obtained when stainless steel is used.

On the other hand, if the volume of the fermenter increases to 20 L, the system mass increases to 24 kg for a standard scenario. For the scenarios P20\_S\_1 and P20\_S\_5 the mass of the system is 34 kg and 48 kg, respectively.

**Figure 3:** Equivalent System Mass Analysis for different scenarios per batch.

Results show that the mass of the system does not change significantly in terms of the organism selected for each batch fermentation system; however, the production of lactic acid is favored when *Escherichia coli* is employed as better yield is achieved. However, as can be seen in Figure 4, in a 10 L fermenter with a glucose concentration of 200 g/L, the total mass of the system using *Escherichia coli* is about 1425 kg/year. The mass of the *Saccharomyces cerevisiae* system is approximately 900 kg/year, 37% less mass than the mass required to operate a system using *Escherichia coli*. For both cases, the mass related to the equipment and shielding is negligible since represents less than 1% of the mass of the system.

### Energy

The energy required to maintain the temperature of the fermentation process to produce lactic acid in one year was evaluated. Considering that the temperature inside the ISS is approximately 23 °C, the energy requirements in terms of mass were evaluated for different fermentation volumes (1 L – 20 L) and operation temperatures (24 °C – 37 °C) (Figure 5). Once we evaluated the energy required to maintain the temperature in the bioreactor, it was multiplied by the factor 87 kg/kW to convert the units of energy into units of mass. The energy required in terms of mass is equal to the factor 0.053 kg per liter per °C for *Escherichia coli*, 0.021 for *Saccharomyces cerevisiae* and 0.01 kg per liter per °C for *Pichia pastoris*. Our findings show that for a temperature equal to 36 °C and a volume fermenter equal to 1 L, the mass per year related to the energy required in the fermentation system is equal to 0.68 kg for *Escherichia coli*; however, the mass increases to 8.48 kg for a volume equal to 20 L.

**Figure 5:** Energy in terms of mass required for the lactic acid fermentation in one year.

**Figure 6:** Annual lactic acid production projections using different organisms

**Figure 4:** Equivalent System Mass Analysis for different scenarios per year.

hosts using glucose as a substrate.

Organism	Production rate (g/l/h)	Yield (g/g)	Reference
<i>Escherichia coli</i>	2.33	0.93	[17]
<i>Saccharomyces cerevisiae</i>	2.34	0.58	[18]
<i>Pichia Pastoris</i>	0.0363	0.22	[19]

### Lactic acid Production

A sensitivity analysis was performed to evaluate the impact of productivity on the production of lactic acid using each of the organisms. Results show that according to the productivity reported for the studied organisms (Table 1), the production of lactic acid per year with *Escherichia coli* in a fermenter volume of 10 L is about 258 kg,

**Table 1:** L-lactic acid production of different microbial

and it is higher than the other organisms evaluated. In the case of *Saccharomyces cerevisiae*, the production of lactic acid is 97.7 kg per year, and using *Pichia pastoris* the production is about 37.1 kg per year. Figure 6 shows the production of lactic acid that can be achieved assuming different yield and fermentation volumes.

## Challenges and Open Questions

Addressing the design of systems under space conditions requires different perspectives and considerations that are difficult to evaluate and reproduce in terrestrial conditions. ESM is a promising tool to evaluate new systems. As a cost metric, ESM may not be capable of capturing how biological performance is impacted by different radiation levels, but it allows us to evaluate the mass of resources involved in the process at different operating conditions. Because of this, research must be carried out to understand how to optimally engineer organisms for space environments. On the other hand, additional analyses are required to identify the trade-offs between engineering hosts to have better performance in high radiation environments compared to the addition of more radiation shielding material. Moreover, other mechanisms to reduce the shielding requirements and organisms' protection against radiation (e.g., different preservation modalities) should be evaluated in the design of space bioprocess. In this regard, immobilized cell methods such as lyophilization and hydrogel systems are good alternatives to suspend cell cultures and sustain long-term metabolic processes. Therefore, for future work, this modeling framework may be complemented with biomanufacturing design alternatives that could reduce the impact of radiation. Such a study could help to better assess trade-offs between strain resistance, preservation modalities, and overall process economics.

## CONCLUSIONS

This study presented a computational design framework for the design of biomanufacturing systems in space using a mass perspective to get an estimate of the launch cost of the system. ESM has been used as a transportation cost metric that involves the principal factors that affect the performance of the biomanufacturing systems such as the mass of the equipment, and all these elements are expressed in units of mass to allow for comparisons among the different design configurations of biomanufacturing systems.

In this work, the bioproduction of lactic acid using *Escherichia coli*, *Saccharomyces cerevisiae* and *Pichia pastoris* were evaluated by considering different fermenter materials and volumes to identify the bottlenecks in the design configurations in terms of mass and yield. Our analysis reveals that lactic acid is favored when *Escherichia coli* is employed. About 258 kg of lactic acid

per year can be produced using *Escherichia coli* in a 10 L stainless steel fermenter. At a shielding material density of 1 g/cm<sup>2</sup> the total mass of the system obtained from the ESM analysis is about 19 kg. Our findings show that most of the mass of the system is related to the water required to produce lactic acid. In this regard, ESM analysis helps to identify the system components that contains greater mass and would result in high launch costs. For future work, we are interested in studying other alternatives to create closed-loop systems involving the available resources inside the ISS.

## ABSTRACT

Aiming to mitigate the environmental impact derived from fossil fuels, we propose an integrated carbon capture-biomass gasification process is proposed to produce low-carbon hydrogen as an alternative energy carrier. The process begins with the pre-treatment of empty fruit bunches (EFB), involving grinding, drying, torrefaction, and pelletization. The resulting EFB pellet is then fed into a dual gasifier, followed by a catalytic cracking of tar and water gas shift reaction to produce syngas, aiming to increase its H<sub>2</sub> to CO ratio. Subsequently, we explore two alternatives (DEPG and MEA) for syngas upgrading by removing CO<sub>2</sub>. Finally, a PSA system is modeled to obtain H<sub>2</sub> at 99.9% purity. The pre-treatment stage densifies the biomass from an initial composition (%C 46.47, %H 6.22, %O 42.25) to (%C 54.10, %H 6.09, %O 28.67). The dual gasifier operates at 800°C, using steam as a gasifying agent. The resulting syngas has a volume concentration (%CO 20.0, %CO<sub>2</sub> 28.2, %H<sub>2</sub> 42.2, %CH<sub>4</sub> 5.9). Next stages of the process focus on removing the CO<sub>2</sub> and increased H<sub>2</sub> through catalytic reactions from the syngas. Thus, the DEPG carbon capture process can decrease the CO<sub>2</sub> concentration to 2.9%, increasing the hydrogen to 95.6% in volume. In contrast, the MEA process reduces the concentration of CO<sub>2</sub> to 5.2% and increases the concentration of H<sub>2</sub> to 93.1%. Moreover, we estimate a levelized costs of hydrogen (LCOH) and carbon capture cost for each method (DEPG and MEA) (LCOC) and CO<sub>2</sub> avoided (LCCA). LCOH: 3.05 USD/kg H<sub>2</sub>, LCOC: 92 and 59 USD/t CO<sub>2</sub> and 183 and 119 USD/t CO<sub>2</sub>, for DEPG and MEA respectively.

## INTRODUCTION

In recent years, processes that generate clean energy have gained relevance in academia and industry. Due to the growing energy demand, supplied by the oil industry, there has been a constant increase in greenhouse gas emissions. It is estimated that CO<sub>2</sub> emissions generated by industries are in the order of 8 billion tons per year, it is estimated that emissions will reach 10 billion tons per year [1].

For this reason, several countries such as Japan, Australia, Germany, and most of the countries of the

European Union have committed to initiating decarbonization processes, in addition to encouraging processes that lead to a circular economy. One of the energy transition strategies consists of the use of hydrogen as an energy carrier [2]. Currently, the demand for hydrogen has undergone a significant increase from 20 MT (million tons) in 1970 to more than 70 MT by 2018 globally. Most of the hydrogen produced, comes from fossil sources with a commercial value of 1 to 3 USD per kg [3].

In the Colombian context, there is a commitment to reduce CO<sub>2</sub> emissions by 51% by 2030 by promoting the production of hydrogen from sustainable sources [4].

The thermochemical processes are one of the most

attractive alternatives in the short term to transform biomass or carbonaceous fuel, into energy and chemical products or their building blocks such as syngas. Depending on the oxygen requirements, the operating temperature and the syngas composition, the thermochemical processes can be classified into pyrolysis, gasification, and combustion [5].

Currently, the predominant transformation process for the biomass is the combustion, which accounts for approximately 90% of its worldwide utilization, generating energy ranging from a few megawatts to 100 megawatts [6]. Nevertheless, nowadays, there is a growing interest in the gasification process due to the flexibility to produce syngas, hydrogen, and biogenic carbon dioxide. As reported by the International Energy Agency (IEA) Bioenergy, as of 2020, there are 686 operational gasifiers worldwide, where 272 plants are producing syngas on a large scale, boasting an energy capacity of approximately 200 *GWh*—equivalent to around 200 *MWh* per installed gasifier[7].

Biomass gasification is challenging due to its high moisture content, high *O/C* ratio, low bulk density, lower grindability, and heterogeneous nature, these features make it difficult to use biomass as fuel, for that reason is necessary to carry out a pre-treatment. Furthermore, higher tar formation during the gasification of raw biomass increases the downstream cost of gas separation. Pre-treatment of biomass through torrefaction could remove some of these limitations, making biomass a more suitable feedstock for gasification[8].

Carbon capture stands out as a promising technology to mitigate climate change. The integration of biomass gasification and carbon capture lead to negative net carbon emissions and may therefore provide an important technological alternative for meeting current greenhouse gas stabilization targets. To this end, syngas from biomass gasification combined with pre-combustion carbon capture can be used to produce either biofuels or electricity [9].

It is expected that the technological development of biomass gasification processes coupled with  $CO_2$  capture might satisfy the energy demand in such a way that they can be considered as a technical, economic and environmental feasible alternative. It is hoped that research such as the one presented here could contribute to the development of these processes.

## PROCESS DESCRIPTION

### Feedstock

The palm oil is a well-established industry in Colombia, this level of industrialization is providing a reliable source of raw material for further transformation into bioenergy, biofuels and biohydrogen among others. We select the empty fruit bunch (EFB), which is a residual

biomass from the palm oil extraction as raw material for the gasification process. The EFB characterization given by the ultimate and proximal analysis is shown in Table 1. In additionally, we consider that the EFB has a moisture content of 48% by weight, with a particle size distribution of 40 *cm* in diameter, following a normal distribution with a mean of 8.3 *cm*. The EFB gasification plant has a design capacity of 80 *t/h*. The biomass was modeled as no-conventional solid, using Aspen plus V12, for enthalpy and density are applied HCOALGEN and DCOALIGT correlations respectively, which are taken by the simulation. The HHV value of biomass moisture provided by simulation is compared to literature data [10].

**Table 1:** Ultimate and proximal analysis.

Ultimate	Value%	Proximate	Value%
C	46.47	Fixed carbon	16.07
H	6.22	Volatile	69.14
O	42.25	Moisture	48.00
S	0.08	Ash	3.86
N	1.12	HHV	18.5
			MJ/Kg
Ash	3.86		

## PRE-TREATMENT

This stage encompasses biomass grinding, drying, torrefaction, and pelletization processes. We select two fluid packages: SOLIDS for processes related to biomass, and Redlich-Kwong-Soave-Boston-Mathias for gases generated from the burning of gases and liquids resulting from torrefaction reactions.

The main objective of the pre-treatment is to increase the energy density of the biomass. Thus, the particle size distribution, *O/C* and *H/C* ratios can be considered as key performance targets of this stage (Figure 1). At the end of the process, 35.7 *T/h* torrefied pellets of EFB are produced, with a mass yield of 0.44 *Kg* pellet torrefied EFB/*Kg* moisture biomass and ratio of energy consumption of 0.16 *KW/Kg* pellet torrefied EFB.

### Grinding

We simulate this process using the correlations provided by Rosin Rammler and Sperling Bennet, which are retrieved from the Aspen plus database.

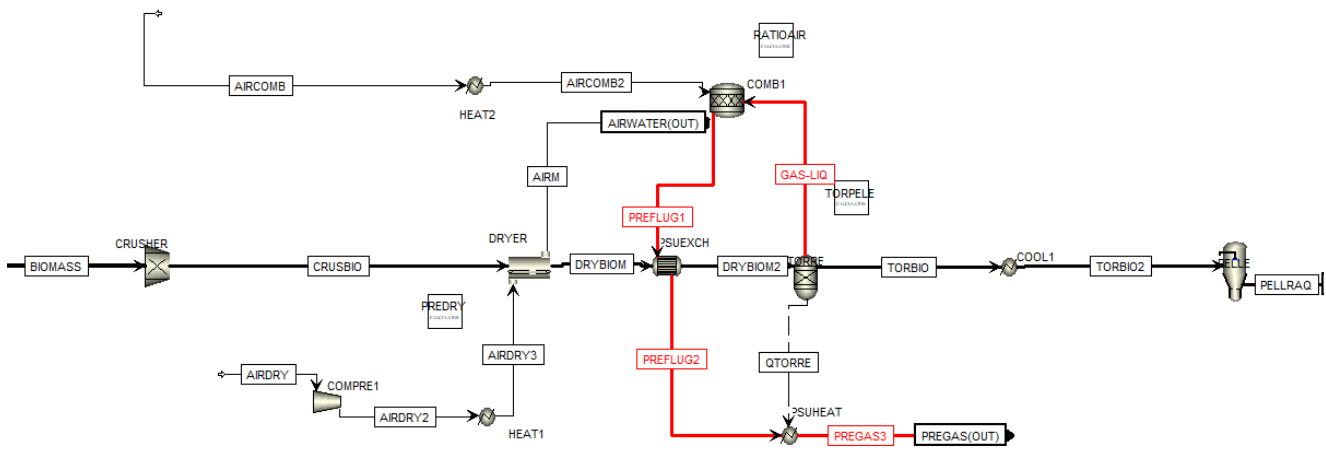

We define a target of 5 *mm* as the particle size, which is predicted as a function of the specific power and Bond work index or Hardgrove grindability index (HGI). The first parameter is given by Ruksathamcharoen with a value of 14 *Kwt/t* [11], and the second one is provided by Montealegre with a value of 12.6 HGI [12]. See the operation unit CRUSHER in the Figure 1.

### Dying

We adapt correlations proposed by Han [13]

**Table 3:** Comparison raw EFB with torrefied pellets of EFB (PTEFB)

Ultimate analysis	Raw EFB	PTEFB	Proximate	Raw EFB	PTEFB
C	46.47	54.10	Fixed carbon	16.07	23.76
H	6.22	6.09	Volatile	69.14	62.14
O	42.25	28.67	Moisture	48.00	5.35
S	0.08	0.11	Ash	3.86	9.43
N	1.12	1.76	HHV[MJ/Kg]	18.5	20.8
Ash	3.86	9.43			

through a CALCULATOR block to predict air demand and sizing for dried. This operation unit is represented by the DRYLER, which was set up to operate in co-current. See details in the Table 2.

**Table 2:** Operations condition and dimensions of DRYLER.

Parameter	value	Units
Length	20.94	m
Cross area	7.02	m <sup>2</sup>
Residence time	23	min
Ratio air biomass	7.89	Kg air/Kg EFB
Input air temperature	180	°C
Outlet moisture	9	Weight (%)

### Torrefaction

This process seeks to improve *O/C* and *H/C* ratios. Thus, the residual biomass can be considered as a vegetal coal, with a performance alike the mineral coal. We represent this operation unit by TORRE and the block calculator TORPELE. We predict yields of solid, liquid and gas and the composition of each phase based on Azir's work [8] [14]. According to the author, the optimum temperature and residence time for the torrefaction process are 250 °C and 40 minutes respectively, which are

considered in this work (see results in the Table 3). The gas and liquid streams of this process are used to provide the energy requirements for the torrefaction (see red line in Figure 1).

### Pelletization

The resulting torrefied EFB is cooled at 100 °C before it is fed to the pelletization stage, which is modeled by the GRANULADOR block called PELLE, defining the calculator TORPELE. It was set up an energy requirement of 30 Kwt/t of EFB to achieve a particle size of 10 mm [15]. Note: The effects of pelletization on the chemical properties of torrefied EFB are not considered.

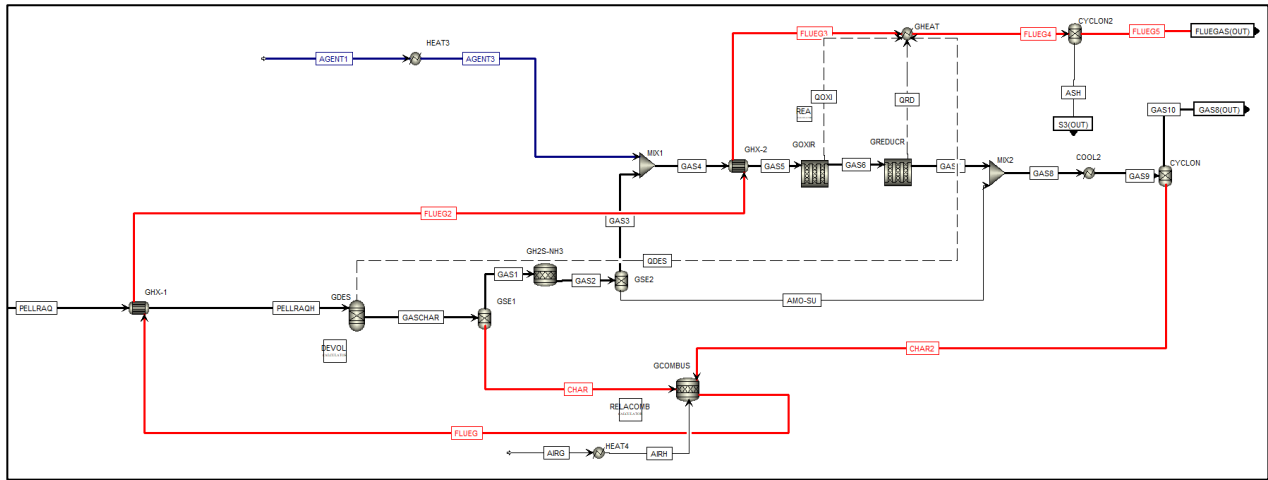

### GASIFICATION

We model a dual gasifier for EFB pellets following the methodology proposed by Puig [16] and Bach [17]. This process operates at atmospheric pressure and using steam as gasification agent. It is selected Peng Robison Boston- Mathias as fluid package for the simulation. In the Figure 2, we represent the gasification process using five blocks (GDES, DEVOL, GH2S-NH3, GOXIR and GREDUCR). The decomposition of torrefied pellets of EFB is modeled by the blocks GDES and DEVOL, using the

**Table 4:** Mass fractions for each part of the gasification process

Component	Decompositions	Gasification	Combustion chamber
C	0.18	0	0
O <sub>2</sub>	0	0	0.04

S <sub>2</sub>	0.001	0	0
Ash	0.06	0	0.02
Flow rate (T/h)	34.516	59.39	94.50
Stream name	GASCHAR	GAS 10	FLUEG4
Ratio steam/Biomass	0	0.9	0

**Figure 2.** Simulation of dual gasifier.

correlations proposed by Neves [18], which are represented by the equations (1-11). As result, we predict the yield for each component ( $CO, CO_2, H_2, H_2O, CH_4, C_2H_4, Tar, C, Ash$ ). Note: The operating temperature is the independent variable. According to Lee, the tar fraction is represented as  $C_6H_6$  allowing this assumption to be made[19].

$$(\sum_j Y_{j,F} - Y_{ch,F} \sum_j Y_{j,ch}) * LHV_G = (Y_{tar,F} * Y_{H_2O,F}) * LHV_G + Y_{C_2H_4,F} * LHV_{C_2H_4} + Y_{CH_4,F} * LHV_{CH_4} + Y_{CO,F} * LHV_{CO} + Y_{H_2,F} * LHV_{H_2} \quad (1)$$

$$Y_{ch,F} = 0,106 + 2,43 * e^{(-0,66*10^{-2}*T)} \quad (2)$$

$$Y_{C,ch} = 0,93 + 0,92 * e^{(-0,42*10^{-2}*T)} \quad (3)$$

$$Y_{O,ch} = 0,07 + 0,85 * e^{(-0,48*10^{-2}*T)} \quad (4)$$

$$Y_{H,ch} = -0,41 * 10^{-2} + 0,10 * e^{(-0,24*10^{-2}*T)} \quad (5)$$

$$Y_{H_2,F} = 1,145 * (1 - e^{(-0,11*10^{-2}*T)})^{9,384} \quad (6)$$

$$Y_{CH_4,F} = -2,18 * 10^{-4} + 0,146 * Y_{CO,F} \quad (7)$$

$$Y_{CO,F} = \left( (3 * 10^{-4} + \frac{0,0429}{1 + (\frac{T}{632})^{-7,23}}) \right)^{-1} * Y_{H_2,F} \quad (8)$$

$$Y_{C,tar} = 1,14 * Y_{C,bio} \quad (9)$$

$$Y_{O,tar} = 0,8 * Y_{O,bio} \quad (10)$$

$$Y_{H,tar} = 1,13 * Y_{H,bio} \quad (11)$$

The carbon and ashes generated in the decomposition stage are sent to a combustion chamber called GCOMBUS, the remaining gas products from decomposition are directed to the stoichiometric reactor called GH2S-NH3, where impurities such as  $NH_3$  and  $H_2S$  are formed. These impurities are temporarily separated from the gas, with the aim of excluding them from the gasification reactions and thus maintaining equilibrium. Subsequently, the gas, free of impurities are mixed with steam and enters the gasification stage conducted in the gas reactor, in this case there is not oxygen in the mix, for that reason only the reduced reactions occur, producing a reduced gas. This reduced gas is then mixed with the impurities to obtain synthesis gas. The equations 11-23 represented the reduction reactions.

The red stream in Figure 2 illustrates the energy exchange between the gases generated by the combustion of the solid phase (carbon and ashes) and the chamber of the bubbling bed gasifier. Table 3 displays the mass composition of different stages of the process.

**Table 5:** Operations condition and dimensions of dual gasifier.

Parameter	value	Units
Temperature gasifier	800	°C
Temperature flue gas	847	°C
Diameter	2.5	m
Length	15	m
Ratio steam biomass	0.9	Kg steam/Kg EFB
Outlet moisture	9	Weight (%)

The proposed model suggests that unreactive char

and ash interchange heat with the flue gas as well as syngas thus, temperature of flue gas and solids should be the same. The temperatures of syngas and flue gas are compared with the experimental case. Table 5 shows the operations conditions of gasifier.

The results obtain in the gasification simulation are compared with the experimental data [20]. When comparing the results, errors of less than 15% are observed with respect to the volumetric composition of the products, except for tar, where the error is 20%. These discrepancies arise from differences in the raw materials used, as well as the absence of torrefaction processes in the evaluation performed by Smich. Another significant factor affecting result accuracy is the presence of transfer phenomena, which are not accounted for in the gasifier.

## GAS CLEANING AND UPGRATING

### Catalytic cracking tar (CCT)

The resulting gas contain quantities of tar ( $C_6H_6$ ) that can cause tube plugging. However, this tar can also be utilized to enhance the process yield. Therefore, it is crucial to eliminate tar through the catalytic cracking process, as depicted in Figure 3.

The diagram illustrates the necessity to raise the outlet gas temperature to 900 °C to achieve tar destruction using dolomite catalyst (see equation 24), Subsequently gas goes into other catalytic reactor to eliminate methane and transform into  $CO$  and  $H_2$  (see equation 25), the final gas contains high concentration of  $CO$ , see Table 6. Both reactions follow the Arrhenius model. The kinetic model is provided by Srinivas who investigates [21].

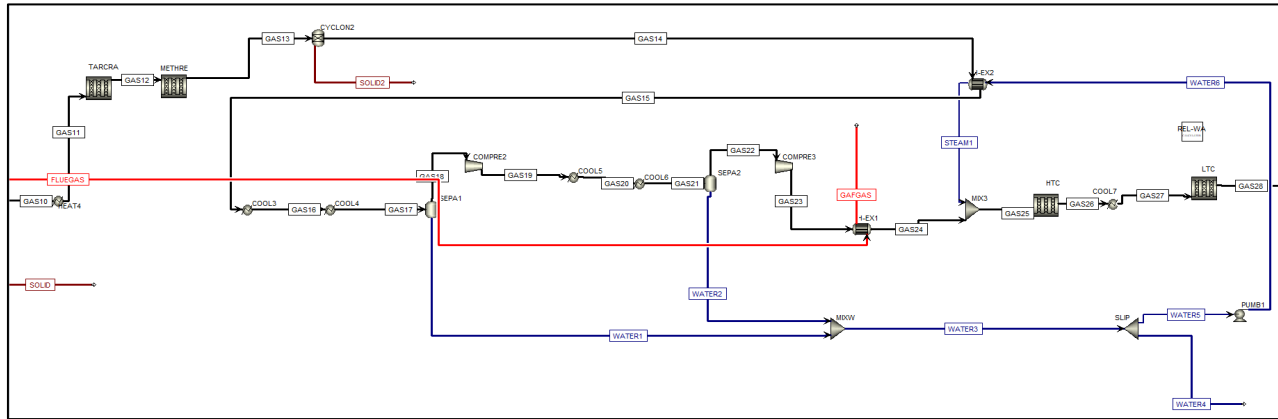

### Water gas shift reaction (WGSR)

Water gas shift reaction usually occurs in a catalytic environment and high pressures, the reactor operates at 28 bar and the process subdivided into two parts. High temperature shift catalytic (HTSC) and Low temperature shift catalytic (LTSC) see the equation (26-27). According to Reza [22] "if high purity of hydrogen is needed, the most common configuration for doing WGSR consist in two consecutive adiabatic fixed bed reactors".

The motive of this arrangement due to the reaction is kinetically favorable at high temperatures while it is thermodynamically at low temperatures. The first reactor used an iron-based catalyst and the second used copper-based catalyst, the Figure 3 shows simulation of

**Table 6:** Volumetric composition at 0 °C of dry syngas for each process

Component	Gasification	Tar cracking	Methane cracking	HTC	LTC
CO	20.0	20.7	23.0	6.9	1.0
CO <sub>2</sub>	28.2	27.4	22.4	32.8	36.5

C <sub>6</sub> H <sub>6</sub>	0.0002	0	0	0	0
NH <sub>3</sub> (Kg/h)	380.5	380.5	380.5	380.5	380.5
H <sub>2</sub> S (Kg/h)	29.7	29.7	29.7	29.7	29.7
Pressure (bar)	1.0	1.0	1.0	28	25
Temperature (°C)	800	900	900	316	189
Dry flow rate (T/h)	34.516	34.716	36.987	42.884	45.274
Stream name	GAS 11	GAS 12	GAS 13	GAS 26	GAS 28
Reactor volume (m <sup>3</sup> )	73.63	1.17	0.20	11.69	2.09

**Figure 3.** Gas cleaning and upgrading.

each reactor. In the Table 6 shows upgrading gas composition at the end of process.

$$R_{HTSC} = A_C \times 10^{2.845} \exp\left(\frac{-111}{RT}\right) P_{CO} P_{CO_2}^{-0.36} P_{H_2}^{-0.09} \left(1 - \frac{P_{CO_2} P_{H_2}}{K_e P_{CO} P_{H_2O}}\right) \quad (27)$$

$$R_{LTSC} = A_C \times 2.96 \times 10^5 \exp\left(\frac{-47400}{RT}\right) \left(P_{CO} P_{H_2O} - \frac{P_{CO_2} P_{H_2}}{K_e}\right) \quad (28)$$

$$K_e = \exp\left(\frac{-4577.8}{T} - 4.33\right) \quad (29)$$

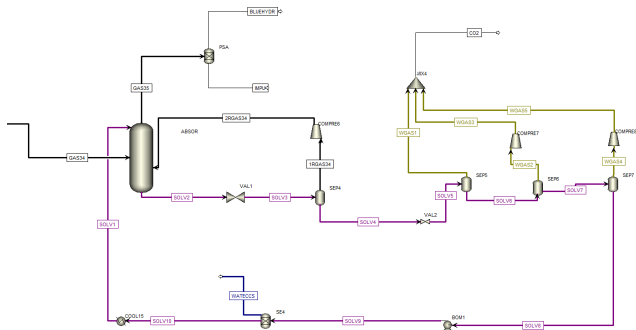

## CARBON CAPTURE

Subsequently, the purified gas, with a high concentration of CO<sub>2</sub> (see Table 6) is directed towards the carbon capture process. In this phase, two alternatives are evaluated based on simulation examples provided by Aspen Plus. Both alternatives employ amines as solvents with the aim of reducing the concentration of

components such as CO<sub>2</sub> and H<sub>2</sub>S present in the gas stream. For both options, a PSA unit must be installed to achieve hydrogen purity of 99.9%. The simulations presented below correspond to examples extracted from the Aspen Plus V12 database, which were modified for the purified stream in this case [23] [24] .

## Physical adsorption

In the first case, DEPG (Dimethyl Ether of Polyethylene Glycol) is employed as the solvent, which eliminates CO<sub>2</sub> through a physisorption mechanism. This system requires high pressure and low temperature. Figure 4 depicts the simulation of the process using DEPG. Table 8 shows the operations conditions.

**Figure 4.** Carbon capture using DEPG as solvent.

### Chemical adsorption

For the second case, MEA is used as the solvent. In this system, the interaction occurs through a chemisorption mechanism. Therefore, it is necessary to specify the equilibrium reaction between the solvent and the gas. Figure 5 illustrates the adsorption with MEA. Table 7 shows the results of adsorption for both cases.

**Figure 5.** Carbon capture using MEA as solvent.

**Table 7:** Volume concentration of gas after capture carbon.

Component	DEPG	MEA
CO	1.1	1.4
CO <sub>2</sub>	2.9	5.2
H <sub>2</sub>	95.6	93.1
N <sub>2</sub>	0.3	0.3

**Table 8:** Operations condition and dimensions of capture processes.

Parameter	DEPG	MEA
Operation temperature (°C)	20	24
Operation pressure (bar)	69	17
Diameter (m)	1.8	1.9
Length (m)	12	3.2
Hydrogen flow rate (T/h)	2.88	3.12
Fluid package	PC-SAFT	ENRTL-RK

It is necessary to mention that although adsorption using MEA results in a higher concentration of hydrogen compared to DEPG (refer to Table 7), there is a loss of

hydrogen of 8.9% by weight when using DEPG, while the loss of hydrogen with MEA adsorption is only 1.24%. Subsequently, the gas proceeds to the PSA unit. For DEPG adsorption, it achieves a throughput of  $58,75 \frac{Tn}{Day}$  whereas for MEA, it is  $63,72 \frac{Tn}{Day}$ . The mass yield of MEA and DEPG processes with PSA corresponds to 0.059 and 0.054 *Kg hydrogen/kg gas*. Additionally, the energy yield is 0.15 and 3.14 *KW /Kg hydrogen* respectively.

### ECONOMICAL ASSESSMENT

According to the simulation results, economic parameters such as CAPEX and OPEX are calculated using different correlations. For the pre-treatment stage, the methodology proposed by Guthrie [25] is employed. The cost and installation of the dual gasifier are calculated using the correlations presented by Gunnarsson [26]. Two-phase separators are assessed using the methodology proposed by Turton [27], while for the combustion reactor in the pre-treatment and the equipment involved (PSA), the methodology presented by Hoffman [28] is followed.

An interest rate of 11% over a duration of 20 years is assumed, with an estimated construction period of 3 years for the plant.

The economic assessment is conducted separately for each stage of the process (pre-treatment, gasification, and carbon capture).

#### Pre-treatment

For economic assessment of pre-treatment. We evaluate the LCOE pellets as parameter in the Table 9 shows the results of assessment.

**Table 9:** Economic assessment of pre-treatment

Parameter	value	Units
CAPEX	\$ 2'490.166	USD
OPEX	\$ 2'304.759	USD
LCOE pellet	77	USD/T pellet
Energy consumption	0.120	MW/T pellet

#### Gasification and gas upgrading

In the gasification process, we utilize the correlation presented in Gunnarsson [26] for cost estimation. Employing the six-rule method, we estimate the equipment cost and operational expenses using the Lower Heating Value (LHV) of syngas. For the stage of gas cleaning and upgrading, the correlations provided by Warren [25] are applied. The results of the assessment are presented in Tables 10 and 11.

The Levelized Cost of Hydrogen (LCOH) includes costs related to gas cleaning and upgrading. According

to GEP company, the LCOH ranges between 2,8 a 3,5 USD/Kg H<sub>2</sub>[29].

**Table 10:** Economic assessment of gasification

Parameter	value	Units
CAPEX	\$ 34'925.863	USD
OPEX	\$ 2'327.240	USD
LCOH	3.05	USD/Kg H <sub>2</sub>

**Table 11:** Economic assessment of gas cleaning and upgrading.

Parameter	value	Units
CAPEX	\$ 97.278.973	USD
OPEX	\$ 12'726.235	USD

## Carbon capture

For the economic assessment, we evaluated both methods of carbon capture. The MEA system was chosen due to its high selectivity to hydrogen compared to the DEPG system. Tables 12 and 13 show the results of the assessment for carbon capture using MEA and DEPG, respectively. In both carbon capture systems, PSA is employed.

The results suggest that the method using DEPG is appropriate, despite its high electricity consumption and low hydrogen production compared to using MEA.

**Table 12:** Economic assessment of carbon capture using MEA with PSA

Parameter	value	Units
CAPEX	\$ 113'685.286	USD
OPEX	\$ 9'682.424	USD
CAPEX/CO <sub>2</sub> T/h	\$ 3'062.331	USD
LCOC	92	USD/T CO <sub>2</sub>
LCOA	183	USD/T CO <sub>2</sub>

**Table 13:** Economic assessment of carbon capture using DEPG with PSA

Parameter	value	Units
CAPEX	\$ 83'075.549	USD
OPEX	\$ 4'781.573	USD
CAPEX/CO <sub>2</sub> T/h	\$ 2'128.205	USD
LCOC	59	USD/T CO <sub>2</sub>
LCOA	119	USD/T CO <sub>2</sub>

## CONCLUSION

Based on the process results, it can be affirmed that the proposed model for torrefaction is valid, as it can

indirectly estimate the higher calorific value of the torrefied EFB.

It is necessary to clarify that the proposed design does not correspond to the optimum. In the cases of gasification, tar cracking, methane cracking, and water gas shift reaction reactors, sensitivity analysis was conducted to estimate the size of equipment for the base case of carbon capture systems. The simulation extracted from the Aspen Plus examples was modified to consider the resulting flow of the plant proposed in this project.

Regarding gasification, the combination of the models proposed by Puig and Bach, along with the energy integration implemented and Neves' model for the decomposition of the EFB, allows for generating a simulation that emulates the experimental results presented by Schmid, including the formation of tar. In the future, it is considered to consider the reactivity of the ashes.

It is observed that the gas upgrading eliminates most of the problems related to the presence of tar, monoxide, and methane. Additionally, increasing the concentration of hydrogen eliminates problems related to subsequent adsorption, as the presence of tar in the stream can affect the efficiency of adsorption.

The cost of this low-carbon hydrogen is close to the market price. The reasons are related to the high quantities of hydrogen produced in gas upgrading processes WGS and CCT.

## ABSTRACT

Plastics are widely used for their affordability and versatility across many consumer and industrial applications. However, the end-of-life (EoL) management stage can often lead to releasing hazardous chemical additives and degradation products into the environment. The increasing demand for plastics is expected to increase the frequency of material releases throughout the plastic EoL management activities, creating a challenge for policymakers, including ensuring proper material segregation and disposal management and increasing recycling efficiency and material reuse. This research designed a Python-based EoL plastic management tool to support decision-makers in analyzing the holistic impacts of potential plastic waste management policies. The constructed tool was developed to reduce the complexity of material flow analysis calculations, estimating material releases, and environmental impacts. The utility of the tool was tested through the hypothetical nationwide adoption of an extended producer responsibility (EPR) program. The decision-making capability of the tool can facilitate the prediction of long-term outcomes, offering technical knowledge and insight for policymakers seeking to mitigate the environmental and health impacts of plastic pollution.

---

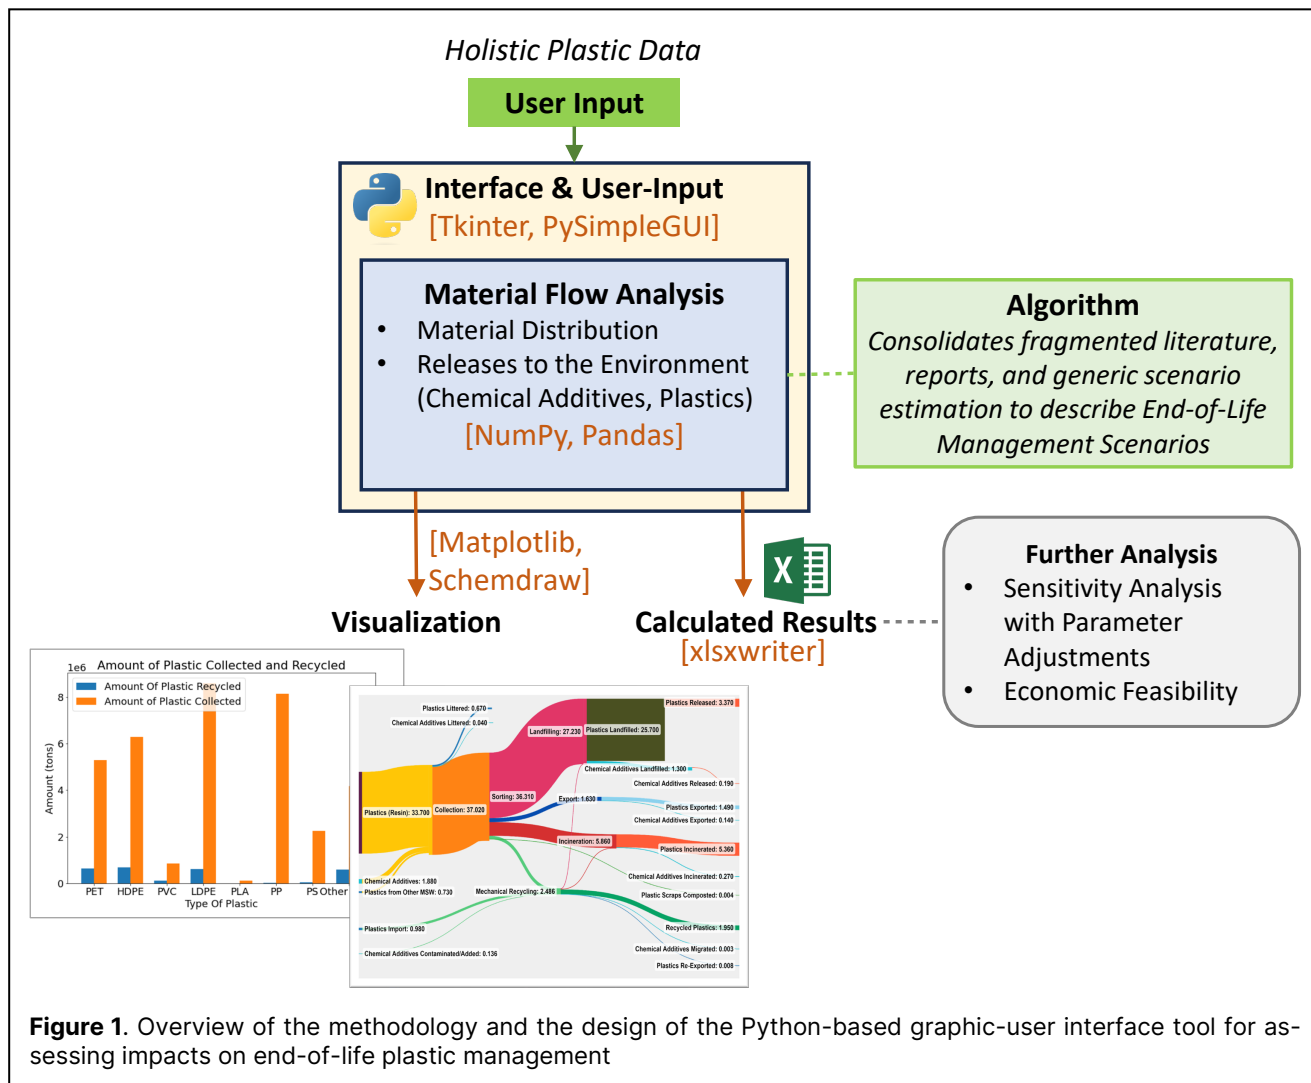

**Keywords:** Polymers, Supply Chain, Modelling

## INTRODUCTION

Plastics are used in many modern applications due to their versatility [1]. Despite their benefits, managing end-of-life (EoL) plastics can release potentially hazardous materials, such as chemical additives, micro- and nano-plastics, and degradation by-products, into the environment [2], [3], [4]. In most cases, chemical additives used during plastic production are not chemically linked to the polymer chain and may migrate to the surrounding environment based on the molecular weight, temperature, compatibility, and solubility in the surrounding medium [5]. These migration mechanisms continue to pose challenges during end-of-life management. The unpredictable nature of plastic waste behavior and the uncertain pathways of chemical additive releases

necessitate a deeper analysis of their impact on the environment, human health, and safety. To minimize the complexities of EoL plastic management analysis, this research introduces a Python-based modeling tool for conducting a holistic analysis of the entire plastic life cycle, simplifying the material flow analysis and scenario-testing process to support decision-making by policymakers and manufacturers. This tool features a holistic overview of plastics and chemical additives released to the environmental compartment (land, water, and air) associated with common EoL management scenarios.

The increasing demand for plastics is expected to double the production rate between 2019 and 2040. Without significant change, the ocean can contain more plastics by weight than fish by 2050 [6]. Reducing plastic pollution requires understanding

the challenges involving all aspects of plastic management before implementing pollution prevention strategies [7].

Chea et al. previously analyzed the existing management of plastics with a material flow analysis to identify potential impacts of releases and exposure scenarios on safety, human health, and the environment [8]. A Python-based modeling tool was initially developed to decrease the complexity of the material flow analysis calculations for decision-making and estimating chemical additive releases and environmental impact [9]. However, the tool was not optimized to model plastics and additives releases under realistic scenarios. This research extended the initial version of the tool by including sensitivity analyses centering on assisting with forecasting the impacts of policies on EoL plastic management efficiency, material releases, and environmental implications. In addition, scenario visualization and graphic user interface (GUI) were improved to streamline the ease of analysis for potential stakeholders. The utility

of the constructed tool was tested in the theoretical implementation of the Extended Producer Responsibility (EPR) program. As a multi-stakeholder problem, the relationships between the potential recycling rate increase and material releases and cost were analyzed. Therefore, the forecasting capability of the tool can assist users with predicting the effects of parameter changes to EoL management practices, ensuring that alterations to the existing designs of EoL management infrastructure are justifiable.

## MATERIALS AND METHODS

### Tool Design and Objectives

The constructed tool is intended to provide a holistic insight into the impacts of policy implementations by using a material flow analysis to estimate relative mass flow intensity and material releases into the environmental compartments (land, water, and air) at various stages throughout EoL management.

The GUI component was constructed in Python using Tkinter and PySimpleGUI modules. Data handling and analysis within this tool utilized NumPy and Pandas. Visualization of the analysis is handled using Matplotlib and Schemdraw. All calculated values from the material flow analysis are transferred through the xlsxwriter module. This method allows for ease of data collection that can be conveniently processed by users unfamiliar with coding. The methodology used to develop a comprehensive assessment tool for evaluating the impacts of policy implementations on EoL plastics management is visually summarized in **Figure 1**.

## Data Collection and Algorithm

The tool user may customize input data as needed to model their community closely. Default values from government reports are available as a starting point without data. The algorithm for completing the material flow analysis is based on a bottom-up approach, which combines and processes the data collected from individual studies to illustrate the complexity of plastic EoL management [8].

**Table 1.** Common Chemical Additives Found in Plastics (Adapted from [2], [10])

Type	Composition Range (%)
Plasticizers	10 – 70
Flame Retardants	3 – 25
Antioxidants	0.05 – 3
UV Stabilizers	0.05 – 3
Heat Stabilizers	0.05 – 3
Slip Agents	0.1 – 3
Lubricants	0.1 – 3
Antistatics	0.1 – 1
Curing agents	0.1 – 2
Blowing agents	0.5 – 20.5
Biocides	0.001 – 1
Colorants	0.25 – 5
Pigments	0.001 – 10
Fillers	0 – 50
Reinforcements	15 – 30

The data used for the algorithm development was sourced primarily through published research data and government reports [2], [11], [12], [13], [14], [15]. The US Environmental Protection Agency (EPA) reported 35.7 million tons of EoL plastic during 2018, which included 14.8% polyethylene terephthalate (PET), 17.6% high-density polyethylene (HDPE), 2.4% polyvinyl chloride (PVC), 24.1% low-density polyethylene (LDPE), 0.3% polylactic acid (PLA), 22.8% polypropylene (PP), 6.3% polystyrene (PS), and 11.7% categorized as other plastics [14]. The chemical additive content of these plastics may vary based on

the intended applications. **Table 1** provides common chemical additives found in plastics and the associated range of usage concentration, demonstrating the uncertainties inherently caused by the knowledge gap between manufacturing and EoL management. These data were converted into usable formats, serving as the basis for conducting the material flow analysis and scenario testing within the tool.

## Case Study Formulation

The utility of the constructed tool was demonstrated through a case study involving adopting a nationwide Extended Producer Responsibility (EPR) program. This program has been widely adopted by the European Union (EU) to enhance plastic waste management strategies, in which producers are expected to design products with the eventual intention of recovery in the EoL management stage and finance the recovery efforts through fees. Plastic packaging waste, in particular, constitutes up to 40.7% of the total plastic waste generated in 2018, 13.6% of which was successfully recycled [14].

The variation in packaging types, collection methods, and existing recycling infrastructure throughout the US attests to the low recycling rate observed. Decision-makers may use the constructed tool to test the effects of implementing the EPR program, which is mandatory to meet specific recycling goals before adopting the regulations.

As of April 2023, six US states (CA, CO, ME, NJ, OR, and WA) have implemented packaging EPR law [16]. Although the focus varies between states, these laws require producers to make packaging recyclable or compostable, achieve higher recycling rates for single-use plastics, reduce plastic packaging volumes, and incorporate post-consumer recycled content into various products. The existing EPR infrastructure within the US includes (1) having a producer responsibility organization collect waste, process, and move waste as needed and (2) allowing municipalities to manage waste then be reimbursed by the producer responsibility organization [17].

These efforts aim to promote a circular economy, reduce landfill waste, encourage sustainable packaging practices, and upgrade recycling systems within each state.

This assessment primarily targeted the enhancement of plastic packaging recycling, the projected increase in recyclable volumes, and estimated potential reductions in releases to environmental compartments (land, water, and air). These releases include EoL plastics, chemical additives, and other byproducts created because of conventional plastic EoL management. An estimation of the economic

recovery from material reclamation from nationwide EPR implementation was also completed. It should be noted that the calculated values are based on plastic EoL management performance from 2018 and do not necessarily represent management trends from other years.

## RESULTS & DISCUSSIONS

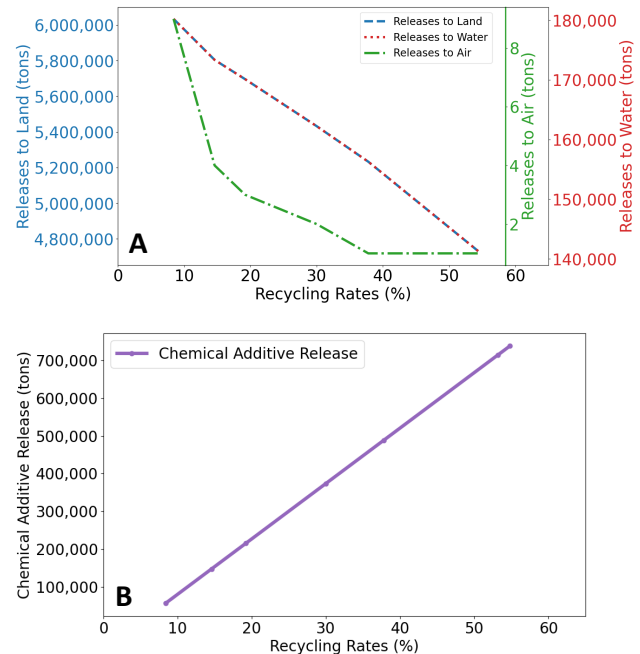

### Recycling Rate Projections and Environmental Implications

The previous study on EoL plastic management in the United States, based on 2018 MSW data, identified that over 35.7 million tons of plastic waste were generated, with only approximately 8.4% successfully recycled [8]. Their material flow analysis highlighted primary plastic types and their allocation in recycling, landfilling, and incineration, emphasizing the limited recycling efforts and substantial landfilling of EoL plastics. Moreover, the potential range of chemical additives in plastic products and the potential environmental implications were reported, emphasizing the need for enhanced processing infrastructure to mitigate environmental releases.

This analysis sets the stage for a comparative analysis between existing EoL plastic management practices and the potential effects of EPR programs, specifically focusing on the EoL plastic packaging component. There is a positive correlation between the recycling rate of packaging plastics and the effective adoption of EPR programs nationwide. This program can effectively reduce the number of plastics sent to the traditional EoL management by requiring manufacturers to take responsibility for their products throughout the material life cycle. Therefore, increased plastic collection and recovery rates and decreased plastic mass in landfills or incineration can be observed.

The effectiveness of EPR programs worldwide has been reported to achieve a packaging recycling rate as high as 75%, while the statistics within the US may theoretically reach a maximum of 48% due to the lack of sustainable funding in various communities throughout the country [18]. Based on the material flow analysis in 2018, over 17 million tons (54.8% of generated EoL plastics) can be removed from the conventional management process. Consequently, material releases to land, water, and air decreases with increasing recovery rate, as illustrated in **Figure 2A**. The recycling rates (%) include practices such as plastic exports and conventional management of non-packaging plastics, which are unaffected by the EPR programs. The inversely proportional relationship observed is expected because the conventional EoL plastic management process can subject the collected materials to many generic steps (reprocessing, incineration, landfilling, composting, transport) because of the knowledge gap between the manufacturer and EoL plastic

management workers. Additional processing steps can lead to the propagation of efficiency issues and material releases into the environment. The EPR program minimizes processing steps by involving the producers with EoL management, reducing the frequency of material releases into the environment.

**Figure 2.** Extended producer responsibility scenario-specific plot generated from the python-based modeling tool. (A) The potential reduction in environmental releases based on the effectiveness of Extended Producer Responsibility (EPR) program. (B) The potential chemical additive releases to the environment as a function of material reprocessing.

The producers are expected to possess the most information regarding the composition and processability of the EoL plastics they created. However, concerns may be raised regarding the presence of chemical additives used. If subjected to physical processing, such as extrusion, chemical additives may migrate from the polymer matrix and be released into the surrounding environment. The extrusion process also can release VOCs, monomers, and other degradation products because of the heat generated from friction [2]. **Figure 2B** illustrates the direct relationship between the plastic recycling rate and the release of chemical additives to the environmental compartments. The recycling rate (%) was varied between the 2018 plastic recycling rate (8.4% wt.) [13] to the maximum recycling rate anticipated by EPR programs in the US (54.8% wt.) [18] to demonstrate the differences between maintaining the existing material management paradigm or implementing EPR programs nationwide. Although EoL management steps have been reduced through the EPR program, reprocessing EoL plastics can

cause unintentional releases and contamination, leading to hazardous workplace exposure [8]. The chemical additive releases occur as a result of the reliance on additives as processing aids in the physical recycling practices. This process subjects plastics to high friction-induced heat, increasing the likelihood of chemical migration to the surrounding environment, especially because chemical additives are generally not linked chemically with the plastic products [2]. The release of chemical additives may be minimized if the EoL plastic structural integrity remains intact and reuse is possible with minimal cleaning. However, additional treatment steps may be required to remove potentially toxic or unknown contaminants. Such an endeavor can be cost-intensive and require case-specific economic analysis.

### Designing Economical Plastic Recycling Infrastructure

Material value reclamation is one of the most crucial economic factors to consider before adopting the EPR program as part of the conventional plastic management processes. **Figure 3** illustrates a proportional relationship between the effective recycling rate of packaging waste and the reclaimed value. Similar to **Figure 2**, the recycling rate (%) was varied between the 2018 recycling rate and the maximum recycling potentials due to implementing the EPR programs in the US (54.8% wt.) The high recovery rate can reduce the raw material requirement for creating new plastic packaging products. This event can incentivize producers to design more recyclable products, promoting the circular economy concept [1].

**Figure 3.** The effects of increasing EoL plastic recycling rate on the potential reclaimed material values following Extended Producer Responsibility (EPR) program

A comprehensive economic analysis at the national level is presently beyond the scope of the holistic assessment tool. Additionally, market variations throughout the US can make a comprehensive economic analysis challenging. Manufacturers may encounter different investment costs for EPR programs ranging between 0 – 1% of their gross revenue, depending on the specific demands

of their markets [19]. Notably, the federal government assumes no financial burden in adopting EPR programs, with all associated costs shifted onto producers and consumers [20]. It is also crucial to recognize that the success of the EPR framework is dependent on effective collaboration between stakeholders, robust regulatory frameworks, and continuous monitoring and adaptation to evolving market conditions. Such measures are essential to ensure that the program remains economically viable and sustainable and contributes meaningfully to the circular economy.

Since EPR inherently subtracts gross revenue from producers, incentives should be offered to encourage participation. Maine has taken the initiative to pass the EPR program for packaging in July 2021, providing reimbursement to municipalities that choose to participate in improving the recycling infrastructure. Exemption to the law was offered for producers that made less than \$2 million in gross revenue threshold or used less than 1 ton of packaging materials. Oregon shortly passed the same law, which gave rise to the Producer Responsibility Organization (PRO), designed to improve and expand recycling service, including funding waste prevention grants and studies related to recycling systems. Other states that have adopted EPR programs have adopted distinct approaches to determining producer fees and recycling goals [21]. However, it can generally be said that incentives and exemptions have demonstrated their usefulness in pioneering EPR programs by encouraging participation from producers, driving behavioral change throughout the plastic life cycle, and offering a competitive advantage regarding sustainability claims.

### Data Limitations

It should be noted that the current version of the tool utilizes public plastic management data in 2018 [13]. Therefore, the calculated values from the analysis are not entirely representative of data from the previous year. However, this approach remains valid if the tool user aims to discover the potential trends from potential policy implementation. Future improvements to the tool may include data from other years to increase the model accuracy and account for variation over time. Learning from the data approach can also be included to determine potential correlations for future projections. Policymakers should consider the complexities of plastic management, releases, and costs while drafting strategies for enhancing plastic waste management.

## CONCLUSIONS

Addressing EoL plastic management challenges requires strategic approaches to ensure maximum material recovery and minimize environmental

releases and reduce cost. The Python-based tool developed herein automates the material flow analysis process, describing plastic flow allocation throughout the life cycle and possible releases to the environmental compartments to aid decision-making.

This tool was used to simulate the implementation of EPR programs within the US from a holistic perspective, which correlated increasing recycling rates to reducing EoL plastics amount within traditional EoL management processes. Therefore, the US recycling infrastructure can shift toward the circular economy state, emphasizing the importance of reclaiming material value to encourage producers to design products with improved inherent recyclability. Ultimately, raw material costs during manufacturing can be reduced. However, there is an inversely proportional relationship between the recycling rate (8.4% base case to 54.8% maximum) and environmental releases because the chemical releases that occur during conventional plastic recycling are unmitigated. Alternative strategies for reducing chemical additive releases and exposure risks are required before the recycled plastics can safely be reused in the subsequent life cycle.

Improving the EoL plastic management is a multi-stakeholder problem. Unexplored factors, such as market variations and diverse manufacturer investment costs between regions, could impede the nationwide implementation of the EPR program. It should be noted that the EPR program case study serves as an example of the application of the tool to improve the management of EoL plastic packaging. Policies affecting the management of other plastic groups and types may also be tested to ensure a feasible EoL plastic management infrastructure design and foster a circular economy.

## ACKNOWLEDGEMENTS

This research was supported in part by an appointment to the US Environmental Protection Agency (EPA) Research Participation Program administered by the Oak Ridge Institute for Science and Education (ORISE) through an interagency agreement between the US Department of Energy (DOE) and the US EPA. ORISE is managed by ORAU under DOE contract number DE-SC0014664.

## ABSTRACT

To mitigate the effects of catastrophic failure while maintaining resource and production efficiencies, energy systems need to be designed for resilience and sustainability. Conventional approaches such as redundancies through backup processes or inventory stockpiles demand high capital investment and resource allocation. In addition, responding to unexpected “black swan” events requires that systems have the agility to transform and adapt rapidly. To develop targeted solutions that protect the system efficiently, the supply chain network needs to be considered as an integrated multi-scale system incorporating every component from individual process units all the way to the whole network. This approach can be readily integrated with analogous multiscale approaches for sustainability, safety, and intensification. In this work, we bring together classical supply chain resilience with process systems engineering to leverage the multi-scale nature of energy systems for developing resilience enhancement strategies that are resource-efficient. In particular, we adapt qualitative risk analysis methods to uncover critical system components and major vulnerabilities to guide resource allocation decisions. To account for these vulnerabilities, we explore the feasible region of operation around each node of the supply chain. An optimization formulation is devised to generate multiscale alternative. The approach is demonstrated through a case study involving the production of biofuels, demonstrating the range of adaptation strategies possible when process-level strategies are incorporated into overall supply chain design.

## INTRODUCTION

The study of energy system resilience, which is typically defined as the ability of systems to manage possible disturbances and recover from them, has increased in importance over the last decade as energy systems become more complex and disturbances become more frequent and severe [1, 2]. The integration of multiple energy sources, including intermittent and geographically-dispersed renewables, facilitates the transition to a more sustainable energy system, but also introduces complexity and vulnerability [2]. Therefore, energy systems need to be designed and operated in such a way that they are prepared to adapt and recover from future disturbances whether or not these disturbances are expected.

In minimizing the impact that a particular

disturbance has on energy system infrastructure, resilience contributes to the sustainability of the energy system in that less waste in the form of broken equipment and unused raw material or product is generated [3, 4, 5]. Additionally, systems that are better able to withstand disturbances are also able to continue operating for a longer period of time, maximizing their useful lifetimes. However, commonly-deployed resilience strategies center around reserving resources (either raw materials or finished products) as safety inventory to maintain high production output for as long as possible [6]. This strategy is useful, but relying solely on storing large amounts of unused inventory also raises its own sustainability and safety concerns [3]. For example, large-scale storage of hydrogen for energy currently relies on artificially-built salt caverns or depleted natural gas reservoirs, but there

may be possible reactions between the stored hydrogen with the microorganisms and mineral constituents of the reservoir, leading to deterioration of the hydrogen storage or unwanted deposits of reaction products [7]. Furthermore, long-term backup inventory storage can represent a financial drain on companies, which may make it economically unattractive. Therefore, cost-effective targeted resilience enhancement strategies need to be considered to balance the issues of resilience, sustainability, and economic cost.

Consideration of energy system resilience (and adjacent concepts) independently and alongside sustainability has been demonstrated in the open literature. Panteli et al. [8] proposed that power system resilience consists of two separate characteristics: operational resilience, which corresponds to the ability to ensure uninterrupted power supply, and infrastructure resilience, which refers to the physical strength of the power system to mitigate faulty portions of the system. Moreno-Sader et al. [9] proposed the use of a modified return-on-investment (ROI) metric that includes safety, sustainability, resilience, and reliability weights to screen process alternatives early in the design process. The weights are calculated based on whether a proposed design reaches a desired target value for each of the four desired objectives. Hosseini-Motlagh et al. [10] designed a power supply chain to minimize unmet electricity demand as well as pollution emission under uncertainty.

The complexities within an energy system not only come from supply chain dynamics such as material flow, customer energy demand, and transportation linkages, but also in the chemical reactions that occur within manufacturing facilities. Harnessing the physical and chemical synergies in energy systems through multi-scale systems engineering could be key to unlocking a variety of targeted resilience strategies that do not require significant resource or capital investments [11]. With a multi-scale approach, tools and methods built for supply chain, process, unit operations, and reaction-scale optimization are integrated to provide an accurate representation of the interactions across spatio-temporal scales [11, 12]. The approach allows bespoke models to be constructed that contains appropriate levels of detail at relevant spatio-temporal scales to open up the possibility for targeted resilience strategies.

Multi-scale approaches have been utilized in the design and optimization of energy systems to achieve economic and/or sustainability goals. Demirhan et al. [12] developed a multi-scale model for an energy system which uses solar and wind resources to supply electricity via various storage technologies at the lowest possible cost. The model accounts for renewable resource availability, storage technology constraints, as well as demand fluctuations. Shao et al. [13] proposed a multi-scale model for a hydrogen-based off-grid microgrid to generate both

power and heat for rural areas. A two-stage stochastic formulation was used to derive optimal capacity sizing and scheduling for both normal and on-emergency scenarios. Lin [14] explored the life-cycle impact of different technology pathways to develop future energy systems that integrate renewable resources, battery storage, and dense energy carrier production.

For a holistic consideration of energy system resilience, a multi-scale modeling approach can be beneficial to integrate risk factors and resilience enhancement strategies on the supply chain level and on the component level. This paper, therefore, aims to illustrate how process-level considerations contribute to overall supply chain resilience in a cost-competitive and sustainable manner. A qualitative resilience analysis is conducted to identify critical model variables that directly affect overall system performance. Next, an integrated system model is constructed around key variables and optimized. What-if scenarios are applied on the optimized network to demonstrate its resilience against several supply chain disturbances. The proposed methodology is demonstrated through a small regional biofuel supply chain.

## METHODOLOGY

### Consideration of Process Feasible Regions

In a typical supply chain optimization formulation, the manufacturing facilities that produce goods to sell are modeled as nodes with a fixed production rate; that is, given some quantity of raw materials, the quantity of products made is known [3, 6]. Responding to disruptions involves adding redundancies into the supply chain superstructure through alternate suppliers or transport routes, excess inventory, and overdesign of manufacturing capacity. Conversely, in process systems literature, a manufacturing facility is modeled as a set of processes (chemical or physical) that can be described by their operating parameters. Given a process design, it is well-known that there exists a region of feasible operation where different operating parameters will yield a different amount of product [15].

In our previous work, we demonstrated the benefits of designing processes with high reliability on enhancing overall supply chain resilience under disruptions [16]. Reliability is achieved through choosing to install process equipment with low failure rates and high repair rates. In this work, we expand on the concept of implementing process-level strategies to enhance supply chain resilience by considering the process feasible region within the supply chain optimization problem [17]. In effect, each manufacturing facility will be represented as a node with operational parameters that can be optimized for different scenarios. This necessitates a mathematical model for the process node that is then integrated into the supply chain optimization formulation.

To formulate a mathematical model of each process, computer-aided simulation software (e.g. Aspen Plus) and functional equations of key units within the module are first used to generate a computer model of the module. Next, the operating parameters that are most critical to process output are identified. A surrogate model for each critical unit is then generated to represent the relationship between the critical parameters with process output. These surrogate models are then integrated as additional constraints in the supply chain formulation. A generalized form of the surrogate model is shown in Eq. 1, where the unit-level parameter realizations  $x_{u,f,t}$  determine the unit efficiency  $Q_{u,f,t}$ .

$$Q_{u,f,t} = \Phi(x_{u,f,t}) \quad (1)$$

## Integrated Model

In this work, the energy system is assumed to be composed of a set of supplier cities that contain a set amount of raw material and could also contain modular refineries of a fixed nameplate capacity for production of a dense energy carrier (DEC). Finally, the product is transported to market cities to fulfill the required demand. Mass balance constraints for a similar system is available in Chrisandina et al. [11]. Additional constraints to include process information are outlined in this section.

## Nomenclature

The symbols used for the rest of the paper are defined in Table 1 below.

**Table 1:** Symbols and definitions for sets, parameters, and variables

Notation	Description
<u>Sets</u>	
$\mathcal{F}$	Set of manufacturing sites
$S$	Set of supplier sites
$M$	Set of market sites
$T$	Set of scheduling time periods
$U$	Set of process units
<u>Parameters</u>	
$yield_f$	Yield of product in site $f$
$G_{max_{m,t}}$	Demand for product in market $m$ at time $t$
$d_{i,j}$	Distance between two locations $i$ and $j$
$service_m$	Minimum service rate for market $m$
$x_u^{Nom}$	Nominal parameter value for unit $u$
$C_t$	Cost of shipping feedstock [\$/mile-ton]
$C_b$	Cost of feedstock [\$/ton]
$C_p$	Cost of shipping product [\$/mile-ton]
<u>Variables</u>	
$G_{f,t}$	Production from site $f$ at time $t$
$G'_{f,m,t}$	Product delivered from site $f$ to market $m$ at time $t$
$B_{s,f,t}$	Raw material from supplier $s$ consumed

	by site $f$ at time $t$
$Q_{f,t}$	Efficiency of process modules in site $f$ at time $t$
$x_{u,f,t}$	Realized parameter value for unit $u$ in site $f$ at time $t$
$Q_{u,f,t}$	Efficiency for unit $u$ in site $f$ at time $t$
$mod_{f,t}$	Number of process modules in site $f$ at time $t$
<u>Generalized functions</u>	
$\Phi(x_{u,f,t})$	Correlation between unit-level parameters and unit efficiency
$\Lambda_u(Q_{u,f,t})$	Correlation between unit efficiency and overall process module efficiency
$\Psi_f(mod_{f,t} T )$	Correlation between number of process modules and capital expense

## Constraints

These constraints are modified from the original mass balance constraints to include process efficiency information.

The product yield at each manufacturing site is governed by the amount of raw material supplied to the site and the efficiency of the process modules placed on site.

$$G_{f,t} = yield_f \times \sum_s B_{s,f,t} \times Q_{f,t} \quad (2)$$

The efficiency of a process module is defined as a multiplier on the nominal process output which depends on the operating conditions to which the process module is set. The process module efficiency is governed by the efficiencies of the critical units within the process module. The specific function that relates unit efficiency with process module efficiency depends on the exact configuration of the module.

$$Q_{f,t} = \Lambda_{u \in U}(Q_{u,f,t}) \quad (3)$$

## Objectives

The main objective of the optimization problem is to minimize total annual cost. This includes the annualized fixed cost in the purchase of process modules, as well as the operating cost (raw material purchase and transportation). The purchase cost is a function of the number of process modules deployed in the supply chain, and the specific function depends on how capacity scales with cost. The annualized fixed cost (AFC) is calculated by dividing the total capital cost across the lifetime of the process modules.

$$Cost = AFC + OPEX \quad (4a)$$

$$CAPEX = \Psi_{f \in \mathcal{F}}(mod_{f,t=|T|}) \quad (4b)$$

$$AFC = \frac{CAPEX}{years} \quad (4c)$$

$$OPEX_t = \sum_f^F \sum_s^S B_{s,f,t} \times Cb + \sum_f^F \sum_s^S (B_{s,f,t} \times d_{s,f} \times Ct) + \sum_f^F \sum_m^M (G'_{f,m,t} \times d_{f,m} \times Cp) \quad (4d)$$

To represent system resilience, we include a constraint on the target demand fill rate required at every scheduling time step.

$$\sum_f^F G'_{f,m,t} \geq G_{max_{m,t}} \times service_m \quad (5)$$

## CASE STUDY

In this work, we adapt the case study introduced by Lopez-Molina et al. [18] where refuse-derived fuel (RDF) is converted to methanol and then sold as fuel. Gasification-based technology is used, and a modular biorefinery is assumed for each manufacturing site. The goal of this case study is to compare the resilience of the supply chain to various external disruptions with and without the incorporation of process surrogate models in the supply chain formulation.

### Background Information

The RDF-to-methanol conversion process occurs via gasification to produce syngas as an intermediary, purification of the syngas, and methanol synthesis as a final step. Technical and operational details of the process are given in the literature [19, 20], and key process inputs

and outputs are shown in Fig. 1. A simplified process flow diagram is shown in Fig. 2. In this work, linear surrogate models (see Eq. 6) are generated for each critical parameter of the process, as listed in Table 2. Linear surrogates are chosen due to the small range of possible values for each critical parameter.

$$Q_{u,f,t} = m_u \frac{x_{u,f,t}}{x_{u,0}} + b_u \quad (6)$$

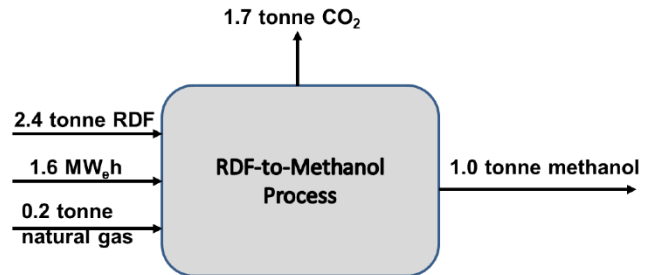

Figure 1: Key process inputs and outputs [18]

We consider the case of six cities: three producer cities which act as suppliers and manufacturers (A, B, C), and three market cities which purchase methanol (D, E, F). The specific supply availability and demand requirements are given in Fig. 3, and as a base-case scenario a 90% target demand fill rate is assumed. A planning horizon of one year with monthly schedules is assumed. The strategic decision to be made is where to locate process modules, and the operational decisions to be made are how many process modules to deploy, tuning of process

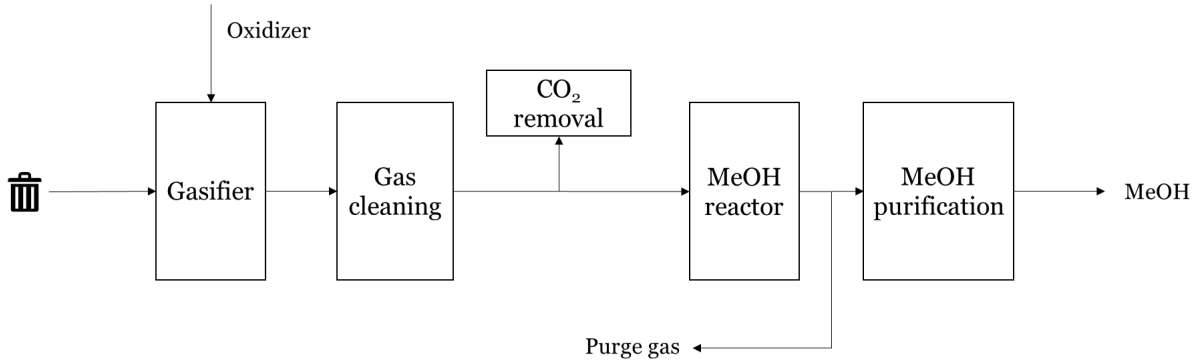

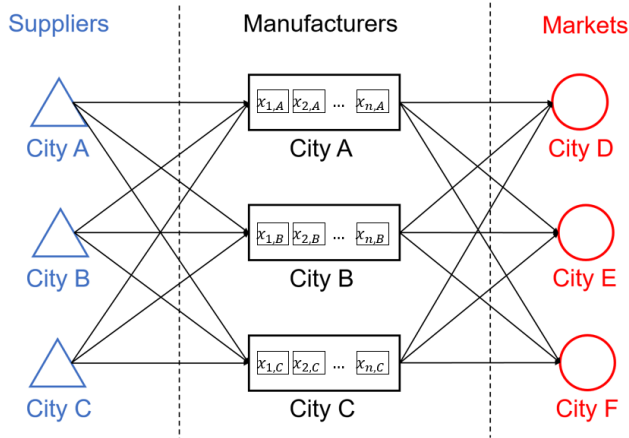

Figure 2: A simplified process flow diagram of the methanol synthesis process

Table 2: Critical parameters for methanol synthesis and their feasible operating range [20]

	Nominal operating condition ( $x_{u,0}$ )	Minimum	Maximum	Gradient ( $m$ )	Intercept ( $b$ )
MSW moisture content [%]	25	15	40	-0.24	1.23
Gasifier temperature [°C]	850	700	900	1.72	-0.72
Gasifier equivalence ratio	0.42	0.35	0.6	-1.31	2.25

## RESULTS AND DISCUSSION

### Qualitative Resilience Analysis Results

In order to identify major risks to the supply chain, a table of potential failure modes and mitigation strategies has been constructed (see Table 3). Failure modes on supply chain entities (suppliers, logistic providers, manufacturing sites, and markets) as well as on process components (gasifier, syngas purifier, methanol reactor) are

considered. It can be seen that there are multiple potential mitigation strategies for each entity failure mode and that in many cases operational changes on the process module level (a sub-entity of a manufacturing site) can help in failure mitigation. It is expected, therefore, that simultaneous optimization of process and supply chain parameters will yield a supply chain schedule that is more resilient to these failure modes. The next sub-section will aim to quantify these benefits.

### Impact of Process Tuning on Supply Chain Performance

In the base-case scenario, processes are operated at their nominal parameter values ( $Q_{f,t} = 1$ ) with a total cost of \$317MM. Several failure scenarios are tested to see if the supply chain is able to adjust. Table 4 shows the feasibility of different failure scenarios that occur in the beginning of the planning horizon. It can be seen that reacting to deviations away from the base-case scenario without process tuning increases the total cost of the supply chain, as more process modules are needed to compensate for additional production. However, process-level tuning allows for existing modules to increase production within their feasible regions as needed, which significantly reduces the additional capital investment needed to meet the new demand. In these cases, raw material and utility costs contribute to the increase in total economic cost but no new process modules were

**Table 3:** Potential failure modes and mitigation strategies

Entity	Sub-entity	Potential failure mode	Mitigation strategies
Supplier		Decline in supply availability	Multiple suppliers Tune process module to increase yield Forecasting – storage for future
Logistics provider		Technical problems with vehicle	Vehicle maintenance Investment in updated vehicles Reroute vehicles
Manufacturing site	Geographical location	Location experiences natural disaster event	Relocate process modules to other manufacturing locations
	Process module	Module temporarily unavailable	Surge production in other manufacturing sites Repair/replace module
	Gasifier	Temperature Moisture content	
	Syngas scrubber	Absorption failure	
	Methanol reactor	Low yield	
Market		Increase in demand	Acquire new modules Surge production in manufacturing sites
		Demand concentrated in one location	Relocate process modules to manufacturing sites in proximity Ship raw material to manufacturing sites in proximity

purchased. Table 5 shows the process parameter realizations that correspond to various service fill rates, which demonstrates how different process units are operated to meet specific market demands. Furthermore, the deployment of additional process modules represents an increase in material consumption that is used to construct the process modules, meaning that process-level tuning also opens up the possibility for lower emission footprint across the supply chain while delivering the same level of service throughout the year.

**Table 4:** Total economic cost of different supply chain scenarios – comparison between supply chain-only design and supply chain design with process surrogate model included

Scenario	Supply chain only	Supply chain + process
Target fill rate increases to 95%	\$357MM (+13%)	\$330MM (+4%)
Target fill rate increases to 100%	\$367MM (+16%)	\$342MM (+8%)
City E demand increases to 110%, start of year	\$357MM (+13%)	\$332MM (+4%)
City E demand increases to 110% for one month	\$343MM (+8%)	\$318MM (+0%)
City B is partially disrupted	\$344MM (+8%)	\$318MM (+0%)

**Table 5:** Process parameter realization for various service fill rates

Process parameter	Base case	Fill rate 95%	Fill rate 100%
MSW moisture content [%]	25	25	25
Gasifier temperature [°C]	850	850	900
Gasifier equivalence ratio	0.42	0.42	0.42
Reactor pressure [bar]	60	66	66
Recycle ratio	4.75	5	5.2

Some scenarios are also tested where failure modes happen in the middle of the planning horizon. Without process tuning, supply chain operational decisions are updated to address failure. With process tuning, however, process module operational decisions are also updated which provides additional options for failure mitigation. Taking Scenario #4 from Table 4 as an example, if the demand increase occurs in the middle of the year

the process module in City C (the closest manufacturing site) slightly increases its capacity temporarily to meet the additional demand without affecting the operations of the other manufacturing sites or investing in additional process modules. This temporary capacity increase is achieved by increasing the reactor pressure by 10% and recycle ratio by 5%. When the demand level lowers, the process module in City C adjusts its operation again to its baseline level.

A scenario where process-level failure occurs is also tested, where the process module in City B experiences a failure that lowers its production capacity until recovery efforts have concluded. In this scenario, City B experiences a partial failure that affects 50% of its capacity and recovery efforts are concluded at the end of the planning horizon. The other manufacturing sites respond to this failure by increasing their production so that demand can still be met, alleviating the need to invest in a replacement process module.

## CONCLUSION

To achieve a resilient and sustainable energy system, incorporating targeted strategies to mitigate potential failures while maintaining efficient resource utilization and low capital investment is critical. A multi-scale approach to design and optimization of energy systems enables a holistic assessment of potential failure modes and mitigation strategies that operate on multiple spatio-temporal scales. In this work, we have demonstrated a first attempt at simultaneous optimization of supply chain and process design by including critical process parameters as additional constraints within a supply chain model formulation. We showed that the consideration of the feasible region around each process allows the energy system design to operate in various disruption scenarios with low additional capital investment and no additional process module constructions, limiting the economic and environmental cost of these mitigation strategies. Furthermore, we also demonstrated that targeted changes can also be implemented in the middle of the planning horizon on specific nodes without affecting the overall system design or other nodes' operations. To further develop this methodology, more bespoke process surrogate models that account for the relationship between multiple critical parameters will be beneficial. Additionally, the emissions footprint of establishing or transporting additional process modules to a different manufacturing site can be incorporated to further elucidate the environmental cost of these resilience strategies. Finally, the effects of running processes at the boundary of their feasible regions on the reliability of the modules themselves need to be studied, as this may lead to an increased need for maintenance.

## ABSTRACT

We study the design and optimization of a multicomponent seawater desalination process with zero liquid discharge (ZLD). The designed process is highly integrated with multiple sub processing units that include humidification-dehumidification, Lithium Bromide absorption chiller, multi-effect evaporators, mechanical vapor compression, and crystallization. Aspen Plus software with E-NRTL and SOLIDS thermodynamic packages are used for modeling and simulation of desalination and crystallization units, respectively. In addition to this, we use data-driven optimization to find the best operating condition (i.e., the temperature of the last effect evaporator) that minimizes the overall energy consumption of the designed plant with an output constraint imposed on the mass fraction of salts going to the ZLD system should be greater than 20 wt.% to achieve the ZLD goal. We use a local sample-based data-driven optimizer, Nonlinear Optimization with the Mesh Adaptive Direct Search (NOMAD) algorithm, to perform constrained simulation-based optimization. The results show that at the optimized temperature (71.58 °C), our design produces 1777 kg/hr drinking water with an energy consumption of 536 kW in comparison to 580 kW of energy consumption for the same plant output in the base case design (not optimized). Thus, data-driven optimization of the evaporator temperature improves the overall energy consumption by 7.5% and achieves higher desalination efficiency. Further, the integration of the crystallizer unit into the overall desalination process allows us to produce about 43 kg/h of NaCl and achieve ZLD.

## INTRODUCTION

The global desalination capacity has experienced significant growth in recent decades due to the rising demand for freshwater. Accordingly, the desalination processes have sustained their position as a dependable means of obtaining potable water. Different desalination technologies including reverse osmosis, multi-stage flash desalination, and multi-effect distillation (MED) are used to produce clean water from seawater [1-2]. However, there are some critical factors to consider when designing and implementing desalination technologies.

The primary area of concern is the environmental impact of desalination. Energy consumption and the challenges associated with brine treatment are the leading causes of environmental issues that surround this technology [3]. From the brine management perspective, the

aquatic ecosystem, natural hydrologic cycles, and public health are all negatively impacted by the large quantities of concentrated brine discharge produced by conventional desalination systems. On the contrary, zero liquid discharge (ZLD) systems aim to recover the vast majority of liquid wastewater, thereby mitigating the release of harmful pollutants and reducing the expenses associated with brine waste disposal [4]. However, ZLD as a brine treatment method is notably high in energy consumption. For example, a predominant approach for achieving ZLD is via mechanical vapor compression (MVC). This technology is utilized by compressing hot water vapor from units, such as evaporators, and recycling the heat from that steam throughout the desalination process with an energy consumption of approximately 20-25 kWh per m<sup>3</sup> of desalinated water produced [5]. Tahir and Al-Ghamdi [6] also proposed a ZLD system that consists of a MED

unit, a humidification-dehumidification (HDH) unit, and an evaporative crystallizer. According to their results, the highest performance ratio (PR) value of 12 is achieved when the brine temperature is 85°C and the temperature differential is 2°C. The HDH system further recovered potable water from the saline waste stream of the MED unit with a recovery ratio of 30% to 40%. A crystallizer unit is then used to produce salts derived from the highly concentrated brine effluent. Overall, their results showed that it was possible to attain a minimum specific energy usage of 720 kJ/kg.

From the energy consumption perspective, many desalination processes are fossil fuel-powered, which comes with a high carbon footprint [7]. There have been many efforts to reduce the energy consumption of seawater desalination by incorporating different technologies such as MVC or using a Lithium Bromide (LiBr) absorption chiller [8,9]. For example, Abdulrahim and Darwish [9] presented a novel arrangement of an absorption cycle that utilizes solar radiation as the driving energy to produce chilled water for air conditioning purposes and feed saturated steam to a thermal desalination process. The proposed process had a gain output ratio of 5.7 with a cooling capacity of 1500 kW for 32 kg/s of seawater feed flow.

Previously, we have also presented a new desalination plant design that integrates multi-effect evaporators (MEEs), a LiBr absorption chiller, an MVC system, and an HDH unit to decrease the energy consumption of seawater desalination [3]. The LiBr absorption chiller and the MVC systems were employed to reclaim thermal energy from the evaporators, while the humidifiers were utilized to intensify the concentration of the brine effluent to a level appropriate for ZLD processing. Our results showed that this highly integrated system exhibited superior performance in terms of gain-output ratio of 11 and recovery ratio of 81% when compared to a conventional HDH system. Additionally, our design offered a cooling capability of 6 kW, which may be utilized for air conditioning purposes. While this proposed process was successful with seawater desalination, it did have room for improvement through mathematical optimization and the addition of a crystallization unit. Especially, data-driven and simulation-based optimization strategies have proven to be a highly successful approach for identifying the optimal process conditions across various applications [10-13].

Motivated by this, in this study, we further expand our process by adding a flash separator, crystallizer, and solid separator units to produce NaCl salts and reduce the brine discharge to almost zero. We also transitioned from two-component analysis to multicomponent analysis, as initially the feedstock was only simulated with water and NaCl. Moreover, we use data-driven optimization to find the optimized operation conditions for the MEEs to reduce the energy consumption of the overall process.

To this end, we use the nonlinear optimization with mesh adaptive direct search algorithm (NOMAD) [14] and impose output constraints on the discharged NaCl concentration in the effluent stream to ensure ZLD.

## METHODOLOGY

In this work, desalination is carried out using seawater as the source water. Previously, we used a two-component system to define the seawater composition (3.5 wt.% NaCl with the remaining being water) [3]. Here, we use a multicomponent analysis for the seawater components with their respective composition values shown in Table 1.

**Table 1:** Seawater feed composition [15].

Component	Mass Fraction
Water	0.966346
NaCl	0.0261789
MgCl <sub>2</sub>	0.00226156
MgSO <sub>4</sub>	0.00323751
KCl	0.000706899
NaHCO <sub>3</sub>	0.000188049
CaCl <sub>2</sub>	0.00108062
LiCl	8.928e-07

## Modeling & Simulation of the Base Case Desalination Units

The base case desalination process consists of the integration of four different technologies: HDH, LiBr absorption chiller, MEE, and MVC. Seawater with a flowrate of 1950 kg/hr first enters the LiBr absorption chiller cycle where it is preheated. Afterward, the preheated seawater stream enters three multi-effect evaporation units where water is evaporated to steam. The effluent steam from the last effect is then compressed in the MVC subprocess, where we compress the incoming vapor up to 1.5 bar. This is then used to activate the generator in the LiBr cycle. The steam exiting the generator is recycled to the evaporators and as energy is released, the steam condenses and is collected as desalinated water. The brine discharged from the MEE units goes to the humidifiers to be further concentrated. This process is modeled in Aspen Plus (V12.0) with the E-NRTL thermodynamic package using the default parameters. The details on model assumptions and simulation setup for this process can be found in [3].

## Path to Zero Liquid Discharge

To reach ZLD and minimize brine discharge, we add a flash separator, crystallizer, and solid filter units to the base case design (Figure 1). The concentrated brine

effluent from the humidifiers goes to the flash separator first, where water vapor is recovered as desalinated water, and the brine is further sent to the crystallizer unit to be precipitated and crystallized.

**Figure 1:** Crystallizer flowsheet with a flash separator, crystallizer unit, and solids separator.

**Table 2:** Solubility data of NaCl in water [15].

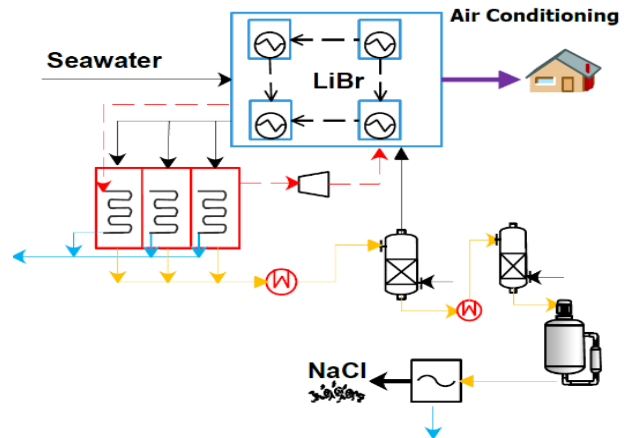

Temperature (°C)	Solubility (g/L)
0	355.2311

60	369.4882

**Table 3:** Operating parameters for the ZLD units.

Unit	Temperature (Celsius)	Pressure (Bar)
Crystallizer	25	0.3
Flash Separator	85	0.4
Evaporator (optimized)	71.58	0.5

To have accurate results for the crystallizer, we use experimentally determined solubility data of NaCl in water [15], as shown in Table 2. This solubility data is utilized by the SOLIDS thermodynamic package in Aspen Plus to determine how much NaCl salt will crystallize. Finally, the output stream of the crystallizer is processed in a solid separator and NaCl salts are recovered. The other salts present within the brine are treated as inert salts, where

we assume that their crystallization is negligible due to their relatively small concentration compared to NaCl. The solid separation efficiency is also assumed to be 100%. The key operating parameters used for simulating the ZLD units are provided in Table 3, with an overview of the process shown in Figure 2.

**Figure 2.** Process overview of the designed multipurpose desalination system.

### Data-Driven Optimization

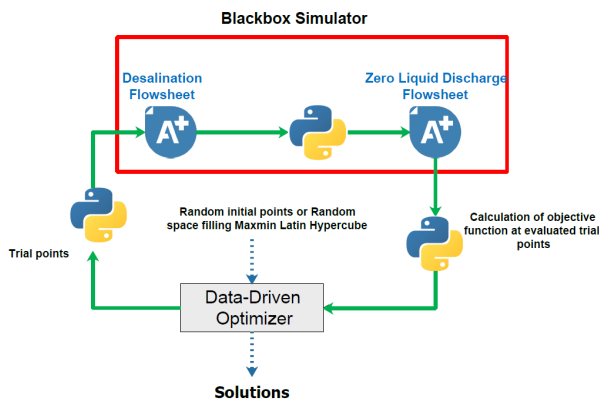

We used data-driven black-box optimization to optimize our operating conditions and minimize the energy consumption of the plant while maintaining ZLD. We formulate the following optimization problem:

$$\begin{aligned}
 & \min_x f(x): \text{Energy consumption} \\
 & \text{s.t.} \\
 & \quad g_i(x) \leq 0 \quad \forall i \\
 & \quad h_j(x) = 0 \quad \forall j \\
 & \quad x \in [x^L, x^U]
 \end{aligned} \tag{1}$$

where  $x$  is evaporator temperature for the last effect (*i.e.*, the decision variable) bounded between 60°C to 80°C,  $g(x)$  is the inequality constraint regarding the mass fraction of salt in the discharge brine which has to be greater than or equal to 21% wt. (*i.e.*,  $g(x) = 0.21 - \text{mass fraction of NaCl in brine} \leq 0$ ), and  $h(x)$  are the equality constraints pertaining mass and energy balances that are satisfied in Aspen Plus. We also performed sensitivity analysis on the base case simulation to identify the operating variables (*i.e.*, decision variables) with the greatest effect on energy consumption. We found that the evaporator temperature had the greatest impact on energy consumption. Here, we do not consider all evaporator temperatures as decision variables because the 1<sup>st</sup> and 2<sup>nd</sup> effect evaporator temperatures depend on the temperature of the last effect. Hence, only the temperature of the last effect evaporator is a true degree of freedom for optimization.

Our strategy for mathematically optimizing this process is considered a black-box optimization, as the

mechanistic expressions are accounted in Aspen Plus and not explicitly available to us. As a result, we collect input-output data from the simulator to identify the best operating condition for the evaporator temperature that minimizes the total energy consumption of the designed plant while achieving ZLD. To this end, we utilize the NOMAD and its progressive barrier constraint handling approach to solve Equation 1, as NOMAD is a local data-driven optimization algorithm. This algorithm is easy to implement and has shown good optimization performance for black-box problems with less than 50 variables. NOMAD can also handle nonlinear inequality constraints with a relatively low computational time [14].

**Figure 3.** Schematic of the connection between two Aspen Plus flowsheets and the flow of information between a generic data-driven optimizer and Aspen Plus.

To perform data-driven optimization, we first randomly initialize the algorithm within the lower and upper bounds of the decision variables. Following that, we solve the Aspen Plus simulation at this sampling point to collect the corresponding output values for the objective function and constraints. It is important to note that we execute Aspen Plus in two separate flowsheets due to having two different thermodynamic packages for the desalination and ZLD units. Once the first simulation (desalination) converges at a given sampling point, the data for the brine output in the first flowsheet is inputted as the feed conditions for the second flowsheet (ZLD). Final energy consumption from both processes is calculated by summing the energy consumption from individual flowsheets, and this serves as the output data along with the discharge brine concentration constraint. This data exchange is facilitated by a Python script (V.3.11) which relays the final input-output data to the NOMAD. After that, the algorithm generates new evaluation points to iteratively improve the incumbent solution, and the loop continues until a stopping criterion is met, such as reaching the maximum number of evaluations, or a tolerance for the mesh size [14]. Figure 3 illustrates how we performed the optimization over two flowsheets for a generic data-driven optimization process. We perform the process

simulation and the data-driven optimization on a Dell Precision Small Form Factor with 11th generation Intel Core i7- 11700, 4.9 GHz processor, and 16GB DDR4 installed memory running Microsoft Windows.

## RESULTS

The simulation results comparing the base case desalination and the new ZLD design are shown in Table 4. The key process parameters such as relative humidity and seawater temperature are set to be 80% and 20 °C, respectively. A full set of the base case parameters can be found in [3]. We observe that the optimization of the evaporator temperature reduced the desalination energy consumption by 7.5% (580 kW energy in the base case to 536 kW energy in the ZLD) for the same feed seawater and freshwater production flowrates. The energy consumption of the crystallizer flowsheet is 164 kW, which comes from the flash separator that is used to further concentrate the brine to a concentration that produces significant crystallization, salt production, and water vapor that can be recycled for heating. We observe that the water vapor is discharged at 217 kg/hr at 85 °C and 0.4 bar from the flash separator. This water vapor can also be condensed which will increase the freshwater production by 217 kg/hr which is another benefit of adding crystallization. The marginally higher total energy consumption from the two flowsheets is also an expected result for the new design, as we added three new units to achieve ZLD.

Moreover, the results show that with the addition of a crystallizer unit, we were able to produce approximately 43 kg/h of NaCl and nearly doubled the total dissolved solids (TDS) concentration of the discharged brine. Initially, according to the composition of seawater, there is about  $1950 \times 0.026 = 50.7 \text{ kg/h}$  of NaCl in our process. This means that our process achieves approximately 85% NaCl removal efficiency.

Furthermore, we show the compositions of the final brine to be discharged in Table 4, and it can be seen that the final brine is highly concentrated (TDS > 530,000 mg/L) with a mass flow rate of 43.88 kg/h. Compared to the process without ZLD units, we reduced the brine discharge from 302 to 43.88, approximately an 85% reduction. This would be valuable in reducing the environmental footprint of desalination. This brine reduction is due to the higher water recovery that we obtained by optimizing the process as well as the flash separator. Before adding the ZLD units to the base case simulation, the water recovery was about 81%. After adding the ZLD units, it further increased by 10 %. In our new design, we can recover 1777 kg/hr of freshwater from 1950 kg/hr of seawater

**Table 4.** Base case and ZLD results.

	Base Case	ZLD
Air temperature [°C]	30	30
Feed seawater Temperature [°C]	20	20
Seawater flowrate [ $\frac{m^3}{hr}$ ]	1.95	1.95
Relative humidity [%]	80	80
Humidifier pressure [bar]	0.5	0.5
Cooling Capacity (kW)	6	6
Crystallizer Salt Production [ $\frac{kg}{hr}$ ]	-	43.27
Freshwater Production [ $\frac{kg}{hr}$ ]	1560	1560+(217)
Energy Consumption of Desalination Flowsheet [kW]	580	536
Crystallizer Unit Energy Consumption [kW]	-	164
	<b>Base Case Brine</b>	<b>ZLD Brine (Filter Output)</b>
NaCl (%)	16.7	16.4
MgCl <sub>2</sub> (%)	2.75	18.92
MgSO <sub>4</sub> (%)	1.17	8.02
KCl (%)	0.75	5.1
NaHCO <sub>3</sub> (%)	0.05	0.2
CaCl <sub>2</sub> (%)	0.65	4.5
LiCl (%)	0.003	0.6
TDS (mg/L)	221,700	537,400
Mass flow (kg/hr)	302	43.88

fed. In this study, we also did a simple calculation of revenue that can be gained by adding the ZLD components to the desalination units. Our base case had freshwater production as a revenue stream; however, with the optimized ZLD case, the amount of freshwater produced increased due to using a flash separator in the crystallizer flowsheet. The ZLD discharge case also produces salt through crystallization, providing another significant revenue stream while desalinating the brine and reducing the environmental impact of the discharge. Table 5 shows a simple calculation of the revenue that we can gain from water and salt production. Our analysis assumes that the average selling price for NaCl salt is 0.2 \$/kg [3] and the water selling cost is \$0.12/kg. The integration of ZLD units will result in generation of 217 kg/h of additional water in compared to process without ZLD units. This will result in \$206,237 /yr revenue from selling water. We also assume that the plant will be operating for 330 days annually.

Our calculations show that adding the crystallization units will result in \$274,776/yr revenue compared to a process without crystallization units. However, a detailed technoeconomic analysis is required to understand the economic viability of the process.

**Table 5:** Revenue streams of the ZLD process.

Revenue source	Assumptions	Amount
Salt Production	0.20 $\frac{\$}{kg}$	68,539 $\frac{\$}{yr}$
Fresh Water Production	0.12 $\frac{\$}{kg}$	206,237 $\frac{\$}{yr}$
Total revenue		274,776 $\frac{\$}{yr}$

## CONCLUSIONS

In this work, we modeled and simulated a zero liquid discharge desalination process using a Lithium Bromide absorption chiller, multi-effect evaporators, and mechanical vapor compression with crystallization. This process enabled us to recover more than 90% of seawater while producing NaCl salts. The results showed that we can have more than 43 kg/hr NaCl out of 1950 kg/hr seawater with approximately 85% NaCl removal efficiency. Our preliminary revenue analysis showed that we can gain \$274,776/yr with fresh water and salt production serving as the main products. In addition to this, we performed data-driven optimization to minimize energy

consumption in the process. Although the optimization in our study only considered the temperature of the last evaporator effect, the results showed that we can reduce the energy consumption by 7.5%. In the future, we will explore the optimization of other operational parameters and characterize their effects on the overall energy consumption. Some additional parameters that we are considering for optimization include the flash separator temperature and pressure as well as the operating pressure of the evaporators. These parameters showed significant influence on energy consumption during our initial sensitivity analysis, but further work must be done to see if they are viable candidates for optimization parameters. Furthermore, we will perform a comprehensive techno-economic analysis and life cycle assessment to quantify the economic and environmental impacts of the process, respectively.

## ACKNOWLEDGEMENTS

This work is conducted with the computing resources provided by the University of Connecticut.

## ABSTRACT

Critical minerals are essential to the future of clean energy, especially energy storage, electric vehicles, and advanced electronics. In this paper, we argue that process systems engineering (PSE) paradigms provide essential frameworks for enhancing the sustainability and efficiency of critical mineral processing pathways. As a concrete example, we review challenges and opportunities across material-to-infrastructure scales for process intensification (PI) with membranes. Within critical mineral processing, there is a need to reduce environmental impact, especially concerning chemical reagent usage. Feed concentrations and product demand variability require flexible, intensified processes. Further, unique feedstocks require unique processes (i.e., no one-size-fits-all recycling or refining system exists). Membrane materials span a vast design space that allows significant optimization. Therefore, there is a need to rapidly identify the best opportunities for membrane implementation, thus informing materials optimization with process and infrastructure scale performance targets. Finally, scale-up must be accelerated and de-risked across the materials-to-process levels to fully realize the opportunity presented by membranes, thereby fostering the development of a circular economy for critical minerals. Tackling these challenges requires integrating efforts across diverse disciplines. We advocate for a holistic molecular-to-systems perspective for fully realizing PI with membranes to address sustainability challenges in critical mineral processing. The opportunities for PI with membranes are excellent applications for emerging research in machine learning, data science, automation, and optimization.

## INTRODUCTION

As of 2022, there are 50 critical minerals [1] essential to renewable energy, such as lithium and rare earth elements (REEs). Lithium is vital to the function of several different types of batteries. REEs, particularly dysprosium, neodymium, praseodymium, and terbium, have unique properties (e.g., magnetic, fluorescence), which make them essential components of many electronics and clean energy technologies (e.g., displays, hard disk drives, wind turbines, electric vehicles). [2] Further, the term “rare” denotes that REEs are economically difficult

to produce or concentrate [3]; although relatively abundant, REEs are generally present in very low concentrations.

Overall, there is a need to diversify the supply of critical minerals, as primary sources (e.g., minerals, clays, and brines) have been declining in quality (i.e., the concentration of critical minerals) [4,5] and the global energy transition (amongst other factors) has increased the demand for critical minerals. The combination of these issues drives a need to develop enhanced recovery processes, including for end-of-life materials, to obtain critical mineral supplies, improve sustainability, and progress

toward circularity goals. [6] These sustainability-driven efforts include moving attention towards alternative feedstocks such as recycled electronic waste and unconventional sources like coal fly ash. Additionally, the concentrations of critical minerals in some alternative and unconventional sources are beginning to surpass those in primary sources. [2,7,8] Regardless of the source, critical mineral processing generally relies on techniques that can use hazardous materials (e.g., acid leaching). [9] One pathway to enhance sustainability and improve the process performance of critical mineral systems may be to integrate membrane technology, which has a track record of success in other industries (e.g., desalination, water treatment, chemical processing, and biomanufacturing). [10]

This brief literature review focuses on opportunities for membrane technologies to optimize and intensify critical mineral processing systems. We emphasize the importance of a molecular-to-systems perspective with close collaborations between process systems engineering (PSE) and other fields (e.g., membrane, data, and computational sciences) to accelerate the development of a circular economy.

## CRITICAL MINERAL PROCESSING

### Evolving Supply Chains

The continued development of domestic critical mineral infrastructure is vital to decreasing reliance on foreign supply chains. Taking the United States as an example, in 2022, the country produced only 14 critical minerals domestically, relying entirely on net imports for 12 critical minerals and more than 50% on net imports for another 31 critical minerals. [11] Developing domestic supply chains will safeguard against unforeseen insecurities in the global market. For example, the COVID-19 pandemic caused disruptions across all aspects of supply chains, where production of certain critical minerals (e.g., manganese) decreased, and consumption of others (e.g., platinum) increased. [11] Therefore, securing reliable supply chains of critical minerals will be essential to national security and the clean energy sector.

The growing dependence on technology and the decreasing quality of primary ore necessitates a more concerted shift towards harvesting critical minerals from secondary and unconventional sources, including recycled materials. In particular, integrating recycled waste into current infrastructure can promote a circular economy for critical minerals; therefore, developing new and existing processes is essential to achieving global climate goals. There has been some progress in recycling practices; for example, the domestic supply of 7 critical minerals in the United States consisted exclusively of recycled materials [11].

## Technology and Challenges

Critical mineral processing systems often contain the four steps presented in Figure 1: mining/extraction, beneficiation/pre-treatment, chemical extraction, and separation/purification. [12] The technology used within these steps depends on the feed stream. For example, mineral ore requires mining techniques (e.g., open-pit, underground, *in situ* extraction) to extract host rocks or the critical minerals [13]; brines frequently need to be pumped from underground [14]; and end-of-life consumer waste (e.g., cell phones) requires diversion from landfills via collecting the products to be recycled (i.e., urban mining). Beneficiation (or pre-treatment) encapsulates the techniques that concentrate the critical mineral feeds by removing unwanted parts (e.g., nonvaluable rock and casings on electronic devices) or physically pre-concentrate liquid sources. Typically, both chemical extraction and separation/purification employ hydrometallurgical (i.e., leaching, solvent extraction, and precipitation) or pyrometallurgical techniques (i.e., high temperatures) [7], which obtain critical minerals in usable quantities and purities.

**Figure 1.** Generalized block-flow diagram for critical mineral processing route.

Overall, there is motivation to revolutionize the processing structure of critical minerals to reduce the environmental impact, physical footprint, or cost of purification. Conventional processing can produce large waste streams, which can be detrimental to the environment, or may have large physical footprints that disturb habitats. For example, acid leaching (hydrometallurgy) dissolves solid critical minerals into a liquid phase, creating acidic waste that requires treatment before disposal. On the other hand, lithium recovery from salt-lake brine has an extensive physical footprint, using large evaporation lakes/ponds to precipitate contaminants out of the solution successively. [15] Separation processes such as solvent extraction use long sequences of settling tanks and separators and have slow process dynamics; thus, they cannot quickly adapt to changes such as new feed concentrations or product specifications. In many of these areas, the focus has shifted to designing processes that reduce the environmental footprint and can address variability in the feed concentrations. Some sustainable solutions address specific environmental concerns (e.g., an

electronic waste recycling process that limits the use of mineral acid leachates [9]); however, the processes are typically bespoke. Replacing certain hydrometallurgical techniques with mass separating agents (e.g., membrane systems) can offer environmental benefits for all critical mineral feed streams and facilitate process intensification (PI).

## CRITICAL MINERAL PROCESS INTENSIFICATION

### Membrane Opportunities

Membranes are uniquely equipped to aid in PI, as they can potentially improve efficiency, energy consumption, and cost in many chemical engineering systems. [10] Table 1 organizes a non-exhaustive set of references by the lithium- or REE-based feed stream and the corresponding applications of membrane technologies.

Recently, there has been significant work in developing membrane units for critical mineral separations. For example, comprehensive lithium recovery processes from salt-lake brine, primarily relying on nanofiltration (NF), have produced high-purity lithium products. [16–18] Kumar *et al.* [19] developed a process for recycling lithium-ion batteries (LIB) that leverages membranes to obtain battery-grade lithium carbonate. However promising, these processes are limited by their bench-scale design for singular feed streams. Membranes with charge-based separation mechanisms have been extensively applied to lithium extraction. For example, NF membranes have successfully separated lithium and magnesium ions in salt-lake brines by leveraging electrostatic interactions. [20] Similarly, liquid membranes have shown similar separation capabilities with REEs from coal fly ash leachate while utilizing less hazardous solvents than conventional solvent extraction. [21] Adsorption-based membrane techniques have demonstrated enhanced separations for both lithium and REEs. [22,23]

Additionally, membrane distillation has been implemented to achieve lithium recovery from brine four times faster than conventional evaporation ponds, with 20 times less surface area, and a corresponding reduction in physical footprint. [24]

PSE can guide future membrane studies like those presented in Table 1. Specifically, membrane cascades, which enable fractionation (i.e., utilize staged separations to isolate single-ion product streams), will be vital within critical mineral processing due to the complex feed streams typical of the industry. For example, batteries in electric vehicles can contain the following critical materials: lithium, cobalt, manganese, nickel, and graphite. [25] While the components are relatively well-defined, the specific material compositions will vary depending on the battery type. [26] Processes to recycle the components of diverse batteries must be able to separate critical minerals from one another for efficient downstream re-manufacture. The optimization of membrane cascades is one of the significant benefits that PSE offers within the critical mineral space.

### Multiscale and Interdisciplinary Challenges

The ability to rapidly develop, optimize, and scale up processes can accelerate circular supply chain development and the ability to meet clean energy (and, by extension, critical mineral production) goals. Multiscale optimization can be achieved with bidirectional (bottom-up and top-down) feedback to link technology breakthroughs at materials and device scales with process scale-up, supply chain optimization, and policy development at process and infrastructure scales. We now elaborate on these themes in five specific research opportunities.

### Machine Learning to Accelerate Material Design

Due to the number of different membrane materials (e.g., organic, inorganic) [27], materials should be chosen optimally for critical mineral separations and process

development. Membrane optimization is usually inefficient when pursued solely through Edisonian experimentation due to the complexity of the design space (i.e., the parameters needed to describe material properties and reaction conditions) and the physical phenomena (i.e., the parameters within the mathematical model). [27] As such, machine learning (ML's) capabilities with high-dimensional data make it well-suited to tackle membrane problems with many degrees of freedom. [27] Membrane development efforts present an opportunity to further improve and enhance the design, environmental impact, and performance of critical mineral and material production systems, with the performance of membrane materials being the limiting factor in new, more environmentally responsible processes. [28] Recently, there have been significant developments in ML techniques to push the functionality of membrane materials. For example, Bayesian optimization (BO) [29] can search the vast design space (i.e., monomer and fabrication conditions) for NF membranes. [30] The advanced capabilities of BO increased the efficiency of membrane design and allowed for the fabrication of membranes that exceeded the upper limit of the trade-off between water selectivity and permeability. [30]

Mathematical modeling and ML can connect material design with larger length scales to enhance technological success. [27,31] For example, Eugene *et al.* [31] explored adsorptive membranes for removing lithium from water, comparing the properties of several sorbents to identify feasibility ranges. Further, the framework enables analysis of membrane performance after scale-up, emphasizing the importance of characterizing materials within the desired operating range. As another example, Rall *et al.* [32] used artificial neural network surrogate models to optimize membranes at the material and process levels. Testing new materials within the desired system will become vital within critical mineral separations as the feed streams evolve. For instance, process development and optimization must occur as new critical mineral sources emerge in recycled products. Employing similar frameworks for newly identified feed streams can accelerate material testing, process development, and scale-up.

## Optimizing Membrane Modules

Computational fluid dynamics (CFD) helps optimize transport and flows in membrane module and device designs. [33] For example, Shirazi *et al.* [34] applied CFD to membrane distillation (MD), a thermally-driven membrane separation process, offering guidance on the physical design of the MD module and improving membrane performance. Recently, Choi *et al.* [35] used CFD with design of experiments (DoE) to identify variables affecting performance and determine the optimal MD module design. Similar optimization strategies using CFD

simulations have been applied to membrane bioreactors. [36,37] The success of CFD techniques in optimizing the physical membrane module design can extend to the critical mineral space to enhance overall process development further.

## Increasing Experimental Efficiency

PSE paradigms motivate the transition from Edisonian research to optimized and automated experiments.

We posit that membrane science is ripe to benefit from experiment automation and optimization advances. Automating experiments can accelerate material discovery by reducing the required time. For example, Muetzel *et al.* [38] automated a diafiltration experiment, reducing experimentation time by 40% and discovering concentration dependence of transport parameters. Similarly, Ouimet *et al.* [39] dosed a diafiltrate (of higher or lower concentration than the feed) into their automated diafiltration system to evaluate an expansive concentration space for water purification, leading to parameter identification five times faster than traditional filtration methods.

More robust efforts in enhanced experimental automation focus on self-driving laboratories (SDLs), which combine robotics and automated lab work with ML techniques to iterate experiments until the desired objective is reached. [40] SDLs improve computational efficiency (compared to the scientist performing the analysis) and increase the speed and precision of repetitive experimental techniques. [40] Further, SDLs can improve material discovery. For example, MacLeod *et al.* [41] recently developed a SDL for palladium film synthesis to quantify the trade-offs between temperature and conductivity. Their SDL required human action every 40-60 experiments, providing a robust dataset of information and overcoming human limitations. [41] Alternatively to SDLs using data-driven ML models, experimentation can be optimized using model-based design of experiments (MBoE). MBoE exploits the mathematical structure of science-based models to identify the experiments that will generate the most informative data efficiently. [42] We anticipate that SDLs driven by MBoE will be critical to navigating the complex (often competing) phenomena that govern efficient membrane separations.

## Process Design and Optimization

Membrane cascades typically have several feasible designs [43], and as the system complexity or size increases, it becomes unfavorable for the researcher to optimize each process individually. Superstructure optimization (SSO) is a popular strategy to assess all configurations using mathematical programming [44], subject to the desired objective (e.g., minimizing energy or cost, maximizing recovery or revenue) and constraints (e.g.,

transport phenomena, number of stages).

The success of SSO for membrane-based processes in other fields (e.g., carbon capture [43,45,46]) can inform future work in the critical mineral space. SSO has optimized membrane cascades within post-combustion carbon capture to identify more efficient designs. [43,45] SSO routinely accommodates multiple objectives (e.g., cost, emissions, water usage). [46] The generalizability of SSO also allows for increased flexibility (e.g., configuration size, separation type, individual module performance). For example, Lee *et al.* [45] found that varying the membrane properties in different stages (higher permeance upstream, higher selectivity downstream) improved process performance and efficiency. The generalized framework of SSO enables the application to diverse applications, allowing adaptation within critical mineral separations. Specifically, diafiltration cascades have used SSO for lithium-cobalt separation systems [47], efficiently optimizing staged separations and evaluating trade-offs in material property targets.

### Supply Chain Optimization

Finally, supply chain optimization can identify the best opportunities for PI to maximize the impact at a global scale by promoting resilient and circular supply chains for critical minerals. For example, Canales-Bustos *et al.* [48] considered economic and environmental factors to optimize a mining supply chain subject to decarbonization goals. Fattahi *et al.* [49] investigated uncertainty in the critical mineral supply chain through multi-stage stochastic programming. Similar studies performing optimization under uncertainty will be essential to developing resilient supply chains, as variability in feed concentration, desired product specifications, market prices, and consumer demand is inevitable. After integrating membranes within process and infrastructure models, PSE methods enable the communication of performance targets back to the materials and device scales. This integrated feedback loop is the key to rapidly optimizing enhanced critical mineral processes within a circular economy.

### CONCLUDING REMARKS

We propose a molecular-to-systems perspective of critical mineral processing and process systems engineering to enable process intensification with membranes. Machine learning techniques enable accelerated material discovery by evaluating material properties and process targets across materials, devices, and systems scales. Material discoveries lead to more robust device design, which can be further enhanced using automation and optimization techniques. Superstructure optimization of membrane cascades increases the generalizability and flexibility of process design and can evaluate

membrane material property targets and design specifications. Finally, supply chain optimization enables multi-stakeholder optimization by managing material and energy flows and determining facility siting. [50] The advancements within the device and materials scales inform process design and infrastructure development, and vice versa, emphasizing the need for a holistic approach involving the materials, membrane, data, and computational science communities.

### ACKNOWLEDGEMENTS

M.D. recognizes support from the Arthur J. Schmitt Presidential Leadership Fellowship. L.L. received support from a Graduate Assistance in Areas of National Need fellowship from the Department of Education via Grant P200A210048 and the Remick Graduate Fellowship in Engineering administered by the University of Notre Dame. This work was kindly supported by the National Science Foundation (NSF) through award 2147605. J.A.O. gratefully acknowledges support from the CEST/Bayer Predoctoral Fellowship. This effort was funded by the U.S. Department of Energy's Process Optimization and Modeling for Minerals Sustainability (PrOMMiS) Initiative, supported by the Office of Fossil Energy and Carbon Management's Office of Resource Sustainability.

## ABSTRACT

Some of the most highly trusted and ubiquitous process simulators have solution methods that are incompatible with algorithms designed for equation-oriented optimization. The natively unconstrained Efficient Global Optimization (EGO) algorithm approximates a black-box simulation with kriging surrogate models to convert the simulation results into a reduced-order model more suitable for optimization. This work evaluates several established constraint-handling approaches for EGO to compare their accuracy, computational efficiency, and reliability using an example simulation of an amine post-combustion carbon capture process. While each approach returned a feasible operating point in the number of iterations provided, none of them effectively converged to a solution, exploring the search space without effectively exploiting promising regions. Using the product of expected improvement and probability of feasibility as next point selection criteria resulted in the best solution value and reliability. Constraining probability of feasibility while solving for the next sample point was the least likely to solve, but the solutions found were most likely to be feasible operating points.

---

**Keywords:** Derivative Free Optimization, Surrogate Modeling, Process Simulation, Global optimization, Carbon Capture.

## INTRODUCTION

Process simulators are trusted sources of property prediction and process design calculations [1]. Some process simulations have characteristics that challenge most optimization algorithms. Black-box simulators have no exploitable functional form, computationally expensive executions, and approximate derivatives. Coupled with highly constrained optimization formulations, these characteristics make most algorithms inefficient when applied to process simulations.

Many different optimization techniques have been applied to process simulators. Gradient-based optimizers have been applied using finite difference approximation for derivatives. Derivative-free optimization techniques can be applied, but many rely prohibitively large numbers of objective function evaluations without extensive parallelization [2]. One approach to mitigate the challenges of expensive black-box optimization is to approximate

the objective and constraint functions with surrogate models. In theory, these types of optimization algorithms should improve in accuracy each time the objective and constraint functions are sampled, learning characteristics of the problem each iteration [3].

Several types of surrogate models have been used to approximate process simulators. Automatic surrogate model generation has been achieved through several routes. ALAMO uses subset selection for constrained regression to generate algebraic models suitable for optimization [4–6]. Others have used parametric [7] and non-parametric regression methods like neural networks [8], radial basis functions [9], and kriging models [10–12] to approximate process simulations.

The Efficient Global Optimization (EGO) algorithm [13] is a prevalent example of surrogate-based optimization. EGO uses a kriging surrogate model in an inner loop optimization to pick the next point to sample. While it has been extensively used in aerospace engineering design

optimization, EGO has rarely been applied to process engineering systems.

Contemporary research studies probability of feasibility, mean kriging predictions, and lower confidence bounds to constrain EGO's inner loop [14, 15]. This work applies EGO with selected constraint approaches to a post-combustion carbon capture process modeled in ProMax®. The objective is to minimize process energy intensity subject to process and reliability constraints.

The results compare the merits of each constraint approach according to constraint faithfulness, final objective value, and solution reliability. Conclusions are drawn to recommend which methods are most effective for the post-combustion carbon capture process.

## CONSTRAINED EGO OVERVIEW

EGO was first published by Jones, Schonlau, and Welch in 1998 [13]. They developed the algorithm to globally optimize expensive objective functions. The overall structure of the algorithm is as follows. Let  $F(x)$  be function of independent variables  $x$  to be minimized that returns a value  $y$ .  $F(x)$  can be sampled at different points  $X = \{x_1, x_2, \dots, x_n\}$  yielding  $Y = \{y_1, y_2, \dots, y_n\}$ . This initial dataset is selected using methods called design of experiments to fill the search space.  $X$  and  $Y$  are used to generate a kriging model  $f$  with mean and variance functions. Equation 1 shows the structure of the kriging model used in this work where  $\beta_i$  and  $\theta_i$  are sets of hyperparameters tuned during the model building process.

$$\hat{\mu}(x) = \sum_{i=1}^n \beta_i y_i + \prod_{i=1}^n \exp(-\theta_i |x_t^{(i)} - x_t^{(j)}|) \quad (1)$$

EGO uses this predicted mean and a predicted variance within selection criteria to determine the next best point to evaluate using the actual objective function. EGO has traditionally maximized a property called expected improvement  $EI$  to select the next point to evaluate. The expected improvement function is written in equation 2, where  $\sigma(x)$  is the prediction standard deviation, and  $\Phi$  and  $\phi$  are the cumulative and probability density functions, respectively.

$$EI(x) = (f_{\min} - \hat{\mu}(x)) \Phi(a(x)) + \sigma(x) \phi(a(x)) \quad (2)$$

$$a(x) = \frac{f_{\min} - \hat{\mu}(x)}{\sigma(x)}$$

Once EGO determines the point that maximizes the expected improvement function, it samples the objective function with the point. The new sampled point is then added to the end of the dataset. As shown in Figure 1, the next iteration then begins by refitting the kriging model with the new dataset.

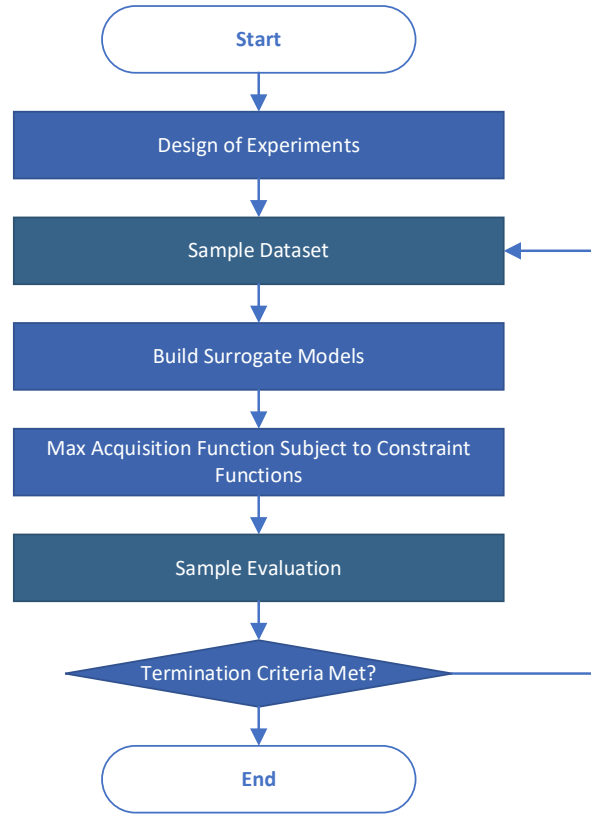

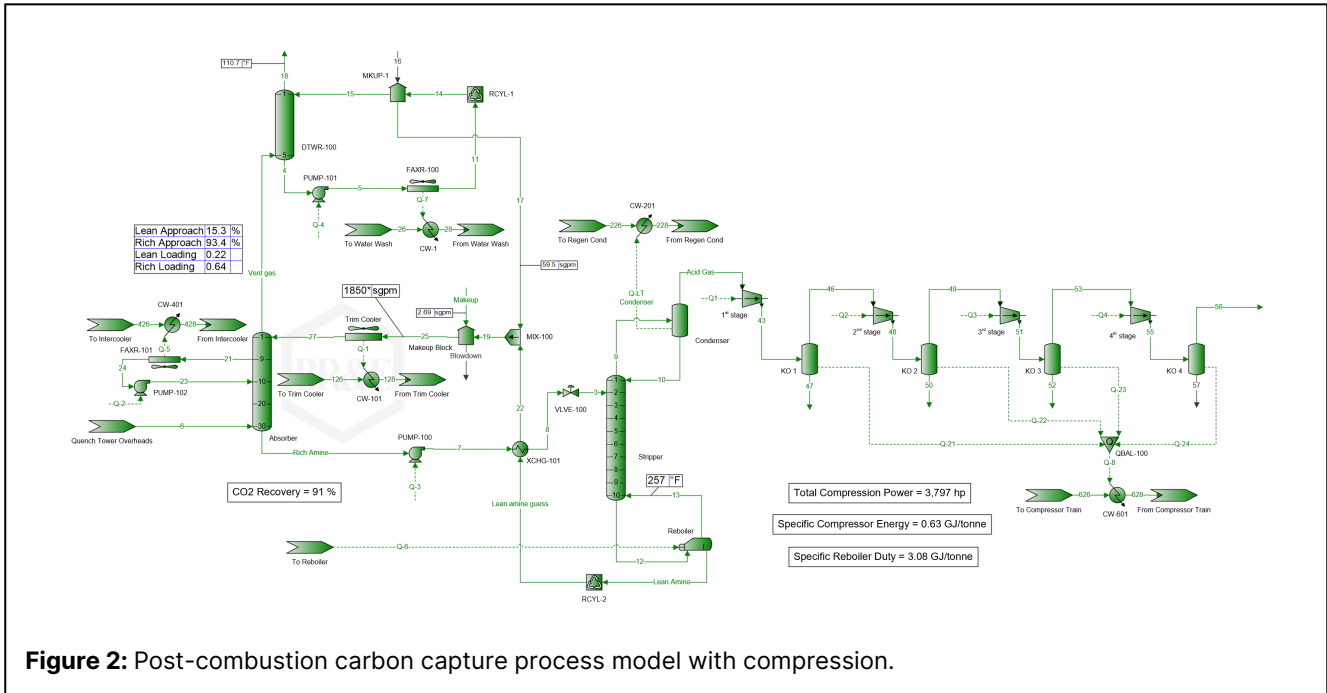

Figure 1. General EGO Algorithm Flowchart

Several constraint-handling methods have been developed for EGO. Modifying the next point selection criteria, the three approaches tested in this work rely on different properties of kriging models to enforce constraint boundaries. Two of these methods rely on a calculated probability of feasibility and were proposed by Sohst et al [14], who found that each method had its merits solving both mathematical test problems and aerodynamic shape optimization. Probability of feasibility can be conceptually understood as the probability that each constraint will be satisfied for a point based on the uncertainty in the kriging model for each constraint function. The formulation is shown in equation 3 where the constraint function is written in the form  $g(x) \leq 0$ . Overall probability of feasibility is just the product of each individual constraint's probability of feasibility.

$$PF(x) = \Phi\left(-\frac{\hat{g}(x)}{\sigma(x)}\right) \quad (3)$$

Probability of feasibility can be used in a few different ways to augment expected improvement within EGO's next point selection criteria. In one method, the product of expected improvement and probability of feasibility is maximized to select the next sample point. This method will be referred to as OFPF (Objective Function x Probability of Feasibility) in this work and is shown in equation 4.

$$\max OFPF(x) \quad (4)$$

**Figure 2:** Post-combustion carbon capture process model with compression.

$$OFPF(x) = EI(x) \cdot PF(x)$$

Another method tested in this work applies a probability of feasibility constraint to the maximization of expected in the next point selection suboptimization problem. This method will be referred to as PFCON (Probability of Feasibility Constraint).

$$\begin{aligned} \max EI(x) \\ \text{s. t. } PF(x) \geq 0.5 \end{aligned} \tag{5}$$

Constraints can also be enforced using a concept called the upper trust bound (UTB) of the kriging value. Given a desired confidence interval, the kriging model can calculate an upper bound on the constraint value by adding a factor of uncertainty. This constraint on the next point selection criteria is shown in equation 7 below where the constraint must be satisfied within three standard deviations of the kriging mean.

$$\begin{aligned} \max EI(x) \\ \text{s. t. } \hat{g}(x) \leq 3\sigma(x) \end{aligned} \tag{6}$$

If EGO selects a point where the objective function or constraint functions are undefined, a sufficiently suboptimal point approximating an infinite objective value can be used [16]. This approach should sufficiently penalize points in regions of the search space that cannot be evaluated.

## CARBON CAPTURE PROCESS MODEL

Gas processors have used amines to recover CO<sub>2</sub> and H<sub>2</sub>S from natural gas for nearly a century. After cooling the flue gas with a quench tower, the process of post-

combustion carbon capture with amines contacts an aqueous amine solvent with a CO<sub>2</sub>-rich stream to chemically absorb CO<sub>2</sub> with the amine. The CO<sub>2</sub>-rich amine is then heated in a still to regenerate the amine. Figure 2 provides a process flow diagram of the example unit used in the case study.

The main difference between post-combustion carbon capture and natural gas treating lies in the partial pressure of CO<sub>2</sub> in the feed gas. The concentration of CO<sub>2</sub> in the flue gas from a natural gas power plant is about 4 mol%. While this is easily within the range of concentrations found in natural gas, the pressure of the flue gas is near atmospheric pressure. The partial pressure of CO<sub>2</sub> in the flue gas will be 10-100 times less than in typical natural gas amine sweetening units, leading to the differences in the design of the two processes.

Flue gas carbon capture units are marked by larger absorber columns, due to the large volume of gas, with extensive water wash sections to reduce amine losses to the atmosphere. The amine solvent lost is not only expensive but also an air pollutant. Some designs also employ a side cooler, a feature not usually afforded for natural gas treating. Cooling the amine in the absorber removes heat of reaction and shifts equilibrium towards absorption in the liquid.

The example facility in this case study has a 30 ft diameter absorber packed with 60 ft of Sulzer IMTP #50 Metal random packing solved with ProMax’s Mass + Heat Transfer calculation method. The regenerator is a 9 ft diameter column modeled with 10 ideal stages of separation. The amine circulated is the CESAR-1 blend of 27 wt% amino methyl propanol (AMP) and 13 wt% piperazine.

**Table 1:** Inlet flue gas properties and composition

<b>Feed Property</b>	
Temperature	117 °F
Pressure	2.5 psig
Standard Vapor Volumetric Flow	406 MMSCFD
<b>Feed Composition</b>	
	mol %
Carbon Dioxide	3.99
Nitrogen	75.03
Oxygen	11.97
Water	9.00

Operators control the plant by manipulating the amine circulation rate, water wash rate, and reboiler duty. Operators are economically incentivized to minimize energy use while achieving a CO<sub>2</sub> recovery greater than 90% and amine losses below a permitted threshold. Utilities are integrated with the power generation facility. The amine reboiler can be powered by a slipstream of low-pressure steam from the heat recovery network of the powerplant. When integrated into the low-pressure steam circuit, the steam dedicated to the reboiler single-handedly reduces net power generation from 100 MW to 87 MW for the base-case simulation. Pumps and compressors can be powered by electricity generated on-site.

**Table 2:** Base carbon capture model power use summary.

<b>Unit Operation</b>	<b>Power</b>
Gas turbine	68 MW
Steam turbines (no CC)	32.7 MW
<b>Total power production</b>	<b>100.7 MW</b>
Reboiler steam power reduction	-12.8 MW
Flue gas blower	-5.1 MW
Amine and process water pumps	-0.1 MW
CO <sub>2</sub> Compression Power	-2.8 MW
Cooling water pumps	-0.6 MW
<b>Total power usage</b>	<b>-21.4 MW</b>
<b>Net power production</b>	<b>79.3 MW</b>

The desired CO<sub>2</sub> recovery depends on several factors including but not limited to local laws, plant scale, CO<sub>2</sub> sequestration or utilization strategy, and investor pressures. For plants located in the United States, the IRS's Section 45Q tax credit for carbon sequestration credits a dollar per ton amount based on the ultimate CO<sub>2</sub> use for eligible facilities [17]. In 2023 for new non-direct air capture processes, 45Q credits up to is \$85/tonne for geologically sequestered CO<sub>2</sub> and \$60/tonne for other qualified uses of CO<sub>2</sub> for the first 12 years of operation. Eligible power plants must capture at least 18,750 tonnes of CO<sub>2</sub> and be designed to capture at least 75% of the plant's emissions. In practice, many of these facilities are designed to capture at least 90% of baseline CO<sub>2</sub> emissions.

Once CO<sub>2</sub> is captured, it will require compression for transportation and its ultimate use. CO<sub>2</sub> transmission lines are designed to operate over 1000 psig in the so called supercritical "dense phase" where the fluid can be effectively pumped like a liquid. In this case, the captured CO<sub>2</sub> leaves the facility at 1500 psig.

## OPTIMIZATION FORMULATION

The implementation of constrained EGO uses the Surrogate Modeling Toolbox [18] package in Python. SMT includes an unconstrained implementation of EGO that was augmented to generate kriging models of each constraint function and use PFCON, UTB, and OFPF as next point selection criteria. The formulations used for next point selection criteria are described in equations (4) – (6) previously. These formulations are solved using a python SLSQP implementation [19] from 20 different starting points.

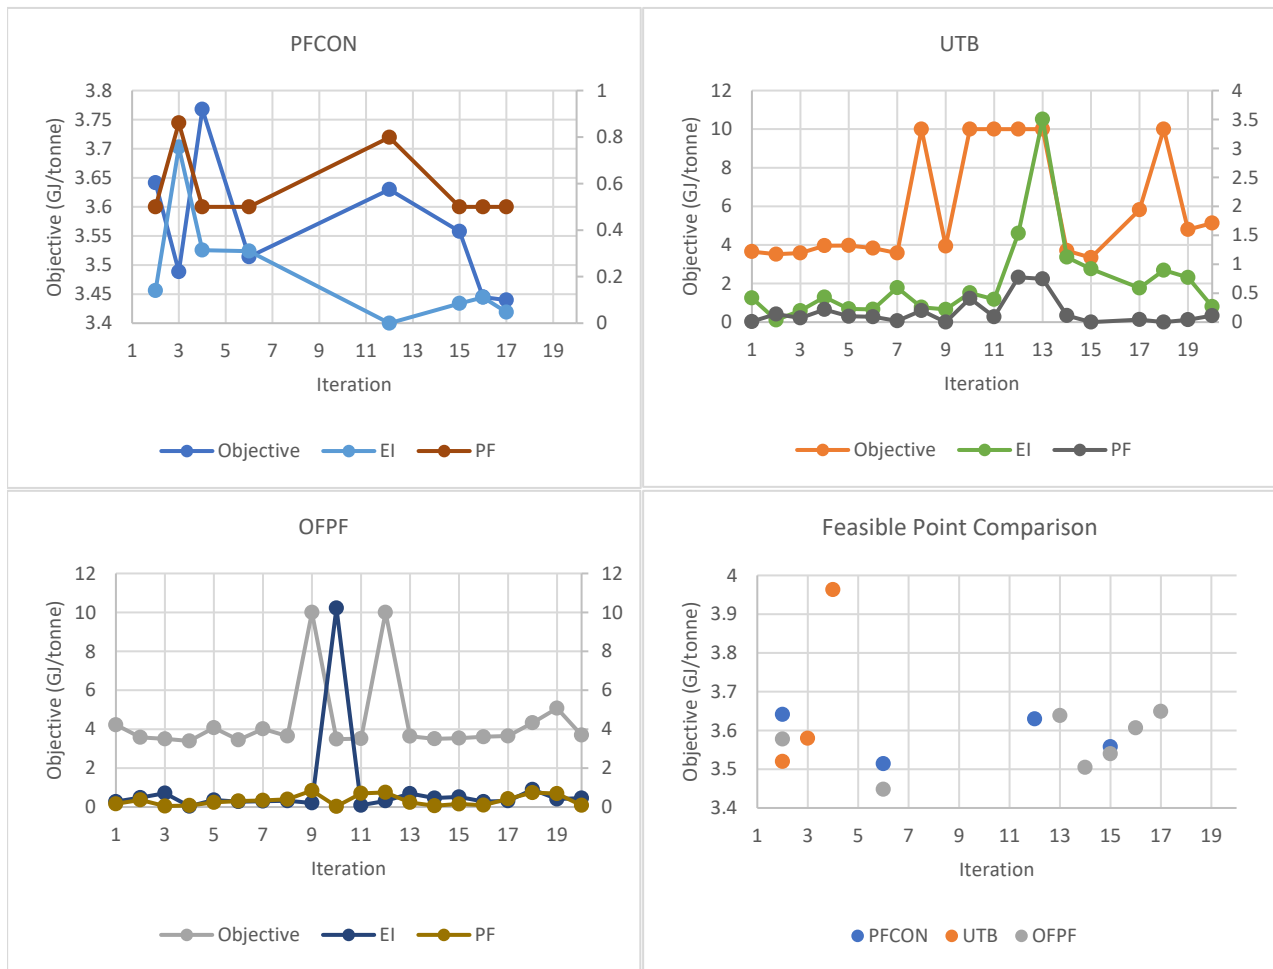

Any simulation run that did not converge in ProMax was given an objective value of 10 GJ/tonne, which was far greater than any observed objective value. Constraints for these unconverged samples were given values of 10 in standard form ( $g(x) \leq 0$ ) to denote a violation of each constraint.

The first task for developing an optimization formulation for a process is determining the most appropriate objective function and the most necessary constraints. For post-combustion carbon capture on power plant flue gas, one useful objective function is to minimize the energy used for carbon capture. Likely all this energy will be supplied by the power plant, so minimizing energy consumption will minimize the impact of carbon capture on plant profitability.

The overwhelming power requirement in the carbon capture process is the heat used to drive the reboiler. Of the power requirements shown in Table 2, the only significant costs that could be affected by the carbon capture unit itself are the reboiler duty and compression power. To avoid penalizing higher CO<sub>2</sub> recovery inherently, the objective function  $\hat{E}(x)$  will be the sum of the energy consumed by both the CO<sub>2</sub> compressors and the reboiler duty per unit of recovered CO<sub>2</sub> in units of GJ/tonne CO<sub>2</sub>.

Constraints are selected to ensure that equipment and operating constraints are met. The facility will be required to exceed 90% CO<sub>2</sub> recovery  $C(x)$ , emit less than 300 tonne/yr of amine solvent  $S(x)$ , and not exceed a calculated 95% fraction flooding in both the absorber  $F_a(x)$  and stripper  $F_s(x)$ .

Decision variables are limited to properties under operational control, leaving amine circulation  $a$ , water wash circulation  $w$ , and reboiler duty as candidates. In this study, the lean loading  $l$ , defined as the molar ratio of CO<sub>2</sub> and amine in the amine entering the absorber, will

**Figure 3:** Comparison of objective function, expected improvement, probability of feasibility, and feasible solution progress by iteration. Missing iterations failed to yield a sample point during sample point selection.

be used as a decision variable since it lends itself better to linear bounds than reboiler duty and should be more independent of other decision variables.

$$\begin{aligned}
 & \min \hat{E}(x) \text{ where } x = (a, w, l) \\
 & \text{subject to } C(x) \geq 90\% \\
 & \quad S(x) \leq 300 \text{ tonne/yr} \\
 & \quad F_a(x), F_s(x) \leq 95\% \quad (8) \\
 & \quad 1500 \leq a \leq 3000 \\
 & \quad 3000 \leq w \leq 5000 \\
 & \quad 0.05 \leq l \leq 0.2
 \end{aligned}$$

Each constraint function is passed to the algorithm in the form  $g(x) \leq 0$ . A Latin hypercube design of experiments is used to sample 30 points. This initial dataset becomes training points for the first kriging model. Next, each constraint-handling method is allowed 20 objective function evaluations to evaluate the search space and find an optimal solution.

One familiar with amine units would expect lower amine circulation rates and higher lean loadings to result in lower objective values. While the heat of absorption per ton of  $\text{CO}_2$  is effectively constant in this system, heating more solvent to the temperature required to desorb  $\text{CO}_2$  requires extra heat. One would also expect the water wash circulation should converge to the minimum required to meet the amine loss constraint.

## RESULTS AND DISCUSSION

The performance of each constraint method is evaluated using three criteria: constraint faithfulness, solution reliability, and best optimal solution. For this case study, each constraint method provides a feasible solution, but none of the methods reliably converged in the allotted number of iterations.

Objective function values for each iteration are shown in Figure 3. Optimal solutions for each run, plus the best solution observed for the problem in the study are stated in Table 3. This best solution was found by

chance in the initial design of experiments. The most optimal solutions had an intermediate value of lean loading between 0.12 – 0.15 mol CO<sub>2</sub>/mol amine which allowed lower circulation rates to meet the 90% CO<sub>2</sub> recovery constraint.

**Table 3:** EGO optimal solutions by constraint method.

	PFCON	UTB	OFFP	Best
Optimal Solution (GJ/tonne)	3.56	3.52	3.50	3.418
Amine Flow (sgpm)	1722	1626	1586	1575
Water Wash Flow (sgpm)	3976	4596	4421	4367
Lean Loading (mol/mol)	0.189	0.139	0.120	0.146

Despite not converging on a consistent operating point, the solutions provided by each method favor the expected minimal amine circulation rate. What was not expected was the extent to which lower lean loadings were preferred. Contacting flue gas with leaner than the maximum required lean loading to achieve 90% CO<sub>2</sub> recovery increased the capacity of each gallon of amine in circulation enough to offset the increased regeneration energy per gallon of amine. This resulted in lower energy requirements per metric ton of CO<sub>2</sub> captured.

Further analysis on the objective function values showed that specific compression power was effectively constant at about 0.63 GJ/tonne CO<sub>2</sub> captured. This indicates that compression power per unit of CO<sub>2</sub> captured was unaffected by regenerator operation while the overhead pressure was held constant.

**Table 4:** EGO run characteristics by constraint method.

	PFCON	UTB	OFFP
Failed Iterations	12	1	0
Feasible Points	4	4	8
Infeasible Points	4	15	12
Simulator	0	6	2
Execution Error			

Table 4 shows the incident rate of sample point selection failures and the tendency of each method to generate feasible solutions. OFFP produced the best optimal solution and the most feasible points with the least inner-loop failures. PFCON rarely converged to a sample point with its inner-loop optimization; however, when a sample point was selected, it had the highest rate of feasible sample points. UTB constraints rarely selected feasible points, and frequently sampled points where the simulator could not converge to a solution. These trends observed between the different constraint methods are consistent with the conclusions of Sohst et al [14].

## CONCLUSIONS

Each of the three tested constraint-handling methods yielded a feasible optimal solution; however, none of these methods were able to converge on an optimum or surpass a solution found in the design of experiments in the allowed number of iterations.

OFFP resulted in the best optimal solution found and had the lowest incidence of failures to select a new sample point. Finding a similar solution to OFFP, UTB sampled far more infeasible points than any of the other algorithms. PFCON suffered from several incidences where the next point selection algorithm failed to yield a sample point. However, when a sample point was determined, PFCON was the most likely to yield a feasible solution. The numerical issues of PFCON could be addressed by modifying the implementation of EGO used.

One potential improvement is to replace the multi-start SLSQP optimization algorithm to find the next sample point. The expected improvement objective function is highly multimodal and evaluates very quickly, lending itself well to heuristic optimization methods that would fight through local minima more effectively.

The effects of different constraint parameter values and larger numbers of EGO iterations on algorithm performance were not studied. More iterations could result in convergence to a better solution. There is a chance that different lower bound for probability of feasibility in PFCON would improve its reliability. Future work could compare parameters for each constraint method on different types of functions over more iterations.

Ultimately, applying these optimization methods to a chemical process simulator produced similar results to previous work on aerodynamic shape optimization. Further improvements on the algorithm would be necessary for constrained EGO to be of practical use for optimizing process simulations.

## ABSTRACT

Utilizing sustainable energy sources is crucial for expanding the range of solutions available to meet the growing energy demand and reducing reliance on environmentally damaging and depleting conventional fuels. Biosolids, a type of biomass, are generated as secondary effluent during wastewater treatment process in municipal and industrial sites. These solids possess the potential to serve as a sustainable energy source due to their richness of carbon. For an extended period, biosolids have been landfilled, even though it can be considered a wasteful use of a precious resource and a possible mean for contamination to the food supply chain. This has served as an extra impetus to investigate the potential for harnessing the capabilities of these substances. While many research studies have looked at different ways to put biomass waste to use, very little has been written on biosolids, especially those derived from industrial sources. This research assesses the feasibility of transforming GTL derived biosolids into value-added commodities that can serve as raw materials in chemical manufacturing or be employed energy generation. The study primarily examines widely recognized thermal conversion processes, pyrolysis and gasification. An evaluation is carried out to analyze the economic, technological, and environmental aspects of the treatment methods utilizing these technologies. The aim is to demonstrate the potential of GTL biosolids conversion and to determine associated costs and environmental impacts. The ASPEN simulation tool is utilized to model thermal treatment pathways, allowing for the generation of economic and environmental estimations for each route.

**Keywords:** Biosolids, Energy, Utilization, Simulation

## INTRODUCTION

Biosolids are a significant waste stream that is discharged from wastewater treatment plants and water management facilities around the world. Although biosolids have traditionally been regarded as a waste by-product and disposed of in landfills for many years, current research has demonstrated that they possess significant value as a result of their nutrient and energy content [1, 2]. They are now formally classified as renewable sources of energy because of the energy value derived from their organic component [3, 4]. The utilization of biosolids for energy generation has a significant potential to promote a circular economy and reduce environmental waste [4]. Possible uses for the recovery of mass and energy from biosolids include using them as fertilizer for

land, composting, anaerobic digestion, combustion, gasification, pyrolysis, and hydrothermal treatment. These applications transform biosolids into valuable resources, such as composts for nutrients or biofuels and char for energy. Each of these uses necessitates a designated preliminary treatment to prepare the biosolids stream. The treatment of biosolids is a significant obstacle in water management and treatment plants due to the substantial electrical and operational expenses involved. These costs make up 20% and 53% respectively of the total wastewater treatment process [1]. Pyrolysis and gasification are two thermal conversion methods that have great potential for transforming biosolids into products that have increased value.

Pyrolysis is a process that involves the combination of thermal cracking and catalytic conversion. It is

conducted at relatively moderate temperatures (400 – 700 °C) and atmospheric pressure [5]. The process of producing bio syngas, oil, and fuel char from biosolids involves heating them in an oxygen-free environment [6, 7]. Gasification is a combustion process that involves burning biosolids with a limited amount of oxygen or air at very high temperatures that can reach up to 1200 °C and 0.6-2.6 MPa. Conceptually, this technology has resemblance to pyrolysis, albeit it differs by utilizing a sub-stoichiometric oxygen input and operating at considerably higher temperature settings [8].

Considerable research is readily accessible that examines the costs and economic evaluations of treating and reusing biosolids. AlNouss et al. performed a techno-economic assessment of biomass gasification for hydrogen production [9]. Ghiat et al. provided a comprehensive economic analysis of a biomass gasification system that is combined with power generation and carbon dioxide recovery. The analysis was conducted using aspen simulation software [10]. [11] conducted a study on the techno-economic factors of power generation using biogas produced by gasifying biosolids, utilizing actual data from a facility [11]. However, there is a scarcity of research that has examined the process of converting biosolids produced by industrial facilities in oil and gas sector.

This study assesses the feasibility of transforming GTL industrial biosolids into high-value products through gasification and pyrolysis processes. Analytical investigation is conducted to compare the technological, economic, and environmental aspects of two treatment methods in order to identify the demonstrate efficient paths for treating GTL derived biosolids. The conversion processes are simulated using Aspen process simulation tool.

## PROBLEM STATEMENT

Gas-to-liquids (GTL) technology transforms natural gas, which is the most environmentally friendly fossil fuel, into premium liquid products that are typically derived from crude oil. The process produces biosolid waste streams that need to be treated to uncover their energy potential and reduce the need for solid waste management.

To assess the feasibility of treating a continuous flow of GTL biosolids, which includes information on flowrate, solid content, and moisture content, it is necessary to examine the viability of employing thermal pyrolysis and gasification methods. Additionally, it is crucial to quantify the costs and environmental impacts associated with these treatment approaches.

## ASPEN MODEL

## Process Flowsheet

The diagram in Figure 1 depicts the process of converting GTL biosolids through pyrolysis and gasification, as simulated using Aspen Plus. The primary feed stream consists of GTL generated biosolids. The thermo-chemical parameters of the GTL biosolids have been determined using proximate and ultimate analysis, as described in the study by Zuhara et al. [12]. The characteristics are succinctly outlined in Table 1. Figure 1 describes the pyrolysis flowsheet. The initial step involves the treatment of biosolids in a decomposition unit, which is simulated using the Ryield reactor model in Aspen Plus. The device disassembles the non-conventional flow of biosolids into its primary elemental components, namely hydrogen, oxygen, carbon, nitrogen, and sulfur. The output of this unit is sent to the pyrolysis reactor, which is simulated using the RGibbs reactor model. This model uses Gibbs energy minimization to estimate the products produced by the reactions. Subsequently, the pyrolysis products are sent to a separator, where the resultant gas is isolated from the solid phase products, namely ash and char. After the separation process, the gas undergoes a cooling process, which leads to the retrieval of biogas as the final outcome.

**Table 1:** GTL biosolids proximate and ultimate analysis [12]

<b>Proximate Analysis</b>	
Moisture	12.29
Volatile matter	47.47
Ash	26.07
Fixed carbon	14.16
<b>Ultimate Analysis</b>	
C	33.69
H	6.18
O	29.03
N	5.03
S	-

The gasification flow sheet illustrated in Figure 2, diverts the elemental components produced in the decomposition unit to an alternative treatment pathway. Post decomposition, a solid separation unit is used to initially separate ash and char products from the gas stream. Subsequently, the gas stream leaving the separation unit is combined with steam and air before being introduced into the gasification reactor. Steam and air act as gasification agents in this process. The gasifier is simulated using the RGibbs reactor model. The gasifier products undergo a cooling process and are subsequently separated in a solid separation unit to obtain biogas and char products.

The simulation utilized thermodynamic calculations employing the Peng Robinson property method with the Boston modification to improve the accuracy of estimating the properties of non-conventional inputs, specifically GTL biosolids and Ash. The operational parameters are concisely outlined in Table 2.

## RESULTS AND DISCUSSION

The simulation model was constructed under the assumption of steady-state operation under atmospheric pressure, disregarding pressure variations throughout unit operations and heat dissipation in gasification and pyrolysis units.

**Table 2** Pyrolysis and Gasification flowsheet operation conditions

Parameter	Unit	Value
<b>Biosolids Feed</b>		
Feed flowrate	Kg/hr	2000
Temperature	°C	25
<b>Pyrolysis</b>		
Inert flowrate	Kg/hr	40
Inert temperature	°C	65
Pyrolysis unit temperature	°C	700
Decomposer temperature	°C	700
<b>Gasification</b>		
Air flowrate	Kg/hr	40
Air temperature	°C	65
Gasifier temperature	°C	800
Decomposer temperature	°C	700

The model presupposes that the char consists entirely of solid carbon.

The simulation model was executed using a feed flowrate of 2000kg/hr of GTL biosolids, as described by the provided approximate and ultimate analysis. Prior to being sent to the conversion units, pyrolysis and gasifier, the decomposition unit transformed the nonconventional biosolid material into its primary components. After the conversion has taken place, The solid splitters were used to separate the ashes and char, while the resulting biogas was pre-cooled to recover heat before being collected as the end product. The composition of the biogas stream was analyzed to determine the amounts of syngas and methane generated during the process. These gases are commonly used for energy production or as raw materials in downstream petrochemical processes. The accumulated ash can be beneficial in several applications for material utilization, such as in the manufacturing of cement.

Char, in its solid state, is a useful energy source that can be used for carbon sequestration and land reclamation, depending on its specific properties [13]. The production rate of each of these components is illustrated in Figure 3.

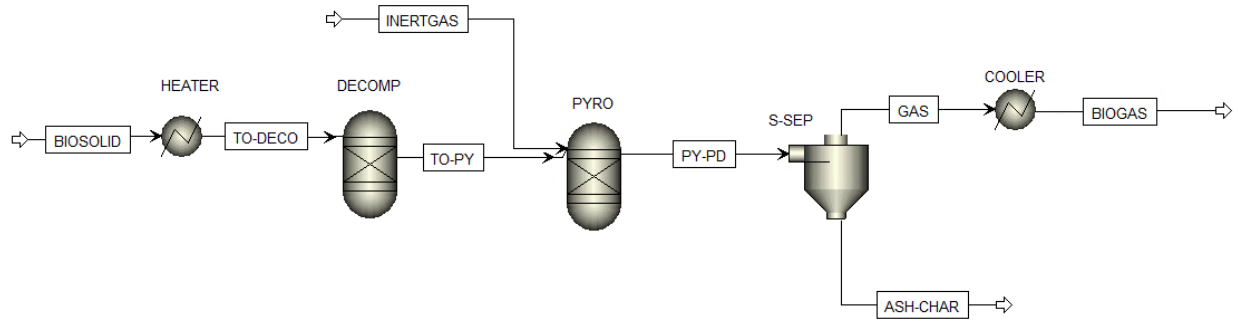

**Figure 3.** Production rate of various thermal conversion products for GTL biosolids feed

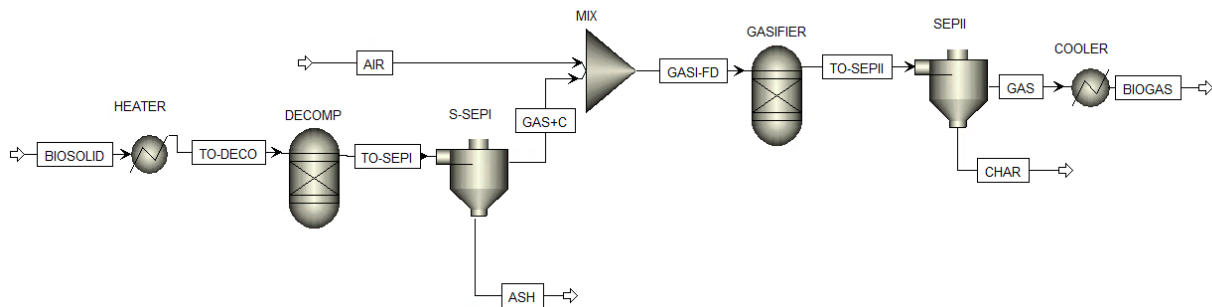

The findings exhibited total transformation of the biosolids into biogas, char, and ash. Upon analyzing the syngas composition in the effluent of the two processes, it is observed that gasification yields 1029 Kg/hr of carbon monoxide (CO) and 121 Kg/hr of hydrogen (H<sub>2</sub>). The generation of CO has increased by approximately 50%, while the production of H<sub>2</sub> has increased by approximately 15% compared to pyrolysis. The increase in syngas creation was achieved at the cost of a 48% decrease in CH<sub>4</sub> output during gasification. The overall quantity of ash exiting the process remains constant in both process outlets, as they possess identical characteristics and receive the same amount of biosolids feed with a predetermined nonconventional ash content, according to the approximate and ultimate analysis of GTL biosolids. Gasification is preferred over pyrolysis when considering the use of biosolids as an extra feedstock stream for a petrochemical plant.

Post process simulation, Aspen program was used to conduct a techno-economic and environmental assessment of the two processes. The model employs the integrated economic analyzer and environmental analysis tool. The tool provided estimates for the financial expenses, capital and operational costs of both scenarios and presented the greenhouse gas (GHG) emissions as carbon equivalents, measured in terms of their ability to contribute to global warming (GWP) [14]. The capital cost encompassed equipment cost estimation via an integrated unit operation mapping and equipment sizing methodology. Figure 4 below provides a concise summary of the cost estimation analysis and the CO<sub>2</sub> equivalent emissions for the two conversion scenarios.

**Figure 1:** Biosolids pyrolysis flowsheet developed in Aspen Plus

**Figure 2:** Biosolids gasification flowsheet developed in Aspen Plus

**Figure 4.** Cost estimation and GHG emissions from biosolids pyrolysis and gasification processes

The results indicate that the capital cost for biosolids gasification is around \$4.6 million, which slightly exceeds the capital required for pyrolysis by 8%. The discrepancy can be rationalized by the disparity in unit operations employed in each scenario's flowsheet and the

chosen materials capable of withstanding the operational temperatures of the conversion units. The model allocated suitable utilities to the various unit operation as per the required duties and pressure and temperature ranges. In order to meet the conversion process requirements in both scenarios, three primary utility categories were chosen: fuel, cooling water, and power. The overall operational cost, with utility expenses being the primary factor, showed an insignificant variance between the two scenarios. The anticipated cost for pyrolysis was \$2.09 million per year, while the cost for the other method was \$1.97 million per year. The CO<sub>2</sub> emissions depicted in Figure 4 exhibit a significant disparity in emissions between pyrolysis at a rate of approximately 1800 kg/hr and gasification 900 kg/hr. According to this model, pyrolysis results in double the amount of gasification GHG emissions. In gasification, the conversion process results in the production of additional CH<sub>4</sub> and CO<sub>2</sub>. However, these gases are then further converted into H<sub>2</sub> and CO products, which helps to reduce greenhouse gas emissions from the process side of operation.

## CONCLUSION

Biosolids are a valuable byproduct that must be effectively treated in order to be utilized. There is a dearth of research exploring the possibilities of utilizing industrial biosolids in literature. This study focuses on examining the transformation of biosolids derived from GTL (Gas-to-Liquid) into biogas products, specifically hydrogen (H<sub>2</sub>), carbon monoxide (CO), and methane (CH<sub>4</sub>). The investigation is conducted through the utilization of an Aspen simulation flowsheet that has been specifically developed for this purpose. Two primary thermal conversion pathways have been developed, which involve the integration of gasification and pyrolysis processes. Gasification emerges as the ideal method for treating biosolids and using them as an additional source of feedstock in a petrochemical plant. The results suggest that gasification produces greater amounts of carbon monoxide (CO) and hydrogen (H<sub>2</sub>) in comparison to pyrolysis, which is beneficial for specific industrial uses. Gasification reduces methane (CH<sub>4</sub>) emissions, while maintaining effective conversion of biosolids into biogas, char, and ash.

The Aspen software allows for technoeconomic and environmental studies, which offer additional insights. Although gasification has a somewhat larger initial investment compared to pyrolysis, the ongoing expenses for both techniques are practically the same. This implies that although the initial cost for gasification may be slightly greater, the operational effectiveness and long-term advantages compensate for this disparity. The environmental impact connected with each activity is of paramount significance. Gasification exhibits a notable superiority over pyrolysis in relation to greenhouse gas emissions since it leads to reduced emissions of carbon dioxide (CO<sub>2</sub>) equivalents. The decrease in emissions is credited to the transformation of excess methane and carbon dioxide into hydrogen and carbon monoxide, effectively reducing greenhouse gas emissions from the operational process.

Ultimately, when it comes to utilizing biosolids as an extra input for petrochemical operations, gasification proves to be a beneficial choice. Gasification, despite having somewhat higher initial costs, has better conversion efficiency, similar running expenses, and reduced environmental effect when compared to pyrolysis.

In conclusion, this study demonstrates the capacity to transform industrial biosolids wastes into a viable energy source or valuable raw material, while simultaneously reducing the amount of solid waste generated. These findings provide valuable insights for decision-making processes as it enables well-informed judgments regarding biosolids treatment strategy that achieves a balance between the efficiency of conversion efficiency, economic feasibility, and environmental impacts.

## ABSTRACT

Modern mechanical recycling infrastructure for plastic is capable of processing only a small subset of waste plastics, reinforcing the need for parallel disposal methods such as landfilling and incineration. Emerging pyrolysis-based chemical technologies can “upcycle” plastic waste into high-value polymer and chemical products and process a broader range of waste plastics. In this work, we study the economic and environmental benefits of deploying an upcycling infrastructure in the continental United States for producing low-density polyethylene (LDPE) and polypropylene (PP) from post-consumer mixed plastic waste. Our analysis aims to determine the market size that the infrastructure can create, the degree of circularity that it can achieve, the prices for waste and derived products it can propagate, and the environmental benefits of diverting plastic waste from landfill and incineration facilities it can produce. We apply a computational framework that integrates techno-economic analysis, life cycle assessment, and value chain optimization. Our results demonstrate that the infrastructure generates an economy of nearly 20 billion USD and positive prices for plastic waste, opening opportunities for compensation to residents who provide plastic waste. Our analysis also indicates that the infrastructure can achieve a plastic-to-plastic degree of circularity of 34% and remains viable under various external factors (including technology efficiencies, capital investment budgets, and polymer market values). Finally, we present significant environmental benefits of upcycling over alternative landfill and incineration waste disposal methods, and comment on ongoing work expanding our modeling methodology to other chemical upcycling pathway case studies, including hydroformylation of specific plastics to chemicals.

**Keywords:** Polymers, Optimization, Supply Chain, Modelling, Interdisciplinary

## INTRODUCTION

With global rates of plastic production reaching upwards of 400 million tonnes per year and growing [1], nations require integrated, reliable plastic waste management systems [2]. Despite reductions in the environmental impacts of plastic production [3], global plastic recycling rates remain well below 10% [4], necessitating the continued use of parallel disposal methods (such as landfilling and incineration) and allowing significant plastics to accumulate in the environment [5].

Most current recycling occurs by well-established mechanical methods, which are designed to accept bottles of polyethylene terephthalate (PET) and high-density polyethylene (HDPE), together making up less than 12%

of post-consumer plastic waste [6]. However, these methods also produce degradation and allow these plastics to only be recycled a finite number of times [7]. Mechanical recycling strategies cannot process most other resins or flexible, multilayer plastics (which account for 35% of plastics currently produced [8]). The parallel disposal methods required for these plastics cause significant environmental and social issues.

Chemical upcycling has been proposed as a complement to mechanical systems. These pathways apply a complex sequence of chemical processing steps to decompose plastics into constitutive chemical species that can be further refined into value-added products, such as fuels, chemicals, and plastic precursors. Due to their improved feedstock versatility, chemical upcycling

pathways can be more scalable than mechanical recycling pathways. We analyze a pathway which requires pre-sorting and purification of mixed plastic waste from post-consumer recyclable streams, occurring at material recovery facilities (MRFs) and plastic reprocessing facilities (PRFs). Sorted plastic waste is baled and mechanically reduced to flakes before undergoing pyrolysis and steam cracking to produce plastic monomers, which can finally be repolymerized into resins (here, low-density polyethylene and polypropylene) with identical quality as the starting materials and the same original properties as virgin plastics [4]. Thus, chemical upcycling pathways can help to achieve a circular economy for plastic waste.

Many recent analyses have explored the potential contributions of upcycling to broader plastic waste management systems [4, 7, 9, 10, 11] and its economic and environmental performance [12, 13, 14]. However, a significant gap exists in our understanding of the deployment of upcycling technologies at scale. Previous works have developed models to analyze plastic waste supply chains [15, 16] and supply chain optimization frameworks for studying these problems at regional scales [6]. Large supply chain models can help to analyze complex economic behavior of networks of processing facilities and track the transportation of products in the value chain.

In this paper, we summarize the methods and results of our recent full paper on the national-scale modeling of an upcycling pathway for the continental US [17], and present updates in ongoing comparative analysis of other upcycling pathways with different process details and outcomes on the same national scale, including the recently explored hydroformylation process [18].

We overview a computational framework to examine the potential for deploying a national-scale upcycling infrastructure for post-consumer plastic waste in the continental US, and present an optimal upcycling value chain solution (see Figure 1) for techno-economic analysis and lifecycle assessment. The infrastructure is optimized to maximize total profit while minimizing investment, operating, and transportation costs. We show that this infrastructure can be interpreted as a value chain (an economy) under which stakeholders exchange plastic waste and derived products to maximize profit. In our model, upcycling creates high value from the production of virgin polymers from post-consumer waste, producing a total economy (market) size of 19.7 billion USD per year and remaining viable under various changes to market inputs.

Upcycling as a national plastic waste management strategy achieves a 34% plastic-to-plastic degree of circularity for converting residential plastic waste into high quality polymers. The system compares favorably to existing disposal methods for mixed plastic by environmental metrics, including 69–75% reductions in greenhouse gas (GHG) emissions relative to incineration and 86 avoided new landfills over the next 50 years).

In contrast to this form of pyrolysis-based upcycling (a plastic-to-plastic method for mixed plastics), hydroformylation has been envisioned as a plastic-to-chemicals pathway for more specific plastic feedstocks. To date, hydroformylation has only been explored for one post-consumer resin (HDPE) and three virgin resins (HDPE, LDPE, and PP) [18]. Thus, hydroformylation would compete with mechanical recycling for HDPE. We comment that current market prices for the products of hydroformylation may not support the pathway's use relative to prices for mechanically recycled HDPE.

## METHODOLOGY

We model the US as a collection of county-level waste-producing centers of population. Our chemical upcycling pathway comprises a series of six processing technologies, including MRFs, PRFs, pyrolysis, steam cracking, LDPE polymerization, and PP polymerization. The value chain contains 16 different products, including inputs (post-consumer recyclables), intermediates (e.g., plastic waste bales, plastic flake, pyrolysis oil, ethylene), and outputs (e.g., LDPE, PP, fuels). Only feedstock recyclables, plastic bales, plastic flake, and pyrolysis oil are modeled as transportable to represent the infeasibility of transporting many intermediates (e.g., ethylene and propylene gas) and simplify analysis of market demand.

Each component of the value chain has techno-economic definitions from Ma et al. [6]. We applied a mixed-integer program (MIP) formulation to our supply chain optimization model, also proposed by Ma et al. [6] to study upcycling in the US Midwest region. The MIP designs a value chain by placing processing facilities in locations that best capture residential waste, maximize profit, and minimize investment, processing, and transportation costs. Furthermore, we apply LCA methodologies to compare GHG emissions of upcycling, landfilling, and incineration. Emission factors for each technology are adapted from Ma et al. [6].

To limit model size and computational complexity for a national case study, we allow transportation routes between adjacent county centers. Still, the national scale presents challenges for current solvers, so we report close-to-optimal solutions with optimality gaps demonstrating their measured distance from the estimated upper bound on total profit.

The model comprises 3,108 county centers and 4,010 sites available for technology placement, with two sizes of technology possible at each potential site. In total, the MIP problem contains 796,756 continuous variables, 8,020 binary variables, and 587,405 constraints.

To implement and run the MIP formulation, we utilize the algebraic modeling package JuMP [17] for the Julia programming language and solve using Gurobi 9.1.0 [20]. We use the MIP to design the physical arrangement

**Figure 1:** Overview of a pyrolysis-based chemical upcycling value chain. In chemical upcycling, waste plastics are recovered as fuels, chemicals, and virgin-quality polymers in a sequence of processing steps. Our case study examines a combination of mechanical recycling for PET (plastic type #1) and HDPE (plastic type #2), and chemical upcycling of mixed plastics (plastic types #3 - #7). This combined network creates an economy worth nearly 20 billion USD annually and processes 100% of US residential plastic waste, achieving a degree of circularity of 33.9% (more than one-third of input waste plastics are recovered as mechanically or chemically recycled plastics) while most other remaining inputs are converted into valuable byproduct fuels and chemicals.

of the upcycling value chain and then perform economic and environmental analysis using the **CoordinatedSupplyChains.jl** package (**CSC.jl**) developed by Tominac and Zavala [21] and modified for this work with visualization capabilities. After 180 hours of computational time, the MIP was solved to an optimality gap of 4.66%, meaning that the identified system design provides an economic result within 5% of the optimal solution. The optimal design reaches all 3,108 counties and captures 100% of residential plastic waste; in other words, the model indicates that there are sufficient economic incentives to harness all the post-consumer waste to obtain virgin plastics.

## RESULTS

### Circularity & Economic Evaluation

The final upcycling network captures 100% of residential waste, recovering 11.6% of input waste plastics (the fraction of PET and HDPE bottles) as mechanically-recycled HDPE and PET through MRFs and PRFs, and 22.3% as LDPE and PP through pyrolysis, steam cracking,

and repolymerization. This leads to a total plastic-to-plastic degree of circularity of 33.9%, but overall, 94.6% of residential plastics are recovered as valuable products (including significant fuel and chemical byproducts of upcycling which enhance upcycling's economic viability).

Prices for plastic waste are positive for all county centers, demonstrating that the upcycling network is economically viable without added incentives through policy, largely due to the production of high-value LDPE and PP through chemical upcycling. Upcycling creates an economy worth 19.7 billion USD annually (a measure of total economic surplus, excluding capital costs) and nearly 10 billion in residential profit, which could be applied to compensate residents for recycling properly (or donating their waste plastics to upcycling systems) at a rate of 31 USD / year.

### Sensitivity Analysis

External market factors and technical specifications impact the economic performance of the upcycling network. Total waste capture remains above 99% for resident offering costs up to 40 USD / tonne (rather than

donating plastic waste for free). Improving the efficiencies of key technologies (such as pyrolysis and steam cracking) increases economic surplus but can exhaust the processing capacity of the network faster, excluding some residential waste providers from the market. Increasing transport costs for feedstocks and intermediates has a minimal impact on process economics (transport costs can be doubled and the system processes 99.47% of residential waste plastic). The network can withstand 20% reductions in LDPE and PP market value (major economic drivers of viability) without significant decreases in waste capture. Finally, limiting the overall capital cost investment available for constructing the network limits its extent of waste capture, prioritizing regions of higher waste production density excluding regions including the Great Plains and Northwest.

### Comparison to Existing Processing Methods

The upcycling network emits 1.387 tonne CO<sub>2</sub> eq / tonne of plastic, including processing and transportation contributions. Landfills produce limited direct GHG emissions (0.0236 tonne CO<sub>2</sub> eq / tonne of plastic), but impose other categories of environmental impacts including land use, leakage and microplastic pollution. Incineration or waste-to-energy (WtE) systems produce 2.3-3.1 tonnes CO<sub>2</sub> eq of direct emissions per tonne of plastic combusted depending on resin type.

However, upcycling and WtE fulfill additional functions not achieved by landfills: upcycling produces virgin-quality polymers and WtE can produce electricity. Applying LCA methodology to credit upcycling for its avoided fossil fuel use and WtE for its avoided grid electricity consumption, we determine revised emissions factors of 0.508 tonne CO<sub>2</sub> eq / tonne plastic (including transport) for upcycling and 1.6-2.0 tonnes CO<sub>2</sub> eq per tonne of plastic combusted for WtE. With credits, upcycling emissions compare more favorably to WtE, whose credits based on grid electricity will gradually disappear as the grid becomes decarbonized.

### Comparison to Hydroformylation

While we model a plastic-to-plastic upcycling pathway with fuel and chemical byproducts, other pathways with other aims also attract the interest of researchers. In particular, Li et al. [18] studied hydroformylation (another pyrolysis-based pathway) to produce aromatics, paraffin, alcohols, and dialcohols from post-consumer HDPE or virgin HDPE, LDPE, and PP. The inputs of this pathway also determine its applications: as developed in this publication for a HDPE waste feedstock, hydroformylation would not be an alternative to pyrolysis-based upcycling in this work and Ma et al. [6] but to mechanical recycling. However, since the pathway is still based upon pyrolysis, it could be applied to mixed plastic wastes in the future.

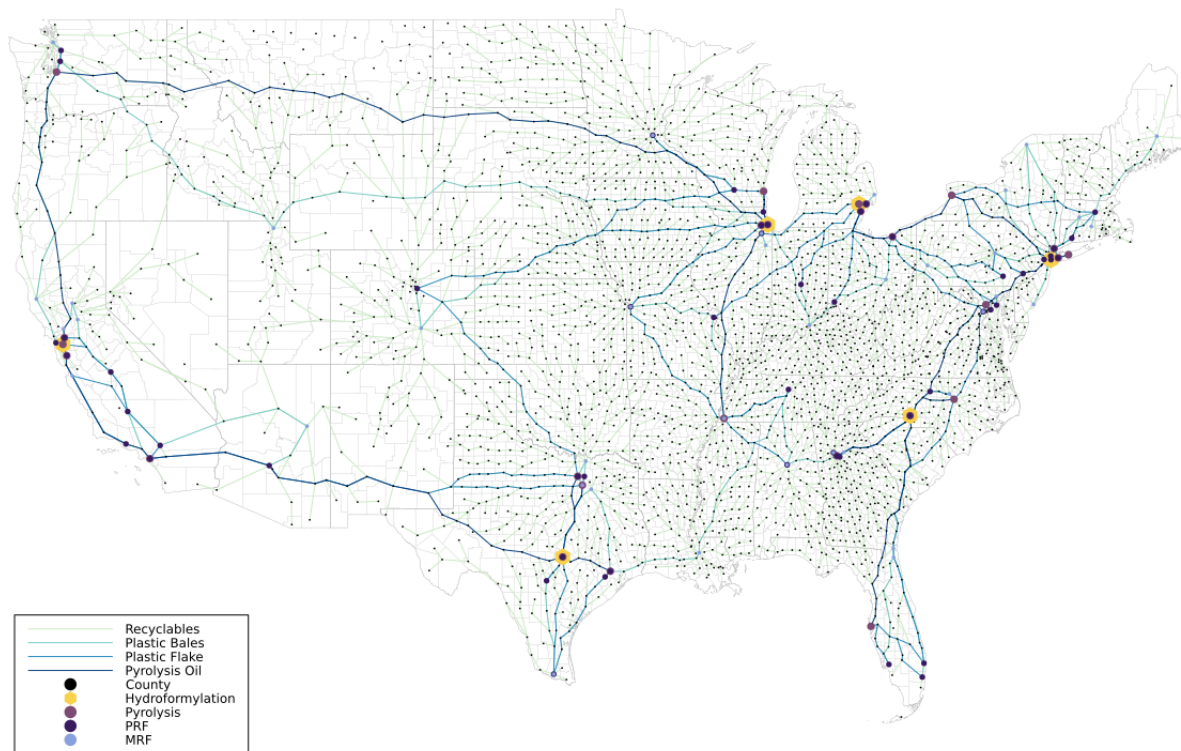

Li et al. [18] report yields and market values of the

four chemical categories produced by hydroformylation of waste HDPE, which we apply as preliminary target yields for the hydroformylation of mixed plastic wastes. We determine that hydroformylation provides a high combined revenue for pyrolysis oil (2154 USD / tonne) from which additional operating costs (644 USD / tonne) detract significantly, leading to an adjusted pyrolysis oil value of 1509 USD / tonne and a corresponding post-MRF-and-PRF plastic waste value of 1035 USD / tonne. This is slightly above the market value prices for recycled HDPE produced at MRFs and PRF used in Ma et al. [6] and this work (991 USD / tonne), but is significantly above the market value produced for post-MRF-and-PRF mixed plastic wastes from plastic-to-plastic upcycling (711 USD / tonne).

We extend our model to consider a hydroformylation pathway and map its optimal infrastructure arrangement and product transportation flows in Figure 2. The comparatively higher value for mixed plastic waste supported by hydroformylation allows plastic waste to sustain greater transportation distances and costs, and thus, the resulting arrangement possesses fewer decentralized components. For example, the plastic-to-plastic upcycling solution placed 336 mostly small-scale MRFs (the first step in each pathway) whereas the hydroformylation solution placed only 38 mostly large-scale MRFs. The total MRF capacity of the hydroformylation solution was nearly 18% lower than that of plastic-to-plastic upcycling, but the utilization of available MRF capacity was much greater (98.8% compared to 81.2%). In contrast, the number of hydroformylation hubs in this solution is roughly comparable to the number of steam cracking and polymerization combined hubs in the plastic-to-plastic upcycling solution.

A more centralized network entails trade-offs with supply, as in the hydroformylation solution, only 99.36% of suppliers (3088 counties out of 3108) participate in the network, compare to 100% in the plastic-to-plastic upcycling solution. Future work will aim to refine this solution to achieve 100% waste capture. For the residents that participate in the hydroformylation network, a potential compensation rate of 30 USD / year is generated through the value chain, which is just below that of plastic-to-plastic upcycling.

Hydroformylation achieves different production objectives than plastic-to-plastic upcycling, and with different environmental performance. The uncredited emissions of the hydroformylation network reach 1.473 tonne CO<sub>2</sub> eq / tonne of plastic processed, which is greater than that of plastic-to-plastic upcycling. We note that this analysis does not consider that hydroformylation products would otherwise be produced by expensive fossil-based pathways. Furthermore, hydroformylation produces only chemicals, so its plastic-to-plastic degree of circularity is 0%.

**Figure 2:** Optimal infrastructure placement and product transportation patterns for a hydroformylation alternative to plastic-to-plastic upcycling.

## DISCUSSION & IMPLICATIONS

Previous research has defined the individual steps of upcycling and modeled their implementation at smaller scales. Our analysis reveals that upcycling remains viable when expanded to the continental US, contributing to a circular economy for plastics driven by the high value of upcycling's end products. Upcycling also presents environmental impact reductions in land use relative to landfills and GHG emissions relative to WtE plants.

As demonstrated in this work, system-level modeling projects have the potential to illuminate not only economic and environmental behaviors of potential value chains, but also comparative results between processing options. Our future work will continue expanding our case studies in hydroformylation and other proposed chemical upcycling pathways, while also incorporating ways to relax some of the major simplifying assumptions in our model structure. We are also interested in more directly modeling policy interventions (including plastic waste source reduction or incentives for upcycling technologies) to better represent the role of policy in national

scale systems and the considerations of current US waste management, recycling, and plastic pollution prevention strategies.

## ABSTRACT

There is a need to drastically reduce greenhouse gas emissions. While significant progress has been made in electrifying transport, heavy duty transportation and aviation are not likely to be capable of electrification in the near term, spurring significant research into biofuels. When coupled with carbon capture and storage, biofuels can achieve net-negative greenhouse gas emissions via many different conversion technologies such as fermentation, pyrolysis, or gasification to produce ethanol, gasoline, diesel, or jet fuel. However, each pathway has a different efficiency, capital and operating costs, and potential for carbon capture, making the optimal pathway dependent on policy and spatial factors. We use the Integrated Markal-EFOM System model applied to the USA, adding a rich suite of biofuel and carbon capture technologies, region-specific CO<sub>2</sub> transportation and injection costs, and government incentives from the Inflation Reduction Act. We find that under current government incentives, biofuels and carbon capture from biorefineries are primarily focused in the Midwest and South of the USA, but play a relatively small role in the overall USA transportation sector even in 2055. However, increased government incentives, biomass availability, or oil price could lead to increased biofuel production and reduced transportation emissions.

## INTRODUCTION

Reducing greenhouse gas (GHG) emissions in the transportation sector is critical for reducing global warming. While improvements in electrification and electric vehicles are expected to play a critical role in reducing emissions from light duty vehicles, heavy duty transportation and aviation are not likely to be electrified in the near term [1]. In these sectors, the high energy density of fuel is important, so liquid fuels are expected to be essential for years to come [2]. Therefore, there has been significant research into renewable liquid fuels.

Renewable liquid fuels can be derived from a variety of sources. One of the most affordable sources has been waste lipids, which can be upgraded through the hydro-processed esters and fatty acids (HEFA) conversion pathway. However, the availability of waste lipids, and purpose-grown oil crops, is currently limited, and expected to remain low [3]. Meanwhile, cellulosic biomass

is widely available and can be converted into ethanol, gasoline, diesel, or jet fuel through a variety of biological and thermochemical pathways [4].

Biofuels have dramatically lower GHG emissions than their fossil fuel counterparts, but there are still emissions from the growth, harvesting, transportation, and conversion of the biomass. However, by coupling biofuel production with carbon capture and storage (CCS), net-negative GHG emissions can be achieved [5]. CCS incurs significant capital and operating expenses, so it is generally only economically viable with government incentives. With the passing of the Inflation Reduction Act (IRA), the USA has a tax credit of \$85/Mg CO<sub>2</sub> captured and stored securely. There is also a higher credit of \$180/Mg CO<sub>2</sub> for CO<sub>2</sub> captured directly from the atmosphere. The USA also provides incentives for the production of renewable liquid fuels, including ethanol, gasoline, diesel, and jet fuel. Notably, the credit for sustainable aviation fuel (SAF) depends on its emission reduction compared for fossil-

based jet fuel. SAF with 50% emission reduction receives a \$1.25/gallon credit, which increases by 1 cent for each additional percent of emission reduction, up to a maximum of \$1.75/gallon at net-zero emissions. This credit exceed that for ethanol, gasoline, and diesel at \$1/gallon.

Many techno-economic analysis have been performed on biofuels with carbon capture and storage (BECCS) systems and the impact of sequestration credits on their economic viability, but many of these studies pick a single conversion pathway and option for CCS. They also typically study a single biorefinery with a single feedstock price for a representative year [6]. However, biomass availability, locations for carbon sequestration, and competition with other fuels are key factors that can only be included with larger systems-level models.

Biofuels, with and without CCS, have featured heavily in integrated assessment models (IAMs). However, IAMs model economic, energy, and environmental sectors and interactions for the globe over long periods of time, so are often limited to a coarse representation of the energy sector [7]. Instead, detailed energy systems model can include a rich suite of conversion pathways.

Other studies of biofuels in energy systems models, and especially those focusing on the USA, have several crucial limitations. First, they typically simplify the wide range of combinations of biomass type, conversion pathway, and CCS to one or two conversion technologies. Second, they consider CCS from only some streams at the biorefinery even for pathways that generate multiple distinct CO<sub>2</sub> streams, such as those based on microbial conversion and gasification. Third, they often simplify the cost of CO<sub>2</sub> transportation and injection to a single value that is independent of region.

In this work, we present a study including a rich suite of biofuel conversion pathways to ethanol, gasoline, diesel, and jet fuel with the option for CCS from each CO<sub>2</sub> stream. We add these pathways to the Integrated MARKAL-EFOM System (TIMES) model applied to the USA. We further improve the model by adding transportation costs and region-specific injection cost curves for CO<sub>2</sub>. We also implement the most recent government incentives to study the role of biofuels and CCS in the USA transportation sector.

## METHODS

### Optimization Model

TIMES is a bottom-up long-term energy system linear optimization model that includes transportation, electricity generation, residential, commercial, and industrial sectors. It is solved considering 5-year timesteps from 2020 through 2055 with perfect foresight to minimize the discounted cost of meeting energy demands. It divides years into seasons, which are further divided into daily time slices. These times slices are used to consider both

seasonal and daily balances for energy demands [8].

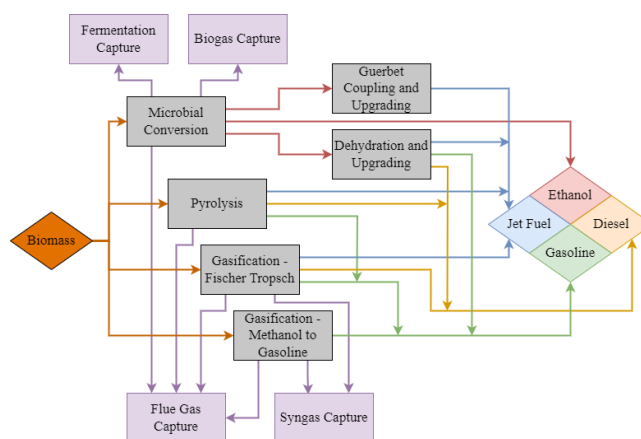

TIMES can be applied to different regions depending on the technologies available, and we use the EPAUS9rT database, which includes the existing energy technologies in the USA and their associated GHG emissions, divided into nine regions [9]. The inclusion of existing capacity and costs for conventional fuel technologies are essential for investigating how biofuel would compete in the current and future energy sector. However, because advanced biofuels are not currently widespread in the USA, the database has little representation for these fuels. Thus, this work adds these advanced biofuel technologies, as outlined in the following sections.

### Biomass Availability and Oil Price

The amount of biomass available and its cost is critical for studying biofuels. The Billion Ton report, updated in 2016, determined supply curves of biomass availability as a function of price for a variety of biomass types under different scenarios [10]. It generates these results assuming that sufficient land for food production is ensured before land is used for biomass production so that there is no competition with food. The study includes agricultural residues, grassy energy crops, corn stover, urban wood waste, forest resources, and woody energy crops. We note that utilizing waste biomass requires no additional land or water. For energy crops, additional water and land is required, but these are not tracked in TIMES and therefore beyond the scope of this study. We generate four scenarios of reference biomass availability and oil price, high biomass availability and reference oil price, reference biomass availability and high oil price, and high biomass availability and oil price.

### Biofuel Conversion Pathways

We include a wide variety of conversion technologies and options for CCS, summarized in Figure 1.

**Figure 1.** Biofuel production and carbon capture technologies considered in this study.

One mature pathway is microbial conversion, in

which fermentation is used to produce ethanol from sugars. In a biorefinery using this pathway, CO<sub>2</sub> is released from the fermentation process, in biogas from anaerobic digestion of wastewater, and in the flue gas from solid residue combustion [11]. Ethanol can be used as a fuel, or further upgraded. The upgrading options begin with Guerbet coupling to produce jet fuel, or with dehydration to produce a range of gasoline, diesel, and jet fuel [12].

Biomass can also be converted thermochemically. Pyrolysis produces a bio-oil that can be further upgraded into gasoline and diesel with hydrogen that can be produced onsite from the fuel gas. In this case, the only stream from which CO<sub>2</sub> can be captured is the dilute flue gas stream [13]. Alternatively, biomass can first undergo gasification to produce syngas. The syngas can then be converted into a range of gasoline, diesel, and jet fuel through Fischer-Tropsch synthesis [14], or to gasoline through a methanol intermediate [15]. For both pathways based on gasification, a very pure stream of CO<sub>2</sub> is produced when cleaning the syngas, and another dilute stream of CO<sub>2</sub> is produced from fuel gas combustion.

While thermochemical conversion technologies can process any type of biomass, the lower carbon content and higher ash content of herbaceous biomass increases costs. The nearly pure CO<sub>2</sub> streams from fermentation and syngas cleaning require only dehydration before compression, transportation, and sequestration. For all other CO<sub>2</sub> streams, we assume that amine absorption is used. We also assume that all the CO<sub>2</sub> in biogas is captured, while 85% of CO<sub>2</sub> in flue gas streams is captured.

### CO<sub>2</sub> Transportation and Sequestration

An important element in CO<sub>2</sub> sequestration not included in the EPAUS9rT database is the availability and injection cost of saline aquifers in each region. To add this to the model, we identified the potential injection sites with injection costs below \$100/Mg CO<sub>2</sub> in the literature. Assuming that each aquifer has a maximum annual injection limit of 1% of its total capacity, we constructed a cost curve of marginal cost of injection as a function of total CO<sub>2</sub> injection within each region. We calculated the CO<sub>2</sub> transportation costs within and between regions by the average distance between the potential locations of biorefineries and the potential injection sites.

## RESULTS

### Existing Credits

With the existing credits, we run the improved model through 2055. The results of biofuel production and the transportation emission reduction are shown in Figure 2. The total biofuel production increases rapidly beginning in 2030, almost entirely comprised of gasification and Fischer-Tropsch synthesis. Biofuel production continues to increase through 2050, but the growth slows as the all

the low-cost biomass sources are used and marginal cost of using additional biomass increases.

**Figure 2.** Biofuel production and corresponding GHG emission reduction over time.

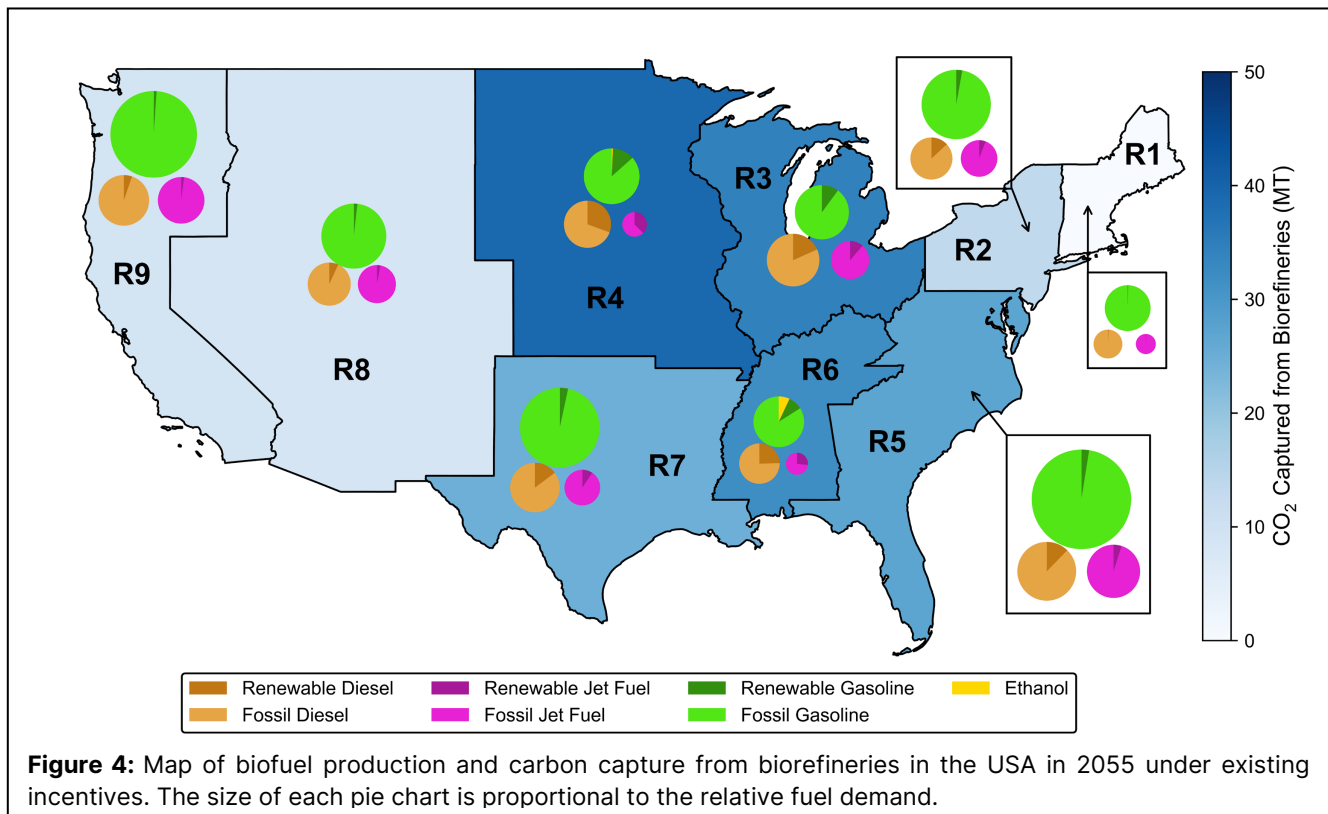

The amount of CCS varies by region depending on the cost of electricity and CO<sub>2</sub> transportation and injection, but on average 60% of biofuel production from Fischer-Tropsch includes CCS in both the stream from syngas cleaning and flue gas, while the remaining 40% includes capture from the syngas cleaning stream only.

Biofuels produce some emissions, but much fewer than fossil fuels. Accordingly, more than one third of emission reduction from BECCS come from the replacement of fossil fuels, while the remaining comes from the direct negative emissions of CCS.

Figure 3 shows the distribution of biomass sources and biofuel conversion pathways selected in 2055. Dedicated woody energy crops are the most used biomass sources, followed by urban wood waste and forest resources. These sources are selected due to their higher yields and lower costs than herbaceous sources.

**Figure 3.** Sankey diagram for energy flows of biomass and biofuels. Results are in petajoules (PJ) in 2055.

Very little herbaceous biomass is used and is limited primarily to producing small amounts of ethanol via microbial conversion. Overall, only a quarter of biomass available is used in 2055.

Figure 4 shows the regional distribution of biofuel production and CCS from biorefineries. Both biofuel production and CCS are focused in the Midwest and South (regions 3-7), which have lower costs and higher availability of both biomass and saline aquifer injection sites compared to the coastal regions. R4 has the highest biofuel production of any region at 445 PJ, and the highest amount of carbon captured at 50 MT/year. In New England (R1), there are no potential injection sites, so any carbon captured would have to be transported a significant distance, which would be expensive. Therefore, in that region a small amount of biomass is converted to fuel using pyrolysis without any CCS, which is the lowest-cost method of producing biofuels when CCS is not available or economically viable. The only region that continues to produce ethanol in 2055 is R6, which produces ethanol from grassy energy crops, instead of from corn as is currently the case in the USA. While there are options to upgrade ethanol to jet fuel via dehydration or Guerbet coupling, no ethanol upgrading pathways are selected due to their high costs compared to the thermochemical conversion pathways based on pyrolysis and gasification.

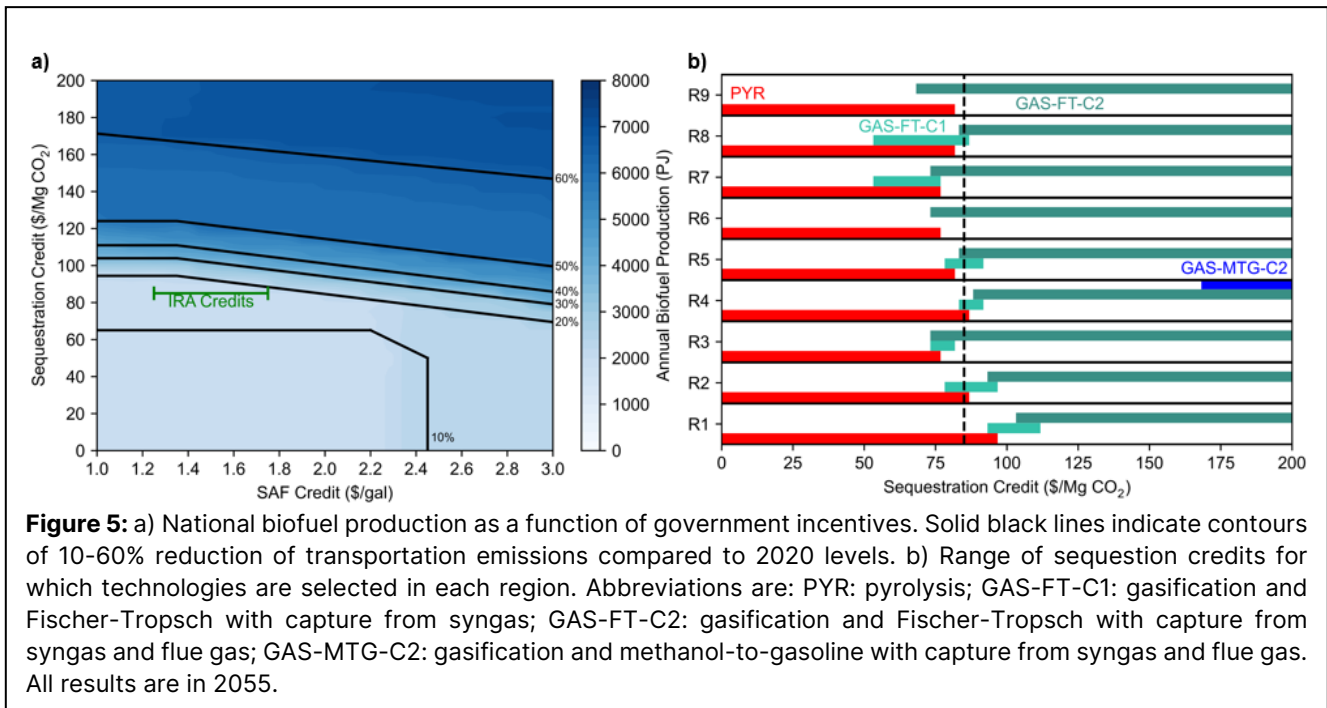

### Impact of changing credits

Relatively little biofuel production is incentivized

with existing credits, so we next explore how changing the value of the credits impacts the choice of technological pathway for biomass to biofuels, total biofuel production, and national transportation emission reduction.

Figure 5a shows that the sequestration credit is much more impactful on biofuel production and emission reduction than the SAF credit. In fact, at low sequestration credits, a SAF credit of over \$2.20 would be required to increase biofuel production by a significant amount. While at current incentives and assumptions in the EPAUS9rT database, annual transportation emissions were reduced by only 15% compared to 2020 levels, minor increases in the sequestration credit can dramatically reduce emissions, reaching 50% emission reduction at \$120/Mg CO<sub>2</sub> with current SAF credit levels.

Figure 5b shows the range of sequestration credits for which biofuel conversion pathways are selected. In all regions, pyrolysis is chosen at low credits, and this transitions to gasification and Fischer-Tropsch at higher credits, with the credit at which the transition occurs varying by region. The transition begins to occur at credits as low as \$55/Mg CO<sub>2</sub> in R7 and R8, where CCS from the syngas stream becomes incentivized. At credits above \$110/Mg CO<sub>2</sub>, gasification and Fischer-Tropsch synthesis with CCS from all sources preferred in all regions. Gasification and methanol-to-gasoline is incentivized in R4 at high sequestration credits because it has a higher ratio of CO<sub>2</sub> captured to fuel produced, allowing it to take greater advantage of the sequestration credit.

### Impact of biomass availability and oil price

Even if sequestration and SAF credits do not change, there are other ways in which biofuel production might be increased. With continuing research in purpose-grown woody and herbaceous energy crops, and the potential of rising oil prices with depletion of reserves and environmental restrictions, biofuels may become economically attractive without increased government incentives. Accordingly, we show in Figure 6 biofuel production by different biomass sources under different scenarios of biomass availability and oil price.

With increasing biomass availability and oil price, the choice of biofuel conversion pathways does not change, though the magnitude of production changes significantly. The high biomass availability (B+) scenario has approximately double the biomass availability in 2055 compared to the reference (R) scenario, and biofuel production correspondingly doubles. The most significant increase between these scenarios is the increased use of woody energy crops, though there is also an increase in grassy energy crops undergoing gasification and Fischer-Tropsch synthesis and microbial conversion. However, R7 is the only region that uses grassy energy crops in this scenario.

When the oil price increases with reference biomass availability (scenario R to scenario O+), the most significant change is the dramatic increase in the use of herbaceous biomass, primarily in R3, R4, and R7. Herbaceous biomass has lower conversion efficiency and higher costs compared to woody biomass that makes it not competitive with fossil fuels in the reference scenario, but the increase in oil price is sufficient to change that. In

this scenario, R2 also begins to produce small amounts of ethanol from grassy energy crops and corn stover. Overall, an increase in the oil price alone increases total biofuel production by a factor of 4.

When an increase in biomass availability is also added on (scenario O+ to scenario BO+), there is less corn stover and significantly more woody energy crops available, which further increases biofuel production to nearly 7500 PJ. In the BO+ scenario, biofuel meets roughly 14% of gasoline, 55% of diesel, and 28% of jet fuel demand, resulting in 60% emission reduction compared to 2020 levels.

**Figure 6:** Biofuel production by biomass type under each biomass availability and oil price scenario in 2055. Abbreviations are: ECG: grassy energy crops; STV: corn stover; AGR: agriculture residues; UWW: urban wood waste; FSR: forest resources; ECW: woody energy crops.

## CONCLUSION

We improved the TIMES model applied to the USA energy sector by adding a rich suite of biofuel conversion pathways with the option for carbon capture from all CO<sub>2</sub> streams generated and region-specific CO<sub>2</sub> transportation and injection costs. With the improved model, we studied how the existing government credits in the Inflation Reduction Act would incentivize biofuel production and carbon capture, finding biofuels to meet only 15% of diesel, 4% of gasoline, and less than 1% of jet fuel demand in 2055. We explored changes in sequestration and SAF production credits and found the sequestration credit to be much more impactful, with a relatively minor increase to \$120/Mg CO<sub>2</sub> reducing emissions by 50%. Lastly, we examined how increases in biomass availability or oil price could increase biofuel production without and change in government incentives. Here, we found similar levels of emission reduction could potentially be achieved in the most biofuel-friendly scenario.

## ABSTRACT

Increases in population and improvements in living standards have significantly increased the demand for animal products worldwide. However, modern livestock agriculture exerts significant pressure on the environment due to high material and energy requirements. These systems also generate significant amounts of waste that can cause severe environmental damage when not handled properly. Thus, if we wish to enable farmers to meet this increased demand in a sustainable way, technology pathways must be developed to convert livestock agriculture into a more circular economy. With this end in mind, we propose a novel framework (which we call ReNuAI) for the recovery of nutrients from livestock waste. ReNuAI integrates existing technologies with a novel biotechnology approach that uses cyanobacteria (CB) as a multi-functional component for nutrient capture and balancing, purifying biogas, and capturing carbon. The CB can be applied to crops, reducing the need for synthetic fertilizers like diammonium phosphate. Using manure profiles obtained from dairy farms in the Upper Yahara region of Wisconsin, we construct a case study to analyze the environmental and economic impacts of ReNuAI. Our results illustrate that the minimum selling price (MSP) of CB fertilizer produced from deploying ReNuAI at a 1000 animal unit (AU) farm is significantly higher than the cost of synthetic fertilizers. We also observe that ReNuAI can return environmental benefits in areas such as climate change and nutrient runoff when compared to current practices. As a result, we see that consideration of environmental incentives can significantly increase the economic viability of the process.

## INTRODUCTION

The UN Food and Agriculture Organization projects that demand for animal products will increase by up to 70% by 2050 [1]. This represents an opportunity for significant economic growth for areas that specialize in livestock agriculture like the Upper Yahara region of Wisconsin. However, meeting this demand also presents a significant sustainability challenge. Livestock agriculture is a resource-intensive venture: production of 1 kg of fat and protein corrected milk requires 2.7 MJ of energy, 2.61 kg of nitrogen (N), and 0.4 kg of phosphorus (P) [2, 3]. While nitrogen is a renewable resource, phosphorus and the required energy are usually sourced from non-renewable feedstocks [4]. Concurrently, these systems generate large amounts of waste, mostly in the form of animal

manure [5]. The most common method for managing this waste is to apply it to cropland where it can serve as a fertilizer. However, this approach leads to several undesirable environmental outcomes. Manure breaks down when exposed to sunlight and releases potent greenhouse gases (GHGs) like N<sub>2</sub>O and CH<sub>4</sub>; this practice has been measured to have a global warming potential (GWP) of 72.5 kg CO<sub>2</sub>-eq/tonne of manure. Additionally, because livestock waste has a low N:P ratio, it is often over-applied to meet crop N requirements; this results in the overloading of soils with P [6]. This, in turn, leads to excess nutrients being washed out into surrounding waterways where they cause harmful algal blooms (HABs). In addition to severe environmental damage to aquatic ecosystems, these eutrophication events also result in significant health and economic damage to the residents of

neighboring communities [7].

Technologies that provide alternative methods for handling livestock manure have existed for decades. The use of anaerobic digesters (ADs), which were developed in the early 20<sup>th</sup> century, in a farm setting was initially considered during the 1970s in response to an energy crisis [8]. ADs use microorganisms that feed on raw manure to generate a gas mixture, commonly referred to as biogas, largely composed of CO<sub>2</sub> and CH<sub>4</sub> that can serve as a renewable energy source. Additionally, by breaking down manure in a more controlled setting, ADs are able to prevent the release of GHG emissions seen in land application. However, the leftover material, known as digestate, has a similar N:P ratio as manure, and also leads to nutrient overloading when applied to cropland. Water recovery systems (WRS) offer a solution to this issue by providing further separation capabilities for the digestate. The central aim of a WRS is to recover clean water from manure. This is achieved using a solids-liquids separator (SLS) followed by ultrafiltration (UF) and reverse osmosis (RO) systems [9]. This allows for the separation of P and N nutrients. The solid product contains most of the P while the N is largely recovered in a concentrated solution following the UF and RO steps [10]. While this allows for variable nutrient loading, additional infrastructure and management protocols are required to ensure that these products are properly stored and applied [9].

Cyanobacteria (CB) are aquatic photosynthetic bacteria with high productivity compared to terrestrial plants [11, 12] that have been shown to be capable of processing nutrient-rich streams like manure or digestate [13, 14]. In fact, HABs are the result of the rapid growth of certain species of CB in nutrient-rich water. We propose harnessing this ability in a more controlled way to cultivate this organism for use as a biofertilizer. In addition to recycling nutrients and reducing nutrient leaching, CB fertilizer has been shown to improve soil health, reduce erosion, and has a smaller carbon footprint when compared to synthetic fertilizers [15-17]. To this end, we present the Renewable Nutrients from Algae (ReNuAl) process, a small and low-intensity operation for the production of CB fertilizer from manure. This technology pathway is centered around the use of CB strains that are engineered to have N and P content ratios that match crop nutrient requirements. We study the economic metrics of this process using a technoeconomic (TEA) model of ReNuAl at a hypothetical 1000 animal unit (AU) dairy farm in the Upper Yahara. The calculated minimum selling price (MSP) of the biofertilizer, while similar to the value reported in another study [18], is significantly higher than the cost of synthetic fertilizers. However, a preliminary life cycle assessment (LCA) of the process indicates that ReNuAl has the potential to deliver substantial environmental benefits when compared to direct land application. Thus, the consideration of environmental incentives

can reduce the fertilizer MSP significantly.

## COMPUTATIONAL FRAMEWORK

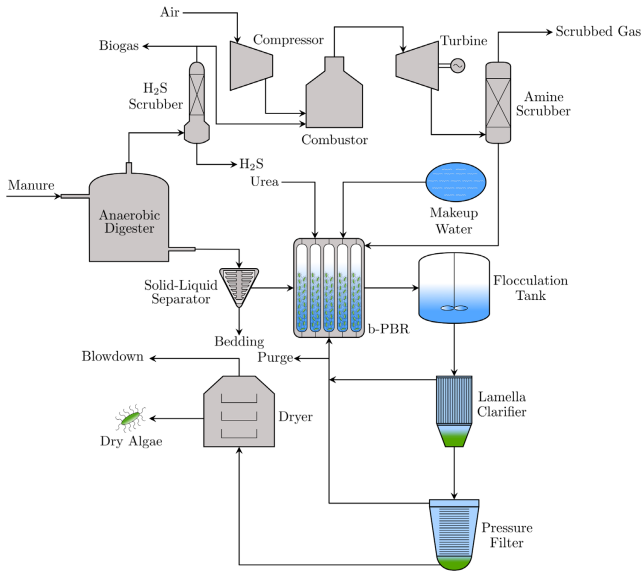

In this section we present the ReNuAl process, state the assumptions made in the process models, and provide a description of the proposed computational framework. As seen in Figure 1, the front end of ReNuAl pairs anaerobic digestion with CB cultivation and harvesting. This integration allows for the continued recovery of energy from manure via biogas in tandem with biofertilizer production, providing the process with multiples product streams. The CB are cultivated in bag photobioreactors (b-PBRs), and their growth is assumed to be light-limited. We assume that two thirds of the produced biogas is exported to the grid while the remaining third is burned for on-site power generation. The flue gas is scrubbed, and the CO<sub>2</sub> is fed to the cyanobacteria. Solids in the digestate are removed in a solids-liquids separation unit, and the liquid fraction is pumped into the b-PBRs along with any additional N required in the form of urea. Once the CB are ready to be harvested, they are sent to a dewatering train consisting of a flocculation tank, clarifier, and pressure filter that yields a concentrated CB solution. This stream is then fed to a thermal dryer to achieve the desired moisture level. CB growth in the b-PBRs is simulated using a detailed growth model based on the work of Straka [22] while the remaining units are simulated with linearized models using yield factors found in the literature. The ReNuAl process is fed 11.7 tonnes/yr of N and 10.6 tonnes/yr of P from 20800 tonnes/yr of manure. The b-PBRs receive 350 μmol/m<sup>2</sup>·s of sunlight and are harvested every 30 days. The P content of the CB is assumed to be 0.023 g P/g CB resulting in a production rate of 419 tonnes/yr of fertilizer. Using these unit operations models and system parameters, we calculate the mass and energy flows of the process and the required size of the process units. This information is then used to determine the capital investment as well the yearly operating costs and revenues of ReNuAl. Note that prices are set in terms of 2020 USD and the process is assumed to have a lifetime of 20 years.

The MSP is calculated by determining the price at which the fertilizer must be sold to achieve a discounted return on investment (DROI) of 15%. The DROI is defined as the discount rate that results in a net present value (NPV) of 0 at the end of the project life where:

$$NPV = C + \sum_{t=1}^T P(1+i)^{-t} \quad (1)$$

The DROI is denoted by  $i$ ,  $T$  is the project lifetime (in years),  $C$  is total capital investment (TCI) and  $P$  is the annual after-tax profit (AATP) and is formulated as:

$$P = (1-r)(p_f \dot{m}_f + p_g \dot{m}_g + p_e \dot{w} - p_o - d) + d \quad (2)$$

**Figure 1.** ReNuAl process configuration

where the production rates of fertilizer, biogas and electricity are represented by  $\dot{m}_f$ ,  $\dot{m}_g$ , and  $\dot{w}$  respectively and these are sold at  $p_f$ ,  $p_g$ , and  $p_w$ . The term  $r$  is the tax rate,  $p_o$  is the total annual operating cost (TOC), and  $d$  is the annual depreciation of the process equipment. Note that the values in (2) are held constant throughout the lifetime of the project. Thus, the MSP is defined as the value of  $p_f$  that results in a value 0 for (1) when  $i = 0.15$ .

We use the material and energy flows calculated by the process model to develop a preliminary LCA to quantify the environmental benefits of ReNuAl over current practices. The LCA is performed using openLCA in conjunction with the Environmental Footprint and AGRIBALYSE databases and the Environmental Footprint impact assessment method [19, 20, 21]. The functional unit is set to be the size of the dairy farm (1000 AU), and we consider that the electricity demands are satisfied using the average electricity mix in the US. The impact categories considered in this study are climate change and water use. We valorize the observed benefits using existing frameworks, such as RIN and LCFS credits and a hypothetical P credit based on the economic impact of P runoff as quantified in [7], in order to determine the effect of these additional cash flows on the product MSP.

## RESULTS AND DISCUSSION

We determined that the construction and operation of the ReNuAl process have a cost of 4.36 MMUSD and 2.73 MMUSD/yr respectively. At these values, the fertilizer would have to be sold for 7.75 USD/kg to meet the DROI target. This is significantly higher than the 0.25 USD/kg that it would cost to obtain the equivalent N and P content using synthetic fertilizers.

From Figure 2, we can see that TCI and TOC are not

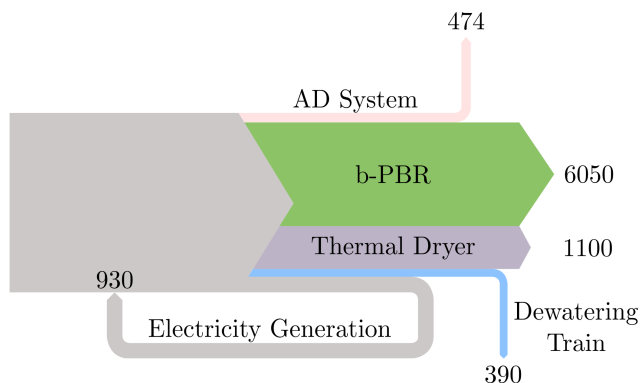

evenly distributed across the various sections of the process. The anaerobic digester and thermal dryer alone account for over 60% of the TCI while the operation of the b-PBRs represents about 75% of the TOC. This indicates that by exploring alternative process configurations or extending the capabilities of the CB, we might be able to significantly decrease these costs and, by extension, the MSP. For example, a CB strain that can clean the biogas by removing  $H_2S$  and  $CO_2$  can reduce the capital cost by 11% by eliminating the need for gas scrubbers. Similarly, if it is not necessary to completely dry the CB or if strains that are more easily recoverable via sedimentation and filtration are used, then it might be possible to reduce the size of the thermal dryer or eliminate it completely.

**Figure 2.** Distribution of total capital (left) and operating (right) costs in MMUSD across the sections of the ReNuAl process

While the economic metrics of ReNuAl seem unfavorable, it should be noted that there is a significant degree of uncertainty surrounding the values of the CB cultivation and harvesting sections; the design of these systems has traditionally focused on biofuels applications. As a result, the scale and complexity of the equipment used is significantly higher than what should realistically be required for ReNuAl; this is especially true of the bioreactors. From Figure 3, we can determine that operation of the b-PBRs accounts for approximately 75% of the energy consumed by the process. This is largely driven by the mixing requirements of the reactors, which alone represent 24% of the TOC. This level of energy demand is reasonable at a biofuel production facility given the large volume b-PBRs must fit to accommodate the high production rates required. However, ReNuAl will use significantly smaller reactors, and, as a result, these will likely require less energy to be well-mixed. Similarly, the labor, maintenance, and replacement costs of the b-PBRs, which together account for 40% of the TOC, would likely be lower than the values we calculated for the same reason.

The preliminary environmental analysis shows that the water use impact is higher for ReNuAl than for current practices. This is unsurprising as CB cultivation operations have high water requirements due to the achievable

**Figure 3.** Yearly energy flows (in MW-hr) for the different sections of the ReNuAI process

titers being fairly low (approximately 1-2g/L). Manure spreading, on the other hand, does not require any additional water as manure has a moisture content of approximately 90%, and, after the removal of suspended solids, it can be easily pumped through a liquids distribution system. However, we also observe that ReNuAI generates 39% fewer GHG emissions than land application of manure. A significant portion of this reduction is due to the production of biogas. Under our framework, ReNuAI is able to export 429 tonnes/yr of methane which make it eligible to receive compensation from government-funded incentives like RIN credits from the EPA's renewable fuel standards program and low carbon fuel standard (LCFS) credits offered by the state of California. Applying the value of the RIN and LCFS credits, we determine that the process is able to generate an additional 600,000 USD/yr of revenue; this lowers the MSP of the CB fertilizer 18% to 6.33 USD/kg.

When we consider the release of nutrients to the environment from the land application of livestock waste with those from ReNuAI, we observe that our process has two distinct advantages. First, the N:P ratio of the biofertilizer more closely matches crop needs than manure, reducing the need for overapplication. Second, CB is a more stable medium and releases nutrients more gradually than manure [15, 16]; this significantly reduces the amount of nutrients carried away during rain events. The HABs caused by nutrient runoff result in the affected waterbodies not being usable for economic activities like fishing and recreation and, as a result, represent a loss for the surrounding communities. Previous studies focusing on the Upper Yahara have estimated these losses to have a cost of 74.5 USD/kg P [7]. Thus, if we apply an equivalent credit, we determine that we can generate an additional 789,700 USD/yr if a CB strain that is able to capture all of the P in the manure can be engineered. If we combine this with the revenue from the RIN and LCFS credits, the MSP of the CB can be reduced further to 4.45 USD/kg. It is important to note that this represents a best-case scenario and additional work must be done to

determine nutrient uptake and leaching rates for the CB.

In addition to highlighting potential knowledge gaps as previously discussed, our framework allows us to understand the sensitivity of process economics to changes in various key parameters. For this analysis we considered the reactor batch time, the fraction of biogas sent to market, the reactor surface area to volume (SA:V) ratio, the light available to the bioreactors, and the P uptake of the CB. Note that this is not an exhaustive selection; rather, these choices are based on the variables we can meaningfully simulate using the current process model.

The results shown in Figure 4 (note we are including RIN and LCFS credits in the calculation of the MSP) indicate that the parameters associated with the design and operation of the b-PBRs, batch time and reactor SA:V ratio, have the largest impact on MSP. Given the cost of operating the reactors, these results are not surprising as these parameters directly affect the amount of reactor volume required.

After the batch time and SA:V ratio, the next most important variable to consider is the fraction of biogas sent to market. Due to the low value of electricity compared to the value of biogas and the cost of the electricity generation section, we observe a 13% decrease in the MSP when we export all of the biogas offsite. However, we should note that a significant portion of the revenue from the biogas comes from RIN and LCFS credits, and changes in policy can reduce the value of these credits.

From the variation in the light intensity, we can conclude that the process is not severely light-limited as shifting light availability up or down by 50% only moves the MSP -5% to +11% from the baseline. This indicates that in the current design it is the reactor surface area to volume ratio that limits the titer that can be achieved. This is due to shading effects which limit the distance that light can penetrate the vessel. As a result, the reactor design should be optimized before exploring methods for increasing light availability.

The results seem to indicate that lowering the P content of the CB might be favorable as this lowers the MSP. However, in this context, it is important to think about the value of CB which is dependent on its nutrient content. The reason the MSP decreases at lower P uptake values is because more of it must be produced to consume all of the available nutrients. As a result, on a nutrient content basis, the biomass is less valuable. A more appropriate question is then if this drop in value is matched by the drop in MSP. From Figure 4, we observe that the answer is no. Conversely, we also see that when the P content of the cells is increased, the MSP increases at a lower rate. Additionally, this decrease in throughput translates to a lower TCI and TOC. Thus, it might be possible to reverse this trend at higher P loading values.

**Figure 4.** Change in MSP of CB product with changes to selected operating parameter

## CONCLUSIONS AND FUTURE WORK

This study presented a framework for the capture and recycling of nutrients in livestock waste. The goal of this process, which we refer to as ReNuAl, is to provide a pathway towards a more circular economy that will allow livestock farmers to meet the projected increase in demand for animal products in a sustainable manner. An initial economic analysis of ReNuAl indicates that the produced biofertilizer is significantly more expensive than current synthetic fertilizers. However, we also determined that there is a significant degree of uncertainty around the economic values calculated for the b-PBR section due to the difference in scales that existing CB cultivation facilities operate at compared to ReNuAl. Thus, we are interested in developing prototypes of the b-PBRs to better understand their operations and obtain more accurate performance metrics.

Our environmental analysis indicates that ReNuAl has the capability to reduce carbon and nutrient-based pollution. However, we also observe that CB cultivation has a high water requirement. As result, identifying methods that allow for high degrees of water reuse and recovery as well as locations that are not water-strained for deployment are important factors to consider moving forward. It is also important to note that these results are preliminary. Moving forward we will focus on improving the accuracy of these values by working with microbial, agronomy, and environmental science experts who can perform field trials to measure variables of interest like maximum attainable titer, nutrient uptake and leaching, and GHG emissions. Additionally, we will also extend our analysis by evaluating other environmental metrics and performing a sensitivity analysis on the energy sources used to power the process as previous studies have shown that changing the energy source to non-fossil alternatives can decrease the climate change impact [23].

Using our TEA model, we were able to identify key operating parameters that can have a significant impact on the viability of the ReNuAl process. Our results indicate that optimization of b-PBR design and operation,

specifically vessel geometry and batch times, can significantly reduce the MSP of the biofertilizer. We also observe that by increasing P-uptake we can make a more nutrient-dense product that can be sold at a lower price (on a nutrient content basis) while also reducing capital and operating expenses. From these results we can conclude that developing fast-growing CB strains that have a high P content using a reactor with as high an areal mass density (high SA:V value) as possible will significantly improve the economics of ReNuAl. Additionally, this work demonstrates how a computational framework serves as a goal-oriented tool for determining promising directions that researchers can proceed in. Moving forward we are interested in exploring the impact of additional CB-specific traits that can potentially improve the economic and environmental performance of ReNuAl such as maximum harvest titer and settling velocity as well as the capacity of the organism to remove CO<sub>2</sub> and H<sub>2</sub>S from the biogas stream; we plan to achieve this by making use of new experimental data to refine our existing process models. In other words, our future work centers around the integration of process and economic models with experiments to allow for continuous model improvement which in turn allows for the accurate identification of key variables and regions of diminishing returns.

## ABSTRACT

This study investigates the feasibility of valorizing pulp and pulp sludge (PPS) into methane through anaerobic digestion (AD) with a focus on techno-economic analysis (TEA). Three scenarios are evaluated: (A) the base case, (B) sludge AD with alkaline pretreatment using green liquor dregs (GLD), and (C) co-digestion with nitrogen-rich feedstocks. The evaluation is applied to a common PPS, consisting of 70% primary sludge (PS) from the primary clarifier and 30% secondary sludge (SS) from biological treatments from a kraft mill. Theoretical methane potential (TMP) is determined using the Buswell equation. The study highlights the significance of co-digestion with nitrogen-rich feedstocks in enhancing the economic viability of the AD process for PPS, providing valuable insights for sustainable waste management and resource recovery in the pulp and paper industries.

---

**Keywords:** Pulp and paper sludge, biomethane, anaerobic digestion, techno-economic analysis, valorization.

## INTRODUCTION

The pulp and paper industry (PPI) generates a significant volume of wastewater that undergoes physical and biological treatment [1,2], resulting in a considerable quantity of pulp and paper sludge (PPS) [3], which is one of the major waste streams of PPI [4]. As global energy demand escalates and concerns over energy security and climate change intensify, anaerobic digestion (AD), which transforms organic materials into methane and carbon dioxide in the absence of oxygen [5], has emerged as a versatile technology for renewable energy production. This microbial-mediated process presents a promising solution for managing PPS, offering an alternative energy source to supplement industrial fossil fuels. PPS contains 45-55% organic matter and various nutrients, including nitrogen and phosphorus [6], making it a potential resource for microorganisms in the production of bio-products and biofuels. The conversion of pulp and paper mill by-products, such as sludge, into value-added goods and bioenergy can significantly contribute to the commercial growth of biorefineries. However, for effective utilization, these by-products must meet specific minimum standards. To enhance efficiency and

profitability, there is a growing interest in evaluating opportunities to generate new revenues from innovative, value-added products within the existing infrastructure of pulp and paper mills. Consequently, this study aims to identify a promising process pathway for a biorefinery integrated with an existing pulp and paper mill, considering various scenarios in pursuit of improved efficiency and profitability.

## METHODOLOGY OVERVIEW

### Process synthesis and design

The techno-economic analysis (TEA) of AD for PPS considers three distinct scenarios (Fig. 1), each representing a unique process aimed at evaluating the economic and technical feasibility of methane production. The sludge mixture constituted 70% PS from the primary clarifier and 30% SS obtained from biological treatments. The sludge generation varies widely among mills. In this context, the input mass flow for the sludge is assumed to be 500 tons per day with a dry matter content of 12%. The dry matter content and mass flowrate specified conform to data obtained from a United States Environmental Protection Agency (EPA) investigation encompassing

104 bleached Kraft mills and are consistent with established industry norms [7,8].

Figure 1. Three TEA scenarios for AD of mixed kraft mill primary and secondary sludge.

### Scenario A: Base case

The base case scenario mirrors the conventional operational conditions of AD. As a baseline condition, scenario A serves as a reference point for assessing the shortcomings and limitations of the existing process in terms of economic viability and methane production efficiency.

### Scenario B: Sludge AD with alkaline pretreatment

Among the various pretreatment methods, alkaline pretreatment is a promising approach that can successfully improve the enzymatic hydrolysis for many lignocellulosic materials [9,10].

As reported in [9], alkaline pretreatment effectively disrupted the floc structure of pulp and paper sludge, leading to a reduction in fiber size. According to reference [9], effective biodegradation in bioreactors was evidence in terms of soluble chemical oxygen demand (SCOD) removal efficiency, which attained the range of 83–93% in bioreactors with pretreated PPS compared with 70% removal for untreated PPS, indicating a significant improvement of 18.6–32.8% in organic removal. These findings show the efficacy of alkali pretreatment as a promising method for enhancing methane yield in the context of PPS.

An alkaline pretreatment typically involves the use of hydroxides like NaOH or KOH [11]. However, it has been suggested that the GLD, a by-product of the kraft pulping process, could be used as a substitute for powerful and expensive alkaline agents like NaOH [12].

### Scenario C: Co-digestion with nitrogen-rich feedstocks

In this scenario, food waste (FW) is specified as a promising nitrogen-rich feedstock for co-digestion with PPS, supported by existing studies on the co-digestion of FW with PPS [13]. Previous work has mentioned nitrogen

deficiency as a major challenge in AD of PPS [14,15]. The ideal carbon-to-nitrogen ratio for AD feedstock typically falls within the 20–30% range [16]. A high C:N ratio, as observed in PPS, accelerates nitrogen consumption by methanogens, adversely affecting microbial population growth and prolonging the carbon digestion process. Conversely, a low C:N ratio leads to elevated ammonia release in the digester and inhibits the AD process.

## Theoretical methane potential

Theoretical methane potential was assessed using the Buswell equation (Eq. (1)), which relies on the stoichiometric balance between biodegradable organic matter and the resulting gaseous products from anaerobic biodegradation [17]. Volatile solids (VS) represent the organic matter content of the sludge that is readily converted to gas during the anaerobic digestion process, and total solids (TS) refer to the total mass of both organic and inorganic matter present in the sludge. These key parameters, VS and TS, play a significant role in determining the efficiency of anaerobic digestion and the potential methane yield. In the specific case of PPS, the Buswell equation can be applied, assuming a 30% volatile solids (VS) removal based on experimental findings [14]. In this context, biodegradation efficiency signifies the proportion of VS degraded during the process.

We can deduce the maximum theoretical methane potential (TMP) using Eq. (2):

$$TMP \left( \frac{m^3}{kgVS} \right) = \left( \frac{(4a+b-2c-3d) \times 22.415}{12a+b+16c+14d} \right) \quad (2)$$

## Economic analysis

### Gross economic potential (GEP)

The gross economic potential is used to assess the economic benefits and potential value generated by the process. The GEP is defined in Eq. (3).

$$GEP = VP + STF - VF \quad (3)$$

where VP is the value of products, STF is savings on tipping fee, and VF is the value of feeds. The value of products refers to the economic value generated from the products resulting from the AD process. In the case of converting sludge to methane, VP would include the revenue or value obtained from selling the methane produced, as well as any other by-products that can be monetized, such as organic fertilizers or other valuable substances extracted from the process. Tipping fees are charges imposed for disposing of waste in landfills. By diverting sludge from landfills and converting it into biogas through AD, the process effectively reduces or

eliminates the need to dispose of the waste in landfills. This saving is a significant factor in the economic assessment, especially given the specific cost of the tipping fee (\$58.47/ton [18]). Value of feeds represents the value of any feeds or materials used in the process. In the context of PPS converted to biogas, the VF is considered zero because PPS is a by-product with no value as a feed or input material.

### Manufacturing cost

The sizing and cost estimation of the pretreatment reactor followed the methodology proposed by Ulrich et al. [19]. However, in the case of the digester, its large size exceeds the range covered by the graphs outlined. Therefore, for the digester, we referred to a similar farm digester documented in the literature as a case study to estimate costs [20]. Capital cost of this case study is scaled to the capacity of AD systems assumed in our scenarios based on the usual 0.6-power rule (Eq. (4)):

$$CC_A = CC_B \times \left(\frac{Cap_A}{Cap_B}\right)^{0.6} \quad (4)$$

In Equation 4,  $CC_A$  and  $CC_B$  represent the capital costs of equipment A and B, respectively, while  $Cap_A$  and  $Cap_B$  denote the capacities of equipment A and B. All cost calculations are based on the chemical engineering plant cost index (CEPCI) of 816 (for 2022). Finally, assuming 18% of the bare module costs for contingency costs and fees based on reference [21], the total module cost ( $C_{TM}$ ) is calculated as Eq. (5) where  $n$  represents the total number of pieces of equipment and  $C_{BM,i}$  is the bare module cost for each piece of equipment  $i$ :

$$C_{TM} = 1.18 \times \sum_{i=1}^n C_{BM,i} \quad (5)$$

In this work, the CAPCOST method was applied to estimate the manufacturing costs [21]. Following the methodology proposed by Ulrich [19], the typical labor requirement for a continuous reactor is estimated at 0.3 workers per unit per shift. The operating labor cost ( $C_{OL}$ ) estimation assumptions considered are:

- On average, a worker at this plant operates five shifts per week for 52 weeks annually.
- The plant operates 365 days a year with three shifts per day.
- The 2022 Mean Annual Wage for Chemical plant and system operators is reported as \$79,290 per year, according to the U.S. Bureau of Labor Statistics [22].

The equation used to evaluate the cost of manufacture (COM) is:

$$COM = \text{Direct Manufacturing Costs} + \text{Fixed Manufact Costs} + \text{General Expenses} \quad (6)$$

Each individual cost item can be estimated

considering the costs of utilities ( $C_{UT}$ ), waste treatment ( $C_{WT}$ ), raw materials ( $C_{RM}$ ) and fixed capital investment (FCI). Turton et al. provide typical ranges for constants (multiplication factors) (Table 8.2. of [21]) to estimate these individual cost items. Since no other information is accessible regarding these costs in our study, we utilize the midpoint value within each range. Depreciation allowance is added separately to compute the cost of manufacturing (COM) using Eq. (7).

$$COM = 0.28 \times FCI + 2.76 \times C_{OL} + 1.23 \times (C_{UT} + C_{WT} + C_{RM}) \quad (7)$$

In Eq. (7), the FCI cost equals the total module cost, given that we are making alterations to an existing facility. In the specific context of our preliminary feasibility study or conceptual design, we adopt a simplified model or scenario wherein the costs of utilities ( $C_{UT}$ ), waste treatment ( $C_{WT}$ ), and raw materials ( $C_{RM}$ ) are ignored. However, it is essential to acknowledge that in real-world scenarios, these costs would typically be significant factors contributing to the overall manufacturing expenses.

## RESULTS AND DISCUSSION

### Buswell method

Based on the results of the elemental composition analysis for sludge derived from Lopes et al. [23] (refer to table 1), we can calculate the theoretical volume of methane using Eq. (2).

**Table 1.** Elemental compositions of the primary sludge (PS) and secondary sludge (SS) and mixed sludge (7:3) [23]

Parameters	PS	SS	Mix
VS/TS (g/g)	0.99	0.85	0.97
C (% TS)	44.10	45.20	44.41
H (% TS)	6.04	5.83	5.98
O (% TS)	48.80	29.80	34.86
N (% TS)	0.06	4.85	1.43
S (% TS)	0.40	1.82	0.81
Ash(%TS)	0.60	12.50	12.51
Total	100	100	100

VS: Volatile Solids; TS: Total Solids

According to the data presented in Table 2 calculated using Eqs. (1) and (2), the TMP for the mixed primary and secondary sludge, with a ratio of 7:3, was approximately 130.95 mlCH<sub>4</sub>/gVS<sub>fed</sub>, assuming a 30% removal of volatile solids (VS). This aligns with experimental findings documented in the literature [14,24]. This

theoretical value provides a preliminary insight into biogas and methane production.

**Table 2.** Biogas product yield and composition from the Buswell equation

Biogas	Yield (ml/gVS <sub>fed</sub> )	Composition (%)
CH <sub>4</sub>	130.95	49.12
CO <sub>2</sub>	126.41	47.42
NH <sub>3</sub>	7.43	2.79
H <sub>2</sub> S	1.79	0.67
Biogas	265.63	100

## Techno-economic analysis

### GEP of the different scenarios

For the base case scenario, the methane yield amounts to 130.95 mlCH<sub>4</sub>/gVS<sub>fed</sub>, equivalent to 269,141.78 ft<sup>3</sup>CH<sub>4</sub>/day and 17.46 tons PPS conversion per day. In a simplified context, assuming full upgrading and considering the lower heating value of methane at 910 Btu/ft<sup>3</sup> [25], the resulting energy production would be approximately 244.92 million Btu/day. Considering a natural gas price of \$6.45 per million Btu [26] and the average cost of landfilling municipal solid waste in the US in 2022 at \$58.47 per ton [18], the GEP of the base case is 0.95 million dollars per year.

In the second scenario, given the absence of specific Volatile Solid Removal (VSR) data in the literature, we approximated the improvement in VSR by referencing the enhancement in Soluble Chemical Oxygen Demand (SCOD) removal. Both SCOD and VSR serve as crucial indicators of organic material removal efficiency, and according to the literature [27], they tend to exhibit similar trends. According to [9] the highest organic conversion rate corresponds to a 33% increase in SCOD removal efficiency. This translates to approximately a 40% conversion of volatile solids for the pretreated PPS in our study, leading us to anticipate a methane yield of 174.60 mlCH<sub>4</sub>/gVS<sub>fed</sub>, equivalent to 358855.71 ft<sup>3</sup>CH<sub>4</sub>/day and 23.28 tons PPS conversion per day. Taking these factors into account, the GEP for the second scenario is estimated to be \$1.26 million per year.

According to the literature, AD of food waste gave a specific methane yield of 470 mlCH<sub>4</sub>/gVS<sub>fed</sub>, which is equal to approximately 70% of the theoretical value (660 mlCH<sub>4</sub>/gVS<sub>fed</sub> with a biogas methane content of 58%) based on the Buswell equation. Also, the food waste exhibited a TS content of 23.9% and a VS content of 21.6% [28]. Assuming the absence of any synergistic effects, the biodegradation efficiency, calculated by averaging the efficiencies of AD for both FW and PPS, stands at 50%. Using the Buswell equation and the elemental composition for the mixture of PPS and FW at a TS ratio of 1:1 (refer to Table 3), the cumulative methane yield reaches 291.76 mlCH<sub>4</sub>/gVS<sub>fed</sub>, aligning with the findings reported

in the literature [29]. With a fixed ratio of 0.94 gVS/gTS [23,28] and a total solids content of 12%, the calculated methane yield amounts to 581,107.51 ft<sup>3</sup>/day, resulting in a converted PPS of 28.2 tons/day. Consequently, for the third scenario, the GEP is \$1.85 million per year.

**Table 3:** Elemental compositions of the food waste and mixed Pulp and paper sludge

Parameters	FW [28]	FW: Mixed PPS (1:1)
VS/TS (g/g)	0.90	0.94
C (% TS)	51.10	47.75
H (% TS)	6.41	6.19
O (% TS)	32.50	33.68
N (% TS)	3.10	2.26
S (% TS)	0.00	0.40
Ash (% TS)	6.89	9.72
Total	100	100

## Sizing and Capital Cost

### Digester

Considering 12% TS and an organic loading rate (OLR) of 5 kgVS/m<sup>3</sup>day, the required digester volume is 11,220 m<sup>3</sup> or approximately 3 million gallons (MG) [30].

The hydraulic residence time (HRT) was calculated as 22.44 days for a 3 MG digester processing 500 tons of feed per day, aligning with established industry standards. The cost estimation is derived from the Synergy Biogas, LLC Case Study [20]. The purchased cost from the case study has been adjusted to suit the assumed capacity of the AD systems in this study. The capital cost for a digester vessel with a volume of 2.2 million gallons, as indicated in the report from the year 2011, is specified at \$1.25 million. The cost was adjusted to fit the 3 MG capacity using Eq. (4) yielding a value of \$1.50 million. Subsequently, converting this cost estimation to the 2022 price, the adjusted cost would be approximately \$2.01 million.

### Pretreatment reactor

The sizing of the pretreatment reactor, determined in accordance with established norms, for a given input flow rate (q) and hydraulic retention time (HRT) of 1 hour is computed using Eq. (8), resulting in a volumetric capacity of 20.83 m<sup>3</sup> (Equivalent to a process vessel with a height of 5 m and an inside diameter of 2.3 m).

$$Volume(m^3) = HRT \times q \quad (8)$$

Based on Ulrich's graphs (see Fig 5.44 of reference [19]), the estimated purchase cost for a carbon steel vessel of this size under atmospheric pressure is approximately \$150,000.

For Scenario B, the total bare module cost for this initial TEA is assessed by combining the purchased costs of digester and pretreatment reactor, totaling \$2.16

**Table 4:** Comparative economic analysis of a PPS-based biogas plant in different scenarios.

Scenarios	CTM (\$MM)	Labor cost (\$MM)	COM (\$MM)	GEP (\$MM)			Payback period (years)	CFRR (%)	NPV (\$MM)
				VP	STF	Total			
A	2.37	0.12	0.99	0.58	0.37	0.95	Undefined	NA	-2.04
B	2.55	0.20	1.26	0.77	0.49	1.26	Undefined	NA	-1.98
C	2.37	0.12	0.99	1.25	0.60	1.85	4.3	22.55	2.50

NA: Not Applicable; C<sub>TM</sub>: Total Module Cost; COM: Cost of Manufacturing; GEP: Gross Economic Potential; CFRR: Cash Flow Rate of Return; NPV: Net Present Value

million. Utilizing Eq. (5), the total module costs for scenarios A, B, and C amount to \$2.37 million, \$2.55 million, and \$2.37 million, respectively.

## Operating Cost

### Labor cost

Based on the specified assumptions, the base case scenario requires 1.5 full-time operators, whereas the scenario involving alkaline pretreatment necessitates 2.5 full-time operators due to an additional reactor.

According to the 2022 yearly mean wage estimates from the US bureau of labor statistics, the reported annual mean wage for chemical plant and system operators is \$79,290 [22]. Using this information, the estimated annual labor cost is \$118,935 for the base case and scenario C and \$198,225 for the scenario incorporating alkaline pretreatment.

### Fixed capital investment

The fixed capital investment (FCI) for the process is equal to the total module cost for each scenario. Finally, using Eq. (7), the total manufacturing cost is estimated to be \$0.99, 1.26, and \$0.99 million for scenarios A, B, and C respectively.

## Cash Flow Analysis

The feasibility of different scenarios is analyzed based on key parameters – i.e., net present value (NPV), cash flow rate of return (CFRR), and payback period. Table 4 summarizes revenue generation through each scenario, and other critical parameters for a 20-year project life (years after Startup). The assumed values, parameters, and equations for the analysis are summarized in Table 5.

Scenario C stands out as the most promising scenario as it was the only one to yield a positive NPV. This favorable outcome is principally due to its high conversion rates and methane production yield, resulting in increased revenue. Although Scenario B has higher conversion rates than the base case scenario, its overall performance is still overshadowed by higher total module cost and comparatively higher COM due to higher labor

costs associated with the additional reactor.

Further research is needed to explore the synergistic effects of co-digesting FW and PPS, ensuring a more comprehensive understanding of their potential economic benefits in AD processes. In addition, to enhance the robustness of our findings and pave the way for future advancements, several additional aspects demand further attention. Considering the potential benefits of co-digesting FW and PPS, along with alkaline pretreatment, presents an opportunity to reveal novel insights for optimizing AD processes. For more accurate cost estimation, it's crucial to integrate biogas upgrading, utility and chemical expenses (covering items such as inoculum for bacterial cultures, buffering agents, antifoaming agents, and, where applicable, enzymes) into the analysis. These efforts will collectively contribute to advancing the economic and environmental sustainability of AD processes in the PPI.

**Table 5:** Parameters and equations employed for the cash flow analysis

Parameter	Unit	Value
Project life	Years	20
Construction period	Years	3
Taxation rate	%	21
Annual interest rate	%	10
Depreciation method	-	MACRS (5-year)
Annual interest rate	%	10
Salvage value	\$	0.1*FCI [21]
Working capital	\$	0.1*(C <sub>RM</sub> + FCI + C <sub>OL</sub> ) [21]

## CONCLUSION

This study investigates the potential of AD to valorize PPS through TEA. Three distinct scenarios are compared: (A) the base case, (B) sludge AD with an alkaline pretreatment, and (C) co-digestion with nitrogen-rich

feedstocks.

The study highlighted the enhanced economic viability of PPS digestion through the integration of food waste (Scenario C). Alkaline pretreatment (Scenario B) also showed potential with a 33% increase in volatile solids conversion.

Further research is needed to investigate the synergistic effects of co-digesting food waste and PPS in AD and integrate biogas upgrading, utility, and chemical expenses in the TEA. Conducting experiments to optimize process parameters such as temperature, pH, TS content, OLR, and retention time could enhance methane production efficiency in the pulp and paper industry's AD processes. In addition, exploring potential applications for the AD digestate could lead to additional revenue streams or beneficial reuse options.

## ABSTRACT

Biorefineries can reduce carbon dioxide emissions while serving the global chemical demand market. Governments are also using carbon pricing policies, such as carbon taxes, cap-and-trade models, and carbon caps, as a strategy to reduce emissions. The use of biomass feedstocks in conjunction with carbon capture usage and storage technologies are mitigation strategies for global warming. Businesses can invest in these technologies to accommodate the adoption of these policies. Rapid action is necessary to halt global warming, which results in aggressive policies. In this work, a multi-period process design and planning problem is developed for the design and capacity expansion of biorefineries. The three carbon pricing policies are integrated into the model and parameters are selected according to the aggressive scenario denoted by the Paris Agreement. The results show that the cap-and-trade policy achieves a higher net present value evaluation over the carbon tax model across all pareto points due to the flexibility of the allowances in the cap-and-trade policy. The carbon cap model substantial investments are required in carbon capture technologies to adhere to the emissions constraints.

## INTRODUCTION

CO<sub>2</sub> emissions from energy combustion and industrial processes have risen from 24.9 Gt CO<sub>2</sub> to 36.8 Gt CO<sub>2</sub> from 2000 to 2022[1]. The Intergovernmental Panel on Climate Change (IPCC) reported that urgent action is necessary to curb global warming to 1.5°C[2]. Towards that end, scientists and policymakers are developing solutions to mitigate CO<sub>2</sub> contributions to the global warming crisis.

Traditional chemical manufacturing uses petroleum-based feedstocks, which are unsustainable resources and result in high CO<sub>2</sub> emissions. In an effort to reduce reliance on petroleum-based feedstocks, scientists have been researching lignocellulosic biomass as a feedstock alternative. Lignocellulosic biomass is an abundant resource and has the potential to be sustainable with low emissions. The biorefinery concept proposes that each major component from lignocellulosic biomass, i.e.,

cellulose, hemicellulose, and lignin, can be fractionated and valorized into chemicals, like petroleum refinery and chemical plant operations. Biorefineries supports decarbonization by transitioning towards a sustainable feedstock and lower emissions processes.

Significant research has been conducted in the Carbon Capture, Utilization, and Storage (CCUS) field that aims to reduce the amount of CO<sub>2</sub> currently emitted by industrial processes and capture CO<sub>2</sub> already existing in the atmosphere. For example, Yusuf et al. evaluated the economic feasibility of producing soda ash from CO<sub>2</sub> heavy flue gas generated from power plants, a Carbon Capture and Utilization (CCU) technology[3]. Wang et al. performed a technoeconomic analysis on the sequestration of CO<sub>2</sub> flue gas from power plants via compression and storage, a Carbon Capture and Storage (CCS) technology[4].

Governments are increasingly leveraging environmental policies to reduce CO<sub>2</sub> emissions. As of 2022, 23%

of all CO<sub>2</sub> emissions are under some form of carbon pricing policy[5]. Fifty-two countries enforce a carbon tax, Emissions Trading System (ETS), or both policies[5]. Twenty countries are currently considering the implementation of these policies as they can provide not only environmental but also social and economic benefits[5]. Under a carbon tax policy, carbon dioxide emitters are charged a financial penalty per ton of CO<sub>2</sub> emitted. An ETS is a system enforcing a cap-and-trade model where the government provides allowances, an amount of permitted CO<sub>2</sub> emissions, for manufacturers. They can purchase additional allowances or sell unused allowances on an open market. Benchmarks have been set via carbon pricing to limit global warming to 2°C. According to the Paris Agreement, emission levels should be reduced by 45% by 2030 and reach net-zero carbon emissions by 2050[5]. An additional benchmark provided by the World Bank states that carbon pricing should be between 61 and 122\$ by 2030[5].

Superstructure optimization is used as a framework for exploring multiple process design alternatives. Luo et al. utilized neural networks to model the biorefinery flexibility index facilitating operational flexibility constraints in superstructure optimization[6]. Multi-period optimization can be used for considering planning problems over a long-time horizon. Sabet et al. used a multi-period formulation to model a global manufacturing capacity management problem[7]. These two approaches can be integrated with environmental policy to optimize process designs.

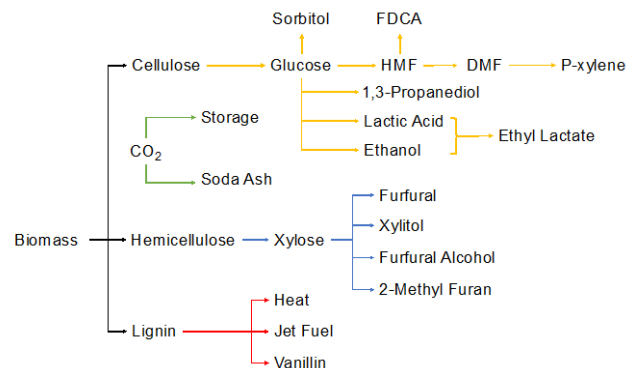

This work incorporates the benchmarks provided by the World Bank and IPCC into a multi-period biorefinery design and optimization problem[2, 5]. Three different carbon emissions policies, namely carbon cap, cap and trade, and carbon tax, are considered as constraints in the formulation. Pareto fronts are constructed for economic and environmental objective functions.

## MULTI-PERIOD PROGRAMMING FOR BIOREFINERY

The multi-period programming formulation is utilized for the long term biorefinery construction and expansion optimization problem. The planning horizon is set for thirty years corresponding to the Paris Agreement goals. Each time period represents one year. In the first year, an initial biorefinery is constructed. In each subsequent time period, the biorefinery can experience capacity expansion or the construction of new units. The problem is constrained by three environmental policies that are increasingly restrictive over each time period to match the IPCC and Paris Agreement benchmarks while maximizing net present value.

A superstructure approach is used. In this work, the superstructure represents all process alternatives

consisting of chemical transformations and separation sequences. The reactions were selected to represent a broad range of chemicals, which is displayed in Figure 1. Commodity chemicals, such as ethanol, and biomass platform chemicals, such as furfural, were included. Drop-in chemicals, such as para-xylene, and biomass derived alternatives, such as furan-dicarboxylic acid, were also included. Different separation steps were considered consisting of crystallization, distillation, extraction, membrane separation, and pervaporation. Shortcut methods and surrogate models are used to characterize the utility usages. Carbon capture storage and carbon capture and utilization technologies were also incorporated into the superstructure to accommodate the dynamic environmental policies.

**Figure 1.** Biorefinery superstructure with CCUS technologies.

## Objective Functions

The objective of the optimization problem is to maximize net present value (NPV) and minimize cumulative emissions (CE) while adhering to the carbon pricing policies. The net present value calculation is shown in Equation (1) where  $ir$  represents the interest rate,  $t$  represents the time period;  $IC_t$  represents the capital investment in time period  $t$ ;  $R_t$  represents the product revenue in time  $t$ ;  $O_t$  represents the operating cost in time  $t$ ; and  $C_{CO_2,t}$  represents the carbon dioxide cost in time period  $t$ .

$$NPV = \sum_{t \in T} (1 + ir)^{-t} \{ -(IC_t - IC_{t-1}) + R_t - O_t \pm C_{CO_2,t} \} \quad (1)$$

The power law model in Equation (2) captures the capital costs where  $a_u$  and  $b_u$  are parameters for unit operation  $u$ , and  $x_{u,t}$  represents the cumulatively capacity of unit  $u$  in period  $t$ . The cost of capacity expansion in time period  $t$  is captured as the difference between the cost of a plant with the cumulative capacity and the cost of the plant in the previous expansion period.

$$IC_t = \sum_{u \in U} a_u (x_{u,t})^{b_u}, t > 1 \quad (2)$$

The revenue,  $R_t$ , generated in time period  $t$  by the

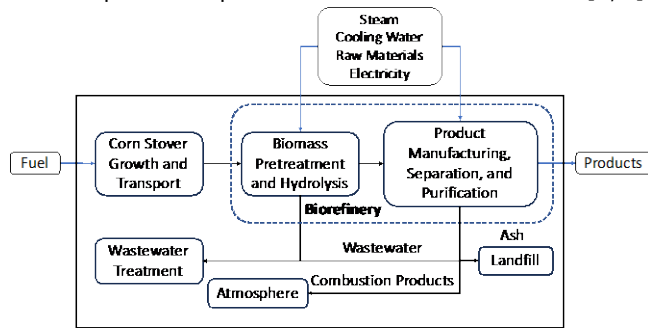

products are captured in Equation (3), where  $b_{i,t}$  is the amount of chemical  $i$  produced in time period  $t$ , and  $C_i$  represents the cost of chemical  $i$ .

$$R_t = \sum_{i \in I} b_{i,t} C_i \quad (3)$$

The operating cost,  $O_t$ , in time period  $t$  is captured in Equation (4), where  $f_{j,t}$  is the operating level of unit operation  $j$  in time period  $t$ ;  $C_j$  is the unit cost of running unit  $j$ ;  $E_{w,t}$  is the energy usage of utility  $w$ ;  $C_w$  is the unit cost of operating utility  $w$ ; and  $fcf$  is the fixed cost factor.

$$O_t = \sum_{j \in J} f_{j,t} C_j + \sum_{w \in W} E_{w,t} C_w + IC_t(fcf) \quad (4)$$

The environment impact calculation is based on a cradle-to-gate life cycle assessment. The system boundary is depicted in Figure 2 and considers biomass transportation, raw material production, utilities, combustion products, landfill, and wastewater treatment. Biomass is assumed to be carbon neutral. The data for the calculations are obtained from the Ecoinvent v.3.8 database, and the Global Warming Potential (GWP) indicator from the ReCipE2016 impact assessment method is used[8, 9].

**Figure 2.** System boundary depicted for environmental impact calculations. Biomass is transported to the biorefinery. Raw materials and utilities are imported into the biorefinery for chemical production. Wastewater is exported for wastewater treatment. Emissions from the combustion of lignin to the atmosphere and the resulting ash sent to the landfill are included.

The environmental impact in time period  $t$ ,  $TE_t$ , is given by Equation (5) where  $GWP_w$  represents the GWP of utility  $w$ ;  $b_{ww,t}$  represents the amount of wastewater generated in time period  $t$ ;  $GWP_{ww}$  represents the GWP of wastewater treatment;  $f_{rm,t}$  represents the amount of raw material  $rm$  used in time period  $t$ ;  $b_{Ash,t}$  represents the amount of ash generated in time period  $t$ ;  $GWP_{Ash}$  represents the GWP of sending the ash to the landfill;  $b_{comb}$  represents the combustion products in time period  $t$ ; and  $GWP_{comb}$  represents the GWP of the combustion product mixture.

$$TE_t = \sum_w E_{w,t} GWP_w + b_{ww,t} GWP_{ww} + \sum_{rm \in RM} f_{rm,t} GWP_{rm} + b_{Ash,t} GWP_{Ash} + b_{comb} GWP_{comb} \quad (5)$$

The second objective function, cumulative emissions (CE), is given by Equation (6) where  $TE_t$  represents the total emissions in time period  $t$ .

$$CE = \sum_t TE_t \quad (6)$$

In this work, it is assumed that the residence time of CO<sub>2</sub> emissions is longer than the planning period and, therefore, that the emissions across the time periods have equal weight.

## Constraints

The processing of materials is described by the molar balance Equation (7) where  $v_{i,j}$  represents the conversion coefficient for compound  $i$  in operation  $j$ ;  $f_{j,t}$  is the extent of process  $j$  in time period  $t$ ; and  $b_{i,t}$  is the amount of chemical  $i$  in time period  $t$ .

$$\sum_j v_{i,j} f_{j,t} = b_{i,t} \quad (7)$$

The unit operation expansion is described by Equations (8a) and (8b) where  $x_{j,t}$  represents the capacity of unit operation  $j$  in time period  $t$ ; where  $x_{j,t}^{exp}$  the additional capacity added to unit operation  $j$  in period  $t$ ; and  $x_j^{init}$  represents the initial capacity built for unit operation  $j$ .

$$x_{j,t} = x_{j,t-1} + x_{j,t-1}^{exp} \quad \forall j; t > 1 \quad (8a)$$

$$x_{j,t} = x_j^{init} \quad \forall j; t = 1 \quad (8b)$$

The capacity expansion is limited in its lower and upper bound as expressed in Equation (9), where  $Y_{j,t}$  is a binary variable that equals 1 when there is capacity expansion; where  $Cap^{Lo}$  represents the minimum possible capacity expansion; and  $Cap^{Up}$  represents the maximum possible capacity expansion.

$$Cap^{Lo} Y_{j,t} \leq x_{j,t}^{exp} \leq Cap^{Up} Y_{j,t} \quad (9)$$

The capacity is limited to a fixed number of expansions represented by Equation (10), where  $Y_{j,t}$  represents expansion in time period  $t$ , and  $E_j$  represents the number of expansions permitted for unit  $j$ .

$$\sum_t Y_{j,t} \leq E_j \quad \forall j \quad (10)$$

The operating level of unit  $j$  is constrained by the maximum capacity of unit  $j$ , which is expressed in Equation (11).  $x_{j,t}$  represents the capacity of unit  $j$  in time period  $t$ ;  $h$  represents the minimum operating ratio; and  $f_{j,t}$  represents the operating level of unit  $j$  in time period  $t$ .

$$hx_{j,t} \leq f_{j,t} \leq x_{j,t} \quad \forall j \in J \forall t \in T \quad (11)$$

The plant size is limited to amount  $m_{bm}$  as expressed in Equation (12) where  $x_{bm,t_{end}}$  represents the biomass feedstock,  $bm$ , processing capacity in the last period.

$$m_{bm} = \sum_{bm \in BM} x_{bm,t_{end}} \quad (12)$$

## Environmental Constraints

The formulations for the carbon policies utilized in this work are presented below. These policies enforce environmental constraints and may affect the NPV calculation.

The carbon cap policy enforces a fixed amount of CO<sub>2</sub> emissions. In this work, we consider the cap to be placed on the aggregated amount of emissions in the time period of one year. The constraint is expressed in Equation (13) where  $TE_t$  represents the amount of CO<sub>2</sub> emitted in time period  $t$ , and  $TE_t^{cap}$  represents the emissions cap in time period  $t$ .

$$TE_t \leq TE_t^{cap} \quad \forall t \in T \quad (13)$$

In the cap-and-trade policy, the governing body allocates a number of allowances to manufacturers. This represents a soft emissions cap, which can be exceeded by purchasing additional allowances from other manufacturers or can be sold for profit. The constraint is expressed in Equations (14-16) where  $P_{CO_2,t}$  represents the price of CO<sub>2</sub> in time period  $t$ ;  $E_t^+$  represents the allowances purchased in time period  $t$ ;  $E_t^-$  represents the allowances sold in time period  $t$ ; and  $TE_t^{cap}$  represents the allowances provided in time period  $t$ .

$$C_{CO_2,t} = P_{CO_2,t}(E_t^+ - E_t^-) \quad (14)$$

$$TE_t \leq TE_t^{cap} + E_t^+ - E_t^- \quad \forall t \in T \quad (15)$$

$$E_t^+ > 0, E_t^- > 0 \quad \forall t \in T \quad (16)$$

Under a carbon tax policy, manufacturers are charged per tCO<sub>2</sub> emitted. The total carbon tax is given by Equation (17), where  $P_{CO_2,t}$  represents the price of one ton of CO<sub>2</sub> emitted in time period  $t$ ;  $TE_t$  represents the amount of CO<sub>2</sub> emitted in time period  $t$ ; and  $C_{CO_2,t}$  represents the carbon tax cost associated with those emissions in period  $t$ .

$$C_{CO_2,t} = P_{CO_2,t}TE_t \quad (17)$$

## CASE STUDY RESULTS AND DISCUSSION

The epsilon constraint method is used to construct a Pareto front for the multi-period biorefinery optimization problem. NPV and CE are the two functions considered in the bi-objective optimization. The nonlinear Equation (2) is reformulated via piecewise linearization to keep

the formulation linear. Consequently, all instances of the model are formulated and solved in GAMS as a MILP using CPLEX solver on an Intel Xeon E-2247G @ 4.00 GHz CPU and 32.0 GB of RAM.

In our case study, a biorefinery is considered in McClean, IL with a plant capacity set at 2984 metric tons per year corresponding to four times the nominal corn stover production in McClean. Additional biomass can be purchased within the five closest counties within McClean. The years 2020 to 2050 are considered to represent a thirty-year time horizon with each time period having a length of one year. The carbon pricing parameters considered correspond with the aggressive scenario set by the Paris Agreement, which aims to maintain global warming below 2°C. Table 1 presents the parameter benchmarks. Linear interpolation is used to determine the parameters in the intermediate years. The carbon tax and cap-and-trade policies are evaluated by constructing pareto fronts to compare economic and environmental trade-offs. The carbon cap policy is analyzed yearly to elucidate the effects of a shrinking carbon cap.

**Table 1:** Carbon pricing policy parameters during milestone years

Year	Carbon Cap (%)	Carbon Tax (\$/tCO <sub>2</sub> )
2020	100	0
2030	45	59
2050	0	295

Figure 3 demonstrates increasing NPV with increasing CE for both cap-and-trade and carbon tax policies. For the cap-and-trade policy, the allowances provided are equal to the carbon cap parameters given in Table 1. Similarly, the carbon prices are set at the carbon tax value in Table 1. At the minimum CE point for both policies, a positive NPV exists. Across all points on the pareto front, the cap-and-trade policy results in a higher NPV than the carbon tax policy. This is a consequence of the allowances that can be sold for a profit when the carbon cap is high as well as the allowances providing tax-free emissions. Additional production incurs a larger financial penalty under the carbon tax policy, resulting in lower overall production. This is noted through the maximum profit point for the carbon tax policy having lower CE than the cap-and-trade policy.

**Figure 3.** NPV and CE pareto curve for cap-and-trade and carbon tax policies

**Figure 4.** Sensitivity analysis for NPV and CE pareto curve for a cap-and-trade policy

A sensitivity analysis was performed for the cap-and-trade and carbon tax policies. The raw material costs were varied by 25%. Figure 4 and Figure 5 show the changes in the pareto curves for the cap-and-trade and carbon tax policies, respectively. In both policies, increasing the raw material price by 25% has a significantly greater impact than decreasing the raw material price by 25%. For the carbon tax policy, the average relative difference to the base case for the 25% increase and decrease case is 9.0% and 2.2%, respectively. For the cap-and-trade policy, the average relative difference to the base case between the 25% increase case and decrease case is 7.1% and 1.4%, respectively. The large decrease in NPV in the 25% increase case is explained by the change in production relative to the base case. In the 25% increase case, production shifts from ethyl lactate to ethanol production which has higher raw material costs. The average relative differences for the carbon tax policy are greater than those of the cap-and-trade policy because

emissions are more heavily penalized under the carbon tax policy.

**Figure 5.** Sensitivity analysis for NPV and CE pareto curve for carbon tax policy

Figure 6 demonstrates the effect of an increasingly restrictive carbon cap over time. It is clear from the emissions curve that the rate of carbon dioxide reduction is greater between 2020 to 2030 than between 2030 and 2050. Despite the rapid reduction in emissions levels, the yearly profit generated is unaffected until 2029. This is a consequence of decreasing production in high carbon dioxide emitting chemicals that do not significantly contribute to profit. After 2030, emissions cannot continue to decrease without decreases to profit. Every year an investment is made, the slope of the annual profit line changes, reflecting the change in operation regimes as more CCS and CCU is required to maintain policy compliance.

**Figure 6.** Annual profit and emissions with time for carbon cap policy with reduced CCS and CCU costs

Table 2 displays the investment capacities and capacity expansions for both CCS and CCU technologies

under the carbon cap policy. In year 2020, there is a small investment in both CCS and CCU technology during the initial construction of the biorefinery. Initially, annual emissions are reduced by altering operations. In year 2033 and 2047, there is a significant investment in CCU technology. In the year 2041 and 2045, there is an additional investment in CCS technology. There is a higher investment in CCU technology overall due to its lower operating cost, despite its higher capital cost.

**Table 2:** Initial capacity and expansions for carbon capture technologies under a carbon cap policy

Year	Carbon Capture Capacity (tCO <sub>2</sub> /yr)	
	CCS	CCU
2020	1.9E3	1.1E5
2033	0	5.6E6
2037	0	4.9E6
2041	3.5E6	0
2045	2.1E6	0

## CONCLUSIONS

This work formulated a biorefinery process design and capacity expansion problem. A multi-period programming approach was utilized to consider the capacity expansion decisions when carbon pricing increases and carbon caps decrease with time in accordance with benchmarks of the Paris Agreements. The carbon tax, cap-and-trade, and carbon cap policies were formulated as constraints to evaluate their effects on the NPV and EI pareto fronts. The framework allows manufacturers to plan biorefinery product portfolios and future expansion projects considering carbon pricing policies.

The cap-and-trade policy is evaluated to be more profitable compared to the carbon tax policy and includes greater flexibility as a consequence of the purchasing and selling of allowances mechanism as well as the portion of carbon tax free emissions. The carbon cap policy has shown the importance and necessity of reducing the cost of CCUS technologies for chemical plants to adhere to increasingly strict carbon caps over time. The carbon tax policy results in decreased chemical production due to the financial penalty further highlighting the need for low cost CCUS technologies to offset emissions and achieve net zero carbon emissions.

## ABSTRACT

This paper introduces a computational framework for selecting green solvents to separate multilayer plastic films, particularly those challenging to recycle through mechanical means. The framework prioritizes the selective dissolution of polymers while considering solvent toxicity. Initial screening relies on temperature-solubility dependence, utilizing octanol-water partition coefficients (LogP) to identify non-toxic solvents ( $\text{LogP} \leq 3$ ). Additionally, guidelines from GlaxoSmithKline (GSK), Registration, Evaluation, Authorization, and Restriction of Chemical Regulation (REACH), and the US Environmental Protection Agency (EPA) are employed to screen for green solvents. Molecular-scale models predict temperature-dependent solubilities and LogP values for polymers and solvents. The framework is applied to identify green solvents for separating a multilayer plastic film composed of polyethylene (PE), ethylene vinyl alcohol (EVOH), and polyethylene terephthalate (PET). The case study demonstrates the framework's effectiveness in identifying environmentally friendly solvents and balancing trade-offs between solvent toxicity and solubility. Furthermore, the framework informs process design by screening for suitable green solvents in selective dissolution processes, potentially leading to the development of more sustainable dissolution processes and the identification of easily recyclable polymer blends in multilayer plastic films.

## INTRODUCTION

Multilayer plastic films have been pivotal in enhancing product safety, security, and handling [1]. These films, mostly comprised of polyethylene (PE), ethylene vinyl alcohol (EVOH), polyethylene terephthalate (PET), polyvinyl acetate (PVA) polymers, etc., serve diverse functions in prolonging the shelf life of food products [2]. Nevertheless, the intricate mix of these polymers complicates the recycling process, resulting in only 5% of multilayer plastic films being recycled in the United States; the rest are disposed of through incineration or in landfills. Various technologies have been utilized for recycling plastic waste, including thermochemical methods such as pyrolysis and thermal oxo-degradation, chemical processes, supercritical fluid application, and mechanical processes, but these processes are often not suitable for multilayer films.

As documented in previous studies, solvent-based separation technologies have exhibited significant potential in recovering virgin resins from multilayer plastic films [3]. An illustrative embodiment of this methodology is the solvent-targeted recovery and precipitation (STRAP™) process introduced by Walker et al. [4]. This approach systematically segregates the polymer constituents of multilayer plastic films by employing selective solvents, capitalizing on the temperature-dependent solubility of polymers in solvents, anti-solvents, or a combination of both, as expounded by Sánchez-Rivera et al. [5]. A critical step in achieving this separation lies in the solvent screening, which serves as the linchpin of the entire procedure. Therefore, prediction of temperature-dependent polymer solubility is a critical requirement. To address this need, molecular-scale models have been harnessed to expediently predict the temperature-dependent solubilities of various plastic components,

including but not limited to PE, EVOH, PET, and PP, across a spectrum of ~1000 solvents [6]. This was realized by modeling polymers as short oligomers, employing molecular dynamics simulations, and the COnductor-like Screening MOdel for Real Solvents (COSMO-RS), grounded in quantum chemistry principles for solubility determinations.

Furthermore, establishing a predictive framework for polymer solubility, as elucidated by the researchers mentioned above, underscores the influence of selective solvent availability in shaping the sequence of polymer resin recovery. This, in turn, informs the design of the overall process and its associated economic and environmental implications.

In addressing critical environmental challenges, deploying solutions like STRAP™ is essential. However, it is imperative to mitigate the emergence of new toxic waste streams proactively. In dissolution-based recycling methods, solvents typically remain unconsumed. Nonetheless, over repeated usage, minute quantities of these solvents tend to escape into the environment or are deliberately disposed of, potentially creating new waste streams. The ecological impact of such waste streams can be substantial when the solvents in question possess toxic attributes. Moreover, using toxic solvents may pose risks to the safety of operation personnel. Therefore, it is crucial to incorporate process safety and toxicity considerations in selecting solvents, influencing both process design and economic factors [7].

Numerous investigations have sought to elucidate the concept of "green" solvents within the framework of green chemistry principles. Saleh and Koller [8] characterize green solvents as those possessing low reactivity and flammability, exemplified by ionic liquids, per the 12th principle of green chemistry. Choi et al. [9] initially identified natural deep eutectic solvents (NADES) and deemed them environmentally friendly due to their derivation from plant sources.

Considering these different perspectives of green solvents, as discussed in the literature, Figure 1 depicts the ideal green solvent and its life cycle. This ideal green solvent, designed to harmonize sustainability and technical efficiency, should ideally originate from a renewable source, notably plant-derived solvents, and maintain cost-effectiveness as a fundamental criterion. Its utility in dissolution-based procedures should also be distinguished by enhanced solubility and reduced energy consumption, exemplifying its advantageous influence on process efficacy. It should also have benign health, safety, and environmental hazards throughout its life cycle. It should also be easily recyclable and biodegradable for disposal. Although it is necessary to find an ideal green solvent that satisfies all these criteria, it is difficult to achieve these metrics.

**Figure 1.** The Ideal green solvent.

The assessment of solvent greenness is subject to variations in ranking based on the chosen metrics. This was demonstrated by the different perspectives considered by the authors mentioned above to classify solvents as green. Nevertheless, Hessel et al. [10] assert that the principal objective of green solvents should be the mitigation of health, safety, and environmental risks. Therefore, it is vital to adopt a holistic approach in screening solvents for specific purposes, hence this study. To date, no existing study in the literature has formulated a comprehensive framework for the systematic evaluation and selection of environmentally friendly solvents designed explicitly for the separation of multilayer plastic films.

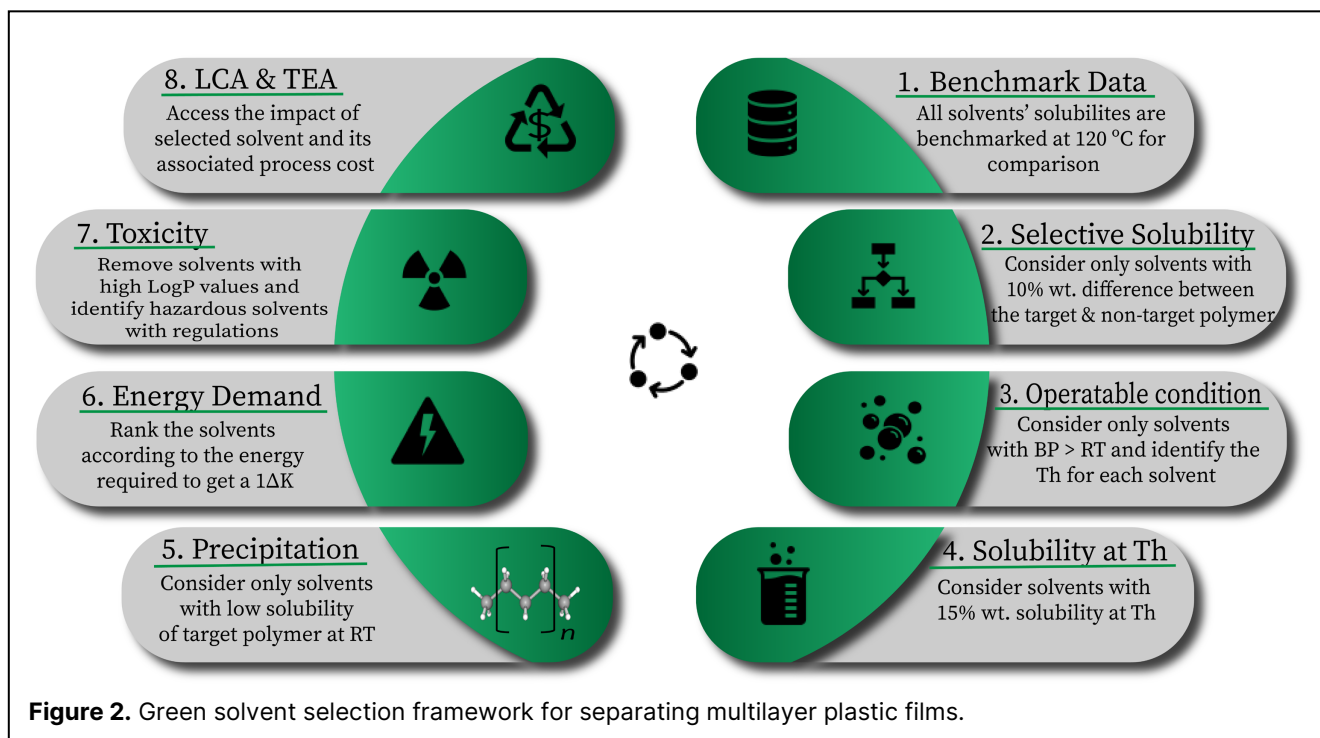

Therefore, in this study, we aim to develop a fast green solvent-screening framework for separating multilayer plastic films into virgin resins that considers solvent solubility and toxicity and how they impact process design and economics. Although this framework was developed in the context of multilayer plastic film separation, it can be extrapolated to any dissolution-based process. This work also elucidates the need to redesign multilayer plastic films, accounting for the ease of recycling food packaging materials. It also motivates the development of new green solvents to separate multilayer plastic films.

## FRAMEWORK DEVELOPMENT

As previously detailed, this study introduces a multistep framework for the fast screening of green solvents in the context of efficiently separating multilayer plastic films into their respective virgin resins, as depicted in Figure 2. The framework starts by predicting solubilities in various solvents at a standard temperature of 120 °C to avoid the thermal degradation of the polymer while providing adequate temperature leeway to achieve optimal solubilities, as per Zhou et al. [6]. While steps (2) through (5) pertain specifically to selective dissolution-based procedures conducted at standard atmospheric pressure, other aspects of this framework are generalizable to solvent-based processes.

### Solubility Prediction and Octanol-Water Partition Coefficient (LogP)

In this investigation, we employed the solubility prediction framework introduced by Zhou et al. [6] to predict the solubilities of target polymers in ~1000 solvents at

**Figure 2.** Green solvent selection framework for separating multilayer plastic films.

120 °C. The target polymers were first modeled as short oligomers in reference solvents using molecular dynamics simulations to obtain different conformational structures. These conformations in the form of trajectories are then optimized and served as inputs into COnductor-like Screening MOdel for Real-Solvents (COSMO-RS) to predict the temperature-dependent solubilities at infinite dilution as described in detail by the authors mentioned above.

The octanol-water partition coefficient (LogP) gives information about a solvent's tendency for bioaccumulation. It is often described as the ratio of concentrations of a chemical in a mixture of octanol (hydrophobic or non-polar phase) and water (hydrophilic or polar phase) in equilibrium. This study employed the COSMO-RS method to predict the LogP values of all solvents.

Solvents with LogP > 0 are considered lipophilic and hence have the possibility of bioaccumulation, while solvents with LogP < 0 are considered hydrophilic. Although solvents with LogP > 0 are generally not regarded as green solvents due to their possibility of bioaccumulating in mammals and aquatic life, this study considered solvents with LogP ≤ 3 as an initial screening process. This choice was to assess the trade-offs among the different selected solvents.

### Fast green solvent screening

Having benchmarked the solubilities of all target polymers in all solvents and computed the required molecular properties described in the preceding sub-section, python-based data analytical techniques were employed to screen for green solvents quickly. To ensure

selective solubility, the solubility difference between the target polymer and other polymers in the multilayer plastic films must be greater than 10 wt.%.

Furthermore, the solvents having boiling points lower than room temperature (RT) were removed. This rule only applies to processes that wish to operate at standard atmospheric pressure. Similarly, the elevated temperature (Th) was set to a degree less than the solvent's boiling point to maintain this operating condition. Solvents with at least 10 – 15 wt.% at Th are then selected. This solubility range has been identified to be reasonable for multilayer plastic film separation [7]. To recover the dissolved layer after hot filtration, the solvent must exhibit low solubility of the target polymer at room temperature for easy precipitation [5]. To assess the first environmental impact of the selected solvents, the minimum energy required by each solvent was determined using Equation 1, and these solvents were ranked accordingly.

$$Q = m C_p \Delta T \quad (1)$$

$m(g)$  denotes the mass of solvent,  $C_p(J/gK)$  denotes the heat capacities of the solvents at the operating temperatures, and  $\Delta T$  is the temperature difference between room temperature and the elevated temperature. Furthermore, solvents with LogP greater than three were removed since these would have a high bioaccumulation tendency. Further solvent screening was subsequently done using data from publicly available industrial solvent selection guidelines. Finally, an LCA and TEA analysis will be done within a process such as STRAP™ to assess the environmental impact and the associated process cost

attached to each selected solvent.

## Solvent toxicity database and regulatory framework

Using a toxic solvent in any solvent-based process runs beyond contributing to the inefficiency of the process. It constitutes the most significant environmental burden to processes resulting from its energy demand and end-of-life fate. This observation has led to different societies and companies developing quantitative toxicity metrics for common solvents as a guide for solvent selection. These guides mostly contain the environmental implications of each solvent's usage. Some of these include guides developed by GlaxoSmithKline (GSK) [11], the ACS Green Chemistry Institute Pharmaceutical Roundtable (ACS GCI-PR) [12], and AstraZeneca (AZ) [13].

The GSK guideline categorized 111 solvents with over ten primary functional groups under six headings. These categories include wastes, environmental impact, health, flammability, reactivity, and life cycle. Scores between 1 and 10 were given to each solvent, with 1 indicating the solvents with the most concern and 10 indicating the solvents with the least concern. Two extra categories were included to classify solvents based on legislation and restriction bans placed by the Environmental Health Services (EHS). Conversely, AZ and ACS GCI-PR guidelines categorized 46 and 63 solvents, with a score of 10 indicating the solvent with the most concern and 1 with the least concern. Although these guidelines contain different metric categories, they all seek to rate solvents based on the Health, Safety, and Environment (HSE) metrics.

This study employed only the GSK solvent guideline because it contains the most solvents, covers the HSE metrics, and includes the legislation and regulatory ban information about some solvents. Although the GSK guide can be used with other guides, the difference in the meaning of the rank assigned to each solvent makes it more difficult. Moreover, using these guides is not the sole toxicity check in this framework, as these guidelines do not contain information about most of the solvents in our database. Hence, other solvent regulatory standards are considered.

The Registration, Evaluation, Authorization, and Restriction of Chemical Regulation (REACH) initiative, a European Union regulation, focuses on limiting the adverse effects of chemicals on human health and the entire ecosystem [14]. This initiative guides the use of solvents both for large-scale processes and our day-to-day lives. This initiative also places restrictions on both common and uncommon chemicals. For example, as of the period of conducting this study, benzene and toluene were enlisted on the list of restricted substances under the REACH [15]. Similarly, the US Environmental Protection

Agency (EPA) aims at securing human lives and the environment from toxic chemicals. The Toxic Substances Control Act (TSCA), established in 1976, provides the EPA with the authority to demand full disclosure of any process relating to chemical substances and mixtures [16].

Furthermore, as of the period this study was conducted, common chemicals like toluene, formamide, and fluorine were included in the list of chemicals covered by the Toxic Release Inventory (TRI) [17]. Processes that use chemicals in this list are generally required to disclose their operations due to their toxicity. Other chemical regulatory frameworks include the Chemical Hazards and Toxic Substances (OCHA) framework, which strives towards similar goals, but rather than enforcing restrictions on chemicals, this framework implements operational standards and handling of chemicals to ensure safe working conditions for personnel.

This study will use the REACH and EPA TSCA solvent list of concern to access the selected solvents from the automated screening process.

## Process Economics and Environmental Impact Assessment

### Techno-economic analysis (TEA)

A techno-economic analysis is done to assess the process cost associated with using a choice solvent within the context of the selected process. This will determine the minimum selling price of the recovered polymer. As illustrated in Figure 1, the ideal solvent must exhibit high efficiency. This translates into a balance across different metrics mentioned in previous sections and process costs. The TEA is done on BioSTEAM, an open-source python-based steady-state process simulator that has been benched marked against existing proprietary software like Aspen Plus [18]. The choice of solvent for multilayer plastic film separation can also inform the dissolution sequence. Hence, the TEA of all possible sequences will be evaluated to consider all scenarios and assess the trade-offs. Although this TEA does not include the process cost associated with the process safety equipment needed for each choice solvent, this can be introduced to this framework in future studies.

### Life Cycle Assessment (LCA)

The impact of using each chosen solvent within the multilayer plastic film separation process on the environment and climate (kg CO<sub>2</sub> eq.) will be measured using an LCA methodology. For simplicity, the functional unit considered in the LCA is the production of 1 kg of multilayer plastic film. Thus, we compare the impact of producing 1 kg of ML film using some choice solvents. BioSTEAM will also be used to perform this assessment. The case study will describe more details of the method employed. This framework does not include accessing the full Life Cycle

Assessment (LCA) of each solvent outside the context of the dissolution process. However, it can be incorporated as an additional step, demonstrating the adaptability of this framework.

## RESULTS AND DISCUSSION

As described earlier, STRAP™, a solvent-based process, has been identified as a state-of-the-art technology for separating complex waste plastics containing multiple polymers as components. Moreover, three different variations of this technology have been developed [5]. STRAP™-A is anti-solvent dependent, whereby solvents and antisolvents dissolve and precipitate the polymer layers. STRAP™-B relies on the solubility dependence on temperature whereby after dissolution occurs at an elevated temperature, the polymer solution is cooled to precipitate the polymer. STRAP™-C employs both anti-solvent and temperature to achieve a similar purpose.

Munguía-López et al. [19] quantified the environmental impact of all three variants using the LCA tool to evaluate the carbon footprint, energy use, water use, and toxicity. It was observed that STRAP™-B (temperature dependent) when applied to a multilayer plastic film manufactured by Amcor, had the best metrics among the three variants. This STRAP™-B variant was also compared to the environmental impact of producing virgin films and outperformed fossil-based virgin films on all metrics. Hence, as this work also focuses on driving a sustainable process, STRAP™-B is adopted as a case study to elucidate the strength of this framework. The STRAP™-B process schematic can be seen in the study mentioned above.

This study delineates two distinct scenarios originating from a systematic, bottom-up approach. The first scenario focuses on selecting a green solvent to separate a two-component system comprising EVOH-PET plastic film. Subsequently, the second scenario pertains to selecting a green solvent for separating a three-component system, specifically involving PE-EVOH-PET plastic film. However, in this paper, only the former scenario will be presented. As depicted in Figure 2, the framework's initial phase involves assessing solubility data for all polymers and solvents at a temperature of 120 °C.

### Two-component system (EVOH-PET)

#### Selective dissolution and precipitation

In alignment with the separation sequence outlined by Sánchez-Rivera et al. [5], our objective is to identify green solvents suitable for the selective dissolution of EVOH (ethylene vinyl alcohol) from a composition of EVOH-PET (polyethylene terephthalate) polymer blend. To ensure the targeted dissolution of EVOH, solvents exhibiting a minimum of 10 %wt. difference in solubility between EVOH and PET at 120 °C were retained. This initial

screening resulted in the identification of 116 potential solvents.

Subsequently, we narrowed our selection to solvents amenable to operation at atmospheric pressure, i.e., those possessing boiling points above room temperature. This criterion led to the exclusion of 19 solvents, resulting in a remaining pool of 97 solvents. We then determined each solvent's elevated temperatures (Th) and selected only those exhibiting a minimum of 15 %wt. solubility at Th to ensure the solubility of EVOH. This refinement further reduced the solvent list to 56 candidates. To facilitate subsequent precipitation processes, we further refined our selection by retaining only those solvents with less than 2% weight solubility of EVOH at room temperature (RT). Consequently, the number of viable solvents was reduced to 45.

#### Energy Demand Evaluation

The minimal energy requirements for each of the 45 solvents were calculated using Equation 1. A representation of some solvents' respective minimum energy requirements is presented in Figure 3. The x-axis of Figure 3 denotes solvents, with each letter signifying a specific solvent and its EVOH solubility at Th in brackets. Although higher energy requirement equals higher carbon emissions, solvents were not screened solely based on energy demand. However, they were considered when quantifying the trade-offs amongst all the green metrics.

#### Toxicity Evaluation

Partition coefficients were next computed to remove solvents with a LogP greater than 3, indicating a propensity for bioaccumulation. Nevertheless, the solvent count remained at 45, and we performed additional screening steps 6 through 8. Furthermore, we aimed to identify solvents with less environmental concerns and regulations. For example, dimethyl formamide (DMF), ethylene glycol monomethyl ether, N,N-dimethyl acetamide, N-methyl formamide, and N-methyl-2-pyrrolidone all have restrictions placed on their usage by the United States Environment, Health, and Safety (EHS) [11]. However, as earlier mentioned, the GSK solvent guideline does not contain all ~1000 solvents studied in this work. Hence, other solvent guides/restriction lists are queried to screen the selected solvents further.

As shown in Figure 3, dimethyl sulfoxide (DMSO) fulfills the selective solubility criteria of this separation process. This observation agrees with the solvent screening process done by Walker et al. [4], showing that DMSO fulfills the selective solubility criteria without necessarily considering its HSE concerns. However, this study's framework considers solvent toxicity. Furthermore, as

**Table 1:** Selected candidate solvents for EVOH dissolution and its associated hazards

S/N	Solvent Name	Hazard	Flash Point (°C)	Operating Temp (°C)	Melting Temp (°C)	Solubility (% wt.)	LogP (-)	Energy (J/g)	Note
1	4-Ethyl Phenol	Corrosive	104	120	46.0	18.2	2.3	760.5	Used as a flavor in pharmaceuticals.
2	Dimethyl Sulfoxide (DMSO)	Irritant	95	120	18.5	35.3	-1.5	770.3	Used as a pharmaceutical.
3	Epsilon-Caprolactam	Irritant	110	120	70.0	18.3	-0.2	851.1	Used as monomer for plastics and paints.

**Figure 3.** The minimum energy required by selected solvents for EVOH selective dissolution.

human health safety is paramount in any process, solvents that pose human health hazards are strongly discouraged from being considered to avoid trace amounts from contacting food. For example, diethanolamine, Ethylene Glycol Monomethyl Ether, and Hexamethylphosphoramide all pose serious health hazards.

Having considered the various hazards associated with each of the 45 solvents based on the data contained in the GSK solvent guidelines, the PubChem public database, the European Chemical Agency (ECHA), and the Environmental Protection Agency (EPA), three candidate solvents with the least known hazards have been

identified as contained in Table 1.

## CONCLUSION AND FUTURE WORK

This study presented a fast green solvent selection framework for multilayer plastic film separations. This work uses STRAP™-B, a variant of STRAP™, to elucidate the need to employ this holistic framework to guide green solvent selection. This will eliminate the risk of producing new toxic waste streams associated with solvent-based approaches.

The framework was developed by benchmarking

the solubilities of all target polymers in ~1000 solvents. This was done by adopting a similar solubility prediction workflow developed by previous researchers. This framework comprises two key components: selective dissolution and solvent greenness. This selective dissolution was achieved by ensuring a 10 %wt. difference between the target polymers and the non-target polymer(s). Subsequently, for a solvent to be selected, the solubility of the target polymer must be at least 15 %wt. at elevated temperatures, and its boiling point must be higher than room temperature to ensure its operability at standard atmospheric pressure.

The solvent greenness screening involved quantifying the energy requirement of each solvent and predicting the octanol-water partition coefficients (LogP) to eliminate solvents with LogP > 3. Selected candidate solvents were further subjected to the GSK solvent screening guide and regulatory frameworks such as the REACH and the EPA. The framework's final stage encompassed evaluating each candidate solvent's cost and environmental impact in a dissolution-based process. Furthermore, this framework was applied to a case study involving separating a 3-component multilayer plastic film (PE, EVOH, and PET) employing a two-step dissolution process. Additionally, the framework's robustness was demonstrated by its application in informing the process design of dissolution-based processes.

The case study employed a separation sequence of PE-EVOH-PET. Initial consideration focused on selectively dissolving EVOH from an EVOH/PET polymer blend, followed by PE selective dissolution from a PE/EVOH/PET polymer blend. In the first separation (EVOH), only 45 out of ~1000 solvents could dissolve EVOH selectively. Three solvents with the least hazards were identified through a solvent greenness screening process. While DMSO (770 J/g) demonstrated a lower energy requirement than epsilon-caprolactam (851 J/g), both solvents exhibited promising features, including negative LogP values. Additionally, epsilon-caprolactam is a precursor in plastic production.

We have demonstrated the efficacy of the initial seven steps within this framework for identifying environmentally friendly solvents in separating multilayer plastic films. In our immediate future work, we intend to apply this framework to the selective dissolution of PE from a PE/EVOH/PET polymer blend. Additionally, to demonstrate how this framework informs process design, we will apply this framework to select feasible separation sequences based on the availability of green solvents using a similar multilayer plastic film blend.

Furthermore, we intend to evaluate each solvent's Techno-Economic Analysis (TEA) and Life Cycle Assessment (LCA) in the context of the STRAP™ process. This assessment aims to establish the framework as a green solvent selection tool and a valuable resource for

informing process design considerations.

While selective dissolution and LogP screenings offer rapid and automated assessments, solvent selection based on specified guidelines and regulatory frameworks is manual and time-consuming. This underscores the necessity to quantify solvent toxicity numerically, considering the diverse regulations imposed on each solvent. Our future research aims to achieve this, expediting the green solvent selection process.

## ABSTRACT

Chemical looping Reforming (CLR) is seen as a promising technology for blue hydrogen production. With proper control, CLR in fixed bed reactors has demonstrated the capability to generate blue hydrogen and nitrogen from a single reactor. To enhance efficiency and H<sub>2</sub> purity in the product stream, integration of a CLR reactor with a heat recovery system and a Shift reactor is essential. This study explores the design and control of an integrated CLR-Shift reactors system. The integrated system yields a product stream with 75% H<sub>2</sub> mole fraction during the Reforming step of CLR, and a nitrogen with high purity (98%) during the Oxidation step. In the best-case scenario, the integrated system produces H<sub>2</sub> and N<sub>2</sub> at a molar ratio of 1.26 with H<sub>2</sub> production efficiency of 80.1%.

**Keywords:** Chemical-looping reforming, shift reactor, optimal control problem, blue hydrogen and nitrogen production.

## INTRODUCTION

The imperative of decarbonization makes hydrogen one of the top candidates to address the need for future energy carriers. Currently, 95% of hydrogen comes from fossil fuels through conventional steam methane reforming, resulting in emissions of over 12 kg of CO<sub>2</sub> per kg of H<sub>2</sub> [1]. This hydrogen production route is known as grey hydrogen. **Figure 1** provides a visual representation of the hydrogen color spectrum, classifying hydrogen based on production techniques, byproducts, feedstock, and energy source. Green hydrogen, generated through water electrolysis powered by renewable energy sources, is regarded as the most environmentally friendly method of hydrogen production. Despite its environmental advantages, the current cost of green hydrogen is nearly four times that of grey hydrogen [2], posing economic challenges for its utilization. Blue hydrogen emerges as a promising alternative. While it still originates from hydrocarbons, this process requires capturing CO<sub>2</sub>, minimizing its release to the atmosphere. This approach allows for the utilization of established hydrogen production technologies, such as steam methane reforming, with the addition of a CO<sub>2</sub> capture process in the plant. Blue hydrogen is considered a cost-effective

solution during this transitional phase until green hydrogen becomes more economically competitive.

The increase in hydrogen production requires a suitable carrier for large-scale transport and storage. A hydrogen carrier becomes imperative to tackle the inherent challenge of hydrogen's low density. Ammonia is considered as a potential candidate for a hydrogen carrier, offering the ability to store larger quantities of hydrogen in a smaller volume. This route is made possible by capitalizing on the existing global ammonia infrastructure developed for the fertilizer industry [3].

**Figure 1.** Hydrogen color spectrum

Chemical-looping reforming (CLR) is considered as a promising method for blue hydrogen production [4]. This process relies on the capability of oxygen carriers, performing a cycle of reduction, oxidation, and catalytic

reforming reactions. Opting for a fixed bed reactor in CLR proves more advantageous than a fluidized bed reactor due to its simplicity, prolonged oxygen carrier's lifespan, and the absence of a need for gas-solid separation. However, using fixed bed reactors require a dynamic switching operation to complete the CLR cycle. With proper control, CLR in a fixed bed reactor yields an exit stream with a high  $H_2$  concentration during Reforming step, and a high  $N_2$  concentration during Oxidation step [5]. In our previous research, the optimized CLR reactor produced  $H_2$  with an  $H_2/CO$  ratio of 3 during REF and  $N_2$  stream with a purity of 98% during OX [5]. From these results, we identified two key improvements necessary for the CLR reactor. The first enhancement involves the incorporation of a shift reactor to increase the hydrogen concentration in the product stream. The second improvement involves introducing a heat recovery system that utilizes the temperature of the exit gas from CLR as a heat source. This heat recovery system has the potential to substantially improve the overall efficiency of the system.

This study focuses on evaluating the performance of an integrated system comprising a CLR reactor, a shift reactor, and a heat recovery system: a preheater and a steam generator. The main goal is to explore an optimal control strategy for the integrated CLR-Shift reactors system by solving a dynamic optimization problem. The specific objective is to maximize  $H_2$  production while concurrently meeting criteria that guarantee nearly pure  $N_2$  production and ensure the safety and operability of each component within the system. The novelty of this work lies in its integrated approach combining a CLR fixed bed reactor, a heat recovery system, and a shift reactor, facilitating the determination of optimal control parameters and a heat management strategy for highly efficient blue  $H_2$  and  $N_2$ .

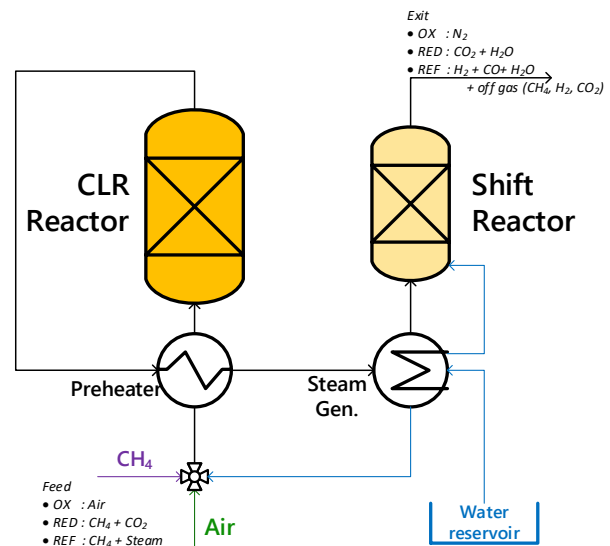

## PROCESS DESCRIPTION

The integrated system consists of a CLR reactor, a shift reactor, a preheater, and a steam generator, as illustrated in the process flow diagram presented in **Figure 2**. In the CLR reactor, CLR cycle takes place performing oxidation (OX), reduction (RED), and reforming (REF) stages alternately. During OX, the oxygen carrier experiences oxidation by air, generating heat within the reactor and leaving  $N_2$  as the primary product in the exit stream. During RED, the oxygen carrier undergoes reduction of the active metal through a gas-solid reaction with the reducing gas (i.e.  $CH_4$ ,  $H_2$ ,  $CO$ ). The exit stream consists of  $CO_2$  and  $H_2O$ , easily separable through condensation for subsequent  $CO_2$  capture and storage. During REF, catalytic reactions occur, resulting in a product stream primarily composed of  $H_2$  and  $CO$ . The heat required for both RED and REF comes from the heat generated during OX. The product stream of CLR reactor in each stage is

directed to the heat recovery system.

The heat recovery system utilizes the high temperature of the CLR product streams as the heat source. Initially, each hot stream enters the preheater and subsequently progresses to the steam generator. Both the preheater and the steam generator operation are synchronized with the ongoing stage in the CLR reactor. In the preheater, the cold feed gas stream of CLR is heated to the target temperature, around  $600\text{ }^\circ\text{C}$ . After the preheater, the product stream is used in the steam generator. In the steam generator, the quantity of steam generated in each CLR stage is tuned based on the enthalpy and temperature difference remaining in the hot stream. At the exit of the steam generator, the temperature of the hot stream is set to be around  $200\text{ }^\circ\text{C}$ .

After the steam generator, the product stream is fed to the Shift reactor. In this reactor, the steam and  $CO$  in the product stream undergo conversion to  $H_2$  through the water gas shift reaction. The reactor bed warms up due to the exothermic nature of the water gas shift reaction. During OX and RED, no reactions occur in the Shift reactor, as the stream cool down the reactor bed, keeping it within the active temperature range of  $200\text{--}350\text{ }^\circ\text{C}$ .

**Figure 2.** The flow diagram integrated system of the reactor

## MODELING

The CLR reactor uses a 1D heterogenous dynamic model of the mass and energy balances for the solid and fluid phases. A summary of the partial differential equations (PDEs) governing the fixed-bed reactor model is presented in **Table 1**. Ni-based oxygen carriers are used in the CLR reactor with reaction kinetics, developed in prior work [6]–[8]. **Table 2** outlines the reactions used in the model, while their corresponding kinetic expressions are provided in [9].

**Table 1:** Summary of the governing equations of the fixed

bed reactors for CLR and Shift and heat recovery system model of the preheater and the steam generator.

### Fixed bed Reactor

#### Fluid phase

Mass Balance:

$$\epsilon_b \frac{\partial C_i}{\partial t} + \frac{\partial u C_i}{\partial z} = \epsilon_b \frac{\partial}{\partial z} \left( D_{ax,i} \epsilon_b \frac{\partial C_i}{\partial z} \right) + k_{c,i} a_v (C_{c,i}|_{Rp} - C_i)$$

Energy Balance:

$$\begin{aligned} \epsilon_b C_{p,f} C_T \frac{\partial T}{\partial t} + C_{p,f} C_T \frac{\partial u T}{\partial z} \\ = \epsilon_b \frac{\partial}{\partial z} \left( \lambda_{ax} \frac{\partial T}{\partial z} \right) + h_f a_v (T_c|_{Rp} - T) \end{aligned}$$

Momentum Balance:

$$\frac{dP}{dz} = - \left( \frac{1 - \epsilon_b}{\epsilon_b^3} \right) \left( \frac{\rho u_o^2}{D_p} \right) \left( \frac{150}{Re_p} + 1.75 \right)$$

Boundary conditions:

$$\epsilon_b D_{ax,i} \frac{\partial C_i}{\partial z} \Big|_{z=0} = u_{in} (C_i|_{z=0} - C_{i,in}),$$

$$\epsilon_b \lambda_{ax} \frac{\partial T}{\partial z} \Big|_{z=0} = u_{in} C_T (T|_{z=0} - T_{in}),$$

$$\frac{\partial C_i}{\partial z} \Big|_{z=L} = \frac{\partial T}{\partial z} \Big|_{z=L} = 0, P|_{z=L} = P_{out},$$

#### Solid phase

Mass Balance:

$$\epsilon_c \frac{\partial C_i}{\partial t} + \frac{1}{r_c^2} \frac{\partial}{\partial r_c} (r_c^2 J_i) = \rho_s \sum R_i$$

Energy Balance:

$$\begin{aligned} \left( (1 - \epsilon_c) \rho_s C_{p,s} + \epsilon_c C_{p,c} C_{T,c} \right) \frac{\partial T_c}{\partial t} \\ = \frac{\lambda_s}{r_c^2} \frac{\partial}{\partial r_c} \left( r_c^2 \frac{\partial T_c}{\partial r_c} \right) + \rho_s \sum (-\Delta H_n) (R_n) \end{aligned}$$

Dusty gas model:

$$-\frac{\partial C_{c,i}}{\partial r_c} = \sum_{j=1}^N \frac{1}{D_{ij}^e} (y_{kj} J_i - y_{ij} J_k) + \frac{J_i}{D_{ik}^e}$$

$$J_i|_{r_c=R_p} = k_{c,i} (C_{c,i}|_{r_c=R_p} - C_i),$$

$$-\lambda_s \left( \frac{\partial T_c}{\partial r_c} \right) \Big|_{r_c=R_p} = h_f (T_c|_{r_c=R_p} - T).$$

### Heat Recovery System

Streams in each side

$$\dot{Q} = m_c c_{p,c} (T_{c,out} - T_{c,in}) = m_h c_{p,h} (T_{h,in} - T_{h,out}),$$

Heat exchanger model

$$\dot{Q} = UA \Delta T_{LMTD}, \Delta T_{LMTD} = \frac{\Delta T_a - \Delta T_b}{\ln(\Delta T_a / \Delta T_b)},$$

Co-current flow

$$\Delta T_a = T_{h,in} - T_{c,in}, \quad \Delta T_b = T_{h,out} - T_{c,out},$$

Counter-current flow

$$\Delta T_a = T_{h,in} - T_{c,out}, \quad \Delta T_b = T_{h,out} - T_{c,in}.$$

Like the CLR reactor, the Shift reactor is modeled using a fixed bed reactor with a 1D heterogenous dynamic model. The corresponding PDEs for the Shift reactor are presented in **Table 1**. Operating at low temperatures (200–350°C), the Shift reactor uses a Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst for the water-gas shift reaction. The kinetic

correlation for this reaction is adopted from [10], [11] and presented in Eq. (1), where  $r_{s,WGS}$  is the reaction rate of the water gas shift reaction,  $d_{cat}$  and  $\epsilon$  are the diameter and the porosity of the catalyst, respectively,  $P_s$  is the pressure in atm,  $y$  is the species mole fraction,  $K_{eq}$  is the reaction equilibrium described in Eq. (2),  $R$  is the gas constant, and  $T_s$  is the gas temperature in the Shift reactor in K. The feed of the Shift reactor is the product stream from the CLR reactor, which has been cooled to 200°C.

**Table 2:** List of feasible reactions in the reduction, reforming, and oxidation using Ni oxygen carriers.

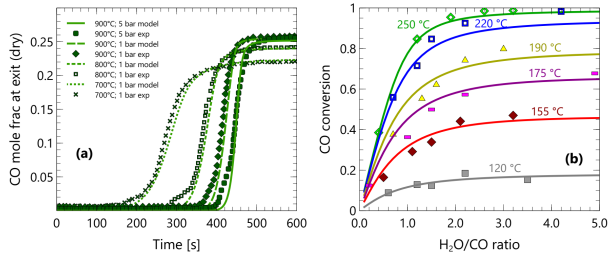

Index	Reactions
(R1)	$H_2 + NiO \rightarrow Ni + H_2O$
(R2)	$CO + NiO \rightarrow Ni + CO_2$
(R3)	$CH_4 + NiO \rightarrow Ni + 2H_2 + CO$
(R4)	$CH_4 + H_2O \leftrightarrow 3H_2 + CO$
(R5)	$CO + H_2O \leftrightarrow H_2 + CO_2$
(R6)	$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2$
(R7)	$CH_4 \leftrightarrow 2H_2 + C$
(R8)	$C + H_2O \leftrightarrow CO + H_2$
(R9)	$C + CO_2 \leftrightarrow 2CO$
(R10)	$O_2 + 2Ni \rightarrow 2NiO$
(R11)	$O_2 + C \rightarrow CO_2$
(R12)	$O_2 + C \rightarrow 2CO$
(R13)	$O_2 + 2CO \rightarrow 2CO_2$

$$\begin{aligned} r_{s,WGS} = d_{cat} (1 - \epsilon) P_s^{(0.5 - P_s/250)} \left( 2.96 \right. \\ \left. \times 10^5 \frac{\text{mol}}{\text{g} \cdot \text{hr}} \right) \exp \left( \frac{-47400 \text{ J/mol}}{RT_s} \right) \\ \times \left( y_{CO} y_{H_2O} - \frac{y_{CO_2} y_{H_2}}{K_{eq}} \right) \end{aligned} \quad (1)$$

$$\begin{aligned} K_{eq} = \exp \left( \frac{5693.5}{T_s} + 1.077 \ln(T_s) + 5.44 \times 10^{-4} T_s \right. \\ \left. - 1.125 \times 10^{-7} T_s - \frac{49170}{T_s^2} - 13.148 \right) \end{aligned} \quad (2)$$

The energy balance in the preheater and the steam generator are summarized in **Table 1**. The momentum balance, pressure drop, and heat loss in both the preheater and the steam generator were neglected. The models for the CLR and Shift reactors were validated with available experimental data and are illustrated in **Figure 3**.

**Figure 3.** Model validation of CLR (a) and Shift (b) reactors using experimental data reported in [12] and [11] respectively

## OPTIMIZATION

The operational challenges associated with a fixed-bed reactor stem mainly from its semi-batch operation. In the fixed bed reactor, the oxygen carrier remains in the reactor while the feed alternates serving CLR stages and complete the cycle. These reactions are kinetically controlled and exhibit different reaction enthalpies. Consequently, the bed temperature and the state of the oxygen carrier experience significant changes during the transition between CLR stages. Each CLR stage produces different gas products, resulting in downstream discontinuities. For  $H_2$  production, the steam-to-methane ratio during REF plays an important role in determining the production of  $H_2$  and in managing carbon deposition. The integration with the heat recovery system and the Shift reactor requires an effective control strategy to ensure the heat generated during OX is appropriately distributed for reactions occurring in the CLR, the heat recovery system, and the Shift reactor. The primary challenge lies in maintaining a high  $H_2$  production while consistently retaining sufficient heat within the integrated system and meeting constraints related to fuel conversion, high  $N_2$  concentration, the energy-temperature difference required for feed gas preheating, steam generation, and the Shift reactor.

To achieve this objective, we formulated an optimal control strategy for the decision variables for the integrated CLR-Shift system. The focus was on maximizing hydrogen production while consistently meeting the dynamic constraints of the system. The decision variables chosen were the time interval of the CLR stages: RED, REF, and OX ( $\tau_{OX}$ ,  $\tau_{RED}$ , and  $\tau_{REF}$ ), feed gas temperatures, steam-to-methane ratio, the percentage of active metal in oxygen carrier, and the steam added to the Shift reactor, as summarized in **Table 3**. The control profile for the feed gas was modeled using piecewise constant functions, denoted as  $\mathbf{u}(\tau_i) = \mathbf{u}$ , where  $\mathbf{u}$  is the vector of temperature, flow, and composition of the gas stream, while  $\tau_i$  is the time duration of the  $i$ -th CLR step, i.e., OX, RED, and REF. The design vector,  $\phi$ , summarizes the set of control variables, and was constrained by upper and lower limits defined within the design space,  $\Phi$ , as presented in Eq. (3).

**Table 3:** Design variables for the optimal control of the integrated CLR-Shift reactors system

Control variables	Notation
Feed gas temperature	$\mathbf{u}_i$
Steam-to-methane ratio @REF	
Methane-to- $CO_2$ ratio @RED	
Steam added into the Shift reactor @REF	
Time interval of OX	$\tau_{OX}$
Time interval of RED	$\tau_{RED}$
Time interval of REF	$\tau_{REF}$
Active metal content in OC	$\omega$

The objective function of the optimal control problem is to maximize hydrogen production during the cyclic steady-state operation of the integrated system. The objective function uses a metric called the hydrogen production efficiency,  $\eta$ , shown in Eq. (4), where  $F_{S-out,H_2}$  is the hydrogen flowrate at the exit of Shift reactor,  $F_{R-in,CH_4}$  is the methane flowrate at the inlet of CLR Reactor,  $t_0$  and  $t_f$  are the initial time and final time of integration, with  $t_f = \tau_{OX} + \tau_{RED} + \tau_{REF}$ .

$$\phi = [\mathbf{u}_i, \tau_{OX}, \tau_{RED}, \tau_{REF}, \omega, F_{S-in,H_2O}] \in \Phi. \quad (3)$$

$$\eta = \frac{\int_{t_0}^{t_f} F_{S-out,H_2}(t) dt}{\int_{t_0}^{t_f} F_{R-in,CH_4}(t) dt}, \quad (4)$$

The optimization of the integrated system is subject to the following constraints. A minimum methane conversion ( $X_{CH_4}$ ) of 96% in the CLR reactor must be achieved during both RED and REF (Eq. (5)). During OX, the CLR reactor must yield a  $N_2$  stream with 98% minimum mole fraction, as shown in Eq. (6), where  $F_{R-out,N_2}$  is the  $N_2$  molar flowrate at the exit of CLR reactor and  $F_{R-out,T}$  is the total flowrate at the exit of CLR reactor. Since the product stream of the CLR reactor is used in the heat recovery system, the total enthalpy carried by the product stream must exceed the enthalpy required for gas preheating and steam generation, Eq. (7), where,  $F_{R-in,T}$  is the total flowrate at the inlet of the CLR reactor,  $c_p$  is the heat capacity of the inlet/outlet streams,  $h_{fg,H_2O}$  is the enthalpy of evaporation of water,  $T_{R-in}$  and  $T_{R-out}$  are the inlet and outlet temperatures at the CLR reactor, respectively. In Eq. (7), it is assumed that in the heat recovery system product streams are cooled to 200 °C, while feed streams are heated up from 25°C.  $F_{R-in,H_2O}$  and  $F_{S-in,H_2O}$  are the molar flowrate of steam fed into CLR reactor and Shift reactor, respectively. To prevent agglomeration and sintering of the Ni-based oxygen carrier, the maximum temperature allowed in CLR reactor,  $T_{R-bed}$ , at any axial location  $z$ , must not exceed 1100°C, (Eq. (8)). The preheater must be able to heat up the cold stream,  $T_{PR-c,out}$ , to between 500 and 700°C, the desired temperature for feed gas of the CLR reactor (Eq. (9)). In the steam

generator, the exit temperature of the hot stream,  $T_{SG-h,out}$ , must be between 200 and 250°C, close to the operation temperature of the Shift reactor as in Eq. (10).

The complete optimal control problem can be formulated as shown in Eq. (11), where  $\mathbf{f}$  is the set of differential-algebraic equations (DAEs) that describe the model of the reactors in the integrated CLR-Shift system, comprising mass, energy, and momentum balance and reaction kinetics,  $\mathbf{x}$  is the vector of state variables (*i.e.*, mass, temperature, and pressure), and  $\dot{\mathbf{x}}$  is time derivatives of  $\mathbf{x}$ . Cyclic steady-state conditions are typically achieved after more than two cycles. Therefore, the optimization time horizon was set to at least two times the  $\tau_{\text{cycle}}$ .

$$X_{\text{CH}_4}(t) = 1 - \frac{\int_{t_0}^{t_f} F_{R-out,\text{CH}_4}(t) dt}{\int_{t_0}^{t_f} F_{R-in,\text{CH}_4}(t) dt} \geq 96\%, \quad (5)$$

$$\beta(t) = \frac{\int_{t_0}^{t_f} F_{R-out,\text{N}_2}(t) dt}{\int_{t_0}^{t_f} F_{R-out,T}(t) dt} \geq 98\%, \quad (6)$$

$$\begin{aligned} \gamma(t) = & \int_{t_0}^{t_f} F_{R-out,T}(t) c_{p,out}(T_{R-out}(t) - 200^\circ\text{C}) dt \\ & - \int_{t_0}^{t_f} F_{R-in,T}(t) c_{p,in}(T_{R-in}(t) - 25^\circ\text{C}) dt \\ & - \int_{t_0}^{\tau_{\text{REF}}} (F_{R-in,\text{H}_2\text{O}}(t) + F_{S-in,\text{H}_2\text{O}}(t)) h_{fg,\text{H}_2\text{O}} dt \geq 0, \end{aligned} \quad (7)$$

$$T_{R-bed}(z) \leq 1100^\circ\text{C}, \quad (8)$$

$$500^\circ\text{C} \leq T_{PR-c,out}(t) \leq 700^\circ\text{C}, \quad (9)$$

$$200^\circ\text{C} \leq T_{SG-h,out}(t) \leq 250^\circ\text{C}, \quad (10)$$

$$\begin{aligned} & \max_{\phi \in \Phi} \eta \\ & \text{subject to:} \\ & \mathbf{f}(\dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t) = 0, \\ & \mathbf{f}_0(\dot{\mathbf{x}}(t_0), \mathbf{x}(t_0), \mathbf{u}(t_0), \boldsymbol{\theta}, t_0) = 0, \quad (11) \\ & \text{Eqs. (5) - (10),} \\ & \mathbf{x}^{\min} \leq \mathbf{x}(t) \leq \mathbf{x}^{\max}, \\ & \mathbf{u}_i^{\min} \leq \mathbf{u}_i(t) \leq \mathbf{u}_i^{\max}, \\ & \boldsymbol{\tau}_i^{\min} \leq \boldsymbol{\tau}_i(t) \leq \boldsymbol{\tau}_i^{\max}, \\ & \boldsymbol{\omega}^{\min} \leq \boldsymbol{\omega} \leq \boldsymbol{\omega}^{\max}. \end{aligned}$$

The system of DAEs were built and solved in the equation-based process modeling platform gPROMS Model Builder, 7.0.9 [13]. For the spatial discretization, the backward finite difference method was used, dividing the reactor's axial direction into 21 nodes and its solid particle radial direction into 11 nodes. The system of DAEs was then solved with the DAEBDF solver. The non-linear optimization was solved with control vector parameterization with single shooting (CVP\_SS) solver available in gPROMS. With control vector parameterization, the control variables were discretized as piecewise constant over a specified time interval, while with the single shooting approach, the control variables were fixed during the entire respective time horizon in each iteration.

## RESULTS AND DISCUSSION

The integrated CLR-Shift system was used to study its performance for small-scale blue hydrogen and nitrogen production. The system was configured to run in parallel with multiple CLR reactors, collectively achieving a production rate of 300 kg-H<sub>2</sub> per day. **Table 4** (top rows) reports the reactor design and operating parameters, including reactor diameter, length, and operating pressure. Eq. (11) was solved, resulting in the optimized control variables reported in **Table 4** (bottom rows). These parameters were then used in simulations to evaluate the performance of the integrated CLR-Shift system.

**Table 4:** Parameters used in the integrated CLR-Shift system. The top rows are the common parameters, while the bottom rows show the optimized parameters.

Parameters	Values		
	OX	RED	REF
CLR Reactor			
- length, [m]		1.5	
- diameter, [m]		0.6	
Shift Reactor			
- length, [m]		0.6	
- diameter, [m]		0.6	
Operating pressure, [bar]		1.5	
Feed vol. flow, [NCMH]	360	36	180
CO <sub>2</sub> -to-CH <sub>4</sub> ratio	--	4.0	--
Steam-to-CH <sub>4</sub> ratio	--	--	1.5
Feed temp., [°C]	600	600	600
CLR stages interval, [s]	150	135	200
Active metal in OC, [%]		5	
Add. steam @ Shift, [mol/s]	--	--	0.81

**Figure 4** presents the exit mole fractions of CLR and Shift reactors at cyclic steady state. At the optimal operating conditions, the exit stream of the CLR reactor (**Figure 4a**) exhibits compositions of 98% N<sub>2</sub> during OX, 70% CO<sub>2</sub> and 30% steam during RED, and 66% H<sub>2</sub> during REF. The N<sub>2</sub> stream with high purity during OX is promising for the further integration with an ammonia plant. In RED, the exit stream, consist of CO<sub>2</sub> and H<sub>2</sub>O, can be separated by a condensing unit before captured or recirculated for plant utility. The 66% H<sub>2</sub> during REF showcases the feasibility of CLR as one promising route for blue hydrogen production. In REF, there is also smaller gas constituents consisting of CO (20%), H<sub>2</sub>O (10%), and CO<sub>2</sub> (2%) that need further purification.

**Figure 4.** The performance of CLR and Shift reactor during cyclic steady-state, simulated at optimized parameters (Table 4). (a) Exit mole fraction at CLR Reactor; (b) exit mole fraction at Shift reactor without additional steam (Case 1); and (c) exit mole fraction at Shift reactor with additional steam (Case 2).

The product stream from CLR goes to the heat recovery system and serves as a heat source. **Figure 5** shows the temperature of the CLR product stream decreasing as it passes through the preheater and the steam generator, respectively. From the CLR reactor, the temperature of product stream is around 950°C. As the product stream exits the preheater, the temperature drops to 300–500°C. The exit temperature at the preheater varies in each CLR stage depending on the enthalpy remaining and temperature difference between hot and cold streams. Nonetheless, the CLR feed gas is successfully preheated to 500–700°C. The product

stream then enters the steam generator producing steam needed for the reforming reactions. The steam generator operates in each CLR stage, using the remaining available enthalpy and temperature in the product stream as a heat source. The portion of the steam generated in each stage was tuned so that the exit temperature of the product stream in the steam generator was close to 200 °C (**Figure 5**).

**Figure 5.** Exit gas temperature in the preheating and steam generating systems. The exit stream of CLR reactor is used as the heat source for the preheating and steam generating systems. The exit preheater cold stream feeds the CLR, while the hot stream from the preheater is used for steam generation.

We explored two scenarios for the Shift reactor: 1) Shift reactor without additional steam (Case 1), and 2) Shift reactor with additional steam (Case 2). In Case 1, the feed of the Shift reactor is the CLR product stream that has been cooled in the heat recovery system. In Case 2, an optimized amount of steam (**Table 4**) is added to the feed during REF. **Figures 4b** and **4c** present the result of Case 1 and Case 2, respectively. In both cases, the Shift reactor increased H<sub>2</sub> mole fraction from 66% to 75–76%. In Case 1, CO conversion was low, only 49.2%, due to the limited steam available for water gas shift reaction. At the exit, around 10% of CO remain unconverted and the H<sub>2</sub> production rate was 3 mol/s. In Case 2, the steam addition increased the extent of the water gas shift reaction and increased CO conversion to 82.7%. At the exit, H<sub>2</sub> production rate was 3.2 mol/s (75.6% of the total stream), with smaller gas constituents consisting of: CO<sub>2</sub> (16.7%), H<sub>2</sub>O (4%), and CO (3.2%).

Overall, the integrated CLR-Shift reactors system successfully generated H<sub>2</sub> and N<sub>2</sub>, with high concentration and efficiency. In Case 1, H<sub>2</sub> and N<sub>2</sub> were produced with a ratio of 1.16 and an H<sub>2</sub> production efficiency of 74.9%. Meanwhile, Case 2 yielded H<sub>2</sub> and N<sub>2</sub> with a ratio of 1.26 and an H<sub>2</sub> production efficiency of 80.1%. Furthermore, the dynamic operation of this integrated system suggest the possibility of integration with an ammonia synthesis process reported in [14].

## CONCLUSIONS

Integration of the CLR reactor, Shift reactor, and heat recovery system demonstrated promising results for blue hydrogen and nitrogen production. An optimized control scheme is crucial to ensure high H<sub>2</sub> production that satisfies the numerous system constraints. Under the optimized control scenario, the integrated CLR-Shift reactors system produced H<sub>2</sub> with a 75% mole fraction during REF, N<sub>2</sub> with 98% purity during OX, and a potential for CO<sub>2</sub> capture during RED. The control scenario is also essential in distributing the heat within the integrated system, meeting the heat requirements for overall reactions, the feed gas preheating and steam generation. The addition of steam in the Shift reactor is essential to maintain steam availability for the water gas shift reaction. Further purification in the downstream product, such as pressure-swing adsorption, must be considered to achieve higher H<sub>2</sub> purity. A future study on multiple reforming reactor system and reactor scheduling will target a continuous flow of hydrogen and nitrogen products.

## ABSTRACT

Designing a digital twin will be crucial in developing automation-based future manufacturing systems. The design of digital twins involves data-driven modelling of individual manufacturing units and interactions between the various entities. The goals of future manufacturing units such as zero waste at the plant scale can be formulated as a model-based optimal control problem by identifying the necessary state, control inputs, and manipulated variables. The fundamental assumption of any model-based control scheme is the availability of a “reasonable model”, and hence, assessing the goodness of the model in terms of stability and sensitivity around the optimal parameter value becomes imperative. This work analyses the data-driven model of an acetaminophen production plant obtained from SINDy, a nonlinear system identification algorithm using sparse identification techniques. Initially, we linearize the system around optimal parameter values and use local stability analysis to assess the stability of the identified model. Further, we use what is known as a conditional sloppiness analysis to identify the sensitivity of the parameters around the optimal parameter values to non-infinitesimal perturbations. The conditional sloppiness analysis will reveal the geometry of the parameter space around the optimal parameter values. This analysis eventually gives valuable information on the robustness of the predictions to the changes in the parameter values. We also identify sensitive and insensitive parameter direction. Finally, we show using numerical simulations that the linearized SINDy model is not good enough for control system design. The pole-placement controller is not robust, and with high probability, the control system becomes unstable to very minimum parameter uncertainty in the gain matrix.

## INTRODUCTION

Design of future manufacturing systems will benefit from building digital twins that can inform the controller design at plant scale. Several future manufacturing goals such as planning and scheduling for zero waste at the plant scale can be formulated as a control system design problem, where an optimal control problem can be formulated and solved.

The design of optimal control mandates a reasonable model. Developing a mechanistic model at the plant scale might involve hundreds of state variables and parameters; hence we adopt a data-driven nonlinear

system identification approach known as SINDy to identify a reduced-order parsimonious model in this work. SINDy uses the idea of sparse identification to discover the underlying governing equations [2]. The SINDy algorithm has already been used to design an entire algal biodiesel industrial network for sustainable design of carbon capture and utilization technologies [3]. In addition to this, SINDy has also been used to identify governing equations of unit operations in a plant and natural systems [7]. In previous work, the authors have used the SINDy algorithm to identify a reduced order dynamical model for the distillation column [6].

The models developed in the above works were

satisfactory in replicating the system dynamics; however, the model has to satisfy additional requirements for designing control systems. The critical factors that affect the control system design are stability, model and parameter uncertainty. The seminal work of Bhattacharyya et al [5] showed that while designing robust and optimal controllers such as  $H_2$  and  $H_\infty$ ; a very small parameter uncertainty in the controller parameters will result in an unstable control system. They argue that the fragility of the controller is a result of the parameter sensitivity of the plant that is transferred to the controller. Hence, it becomes imperative to assess the sensitivity of the plant before the controller design; otherwise, uncertainty in the controller output will impact the overall performance metrics.

In this work, we propose a method to analyze the control relevance of the SINDy model; even though this method is applied to models developed from SINDy, in general, this proposed method can be used for any surrogate dynamical model. The novelty in the present work is proposing a new method to assess the robustness of a pole-placement control system design by assessing the model's parameter space by introducing the concept of conditional sloppiness. In general, it is a novel method to assess whether the estimated model is control-relevant. As a first step, we analyze the stability of the linearized model around the operating point. We use sloppiness analysis as a next step to characterize the model's behaviour around the nominal parameter set. Sloppiness is a phenomenon where there are regions in the parameter space over which model predictions are nearly identical. The role of sloppiness in system identification has been extensively studied in the past two decades [1,4]. Here, we use what is known as conditional sloppiness to assess the model sensitivity. Together with stability and sloppiness analysis we provide directions to refine the estimated model. When the model sensitivity index is very high in the vicinity of the parameter space, the model is unsuitable for controller design. This has been demonstrated using a simple pole-placement controller design.

The rest of the paper is organized as follows: Section 2 presents the preliminary concepts, Section 3 illustrates the detailed methodology for assessing the model structure, we assess the goodness of the model of a pharmaceutical node (single plant) in Section 4, and the paper ends with some concluding remarks in Section 5.

## PRILIMINARIES

### Local Stability Analysis

Analysing the stability of the model plays a crucial role in designing the controllers. The dynamics of industrial systems are predominantly represented by a set of first-order nonlinear differential equations, these are known as state-space models. The set of solution to

these nonlinear differential equations are known as state trajectories. A system is completely characterized by the values of the state variables at any given instance of time. The generic nonlinear model representation is given below

$$M: \begin{cases} \frac{dx(t)}{dt} = f(x(t), u(t), \theta) \\ y(t) = g(x(t), u(t), \theta) \end{cases} \quad (1)$$

where,  $x(t)$  is the state vector,  $u(t)$  is the input vector and  $\theta$  is the parameter vector. Even though the dynamics is nonlinear, in most cases it can be approximated to a linear dynamics around the operating region. Hence, in this work we use linear stability analysis on the linearized state space model of Eqn 1. The linearized model is given in Eqn 2.

$$\tilde{M}: \begin{cases} \dot{x} = Ax(t) + Bu(t) \\ y(t) = Cx(t) + Du(t) \end{cases} \quad (2)$$

where A, B, C and D are state-space matrices obtained by evaluating Jacobin of Eq (1) at the operating point  $(x^*, u^*)$ . The eigenvalues of the A matrix will indicate the stability of the linear perturbation system (2).

### Sloppiness

In models with nonlinear predictors, often there are large regions in the parameter space over which the model predictions are nearly identical, this is known as sloppiness or model sloppiness. For infinitesimal perturbations sloppiness is quantified by the inverse of the condition number of the Hessian of the cost-function. The Hessian of the cost function can be approximated as

$$H_{ij} = \frac{1}{N} \sum_{n=1}^N \frac{\partial y}{\partial \log \theta_i} \frac{\partial y}{\partial \log \theta_j} \quad (3)$$

where  $y$  denotes model output. More formally, for non-infinitesimal perturbations, sloppiness can be conditioned on the experiment space known as conditional sloppiness. A model  $\mathcal{M}$  is conditionally  $(\epsilon, \delta)$  sloppy with respect to an experiment space  $\mathcal{Z}_{\mathcal{M}}$  at  $\theta^* \in \mathcal{J} \subset \mathcal{D}_{\mathcal{M}}$ , if

$$\|\theta^* - \theta_1\|_2 > \delta \quad \forall \theta \in \mathcal{S} \subset \mathcal{J} \quad (4)$$

$$\|y(\theta^*, t) - y(\theta_1, t)\|_2^2 < \epsilon \quad \forall u \in \mathcal{Z} \subset \mathcal{Z}_{\mathcal{M}} \quad (5)$$

for every  $(\theta_1, \theta^*)$  satisfying (4) and (5).  $\epsilon$  is arbitrarily small.  $\delta \gg \epsilon$ .

The role of sloppiness in the system identification has been extensively studied in. Sloppiness often affects the uncertainty in the parameter estimates. it is well known the uncertainty in the model structure and parameter estimates affects the robustness of the controller and hence, assessing the parameter uncertainty of the model becomes imperative to a satisfactory control system design. In this work, we use

conditional sloppiness analysis to assess the insensitivity in the parameter directions in SINDy models.

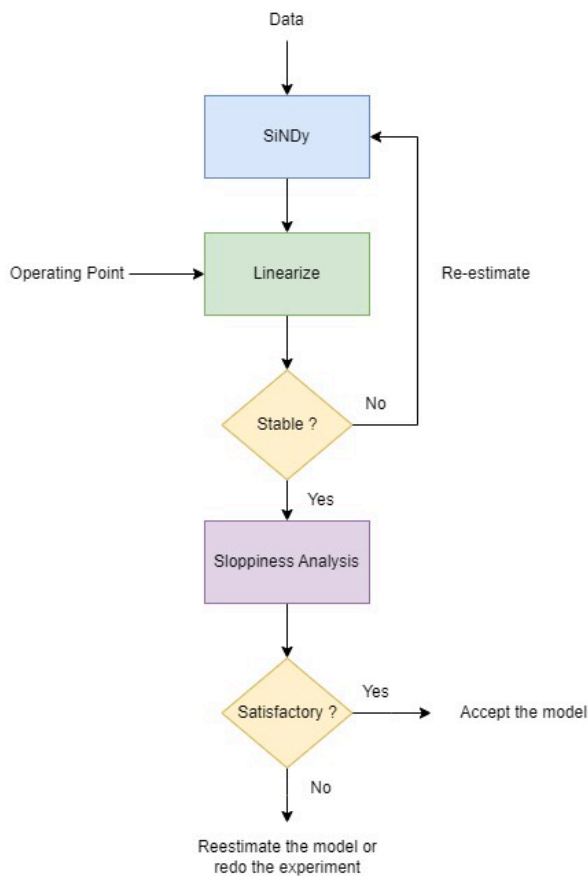

Figure 1: Algorithm for model assessment.

## METHODOLOGY

This section illustrates the method proposed for assessing the goodness of the model estimated using the SINDy algorithm. However, the method proposed, in general, can be used to evaluate any model. The proposed method has two significant steps: Firstly, assessing the stability of the local perturbation model (Linearized) and model sloppiness. As a next step, we construct what is known as a  $(\delta - \gamma)$  plot as proposed in [1] for conditional sloppiness analysis around the optimal parameter estimated from the SINDy algorithm. The central idea of this analysis is to characterize the model's behaviour around the point of interest in the parameter space; this is done by constructing an n-ball and evaluating the change in the model's output for all the parameters inside the n-ball with respect to the reference point. The procedure for constructing the  $(\delta - \gamma)$  plot is in Figure 2.

One of the main advantages of the proposed method is its ability to identify the parameters that are likely to be estimated with poor precision. When those parameters belong to stiff region/sensitive region, then with high probability, the controller system designed may become fragile. In the next section, we demonstrate the working of the proposed method in a dynamical model of an industrial node developed from the SINDy algorithm.

## Numerical Results

In this section, we demonstrate the working of the proposed method in a model developed for acetaminophen production plant.

### A linearized state-space model of acetaminophen production network

To demonstrate the working of the proposed method, we consider a process where Para-

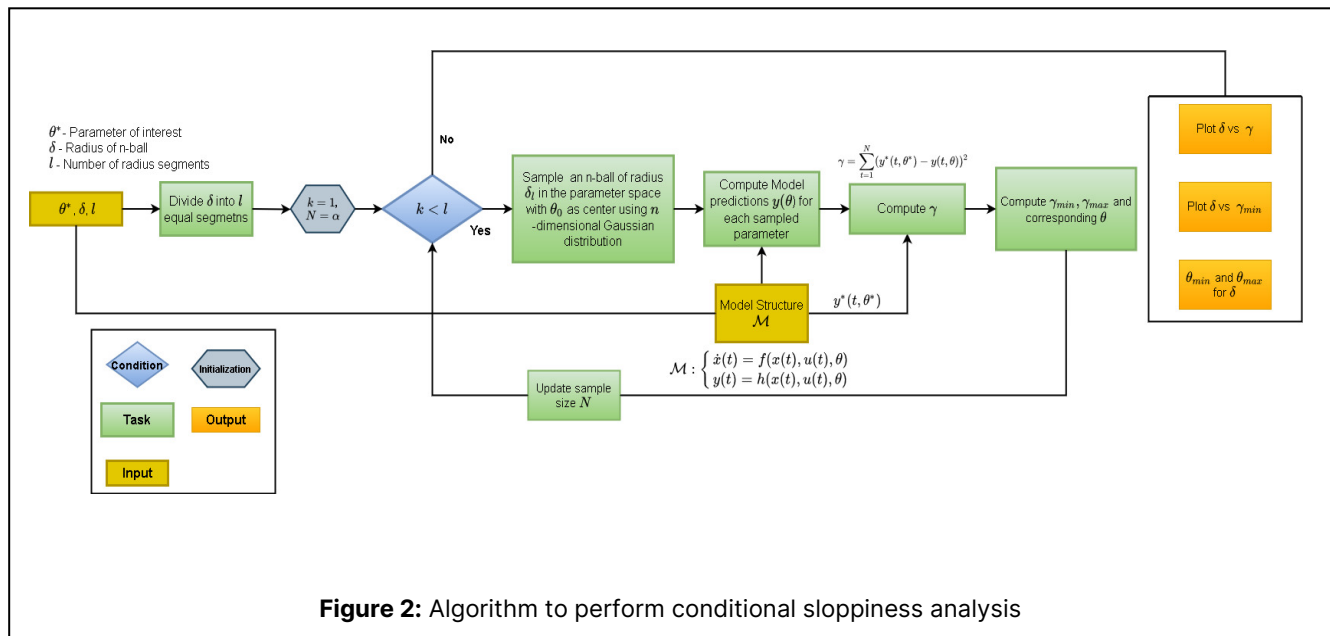

Figure 2: Algorithm to perform conditional sloppiness analysis

Aminophenol(PAP) reacts with Acetic Anhydride to produce Acetaminophen (A-PAP). Equation 7 is the linearized model obtained from the non-linear SINDy model. The detailed state variables and input variables are given in Table 1. The nonlinear ODE model identified using SINDy algorithm is linearized around the operating point. The Operating point and the linearized model is given in the Table 1 and equation 4

$$\dot{x}(t) = \begin{bmatrix} -16.34 & -5.06 & -15.83 & 9.04 \\ 12.22 & -3.41 & 10.72 & 3.43 \\ -0.07 & 7.85 & -1.10 & -5.63 \\ 3.70 & 0.006 & 2.97 & -3.90 \end{bmatrix} x(t) +$$

$$\begin{bmatrix} 11.15 & 3.21 & 4.39 & -7.56 \\ 2.84 & -0.62 & 2.38 & 7.58 \\ 0.76 & 2.78 & -1.91 & -3.52 \\ -0.03 & 4.80 & 4.36 & -0.96 \end{bmatrix} u(t) \quad (6)$$

$$y(t) = [1 \ 0 \ 0 \ 0]x(t) \quad (7)$$

where  $x_1(t)$  is APAP,  $x_2(t)$ ,  $x_3(t)$  and  $x_4(t)$  are the waste materials produced and  $u_1(t)$  is PAP.Fm,  $u_2(t)$  is Acetic Anhydride.Fm,  $u_3(t)$  is water and  $u_4(t)$  is water

The Eigen values of the system matrix A are given below

$$\lambda(A) = [-19.27 \quad -5.28 \quad -0.1 + 3.43i \quad -0.1 - 3.43i]$$

The system has both real and complex poles with negative real parts, which guarantees that the system is capable of damped oscillations. It is also worth noting that the complex poles have real parts that are close to zero value, which says that the system is on the verge of instability. However, the system is in the verge of instability. In the next section we perform conditional sloppiness analysis to study the sensitivity of the system to the parameter perturbations.

### Conditional Sloppiness Analysis

In this section, we do the conditional sloppiness analysis for the unforced system, i.e. the input is turned off in the Eq (6) and the  $x(1)$  is measured as the output. The model output is generated with the same initial conditions for  $t=0$  to  $t=10$  seconds. In this work, we analyzed the system for  $\delta = 10^{-5}$ , an infinitesimal distance from its optimal parameter. The visual plots for the model assessment are given below.

From Fig. 3 it is clear that the model is extremely sensitive in the vicinity of the operating initial condition. The system clearly becomes unstable. In addition to that, it is observed that the system is sensitive is almost identical in all the directions. The Model sensitivity index shows that the model is locally unidentifiable, ie there exist several parameter sets in the vicinity that results in an unstable model. In summary, the model identified by SINDy is extremely sensitive to parameter perturbations and a very small perturbation leads to instability. In the next section we demonstrate the role of this insensitivity

in the controller design.

Figure 3: Minimum and Maximum sensitivity plot

Figure 4: Model sensitivity index

### Analysis of controller design

In the previous section, using conditional sloppiness analysis, we showed that the model is very sensitive in the vicinity of the operating region, and an infinitesimal perturbation from the equilibrium position has destabilized the system. In this section, we show that designing the controller for such a system leads to a fragile controller, in the sense a very small perturbation in the controller parameters will destabilize the system. To demonstrate this, we adopt a pole-placement controller design. We place the poles on the following location to stabilize the oscillations in the system  $p = [-0.5 \ -1 \ -1 \ -0.5]$ .

The gain matrix is obtained for the given A, B and p. The gain matrix is given below. We add a Gaussian random matrix with the controller gain matrix to analyse the controller fragility. We generate a hundred such matrices and compute eigenvalues of the closed-loop system matrix.  $A_k = A - BK$  and plot the histogram of the real part of the eigenvalues in Figure 5. It is evident that the controller design is not robust with respect to very small uncertainty in the controller parameters as the

distributions shows that are positive real eigen values with significantly high probability. This analysis shows that the presence of sloppy and stiff directions in the parameter space of the plant affects controller robustness.

**Figure 5:** Histogram of real part of the closed loop system matrix.

## CONCLUSION

In this work, we proposed a novel method to assess the goodness of data driven surrogate dynamical models developed using the SINDy algorithm for control system design. We analyzed the model generated from the acetaminophen production plant. The original model is a nonlinear ODE. The model is then linearized for the stabilized operating conditions. The analysis revealed that the linearized model is on the verge of instability, and the sloppiness analysis revealed that a tiny perturbation leads to instability. To assess the role of sensitivity in the controller design, we designed a pole placement controller to stabilize the oscillations. We added a small amount of noise to the controller parameters. The Monte Carlo simulations revealed that the closed-loop system would become unstable with a significant probability of minimal uncertainty in the controller parameters. This re-emphasizes that the model identified using the SINDy algorithm is not good enough for control system design. As a logical extension to this work, we propose to formulate and solve a multi-objective robust-optimal control problem to ensure stability, achieve zero waste and maximize the productivity of acetaminophen. This study opens up new avenues in the controller design for sloppy systems.

## ACKNOWLEDGEMENTS

## ABSTRACT

Achieving worldwide sustainable development is a practical challenge that demands an efficient management of resources across their entire value chains. This practical task requires the optimal selection of pathways for extracting, processing, and transporting resources to meet the demands in different geographic regions at minimal economic cost and environmental impact. This work addresses the challenge by proposing a systematic framework for designing resource-processing networks that can be applied to resource management problems. The framework considers the integration and resource exchange within and across multiple processing clusters. It allows for the life cycle assessment of the environmental and economic impacts of the defined value chains, and design accordingly the different processing and transport systems from extraction to final use. The proposed representation and optimization model are demonstrated in a case study to assess the impact of energy transition under decarbonization constraints on long-distance energy supply chains. The objective is to identify optimal cluster designs and interconnecting transportation networks for decarbonized energy supply between energy exporters and importers.

**Keywords:** Optimization, Supply Chain, Energy, Carbon Dioxide, Life Cycle Analysis

## INTRODUCTION

Population growth is associated with increased demand for resources (water, energy, food, products...), fuel combustion, emissions levels, and waste production. Addressing these challenges requires effective resource management to ensure economic prosperity and avoid environmental disasters. Achieving the goals of sustainable development globally requires a life cycle view of the resource management problem.

Process systems engineering has provided different methods and approaches to manage material and energy resources through optimal integration. Heat [1] and mass [2] integration have been implemented at the chemical process scale to minimize feedstock intake and waste generation while meeting a defined production level. The scope of integration has been extended through total site analysis [3] to include exchanging resources between different plants within close vicinity.

Process Integration has been the basis for designing integrated systems, where different plants can exchange specified resources to achieve defined objectives

(economic or environmental). Many problems in this field are developed as mathematical programming models whose solutions yield the optimal outcomes for the defined problems. For example, Almansoori and Shah [4] proposed a mixed integer linear programming (MILP) model for optimizing the design and operation of H<sub>2</sub> supply chains. Alnouri et al. [5] proposed an optimization model for water integration and optimal brine management. Al-Mohannadi et al. [6] proposed a mixed integer linear programming model for integrating CO<sub>2</sub> across sources and sinks to optimize the design of CO<sub>2</sub> capture, utilization, and sequestration (CCUS) systems. These are some applications among many of the Process Integration approaches that have been widely described and reviewed [7]. Many of these approaches focus on a specific number of resources, which limits the scope of such approaches. Expanding the scope would then require developing new models that account for the missing opportunities.

To address this gap, new methods have been proposed that consider more holistic sets of resources by incorporating more materials. For example, the C-H-O

approach balances carbon, hydrogen, and oxygen elements in integrated processing clusters [8]. Different energy streams have been considered in multi-sectoral energy systems design through simulations and linear programming [9]. Although such approaches provide more generic frameworks than the direct applications described earlier, they still lack the comprehensiveness of integrated designs needed when considering different raw materials, intermediates, waste, and emissions streams. Ahmed et al. [10] proposed a resource integration representation of a processing cluster and a MILP model for maximizing the profit of the integrated system while abiding by environmental constraints. The flexible representation allows a complete accounting of all material and energy resources. The framework considers the specifications and conditions at which resources can be exchanged, with an inclusive accounting for the economics of processes and flows. However, this resource integration representation allows resource extraction, production, use, and reuse only within a defined system, which is limiting when it comes to life-cycle assessment considerations or representing the interactions across geographic locations.

Some of the energy systems modeling tools have considered the spatial aspect of the integration problem [11]. In such approaches, the transportation network is an infrastructure dedicated to one of the energy vectors (like a pipeline that transports  $H_2$  from location A to location B). Besides the fact that such models are limited to the energy systems they present (by the resource and process selection), the representation of the transportation network does not allow the consideration of multiple options that may impact the processing in different locations. This work proposes a framework for simultaneous resource integration within and across multiple processing clusters. The novel approach builds on Ahmed et al.'s [4] representation and expands the scope to include multiple systems with supply chains for exchanging resources. The transportation networks and processing clusters have similar generic representation which allows the consideration of multiple technologies for processing and transportation of the resources. A MILP model is proposed to minimize the integrated system's costs. This is the first generic framework for resource integration that yields optimal value chains under environmental limitations while considering transportation networks as processing clusters. An illustration of the model is presented by considering the problem of decarbonizing the energy supply chain between an energy importer and an energy exporter, including long-distance shipping of energy carriers and  $CO_2$ . The case study considers the emissions across the energy value chain in the different systems, as well as different decarbonization pathways, to propose cost-optimal strategies for achieving decarbonization targets at the global level.

## PROBLEM STATEMENT

Given is a system characterized by multiple processing clusters and different resources that can be processed and exchanged within and across the clusters. Each cluster is characterized by a set of processing options that can consume, produce, and convert the resources accessible by the cluster. The aim is to find the optimal capacities of the processing options that result in minimizing the net cost of the overall system while meeting the defined demands of resources in each cluster and abiding by defined footprint limitations.

The proposed representation allows for considering generic systems representing resources' value chains. Each processing cluster can be attributed to a geographic location or a transportation network. This allows the consideration of resource or process availability that may vary across geographic regions. Supply chains or transportation networks can access resources in different geographic locations, which allows for considering different modes of transport, each of which can be characterized as a processing option within the supply chain cluster. Integrating supply chains into the design of processing networks allows accounting for all possible opportunities to determine optimal configurations that meet defined demands at constrained footprint impacts. For example, when designing energy vectors for long-distance shipping, while some pathways may be considered better for shipping (due to high energy density, for example), they might produce more emissions or require higher costs for processing with respect to other less energy-dense carriers. Hence, considering the different processing and transportation options of the various resources simultaneously allows the identification of the synergies and trade-offs to support efficient decisions.

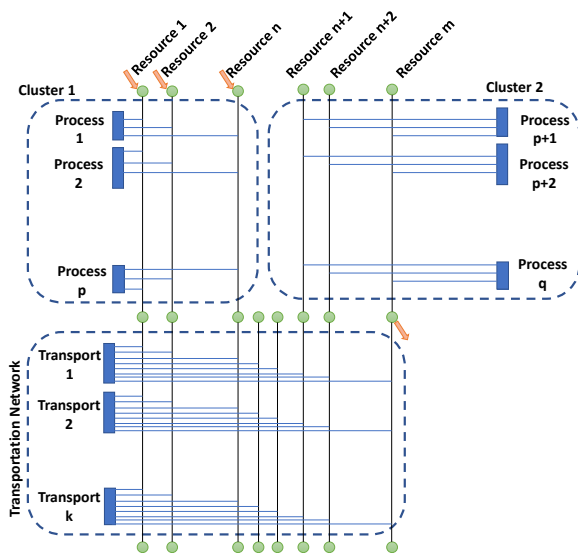

This work proposes a generic approach for considering integrated value chains, giving the user flexibility in defining the specifics of the problem. The aim is to determine the optimal processing options, their location, and their capacity by designing low-cost, low-footprint value chains.

## CLUSTER-OF-CLUSTERS REPRESENTATION

Figure 1 illustrates an example of a superstructure considered in the proposed framework. Each resource that can be consumed, produced, or exchanged within each system is characterized and tracked along the corresponding resource line. Each resource line is characterized by its physical properties (temperature, pressure, composition, AC/DC power, frequency, etc.) and geographic location. The characterization builds upon common infrastructures for energy and material transmission (like power, feedstock, waste, etc.).

Different resources can be imported to each system as fresh feedstock or energy/power inputs, or exported as products, by-products, waste streams, etc. The processes shown in the representation act as conversion units with connections to each resource line. These conversion processes account for any processing a resource line must go through to change its location or specifications. The units are characterized by their costs and capacity limitations, allowing full economic accounting across the entire systems.

The proposed methodology provides a comprehensive scope for considering the integration and resource exchange within and across multiple processing clusters. Each cluster is defined based on accessibility to the available processes and resources. This incorporates the spatial dimensions into the planning framework. The proposed representation considers the supply chains as systems with different transport modes that can exchange resources between different geographic locations. By considering the exchange of resources between multiple clusters, the entire value chain can be assessed, and the impact of transportation modes on resource production and utilization in different systems can be evaluated.

**Figure 1.** Resource integration across multiple clusters.

## OPTIMIZATION MODEL

Given are a set of resources  $R = \{r_1, r_2, \dots, r_n\}$ , a set of processes  $P = \{p_1, p_2, \dots, p_n\}$ , a set of components  $C = \{c_1, c_2, \dots, c_n\}$ , and a set of systems (or clusters)  $S = \{s_1, s_2, \dots, s_n\}$ . Note that the transportation units are considered in the proposed representation as “processes” since they “convert” resource lines from one location to another. Cost, capacity limits, and environmental impact characterize each processing and transportation unit. The proposed framework uses MILP to select the

processing and transportation units to minimize the system's cost under defined constraints on resource imports and exports (resource availability, demand, environmental constraints, etc.). The optimization variables are: the capacities of the different processes (and transportation options) in each system, the resources imports and exports flow rates into and out of each system, the flows of resources exchanged between systems, and the binary variables that activate each of the processes in each system.

The parameters used for characterizing the processes and resource lines are as follows: the conversion parameters, which are defined as the ratio of the flow rate of resource  $r$  produced by process  $p$  in system  $s$  relative to  $F_{p,s}$ , the composition of each component in each resource line in each system, the minimum and maximum capacity of each process in each cluster, the minimum and maximum resource import and export flowrate from each system, and the minimum and maximum resource flow rates of resources exchanged across the different systems.

The following parameters are considered in establishing the economic model to formulate the objective function: the capital expenditure of the processing units in each system is represented as the ratio of the annualized capital costs relative to the capacity of the units, the operating costs of the processing units in each system are represented as the ratio of the operating costs relative to the capacity of the units, and the selling and buying prices of each resource at each system. Economies of scale may result in cost advantages at high production capacities, leading to a non-linear relationship between the capital cost and the capacity. However, when the capacities are high enough, the impact of the economies of scale diminishes, which justifies the linear relation assumed in this work.

The model is set by defining the following constraints that ensure the applicability of the solution and its abidance to mass and energy balances and technical and environmental constraints defined by the user:

- Resource balance: resource balances are defined for each resource line to ensure mass and energy conservation across exports, imports, exchanges, and process conversions.
- Capacity limits: the lower and upper limits on the capacity of each considered process are introduced to ensure the applicability of the solutions based on the process's technical limitations.
- Flowrates limits: the limits on the flowrates of resource imports, exports, and exchanges between the different clusters are introduced to allow the user to define resource demands, consider resource availability, and account for any

limitation on the exchanges between systems.

- Components limits: the limits on the components in the resource exports and imports are defined to allow for the consideration of environmental limitations (such as emissions reduction targets, waste discharges, toxicity limits, etc.).

The total net cost of the overall system (the cluster of all clusters) is determined by accounting for the costs of installing and operating the processing (and transportation) units, the costs of acquiring the resources in the different clusters, and the revenues from selling the resources in each system. The objective function is developed by defining the net cost based on all the accounted costs and revenues to minimize it.

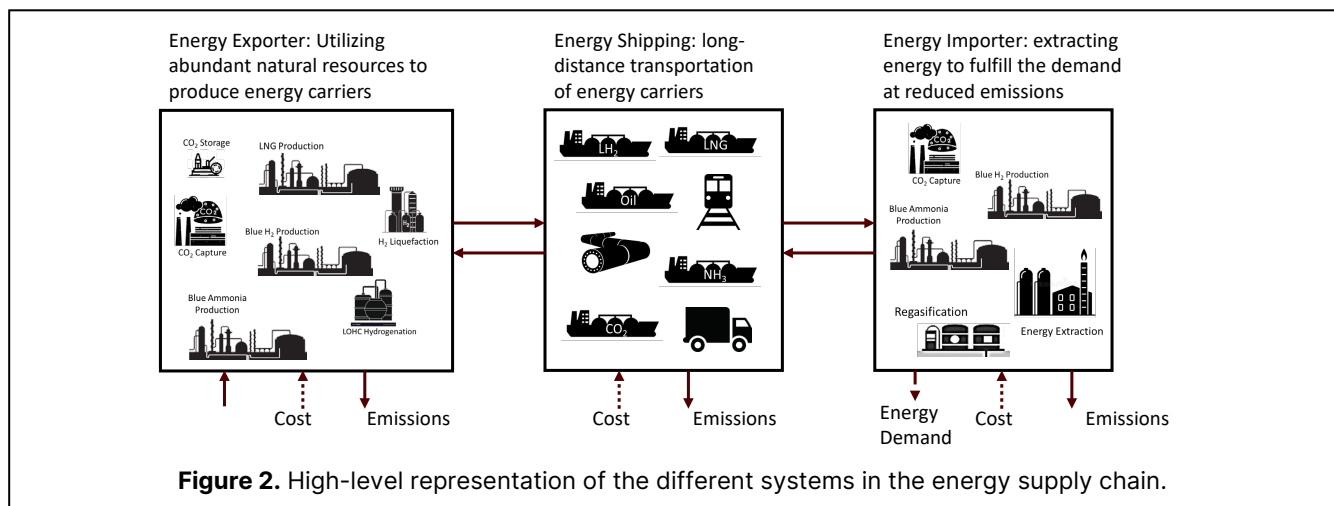

Considering the spatial dimension coupled with the ability to exchange resources across the clusters allows a holistic vision of the interactions between the systems, where the decisions in one system affect the entire value chain. The MILP model can efficiently screen through all possible combinations to give real-time solutions and suggestions on the optimal technology mix of the whole supply chain (from production to transportation, to final use). Note that all the optimization runs performed in the case study (the following section) gave solutions in less than 1 second.

## CASE STUDY: DECARBONIZING LONG-DISTANCE ENERGY SUPPLY CHAIN

The framework applies to analyzing energy supply chains, which can be represented by three systems: an energy importer, an energy exporter, and energy shipping. Figure 2 shows a high-level representation of the considered systems. The energy exporter utilizes abundant natural resources to produce energy carriers that an energy importer can store, transport, and use to supply a defined demand. The case study presented here is based on exporting energy between an energy importer and an

energy exporter 8000 nautical miles apart. The base case corresponds to exporting Liquefied Natural Gas (LNG). This case establishes a performance benchmark for supply chain costs and emissions against which decarbonization is assessed. The emissions from the supply chain can be reduced either through CO<sub>2</sub> capture, shipping, and storage to decarbonize the LNG-based energy supply chain, or by replacing natural gas with alternative hydrogen fuels and carriers. Applying the proposed framework to the described problem allows determining the processes to be implemented in each system (importer, exporter, and shipping) and their capacities, and the flowrates of the different resources imported, exported, and exchanged across the systems. These variables directly relate to key decisions for the optimal supply chain design, which include the following: What are the cost-optimal supply chain decarbonization pathways? Where can decarbonization technologies be applied to reduce targeted supply chain emissions? Which energy carriers should be produced and shipped? Where to produce alternative fuels? How will the cost-optimal decarbonization affect the direct costs and emissions incurred by each system? Considering all the systems constituting the supply chain simultaneously in this design process allows accounting for the impact each of the considered pathways has on the others. For example, transitioning to H<sub>2</sub> based fuels at the importer would decrease the LNG production level at the exporter, given that the energy demand to be supplied at the importer is fixed. This would affect the scale of CO<sub>2</sub> capture and storage from the LNG production process, and the shape of the required shipping fleet (type and number of ships).

The different decisions are considered by defining energy carriers' production processes at the exporter and the corresponding shipping and processing units in the remaining systems. The energy carriers considered are LNG (base case), H<sub>2</sub>, which can either be directly shipped as a liquid or loaded on a liquid organic H<sub>2</sub> carrier (LOHC), and Ammonia. An additional case is investigated

considering LNG as an energy carrier (EC) and decarbonizing the supply chain by capturing the CO<sub>2</sub> at the exporter and the importer. The captured emissions at the importer are shipped back to the exporter to be stored, as CO<sub>2</sub> sequestration may result in safety concerns in some locations [12]. An option for decarbonizing the ships using the shipped alternative fuels (H<sub>2</sub> and NH<sub>3</sub>) as fuel for shipping instead of heavy fuel oil (HFO) is

considered.

Defining the energy supply chain problem in the cluster-of-clusters framework requires introducing the following resources: energy carriers (H<sub>2</sub>, NH<sub>3</sub>, LNG), the processed H<sub>2</sub> conditioned for shipping (liquid or loaded on LOHC), forms of direct energy, CO<sub>2</sub> footprint (from each of the processes), and CO<sub>2</sub> streams in the supply chain (captured, compressed, and liquified CO<sub>2</sub>).

**Table 1:** Key parameters characterizing energy carriers' production and processing units at the exporter.

Process	Cost (\$/GJ)	Natural Gas Intake (GJ NG/GJ)	Power Intake (MWh/GJ)	CO <sub>2</sub> emissions (kgCO <sub>2</sub> /GJ)
LNG production	2.61	1.17	0	17.8
Blue H <sub>2</sub> Production	4.54	1.46	0	10
H <sub>2</sub> Liquefaction	5.82	0	59	0
LOHC Hydrogenation	0.40	0	0.58	0
Blue NH <sub>3</sub> production	13.90	1.52	24	2.2

**Table 2:** Key parameters characterizing energy carriers' processing units at the importer.

Process	Cost (\$/GJ)	EC Usage for heat (%)	Power Intake (kWh/GJ)
LNG Regasification	0.34	1.5%	0.10
H <sub>2</sub> Regasification	0.14	0%	1.2
LOHC Dehydrogenation	1.28	21%	2.3

**Table 3:** Key parameters characterizing energy carriers' ships in the shipping system.

Process	Cost (\$/GJ)	EC loss (%)	CO <sub>2</sub> emissions (kgCO <sub>2</sub> /GJ)
LNG Ships	1.66	6.21%	3.13
H <sub>2</sub> Ships	7.59	7.31%	10.7
LOHC Ships	5.15	0.00%	12.4
NH <sub>3</sub> Ships	3.23	0.15%	7.22
H <sub>2</sub> -fueled LOHC ships	3.44	16.3%	0
NH <sub>3</sub> -fueled NH <sub>3</sub> ships	2.25	9.64%	0

**Table 4:** Key parameters characterizing the different units across the CO<sub>2</sub> supply chain.

System	Process	Cost (\$/tCO <sub>2</sub> )	Natural Gas Intake (GJ/tCO <sub>2</sub> )	Power Intake (kWh/tCO <sub>2</sub> )	CO <sub>2</sub> emissions (tCO <sub>2</sub> /tCO <sub>2</sub> )
Exporter	CO <sub>2</sub> capture and compression	60	3	108	0.11
	CO <sub>2</sub> Processing	3.26	0	4	0
	CO <sub>2</sub> Storage	10	0	0	0
Shipping	CO <sub>2</sub> Ships	70	0	-	0.12
	LNG Fueled CO <sub>2</sub> ships	61	1.05	-	0.09
Importer	CO <sub>2</sub> Capture	48	3	28.7	0.11
	CO <sub>2</sub> Liquefaction	8.5	0	83.1	0

The system contains a three clusters, 24 resources, and 25 processes. The resources and processes are defined within each cluster based on availability, cost, energy requirements, and CO<sub>2</sub> emissions levels. The systems incorporate two major supply chains for shipping energy and CO<sub>2</sub>. The optimization problem aims to find the optimal configuration that supplies the energy demand for the importer at minimum cost while abiding by a defined supply chain emissions level. The energy demand at the importer is set to 140 million GJ/y.

Tables 1 through 4 summarize the data used in setting up the case study. The data on LNG production is based on Katebah et al. [13] and Raj et al. [14]. LNG regasification parameters are estimated based on Hafner and Luciani [15] and Park et al. [16]. The data on blue H<sub>2</sub> production is based on the integrated process reported by Katebah et al. [17]. The parameters characterizing the blue ammonia production process are based on the description of the ammonia process in Ullmann's Encyclopedia [18] and on data reported by Wang et al. [19] and Pfromm [20] on the ammonia process and CO<sub>2</sub> capture [21]. The studies reported by Raab et al. [22] and Niermann et al. [23] were used to estimate the data for H<sub>2</sub> liquefaction and LOHC hydrogenation and dehydrogenation. CO<sub>2</sub> capture data are based on the parameters of CO<sub>2</sub> capture from a natural gas combustion flue gas [24]. The costs of CO<sub>2</sub> sequestration are based on a report by the Global CCS Institute [25], assuming 10 \$/tCO<sub>2</sub> storage and transportation costs. The parameters characterizing CO<sub>2</sub> liquefaction, processing, and CO<sub>2</sub> ships are based on a report published by Element Energy Limited [26] in collaboration with Brevik Engineering, Polarconsult, TNO, and SINTEF. Note that the parameters shown in the tables are used to define the conversions of the different processes based on the intake and production levels of the different resources with respect to their capacities. This allows defining clear boundaries for each process to avoid double counting. For example, the power requirements parameter is defined as zero for some processes. This means that the process does not require importing the resource "power" from the integrated cluster. Power may be produced and consumed within the process boundaries, which may impact the conversion factors of the resources like cost and CO<sub>2</sub> emissions (which are also stated in the tables).

Table 1 shows the key parameters that define the energy carrier's production (from natural gas) and processing units in the cluster representing the energy exporter. The parameters are reported based on LHV energy content in the fuels produced and processed by each unit. Note that the reported costs do not include the cost of natural gas or power, which are considered as resources imported into the cluster as fresh feeds. The power is assumed to be obtained from natural gas-fired power plants with an emissions factor of 0.54

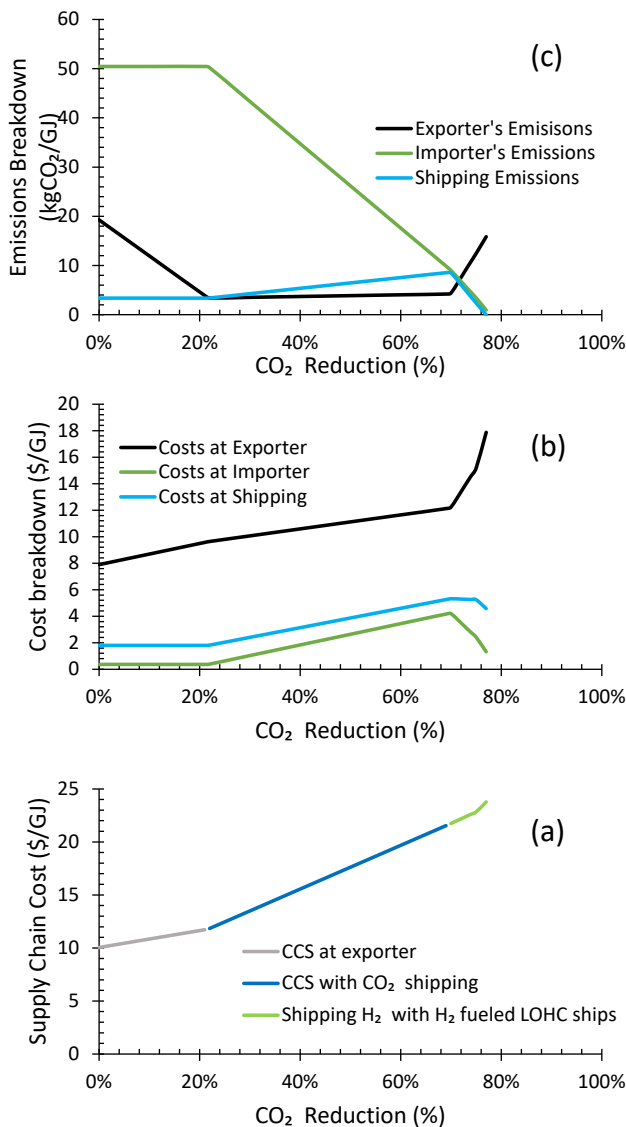

kgCO<sub>2</sub>/kWh. The power price at the exporter is assumed to be 0.032 \$/kWh, and the natural gas cost is 4 \$/GJ. Table 2 shows the parameters used to characterize the processing units at the importer. These units treat the received energy carriers from the ships to be at conditions suitable for energy extraction (through combustion). The heat requirements of these units are covered by the corresponding energy carriers, which is accounted for through the inefficiency or the EC loss parameter. LOHC dehydrogenation is an endothermic process that results in high energy requirements covered by the shipped H<sub>2</sub>. The power is assumed to be covered by a natural gas power plant at a price of 0.19 \$/kWh. Natural gas combustion at the importer (from the case of shipping LNG) produces 50.3 kgCO<sub>2</sub>/GJ. Table 3 presents the parameters characterizing the shipping fleets. The reported costs include heavy fuel oil (HFO), used as the fuel for H<sub>2</sub> ships, LOHC ships, and NH<sub>3</sub> ships. Energy carriers' losses from the ships are due to EC evaporation (LNG and H<sub>2</sub> and NH<sub>3</sub>) or due to utilizing the shipped EC as shipping fuels (H<sub>2</sub>-fueled and NH<sub>3</sub>-fueled ships). The evaporated energy carriers are recovered and used onboard to supply power to the ship's engine (with HFO). CO<sub>2</sub> emissions from the ships are due to the combustion of the shipping fuels (HFO and LNG). The costs of the decarbonized ships are determined by assuming a 20% increase in the ship's capital costs. The cost reduction is due to not utilizing HFO on the decarbonized ships. The trade-off is between avoiding the HFO cost or reducing the energy efficiency of the supply chain by using the energy carriers as fuels. Table 4 shows the parameters that characterize the different units along the CO<sub>2</sub> supply chain. CO<sub>2</sub> is captured from the LNG production, compressed, and stored at the exporter. The CO<sub>2</sub> captured from natural gas combustion at the importer is treated and shipped back to the exporter, where it is processed and stored. The heating requirements for CO<sub>2</sub> capture are covered by burning the natural gas in the supply chain. Two options for fueling the CO<sub>2</sub> ships are considered: HFO or LNG (produced at the exporter) as shipping fuels. Natural gas power is assumed to cover the power requirements of CO<sub>2</sub> processing units.

## RESULTS

The optimization model, based on the defined system, contains 870 constraints and 654 variables. The model is set up in Python and solved using Gurobi. The optimal scenario with the highest emissions flow rate was obtained by running the optimization model at relaxed emissions constraint. This scenario corresponded to producing LNG at the exporter and exporting it on LNG carriers to the importer, where it is regasified, and natural gas is combusted to cover the 140 million GJ/y energy demand. The corresponding emissions level in that

scenario is 10.23 MMtCO<sub>2</sub>/y (26% from the exporter, 69% from the importer, and 5% from the ships).

**Figure 3.** The total supply chain cost (a) and the breakdown of costs (b) and emissions (c) across the three systems at different CO<sub>2</sub> reduction levels.

The emissions limit constraint was then introduced by setting an upper limit on the CO<sub>2</sub> exports across all the systems. The CO<sub>2</sub> emission limit was reduced from 10.23 MMtCO<sub>2</sub>/y to 2.35 MMtCO<sub>2</sub>/y. Further CO<sub>2</sub> reduction was not attainable considering the described technologies. The supply chain cost and the costs and CO<sub>2</sub> emissions of each considered system are tracked. Figure 3 shows the results obtained at varying CO<sub>2</sub> emissions reduction. Three different system configurations were identified as the CO<sub>2</sub> emissions reduction target increased. Low emissions reduction levels (up to 21%) could be achieved by capturing the emissions from LNG production and storing

them at the exporter. This results in maintaining the cost and emissions level in the shipping system and at the importer, as no changes in the designs are required. The emissions at the exporter drop while the cost increases due to the investment in CO<sub>2</sub> capture and storage (CCS).

Emissions reduction between 21% and 69% can be achieved by capturing the emissions of the exporter and the importer and storing them at the importer. The captured emissions from the importer are shipped back to the exporter on CO<sub>2</sub> ships. This configuration increased the costs for all three systems due to the investments required in CO<sub>2</sub> capture, shipping, and storage. The emissions at the exporter were maintained at the same level achieved in the previous configuration as all the emissions were captured. The importer's emissions level dropped significantly, while the level of emissions from shipping increased. The rise in the shipping energy level is due to introducing a new shipping fleet that burns fuel onboard. Going beyond 69% emissions reduction requires a transition in the energy system at the importer from LNG to H<sub>2</sub>. The optimization solution showed that blue H<sub>2</sub> would be produced and loaded on LOHC at the exporter and then shipped to the importer on oil tankers fueled by H<sub>2</sub>. This scenario reduces the cost and emissions level in the shipping system and at the importer due to burning a fuel mix with less carbon content in both systems. The cost and emissions level increase at the exporter. This is because of the higher cost of blue H<sub>2</sub> production relative to LNG production. Moreover, a high amount of CO<sub>2</sub> is captured from the H<sub>2</sub> production, resulting in high emissions due to the capture inefficiency. The results indicate a variation in the performance of the systems as the emissions reduction target increases. An option that achieves global emissions reduction may increase emissions at a singular system level. At the same time, an option that results in global cost reduction may require an unevenly distributed investments. This indicates the necessity for fair crediting of CO<sub>2</sub> reduction to promote efficient implementation globally.

## CONCLUSIONS

This work presented a methodology for cost-optimal integration of different resources within and across multiple systems. The representation allows tracking energy and material streams based on their defined specifications. The generic representation of resources and processes gives the user flexibility in defining the problem by considering multiple material and energy resources that can be integrated across different processing units. The model allows full economic accounting by considering the cost of processes and transportation pathways, the cost of imported resources, and revenues from selling the exports. A comprehensive environmental accounting is allowed by considering multiple footprints.

Considering the design of multiple processing systems simultaneously results in insightful decision-making that accounts for the impact of systems interactions. The method can be applied to a wide range of problems like circular value chains, industrial symbiosis beyond eco-industrial parks, and the net-zero transition. This study presented an application of the framework for decarbonizing the energy supply chain by defining three systems: an energy carrier, an energy importer, and an energy exporter. Such a problem has been addressed in literature by analyzing one or two supply chains, but no work has considered multiple options simultaneously in an optimization framework. In this work, different technologies are considered for decarbonizing the different systems, and the interconnectivity of the decision-making was accounted for in the proposed method. The results showed that cost-optimal decarbonization starts with CO<sub>2</sub> capture and storage at the exporter (reducing 21% of the emissions), followed by CO<sub>2</sub> capture at the importer (with CO<sub>2</sub> shipping, which reduces up to 69% of the emissions), and energy transition to H<sub>2</sub> is activated at high CO<sub>2</sub> emissions reduction targets, which allows for 77% emissions reduction. The CO<sub>2</sub> marginal abatement cost increases from 110 \$/tCO<sub>2</sub> to 250 \$/tCO<sub>2</sub> as the reduction targets rise. The analysis showed that the environmental and economic impact of the decarbonization transition on the different systems varies with the targeted reduction levels. Hence, the implementation of an optimal transition calls for fair crediting of emissions reduction (environmentally and economically) across the systems.

## ABSTRACT

In a world grappling with mounting plastic waste, the pursuit of sustainable plastic waste management has become pivotal in aligning with Circular Economy (CE) goals, with a strong emphasis on resource conservation, product durability, and carbon footprint reduction. The strategic implementation of recycling methods serves as a stepping stone for transitioning from linear to circular models. This work delves into plastic waste recycling technologies, specifically focusing on open and closed-loop approaches, providing a comprehensive evaluation anchored on economic, environmental, and circularity criteria. Different recycling techniques are thoroughly examined, with particular attention given to chemical recycling methods such as pyrolysis and gasification. This work introduces a comprehensive screening model driven by a new proposed circularity metric validated through a case study to assess these recycling pathways. The results reveal the substantial potential of chemical recycling technologies compared to conventional incineration for energy recovery. Pyrolysis refinery and methanol production from plastic waste demonstrate triple and double the profitability of incineration while significantly enhancing the overall contribution of CE. This work emphasizes the imperative of a sustainable approach to plastic waste management by balancing different metrics considerations.

---

**Keywords:** Plastic waste, Chemical recycling, Circular economy, Circularity

## INTRODUCTION

Plastic materials have become increasingly prevalent as lightweight, robust, and cost-effective alternatives. The annual production of plastics is estimated to reach 430 million metric tons by 2023, of which 139 million metric tons will become waste [5]. The accumulation of plastic waste pollutants poses a pressing global challenge due to its degrading effects on ecosystems and threats to living and nonliving systems [6]. Therefore, sustainable plastic waste management methods are urgently needed to fulfill the requirements of the Circular Economy (CE) [7]. Recycling strategies are imperative for the shift from linear to circular models [8]. Recycling techniques are divided into material and chemical recycling. Material recycling could involve mechanical processes to produce regranulates and degraded plastic quality [9] or physical recycling that relies on solvent-based separation methods [5]. On the other hand, chemical recycling, or molecular recycling, involves breaking

down polymer chains into oligomers, monomers, or other basic chemicals through high-temperature processes. It includes pyrolysis, gasification, and depolymerization. Pyrolysis is a method that thermally degrades long-chain polymer molecules into smaller, less complex molecules, producing valuable products like oil, gas, and char [10]. Gasification is a thermo-chemical process transforming carbon-based materials through partial oxidation into synthetic gas [11]. Depolymerization, or Chemolysis, uses solvents to break polymer chains, making it ideal for homogeneous plastics.

Recycling methods are categorized into polymer, monomer, and molecular loops. Material recycling belongs to the polymer loop, producing purified plastic waste identical to the input. Chemical recycling includes depolymerization of the monomer loop, whereas pyrolysis and gasification are classified as molecular loops. Closed-loop recycling, which allows for the potential production of virgin-quality plastic from recycled materials, is commonly linked to monomer and molecular loops [5].

The potential of chemical recycling technologies comes with the challenge of identifying the most sustainable options, given the numerous possibilities and the early stages of research and development. This approach, which transforms waste into a resource, demands an efficient screening method to explore all possibilities [12]. Moreover, exploring plastic waste management pathways is a pivotal driver toward a CE model, emphasizing sustainability through waste minimization and resource optimization with the potential to mitigate pollution resulting from landfilling and direct combustion [13].

## BACKGROUND

Various state-of-the-art and critical literature studies have contributed significantly to our understanding of sustainable waste management practices. [14] proposed a method integrating mass flow analysis, techno-economic assessment, and life cycle assessment to evaluate primary plastics production and sorting. [15] compared thermochemical depolymerization technologies for LDPE waste, while [16] analyzed closed-loop recycling technologies for common consumer polymers. [17] conducted simulations of recycling processes for PP, and [18] compared thermochemical technologies for MSW treatment. Additionally, [19] and [20] assessed energy recovery options from MSW in Brazilian cities and southern Spain, respectively, providing valuable insights for sustainable waste management practices.

Nevertheless, limited research has focused on building optimization models to assess waste management pathways and enhance CE objectives. For example, [12] proposed a framework utilizing mixed integer linear programming to optimize waste recovery processes, aligning with circular economy principles. [13] introduced a mixed-integer nonlinear programming model for sorting and recycling mixed plastic waste, emphasizing economic feasibility and environmental impact. [6] presented a comprehensive superstructure and a multi-objective mixed integer nonlinear fractional programming model for HDPE recycling. [21] expanded on this work with a multi-objective MINLP model to optimize plastic waste sorting and recycling processes. [22] developed a systematic framework that integrates life cycle assessment and optimization methods for analyzing circular systems and synthesizing processes. Most of these studies have focused on evaluating the viability of diverse waste management technologies for transforming plastic waste into value-added products. However, comparatively less attention has been given to utilizing the primary products derived from chemical recycling processes, such as pyrolysis oil and synthesis gas. Despite their potential as excellent raw materials, they can enable both closed-loop (plastic to plastic) recycling, such as olefin production, as well as open-loop (plastic to product) recycling

options, such as hydrogen, ammonia, and Fisher-Tropsch synthesis. Although most literature studies focus on economic and environmental aspects, they overlook crucial circular economy factors such as material and energy utilization, product recyclability, quality, and durability. A comprehensive evaluation of these aspects is essential for adhering to circular economy principles in open and closed-loop recycling approaches. It is crucial to explore these pathways' potential thoroughly to advance these principles and establish a more sustainable approach to plastic waste management. Furthermore, addressing a common misconception suggests every product and material should undergo maximum recycling is essential. However, it is crucial to recognize that specific disposal methods may be more environmentally friendly for certain products. This distinction is vital because recycling processes for some products can be energy and carbon-intensive [23, 24]. Therefore, a well-balanced and comprehensive evaluation is essential to overcome this trade-off.

Expanding research on plastic waste treatment, mainly through chemical recycling, is crucial to address existing limitations. This work introduces significant contributions to the field by presenting a screening model and decision-making framework for evaluating plastic waste recycling technologies, with a particular focus on chemical recycling and various upgrading and processing technologies within both closed-loop and open-loop pathways to achieve holistic, sustainable waste management strategies, facilitating sophisticated decision-making by balancing economic, environmental, and circularity aspects. Moreover, the model introduces a novel circularity indicator integrating various metrics to assess circularity comprehensively. The introduced measure considers factors such as material consumption, energy demand, and economic viability, thereby enhancing sustainability in plastic waste management. It emphasizes not solely evaluating one factor but focusing on multiple factors simultaneously. This approach ensures a comprehensive assessment of the downstream implications for resulting products, contributing to a more holistic evaluation of plastic waste management strategies.

## METHODS

This work focuses on investigating various plastic waste recycling technologies. Figure 1 provides an overview of potential pathways for plastic waste management and the final products. The approach to screening different plastic waste treatment methods involved conducting a thorough literature review and collecting data from real-life plants and simulations. A structured database covering various technologies was analyzed for techno-economic and environmental performance. A screening model formulated using mixed integer linear

programming aimed to maximize the overall net profit while considering circularity indicators. Validation through a comprehensive case study confirmed the model's effectiveness. The model's primary objective is represented by Eq (1) and subjected to multiple equality and inequality constraints illustrated by Eq (2) and Eq (3). These constraints include material and energy balance, capacity limits, economics considerations, and the degree of circularity metric (DCM) constraints. The net profit of the recycling route is determined by subtracting annual income from total production costs. Capital expenditure (Capex) information is estimated through regression modeling with piecewise linearization to handle nonlinear data. Circularity is measured through multiple factors including Material Indicator (MI), Energy Indicator (EI), Water Indicator (WI), Solid-Waste Indicator (SWI), Global Warming Potential Indicator (GWPI), Economic Indicator (ECI), Co-product Utilization Indicator (CPI), Recyclability Indicator (RI), the product's Quality Indicator (QI), and Technology Readiness Level Indicator (TRLI). The individual indicators are classified into two categories: "Higher the better," where higher values emphasize better circular economy contribution, and the second category, "Lower the better," where lower values are more useful for overall circularity performance. Both categories have been normalized on a scale of 0 to 1 Max-Min normalization method [25], where 1 represents the

best-case scenario, and 0 is the worst-case scenario for both. Simultaneously, higher values of DCM are desirable, ensuring better technology sustainability. All these factors collectively form the total DCM, as shown in Eq (4). Moreover, each indicator in both categories is given a specific weight in the total circularity indicator using the Simple Additive Weighting (SAW) method [25]—more details about how each indicator and the total DCM are illustrated in the supplementary materials. A case study was conducted and evaluated to validate the model's efficacy. The proposed MILP and optimization problem have been solved with Python 3.10.2 - Pyomo 6.4.0 and Gurobi solver 10.0.1. Optimal solutions have been consistently obtained within a few seconds.

$$\text{MAXIMIZE (Net profit)} = f(x) \quad (1)$$

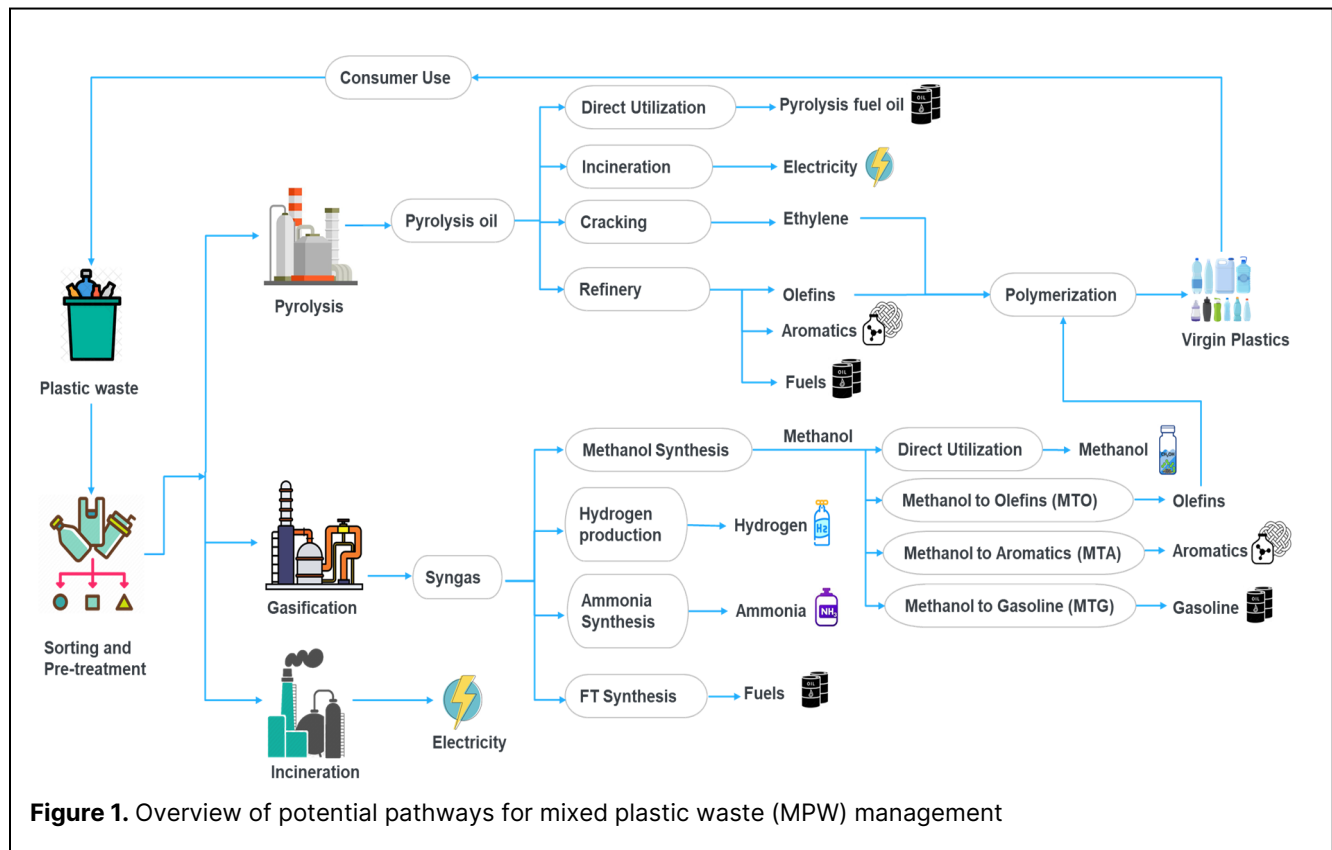

Subject to:

$$g_i(x) \leq 0, \quad i = 1, \dots, m \quad (2)$$

$$h_j(x) = 0, \quad j = 1, \dots, n \quad (3)$$

$$\text{DCM}_k = MI_k + EI_k + WI_k + SWI_k + GWPI_k + ECI_k + CPI_k + RI_k + QI_k + TRLI_k, \quad k = 1, \dots, p \quad (4)$$

Where  $k$  is the set of plastic waste recycling technology alternatives, and  $p$  represents the total count of technology alternatives.

**Figure 1.** Overview of potential pathways for mixed plastic waste (MPW) management

**Table 2.** Required materials and utilities in kg/ tons of plastic waste input and MWh/ton waste for electricity.

Name	NaCl	Sulfolane	H <sub>2</sub>	Bauxite	Limestone	O <sub>2</sub>	He	Water	Solid waste	Energy	Reference

IER	6	0	0	6	9	0	0	3830	98	0.3	[4]

## CASE STUDY

The case study considers three pathways: gasification, pyrolysis represented by methanol production, and pyrolysis refinery, both closed-loop pathways capable of producing new plastic, and incineration for energy recovery serving as an open-loop base case scenario. The model aimed at achieving maximum economic profit and maximum contribution to the circular economy through the higher values of DCM. The case study is scaled based on sources that generate 100,000 tons of mixed plastic waste annually [26]. Detailed technical information about each scenario, such as the yield, material consumption requirements, energy, utility requirements, waste generation, and emissions, are provided in Table 1 and Table 2.

**Table 1.** Pathways considered in the case study.

Name	Main products	Yield %	Ref.
Gasification to Methanol Synthesis (GTM)	Methanol CO <sub>2</sub> (carbon credit)	1.23 0.1	[1]
Pyrolysis+ Refinery (PR)	Ethylene Propylene Aromatics mix. LMWHC (Gasoline) HMWHC (Diesel)	0.20 0.13 0.04 0.54 0.05	[2, 3]
Incineration for energy recovery (IER)	Electricity (Gas, LHV=40.5 kJ/kg)	0.90	[4, 27]

## RESULTS AND DISCUSSION

Figure 2 illustrates the individual circularity indicators that contribute to the DCM. It is important to note that an assumption of equal weight distribution has been given to individual metrics impacting the final DCM value, set at 10% each. In the case of methanol production, the MI is notably low at 0.005, indicating inefficient material

utilization and the requirement of extensive materials for recycling the given plastic waste quantity. However, the EI is 0.07, demonstrating good energy efficiency with minimal energy demands. The WI is 0.08, reflecting efficient water use, while the SWI is also 0.08, suggesting minimal solid waste generation. The GWPI stands at 0.08, highlighting efficient waste management practices. The ECI is 0.06, indicating economic feasibility. In contrast, the CPI is very low at 0.02, signifying minimal co-product generation within the process. The RI and QI are at 0.100, emphasizing full recyclability and high product quality. Lastly, TRLI is 0.07, indicating a mature technology. Low MI, EI, ECI, and CPI values signify inefficient resource usage and high annualized costs in the pyrolysis refinery process. Conversely, high WI and GWPI values indicate effective water conservation, reduced emissions, and moderate waste generation. The process excels in recyclability and product quality, underscoring its commitment to sustainability and circular economy goals, as RI and QI values indicate.

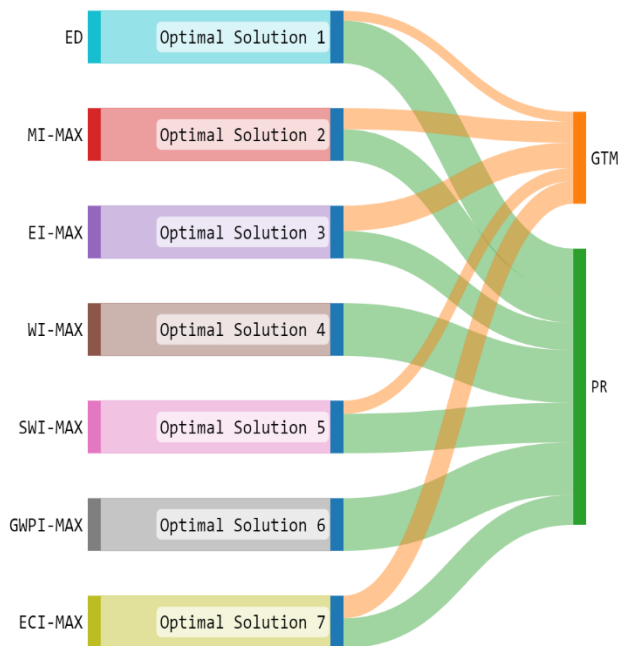

**Figure 2.** Individual circularity indicators for all pathways.

The high TRL reflects a mature technology that efficiently utilizes energy (high EI) and exhibits economic viability (high ECI) for the incineration energy recovery pathway. However, low MI, WI, SWI, GWPI, CPI, RI, and QI values raise environmental concerns.

**Figure 3.** DCM Breakdown.

This pathway consumes substantial materials and water, generates significant waste, emits pollutants, produces non-recyclable products, and lacks co-products. The DCM values are represented in Figure 3, where higher values indicate higher circularity levels. The incineration base case achieves the lowest DCM of 0.48, while methanol synthesis contributes to circular economy principles, boasting a DCM of 0.67, nearly 40% better than the base case. Pyrolysis refinery follows closely with a DCM of 0.61, exceeding the base case by 27%. Regarding profitability, all technologies are economically viable and generate positive economic impacts. The base case yields an annual profit of 11 M USD. In contrast, methanol synthesis and pyrolysis refinery outperform, with net earnings of 26 M USD and 33 M USD per year, respectively, doubling and tripling the base case's net profit.

**Figure 4.** Capacity allocation of the optimal solution using different indicator weights.

After conducting a multi-criteria analysis, the optimization model was tested with an objective function aimed at maximizing the net profit of the technology while pursuing the maximum possible circularity. The first case was solved with equal weight distribution (ED) of the individual metrics comprising the DCM. However, the specific preferences for each indicator depended on the context and objectives of circularity within the technology or system. Sometimes, prioritizing one indicator was essential based on geographical location, system needs, and regulatory perspectives. Therefore, the analysis included a second case of assigning a high weight of 55% to the indicator under focus, while other indicators received a minimum equal contribution of 5% each. This part of the analysis explored the optimal solution when one indicator was significant, with the remaining indicators being critical. Both cases were solved using suitable constraints for the same objective function, resulting in the optimal allocation of the proposed capacity depicted in Figure 4.

**Figure 5.** Profitability (M USD/y) of the optimal solutions in comparison to the base case, GTM, and PR processes.

Furthermore, the net profit and DCM values, as illustrated in Figure 5, and Figure 6 respectively, show that the optimal solutions will always have better profitability and circularity contribution compared to the base case. Maximizing the value of the weight of MI, EI, WI, SWI, GWPI, and ECI in the total DCM will not significantly affect the overall economic feasibility of the optimal solutions as reflected by the values of net profit of 27, 26, 33, 29, 33, and 27 M USD/y respectively. Moreover, the DCM faces an apparent variation with values of 68%, 74%, 80%, 72%, 77%, and 72% respectively.

**Figure 6.** Degree of Circularity Metric DCM (%) of the optimal solutions in comparison to the base case, GTM, and PR processes.

## CONCLUSIONS

Given the projected annual increase in plastic waste, sustainable plastic waste management has become necessary. This work delves into open and closed-loop plastic waste recycling technologies. The novel screening model introduced here is a robust tool for evaluating these recycling pathways. The case study centered around 100,000 tons of mixed plastic waste generated annually, considers three pathways: gasification, pyrolysis represented by methanol production, and pyrolysis refinery, both closed-loop pathways capable of producing new plastic, and incineration for energy recovery serving as an open-loop base case scenario. The results reveal chemical recycling technologies' considerable potential. Methanol synthesis and pyrolysis refinery emerge as the stars, generating net profits of 26 M USD and 33 M USD per year, respectively, substantially exceeding the base case's annual profit of 11 M USD. While economic viability is crucial, this analysis emphasizes circularity considerations. The incineration base case records the lowest DCM at 0.48, while methanol synthesis shines as a circular economy champion, boasting a DCM of 0.67, nearly 40% better than the base case. The pyrolysis refinery has a DCM of 0.61, surpassing the base case by 27%. Moreover, the analysis also investigated the impact of different indicator weights on the optimal solutions, allowing for tailored solutions based on specific system needs and preferences. The optimal solution varied accordingly, highlighting the importance of selecting relevant indicators for the given context of the system. In conclusion, the presented approach provides valuable

insights for decision-makers and stakeholders, enabling them to choose appropriate recycling technologies based on their objectives and priorities. The results emphasize the crucial role of circularity in improving both environmental sustainability and economic viability. Future research can build upon these findings, exploring additional factors and technology options to enhance plastic waste management further and contribute to advancing the circular economy concept.

## ABSTRACT

The food-energy-water nexus (FEWN) has been receiving increasing interest in the open literature as a framework to address the widening gap between natural resource availability and demand, towards more sustainable and cost-competitive solutions. The FEWN aims at holistically integrating the three interconnected subsystems of food, energy and water, into a single representative network. However, such an integration poses formidable challenges due to the complexity and multi-scale nature of the three subsystems and their respective interconnections. Additionally, the significant input data uncertainty and variability, such as energy prices and demands, or the evaluation of emerging technologies, contribute to the system's inherent complexity. In this work, we revisit the FEWN problem in an attempt to elucidate and address in a systematic way issues related to its multi-scale complexity, uncertainty and variability. In particular, we provide a classification of the sources of data and technology uncertainty from historic data, forecasting and process parameters, and propose ways to quantify their impact on the integrated system analysis. To effectively tame the FEWN's multi-scale complexity, we distinguish between the introduced error of approximation and optimization of employed surrogate models. In turn, it is possible to characterize their impact on optimal FEWN decision-making based on the quantification of the introduced errors at all levels. Thus, we present strategies to systematically characterize FEWN process systems modeling and optimization. Ultimately, this facilitates translating obtained solutions into actionable knowledge by quantifying the level of confidence one can have in the derived process model and optimal results.

## INTRODUCTION

The food-energy-water nexus (FEWN) has been identified in the open literature as an effective methodology to address the increasing disparity between natural food, energy and water resource availability and the respective resource demands sustainably. Based on a detailed analysis of the interconnections of the food, energy, and water subsystems, the FEWN aims to facilitate synergies among the three resource network subsystems, whereas competition is to be avoided to ultimately uncover trade-off solution strategies [1]. This proposed sustainable systems integration approach poses

formidable challenges from a process systems engineering (PSE) perspective, including but not limited to multi-scale uncertainty, appropriate system boundary definition, together with multiple and often conflicting stakeholder perspectives [2]. Furthermore, it has been shown that FEWN research does not produce sufficient actionable knowledge [3], meaning that obtained PSE FEWN frameworks and results are not translated into real world impact. In turn, the achievable synergy level of obtained optimal FEWN solutions is not only limited by the data availability, but also by the utilized modeling and complexity reduction techniques due to the introduced uncertainties and errors [4, 5].

Therefore, this work revisits the FEWN problem statement to systematically address its multi-scale complexity and uncertainty. More specifically, the scope of this work is to present methods to quantify introduced errors across all scales stemming from the necessity to overcome uncertainty, modeling, and computational complexity. While characterizing data uncertainty is well established in the literature, this work presents a novel distinction among the errors of approximation and optimization to fully characterize modeling complexity based on a representative surrogate energy-water supply model. Bridging the computational complexity of the surrogate model is evaluated via clustering of operational decisions of the water supply system. In turn, this work presents a framework to characterize introduced errors at all levels to provide decisionmakers, such as stakeholder or policymakers, with a quantifiable level of confidence one can have in the derived process model and optimal results.

The similarities among data uncertainty and complexity mitigation strategies are a central narrative of this work, the basis of which is elucidated via a representative energy-water supply system in the section FEWN Modeling. For impactful FEWN system modeling and optimization relevant system parameters have to be defined according to historic data which inherently introduces errors due to data uncertainty. Regarding data uncertainty the major challenges can be identified as (i) data variability, (ii) data aggregation, and (iii) data forecasting. All of this is discussed as part of the FEWN Modeling section. Due to the multi-scale complexity of the FEWN an interconnected system model cannot be optimized directly. In turn, modeling complexity mitigation via surrogate modeling, such as feedforward artificial neural networks (ANNs) or linear regression, and computational complexity reduction via algorithmic strategies, such as clustering or rolling horizon approaches, are discussed in the section System Complexity. It is important to note that the observations discussed in this work can readily be extended from FEWN approaches to general PSE problem statements tackling interconnected process systems and are essential for deriving actionable knowledge by quantifying the introduced errors stemming from data uncertainty and variability, as well as from the selected approximation and optimization methods.

## FEWN MODELING

The assumed system boundary inherently influences the FEWN system's modeling and solution generation. Accordingly, it has to be identified based on the defined research goals for impactful decision-making of FEWN frameworks [6]. This work investigates the quantification of complexity and data uncertainty mitigation errors across all scales of FEWN systems for the

derivation of actionable knowledge. Accordingly, a representative FEWN process system, based on benchmark resource supply systems, is selected as the relevant system boundary.

A renewable energy supply system for the identification of the cost-optimal mix of renewable energy generation and storage system has been selected as a representative energy supply system due to its reduced greenhouse gas emissions and therefore key role in the energy transition [7].

$$P_D(t) \leq \sum_t (P(t) - EC(t) + \sum_{t,k} [P_{rel,k}(t) - P_{stor,k}(t)]) \quad (1)$$

$$P(t) = \sum_{Tech} n_{Tech} \cdot p_{Tech}(t) \quad (2)$$

$$P_k^{bat}(t) = P_k^{bat}(t-1) + P_{stor,k}(t) - P_{rel,k}(t) \quad \forall k \in K \quad (3)$$

The governing equations of the energy supply system are summarized for every time point  $t \in T$  from Eq. (1) to (3). The energy demand  $P_D(t)$  has to be satisfied by generating renewable energy from different technologies such as biomass, wind turbines, single axis tracking or fixed angle solar panels (see Eq. (2)) or releasing energy from available energy storage systems ( $P_{rel,k}(t) \quad k \in K$ ). In turn, a surplus of renewable energy availability can be used to store energy ( $P_{stor,k}(t) \quad k \in K$ ) or satisfy the energy consumption of the water supply system ( $EC(t)$ ).

Reverse osmosis (RO) desalination water supply systems have already been identified as benchmark water supply systems in the literature and are accordingly selected for this study [8].

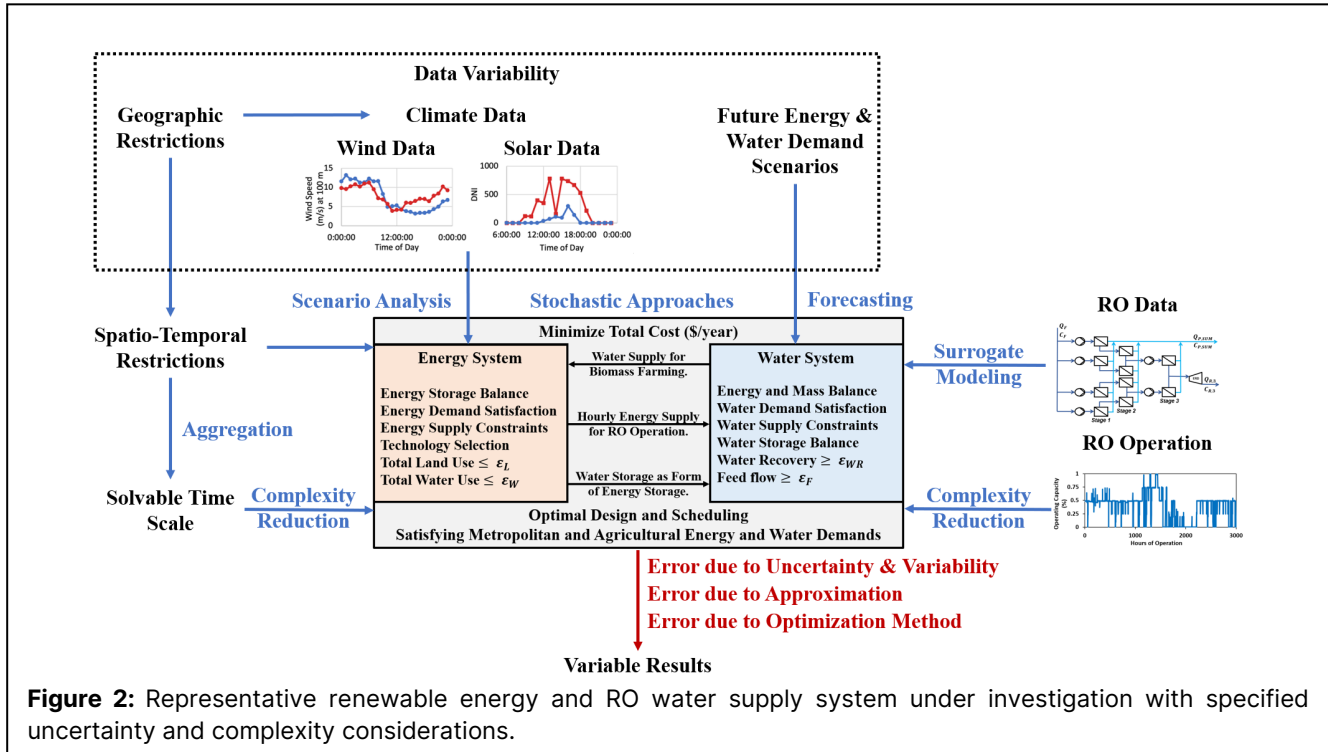

$$SEC(t) = \frac{1}{WR^{sys}(t)} \cdot \left( \frac{1}{4 \cdot \eta_1} \sum_{j=1}^4 P_{f,1,j}(t) + \dots \frac{(1-WR_1(t)) \cdot (1-WR_2(t))}{\eta_1} \left[ \frac{1}{2} \sum_{j=1}^2 P_{f,3,j}(t) - \frac{1}{4} \sum_{j=1}^4 P_{r,2,j}(t) \right] - \dots \frac{(1-WR_1(t)) \cdot (1-WR_2(t)) \cdot (1-WR_3(t)) \cdot \eta_2}{2} \sum_{j=1}^2 \Delta P_{ERD,j}(t) \right) \quad (4)$$

$$EC(t) = SEC(t) \cdot Q_p(t) \quad (5)$$

$$Q_p(t) = WR^{sys}(t) \cdot Q_f(t) \quad (6)$$

$$WR^{sys}(t) = WR_1(t) + (1 - WR_1(t)) \cdot WR_2(t) + (1 - \dots WR_1(t)) \cdot (1 - WR_2(t)) \cdot WR_3(t) \quad (7)$$

Eq. (4) to (7) summarize the governing RO desalination system equations. The specific energy consumption can be calculated based on the feed pressures ( $P_{f,i,j}(t)$ ) of every stage ( $i$ ) and parallel flow ( $j$ ), as well as water recoveries per stage ( $WR_i(t)$ ) and of the overall system ( $WR^{sys}(t)$ ), together with the pressure difference across the energy recovery device ( $\Delta P_{ERD,j}(t)$ ). The remainder of the RO system is characterized by the system's energy consumption ( $EC(t)$ ), together with its produced permeate ( $Q_p(t)$ ) and required feed flow ( $Q_f(t)$ ).  $Q_p(t)$  can then be used to satisfy the municipal water demand and the water demand for biomass farming of the renewable energy supply system. In addition, a water storage balance analogous to Eq. (3) can be added to the RO desalination system.

**Figure 2:** Representative renewable energy and RO water supply system under investigation with specified uncertainty and complexity considerations.

For semi-arid and arid water scarce regions with high temperatures and harsh external conditions, outdoor agriculture is neither a viable nor a sustainable option. Therefore, greenhouse farming systems providing a controlled environment for secure plant growth are selected as a representative food supply system [9].

To reduce the overall system complexity only the renewable energy supply system and the RO water supply system are considered in detail. The greenhouse system is considered via water and energy demand fulfillment constraints in addition to metropolitan energy and water demand constraints [10]. Accordingly, optimal solutions specify the design and operation of an interconnected renewable energy supply system and RO water supply system with energy and water storage consideration for the dynamic water and energy demand fulfillment as specified by the demands of an urban center and a greenhouse farming system.

The overall representative energy-water supply system for metropolitan and agricultural ecosystems is summarized together with all encountered data uncertainties and modeling complexities in Figure 2. The detailed mathematical model of the renewable energy supply system can be found in [7], of the RO water supply system in [8,11] and their modeled interconnections in [10]. The novelty of this work consists of revisiting the FEWN problem statement by systematically discussing mitigation strategies overcoming data uncertainty and variability, as well as system modeling and computational complexity. Dependent on the complexity mitigation strategy not only the feasible region of the optimization

model, but also the obtained optimal results in the form of the objective function and optimization variable values can potentially be altered [11]. To maintain the practicability of derived FEWN frameworks and results, it is of the utmost importance to quantify the introduced errors. This represents a certified level of confidence decision-makers can have in the proposed FEWN process systems solutions.

The identification of relevant data of reduced order compared to the historically available data remains one of the main challenges of solving FEWN problems toward practical impact. To operationalize the FEWN researchers have to not only mitigate data variability, but also derive representative data from a plethora of historical data (aggregation) and extrapolate currently available data to future trends (forecasting), as depicted in Figure 2. For all of these data uncertainty challenges, a sensitivity analysis of derived results can be leveraged as a proxy of the introduced error. One of the most direct ways to quantify the sensitivity of optimal solutions dependent on changing parameter values is multi-period or what-if scenario analysis. These approaches attempt to integrate uncertainty into policymaking through iterative exploration of possible optimal solutions [12]. Here, this can be understood as varying assumed input climate data profiles, such as solar direct normal irradiance (DNI) or wind speeds, or potential future energy and water demand profiles and prices. Other strategies to capture data variability include stochastic approaches which leverage probability distributions to approximate the variable input

data [13]. In this instance, the original deterministic optimization model becomes stochastic and can be solved via either Monte Carlo simulation, chance-constrained or robust programming.

To extrapolate patterns and behavior from historic data into the future forecasting techniques are utilized. Here, the introduced error of uncertainty stems from the quality of representative data utilized for forecasting and how accurate future trends can be captured based on this training data set. While there exist long term projections of future water demands, this is not the case for future energy demands and prices. To address this challenge, Baratsas et al. [14] established a quantitative framework to evaluate the integrated price of energy, the Energy Price Index (EPIC), which, influenced by both the demand and prices of energy products, signifies the average monthly price of energy for end-use consumers. To predict the present value for the demand and price of the energy products, a rolling horizon methodology is utilized since the availability of data for the demand and prices for certain energy products is often lagged by one to three months [15].

The interested reader is advised to consult [16] for a general review of advantages, disadvantages, and novelties of time series forecasting techniques applied to the energy sector. It is important to note that the degree of uncertainty significantly increases with the projected time scale of the forecast. This is for example illustrated by the divergence of long-term projections for industry sector energy consumptions due to varying base and final year assumptions and if non-monetary drivers are used to project material demand [17]. Even if long-term projections are generated via a rolling horizon approach, the introduced uncertainty increases with every forecasted time step due to the possibility of compounding the forecasting error.

Aggregation aims at reducing comprehensive historic data into a manageable representative data set which is subsequently used to replace the original historic data. This is for example applied to hourly or daily wind speed or solar direct normal irradiance profiles for renewable energy systems optimization or available subland clusters for land-use optimization. Accordingly, an error of uncertainty is introduced in the process system due to the scale reduction. However, this scale reduction also reduces the computational complexity which simultaneously introduces an error of optimization. Here, one can appreciate the interconnectedness of complexity reduction and data uncertainty. To address the computational burden associated with hourly time discretization and extensive time horizons in optimization models, Tso et al. [18] proposed a decomposition algorithm based on agglomerative hierarchical clustering (AHC), moving away from traditional k-means clustering, to preserve the time chronology of the input data. To select the optimal

number of clusters, a cut-off threshold, showing the percentage of slope decrease in within-cluster variance, is applied, which can be understood as the allowable aggregation error.

## SYSTEM COMPLEXITY

The individual renewable energy supply system and the RO water supply system are highly complex to model and optimize due to their nonlinear behavior. In fact, dependent on the selected time scale the interconnected model is computationally intractable [10]. However, solely optimizing each subsystem individually is not sufficient to uncover synergies among the supply systems [1]. In turn, researchers employ surrogate models together with advanced algorithmic strategies to overcome modeling and computational complexity [19]. While these are effective approaches to reduce system complexity, these methods introduce errors due to the leveraged approximation and optimization strategies.

The error of approximation is well studied in the literature and can readily be quantified based on the coefficient of determination ( $R^2$ ) or the mean squared error (MSE). On the contrary, the introduced error due to the selected optimization method can be understood as the introduced change in objective function value and degrees of freedom (DOF) due to the utilization of a surrogate model or advanced algorithmic strategy. The variation of DOF and objective value ( $Err_{opt}$ ) can be quantified by calculating the  $R^2$  (or MSE) of the "original" optimization model ( $x_i$ ) and the surrogate model optimization results ( $\hat{x}_i$ ), as shown in Eq. (8). In this case,  $R^2$  can be understood as the amount of original model variability explained by the surrogate model and optimization method which should ideally be one. To summarize all introduced errors,  $R^2$  for each approximation or optimization approach can be calculated and subsequently be multiplied to obtain a final value for the introduced error due to the necessity of system complexity mitigation.

$$Err_{opt} = 1 - R^2 = 1 - \frac{\sum_{i=1}^n (x_i - \hat{x}_i)^2}{\sum_{i=1}^n (x_i - \bar{x})^2} \quad (8)$$

$$Err_{obj} = 1 - \frac{\hat{y}}{y} \quad \hat{y}, y \geq 0 \quad (9)$$

Further, the change in objective function value can be quantified based on Eq. (9), where  $Err_{obj}$  denotes the introduced error based on the derived objective function values. In this case,  $\hat{y}$  denotes the optimal solution obtained via the surrogate optimization model, whereas  $y$  represents the originally obtained optimal solution. Based on this definition we can conclude that if

- $Err_{obj} > 0$ , then  $\hat{y}$  is a lower bound for  $y$ .
- $Err_{obj} < 0$ , then  $\hat{y}$  is an upper bound for  $y$ .

This deduction is only valid if the objective function values are positive. For negative objective function values,

the reversible observations are applicable.

## Modeling Complexity

As previously mentioned, the RO water supply system is selected to illustrate the influence of surrogate modeling on optimal decision-making. We selected simple linear regression, first-order Taylor approximation, multiple linear regression, and feedforward artificial neural networks (ANNs) with rectified linear units (ReLU) as activation functions as potential surrogate models. Shallow ANNs with a limited number of neurons utilizing ReLUs can be interpreted as a multiple variable piecewise linear regression. If one of these models, in the presented sequence, satisfied a set quality of approximation criterion ( $R^2 \geq 0.95$ ) the corresponding model has been selected to balance simplicity and accuracy.

Here, the specific energy consumption ( $R^2=0.99$ ) and the energy consumption ( $R^2=0.99$ ) of the RO plant can both be calculated based on individual shallow ANNs utilizing ReLUs as activation functions. The RO plant's overall permeate flow ( $R^2=0.98$ ) and water recovery ( $R^2=0.98$ ) can be approximated via first-order Taylor expansions. In this instance, the surrogate model explains approximately 94% of the observed variability of the original model and thus we can certify the introduced error due to approximation to be 6%. Accordingly, the original mixed-integer nonlinear programming (MINLP) problem can be successfully approximated by a mixed-integer linear programming problem (MILP) [11].

**Figure 3:** Results of RO modeling and optimization. Lines: Original MINLP model; Points: MILP Surrogate model.

In turn, the error of optimization can be quantified by optimizing both the MINLP and MILP for the same set of constraints. The optimization models have been solved in GAMS with the Gurobi solver for the MILP problem and the BARON solver for the MINLP problem. Results of this analysis in terms of a direct comparison between the optimal energy consumption of the RO plant for changing feed flows and efficiencies of the MINLP and MILP problem are displayed in Figure 3. Here, we can appreciate how the differences in minimized energy consumption

between the MILP and MINLP model shrink with increasing water recovery and decreasing feed flow. The difference between the two optimization approaches results in  $R^2=0.98$ , meaning that solely based on the optimization approach an additional error of 2% is introduced in the objective function values. This change in objective function value can also be quantified by calculating  $Err_{obj}$  (Eq. (3)) for every pair of feedflow and water recovery. Interestingly, the error of objective function value does not change significantly with changes in feed flow, which is exemplified by a maximum standard deviation of 0.0026 across all values.

**Figure 4:** Results of RO modeling and optimization. Introduced error due to the selected optimization method.

Accordingly, the average  $Err_{obj}$  for each water recovery has been calculated which is depicted in Figure 4. On first glance we can postulate that the MILP problem provides in all cases a lower bound to the true optimal solution ( $Err_{obj} > 0$ ). It is interesting to see how the error of optimization decreases with increasing water recovery, i.e. system efficiency. For water recoveries higher than 0.6, the introduced error in the objective function value is less than 0.133. Besides the change in objective function value, the utilization of surrogate models can also influence the obtained values of optimization variables.

**Figure 5:** Results of RO optimization. Comparison of the SEC of system solutions for the MINLP and MILP case. For RO systems, key performance indicators besides the

plant's energy consumption are the system's overall water recovery, overall permeate output and specific energy consumption. Both, the MINLP and MILP optimization problem, result in the same system water recovery and permeate output, meaning that the RO systems operate at the same efficiency and output level.

Interestingly, the SEC consumption of both models differ due to the selection of different operational pressures and water recoveries per stage across the plant (see Eq. (4) and (7)). This is possible since the same water recovery of the system can be achieved with different water recoveries per stage and since the same water recovery per stage can be achieved with different pressures per stage and parallel flow across the plant. To measure this difference in operational decisions the SEC for the MINLP and MILP case are visualized in Figure 5. It is important to note that it has been shown that the SEC is only dependent on the water recovery [8] explaining the reduction in data points between Figures 3 and 5, similar to the observation regarding Figures 3 and 4. Ideally, the data points would follow a straight line of slope one indicating that the SEC results of the respective models are identical. Since this is not the case, we can appreciate the introduced optimization method error as departures from said line, which can be quantified as  $R^2=0.95$ . In turn, this represents an introduced error of 5% in terms of decision variable values.

Taking into account this additional error, the optimization model can only capture 88% of the original model's behavior, instead of the initial 94%. Arguably, the error due to the selected approximation approach is approximately the same as the error introduced stemming from the selected optimization approach (both 6%). This observation indeed underlines the importance of quantifying the quality of obtained surrogate model optimization results, although this is a difficult task which might not always be possible because of the potential non-solvability of the underlying physics-based models.

## Computational Complexity

The spatial and temporal multi-scale complexity of the FEWN results in large scale optimization models, which is one of the main reasons that derived optimization frameworks are computationally intractable. It already has been shown that the full energy-water supply system cannot be solved at an hourly time scale over a one-year time horizon. To obtain an upper bound on the true optimal solution, the RO system has been restricted to a single operating point whereas the full dynamic renewable energy system is solved over a one-year time horizon [10]. In this extreme case, the RO system is effectively clustered to a single representative operating point specifying only once its constant  $EC$ ,  $Q_p$ ,  $Q_f$  and  $WR^{sys}$ . This is analogous to assuming that there exists only a single time period of operation of the RO system according to a "short-sighted" rolling horizon approach and can effectively be understood as introducing a different time scale for the water supply system. In turn, this inherently limits the system's flexibility and potentially its ability to adjust to the variability of the renewable energy supply system. Accordingly, altering the frequency of operational clustering corresponds to evaluating the importance of considering varying or equal time scales among the interconnected supply systems.

However, the quality of the obtained upper bound on the true optimal solution has not been quantified yet. In theory, better upper bounds to the true optimal solution can be obtained by adding more operational RO clusters to the system. This clustering of operating points can directly be compared to similar approaches for data aggregation. Alternatively, instead of solving the optimization model over a one-year time horizon, the model can only be solved for one month and then resolved 12 times to approximate the annual solution, similar to a rolling horizon strategy [20].

To evaluate the potential of operational RO clustering for complexity mitigation, this work solves the full energy-water model for two weeks at an hourly time scale

(336 hours), as well as for one month at an hourly time scale (730 hours). In both instances, the RO operation is successively restricted from the full dynamic model to a single operating point. Special attention is placed on how the solution times and objective function values change with increasing operational restriction. It is expected that in all cases  $Err_{obj} \leq 0$  since this clustering approach of the RO system can only provide upper bounds to the true optimal solution. For all cases an optimal solution and mixed-integer programming (MIP) gap of 0% is enforced.

As shown in Figure 6, the solution time decreases significantly with decreasing number of clusters for both cases. However, starting at 12 clusters for the 336 hour time scale and at 10 clusters for the 730 hour time scale no significant speed-ups in solution time can be observed. Moreover, for both cases,  $Err_{obj}$  is negligible over the complete cluster horizon as illustrated by a mean of  $-1.4215 \cdot 10^{-6}$  (standard deviation of  $2.3877 \cdot 10^{-7}$ ) and  $-1.4640 \cdot 10^{-4}$  (standard deviation of  $3.9754 \cdot 10^{-7}$ ), for the 2 week and the 1 month case study, respectively. These results suggest that there is a cluster threshold after which no speed-up in solution time and no significant changes in objective function value are expected, meaning there is an advantageous trade-off between operational flexibility (number of clusters), system solvability (solution time) and accuracy ( $Err_{obj}$ ). However, we can also deduct that collapsing a bi-weekly or monthly operation in a single operating point does not result in a significant loss of information ( $Err_{obj} < 1.4 \cdot 10^{-4}$ ). Therefore, it is suggested to evaluate how the solution of the full-time scale FEWN problem changes with increasing RO operational flexibility (yearly, monthly, bi-weekly, daily, every 12 hours). In this case the model was solved to an optimal solution and MIP gap of 0%.

**Table 1:** Results of solving the full-scale energy-water nexus supply model (8760 hours). Model size is specified according to the dimensions of the constraint matrix.

RO Operation	Clusters	Model Size	$Err_{obj}$
Yearly	1	[175331, 122778]	Basis
Monthly	12	[176310, 123801]	$3.925 \cdot 10^{-6} \%$
Bi-Weekly	24	[177378, 124917]	$7.860 \cdot 10^{-6} \%$
Daily	365	[207727, 156630]	$1.426 \cdot 10^{-5} \%$
12 hours	730	[240212, 190575]	$1.630 \cdot 10^{-5} \%$

Interestingly, the objective function value does not change for all practical purposes by allowing for more flexible operational RO decisions over one year, as shown in Table 1. In addition, the energy and water storage

schedules differ only insignificantly among obtained solutions. For all intents and purposes, the obtained optimal solutions are virtually identical. The solution times on the other hand vary from 250 seconds for the yearly case to 6400 seconds (around 2 hours) and even 53,000 seconds (more than 14 hours) for the daily and every 12 hours RO operational decision strategy, respectively. For the case study presented here, the RO clustering does not seem to have an impact on the overall solution accuracy. This novel analysis overall strengthened our confidence in the harsh sounding assumption of allowing only one RO operating point over one year to obtain a valid upper bound on the true optimal solution. However, this statement can only be generalized if the solution of the full-time scale FEWN model can be obtained, i.e. via decomposition strategies. It is expected that there exists a solution drop-off with an increasing number of clusters towards the full-time scale model. The obtained results can also aid in the convergence time of the full-scale optimization model by providing valid upper bounds to the problem which potentially shrinks the solution gap significantly depending on the quality of the lower bound.

## CONCLUSION

In this work, we revisited the FEWN problem statement by addressing data uncertainty and system complexity through the lens of a representative surrogate energy-water supply system. Sources of introduced data uncertainty and complexity mitigation errors have been discussed in detail. While it is difficult to quantify the introduced modeling and data uncertainty errors it is an essential task to maintain confidence in derived FEWN optimization frameworks and results. Implications of approximation and optimization methods for a RO water supply system have been discussed in detail, which has then been extended to an operational RO clustering approach to mitigate the computational complexity of the interconnected energy-water supply system optimization.

Policy makers and stakeholders are crucial in translating obtained PSE FEWN methodologies and results into real-world implementation. Being able to quantify a level of confidence one can have into proposed modeling strategies aids in this process. The proposed error quantification strategies can be leveraged to certify how much uncertainty in the obtained optimal solution is added with every data processing and modeling step. In turn, this uncertainty can be utilized to provide interpretable ranges of optimal results instead of single values, similar to confidence intervals, for transparent and effective decision-making across all levels.

## ABSTRACT

This paper considers the optimal incorporation of renewable ammonia production facilities into existing supply chain networks which import ammonia from conventional producers while accounting for uncertainty in this conventional ammonia price. We model the supply chain transition problem as a two-stage stochastic optimization problem which is formulated as a Mixed Integer Linear Programming problem. We apply the proposed approach to a case study on Minnesota's ammonia supply chain. We find that accounting for conventional price uncertainty leads to earlier incorporation of in-state renewable production sites in the supply chain network and a reduction in the quantity and cost of conventional ammonia imported over the supply chain transition horizon. These results show that local renewable ammonia production can act as a hedge against the volatility of the conventional ammonia market.

## INTRODUCTION

Ammonia is one of the most important industrial chemicals and serves as the backbone of modern agriculture in its use either directly or as a precursor to other nitrogen fertilizers. The standard production of ammonia is based on the Haber-Bosch process, which uses fossil fuels as the feedstock hydrogen source and operates at high pressure and temperature [1]. These facilities generally have capacities greater than 1,000,000 metric tons per year (mt/y) to take advantage of economies of scale [2]. This production paradigm leads to high transportation costs and carbon emissions in the operation of the supply chain because ammonia is transported through national and even global networks of ships, pipelines, rail, and trucks from a few production sites to the final customers [3].

The transition to a more sustainable supply chain network can be achieved by reducing the carbon emissions related to the manufacturing and distribution of ammonia. Renewable or green ammonia production recently has been the subject of extensive research and development as an alternative to the standard ammonia manufacturing paradigm [4]. In this approach, renewable

resources such as wind and solar are used to produce hydrogen via electrolysis and nitrogen via air separation, reducing the carbon intensity of producing ammonia. The Midwest region of the United States uses the most nitrogen fertilizer in the country while also being home to rich wind resources [5]. This gives rise to an opportunity to produce renewable ammonia closer to where it is used, thus reducing the cost and carbon intensity of ammonia distribution [6]. Producing ammonia using renewable energy also offers the potential for ammonia production cost stability. The feedstock renewable energy can have a close-to-constant price in this production setting, whether this energy is sourced through multi-year power purchase agreements (PPA) or the ammonia producer owns and operates the necessary renewable generation. In contrast, ammonia is currently traded on a global market and its price is subject to variability due to a number of factors including natural gas prices, food prices, and global conflict (see Figure 1). Given the transformative potential of renewable ammonia, achieving economical deployment through optimal design of manufacturing facilities and the supply chain network is of critical importance. In this work, we focus on the latter.

The transition of existing ammonia supply chain

networks to incorporate renewable production will likely occur over multiple years and will be affected by multiple sources of uncertainty. Identifying optimal investment decisions over a fixed planning horizon is a widely studied problem in process systems engineering and operations research and is formally known as the capacity expansion problem [7]. However, the application of the capacity expansion formalism to the transition of ammonia supply chain networks is rather limited. Recently, we have proposed a multiperiod deterministic capacity expansion model that considers the optimal transition of ammonia supply chain networks [8]. The model optimizes the investment decisions regarding the installation year and capacity, such that the overall net present cost is minimized while ammonia fertilizer demand is satisfied.

**Figure 1.** U.S. Gulf Coast ammonia price from 2010 to 2022 [9].

In this work, we consider the effect of uncertainty on the optimal transition of existing ammonia supply chain networks. The primary sources of uncertainty in an ammonia supply chain are the ammonia demand and the market price of ammonia. Although the demand for ammonia can be predicted from total fertilizer demand estimates, the ammonia price is more volatile. Accounting for the significant price variability and uncertainty is essential for the optimal expansion of existing supply chain networks.

We propose a two-stage stochastic programming approach where the uncertainty in price is accounted for in the form of scenarios [10,11]. Such a conceptual approach has been previously employed in supply chain optimization models in a number of different industries, for example, waste-to-bioethanol [12], biodiesel production from wastewater treatment byproducts [13], and coal-to-liquids [14]. In our model, the installation decisions (the location, capacity, and construction year for new renewable ammonia manufacturing facilities) are the first stage decisions, and the distribution of ammonia from the installed renewable sites and the conventional producers

to the customers for the different ammonia prices (scenarios) are the second stage decisions. We consider a case study on Minnesota’s ammonia supply chain network. The results show that accounting for uncertainty in the price of ammonia, especially high prices, requires investments earlier in the planning horizon, compared to assuming a nominal price. Furthermore, we simulate the supply chain obtained from the deterministic and stochastic models, and we find that for high ammonia prices, the design obtained via stochastic programming results in lower net present costs. These results highlight the ability of locally-produced renewable ammonia to act as a hedge against high prices on the conventional ammonia market. The rest of the paper is organized as follows: First, we present the two-stage stochastic optimization model, then we present the case study and, finally, the numerical results.

## TWO-STAGE STOCHASTIC OPTIMIZATION MODEL

We consider an existing supply chain network that delivers ammonia to a set of counties  $\mathcal{C} = \{1, \dots, C\}$  via distribution centers  $\mathcal{D} = \{1, \dots, D\}$ . In the original network, the demand  $\delta_c$  at each county is satisfied by purchasing ammonia from conventional producers  $\mathcal{P} = \{1, \dots, P\}$  with price  $\alpha_p$ . Given a set of candidate locations for renewable ammonia production facilities  $\mathcal{R} = \{1, \dots, R\}$ , the goal is to find the optimal investment decisions over a planning horizon  $\mathcal{K}$ , such that the total net present cost of the supply chain is minimized, demands are met for each period of the planning horizon, and at the end of the horizon the entire demand is satisfied using renewable ammonia. We assume that the capacity investment decisions are made annually and the planning horizon  $\mathcal{K}$  is discretized into  $K$  time periods. We define variable  $x_{rk}$  as the capacity installed at candidate renewable site  $r$  at time period  $k$ , and binary variable  $z_{rk}$  which is equal to one if an investment is made at candidate site  $r$  at time period  $k$  and zero otherwise. We assume that the only uncertain parameter is the price of ammonia imported from conventional producers. We model the renewable ammonia production investment decisions, specifically the time period when an investment is made  $z_{rk}$  and the production capacity  $x_{rk}$  at a given candidate location  $r$ , as first-stage decisions. The amount of ammonia sent to each county through a combination of purchases from conventional producers routed through distribution centers and from new renewable production facilities are the second stage decisions. We follow a scenario-based formulation and define the set  $\mathcal{S} = \{1, \dots, S\}$  which represents the scenarios of the price of ammonia, where each scenario has probability  $p_s$ , and the price of ammonia for producer  $p$  and scenario  $s$  is  $\alpha_{ps}$ .

Given this problem setting, first, we define

constraints related to the maximum and minimum capacity that can be installed in each location and time period by the following constraints

$$x_{rk} \leq \bar{x}^U z_{rk} \quad \forall r \in \mathcal{R}, k \in \mathcal{K} \quad (1)$$

$$x_{rk} \geq \bar{x}^L z_{rk} \quad \forall r \in \mathcal{R}, k \in \mathcal{K}, \quad (2)$$

where  $\bar{x}^U, \bar{x}^L$  are the upper and lower bounds on the size of renewable sites. Each renewable candidate site has a certain wind capacity  $\Omega_r$ , electrolysis capacity  $\Omega_{k_i}$ , and a construction period of two years, which constrain the maximum capacity that can be installed and the time that the capacity is available as follows

$$\sum_{k'=1}^k x_{rk'} \omega_{rk'} \leq \Omega_r \quad \forall r \in \mathcal{R}, k \in \mathcal{K} \quad (3)$$

$$\sum_{r \in \mathcal{R}} x_{rk} \xi_{rk} \leq \Xi_k \quad \forall k \in \mathcal{K}. \quad (4)$$

We define variable  $y_{pdks}$  as the amount of ammonia purchased from conventional producer  $p$  and shipped to distribution center  $d$  at time period  $k$  and scenario  $s$ . We also define variable  $y_{dcks}$  as the amount of ammonia shipped from distribution center  $d$  to county  $c$  at time period  $k$  and scenario  $s$ , and the amount of ammonia shipped from the renewable site  $r$  to county  $c$  at time period  $k$  and scenario  $s$  is  $y_{rcks}$ . The demand satisfaction constraints are

$$\sum_{r \in \mathcal{R}} y_{rcks} + \sum_{d \in \mathcal{D}} y_{dcks} \geq \delta_{ck} \quad \forall s \in \mathcal{S}, c \in \mathcal{C}, k \in \mathcal{K} \quad (5)$$

$$\sum_{p \in \mathcal{P}} y_{pdks} \geq \sum_{c \in \mathcal{C}} y_{dcks} \quad \forall s \in \mathcal{S}, d \in \mathcal{D}, k \in \mathcal{K} \quad (6)$$

$$\sum_{d \in \mathcal{D}} y_{pdks} \leq \Lambda_p \quad \forall s \in \mathcal{S}, p \in \mathcal{P}, k \in \mathcal{K} \quad (7)$$

$$\sum_{c \in \mathcal{C}} y_{rcks} \leq \sum_{k'=1}^{k-2} x_{rk'} \quad \forall s \in \mathcal{S}, r \in \mathcal{R}, k \in \mathcal{K} \quad (8)$$

$$\sum_{p \in \mathcal{P}} \sum_{d \in \mathcal{D}} y_{pdks} = 0 \quad \forall s \in \mathcal{S}. \quad (9)$$

The objective function is the net present cost of the supply chain transition over the planning horizon. It can be partitioned into two terms. The first term,  $Z_k$ , is the sum of the capital  $CAP_k$  and operating costs  $OP_k$  which depends only on the first-stage decisions, and are computed as follows

$$CAP_k = \frac{1}{\theta} \sum_{r \in \mathcal{R}} \sum_{k'=1}^k x_{rk'} \sigma_{rk'} + z_{rk'} \gamma_{rk'} \quad (10)$$

$$OP_k = \sum_{r \in \mathcal{R}} \sum_{k'=1}^k x_{rk'} \zeta_{rk'}. \quad (11)$$

The capital cost of a renewable production facility is modeled as a piece-wise affine function of the installed capacity, with slope  $\sigma_{rk}$  and intercept  $\gamma_{rk}$ , to capture the effect of economies of scale. These parameters vary with both renewable site  $r$  and time period  $k$  to capture the effects of varying renewable potential and expected technology cost reductions respectively. The capital cost is annualized using scaled plant lifetime  $\theta$  which is equal to  $10.23 \text{ y}^{-1}$ . The operating cost is assumed to scale linearly with the installed capacity with proportionality constant  $\zeta_{rk}$ . This parameter is assumed to remain constant after installation and also varies with renewable site and

period to capture the effects described above.

The second term in the objective,  $\bar{Z}_{ks}$ , is the sum of the distribution of renewable ammonia  $DR_{ks}$ , transportation of ammonia from the conventional producers to the distribution centers  $TC_{ks}$ , and distribution of conventional ammonia  $DC_{ks}$ . The individual costs are equal to

$$DP_{ks} = \sum_{r \in \mathcal{R}} \sum_{c \in \mathcal{C}} y_{rcks} \tau_{rc} \quad \forall k \in \mathcal{K}, s \in \mathcal{S} \quad (12)$$

$$PC_{ks} = \sum_{p \in \mathcal{P}} \sum_{d \in \mathcal{D}} y_{pdks} \alpha_{ps} \quad \forall k \in \mathcal{K}, s \in \mathcal{S} \quad (13)$$

$$TC_{ks} = \sum_{p \in \mathcal{P}} \sum_{d \in \mathcal{D}} y_{pdks} \tau_{pd} \quad \forall k \in \mathcal{K}, s \in \mathcal{S} \quad (14)$$

$$DC_{ks} = \sum_{d \in \mathcal{D}} \sum_{c \in \mathcal{C}} y_{dcks} \tau_{dc} \quad \forall k \in \mathcal{K}, s \in \mathcal{S} \quad (15)$$

$$Z_k = CAP_k + OP_k \quad \forall k \in \mathcal{K} \quad (16)$$

$$\bar{Z}_{ks} = DC_{ks} + PC_{ks} + TC_{ks} + DP_{ks} \quad \forall k \in \mathcal{K}, s \in \mathcal{S}. \quad (17)$$

The two-stage optimization problem is

$$\begin{aligned} \min & \sum_{k \in \mathcal{K}} \phi_k Z_k + \sum_{s \in \mathcal{S}} \rho_s (\sum_{k \in \mathcal{K}} \phi_k \bar{Z}_{ks}) \\ \text{s. t.} & \text{Eq. 1 - 9} \end{aligned} \quad (18)$$

$$x_{rk} \geq 0, z_{rk} \in \{0,1\}$$

$$y_{rcks} \geq 0, y_{dcks} \geq 0, y_{pdks} \geq 0$$

The parameter  $\phi_k$  is the discounted value of cost contributions in time period  $k$ .

## CASE STUDY

We herein provide a concise description of the case study on Minnesota's ammonia supply chain. For a more detailed case study description, please refer to our previous work [8]. We consider a supply chain planning horizon from 2024 to 2032. We consider an 8.5% discount rate as it pertains to cost flows beyond 2024. Minnesota has 82 counties in which ammonia demand must be met for each period of the supply chain transition optimization. In 2024, the total ammonia demand assumed to be 795,000 mt/y and this is assumed to increase by 0.5% per year. This ammonia can be purchased from 10 conventional producers which are located outside of Minnesota. The average conventional ammonia price from 2010 to 2022 was \$500/mt. Ammonia purchased from these producers is routed through one of three distribution centers in Minnesota. Conventional producers located further from Minnesota have higher associated costs to transport ammonia to a given distribution center. Producer-to-distribution transportation costs range from \$59/mt to \$141/mt, while distribution center-to-county transportation costs range from \$1/mt to \$36/mt.

We consider 26 candidate locations for new in-state renewable ammonia production. Capital costs of a given facility are incurred two years before renewable production begins to represent a two year construction period. The operating cost includes renewable power purchases from PPAs with wind generators assumed to be co-

located with the renewable ammonia production facility. The operating cost also includes revenue from hydrogen production tax credits (PTCs) contained in the U.S. federal government Inflation Reduction Act [15]. These credits provide \$3/kg of hydrogen produced for the first 10 years of facility operation. Renewable ammonia is assumed to be transported from new production facilities directly to counties. These transportation costs range from \$1/mt to \$47/mt. The capacity of each new renewable ammonia facility is constrained to a maximum associated wind generation capacity of 250 MW (Eq. 3). The total installed capacity of renewable ammonia production across all facilities in a given year is constrained by electrolysis availability, which increases from 250 MW in 2024 to 850 MW in 2032 (Eq. 4). The optimization model is implemented in Pyomo [16] and is solved using Gurobi 10.0.2.0 [17] on an Apple MacBook Pro M1 with 8 physical cores and 16 GB of RAM.

## NUMERICAL RESULTS

### Deterministic case

First, we solve a deterministic model using a \$500/mt historical average conventional ammonia price, i.e., using the two-stage model with one scenario with probability one and price \$500/mt. The optimization problem has 22,194 (234 binary and 21960 continuous) variables, 1,803 constraints and is solved in 6.7 seconds. The total net present cost is \$3,002 million (MM) and renewable ammonia production is installed at eight new sites, as presented in Table 1. Three renewable ammonia facilities are installed in 2027, meaning that in-state production does not begin until 2029 and all ammonia is purchased from the conventional market for the first five years of the planning horizon (see Figure 3).

**Table 1:** Installation year, location, and capacity for new renewable ammonia production in the deterministic case. Annual average wind capacity factors for each selected candidate location are provided in parentheses to describe wind potential.

Year	Location	Capacity (1,000 mt/y)
2027	Lake Wilson (52%)	121.4
2027	Chandler (52%)	121.4
2027	Worthington (52%)	55.2
2028	Luverne (52%)	121.2
2028	Wilmont (52%)	110.4
2028	Worthington (52%)	66.0
2030	Blue Earth (47%)	116.1
2030	Winnebago (47%)	114.8

Three additional facilities are installed in 2028. These first six facilities are all located in Southwest

Minnesota, which has the highest wind capacity factors at 52%. In both 2027 and 2028, 575 MW of electrolysis is procured, the maximum allowable amount in each year. This is the reason that two smaller facilities are installed in Worthington in consecutive years. The final facilities are installed in 2030 to ensure that all ammonia is obtained via renewable production by 2032. These are both installed in Southeast Minnesota, which also has a high wind capacity factor at 47%. With the exception of the two smaller facilities in Worthington, all others use at least 225 MW of co-located wind generation in an attempt to achieve economies of scale.

### Stochastic case

We use the data presented in Figure 1 and generate the histogram presented in Figure 2 using ten bins, and obtain the price at the edge of each bin and the number of data points in each bin. Given these data, we generate the scenarios where the price of ammonia in scenario  $s$  is set equal to the edge price in the bin  $s$  and the probability  $p_s$  is the number of data points in the bin  $s$  divided by the total number of data points.

**Figure 2.** Histogram of U.S. Gulf Coast ammonia prices from 2010 to 2022. The width of each histogram bin is \$117.5/mt. In the stochastic optimization model, the probability of the conventional ammonia price being within each bin is listed above that bin.

The optimization problem has 217,566 (234 binary and 217332 continuous) variables, 11,927 constraints, and the solution time is 78 seconds. The total net present cost is \$3,230MM and the renewable sites installed are presented in Table 2. As with the optimal solution of the deterministic model, eight new renewable production facilities are installed. However, these installations occur earlier in the optimal stochastic supply chain transition.

One new facility each is installed in 2024 and 2025, which allows some market penetration of renewable ammonia by 2026 (see Figure 3). Both of these facilities are

installed in locations with the highest wind potential and use the maximum allowable 250 MW of co-located wind generation capacity. In 2027, three additional facilities are added and these cumulatively use 575 MW of electrolysis, the upper bound for that year. The facilities in both Luverne and Worthington use 250 MW of wind generation. We point out that these facilities have slightly higher production capacity than those in Lake Wilson (2024) and Chandler (2025) due to the more efficient electrolysis expected to be available in future years. The third 2027 facility is located in Southeast Minnesota despite its lower wind potential, unlike in the deterministic supply chain. This enables another facility which uses 250 MW wind to be installed in Wilmont in 2028; all five facilities with the highest wind potential (52% capacity factor) use this maximum amount of wind capacity to achieve economies of scale. Another facility is installed in Southeast Minnesota in 2028, also at the 2050 MW scale. Finally, a smaller facility is installed in Southeast Minnesota in 2030 to ensure a fully renewable supply chain by 2032.

**Table 2:** Installation year, location, and capacity for new renewable ammonia production in the two-stage stochastic case. Annual average wind capacity factors for each selected candidate location are provided in parentheses to describe wind potential.

Year	Location	Capacity (1,000 mt/y)
2024	Lake Wilson (52%)	117.7
2025	Chandler (52%)	117.7
2027	Luverne (52%)	121.14
2027	Worthington (52%)	121.14
2027	Winnebago (47%)	50.71
2028	Wilmont (52%)	121.24
2028	Blue Earth (47%)	111.11
2030	Fairmont (47%)	65.34

### Comparison between deterministic and stochastic cases

The optimal transition in the stochastic case results in less conventional ammonia purchases and more in-state renewable production over the planning horizon compared to the deterministic transition. This difference leads to a reduction in the total amount of ammonia purchased leading to lower cumulative purchase, transportation, and distribution costs for conventional ammonia over the planning horizon (see Figure 4). Conversely, the capital cost for renewable ammonia production is higher in the stochastic transition even though the same total capacity of renewable production is installed in both cases. This is due to earlier installation using more expensive constituent technologies in the stochastic case.

This also contributes to higher renewable ammonia operating costs over the planning horizon, though these are also higher simply because more renewable ammonia is being produced. Overall, the net present cost of the supply chain transition is 7.6% (228 MM\$) higher in the stochastic case than the deterministic case.

**Figure 3.** Amount of ammonia (mt) in each time period from conventional purchases (black bar) and in-state renewable ammonia production (gray bar) for the deterministic (top figure) and stochastic (bottom figure) cases.

**Figure 4.** Cost contributions to optimal net present cost for the deterministic and stochastic cases. The cost acronyms are defined as follows: CAP - Renewable capital, OP - Renewable operating, DR - Renewable distribution, PC - Conventional purchase, TC - Conventional transportation to Minnesota, DC - Conventional distribution.

We compare the supply chain configurations obtained via the deterministic and stochastic transition optimizations for different conventional ammonia prices to

elucidate the benefit of the stochastic approach. Specifically, we discretize the ammonia price uniformly in 100 points between \$214/mt and \$1389/mt, and for each price, we fix the investment decisions (timing of investments, i.e., binary variables and installed capacity) and compute the net present cost of supply chain transition (see Figure 5). We observe that for high prices of conventional ammonia (above \$700/mt), the net present cost of the supply chain obtained via stochastic programming is meaningfully lower than the cost of the deterministic design, whereas if the price is low (below \$400/mt) the design obtained by the deterministic model has a meaningfully lower net present cost. This difference can be attributed to the different investment strategies for the stochastic and deterministic cases (i.e., more ammonia is manufactured in-state for the stochastic case) as discussed in the previous paragraph.

**Figure 5.** Levelized cost for the deterministic and stochastic design as a function of ammonia price.

## CONCLUSIONS

In this work, we focused on quantifying the effect of uncertainty in conventional ammonia prices on Minnesota's transition from importing fossil-derived ammonia from out-of-state conventional producers to in-state renewable ammonia production. We used a two-stage stochastic programming approach to determine the optimal investment profile for in-state renewable ammonia production over a fixed planning horizon such that the demand of ammonia is satisfied while the net present cost is minimized. The results show that when accounting for uncertainty in the conventional ammonia price, investments are made earlier in the planning horizon compared to a deterministic supply chain transition model. This leads to a reduction in the amount of ammonia purchased from conventional producers. This can bring significant cost savings for higher-than-average ammonia prices. Overall, the stable production cost afforded by in-state

renewable ammonia production can act as a hedge against conventional ammonia price uncertainty and the possibility of very high prices on the conventional ammonia market.

This work used a two-stage approach to account for conventional price uncertainty, but in practice these prices could evolve different multi-year trajectories. Future work will therefore develop multi-stage stochastic programming models for the supply chain transition problem. Furthermore, technology cost reductions are also subject to uncertainty, especially further into a given planning horizon. For example, electrolysis costs are expected to decrease, but the magnitude of this reduction is not well-established at present. Thus, these types of uncertainties will also be incorporated into future supply chain transition models.

## ABSTRACT

Multilayer plastic films are widely used in packaging applications because of their unique properties. These materials combine several layers of different polymers to protect food and pharmaceuticals from external factors such as oxygen, water, temperature, and light. Unfortunately, this design complexity also hinders the use of traditional recycling methods, such as mechanical recycling. Solvent-based separation processes are a promising alternative to recover high-quality pure polymers from multilayer film waste. One such process is the Solvent-Targeted Recovery and Precipitation (STRAP™) process, which uses sequential solvent washes to selectively dissolve and separate the constituent components of multilayer films. The STRAP™ process design (separation sequence, solvents, operating conditions) changes significantly depending on the design of the multilayer film (the number of layers and types of polymers). Quantifying the economic and environmental benefits of alternative process designs is essential to provide insights into sustainable recycling and film (product) design. In this work, we present a fast computational framework that integrates molecular-scale models, process modeling, techno-economic and life-cycle analysis to evaluate STRAP™ designs. The computational framework is general and can be used for complex multilayer films or multicomponent plastic waste streams. We apply the proposed framework to a multilayer film commonly used in industrial food packaging. We identify process design configurations with the lowest economic and environmental impact. Our analysis reveals trends that can help guide process and product design.

**Keywords:** Polymers, Process Design, Modelling and Simulations, Technoeconomic Analysis, Life Cycle Analysis

## INTRODUCTION

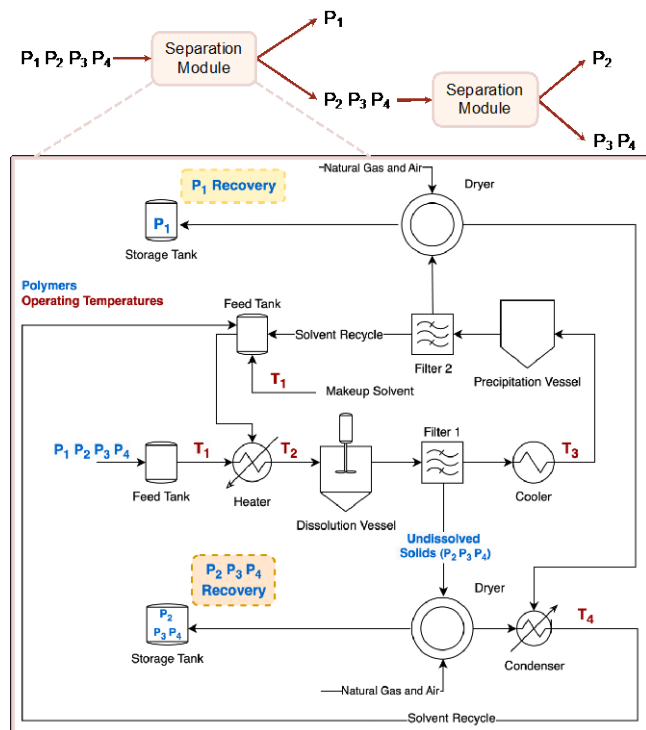

A wide range of packaging applications use multilayer plastic films to protect products from external factors (e.g., oxygen, water, temperature, and light). Multilayer films are complex and diverse because they combine several layers of distinct polymers to leverage their unique properties. The multilayer film design can vary for different applications; for instance, industrial films can include more than ten polymer layers. This complexity hinders direct mechanical recycling. Solvent-based approaches have emerged as a promising alternative to recover and recycle their constituent polymers. One such technology is the Solvent-Targeted Recovery and Precipitation (STRAP™) process, which uses sequential

solvent washes to selectively dissolve and separate the constituent components of multilayer plastic films [1]. The solvents used need to be properly selected to dissolve only a target component in each step. Thus, each selected solvent must have a high solubility for the target component and a low solubility for the other components of the multilayer film. This target component can refer to one or multiple polymers [2].

Molecular-scale models have been employed to predict polymer solubilities for solvent selections in such recycling processes. We recently introduced a joint computational and experimental workflow that can perform large-scale temperature-dependent polymer solubility predictions. Based on this approach, we generated a solubility database for common polymers and a large

number of solvents [3]. The database has enabled the creation of a computational tool that automates solvent selections for solvent-based processes. This tool can screen and rank solvent candidates based on the solubility requirements of separation sequences. Once the solvent for the target component is selected, the next steps of the STRAP™ process can be taken as described below.

**Figure 1** provides an example of the modules and process flow diagram that we use to represent the separation of different components using the STRAP™ process. For instance, for a multilayer film of 4 components, the first component can be separated as shown in the process flow diagram. In this example, each component comprises one polymer. The process steps are as follows: first, the multilayer film is mixed with a previously chosen solvent (that selectively dissolves only the target polymer  $P_1$ ) and heated; next, the solution is filtered to separate the undissolved solids (polymers  $P_2, P_3, P_4$ ); finally, the target polymer  $P_1$  is precipitated via temperature reduction, filtered, and recovered. Most of the solvent is also recovered and recycled. Then, the process is repeated to separate the remaining components (polymers  $P_2, P_3, P_4$ ). Hence, the separation of an  $n$ -component multilayer film requires  $n-1$  separation stage(s).

**Figure 1.** Simplified flow diagram of the STRAP™ process for one separation module.

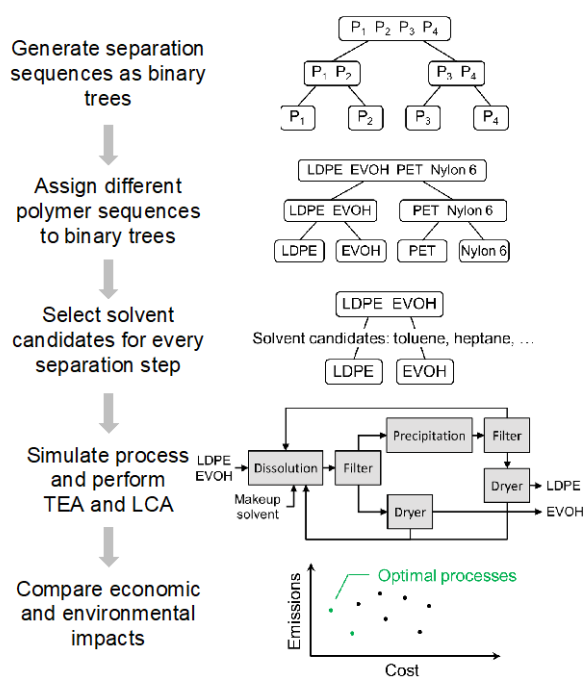

A couple of precipitation techniques have been previously reported [2]. One is temperature-driven

precipitation, which is economically and environmentally feasible and can be used for several polymer-solvent combinations. If the precipitation cannot be done via temperature, an antisolvent can be added to enable precipitation. However, adding an antisolvent leads to higher energy requirements because a distillation unit is required to separate the resulting mixture of solvents. Previous research has shown that the economic and environmental performance of the process is better when the precipitation is temperature-driven [4]. Therefore, in this work, we will select solvents that can enable temperature-driven precipitation only. It is worth highlighting that the solvent and operating temperatures can change if the separation sequence changes (for example, with  $P_2$  as the target polymer). These changes can impact the economic and environmental benefits of the process. Additionally, identifying the proper conditions to achieve a high solvent recovery rate is key for the process benefits. Previous techno-economic analysis (TEA) and life cycle assessment (LCA) of the different STRAP™ process variations have also shown significant differences in costs and  $\text{CO}_2$  emissions due to solvent selection and separation sequence [5,6]. While these models have been useful to determine the economic and environmental feasibility as well as process design bottlenecks, they have also shown the need for a general framework to guide the design of solvent-based processes.

In this work, we present a fast computational framework that integrates molecular-scale models, process modeling, TEA and LCA to provide insights into sustainable solvent-based process design. We also aim to provide guidelines for multilayer film designs that are easier to recycle or have a lower recycling impact. This framework can determine the economic and environmental impacts of several process design scenarios, including different separation sequences, solvents that enable temperature-driven precipitation, and process operating conditions (for dissolution, precipitation, and solvent recovery). The computational framework is general and can be used for complex multilayer films or multicomponent plastic waste streams.

## COMPUTATIONAL FRAMEWORK

Our computational framework follows a series of steps to determine the economic and environmental impacts of each process design feasible scenario. The computational steps are summarized in **Figure 2**.

**Figure 2.** Schematic representation of the proposed framework.

First, for any given multilayer film, the framework generates all possible separation sequences. **Figure 3** provides an example of the binary trees that we use to represent the separation sequences for a multilayer film composed of 4 polymers. Here, we use the left branch to denote the dissolved polymer(s) and the right branch to refer to the undissolved polymer(s). For this example, we can see that every separation step only dissolves one polymer. Therefore, this example has a  $D^n = 1$ , which represents the number of polymers being dissolved in each step. Also, this binary tree only shows such separation sequence. Changing the separation order of the sequence provides all possibilities for the case of  $D^n = 1$ . Therefore, the permutation of the set of polymers  $\{P_1, P_2, P_3, P_4\}$  results in 24 different sequences.

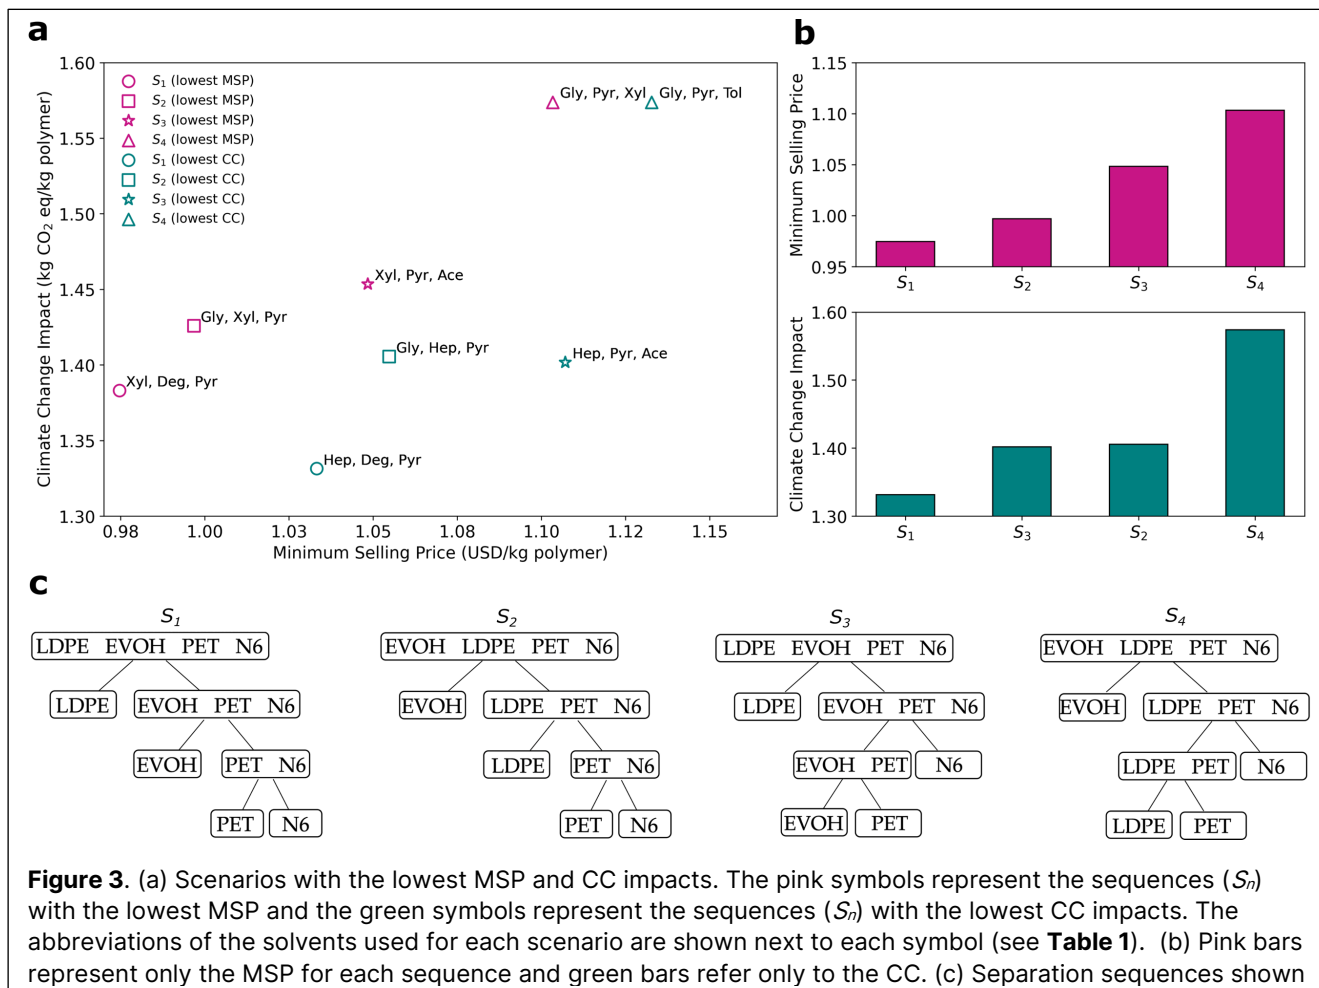

**Figure 3.** Binary tree illustrating a possible separation sequence for a multilayer film composed of 4 polymers.

To determine all the possible sequences, we also consider the binary trees where 2 polymers are dissolved in a certain step ( $D^n = 2$ ), resulting in 2 different binary trees and 48 sequences. Similarly, when there are 3 polymers dissolved together, 2 different binary trees and 48 sequences are possible. Therefore, the separation of a 4-polymer mixture has in total 5 possible binary tree structures, which correspond to 120 sequences. **Table 1** presents a summary of the number of sequences and binary trees generated based on the value of  $D^n$  for the 4-polymer mixture. It is worth highlighting that this combinatorial complexity increases rapidly with the number of polymers. For example, a 5-polymer mixture will have 14 different binary tree structures, which leads to 1680 possible sequences.

**Table 1:** Possible binary trees and sequences for a 4-polymer mixture considering the different possible numbers of dissolved polymers in a certain step ( $D^n$ ).

$D^n$	Binary Trees	Sequences
1	1	24
2	2	48
3	2	48

As shown in **Figure 2**, the next step is to assign different polymer sequences to the binary trees and eliminate the unfeasible sequences based on empirical rules from previous research (e.g., composition, polymer solubility, and maximum number of polymers dissolved in each step) [3-6]. After this, we use the computational tool to identify all the solvent candidates for the target polymer(s) in each separation step. This tool selects solvents (only based on solubility) from the previously reported database that includes predicted temperature-dependent polymer solubilities from molecular-scale models [3]. The criteria to select the feasible solvents is that the solubility of the target polymer(s) should be greater than 15 wt% and the solubility of the non-target polymer(s) should be lower than 3 wt%. Once the solvents have been identified, we estimate the required temperature of the condenser to achieve a high solvent recovery rate (~99.90%) given the inlet temperature from the dryer. Previous studies indicate that achieving a solvent recovery of ~99.99% enhances the economic viability of the separation process. However, solvents with low boiling points, such as toluene, pyridine, and acetic acid, face challenges in attaining this recovery rate. In contrast, solvents like glycol, dodecane, and diethylene glycol can achieve this target. It is equally essential to avoid solvents with high boiling points, as they can escalate the energy consumption in the distillation process during solvent mixture recovery (which occurs in precipitation via antisolvent addition). Therefore, the solvent recovery is

**Figure 3.** (a) Scenarios with the lowest MSP and CC impacts. The pink symbols represent the sequences ( $S_n$ ) with the lowest MSP and the green symbols represent the sequences ( $S_n$ ) with the lowest CC impacts. The abbreviations of the solvents used for each scenario are shown next to each symbol (see **Table 1**). (b) Pink bars represent only the MSP for each sequence and green bars refer only to the CC. (c) Separation sequences shown

set at ~99.90%, and future considerations will include evaluating the trade-offs associated with each solvent. The condenser temperature is estimated by simulating a heat exchanger and iterating over different temperatures to achieve the recovery rate specification as a pre-process simulation. The process model simulation for the heat exchanger is performed in the open-source platform BioSTEAM [7]. This Python process simulator has been validated against proprietary software (SuperPro Designer and Aspen Plus).

Next, we use the collected inputs (mass, polymers, composition, separation sequence, solvent, and operating conditions) to simulate the STRAP™ process and perform the TEA in BioSTEAM. We use the minimum selling price (MSP) as the economic metric to compare different scenarios. After this, we evaluate the environmental impact of each scenario using an LCA methodology. The LCA was performed using the open-source software openLCA [8], the Environmental Footprint and AGRIBALYSE databases and the Environmental footprint impact assessment method [9,10]. We consider all the inputs to the process (electricity, steam, water) and we estimate the climate change (CC) impact for each scenario. Since there are limited data for solvents in the LCA

databases and we are considering high recycling rates, we do not include the impact of solvents for this analysis. Finally, we store the economic (MSP, expressed in USD per kg of polymer sold) and environmental (CC impact, expressed in kg CO<sub>2</sub> per kg of polymer) outputs of all feasible process design scenarios (including different sequences and solvents).

## RESULTS AND DISCUSSION

We applied the proposed computational framework to a multilayer film composed of LDPE, EVOH, PET, and Nylon 6 (N6). This 4-polymer multilayer film is commonly used for food packaging applications [11]. As mentioned above, there are 120 possible sequences for a 4-polymer mixture.

To identify the sequences and solvents that lead to the best economic and environmental performance, we compare the MSP and CC impact of all the generated scenarios. We consider all the separation modules required to recover the 4 constituent polymers of the multilayer film using the STRAP™ process. As a benchmark, we also estimate the climate change impact of producing the 4 polymers from fossil sources and their average

market prices.

First, we identify the solvents that lead to the lowest MSP in each separation step of the different generated sequences and report the corresponding CC impact of these sequence-solvent combinations. Similarly, we identify the solvents that lead to the lowest CC impact and their corresponding MSP. **Figure 3a** presents the scenarios with the lowest MSP (pink symbols) and the lowest CC impact (green symbols). It should be noticed that each symbol refers to a different sequence (represented by  $S_i$ ) and set of solvents used for all the required separation modules. Solvents are represented by an abbreviation which is related to the solvent common name in **Table 2**. From **Figure 3a**, we can see that there are trade-offs between the economic and environmental metrics. For instance, the sequence  $S_7$  with the set of solvents p-Xylene, Diethylene glycol and Pyridine (represented by the pink circle) leads to the lowest MSP (0.97 USD/kg), but it does not lead to the lowest CC impact. On the other hand, the sequence  $S_7$  with the set of solvents n-heptane, Diethylene glycol and Pyridine (represented by the green circle) leads to the lowest CC impact (1.33 kg CO<sub>2</sub>/kg) but leads to a higher MSP.

We compare these results with previous STRAP<sup>TM</sup> studies to show the viability of the proposed framework. A TEA [2] and an LCA [4] for a similar multilayer film composed of LDPE, EVOH, PET, and EVA are used as references. Here, the sequence used was similar to sequence  $S_7$  and was demonstrated experimentally. We find that the reported MSP is 1.1 USD/kg and the CC is 1.18 kg CO<sub>2</sub>/kg. Although the polymers, composition, and solvents used are not equal to the multilayer film addressed in this study, we can see that the economic and environmental impacts are similar which highlights the applicability of the proposed framework. Future work will include evaluating the previously reported multilayer film (LDPE, EVOH, PET, and EVA) with our framework to identify other feasible sequences and solvents that could be tested experimentally. **Figure 3b** provides a summary of the MSP (pink bars) and CC impact (green bars) for each sequence. To compare these values to the price and climate change impact of virgin polymers we consider the following. As a reference, we find that the average market prices of the recovered polymers are 1.2–2.6 USD/kg. Furthermore, the multilayer film addressed in this study has a market price of 2.9 USD/kg [11, 12]. From previous research, we know the range of the required scale to achieve an MSP comparable to these market prices [5]. Therefore, the results presented in this work were obtained for a fixed plant capacity of 6,400 tons per year. As we can see in **Figure 3b**, the MSP of the recovered polymers is comparable to the average market prices. However, this trend is sensitive to the scale of the process and can change with other capacity factors.

**Table 2:** Common name of selected solvents for the scenarios with the lowest impacts.

Solvent Abbreviation	Solvent Common Name
Ace	Acetic acid
Deg	Diethylene glycol
Gly	Glycol
Hep	n-heptane
Xyl	p-Xylene
Pyr	Pyridine
Tol	Toluene

Regarding the environmental impact of virgin polymers, we estimate the CC impact of the production from fossil sources of the constituent polymers of the multilayer film considered in this work (LDPE, EVOH, PET, and N6). Considering that every polymer represents 25 wt% of the film, we find that 4.81 kg CO<sub>2</sub> per kg of polymer are generated. From **Figure 3b**, we can see that all the different STRAP<sup>TM</sup> sequences have a lower CC impact. Specifically, sequence  $S_7$  results in around 60% fewer emissions than the production of the multilayer film from fossil sources.

**Figure 3c** presents the different sequences as binary trees showing the dissolved polymers in each separation step (left branch). From the MSP and CC plots, we observe that sequence  $S_7$  results in the lowest economic and environmental impacts. This sequence refers to dissolving one polymer in each separation step in the following order: LDPE, EVOH, PET, and N6. However, the set of solvents that lead to the lowest MSP and CC are different for each sequence. There are different factors that determine if one sequence and solvent is better for the economic or environmental metrics, such as the amount of required solvent (which is determined by the polymer solubility) and the thermodynamic properties of the solvents. This first analysis provides initial suggestions of the key variables that impact the economic and environmental performance. For instance, the dissolution temperature is dependent on the boiling point of solvents. Therefore, solvents with low boiling points result in lower energy requirements and environmental impacts. On the other hand, we found that the solvents that require a lower polymer-solvent ratio (due to higher solubility) were selected for the scenarios with the best economic performance. Such solvents had a higher boiling point.

## CONCLUSIONS AND FUTURE WORK

This work presented a fast computational framework to provide insights into the STRAP<sup>TM</sup> process design. The proposed framework helps identify the separation sequence, solvents, and process operating

conditions with the lowest economic and environmental impact. We use the framework to identify process designs with low impacts for a multilayer film composed of 4 polymers. From these results, we conclude that the environmental performance is mainly driven by the boiling point of solvents while the economic performance is guided by the polymer solubility. Our framework is general and can help guide the design of other solvent-based processes to efficiently treat complex multilayer waste streams. Therefore, future work will include analyzing case studies with different polymers and number of layers. Furthermore, we will consider varying recycling rates for the solvents. We will also evaluate other processing plant scales and the recovery of only selected polymers (for streams with large number of polymers).

## ABSTRACT

Plastic packaging plays a fundamental role in the food industry, avoiding food waste and facilitating food access. The increasing plastic production and the lack of appropriate plastic waste management technologies represent a threat to the environmental and human welfare. Therefore, there is an urgent need to identify sustainable packaging solutions. Circular economy (CE) promotes reducing waste and increasing recycling practices to achieve sustainability. In this work, we propose a CE framework based on multi-objective optimization, considering both economic and environmental impacts, to identify optimal packaging designs and waste management technologies. Using mixed-integer linear programming (MILP), techno-economic analysis (TEA), and life cycle assessment (LCA), this work aims to build the first steps in packaging design, informing about the best packaging alternatives and the optimal technology or technologies to process packaging waste. For the economic analysis, we consider the minimum increase in price (MIP) when adding recycling to the cost of each packaging solution, while for the environmental analysis, the greenhouse gas emissions impact was considered. A case study on ground coffee packaging is used to illustrate the proposed framework. The results demonstrate that the multilayer bag option is the most convenient when considering both the chosen economic and environmental impacts.

**Keywords:** Optimization, Life Cycle Analysis, Technoeconomic Analysis, Supply Chain, Modelling

## INTRODUCTION

Approximately 35-40% of plastics produced are discarded as waste after their first use, this percentage is expected to rise in the coming years based on current projections [1]. Containers and packaging represent around 28% of the municipal solid waste. Plastic containers account for around the 18%, and more than half of them are disposed in landfills [2]. The growing generation of plastic waste and the lack of initiatives to upcycle it, along with the irresponsible disposal of waste, threatens both marine life and humans [3].

The food industry is one of the largest manufacturing sectors contributing to the global economy. Packaging plays a crucial role in the food industry considering factors such as food quality and preservation, marketing appeal, and proper product identification. The final disposal or management of the packaging at the end of its

life is a critical factor that should be incorporated during the packaging design stage, given the environmental concerns around plastic pollution. Over the past years, food packaging has evolved to increase efficiency (extend shelf-life while maintaining the freshness of the product) increasing food accessibility and reducing food waste. However, plastic food packaging is considered to follow a linear economic model, where it is designed and produced just in accordance with its intended use [4]. The need for sustainable food packaging solutions has become increasingly significant as the proportion of food packaging waste in municipal waste is on the rise.

Moreover, the increasing production of plastic implies a growing stress on resources. Materials extraction along with the processing of materials, fuels, and food contribute to water stress, biodiversity loss, and accounts for around 50% of the greenhouse gas (GHG) emissions [5]. The growing production of plastics not only

implicates using more virgin materials, but also the use of more resources, including energy and water, for the manufacturing of products. To tackle this, circular economy emerges as a system to promote the transition towards achieving environmental, economic, and social sustainability [6]. CE endorses, among other objectives, the closed-loop handling of natural resources to achieve minimal waste and to maintain the value of materials and products to their highest quality for as long as possible. Zhu et al notes that the design of packaging has been acknowledged as the essential initial step in moving toward CE [4]. Transitioning to more sustainable packaging solutions requires analyzing the impacts of alternative materials and their corresponding waste management technologies. Reducing the waste generated and increasing the compatibility of materials with recycling processes are fundamental to achieving recyclability targets [7].

Often, recycling complex plastic containing products can be more resource intensive than using the virgin plastic resins. For instance, PET possess a great resistance to high temperature which involves a considerable amount of energy to recycle it. Another example is multi-layer plastic films that require fewer resources given the efficient combination of materials. However, this configuration affects its recyclability. Therefore, the waste management processes for packaging should be taken into consideration during the design of the packaging.

To this end, we present a circular economy system engineering framework and decision-making tool that examines alternative food packaging design options and waste management possibilities. Using a superstructure approach, the present work employs a mixed-integer linear programming model for determining the optimal combination of packaging and recycling technologies based on economic and environmental criteria. As a case study, we have chosen coffee, which is the second largest traded commodity.

## LITERATURE REVIEW

The state-of-the-art of sustainable packaging design consists of articles focusing on material selection, conceptual design, design development, and design validation. The material selection work focuses on reusability, biodegradable materials, and processability. The conceptual design phase involves topics such as the integration of reusing, and the abstention of a variety of impactful materials. The design development can incorporate the definition of appropriate features like size and weight, as well as the use of labels. Regarding the design validation phase, LCA tools and CE indicators are commonly used [4]. Although, the design guidelines should consider the facilitation of packaging waste management [8].

Karayilan et al [9] proposes a single-objective optimization model to evaluate environmental benefits (climate change and marine ecotoxicity) and material circularity within the packaging value chain. However, other circularity metrics and the economic aspect are not evaluated. Other studies, [10], focus on assessing the performance of different waste management systems for plastic waste, without considering the design of packaging.

Life Cycle Assessment (LCA) studies have been conducted to analyze the environmental performance of food packaging. Toniolo et al [11] performed a comparative LCA to estimate the appropriate recycling percentage for food packaging. However, most studies typically focus on evaluating metrics for the production and use of different packaging materials or designs. Siracusa et al [12] performed an environmental assessment for a single type of multilayer food packaging with a cradle to factory-gate scope. On the other hand, other LCA and techno-economic assessments evaluate various packaging options, but they concentrate on a specific recycling technology. Xie et al [13] reported an LCA on the recycling of Al-PE composite packaging. Some focus on comparing one or few alternative packaging solutions to the conventional, for example, reusable containers with single-use containers [14]. Jeswani et al [3] presented an LCA for mixed plastic waste considering pyrolysis, mechanical recycling, and energy recovery. Similarly, Munguia-Lopez et al [15] studied the environmental benefits of using solvent-based processes to recycle multilayer plastic films.

Optimization studies can enable the identification of optimal solutions for scenarios considering CE principles. Systems engineering frameworks involving multi-objective modeling can be used for the optimization of supply chains or technology allocation. Komly et al [16] presents a multi-objective optimization strategy to find the optimal allocation of PET bottles and recycling technologies to minimize environmental impacts.

However, a comprehensive economic and environmental assessment and/or optimization study considering the production, use, and waste management for different packaging designs is still lacking.

## METHODOLOGY

The methodology followed will be described based on the case study for coffee packaging. Ground coffee currently comes in several packaging types, including disposable and non-disposable alternatives (refilling and reusing options). These options encompass monolayer film bags, containers, multi-layer film bags, and metal cans, that utilize materials ranging from polyethylene and/or aluminum to polyethylene terephthalate and polylactic acid (PLA). Waste management processes also offer various options, spanning traditional landfilling,

incineration, and mechanical recycling, to more recent technologies like pyrolysis, and solvent-targeted recovery and precipitation (STRAP). Previous research has used LCA and multi-objective optimization to achieve a sustainable supply chain for coffee analyzing environmental and economic impacts but considering coffee production and distribution, but not its packaging [17-18]. The proposed methodology focusing on the optimal design and waste management of ground coffee packaging is divided into the four steps described below.

### Packaging option identification

The first step in this analysis, is the identification of coffee packaging options currently available in the market. Between the packaging alternatives, various materials are utilized to consolidate different presentations of packaging. Among the bags considered, there are two plastic film options: monolayer and multilayer films. A multilayer film is a flexible plastic packaging that is composed of different materials that are combined to achieve specific properties that cannot be achieved with monolayer films alone. For example, in the case of coffee, a common multilayer film is composed of PE, PET, and aluminum. By combining the specific attributes of these materials, a packaging with high barrier properties and protection from light and oxygen is achieved, therefore, high-quality coffee is guaranteed. However, multilayer films are difficult to recycle using certain technologies such as mechanical recycling because of the incompatibility of the materials. Before multilayer films arose, monolayer films dominated the market, and some options are still present today.

The use of renewable resources to produce plastics arises as an alternative to avoid the dependence on fossil fuels (non-renewable energy sources) and address environmental concerns. Common plant-based feedstocks like sugarcane and corn can be processed into polymers that would have the exact same structure as the fossil fuels-derived ones. The production of these biobased materials is expected to result in a reduced carbon footprint owing to the carbon sequestration occurred during the cultivation of the plants. However, due to the various estimation methods and the conflicting results based on considerations like land use, the present study considers the carbon uptake outside of the scope.

Therefore, four options for ground coffee packaging were considered in this study: i) multi-layer film bags made with PE, aluminium, and PET, ii) monolayer film bags made with PE, iii) monolayer film bags made with biobased PE, and iv) rigid HDPE containers.

### Waste management options identification

The most common plastic waste management technologies consist of landfilling, incineration, and mechanical recycling. Given the limited landfill disposal and

growing environmental concerns, more efforts have been put into the development of new recycling technologies. Therefore, processes like energy recovery, mechanical recycling, and chemical recycling have been proposed. Chemical recycling through pyrolysis transforms mixed plastic waste (MPW) into a chemical feedstock that can be used instead of virgin materials to remanufacture polymers. Alternatively, STRAP emerges as an alternative to recycle multilayer films by using solvents to separate the film into its different layers [19-20]. The process selectively dissolves target polymers of multicomponent waste with specific solvents.

Packaging waste management begins with the collection and sorting of municipal waste, and the subsequent production of bales from plastic waste all of which takes place at a materials recovery facility (MRF). The second stage that transforms these plastic bales into a suitable feedstock for the different upcycling technologies occurs in a plastics reprocessing facility (PRF). In PRFs, plastic bales are reduced into plastic flakes and impurities are removed from the stream.

Therefore, in this study five options for plastic packaging waste management are considered: i) mechanical recycling, ii) STRAP, iii) pyrolysis, iv) incineration, and v) landfilling. All these waste management options have as a common denominator MRFs. Pyrolysis and mechanical recycling technologies also require PRFs.

### Economic and Environmental Impact Assessment

This case study assumes the coffee companies will be responsible for recycling the post-consumer waste packaging following the Extended Producer Responsibility trend. The scope considered for the TEA starts with the purchasing of the plastic packaging by the coffee company. Moreover, the fixed and variable operational costs for the recycling technologies are considered, as well as the sales of the resulting products. The packaging costs are estimated according to the price market. The recycling technologies costs are calculated based on literature data [21-23]. The products costs are defined based on the quality and the corresponding price in the market. The difference between the costs of packaging and recycling, and the revenue from sales provides the minimum increase in price, a metric that is used to quantify the economic behavior.

For the GHG emissions assessment, the production of the packaging, along with the recycling process are considered. The climate change factors contemplated to perform the LCA are obtained from the Environmental Footprint database [24-25]. The factors of climate change used for the packaging take into consideration the steps that the production of each packaging requires, such as pellets production, film extrusion, or lamination. The same applies to the climate change impact for the

recycling technologies. The factors from the stages of the recycling processes, MRF and PRF, are included in the applicable scenarios. The different inputs required for the recycling technologies are collected from studies in the literature [21-23].

Previous studies have reported the economic and environmental feasibility of using STRAP to recover the constituent polymers of diverse multilayer films [19-20]. However, the multilayer film commonly used for coffee packaging (composed of PE, PET, and Al) has not been studied. Following the previous approaches, in this work, we propose a STRAP variation to treat such multilayer films. We performed STRAP experiments that showed that the recovery of all components and ink removal was feasible. The experimental yields were higher than 95 wt%. and the composition of the packaging was determined to be: 49 wt% of PE, 32 wt% of PET, 17 wt% of aluminium and 2 wt% of ink. The recovered polymers have comparable properties to the corresponding virgin resins. The collected experimental data was used to simulate the STRAP process and perform the TEA and LCA analysis [26].

### Superstructure Representation and multi-objective MILP model

For each packaging, all the possible options among waste management technologies and the subsequent products are contemplated. Figure 1 illustrates the superstructure considered for this study.

Following the alternatives previously described, seven scenarios are considered for the four most common coffee packaging options. Pyrolysis, landfill, and incineration are contemplated for all the packaging, as shown in the superstructure in Figure 1. Pyrolysis is divided into two scenarios: one that extends to the production of the pyrolysis oil and another that additionally involves the polymerization of new polymers from the pyrolysis oil. Mechanical recycling can process only monolayer packaging (films or rigid containers) and STRAP, only multilayer films. Two scenarios were defined for STRAP: one with ink removal that separates all the layers of the packaging using: one solvent to remove the PE layer, a second solvent to separate the aluminum and PET leftover along with the ink, and an eddy current separator to separate the metal from the polymer. The second scenario with no ink removal just removes the initial layer of PE (which constitutes the largest portion following the common composition of coffee packaging [27]) and directs the remaining residue to landfill. The use of more solvents conveys a larger use of resources that generate more emissions, then a scenario considering STRAP and landfill is analyzed as an additional alternative. The basis for the study is defined as 1000 containers.

Figure 1. Superstructure considered in the study.

Under the economic criteria, the goal is to find the minimum increase in price that the company or the customer will have to cover. On the other hand, for the environmental criteria, the objective is to select the process that would generate the least GHG emissions. Given these two competing objectives, this work proposes the use of a multi-objective optimization to evaluate the trade-offs between the different packaging designs and waste management technologies. Hence, the resulting pareto front of this circular economy framework serves as a decision-making tool.

The basis for the study was defined based on a typical 500-gram ground coffee container, and the model was defined using the following nomenclature.

### Nomenclature

#### Sets and Index

$P, p$	set of packaging, packaging index
$R, r$	set of recycling technologies, recycling technology index
$m$	Individual materials index
$mt$	multilayer packaging
$mn$	monolayer packaging
$bm$	biobased monolayer packaging
$hp$	HDPE rigid container
$po$	pyrolysis with oil production
$pp$	pyrolysis with polymerization
$sr$	STRAP with ink removal
$sn$	STRAP with no ink removal and landfill
$mr$	mechanical recycling
$lf$	landfill

<i>we</i>	waste to energy
<b>Decision Variables</b>	
$I_p$	total input of packaging
$B_p$	number of bags for packaging p
$F_{p,r}$	flow from packaging p to technology r
$C_p$	total cost for purchasing packaging p
$CR_{p,r}$	total cost for recycling packaging p through technology r
$S_{p,r}$	sales of products obtained from processing packaging p through technology r
$D_{p,r}$	difference between cost of recycling and sales for packaging p and recycling technology r
$EP_p$	CO <sub>2</sub> eq. emissions from the production of packaging p
$ER_{p,r}$	CO <sub>2</sub> eq. emissions from the recycling of packaging p with technology r
<b>Constants</b>	
$M_p$	material per bag for packaging p
$W_p$	weight of packaging p
$W_m$	weight of individual material
$X_p$	cost of packaging p per ton
$X_m$	cost of individual material
$Cost_r$	cost of waste management technology r per ton
$Cost_{MRC}$	cost for mechanical recycling for an hdpe rigid container
$n_{p,r}$	yield of processing packaging p with technology r
$nl_{p,pp}$	yield of the polymerization of LDPE
$np_{p,pp}$	yield of the polymerization of PP
$X_{p,r}$	cost of product from packaging p processed through technology r
$X_{pp}$	cost of PP
$X_{bp}$	cost of polymerization by-products
$G_p$	Climate change factor for packaging p or material
$G_m$	Climate change factor for individual material
$G_{p,r}$	Climate change factor for packaging p processed through technology r

The packaging alternatives have a set of possible recycling technologies  $r$  available. The set of packaging is:  $P = \{mt, mn, bm, hp\}$ . The set of technologies is:  $R = \{po, pp, sr, sn, mr, lf, we\}$ . Additionally, a set of materials is defined to refer to the components present in the multi-layer film:  $M = \{PET, Al, PE\}$ .

The selection or not of the packaging and the technology is given by the following two binary variables:

$$y_p \forall p \in P \quad (1)$$

$$z_r \forall r \in RT \quad (2)$$

The decision variables depend on the following continuous variables:

$$B_p \leq 1000 y_p \quad \forall p \in P \quad (3)$$

$$\sum_p B_p = 1000 \quad \forall p \in P \quad (4)$$

$$I_p = B_p M_p \quad \forall p \in P \quad (5)$$

The amount that should come from packaging p to recycling technology  $r$  is given by the continuous variable:

$$\sum_r F_{p,r} = I_p \quad \forall r \in R, \forall p \in P \quad (6)$$

The following equations are general constraints considered for the model:

$$F_{p,sr} = 0, \forall p \in \{mn, bm, hp\} \forall r \in \{sr, sn\} \quad (7)$$

$$F_{mt,mr} = 0 \quad (8)$$

$$\sum_p y_p \geq 1 \quad \forall p \in P \quad (9)$$

$$\sum_r z_r \geq 1 \quad \forall r \in R \quad (10)$$

$$F_{p,r} \leq 100000 z_r \quad \forall r \in R, \forall p \in P \quad (11)$$

$$F_{p,r} \leq 100000 y_p \quad \forall p \in P, \forall r \in R \quad (12)$$

The packaging cost, the recycling cost and the products sales considered for the economic assessment are given by equations 13-22:

$$C_p = W_p X_p B_p \quad \forall p \neq mt \quad (13)$$

$$C_{mt} = (W_{Al} X_{Al} + W_{PET} X_{PET} + W_{PE} X_{PE}) B_{mt} \quad (14)$$

$$CR_{p,r} = F_{p,r} Cost_r \quad \forall p \in P, \forall r \in R - \{i = hp, j = mr\} \quad (15)$$

$$CR_{hp,mr} = F_{hp,mr} Cost_{MRC} \quad (16)$$

$$S_{p,r} = F_{p,r} n_{p,r} X_{p,r} \quad \forall p \in P, \quad \forall r \in RT : r \neq pp, lf, sr, sn \quad (17)$$

$$S_{p,pp} = F_{p,pp} (nl_{p,pp} X_{PE} + np_{p,pp} X_{PP} + n_{p,po} + X_{bp}) \quad (18)$$

$$S_{p,sr} = (F_{p,sr} n_{p,sr}) (0.49 X_{PE} + 0.32 X_{Al} + 0.17 X_{PET}) \quad (19)$$

$$S_{p,sn} = F_{p,sn} n_{p,sn} 0.49 X_{PE} \quad (20)$$

$$S_{p,lf} = 0 \quad (21)$$

$$D_{p,r} = S_{p,r} - CR_{p,r} \quad \forall p \in P, \forall r \in R \quad (22)$$

$$Profit = \sum_p \sum_r D_{p,r} - \sum_p C_p \quad (23)$$

The computation of the emissions used for the analysis of the environmental impact follow equations 24-27:

$$EP_p = W_p G_p B_p \quad \forall p \in P: p \neq mt \quad (24)$$

$$EP_{mt} = (W_{Al}G_{Al} + W_{PET}G_{PET} + W_{PE}G_{PE}) + M_{mt}G_{mt}B_{mt} \quad (25)$$

$$ER_{p,r} = G_{p,r}F_{p,r} \quad \forall p \in P, \forall r \in R : p \neq mt \quad (26)$$

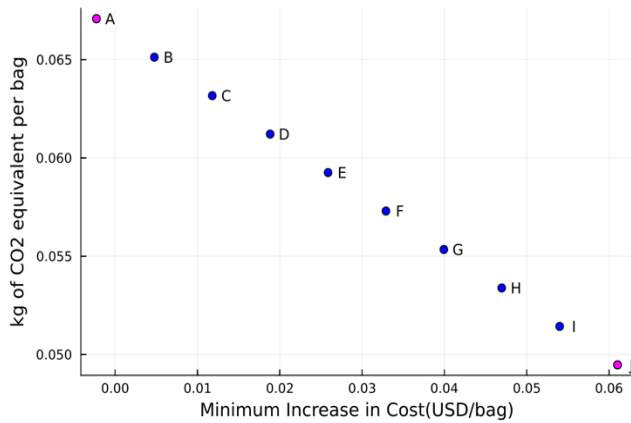

$$ER_{p,sn} = G_{p,sn}F_{p,sn} + (F_{p,sn}0.22)(0.65G_{lf} + 0.35G_{ldA}) \quad (27)$$

$$Emissions = \sum_p EP_p + \sum_p \sum_r ER_{p,r} \quad (28)$$

The model objective functions are given by the maximization of profit and the minimization of emissions, as shown in equations 23 and 28.

## DISCUSSION AND RESULTS

The mixed-integer optimization model was implemented in Julia 1.8.5 and solved with Gurobi v1.0.1. For the multi-objective problem, the  $\epsilon$ -constraint method was utilized [28]. The resulting pareto front is illustrated in Figure 2, with the details of each pareto solution presented in Table 1.

**Figure 2.** Superstructure considered in the study.

**Table 1:** Percentage of multilayer film bags processed by the selected technologies for the points of the obtained pareto front.

Points	Technology	Bags Allocation
● A	STRAP with ink removal	100%
● B	STRAP with ink removal	89%
	Landfilling	11%
● C	STRAP with ink removal	78%
	Landfilling	22%
● D	STRAP with ink removal	67%
	Landfilling	33%
● E	STRAP with ink removal	56%
	Landfilling	44%
● F	STRAP with ink removal	44%
	Landfilling	56%
● G	STRAP with ink removal	33%
	Landfilling	67%
● H	STRAP with ink removal	22%

	Landfilling	78%
● I	STRAP with ink removal	11%
	Landfilling	89%
● J	Landfilling	100%

The results indicate that the most profitable scenario is STRAP with ink removal for a multilayer film with an increase in price of approximately zero per bag due to the high selling price of the recycled polymers. However, its emissions reach 0.067 kg of CO<sub>2</sub>eq. per bag. The minimum increase in price shows a negative value in the pareto front due to a minimum profit of 0.0018 \$ per bag that for simplicity is approximated to zero. On the other hand, the least GHG-emitting alternative is the landfilling of multilayer packaging with the lowest emissions of 0.05 kg CO<sub>2</sub>eq. per bag. Nevertheless, the extra cost reaches \$0.06 per bag.

The packaging type selected in all pareto points is the multilayer PE-Al-PET bag. The set of solutions show possibilities for: a combination of two technologies (blue points) or just one technology (pink points). The technologies contemplated are STRAP with ink removal and landfilling. Given the set of solutions found, it is shown that the reduction of materials together with the proper feasible recycling technology are key to sustainable packaging solutions.

The costs and emissions for processing different packaging types even when using the same technology differ due to the different amounts of material present in each type of container. A trade-off between the amount of material needed and the desired performance of the packaging is highlighted. Multilayer films require less amount of material than monolayer packaging to achieve a high performance. However, the multilayer films characterize by greater complexity that results in a challenge for traditional recycling technologies. Therefore, the recently proposed process STRAP represents a breakthrough technology. It would solve the recyclability limitation generally attributed to multilayer films, while promoting a packaging solution that is less resource intensive. Furthermore, multilayer films represent a substantial advantage as the light weight leads to decreased energy consumption during transportation and consequently lower emissions.

The integration of environmental and economic considerations is suitable to determine the most convenient sustainable solutions. The LCA takes into consideration the emissions generated from the resources used in each of the technologies, like solvents, water withdrawal and energy requirements. Then, the CO<sub>2</sub> equivalent emissions obtained from the LCA, enables an appropriate comparison of the environmental impact of the different processes. However, there are other environmental impacts that should be considered. While landfilling has been selected as the most environmentally convenient alternative when considering the GHG emissions, there are other

potential impacts of landfills to the environment including: soil contamination, water and air pollution, and loss of resources. Landfilling is recognized to have long-lasting environmental impacts. Even after closure treatment and some years, landfills can still release gases and leach contaminants within the surrounding area [29].

The model enables the quantification of alternatives that, while initially deemed beneficial, were ultimately excluded from the set of chosen solutions. A packaging choice anticipated as a green alternative, yet not selected was the biobased polyethylene bag. Despite biobased polyethylene being an environmentally friendly alternative due to its origin, it involves higher prices than fossil-fuel derived polymers and accounts for the same disposal issue (recycling requirement) as fossil-based plastics. The emissions for the biobased packaging (based on the system boundaries) with the landfill alternative increase to 0.29 kg CO<sub>2</sub>eq. per bag. Another packaging option that was not selected as solution is the HDPE rigid container. Even though the packaging facilitates the recycling of the plastic waste, the amount of material required makes it less environmentally friendly. For this alternative, the emissions increase to 0.23 kg CO<sub>2</sub>eq per bag considering landfill.

Besides recycling, the scope of the study takes into consideration the resulting products of the process. The outputs for the different scenarios are analyzed given that the products (and even the quality of the pellets) might vary. Depending on the products, the sales can be altered. Some LCA studies that compare mechanical with chemical recycling, don't take into consideration important factors such as the quality of the outputs of the process, affecting the alternatives that provide a higher quality recycled product. The ideal case would be to obtain the most valuable product, like in the case of pyrolysis with polymerization, however, that would imply higher costs and emissions for the further processing of the material. The output of STRAP for the coffee packaging is of high quality and is obtained at a low cost, providing an economically feasible scenario.

As previously noted, certain recycling technologies may degrade the plastic's quality because they affect its mechanical properties [31]. Others instead produce a virgin-like quality plastic without deterioration and application restrictions [3]. Moreover, some processes might produce more waste or consume more resources than others. Consequently, the next logical step involves implementing a comprehensive circularity assessment framework to holistically explore environmental impacts [32].

## CONCLUSIONS

Plastic packaging plays a significant role in modern society given its multiple benefits; however, a

responsible management is required. Global efforts are put into the development of sustainable alternatives to reduce environmental impacts, such initiatives highlight the need to evaluate the required recycling infrastructure. The CE framework proposed in this work contributes to literature by analyzing the optimal packaging configuration based on the recycling technologies available to process it and materials used for packaging. Packaging solutions that are environmentally and economically viable are required. Both objectives are evaluated individually and as competing objectives. The use of multi-objective optimization generates a set of solutions valuable for decision-making. The case study of coffee provides an insight into the minimum increase in price if coffee companies were responsible for the packaging recycling. The prices are obtained for a combination of technologies with the best packaging resulting in different levels of emissions.

Despite their initial classification as environmentally unfriendly, multilayer films prove to be the most convenient option when equipped with a recycling technology to process it like STRAP. The technologies that are part of the solution encompass STRAP with ink removal and landfilling. The most economically viable technology is STRAP with a zero-price increase, but emissions of 0.07 kgCO<sub>2</sub> eq. per bag. Conversely, the most environmentally friendly alternative is landfill with 0.05 kgCO<sub>2</sub>eq. per bag, but an extra cost of 0.06 USD per bag. However, given the multiple environmental impacts caused by landfilling, further analysis is required. The toxicity of the leachate is one of the principal sources of contamination. Therefore, an analysis of their composition and their related impacts can provide insights in the environmental and human health effects [29,33]. This can be quantified under a metric that considers toxicity or the impact on water, air, land quality and human health. An alternative to assign a monetary value to environmental goods is to use an economic valuation technique [34]. Additionally, for future work a further analysis for biobased packaging can be explored taking into account carbon uptake with different system boundaries and considerations.

Regardless, the environmental and economic assessment is a good approximation and first approach, a holistic evaluation of circularity needs to be developed. For that reason, the future work will focus on applying a circularity calculator to the different management technologies to extend the analysis and visualize the trade-off between circular and economically feasible scenarios. The ultimate goal would be to provide insights to design more sustainable packaging and supply chains. Furthermore, there are a few biodegradable packaging options emerging today. However, it will be considered in the future study together with reusing practices and alternative disposal technologies such as composting and home-composting.

## ACKNOWLEDGEMENTS

## ABSTRACT

The oil and gas energy sector uses billions of gallons of water for hydraulic fracturing each year to extract oil and gas. The water injected into the ground for fracturing along with naturally occurring formation water from the oil wells surfaces back in the form of produced water. Produced water can contain high concentrations of total dissolved solids and is unfit for reuse outside the oil and gas industry without desalination. In semi-arid shale plays, produced water desalination for beneficial reuse could play a crucial role in alleviating water shortages and addressing extreme drought conditions. In this paper we co-optimize the design and operation of desalination technologies along with operational decisions across produced water networks. A multi-period produced water network model with simplified split-fraction-based desalination nodes is developed. Rigorous steady-state desalination mathematical models based on mechanical vapor recompression are developed and embedded at the desalination sites in the network model. An optimal common design is ensured across all periods using global capacity constraints. The solution approach is demonstrated for multi-period planning problems on networks from the PARETO open-source library. Model formulation and challenges associated with scalability are discussed.

## 1 INTRODUCTION

Hydraulic fracturing accounts for about half of current US crude oil production [1]. It involves the injection of large volumes of water underground to build pressure and force open rocks to release underground oil and gas reserves. The injected water along with natural formation water is returned to the surface as shown in Figure 1 and contains dissolved solids, oil, grease, and chemicals used during the well stimulation. The volume and quality of the water varies over time and is different from well to well. The oil and gas industry produces billions of gallons of high total dissolved solids (TDS) produced water every year due to oil and gas operations. There is a need to manage that water in cost-efficient and environmentally sustainable ways.

Currently, produced water is either disposed or recycled for well development purposes with pre-treatment by adding friction reducers or other chemicals. Strategic planning and optimal operational policies in

produced water management have shown to increase water reuse within the oil and gas industry, making the process more sustainable [2-3]. Several efforts have focused on building infrastructure for produced water management for economic and environmental benefits. For example, optimization models that minimize the cost of produced water management have been developed that consider reuse, storage and simplified treatment [4]. Multi-period planning models involving network infrastructure expansion and strategic decisions have been shown to significantly improve profitability for upstream operators [5]. Due to large quantities of produced water and fracking scheduling, it may not be feasible to recycle a 100% of produced water within the oil and gas industry [6].

To reuse produced water outside the oil and gas industry, it requires extensive treatment (i.e., desalination) to bring its quality to acceptable levels by lowering TDS concentrations. Desalination technologies for produced water are mainly classified into thermal-based [7-9] and

membrane-based [10–11] technologies. Several studies have focused on developing detailed mathematical models for the desalination units to develop techno-economic analyses and determine the effectiveness of different desalination technologies [12–14]. Multi-effect evaporation with mechanical vapor recompression (MEE-MVR) is a potential desalination technology for produced water at an industrial scale [7]. A thermo-economic model for an MEE-MVR process has been developed in [15]. Also, detailed nonlinear programming (NLP) models for the MEE-MVR process were developed in [16] with heat integration for the desalination of produced water from shale gas plays. These models were further used to minimize the total annualized cost (TAC) of the desalination unit and determine the optimal design and operation given the feed flow and salinity of produced water.

**Figure 1:** Hydraulic fracturing

Although produced water network optimization and optimization of rigorous desalination units have been individually explored, there is a gap with respect to integrating these two research areas to create an overall optimal decision-making system. In [12] a network optimization model was developed for the Marcellus shale play by using a treatment cost model, obtained using techno-economic assessment of membrane distillation. Simplified costing models for treatment have been used in several works which consider produced water management optimization [2, 4]. However, these formulations don't provide the optimal treatment system design and operational decisions of the treatment units.

This work supports the development of PARETO – a DOE-sponsored, free, and open-source optimization framework for onshore produced water management ([www.project-pareto.org](http://www.project-pareto.org)), by integrating detailed desalination models into the existing produced water management framework. Specifically, in this paper, we introduce a formulation for integrating steady-state desalination units into multi-period produced water network models for the co-optimization of design and operational decisions. A multi-period produced water network model consisting of production pads, completion pads, storage, disposal, and desalination units has been developed.

Since the resulting integrated formulation is nonlinear, it is crucial to ensure that there are no singularities arising due to zero flows in the network. Therefore, separate flow variables for solid and liquid flows are used for the mass balances to avoid bilinear terms in each network arc. We use the MEE-MVR model [16] with heat integration for the rigorous desalination unit with a separate MEE-MVR model for each period. A common design is ensured across all periods using global capacity constraints on the design variables. In Section 2 we provide the mathematical formulation for the produced water network model, desalination units, and the integrated problem. Section 3 consists of case studies on a multi-period network with integrated desalination models. Section 4 concludes the paper with a discussion on scaling up the problem to larger networks.

## 2 MODEL FORMULATION

### Network Model

A typical produced water network consists of production pads (well sites) comprising mature oil or gas wells, which produce hydrocarbons and water, and completion pads, which have a water demand for drilling and hydraulic fracturing. It also consists of disposal wells, storage units, and – in the future – may involve desalination units where excess produced water can be sent. Completions pads' water demand (for hydraulic fracturing) can be met using existing water from the production pads or by procuring fresh water; this depends upon the cost of transportation vs. the cost of sourcing. Figure 2 shows a schematic of a produced water network along with all possible network arcs.

**Figure 2:** Produced water network.

In this section we describe our model formulation with mass balances for the produced water network model. Table 1 describes all the sets, variables, and parameters used in the formulation.

**Table 1:** Description of sets, variables, and parameters for the network model.

#### Sets

$\mathcal{N}^P, \mathcal{N}^C, \mathcal{N}^{MS}$	Production pads, completion pads, mixers, or splitters respectively
$\mathcal{N}^{T,IN}, \mathcal{N}^{T,TW}, \mathcal{N}^{T,CW}$	Desalination inlet, treated water, and concentrated water nodes
$\mathcal{T}$	Total time periods
$\mathcal{T}_n^P, \mathcal{T}_n^C, \mathcal{T}_n^0$	Periods when node $n$ is producing, consuming, or neither, respectively
$\mathcal{Q}$	Components in the stream
$\mathcal{A}$	Arcs in the network
$\mathcal{A}_n^{In}$	Arcs to the inlet of node $n$
$\mathcal{A}_n^{Out}$	Arcs from the outlet of node $n$
$\mathcal{N}^{Up}(n)$	Upstream node of node $n$
$a^{In}(n), a^{Out}(n)$	Arcs in or out of node $n$ , respectively

### Variables

$F_{at}$	Flowrate of water in arc $a$ at time $t$
$S_{aqt}$	Flowrate of solids $q$ in arc $a$ at time $t$
$C_{nqt}$	Concentration of $q$ at node $n$ at time $t$
$C_{nt}^{total}$	Total concentration at node $n$ at time $t$
$I_{nt}$	Water in inventory unit $n$ at time $t$
$I_{nqt}^s$	Solids $q$ in inventory unit $n$ at time $t$
$\alpha_{nt}$	Water recovery fraction at desalination unit $n$ at time $t$

### Parameter

$\hat{F}_{nt}^{Prod}, \hat{F}_{nt}^{Cons}$	Flowrate of water produced and consumed at node $n$ at time $t$
$\hat{S}_{nqt}^{Prod}, \hat{S}_{nqt}^{Cons}$	Flowrate of solids $q$ produced and consumed at node $n$ at time $t$
$\hat{C}_{nqt}^{Prod}$	Concentration of solids $q$ produced at node $n$ at time $t$
$\hat{I}_n^0$	Initial water inventory at the inventory node
$\hat{I}_n^{s0}$	Initial TDS level at the inventory node
$\hat{C}_{min}^{total}, \hat{C}_{max}^{total}$	Concentration bounds for the desalination inlet stream
$\hat{F}_n^{min}, \hat{F}_n^{max}$	Flowrate bounds for desalination inlet node $n$
$\Delta t$	Time discretization

A general flow balance for water and solids can be written for each network connecting the mixers, splitters, and the production pads:

$$\sum_{a \in \mathcal{A}_n^{In}} F_{at} + \hat{F}_{nt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} F_{at} + \hat{F}_{nt}^{Cons} \quad \forall n \in \mathcal{N}^P \cup \mathcal{N}^{MS}, t \in \mathcal{T}$$

$$\sum_{a \in \mathcal{A}_n^{In}} S_{aqt} + \hat{S}_{nqt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} + \hat{S}_{nqt}^{Cons} \quad \forall n \in \mathcal{N}^P \cup \mathcal{N}^{MS}, q \in \mathcal{Q}, t \in \mathcal{T}$$

The outlet lines of the splitters contain equal concentration of solids. This constraint can be expressed as:

If  $|\mathcal{A}_n^{Out}| > 1$ ,

$$\hat{S}_{iqt} \sum_{a \in \mathcal{A}_n^{In}} F_{at} = F_{it} \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} \quad \forall i \in \mathcal{A}_n^{Out}, n \in \mathcal{N}^{MS}, q \in \mathcal{Q}, t \in \mathcal{T}$$

For the inventory nodes, the mass balance is given by:

$$I_{nt} = I_{nt-1} + \sum_{a \in \mathcal{A}_n^{In}} F_{at} - \sum_{a \in \mathcal{A}_n^{Out}} F_{at} \quad \forall n \in \mathcal{N}^S, t \in \mathcal{T}$$

If there is a pretreatment unit installed before the inventory node, the concentration of solids in the inventory is zero. Otherwise, a solids mass balance is required to track the concentration of solids in the inventory:

$$I_{nqt}^s = I_{nqt-1}^s + \sum_{a \in \mathcal{A}_n^{In}} S_{aqt} - \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} \quad \forall n \in \mathcal{N}^S, q \in \mathcal{Q}, t \in \mathcal{T}$$

The solids flow out of the inventory, depend on the concentration of the stored water and are given by:

$$S_{aqt} = F_{at} C_{nqt}, \quad C_{nqt} I_{nt} = I_{nqt}^s \quad \forall n \in \mathcal{N}^S, q \in \mathcal{Q}, t \in \mathcal{T}$$

Completions pads can consume water, produce water, do both simultaneously, or neither produce nor have demand. Depending upon the mode of operation, the completions pad mass balances need to be written differently. If the completions pad is consuming water:

$$\hat{F}_{nt}^{Cons} = \sum_{a \in \mathcal{A}_n^{In}} F_{at} \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^C$$

$$\sum_{a \in \mathcal{A}_n^{Out}} F_{at} = 0, \quad \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} = 0 \quad \forall n \in \mathcal{N}^C, q \in \mathcal{Q}, t \in \mathcal{T}_n^C$$

If the completions pad is producing water:

$$\hat{F}_{nt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} F_{at} \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^P$$

$$\hat{S}_{nqt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^P, q \in \mathcal{Q}$$

$$\sum_{a \in \mathcal{A}_n^{In}} F_{at} = 0, \quad \sum_{a \in \mathcal{A}_n^{In}} S_{aqt} = 0 \quad \forall n \in \mathcal{N}^C, q \in \mathcal{Q}, t \in \mathcal{T}_n^P$$

If the completions pad is simultaneously producing and consuming:

$$\hat{F}_{nt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} F_{at}, \quad \hat{F}_{nt}^{Cons} = \sum_{a \in \mathcal{A}_n^{In}} F_{at} \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^{PC}$$

$$\hat{S}_{nqt}^{Prod} = \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^{PC}, q \in \mathcal{Q}$$

If the completions pad is neither consuming nor producing water:

$$\sum_{a \in \mathcal{A}_n^{In}} F_{at} = 0, \quad \sum_{a \in \mathcal{A}_n^{Out}} F_{at} = 0 \quad \forall n \in \mathcal{N}^C, t \in \mathcal{T}_n^0$$

$$\sum_{a \in \mathcal{A}_n^{In}} S_{aqt} = 0, \quad \sum_{a \in \mathcal{A}_n^{In}} S_{aqt} = 0 \quad \forall n \in \mathcal{N}^C, q \in \mathcal{Q}, t \in \mathcal{T}_n^0$$

The desalination unit node in the network is broken down into three parts: the inlet node, the concentrated water node, and the treated water node. For the desalination inlet node, we ensure that there is only one inlet connection. If there are multiple inlet lines going into a desalination unit, we add a mixer node with one outlet that goes to the desalination unit. The desalination inlet node equations are given by:

$$C_{nt}^{total} \sum_{a \in \mathcal{A}_n^{In}} F_{at} = \sum_{q \in \mathcal{Q}} \sum_{a \in \mathcal{A}_n^{In}} S_{aqt} \quad \forall n \in \mathcal{N}^{T,In}, t \in \mathcal{T}$$

The treated water stream from the desalination unit is considered fresh with zero salinity. This assumption is true in the case of MEE-MVR, since the condensate from the evaporators contains negligible amounts of solids. The concentrated water node consists of the brine from the desalination unit. The flow in and flow out are related by the water recovery fraction:

$$F_{a^{out}(n)t} = \alpha_{n't} F_{a^{in}(n')t} \quad \forall n \in \mathcal{N}^{T,TW}, n' \in \mathcal{N}^{Up}(n), t \in \mathcal{T}$$

$$F_{a^{out}(n)t} = (1 - \alpha_{n't}) F_{a^{in}(n')t} \quad \forall n \in \mathcal{N}^{T,CW}, n' \in \mathcal{N}^{Up}(n), t \in \mathcal{T}$$

$$C_{nqt} F_{a^{out}(n)t} = C_{n'qt} F_{a^{in}(n')t}, S_{a^{out}(n)qt} = C_{nqt} F_{a^{out}(n)t} \quad \forall n \in \mathcal{N}^{T,CW}, n' \in \mathcal{N}^{Up}(n), t \in \mathcal{T}, q \in \mathcal{Q}$$

We assume that the desalination unit has a minimum flow and concentration restriction. This assumption is reasonable as the startup procedure for the desalination units can be time consuming and expensive compared to running them at some minimum capacity for the entire planning horizon. Therefore, the bounds on desalination operation can be written as:

$$\hat{C}_{min}^{total} \leq C_{nt}^{total} \leq \hat{C}_{max}^{total} \quad \forall n \in \mathcal{N}^{T,In}, t \in \mathcal{T}$$

$$\hat{F}_n^{min} \leq \sum_{a \in \mathcal{A}_n^{In}} F_{at} \leq \hat{F}_n^{max} \quad \forall n \in \mathcal{N}^{T,In}, t \in \mathcal{T}$$

The disposal sites also have disposal limits on the volume of water that can be disposed in a particular period:

$$\sum_{a \in \mathcal{A}_n^{Out}} F_{at} \leq \hat{F}_n^{max} \quad \forall n \in \mathcal{N}^D, t \in \mathcal{T}$$

We assume that the salinity of the fresh water sourced is near-zero and that there are capacity constraints on the volume of water that can be sourced:

$$\sum_{a \in \mathcal{A}_n^{Out}} F_{at} \leq \hat{F}_n^{max}, \sum_{a \in \mathcal{A}_n^{Out}} S_{aqt} = 0 \quad \forall n \in \mathcal{N}^D, q \in \mathcal{Q}, t \in \mathcal{T}$$

The main advantage of including the solids flow stream into the network model is that we can bound the solids flow when the flow of water in any arc is zero:

$$S_{aqt} \leq \hat{C}^{max} F_{at} \quad \forall a \in \mathcal{A}, q \in \mathcal{Q}, t \in \mathcal{T}$$

This constraint avoids singularities in the problem formulation and improves the robustness of the model while optimizing.

The operating cost of the network includes costs for transportation, storing water in the inventory units, sourcing fresh water, and produced water disposal or injection. The desalination of water and the removal of water from the inventory unit has a reward associated with it to encourage desalination and discourage storage of produced water. The desalination cost comes from the detailed MEE-MVR process model costs and hence is not included in the network cost here:

$$C_{net} = \sum_{t \in \mathcal{T}} \left[ \sum_{a \in \mathcal{A}} \beta_{ar} F_{at} + \sum_{n \in \mathcal{N}^S} \sum_{a \in \mathcal{A}_n^{In}} \beta_s F_{at} + \sum_{n \in \mathcal{N}^W} \sum_{a \in \mathcal{A}_n^{Out}} \beta_s F_{at} \right. \\ \left. + \sum_{n \in \mathcal{N}^D} \sum_{a \in \mathcal{A}_n^{In}} \beta_d F_{at} - \sum_{n \in \mathcal{N}^S} \sum_{a \in \mathcal{A}_n^{Out}} \gamma_s F_{at} \right. \\ \left. - \sum_{n \in \mathcal{N}^{T,TW}} \sum_{a \in \mathcal{A}_n^{Out}} \gamma_T F_{at} \right] \Delta t$$

## Desalination Model

An MEE-MVR process unit consists of single or multiple evaporator stages where the feed water enters on the shell side. As seen in Figure 3, hot steam flows through the evaporator tubes and the resulting heat transfer evaporates the feed water, which is split into liquid brine and vapor streams. In a multistage evaporation setting, the vapor from the  $i^{th}$  evaporator is fed into the tubes of the  $(i+1)^{th}$  evaporator and the brine from the  $i^{th}$  evaporator is fed into the  $(i-1)^{th}$  evaporator. A compressor is used for vapor recompression from the last evaporator stage to feed it into the tubes of the first evaporator in the sequence. A preheater is used to exchange heat between the condensate and the feed to pre-heat the feed for better energy integration.

A rigorous MEE-MVR process model is developed based on [16], the mathematical model consists of mass and energy balances and non-linear pressure and temperature relationships along with bounds for feasible operation. The detailed modeling equations are provided in the digital supplementary material. The main costs associated with the desalination unit are the CAPEX from the evaporators, preheater, and the compressor and the OPEX from using electricity to run the compressor. The CAPEX was calculated using correlations from [17] and was annualized using an amortization period of 10 years and an interest rate of 10%.

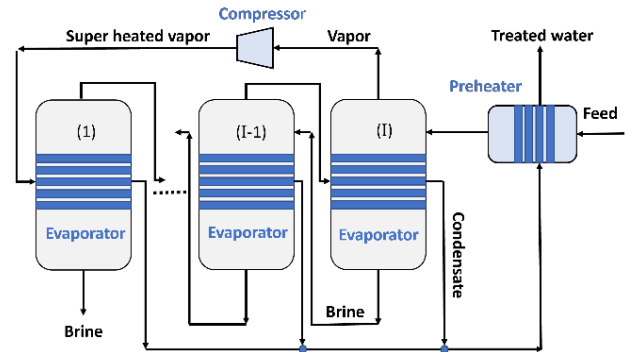

Figure 3. MEE-MVR process with heat integration.

## Integrated Model

To formulate the multi-period integrated problem, a steady-state MEE-MVR unit model is written in each period of the network. The variables from the network are linked with the input variables (represented by a bar on top of the variables) to the desalination unit using linking constraints. To ensure a common desalination design across all periods and feasible operation in every period, we use global capacity constraints on the capacity variables of the desalination model. The annualized CAPEX and OPEX are converted to daily CAPEX and OPEX given by  $CAPEX_{\Delta t}$  and  $OPEX_{\Delta t}$ . The integrated model formulation is given by:

$$\min C_{net} + \sum_{t \in \mathcal{T}} (CAPEX_{\Delta t} + OPEX_{\Delta t}^t) \Delta t$$

$$\text{s.t } \sum_{a \in \mathcal{A}_n^{\text{in}}} F_{at} = \bar{F}_{nt}^{\text{in}} \quad \forall n \in \mathcal{N}^{T, \text{In}}, t \in \mathcal{T}$$

$$C_{nt}^{\text{total}} = \bar{C}_{nt}^{\text{in}} \quad \forall n \in \mathcal{N}^{T, \text{In}}, t \in \mathcal{T}$$

$$\alpha_{nt} = \bar{\alpha}_{nt} \quad \forall n \in \mathcal{N}^{T, \text{In}}, t \in \mathcal{T}$$

$$CAPEX_{\text{evap}}^{(i) \text{global}} \geq \bar{CAPEX}_{\text{evap}, t}^{(i)} \quad \forall i \in \{1, \dots, I\}, t \in \mathcal{T}$$

$$CAPEX_{\text{ph}}^{\text{global}} \geq \bar{CAPEX}_{\text{ph}, t} \quad \forall t \in \mathcal{T}$$

$$CAPEX_{\text{comp}}^{\text{global}} \geq \bar{CAPEX}_{\text{comp}, t} \quad \forall t \in \mathcal{T}$$

All network equations and desalination model equations in each period

The  $CAPEX_{\Delta t}$  is calculated using the global CAPEX of individual equipment. It is assumed that there are no uncertainties in the model. The integrated problem is a non-linear model, developed in Pyomo [18] and solved using the open source NLP solver IPOPT [19].

### 3 RESULTS

In this section we demonstrate the results of our integrated optimization approach on a small network case study provided by “Project PARETO”. The network consists of four production pads, one completions pad, two disposal sites, two fresh water sources, one storage site, and one prospective desalination site as shown in Figure 4. A planning horizon of 52 weeks is considered with a weekly discretization. The completions pad has a water demand between weeks 1 to 12 and weeks 45 and 52. In the remaining time there is completions flowback, which means there is no demand for water within the network during that time. We perform three case studies:

1. Embedding a single-stage MVR at R01
2. Embedding at two-stage MVR at R01
3. Embedding a three-stage MVR at R01

#### Case Studies

A single-stage desalination unit is embedded at desalination site R01. The problem consists of 6,972 variables, 6,015 equality constraints, and 2,860 inequality constraints. The optimal network operation profiles are shown in Figure 5. When there is no water demand in the network, the desalination unit is run at its maximum capacity as shown in Figure 5b. When there is completions demand, the optimal solution balances recycling and desalination to reduce costs incurred from freshwater sourcing. From Figure 5c, we observe that initially, when there is completions demand, the inventory is depleted to meet the demand, and then there is inventory build-up to meet the completions demand in the later weeks of the year. Finally, at the end of the year the inventory is completely depleted as there is no incentive to store excess water. The optimal solution indicates that 53% produced water is sent to desalination, 14% is reused to meet completions demand, and 33% is sent to disposal. 4.2 million

barrels of fresh water are sourced to meet the completions demand. Table 2 shows the optimal design variables for the desalination plant.

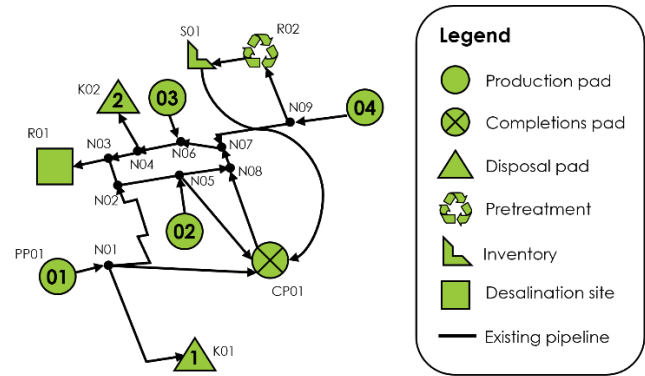

Figure 4. Produced water network case study.

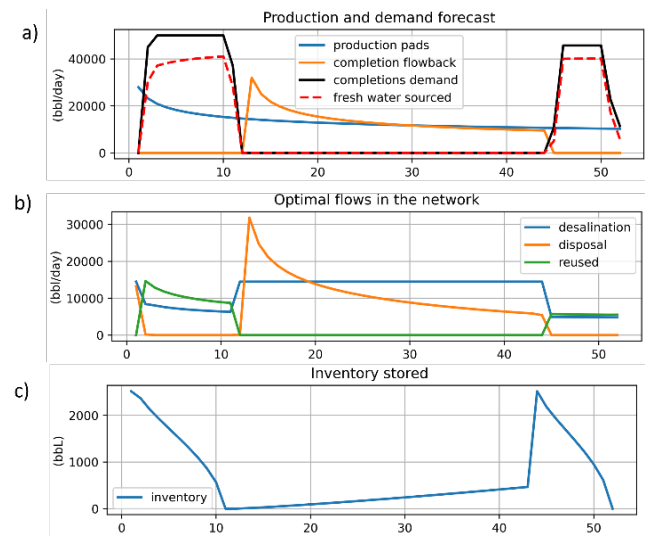

Figure 5. Optimal flow profiles for a single-stage desalination unit at R01. A) Production and demand forecasts against time and fresh water sourced in each period. b) Optimal water disposal, desalination, and reuse in each time period. c) Optimal volume of water stored in S01 in each period.

When a two-stage desalination unit is embedded at R01, the problem has 8,064 variables, 7,055 equality constraints, and 3,328 inequality constraints. The optimal flow profiles obtained are nearly identical to the single-stage unit. The optimal design variables for the two-stage desalination plant are shown in Table 2. The two-stage desalination plant needs a smaller compressor due to the separation process being split over two evaporator stages. Hence, the CAPEX and the OPEX are both smaller for a two-stage unit compared to a single-stage unit. Overall, the network with a two-stage desalination unit is 31% cheaper than with a single-stage unit in this example.

When a three-stage unit is installed, the desalination

unit doesn't run at its full capacity because the compressor reaches its maximum compression ratio at a lower inlet flowrate to the desalination unit. Thus, the water sent to desalination is decreased, with only 48% water sent to desalination compared to the two-stage and single-stage case. Also, a smaller compressor is installed but the cost of installing three evaporator stages offsets the cost reduction obtained by installing the smaller compressor. Table 3 shows the cost breakdown of the network costs and desalination costs for each case study. Overall, the two-stage desalination unit has the smallest objective function and is therefore optimal in this case. All problems solve with IPOPT within an order of 100 s.

**Table 2:** Optimal design of the desalination units obtained by solving the integrated problem.

Unit type → Equipment ↓	Single-stage	Two-stage	Three-stage
Evaporator area 1	372 m <sup>2</sup>	372 m <sup>2</sup>	372 m <sup>2</sup>
Evaporator area 2	–	372 m <sup>2</sup>	372 m <sup>2</sup>
Evaporator area 3	–	–	372 m <sup>2</sup>
Preheater area	73.87 m <sup>2</sup>	118 m <sup>2</sup>	78 m <sup>2</sup>
Compressor capacity	2750 Hp	1790 Hp	1449 Hp

**Table 3:** Optimal costs obtained by solving the integrated problem.

Unit type → Costs (kUSD) ↓	Single-stage	Two-stage	Three-stage
Objective function	9882.9	9094	9575
Transportation	370	370	366
Storage	5.8	5.03	6.12
Disposal	917.5	918	1060
Fresh water	12682	12684	12680
Desalination CAPEX	406	374.8	388
Desalination OPEX	2143.2	1384.2	1075
Storage reward	0.58	0.50	0.61
Desalination reward	6640.6	6641.7	6002

## 4 CONCLUSIONS

In this paper, we develop an integrated optimization framework for the co-optimization of desalination units with operational decision-making in produced water networks. The framework is demonstrated on a multi-period network problem with three case studies embedding MVR desalination units with different number of stages into the network. The results show that in this case, a two-stage MVR leads to the lowest objective function. The framework gives the optimal operation variables in the network along with the optimal design and operation variables in the rigorous desalination units.

Future work involves developing decomposition techniques for scaling the framework for application on larger network instances. We also plan on incorporating

bi-directional flow and strategic decision making into the network model.

## ABSTRACT

Inspired by Nature, we propose that synergies between biorefinery and mineral refinery can be exploited so that at least a part of the carbon is captured before being released to the atmosphere. In doing so, carbon is captured not only from CO<sub>2</sub> but also from biomass and developing more such processes may be the cornerstone for controlling CO<sub>2</sub> emissions. A comparison of circular economy in traditional biorefineries and bio-mineral refineries is done by using general chemical formulas and it is shown that the bio-mineral refinery captures carbon. In this work, we have shown that Serpentine may be used to partially neutralise biomass pyrolysis oil. The extracted oil may be used as feedstock to produce downstream chemicals and further studies are required to produce the same.

## INTRODUCTION

Circular economy, a concept that focuses on recycle, is viewed as a potential means of reducing new resource usage, thus limiting CO<sub>2</sub> emissions. Applying the concept of circular economy to the chemical process industries; biomass, fossil resources, all the chemical products and CO<sub>2</sub> can be considered as the intermediates, while energy to the system comes from the Sun. Currently, the rate of CO<sub>2</sub> emissions is greater than the rate of biomass regeneration and this is leading to CO<sub>2</sub> accumulation in the atmosphere, and this is viewed as being linear. Furthermore, CO<sub>2</sub> utilization/mineralization to reduce atmospheric CO<sub>2</sub> accumulation may be viewed as the process of closing the loop in a circular economy; however, doing so is energy intensive and leads to further CO<sub>2</sub> emissions. Biorefineries have been proposed as a panacea since they can potentially substitute fossil sources, and the energy for CO<sub>2</sub> capture and production of biomass is taken directly from the sun. However, biorefineries have had limited success, and most are single product chemical plants.

The critical difference between fossil sources such as crude oil, natural gas and biomass is that biomass has about 40% (w/w) oxygen and the same is almost non-

existent in the fossil sources. In view of this, one can expect that biomass to chemicals/fuels is going to be expensive especially if oxygen elimination is necessary. Another critical difference is that fossil source is produced by natural interaction of dead biomass with the environment surrounding them and it is unknown how many tonnes of biomass produced one tonne of fossil source. On the contrary, biomass to chemicals process must have high productivity and the mass balance is stacked against bio-refineries. While this is challenging, our efforts must continue to focus on the use of biomass since it replaces fossil sources. Where possible, this skewed mass balance must be turned to our advantage by furthering our research. Further, the effect of the natural environment on biomass is not completely simulated in a biorefinery. In view of this, we try to simulate the interaction of biomass with the environment by combining biorefinery and mineral refinery. This inspiration comes from the fact that animals, which are complex chemical systems, take biomass as feed, produce complex (bio) chemicals within their body and leave mineral carbonates as bones at the end of their life cycle.

The objective of this work is thus to demonstrate that it is possible to combine biorefineries and mineral refineries such that synergies can be explored for the

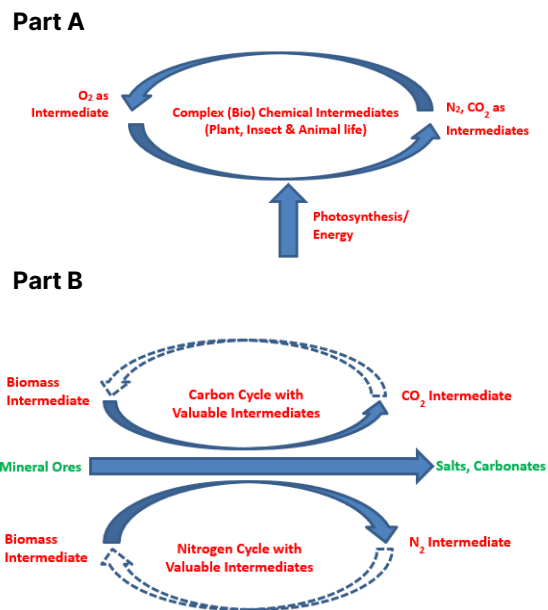

benefit of CO<sub>2</sub> mineralization. In view of this, we present details of two chemical processes where the synergies between biomass refining and mineral refining can be explored, and carbon is captured. They are the production of acetone and acetamide/acetonitrile. While the two processes are based on existing know-how, we also apply the concept to demonstrate that the field of “Bio-mineral refinery” can be developed to exploit the synergies while using raw biomass source. In view of this, we use biomass pyrolysis oil with Serpentine and the concept of Biomineral refinery is introduced by conducting preliminary experiments. In doing so, a multiproduct bio-mineral refinery is designed; carbon is captured both from biomass and CO<sub>2</sub> and good productivity achieved.

## CIRCULAR CHEMICAL ECONOMY WITH BIO-MINERAL REFINERIES

In the natural world, dead biomass degrades by bacterial action while producing organic acids that dissolve the surrounding mineral ores. The process produces mineral salts that serve as nutrients to plant life and plants support the insect and animal life. At the end of their life, the biomass from the insects, plants and animals degrades and the cycle continues. This entire process can be viewed as a circular (bio) chemical system with several recycle loops where the biomass, insects, animals, O<sub>2</sub> and CO<sub>2</sub> are considered as intermediates and energy is input to the system in the form of sunlight (Fig. 1A). Similarly, the processes in the chemical and allied industries can also be visualized where all the materials move in a loop with several recycles and energy is input to the system in the form of heat and electricity.

On further examination, we can see that the animal life leaves mineral carbonates at the end of their life cycle. Hence, the entire process can be viewed as a circular (bio) chemical system that is supported by a linear process where mineral ores are converted to mineral carbonates. We can see that there are synergies between the circular (bio) chemical system and linear mineral processes, and it is this synergy that we must exploit to develop new chemical processes. The overall process can be viewed as the carbon and nitrogen cycles interacting with the linear mineral processes (Fig. 1B). Here we present two processes in support of the Nature inspired ‘linear supported circular (bio) chemical system’. They are theoretically feasible and further research must be carried out to evaluate the productivity, energetics, and the economic feasibility. The first is a bio-mineral refinery based on the carbon cycle and the second is based on carbon and nitrogen cycles. Briefly, mineral ores such as Wollastonite and Serpentine are used as raw materials to produce mineral carbonates and other inorganic products. One of the common products of biomass degradation is acetic acid and we present on the use of palm

empty fruit bunch (EFB, C6H10.8O3.72) [1] derived acetic acid as one of the raw materials to produce organic intermediates such as acetonitrile and acetone. The materials thus produced can be treated as intermediates and these chemicals can be used as platform materials to produce downstream chemicals. In the proposed Circular Chemical Economy, we consider carbon capture both from biomass and from CO<sub>2</sub> thus limiting CO<sub>2</sub> emissions to the atmosphere.

**Figure 1.** Part A: A traditional circular (bio) chemical system. Intermediate materials move in cycles with energy from the sun. Part B: A circular (bio) chemical system that is dependent on a linear mineral process. Dotted arrows represents natural processes.

## CO<sub>2</sub> MINERALIZATION POTENTIAL

The reactions that may occur in a circular chemical economy to produce fuels and/or chemicals may be written by assuming a general formula for biomass. Given, ‘n’ is the number of moles of biomass used to produce the products and capture CO<sub>2</sub>, ‘i’ is the number of moles of CO<sub>2</sub> mineralized, ‘m’ is the number of moles of biomass combusted in order to provide heat to the process and ‘e’ is the CO<sub>2</sub> consumed/emitted by the process; where ‘i’ is a positive integer, ‘e’, ‘m’ and ‘n’ are real numbers; when i=0, the proposed bio-mineral refinery becomes a traditional biorefinery i.e., no carbon is captured. The same is depicted in Fig. 2 with reference to the circular economy. Biorefineries emit CO<sub>2</sub> either by way of energy uses in the process or as a byproduct and a sequestration process is necessary to minimize the CO<sub>2</sub> emissions. On the contrary, a part of the carbon is mineralized in Bio-mineral refineries and over a period of several cycles, the amount of carbon mineralized would be far greater than the

carbon emitted as CO<sub>2</sub> and thus, the process turns from being a CO<sub>2</sub> emitting process to carbon sequestration process.

We can see from Fig. 2. that carbon is mineralized in each cycle as mineral carbonates; hence the Bio-Mineral refineries become net CO<sub>2</sub>/carbon negative processes after a few cycles. The total CO<sub>2</sub> emissions (tonnes/tonne of CO<sub>2</sub> mineralized) can be calculated to be equal to  $(mx+e)/i$  and the number of cycles required for the process to become net carbon negative from being a CO<sub>2</sub> emitting process is also  $(mx+e)/i$ . We can conclude that 'e' and 'm' must be as small as possible and 'i' must be as large as possible so that maximum amount of carbon is mineralized while the input energy to the process is low. However, as 'm' and 'n' increases, the amount of valuable products produced per ton of CO<sub>2</sub> increases and this needs to be high to recover the cost of production. In view of this, detailed analysis on individual processes is necessary to understand the trade-off between the opposing objectives of maximizing the amount of CO<sub>2</sub> mineralized (with low chemical production) and maximizing the mass of valuable products produced (with low CO<sub>2</sub> mineralization).

**Figure 2.** A comparison of circular economy in traditional biorefineries ( $i=0$ ) and bio-mineral refineries ( $i>0$ ) is depicted here.

$$\text{where, } p = nx - i - e; q = nz - 2i - 2e$$

### Bio-Mineral refinery – Carbon Cycle

Acetic acid can be produced from biomass by (bio) chemical action. The chemical process has faster kinetics when compared to the bioprocess and may be suitable for large scale production. First, methanol is produced from biomass derived Syngas, next acetic acid is produced by the carbonylation of methanol (Monsanto and Cativa process) where the carbon monoxide may be produced from biomass derived carbon. Acetic acid can be

used for leaching Wollastonite and SiO<sub>2</sub> is precipitated [2] in the process. The salt that is produced, calcium acetate, can be separated and used to produce acetone while calcium carbonate is precipitated [3]. Acetone serves as a platform chemical [4] to produce downstream chemicals such as isopropyl alcohol, propane, solvents (Methyl isobutyl alcohol, methyl isobutyl ketone), Bisphenol-A (Polycarbonates, Polyurethanes, epoxy resins), Methyl methacrylate, among others. Acetone thus produced can potentially reduce the dependence on acetone from the Cumene process and hence some of the crude oil can be used in the production of other petro-chemicals and the overall use of crude oil reduced. Benzene may also be produced in a bio-mineral refinery to offset loss on production via Cumene process. Hydrogen from biomass derived Syngas may be used to meet downstream demand. The schematic of the processes is shown in Fig.3 and the detailed chemical reactions for Fig. 3. are given in Table 1. Briefly, Carbon either from biomass or from CO<sub>2</sub> is converted into mineral form thus removing some of it from the system. While such processes occur in geological time scales in the earth, chemical reactions in chemical plants are targeted to have faster chemical kinetics and it is hoped that the process of mineralization can be fastened.

The carbon and nitrogen cycles-based bio-mineral refinery produces acetamide/acetonitrile by using serpentine. These details, corresponding to Fig. 4., are only shown briefly due to limitation of space.

EFB is used to produce both Syngas which is later used to produce acetic acid. We can see from Table 1 that 1.32 moles of EFB successfully mineralizes 1.9 moles of CO<sub>2</sub> as CaCO<sub>3</sub> when Wollastonite is used. This is equivalent to sequestering 0.44 tons of CO<sub>2</sub>/tonne of EFB used while producing 0.59 tonnes of acetone and 0.61 tonnes of Silica that can generate income. Like the Wollastonite process, we observed that 1.32 moles of EFB successfully mineralizes 1.9 moles of CO<sub>2</sub> as MgCO<sub>3</sub> when Serpentine is used. The same amount of CO<sub>2</sub> is mineralized while producing 1.19 tons of acetamide. The amount of acetamide produced per tonne of EFB is higher compared to the amount of acetone produced. This is obvious because CO<sub>2</sub> is mineralized from biomass when acetone is produced, and flue gas is used as the CO<sub>2</sub> source when acetamide is produced. Here, we have assumed 100% conversion, and the actual values will be much different. In view of this, we take the basis as the amount of valuable product produced as it is straight forward and these values won't be dependent on the conversion, but only on reactions R8 (Fig. 3) or R12 (Fig. 4). When Wollastonite and Serpentine are used, 0.76 tonnes of CO<sub>2</sub>/tonne of acetone and 0.37 tonnes of CO<sub>2</sub>/tonne of acetamide (or 0.54 tonnes of CO<sub>2</sub>/tonne of acetonitrile) is mineralized respectively. We can see that the amount of CO<sub>2</sub> mineralized per tonne of valuable product is large and these

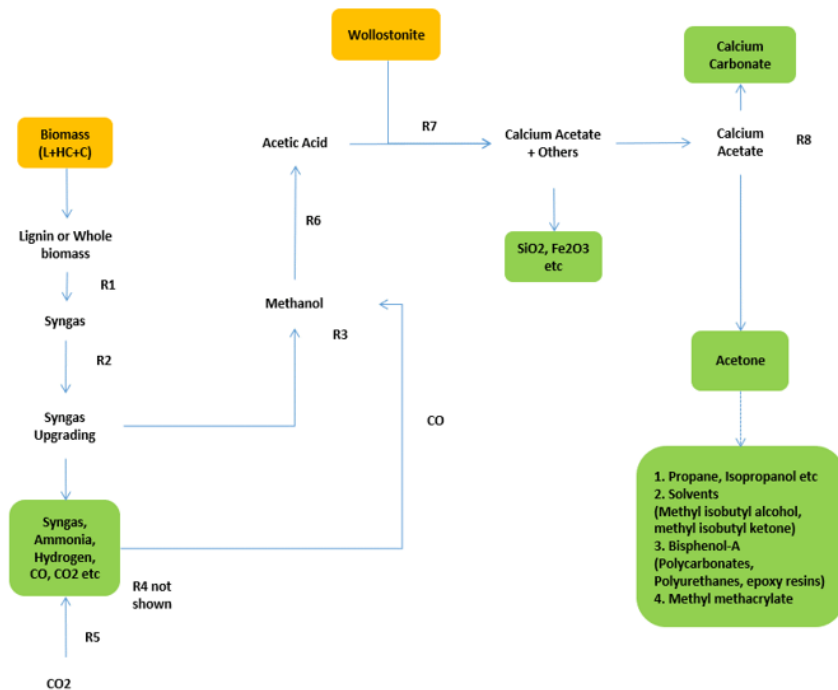

processes potentially can be used to produce valuable chemicals while simultaneously capturing CO<sub>2</sub>. The CO<sub>2</sub> emissions from the use of energy and the penalty thereof must be estimated separately and this is estimated from the values presented in Table 1. To calculate the energy requirements of the processes, we only consider the endothermic energy of the processes; any gains by heat integration associated with exothermic processes is neglected as these must be subjected to detailed heat integration calculations.

Based on Fig. 4. each cycle 6.95 tonnes or 8.78 tonnes of CO<sub>2</sub> is released into the atmosphere for every tonne of CO<sub>2</sub> mineralized (detailed reactions not shown). Here, the amount of CO<sub>2</sub> released to the atmosphere is large compared to the CO<sub>2</sub> mineralized, and hence the proposed concept of circular chemical economy through bio-mineral refineries holds. In view of this, over a period of 7 and 9 cycles the net CO<sub>2</sub> emitting processes become CO<sub>2</sub> neutral processes since the atmospheric CO<sub>2</sub> is effectively an intermediate that will be taken up in biomass

**Table 1:** Reactions in a Bio-Mineral refinery that uses palm EFB and Wollastonite as feed.  $\Delta H$  at a given temperature is calculated using HSC 6.1 software [5]. Calculations for Serpentine (Carbon-Nitrogen cycle) are not shown.

Use of Wollastonite as Feed & Production of Acetone		Rxn. T (°C)	$\Delta H$ (kJ)
Syngas Production (R1)	$C_6H_{10.8}O_{3.72} + 1.14O_2 \rightarrow 6CO + 5.4H_2$	700	2802
Syngas Upgrading (R2)	$6CO + 5.4H_2 + 2.2H_2O \rightarrow 3.8CO + 7.6H_2 + 2.2CO_2$	300	86
Methanol Production (R3)	$3.8CO + 7.6H_2 \rightarrow 3.8CH_3OH$	250	373
Carbon production (R4)	$0.32C_6H_{10.8}O_{3.72} + 0.532O_2 \rightarrow 1.9C + 1.71H_2O$	1300	563
CO production (R5)	$1.9C + 1.9CO_2 \rightarrow 3.8CO$	800	-323
Acetic Acid Production (R6)	$3.8CH_3OH + 3.8CO \rightarrow 3.8CH_3COOH$	200	620
Mineral Digestion (R7)	$1.9CaSiO_3 + 3.8CH_3COOH \rightarrow 1.9(CH_3COO)_2Ca + 1.9SiO_2 + 1.9H_2O$	50	209
Mineralisation (R8)	$1.9(CH_3COO)_2Ca + Heat \rightarrow 1.9CH_3COCH_3 + 1.9CaCO_3$	160	-183

**Figure 3:** Schematic of the process of producing Acetone from Biomass and Wollastonite. Acetone can be used a precursor to many other chemicals.

regeneration. After the 7 or 9 cycles the processes become purely CO<sub>2</sub> mineralization processes. A cycle is complete when the CO<sub>2</sub> emitted by the process is taken up in biomass regeneration. Hence, biomass doubling time can be considered as time for one cycle i.e., the cycle time is dependent on the biomass growth rate which in turn is dependent on the land area and the type of crop that is cultivated. Clearly, over the long term these processes have the potential to sequester large amounts of CO<sub>2</sub> and effectively de-carbonize the atmosphere. In contrast to the traditional biorefinery where fuels and/or chemicals are produced and no CO<sub>2</sub> is captured, a bio-mineral refinery captures at least some amount of carbon as mineral carbonates and partially prevents atmospheric CO<sub>2</sub> accumulation. This contrast is the key to the successful development of circular chemical economy because the focus is on carbonate accumulation and not on CO<sub>2</sub> accumulation in the atmosphere. EFB is produced at the rate of 18 to 30 tonnes/hectare/year [6]. Considering the lower value of 18 tonnes/hectare/year, each tonne of CO<sub>2</sub> mineralized requires about 0.21 hectares or 0.26 hectares of land for CO<sub>2</sub> recycle and biomass regeneration. However, the land required to produce biomass that is used as feedstock is larger at 0.33 hectares or 0.38 hectares per tonne of CO<sub>2</sub> mineralized since all the carbon in the biomass is not released to the atmosphere, but carbonates and valuable products are produced. Thus, we have demonstrated through two examples that there is scope for developing circular chemical economy with carbon mitigation and the development of other processes to produce valuable products must be explored.

While the proposed routes are interesting, the apparent question is how fast each loop in the circular economy is. To answer such a question, detailed kinetics studies are necessary. While it suffices to say here that since CO<sub>2</sub> of about 10 % (based on less than 10 cycles) is mineralized and that reactions in chemical industries are typically faster in the matter of minutes to hours, we also need to answer this in terms of the amount of mineralization with reference to the mass of products produced. The same was presented earlier as 0.44 tonnes of CO<sub>2</sub>/tonne of EFB is mineralized for each of the two processes. While this is theoretical conversion, the efficiency related to energy penalty in such processes are expected to be 50% [7, 8] and may be appropriate to assume that 0.22 tonnes of CO<sub>2</sub> are mineralized per tonne of EFB after scale-up.

Although more such examples exist in literature where biomass derived chemicals can be used for CO<sub>2</sub> mineralization and the production of valuable chemicals in a bio-mineral refinery, the key for successful implementation of the processes in a commercial scale is to use whole biomass so that the number of processing steps and the associated costs are reduced. The possibility that whole biomass, which has a large amount of

oxygen, be de-oxygenated by Ketonic decarboxylation must be explored so that valuable hydrocarbons and inorganic products are produced, and carbon is mineralized. Biomass has phenols and other aromatic compounds, and it may (not) be possible to produce higher hydrocarbons which have a high C/O ratio using biomass as feedstock. Considering the variety of compounds in biomass, it would be rather difficult to predict the type of products that can be produced in hydrothermal/thermochemical treatment of biomass & mineral ore mixtures. Further, addition of acid for acid hydrolysis of biomass and/or leaching of the mineral ore and production of salts thereof would lead to increased complexity. In view of this, experiments to study the products and the mechanism of product formation in biomass-mineral interactions are warranted for the development of bio-mineral refinery based circular chemical economy that can at least partially replace fossil fuel based chemical economy. Hence, we have conducted experiments using biomass pyrolysis oil and serpentine mineral and present the same here.

**Table 2:** CO<sub>2</sub> capture potential of the proposed processes. W-wollastonite; S-serpentine.

	<b>W</b>	<b>S</b>
Endothermic energy required (MJ)	4.65	5.91
Biomass for energy supply (80% energy efficiency, kg)	0.31	0.39
CO <sub>2</sub> emissions from Biomass combustion (kg)	0.57	0.72
Total Biomass required (tons/ton CO <sub>2</sub> mineralized)	5.92	6.91
Total CO <sub>2</sub> emissions (kg)	0.58	0.73
CO <sub>2</sub> emissions (tonnes/tonne CO <sub>2</sub> mineralized)	6.95	8.78
Products produced (tonnes/tonne CO <sub>2</sub> mineralized)	1.32 (acetone)	2.68 (acetamide)
Number of Cycles required for the process to become net CO <sub>2</sub> capture process	7	9
Land area for feedstock biomass production (hectares/tonne of CO <sub>2</sub> mineralized)	0.33	0.38

## CAPTURING CARBON FROM BIOMASS

### Preliminary Experiments

In this work, we need to first establish if bio-oil would react with Serpentine. In view of this, 20 grams of serpentine were mixed with 260 ml of water-soluble bio-oil (60 ml water soluble component from 100 ml pure bio-oil and 200 ml water) and stirred overnight. Then the solid samples, serpentine that gets disassociated, were collected, and analyzed. We were able to collect 12.8 grams

of suspended solids (fine solids), 9.5 grams of settled solids (coarse) and 0.75 grams of magnetic material that sticks to the magnetic bar. The samples were left to air dry for three days inside a fume-hood and weighed again. The measured weights are as follows: 10.1 grams of suspended solids (fine solids), 9.3 grams of settled solids (coarse) and 0.69 grams of magnetic material. It was observed that there was a pH change from 1.0 to 4.3 due to the addition of Serpentine.

Separately, 100 ml of biomass pyrolysis oil is mixed with 200 ml of water. The water-soluble mixture is decanted (260 ml) and 10 g of serpentine is added to it and stirred for 4 hrs. A sample was collected for analysis by GC-MC. This mixture is heated in a Parr reactor at 175°C for 4 hrs. at a maximum CO<sub>2</sub> pressure of 20 barg. The Parr reactor is left to cool over-night before opening. The contents are allowed to settle at RTP for 2 hrs. after opening and before filtration to allow for the dissolved CO<sub>2</sub> to escape. 23 g of cake is collected, and this is allowed to air-dry in a fume hood for two days after which the weight was observed to be 16 g. Elemental Analysis and TGA

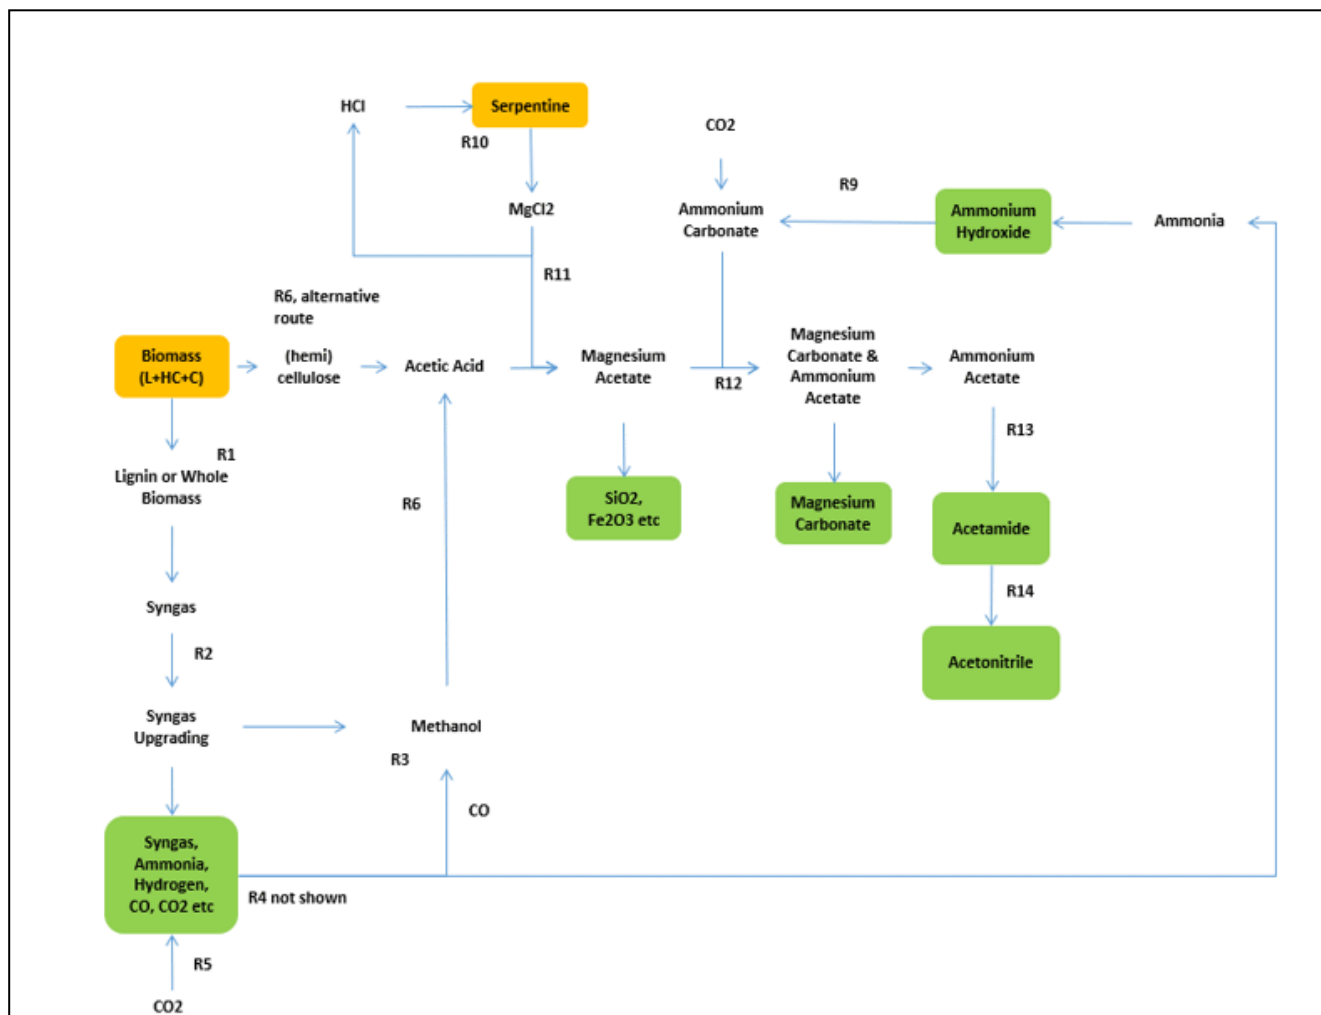

were conducted on this solid residue. A liquid sample is collected for analysis by GC-MS (results not presented).

### Preliminary Results

TGA has shown that there is a 44% weight loss when heated up to 800°C; hence we can conclude that 56% (8.96 g) of the material is inorganic oxides and this is reasonable since serpentine (10 g) is expected to have about 10% water of hydration and this would be lost during calcination at high temperature [9]. The rest of the mass (7.04 g) can be expected to be organic matter. The elemental analysis of the material indicated 41.22% carbon, 0.32% nitrogen, 4.11% hydrogen and 0.21% sulphur, leading to a total weight of 101.8% and this excess can be expected to be due to instrument error.

### Alternative uses

One of the uses for the residual water insoluble solids is the production of construction material. With respect to carbon capture, the precipitate so produced can then be compressed into bricks and stored as a material

**Figure 4:** Schematic of the process of producing Acetamide/Acetonitrile from Biomass and Serpentine.

that effectively captured carbon. The solid material was mixed with water and shaken for 15 min and allowed to settle overnight. It was observed that the solid and water separated indicating that the material is largely insoluble in water. The advantage of this process is that the precipitate holds more carbon than if the mineral serpentine were to be reacted with CO<sub>2</sub> and hence this process would require mining of fewer serpentine. In general, a gram of serpentine can hold up to a third of a gram of CO<sub>2</sub> to produce its mineral carbonate [10] and this is equivalent to about a tenth of a gram of carbon. In contrast, the precipitate we produced holds about 0.66 g of carbon per gram of serpentine used. In view of this, it is worthwhile to explore two options; the first is to hydrogenate these residual water-soluble organics to produce a fuel. Preliminary results of hydrogenation of the mixture without the use of an additional catalyst were performed at 10 barg initial H<sub>2</sub> pressure and a temperature of 175°C in a Parr reactor. The Parr reactor was allowed to cool overnight, and the hydrogenation is repeated at the same conditions and this process is repeated on 4 consecutive days to test the catalytic effect of the mineral; the resultant liquid samples were analyzed by GC-MS. It was observed that the composition of the product is rather different compared the starting material indicating that serpentine has some catalytic effect, but the process did not produce any fuel or water insoluble materials (results not presented) and it may be necessary to use a commercial catalyst at a higher pressure and/or temperature to produce a fuel. The second option is to use this water-soluble bio-oil as a substrate in a biochemical reactor to produce higher value chemicals in view of the current low crude oil price. Preliminary results have shown that the treated bio-oil is not bactericidal unlike the untreated pyrolysis oil. Notwithstanding the economics, we are of the opinion that this concept must be explored further with a view of developing more Bio-Mineral refineries to mitigate climate change and hence we suggest other possible routes that could be explored.

### Other Possible Routes

We present more examples where biomass derived chemicals are used to produce valuable products through decarboxylation. Propionic acid [11], Levulinic acid and Adipic Acid [12], Benzoic Acid [13], Butanol [14] and Butyric Acid [15] can be derived from biomass and used in bio-mineral processes. Briefly, Cyclopentanone and Cyclopentene from Adipic Acid [16], 3-pentanone from Propionic Acid [17], Acetic acid or acetone and a mixture of Cyclopentenones from Levulinic Acid [18], Benzene from Benzoic Acid [19], 5-nonanone from Pentanoic Acid [20, 21] and 4-heptanone from Butanol via Butyric Acid [22] are other examples of bio-mineral processes where different metal oxides are used for decarboxylation. A list of possibilities using two different chemicals in a single

Ketonic decarboxylation reaction can be found elsewhere [23]. The ketones so produced can be hydrogenated and dehydrated to produce olefins [24]. Considering that it is possible to capture carbon as a by-product of a chemical process, it may be possible to reengineer the crude oil, biorefinery and mineral refinery supply chains by the development of Bio-Mineral refineries that capture carbon and control climate change. Hence, it may be worthwhile to pursue research in this direction for the betterment of the planet.

## CONCLUSIONS

We have proposed a circular chemical economy to produce silica, acetone and acetamide/acetonitrile while capturing carbon as mineral carbonates. The proposed concept relies on the notion that valuable chemicals can be produced in a circular economy while synergies between circular bio-economy and linear mineral economy are exploited. Details of two examples of multi-product bio-mineral refineries are given to demonstrate the concept. Such refineries can capture some of the carbon before it is released into the atmosphere, while also capturing CO<sub>2</sub> from flue gas. We have shown that the proposed processes turn from being net CO<sub>2</sub> emitters to being CO<sub>2</sub> neutral processes in 7 or 9 cycles, after which they can be treated as CO<sub>2</sub> mineralization processes with the production of valuable chemicals as by-products. While the proposed processes are technically feasible, it is of importance to optimize them and identify more such processes, keeping in mind the large number of chemical products that potentially need to be replaced with alternative processes to mitigate climate change. Further, it may be worthwhile to study the use of biomass along with mineral ores and reduce the number of processing steps which have a direct impact on the overall cost of production. Hence, we have conducted experiments using biomass pyrolysis oil and serpentine and these show promise for further studies. In view of this, detailed studies are necessary to further develop this research area.

## ACKNOWLEDGEMENTS

Financial support for this work under “ICES/16-230A01: Bio-mineral refineries: Biomass pre-treatment and capturing carbon from biomass/CO<sub>2</sub>” is gratefully acknowledged. The author would like to thank Prof. Paul Sharratt and Dr. Veeresh Juturu for valuable insights.

## ABSTRACT

In response to the global imperative to address climate change, this research focuses on enhancing the transparency and efficiency of the Carbon Capture Utilization and Storage (CCUS) supply chain under carbon tax. We propose a decision-making framework that integrates the CCUS supply chain's optimization model, emphasizing carbon tax policies, with a blockchain network. Smart contracts play a pivotal role in automating the exchange and utilization of carbon emissions, enhancing the digitalization of the CCUS supply chain from source to sink. This automation facilitates seamless matching of carbon sources with sinks, efficient transfer of emissions and funds besides record-keeping of transactions. Consequently, it improves the monitoring, reporting, and verification processes within the CCUS framework, thereby simplifying compliance with regulatory mandates for net emission reductions and carbon taxation policies. By eliminating reliance on third-party verifiers, our blockchain-based CCUS system reduces verification costs and ensures reliable tracking of emissions, mitigating the risk of carbon leakage. Policymakers and stakeholders gain valuable insights to optimize the CCUS network design, specifically considering the impact of carbon tax. This study represents an advancement in sustainable practices, providing a robust tool for decision-makers engaged in climate change mitigation efforts.

## INTRODUCTION

Climate change arises as an escalating global crisis, primarily fueled by soaring levels of greenhouse gas emissions, notably carbon dioxide. Alarming statistics from 2019 reveal a 54 % surge in net anthropogenic greenhouse gas emissions since 1990, underscoring the urgency of transformative solutions [1]. Carbon Capture Utilization and Storage (CCUS) emerges as a pivotal intervention. Projections from the International Energy Agency [2] highlight the growing significance of CCUS, foreseeing a 12 % cumulative reduction in emissions by 2050, particularly in sectors like cement, steel, and chemicals.

The intersection of CCUS with carbon tax policies introduces a nexus laden with challenges and promises. Precise measurement and verification of captured and

stored carbon dioxide pose intricate hurdles in a carbon tax regime. Challenges like low capture efficiency, operational costs, and the lack of international cooperation inhibit the holistic development of CCUS [3,4]. Carbon taxes, wielding economic influence, are instrumental in steering industries toward sustainable practices. They not only curtail energy consumption but also propel advancements in emission reduction technologies [5].

However, the amalgamation of carbon taxes and CCUS confronts multifaceted obstacles encompassing cost implications, technology maturity, and governance complexities. The efficacy of carbon taxes hinges on meticulous governance mechanisms to ensure precision in measurement, verification, and transparency, necessitating innovative solutions. Blockchain technology emerges as a disruptive force, offering a decentralized, transparent, and tamper-proof solution to address these

challenges and fortify the CCUS-carbon tax framework.

Blockchain, with its immutable ledger system, stands poised to support the monitoring and verification of carbon emissions and cash flows. Its decentralized nature instills trust in reported data, mitigates fraud, and fosters international collaboration in the pursuit of climate change mitigation. This paper proposes a blockchain-based approach for CCUS-carbon tax nexus, propelling us toward a sustainable future. As we explore the challenging landscape of environmental responsibility and technological advancement, this study reveals a promising path where CCUS-carbon tax supply chains, and blockchain technology intersect. The subsequent sections delve into overview of blockchain technology, provide a summary of existing studies in the literature, elucidate the proposed framework, explore current challenges, and conclude with insights into future directions.

## BLOCKCHAIN TECHNOLOGY OVERVIEW

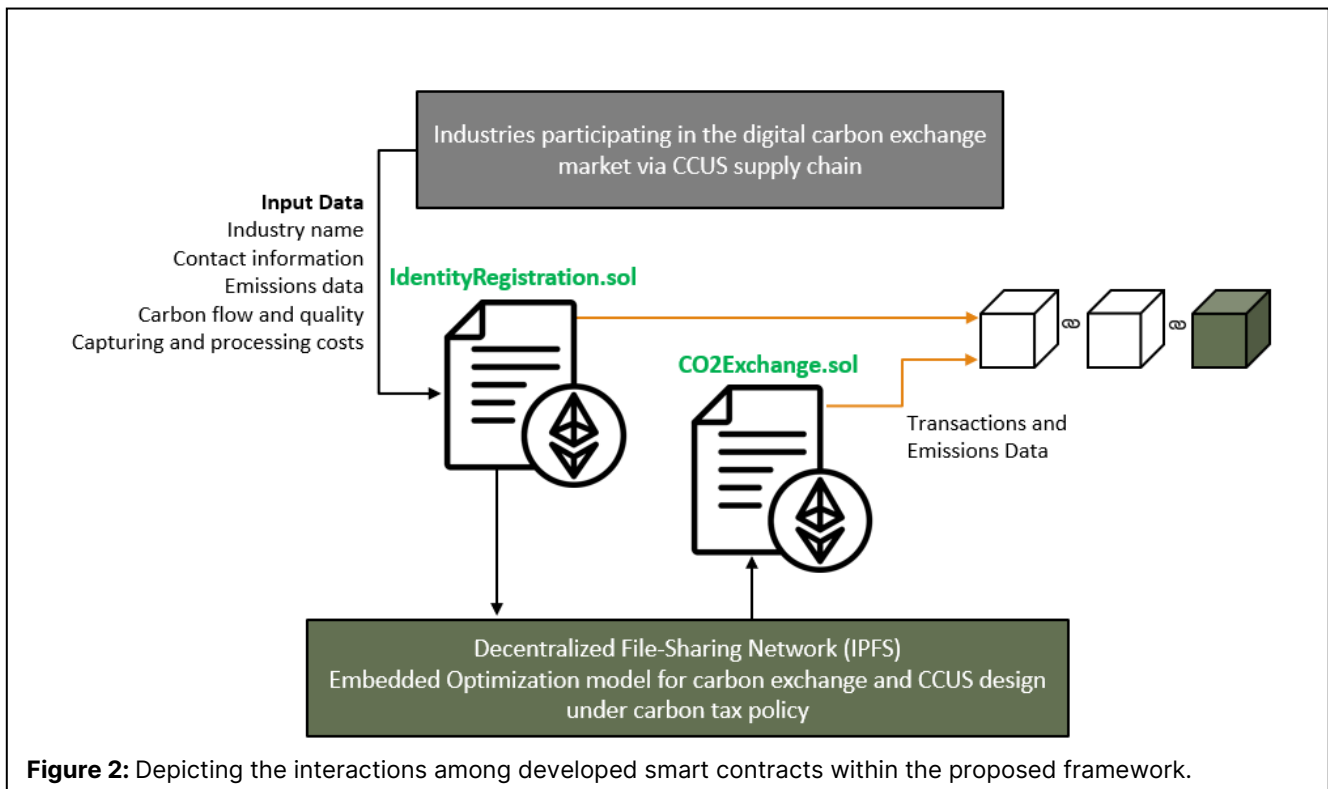

Blockchain is a decentralized technology for recording and managing data and transactions in a transparent, secure and tamper-proof manner [6]. The emerging technology is a distributed ledger that ensures integrity and immutability of data using cryptography and via the replication and allocation of transactions across a network of computers [7]. Blockchain technology has the potential to eliminate security vulnerabilities, eradicate fraudulent activities, and establish an unprecedented level of transparency obviating the necessity for a reliable third-party entity [8]. Blockchain technology is used

to manage tangible and intangible assets using a chain of blocks each containing a set of digital transactions via a decentralized and peer-to-peer network [9].

The decentralization characteristic disperses authority among network nodes, eradicating the need for central oversight. Integral cryptographic techniques bolster data security and integrity [9]. The consensus mechanism arranges validation and transaction sequencing, often via Proof of Work (PoW) or Proof of Stake (PoS). This distributed ledger is bolstered by redundancy across network nodes, thwarting single points of failure. Smart contracts enable self-executing agreements. Blockchains can be public or private, and they imbue data with immutability, making alterations difficult. Furthermore, their permissioned or permissionless nature adds a layer of flexibility to their applications. These multifaceted features collectively empower blockchain's versatility in diverse domains, from cryptocurrencies to supply chain management and beyond [8]. Figure 1 represents blockchain working mechanism, showcasing decentralized, secure, and transparent data sharing among validating nodes, ensuring integrity and traceability in information recording and verification.

## LITERATURE REVIEW

CCUS plays a pivotal role in global climate change mitigation, particularly in challenging industries. Recent advancements emphasize trade-offs between economics and environmental impact, showcasing the benefits of CCUS in achieving net-zero energy systems [10].

**Figure 2:** Depicting the interactions among developed smart contracts within the proposed framework.

Another study focused on optimal cost and environmental benefits of deploying CCUS supply chains at scale in Guangdong Province, China [11]. Some researchers evaluated comprehensive benefits of CCUS networks in coal-fired power plants [12], while others optimized CCUS deployment considering carbon neutrality, cost efficiency, and water stress [13]. These studies highlight evolving CCUS models, addressing economic viability, environmental impact, and sector-specific applications.

Carbon tax is pivotal in incentivizing CCUS adoption. The impact on CCUS source-sink matching in China was analyzed [14], and a stepwise deployment strategies was proposed in Canada based on varying carbon tax levels [15]. CCUS systems in Italy and Germany were explored considering carbon tax in their comprehensive objective function [16]. Other work delved into a risk management framework under carbon tax uncertainties [17], and CO<sub>2</sub> storage potential in shale reservoirs was assessed factoring in economic viability and carbon tax implications [18]. These studies emphasize the role of carbon taxes in shaping CCUS strategies.

Blockchain integration transforms CCUS governance. A blockchain-based carbon trading mechanism was proposed [19], and a permissioned blockchain for emissions trading was modeled [20]. A Sovereign blockchain for carbon trading was explored [21] and a token-based economy for carbon trading was suggested [22]. The intersection of blockchain, carbon trading, and CCUS governance offers a promising avenue for transparency

and efficiency in climate change mitigation.

Existing literature focuses largely on CCUS modeling, optimization, and the impact of carbon taxes, leaving a research gap in exploring blockchain's potential beyond carbon trading in the CCUS landscape. This study addresses this gap by proposing an approach for integrating blockchain into CCUS supply chain optimization models under carbon tax influence. By harnessing blockchain's transparency and tamper-proof nature, we aim to enhance data accuracy, prevent fraud, and foster global collaboration for effective climate change mitigation. This integration offers a comprehensive solution to key challenges in CCUS governance, contributing to a sustainable future.

## PROPOSED APPROACH

Transparency of the CCUS supply chains necessitates the inclusion of emissions and cost data from various stages, encompassing CO<sub>2</sub> capture, compression, utilization, and geological storage. To enhance transparency in designing CCUS supply chains with consideration of carbon tax, this study provides a framework integrating blockchain technology. This integration involves embedding the CCUS-carbon tax optimization model with the blockchain network, aiming for an optimal CCUS network design that fosters improved transparency in emissions reduction, tracking, and cost management. The integration ensures the recording of emissions and cost data, facilitating transparent emission reduction

verification and limiting carbon leakage. The proposed framework empowers CCUS network optimization under carbon tax, fostering a distributed ledger containing transparent CCUS emissions and cost data across various stages.

In this study, we developed two smart contracts utilizing Solidity, the primary programming language for crafting smart contracts on the Ethereum blockchain platform. These contracts, named IdentityRegistration.sol and CO2Exchange.sol, were meticulously designed to support our research framework. To verify their integrity and operational effectiveness, both smart contracts underwent a comprehensive process of compilation, testing, and deployment. This rigorous validation process ensured that they met our stringent requirements for security, efficiency, and reliability, making them integral components of our blockchain-based CCUS system.

The IdentityRegistration.sol smart contract constitutes the foundational layer of our blockchain-based system. This pivotal contract is designed to facilitate a range of critical activities, including the registration of new industries and verification entities. It enables the enrollment of carbon sources, sinks, and verifiers by capturing essential details such as name, industry, address, contact information, email address, industry identification number (ID), verifier ID, carbon flow characteristics, quality parameters, physical properties, and associated costs, including treatment expenses for sources and processing charges for sinks, alongside data on secondary emissions. This smart contract incorporates functions that allow for the retrieval of information about registered entities, enhancing transparency and accessibility within the system. A significant feature of this contract is its built-in mechanism to prevent duplicate registrations, thereby ensuring the integrity of the registration process. It achieves this by conducting preliminary checks against existing records before finalizing any new registrations, thus maintaining an accurate and reliable database of participants in the CCUS ecosystem.

The CO2Exchange.sol smart contract is a critical component of our blockchain-based framework for managing the CCUS supply chain under carbon tax, facilitating the effective exchange and utilization of captured carbon dioxide. This contract is designed to execute several key functions crucial for the transparency and efficiency of the CCUS process. It is responsible for accurately documenting carbon emissions at each stage of the CCUS supply chain, including emission sources, treatment units, transportation mechanisms, and storage or utilization sinks. Additionally, it enables the seamless transfer of funds among carbon sources, sinks, and the government, thereby ensuring compliance with carbon tax regulations and supporting the economic aspects of carbon trading by managing the flow of funds within the

system. This includes the recording of all related transactions, providing a transparent and immutable ledger of carbon emissions and financial exchanges.

**Table 1:** Algorithms of Smart Contracts.

---

**IdentityRegistration.sol: Initializing CO<sub>2</sub> utilization and exchange**

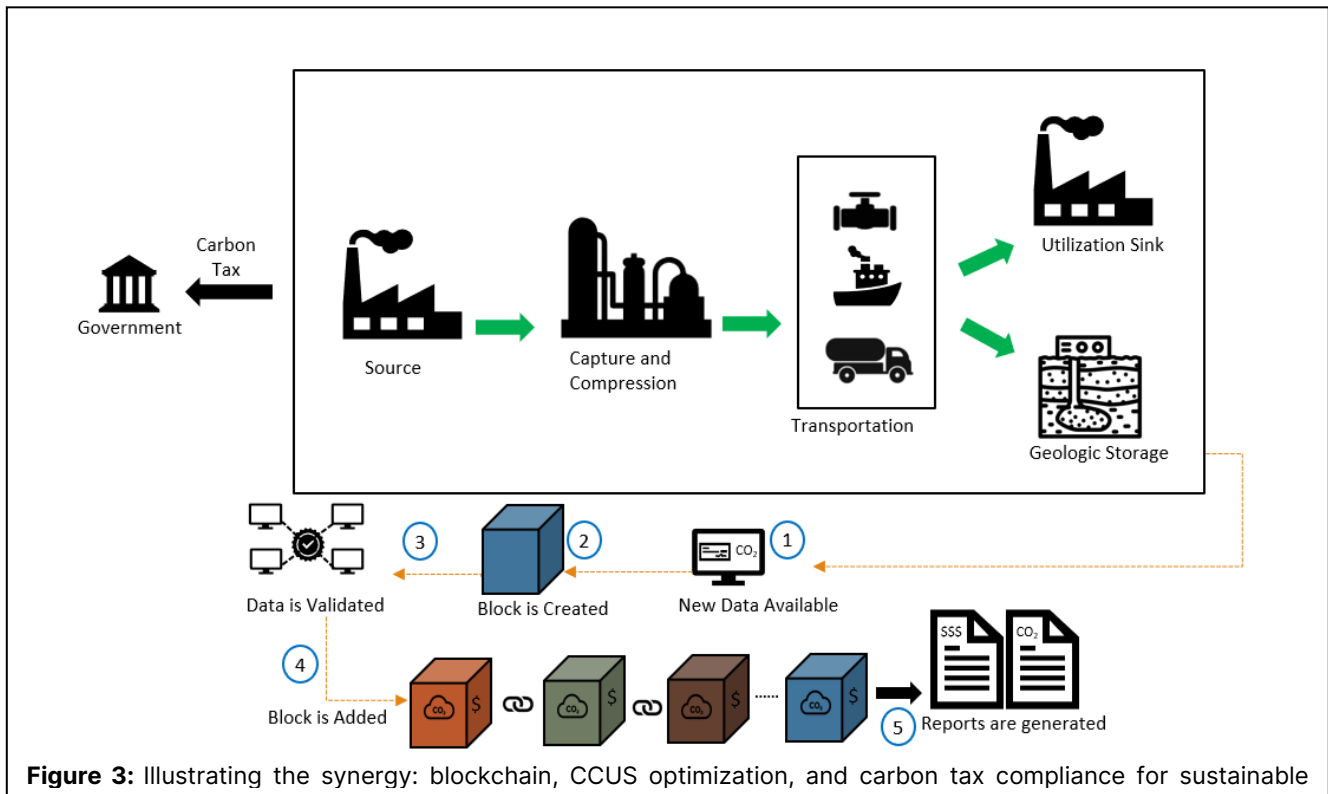

1. Declare a contract called IdentityRegistration.
2. Define structs for Sources, and Sinks considering relevant information such as industry name, type, address, contact information, email, industry ID, carbon flow, and quality.
3. Define struct for Verifiers including relevant information such as verifier name, industry, contact information, email, and verifier ID.
4. Define mapping variables to map industry ID to Source/Sink structs.
5. Define mapping variables to map verifier ID to verifier struct.
6. Define events for NewSource, NewSink, and NewVerifier.
7. Define functions to register new industries and verifiers and retrieve their information.

**CO2Exchange.sol: Transaction and tokenization process**

1. Declare a contract called CO2Exchange.
  2. Define struct for CO<sub>2</sub> transaction.
  3. Define mapping variables to map transaction ID to the transaction struct.
  4. Define function to record emissions from each stage including sources, capturing units, transportation, and sinks.
  5. Define function to transfer funds from sinks to sources and from sources to government.
  6. Define function to record transactions.
- 

The operational logic and step-by-step functionality of these smart contracts are detailed in Table 1, providing a clear schematic of their roles within the CCUS system. Figure 2 visually depicts the dynamic interactions facilitated by the developed smart contracts, illustrating how they interconnect within the blockchain-enabled CCUS supply chain under carbon taxation. This representation underscores the smart contracts' pivotal role in streamlining the CCUS process to form a cohesive system that not only tracks carbon emissions and transactions but also facilitates the regulatory and economic mechanisms essential for effective carbon management and mitigation efforts.

The commencement of the CCUS-blockchain system takes place upon the availability of emissions and cost data, resulting in the creation of a new block. This block then undergoes a secure and decentralized distribution process among validating and authorizing nodes, with the assumption that both government entities and

**Figure 3:** Illustrating the synergy: blockchain, CCUS optimization, and carbon tax compliance for sustainable

participating industries hold authorized access. The confirmed data blocks are smoothly added to the ongoing sequence by network nodes, safeguarded by distinctive hashes and the hash of the preceding block. Emissions and cost data from each stage are documented within authenticated and encrypted blocks, assuring the preservation of data integrity across the entire blockchain network. Figure 3 demonstrates the proposed approach, integrating CCUS-carbon tax optimization models with a blockchain network for enhanced transparency in emission and cash flow tracking.

Incorporating blockchain technology within the CCUS carbon tax nexus presents a promising avenue for enhancing data integrity, transparency, and stakeholder trust. However, it introduces certain risks and drawbacks that necessitate careful consideration for successful implementation. The adoption of blockchain technology significantly increases the operational complexity of the CCUS supply chain. Establishing a blockchain infrastructure requires substantial initial investments not only in technology but also in training personnel and developing new operational protocols. This upfront cost and the effort needed for integration can deter stakeholders, particularly in regions where CCUS technologies are still in nascent stages. The complexity associated with blockchain can also slow down the decision-making processes, potentially delaying critical CCUS deployments needed to meet urgent carbon reduction targets.

While blockchain enhances data sharing and transparency, it raises significant data privacy concerns. The

immutable nature of blockchain means that once data is entered, it cannot be altered or removed, posing potential risks in handling sensitive or proprietary information. Ensuring that the blockchain architecture complies with global data protection regulations requires sophisticated solutions that can segregate and protect sensitive data without undermining the benefits of transparency and traceability that blockchain offers. A notable paradox in utilizing blockchain for environmental initiatives like CCUS is the technology's own environmental footprint, particularly for systems that rely on energy-intensive consensus mechanisms like Proof of Work (PoW). The additional energy consumption required for blockchain operations could contribute to the greenhouse gas emissions that CCUS seeks to mitigate. This aspect is critically important when considering the overall sustainability and environmental impact of integrating blockchain into CCUS frameworks.

As CCUS initiatives expand, the blockchain system must be able to scale accordingly without compromising performance or security. Achieving scalability while maintaining the decentralized nature of blockchain poses technical challenges. Furthermore, the decentralized decision-making process inherent in blockchain networks requires consensus among all participants, which can be difficult to achieve across a diverse stakeholder group with varying interests, technological readiness, and priorities. To overcome these challenges, collective efforts from stakeholders, government bodies, and

technological experts are imperative to ensure the smooth integration of CCUS supply chains with blockchain technology, facilitating transparent and effective strategies for emission reduction and cost management.

Considering these complexities, our research emphasizes the need for a balanced approach that leverages blockchain's strengths while addressing its inherent drawbacks. We propose a blockchain architecture that combines the transparency and immutability of public and private blockchain features through smart contracts. This approach, coupled with the development of smart contracts tailored to automate and streamline CCUS-specific operations, aims to minimize the operational and environmental drawbacks of blockchain, ensuring that its integration into the CCUS carbon tax nexus contributes positively to the global effort against climate change.

The consensus mechanism adopted in this study is the Delegated Proof of Stake (DPoS), which is strategically chosen for its efficiency in reducing the computational power required for transaction validation and consensus achievement. Unlike the conventional Proof of Work (PoW) mechanism, which is known for its high energy consumption and consequent environmental emissions, DPoS significantly minimizes these impacts. This approach not only aligns with our environmental sustainability goals but also enhances the overall efficiency and scalability of the blockchain network by delegating the responsibility of transaction validation and block creation to a select group of trusted elected representatives. This mechanism ensures a more environmentally friendly and cost-effective solution for the blockchain framework employed in our CCUS system under carbon tax policy.

Our approach introduces a blockchain architecture within the CCUS carbon tax nexus, significantly advancing current methodologies by balancing the need for transparency, data integrity, and stakeholder privacy. The proposed approach utilizes public and private features of smart contracts. It ensures the immutability and transparency critical for public trust and regulatory compliance while also providing the privacy and scalability necessary for industrial adoption and efficient operation. This innovative framework addresses key concerns around data privacy, scalability, and operational complexity that have hampered broader blockchain application in environmental and carbon management systems.

A cornerstone of our approach is the strategic use of smart contracts to automate critical processes within the CCUS supply chain, from carbon emission verification to carbon tax computation and compliance reporting. This automation significantly reduces administrative overhead, minimizes human error, and speeds up the decision-making process, allowing for more dynamic and responsive CCUS operations. Moreover, by eliminating the need for third-party verification, we expect to see a reduction in operational costs, further incentivizing the

adoption of CCUS technologies by industries.

The expected benefits of our approach are profound. By enhancing the transparency and integrity of carbon and tax data, we aim to foster greater trust among stakeholders, including regulatory bodies, industries, and the public, thereby facilitating a more collaborative and efficient approach to carbon management. The reduction in operational costs and the improved efficiency of regulatory compliance processes are anticipated to accelerate the deployment of CCUS technologies, contributing significantly to global efforts to mitigate climate change. Furthermore, the environmental impact of blockchain operations is minimized through our energy-efficient blockchain design, aligning the technology's application with the overarching goal of reducing greenhouse gas emissions.

In essence, our approach not only addresses the immediate challenges faced by the CCUS carbon tax nexus but also sets a new standard for the integration of blockchain technology in environmental governance, promising a more sustainable, transparent, and efficient framework for global climate change mitigation efforts.

## ILLUSTRATIVE EXAMPLE

This section presents an illustrative case study for the proposed approach of integrating CCUS optimization models with consideration for carbon tax implications through blockchain technology. The methodology builds upon a previously developed Mixed Integer Non-Linear Optimization Model (MINLP) [23]. The objective function, as expressed in Equation (1), seeks to minimize the Total Annual Cost (TAC), encompassing tax cost  $C_s^{\text{Tax}}$ , treatment  $C_{s,k}^{\text{Treat}}$ , compression  $C_{s,k}^{\text{Comp}}$ , transportation  $C_{s,k}^{\text{Trans}}$ , and utilization  $C_{s,k}^{\text{Sinks}}$  costs.

The objective function subject to constraints ensuring that the carbon flow from each source equals the treated flowrate  $T_{s,k,t}$ , untreated flowrate  $U_{s,k}$ , and CO<sub>2</sub> emissions to the atmosphere  $R_{s,\text{emit}}$  as indicated via Equation (2). The CO<sub>2</sub> utilized in each sink  $F_k$  defined as the sum of treated  $T_{s,k,t}$  and untreated  $U_{s,k}$  CO<sub>2</sub> transported from different sources as shown in Equation (3). Chemical absorption amine units were employed for CO<sub>2</sub> treatment due to its maturity. The costs associated with capturing, compression, transportation, and utilization were computed following the methodology outlined in [23].

$$\text{TAC} = C_s^{\text{Tax}} + C_{s,k}^{\text{Treat}} + C_{s,k}^{\text{Comp}} + C_{s,k}^{\text{Trans}} + C_k^{\text{Sinks}} \quad (1)$$

$$R_s = \sum_{k \in K} \sum_{t \in T} T_{s,k,t} + \sum_{k \in K} U_{s,k} + R_{s,\text{emit}} ; \forall s \in S \quad (2)$$

$$F_k = \sum_{s \in S} \sum_{t \in T} T_{s,k,t} + \sum_{s \in S} U_{s,k} ; \forall k \in K \quad (3)$$

Data detailing CO<sub>2</sub> composition ( $X_{CO_2}$ ), flow rate, treatment cost parameter ( $C_t$ ), sink processing cost parameter ( $C_s$ ), and emission factors ( $C_e$ ) which are expressed in tons of CO<sub>2</sub> emitted per tons of CO<sub>2</sub> processed, for CO<sub>2</sub> sources and sinks were acquired following the registration of emission sources and sinks through the IdentityRegistration.sol smart contract. The data are presented in Tables 2 and 3, respectively. CO<sub>2</sub> compositions and flow rates exhibit variations across industries. This study examined four carbon emission sources: ammonia production facility, steel-iron mill, power generation plant, and refinery. Furthermore, it included five carbon dioxide sinks, specifically: algae-based carbon utilization system, saline aquifer storage, and the production processes for methanol, urea, and acetic acid. The study sets a target net emission reduction limit of 2.48 MM t CO<sub>2</sub>/yr and a tax rate of 50 \$/t CO<sub>2</sub>. Industrial facilities face a decision to either adopt CCUS technologies or remit a carbon tax to meet the government-mandated net emissions reduction target. The choice is based on minimizing the total annual cost. All plants are assumed to operate 8000 h per year. The blockchain-based CCUS-carbon tax optimization model was implemented, and the results are discussed below.

**Table 2:** Carbon dioxide source data.

Source	$X_{CO_2}$ (wt%)	CO <sub>2</sub> Flow (t/d)	$C_t$ (\$/t CO <sub>2</sub> )
Ammonia	100	977	0
Steel-iron	44	3451	29
Power plant	7	9385	43
Refinery	27	1092	35

**Table 3:** Carbon dioxide sink data.

Sink	$X_{CO_2}$ (wt%)	Flow (t/d)	$C_s$ (\$/t CO <sub>2</sub> )	$C_e$ (t/t CO <sub>2</sub> )
Algae	6	344	-7	0.28
Storage	94	7500	9	0
Methanol	99	2072	-20	0.17
Urea	99	1488	-17	0.11
Acetic Acid	99	2500	-26	0.34

The optimal design achieved, through the implementation of CCUS, a carbon reduction of 1.5 million tons of CO<sub>2</sub> per year, while the remainder of the net reduction goal was released into the atmosphere and subsequently subjected to taxation. The total annual cost of the optimal design is 19 MM \$/yr, with a carbon tax cost amounting to 49 MM \$/yr. Table 4 delineates the composition of the net carbon dioxide reduction target, illustrating that a significant portion was achieved through the implementation of CCUS technology, while the remainder, not captured, was emitted, and subsequently subjected to

taxation. This underscores the efficacy of carbon taxation as a driving force behind the adoption of CCUS technologies.

**Table 4:** Analysis of carbon dioxide emission reduction target.

Element	Flow (MM t CO <sub>2</sub> /yr)
Net reduction target	2.48
Carbon captured	1.5
Carbon emitted	0.98

Optimal source to sink carbon allocations were identified and presented in Figure 4. The percentages on the left side of Figure 4 depict the CO<sub>2</sub> usage across different sources, whereas the percentages on the right show how well the CO<sub>2</sub> demands of each sink were satisfied. CO<sub>2</sub> from all sources was fully captured, utilized, or stored, except from the power plant as the low carbon quality limited utilization. To meet the government's targeted net reduction, CO<sub>2</sub> was directed towards economically profitable sinks such as algae, methanol, urea, and acetic acid, where the demand for carbon was completely satisfied, leveraging the economic benefits derived from these CO<sub>2</sub> utilization pathways. Conversely, the use of saline storage as a sink was not maximized due to its associated higher costs, including those for treatment, transport, and processing. Consequently, the CO<sub>2</sub> that was not sequestered or utilized was released into the atmosphere, resulting in it being subject to carbon taxation.

**Figure 4:** CO<sub>2</sub> source to sink allocation for the proposed system.

Most of the carbon demands for the algae sink are satisfied by the refinery's emissions, which do not require further treatment to align with the algae's carbon flow and quality specifications. Carbon from the steel-iron

sector is predominantly processed and then used to supply the necessary carbon flow for both methanol and urea production. The carbon requirements for the methanol sink are primarily fulfilled using processed carbon emitted by the steel-iron facility, whereas urea benefits from treated carbon emissions from both steel and refinery operations. Additionally, the carbon demands for acetic acid production are mainly met by emissions from ammonia and power generation plants. Notably, most of the carbon utilized in these processes is treated, except for the direct use of pure CO<sub>2</sub> from ammonia sources and emissions from refineries to algae sinks. This exception is due to the refinery's emissions directly meeting the algae's relatively low-quality carbon requirements.

Table 5 illustrates carbon emissions at various stages of the CCUS process, encompassing emissions from sources, capture units, transportation, and sinks. The emissions detailed on the source side reflect those discharged post-CCUS implementation. The predominant sources of emissions are identified as the main source of emissions, succeeded by carbon sinks, transportation, and capture facilities in terms of contribution. All emissions data are logged as transactions in the blockchain, facilitating the monitoring of CO<sub>2</sub> emissions throughout the CCUS supply chain.

**Table 5:** Carbon dioxide emissions from CCUS subsystems.

CCUS module	Flow (t CO <sub>2</sub> /d)
Sources	7883
Capturing unit	190
Transportation	245
Sinks	1462

Each transaction plays a crucial role in ensuring accountability, traceability, and reliability throughout the optimal CCUS network. The first transaction provides carbon dioxide generation data from sources, providing a foundation for mitigation strategies. The second transaction records emissions data from treatment units and the third transaction details emissions during compression and pumping, crucial for evaluating the environmental impact of transportation. The fourth transaction monitors sinks emissions, offering insights into sink's effectiveness. The final transaction summarizes financial aspects, including carbon tax payments, and total annual cost essential for assessing the project's economic viability and ensuring sustainable carbon management.

The blockchain-based optimal CCUS supply chain ensures transparency, accountability, and trust throughout the CCUS process, supporting environmental and economic goals. The study successfully meets the net emission capture target, and comprehensive results, encompassing both carbon dioxide flow rates and financial

implications, are securely recorded in the blockchain, ensuring tamper-proof integrity.

## CONCLUSIONS

This study highlights the significant potential of blockchain technology to enhance transparency, efficiency, and regulatory compliance in CCUS supply chains under carbon tax regimes. By developing and implementing the IdentityRegistration.sol and CO2Exchange.sol smart contracts, we established a framework for automating carbon emissions tracking and regulatory reporting, addressing key challenges such as emission verification and carbon leakage. The adoption of the Delegated Proof of Stake (DPoS) consensus mechanism further aligns our approach with environmental sustainability by minimizing the energy consumption of blockchain operations. Our case study demonstrates that a substantial portion of carbon reduction targets can be met through CCUS, with carbon taxation serving as a compelling incentive for technology adoption. This research contributes to the optimization of CCUS networks, offering a scalable and sustainable solution to climate change mitigation and highlighting the critical role of innovative technologies in achieving global sustainability goals.

## ACKNOWLEDGMENT

The authors would like to express their gratitude to Qatar Foundation (QF) for providing financial support and resources for this research. This study on the integration of CCUS, carbon taxes, and blockchain technology has been made possible through the funding received under the fellowship program supported by QF.

## ABSTRACT

Critical minerals and rare earth elements play an important role in our climate change initiatives, particularly in applications related with energy storage. Here, we use discrete optimization approaches to design a process for the recovery of Lithium and Cobalt from battery recycling, through membrane separation. Our contribution involves proposing a Generalized Disjunctive Programming (GDP) model for the optimal design of a multistage diafiltration cascade for Li-Co separation. By solving the resulting nonconvex mixed-integer nonlinear program model to global optimality, we investigated scalability and solution quality variations with changes in the number of stages and elements per stage. Results demonstrate the computational tractability of the nonlinear GDP formulation for design of membrane separation processes while opening the door for decomposition strategies for multicomponent separation cascades. Future work aims to extend the GDP formulation to account for stage installation and explore various decomposition techniques to enhance solution efficiency.

**Keywords:** Critical Minerals, Lithium Recovery, Diafiltration Cascade, Superstructure Optimization, Generalized Disjunctive Programming, Mixed-Integer Nonlinear Programming.

## INTRODUCTION AND RELATED WORK

The U.S. relies on the import of rare earth elements (REE) and critical minerals (CM) which are central to our climate change initiatives, particularly in applications such as electric vehicles and energy storage [1]. With an increasing demand for REE and CM, restrictions by competitors on exports have disrupted the U.S. supply chain and pose a risk to the national economy [2]. Projections by the IEA indicate a staggering 60% surge in renewable energy power capacity from 2020 to 2026 [3]. As a result, recycling REE and CM has become one of the main objectives of the Department of Energy (DOE) since 2014 [1].

One potential source of Lithium recovery is Lithium-ion battery recycling [4]. This process addresses the lack of domestic CM production [5], as it can recover battery-grade Lithium and Cobalt for a fraction of the materials extracted from either brine or ores [6]. However, concerns arise from improper recycling, which affects human

health and the environment [7], prompting opportunities to employ energy efficient processes with minimal environmental impact like membrane separation.

Diafiltration membranes offer significant advantages in the efficiency of recycling CM over existing battery recycling pathways, reducing energy needs and chemical use and cost. In a diafiltration membrane, the process employs a dilute solution, called diafiltrate, to reduce the solubility limit effect that leads to fouling. This approach allows the staging of membrane units into cascades, facilitating the extraction of lithium and cobalt from leach liquors.

There is a growing interest in utilizing membranes for the recovery and extraction of CM, as evident in recent literature. A comprehensive review and feasibility assessment for membrane-based technology in lithium recovery were provided by Li et al. [8]. Similarly, Alvarez et al. [9] demonstrated the potential to enhance water security by utilizing membranes to filter out metals during water treatment. In the realm of lithium recovery

methods, Bae et al. [10] conducted a study that investigated and compared various proposed techniques, including chemical extraction and selective membrane processes, with a focus on quantitative efficiency and purity based on existing literature. Razmjou et al. [11] delved into the physical construction of a nanofiltration membrane for lithium recovery, proposing design principles to enhance selectivity. The prevailing trend in the current literature emphasizes a primary understanding and performance evaluation of membrane processes, while rigorous mathematical optimization is less commonly addressed.

In a prior study conducted by Wamble et al. [12], a superstructure formulation was introduced to determine the optimal configuration of a membrane cascade. This superstructure selects design variables (e.g., flow, concentration, stage length) while maximizing Cobalt recovery and adhering to a minimum Lithium recovery fraction, employing the epsilon constraint approach. This superstructure was posed as a nonlinear program (NLP), which was solved using IPOPT.

In the earlier method, the determination of stream connectivity was performed continuously, allowing for the division of feed, diafiltrate, and refluxed streams. However, the authors noted that this continuous approach failed to consistently generate "physically sensible cascade designs" [12]. To address this issue, the authors introduced a second optimization step. In our proposed extension of this approach, we suggest modeling stream connectivity as a discrete decision, ensuring the singular allocation of side streams. As the model incorporates bilinear mixing and nonlinear performance constraints, the proposed method requires solving a nonconvex mixed-integer nonlinear programming (MINLP) problem. Additionally, we propose formulating the MINLP superstructure as a Generalized Disjunctive Program (GDP), a widely employed approach in the literature for superstructure optimization. The motivation behind this is the fact that GDP effectively avoids singularities in nonlinear expressions, particularly when variables become zero, a phenomenon recognized in the literature as zero-flow issues [13]. This approach allows for the identification of the globally optimal superstructure and facilitates future extensions for the optimal determination of the number of separation stages.

## Generalized Disjunctive Programming

Generalized Disjunctive Programming (GDP) corresponds to a mathematical optimization framework designed for modeling and solving problems characterized by embedded logic. Within GDP, the feasible region is represented by the intersection of disjunctions of sets, employing Boolean variables as indicators for each set. In this context, a *True* value for a Boolean variable indicates that the solution resides within the corresponding set

[14]. The general formulation of a GDP is as follows:

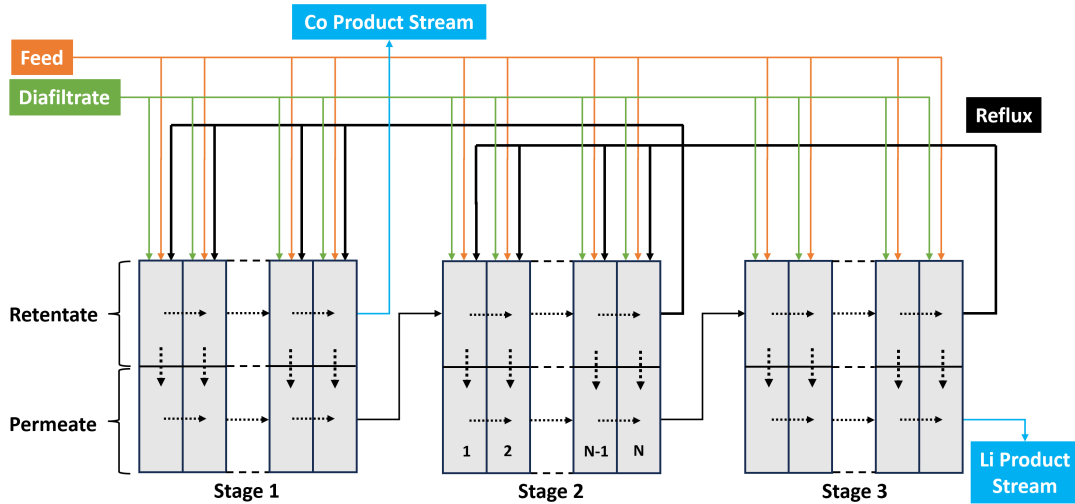

$$\begin{aligned} & \min f(x) \\ & \text{s. t. } g(x) \leq 0 \\ & \quad \bigvee_{i \in D_k} \left[ r_{ik}(x) \leq 0 \right], \quad k \in K \\ & \quad \Omega(Y_{i,k}) = \text{True} \\ & \quad x \in \mathbb{R}^n \\ & \quad Y_{ik} \in \{\text{True}, \text{False}\}, i \in D_k, k \in K \end{aligned}$$

where, an objective function  $f(x)$  is to be minimized over a set of continuous real variables  $x$  subject to a set of global constraints  $g(x) \leq 0$ . Boolean variable  $Y_{ik}$  acts as the indicator for the set implied by constraints  $r_{ik} \leq 0$ , standing for the  $i^{\text{th}}$  disjunct set of the  $k^{\text{th}}$  disjunction. Each of the  $K$  disjunctions are related with an exclusive OR operator ( $\bigvee$ ), which can be interpreted as an *exactly-One* operator when  $|D_k| > 2$ . The set of logical propositions  $\Omega$  is composed of logical clauses connected with logical operators such as AND ( $\wedge$ ), OR ( $\vee$ ), XOR ( $\bigoplus$ ), negation ( $\neg$ ), implication ( $\Rightarrow$ ), and equivalence ( $\Leftrightarrow$ ). Here,  $\Omega$  is required to be *True* to indicate that all the propositions must be satisfied.

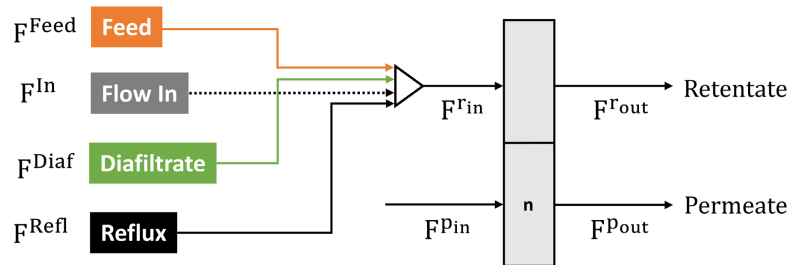

GDP offers a dual advantage by providing an intuitive means to model the logic inherent in problems and presenting a diverse array of solution methods that can be broadly categorized in two groups. One major category involves reformulating the GDP as a mixed-integer (non)linear program through various transformations. These transformations translate the logical structure of the problem into a mathematical formulation suitable for traditional MINLP optimization algorithms. Examples of such transformations include Big-M [15], Hull [16], and Hybrid Planes [17], among others. The second category encompasses logic-based decomposition methods that directly operate on the logical structure of the problem. Tailored methods within this category include Logic-based Outer Approximation [18], Logic-based Branch and Bound [16], and the Logic-based Discrete-Steepest Descent Algorithm [19], providing specialized approaches to address the unique complexities associated with the logic of the problem at hand.

## PROBLEM STATEMENT

Given is the following information for the optimization of a multistage diafiltration cascade aimed at separating Lithium from Cobalt. The provided parameters include the predetermined number of separation stages and the number of discretization elements per stage. Additionally, the model involves the flows and concentrations associated with both the feed and diafiltrate streams. Relevant membrane parameters, such as the stage width, solvent flux across the membrane, and the

**Figure 1:** Superstructure sketch for a three-stage ( $|K| = 3$ ) diafiltration membrane cascade.

**Figure 2:** Sketch of the flow structure of a single discretized element.

sieving coefficients for both components, are also specified. Furthermore, the model includes the performance relationships that govern the system's behaviour as provided in Wable et al. [12].

Design variables that specify the optimal diafiltration membrane cascade superstructure need to be determined. Firstly, the optimal stream connections within the superstructure must be established. This involves identifying the position (in terms of stage and discretized element) for the feed, the diafiltrate, and the recycle from upstream stages. Additionally, the length of each stage in the diafiltration cascade needs to be determined to achieve an efficient separation process. Moreover, comprehensive determination of all flows and concentrations in regard to both components (Lithium and Cobalt) throughout the entire system must be determined. This comprehensive set of determinations forms the basis for configuring an optimized and well-functioning multistage diafiltration system for the separation of Lithium and Cobalt.

The primary objective of the optimization model is to maximize the recovery of Cobalt within a Cobalt-rich stream extracted from the retentate flow of the initial stage in the diafiltration cascade. This goal is set against the constraint of ensuring a minimum recovery of Lithium

within a Lithium-rich stream exiting the permeate flow of the final stage. In essence, the goal is to manage the inherent multi-objective nature of recovering both Lithium and Cobalt. In this work, we consider the system to be isotropic, meaning that all stages share identical lengths. The configuration of the superstructure is presented in Figure 1.

## PROPOSED GDP SUPERSTRUCTURE

In this section, we illustrate the modifications made to the original model, primarily focusing on incorporating the necessary logic into the GDP framework to represent installing a singular position for the feed ( $F^{Feed}$ ), diafiltrate ( $F^{Diaf}$ ), and reflux per stage ( $F_n^{Refl}$ ). To accomplish this objective, we model each discrete element individually, as illustrated in Figure 2, wherein the incoming side flows are handled in a disaggregated manner. Through this approach, the following disjunctions are implemented, allowing for the activation or deactivation of incoming streams, thereby determining the existence of an incoming side stream. Here, the Boolean variables  $Y_{nk}^{Feed}$ ,  $Y_{nk}^{Diaf}$ , and  $Y_{nk}^{Refl}$  indicate the existence of a feed, diafiltrate or reflux in a particular position respectively.

$$\left[ \begin{array}{c} Y_{nk}^{Feed} \\ F_{nk}^{Feed} = \hat{F}^{Feed} \\ x_{cnk}^{Feed} = \hat{x}_c^{Feed} \quad \forall c \in C \end{array} \right] \vee \left[ \begin{array}{c} \neg Y_{nk}^{Feed} \\ F_{nk}^{Feed} = 0 \\ x_{cnk}^{Feed} = 0 \quad \forall c \in C \end{array} \right],$$

$$\forall n \in N, k \in K \quad (1)$$

$$\left[ \begin{array}{c} Y_{nk}^{Diaf} \\ F_{nk}^{Diaf} = \hat{F}^{Diaf} \\ x_{cnk}^{Diaf} = \hat{x}_c^{Diaf} \quad \forall c \in C \end{array} \right] \vee \left[ \begin{array}{c} \neg Y_{nk}^{Diaf} \\ F_{nk}^{Diaf} = 0 \\ x_{cnk}^{Diaf} = 0 \quad \forall c \in C \end{array} \right],$$

$$\forall n \in N, k \in K \quad (2)$$

$$\left[ \begin{array}{c} Y_{nk}^{Refl} \\ F_{nk}^{Refl} = F_{|N|, \{k+1\}}^{r_{out}} \\ x_{cnk}^{Refl} = x_{c, |N|, \{k+1\}}^{r_{out}} \quad \forall c \in C \end{array} \right] \vee \left[ \begin{array}{c} \neg Y_{nk}^{Refl} \\ F_{nk}^{Refl} = 0 \\ x_{cnk}^{Refl} = 0 \quad \forall c \in C \end{array} \right],$$

$$\forall n \in N, k \in K \setminus \{K\} \quad (3)$$

where  $\hat{F}^j$  and  $\hat{x}^j$  represent the known flow and composition of the incoming side stream  $j \in \{Feed, Diaf\}$ . The first two disjunctions establish connections between the incoming stream and known parameter values. In contrast, the third disjunction, which models the recycle, links a discretized element to the stream coming from the retentate of the subsequent stage. While these disjunctions exclusively represent the presence of a stream at a given position, we also ensure a singular feed and diafiltrate throughout the entire structure, as well as a singular recycle per stage. To account for this logic, the following cardinality clauses are introduced.

$$exactlyOne([Y_{nk}^{Feed} \quad \forall n \in N, k \in K]) \quad (4)$$

$$exactlyOne([Y_{nk}^{Diaf} \quad \forall n \in N, k \in K]) \quad (5)$$

$$exactlyOne([Y_{nk}^{Refl} \quad \forall n \in N]), \quad k \in K \setminus \{K\} \quad (6)$$

Equations (1-6) represent the modeling logic of the superstructure. Next, with the introduced side stream disaggregation, the per-element mass balances are outlined as follows:

$$F_{nk}^{In} + F_{nk}^{Feed} + F_{nk}^{Diaf} + F_{nk}^{Refl} = F_{nk}^{r_{in}}, \quad \forall n \in N, k \in K \quad (7)$$

$$F_{nk}^{In} x_{cnk}^{In} + F_{nk}^{Feed} x_{cnk}^{Feed} + F_{nk}^{Diaf} x_{cnk}^{Diaf} + F_{nk}^{Refl} x_{cnk}^{Refl} = F_{nk}^{r_{in}} x_{cnk}^{r_{in}}, \quad \forall c \in C, n \in N, k \in K \quad (8)$$

$$F_{nk}^{r_{in}} + F_{nk}^{p_{in}} = F_{nk}^{r_{out}} + F_{nk}^{p_{out}}, \quad \forall n \in N, k \in K \quad (9)$$

$$F_{nk}^{r_{in}} x_{cnk}^{r_{in}} + F_{nk}^{p_{in}} x_{cnk}^{p_{in}} = F_{nk}^{r_{out}} x_{cnk}^{r_{out}} + F_{nk}^{p_{out}} x_{cnk}^{p_{out}}, \quad \forall c \in C, n \in N, k \in K \quad (10)$$

The permeate mass balance is a function of the membrane flux ( $J$ ), the width of the stage ( $w$ ) and the element

length ( $\hat{L}$ ) as:

$$F_{nk}^{p_{in}} + Jw\hat{L}_{nk} = F_{nk}^{p_{out}}, \quad \forall n \in N, k \in K \quad (11)$$

In the previous study, the performance equation was examined in terms of a log transform. However, we suggest maintaining the equation in its exponential form and rearrange the expression to remove the fraction. This reformulation ensures a well-defined expression within the domain of our variables, mitigating the risk of evaluation errors and contributing to the overall stability and well-behaved nature of the NLP formulation. The resulting expression where,  $S$  is the sieving coefficient per component is as follows:

$$x_{cnk}^{r_{out}} = x_{cnk}^{r_{in}} \left( \frac{F_{nk}^{r_{out}}}{F_{nk}^{r_{in}}} \right)^{S_c - 1}, \quad \forall c \in C, n \in N, k \in K \quad (12)$$

The elements can now be interconnected to create stages, where the key concept is to establish connections between the flow and composition exiting the permeate of one stage with the retentate entering the subsequent stage. These connections can be expressed as:

$$F_{n\{k-1\}}^{p_{out}} = F_{nk}^{r_{in}}, \quad \forall n \in N, k \in K \setminus \{1\} \quad (13)$$

$$x_{cn\{k-1\}}^{p_{out}} = x_{cnk}^{r_{in}}, \quad \forall c \in C, n \in N, k \in K \setminus \{1\} \quad (14)$$

Moreover, the permeate and the flow-in entering the first element of each membrane are both assigned a value of zero. Similarly, in the last stage, there is no recycle entering.

$$F_{1k}^{p_{in}} = F_{1,1}^{r_{in}} = 0, \quad \forall k \in K \quad (15)$$

$$x_{c1k}^{p_{in}} = x_{c1k}^{r_{in}} = 0, \quad \forall c \in C, k \in K \quad (16)$$

$$F_{n|K|}^{Refl} = 0, \quad \forall n \in N \quad (17)$$

$$x_{cn|K|}^{Refl} = 0, \quad \forall c \in C, k \in K \quad (18)$$

A minimum Lithium recovery ( $R_{\min}^{Li}$ ) from the lithium-rich stream in the permeate exiting the last stage must be satisfied.

$$F_{|N||K|}^{p_{out}} x_{Li, |N||K|}^{p_{out}} \geq R_{\min}^{Li} (\hat{F}^{Feed} \hat{x}_{Li}^{Feed} + \hat{F}^{Diaf} \hat{x}_{Li}^{Diaf}) \quad (19)$$

The objective function is to maximize the recovery of Cobalt in the Cobalt-rich stream exiting the permeate of the first stage. Considering that the cobalt entering the system remains constant, it suffices to maximize the following expression:

$$\max F_{|N|,1}^{r_{out}} x_{Co, |N|,1}^{r_{out}} \quad (20)$$

For the remaining aspects of the model formulation and parameter values along with a deeper understanding of the system's physical intuition, we direct the readers to Wamble et al. [12].

## RESULTS

The proposed GDP superstructure model was transformed into a nonconvex MINLP problem via a Big-M transformation. To solve this MINLP, the solver SCIP v8.0 was used, implemented through GAMS 40.4.0. The computation was performed on a Linux machine featuring 8 Intel Xeon Gold 6234 CPUs operating at 3.30 GHz, with a single hardware thread, and equipped with 1 TB of RAM, all within the Ubuntu environment. It is worth mentioning that we attempted solving the same problem using BARON v22.7.23 but the solver, incorrectly, found the problem to be infeasible.

We conducted a study of the scalability and solution quality of the proposed superstructure. For this, we opted for a three-stage ( $|K| = 3$ ) membrane cascade superstructure, varying the number of discretized elements. All superstructures were solved to global optimality (up to 0.001% gap). Figure 3 encapsulates the outcomes, specifically summarizing the results for the case where a minimum Lithium recovery ( $R_{\min}^{Li}$ ) of 60% was required.

**Figure 3:** Cobalt recovery and solution time of a three-stage superstructure with a minimum Lithium recovery of 60% for different number of discretized elements per stage.

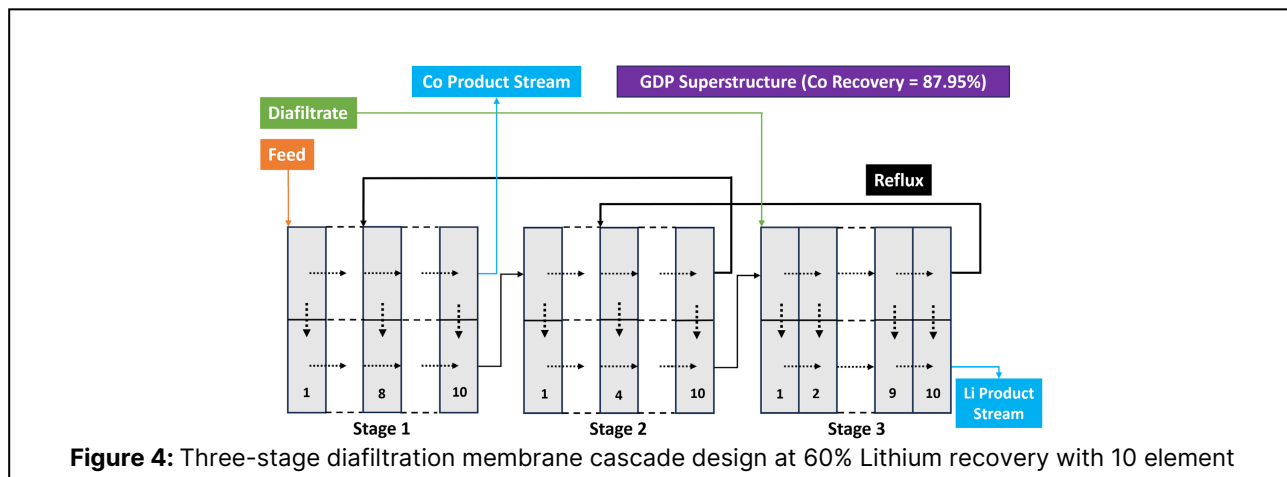

As anticipated, the solution time exhibits rapid growth with the increasing size of the superstructure, as a larger number of elements results in a larger model. This poses a significant limitation when compared to the previous methodology that could solve large superstructures within seconds. The challenge arises from the fact that achieving global optimality in solving a nonconvex

MINLP is computationally much more demanding than solving an NLP to local optimality. However, despite this computational complexity, the proposed approach demonstrates a slightly better solution compared to the previous methods. Figure 4 shows the resulting three-stage superstructure (with  $|N| = 10$ ) for a lithium recovery of 60%. It is noteworthy that the locally optimal superstructure obtained by Wamble et al. [12] exhibits the feed stream split at two different locations, while our superstructure is characterized by a single side stream allocation. Nevertheless, our approach yields a similar Cobalt recovery (0.25% increase) while also ensuring the construction of a physically sensible membrane cascade. Considering that we are dealing with a membrane design problem that requires a one-time solution, it may be preferable to tackle the problem to achieve global optimality. Furthermore, we want to extend this approach to use GDP methods for multicomponent cascade recycling.

We proceed to assess the scalability of the number of stages, opting for a discretization of only two elements per stage. This choice was informed by the examination of objective values presented in Figure 3, revealing a relatively stable Cobalt recovery. Notably, this value does not exhibit a monotonic trend in relation to the number of discretized elements. Therefore, for this specific membrane system and its performance equations, the resolution achieved by increasing the number of discretization elements does not substantially impact the objective. Consequently, a coarser discretization can be employed. The outcomes of this scalability analysis can be found in Figure 5.

As expected, the Cobalt recovery rises as we include more stages. Interestingly, and in contrast to the scenario where discrete elements were added, an increase in the number of stages leads to a substantial rise in the recovery. It can be appreciated that the recovery values almost double when progressing from 2 stages to 12. This captures the trade-off between the profit of recovering Cobalt in kg/hr and the expense associated with installing an additional membrane stage. Although current solution approaches cannot easily address this problem, within the GDP framework, tackling this trade-off is straightforward. To achieve this, a Boolean variable can be introduced to represent the presence or absence of a stage. When the Boolean variable is *True*, the performance equations for the stage are considered. Conversely, when the Boolean variable is *False*, the stage operates as a bypass, and no side streams can be installed.

Regarding the solution time, it is evident that reducing the number of discretized elements has diminished the model's size, enabling the solution of larger structures. Although this reduction may lead to a loss in resolution, potentially impacting the quality of the solution, as discussed earlier, we anticipate the recovery values to remain within a similar order for a higher discretization.

Furthermore, the application of decomposition strategies will be investigated to tackle large-scale conceptual design problems.

**Figure 5:** Cobalt recovery and solution time for a superstructure with a minimum Lithium recovery of 95% for different number of stages.

## CONCLUSIONS

This study introduces a Generalized Disjunctive Programming formulation for optimizing the superstructure design of a multi-stage diafiltration cascade aimed at separating Lithium and Cobalt. The proposed superstructure ensures a unique side stream allocation for the feed, fresh diafiltrate, and recycle streams. We successfully solved the model to global optimality and investigated how the solution time and Cobalt recovery varied with different numbers of stages and discretized elements per stage. The results demonstrate the value of pursuing solutions with global optimality and highlight a trade-off between capitalizing on recovered Cobalt and the installation of additional membranes. Future research directions include expanding the GDP formulation to account for stage existence, addressing the aforementioned trade-

off. Moreover, given the computational expense of solving the superstructure directly, exploration of decomposition techniques to improve solution time is warranted. In this context, the Logic-based Steepest-Descent Algorithm (LD-SDA) [19] emerges as a promising alternative, particularly due to its suitability for handling spatially ordered Boolean decisions inherent in the membrane superstructure.

## ABSTRACT

Carbon capture is a promising option to mitigate CO<sub>2</sub> emissions from existing coal-fired power plants, cement and steel industries, and petrochemical complexes. Among the available technologies, membrane-based carbon capture presents the lowest energy consumption, operating costs, and carbon footprint. In addition, membrane processes have important operational flexibility and response times. On the other hand, the major challenges to widespread application of this technology are related to reducing capital costs and improving membrane stability and durability. To upscale the technology into stacked flat sheet configurations, high-fidelity computational fluid dynamics (CFD) that describes the separation process accurately are required. High-fidelity simulations are effective in studying the complex transport phenomena in membrane systems. In addition, obtaining high CO<sub>2</sub> recovery percentages and product purity requires a multi-stage membrane process, where the optimal network configuration of the membrane modules must be studied in a systematic way. In order to address the design problem at process scale, we formulate a superstructure for the membrane-based carbon capture, including up to three separation stages. In the formulation of the optimization problem, we include reduced models, based on rigorous CFD simulations of the membrane modules. Numerical results indicate that the optimal design includes three membrane stages, and the capture cost is 45.4 \$/t-CO<sub>2</sub>.

## INTRODUCTION

Climate change remains a relevant environmental concern with the global average temperature of Earth steadily rising, and this phenomenon is associated with the high concentration of carbon dioxide (CO<sub>2</sub>) in the atmosphere. The current levels of carbon dioxide are over 50% greater than those observed prior to the industrial era, achieving values of 424 ppm of CO<sub>2</sub> concentration [1]. CO<sub>2</sub> takes the lead as the primary contributor to climate change, and human activities, especially CO<sub>2</sub> emissions from the energy and industrial sectors, are significant drivers.

In this context, carbon capture approaches offer hope in reducing greenhouse emissions since these processes can isolate carbon dioxide at point sources. Using

this strategy, existing facilities can be retrofitted with capture plants, without changing the current industrial process significantly. Carbon capture technologies are crucial to achieving a net-zero emission scenario that limits the global average temperature increase below 1.5 °C [2]. Current CO<sub>2</sub> capture alternative pathways include absorption, adsorption, membrane-based, and cryogenic processes [3].

In contrast to adsorption and absorption, membrane-based carbon capture does not need a regeneration process, indicating potential capital and operating savings. Recent advancements in polymeric materials for gas separation, coupled with its straightforward plant design and operation, compactness, lightweight nature, and mobility, all combine to position membrane technology as a promising and feasible alternative for CO<sub>2</sub> capture [4].

Polymeric membranes present a range of advantages across diverse applications. Their straightforward fabrication simplifies technology adoption, ensuring accessibility and cost-effectiveness. Moreover, they exhibit reduced material requirements for module construction, offering both flexibility and cost savings. Additionally, their inherent processability empowers customization and adaptability, rendering them a versatile and appealing choice for various industries. For instance, the National Energy Technology Laboratory (NETL) has developed a rubbery thin film composite (TFC) membrane that exhibited high CO<sub>2</sub> permeance, high CO<sub>2</sub>/N<sub>2</sub> selectivity, and stable performance in the presence of water vapor and non-aging behavior [5].

Several types of membrane modules are investigated in experimental work for flue gas separation [6]. Researchers frequently employ plate-and-frame (flat sheet), tubular, and hollow fiber membrane modules. In particular, the plate-and-frame configuration offers the benefit of a low-pressure drop, which holds greater significance in high-volume, low-pressure applications. In addition, this kind of membrane is easy to clean and to replace. On the other hand, additional supports are required for the membrane, and it offers low area-to-volume ratios.

When compared to modeling approaches, conducting CFD simulations can be a cost-effective and efficient means to simultaneously study variable effects while ensuring accuracy in the outputs [7]. Specifically, CFD techniques provide the capability to analyze polymeric membranes under conditions that surpass the limits of experiments, enabling the generation of diverse trend analyses for better comprehension of the model results. CFD analysis proves valuable for assessing the viability and performance of specific membrane modules for industrial applications.

Regarding the implementation of the technology at process scale, it was concluded that a single-stage membrane process is unable to achieve high capture rates and high purity simultaneously [8,9]. Therefore, multi-stage membrane processes have been proposed to overcome this issue. In order to address the design problem using a holistic approach, membrane systems engineering has evolved as an important research area to understand the trade-offs among operating variables at plant scale, through mathematical modeling, simulations, and optimization techniques. In this context, superstructure optimization plays a crucial role in the formulation of the optimization problems since it involves creating a comprehensive network that includes all possible components, units, and interconnections relevant to the case study. Qi and Henson [10] addressed the separation of acid gases (CO<sub>2</sub> and H<sub>2</sub>S) from crude natural gas, by introducing a superstructure with potential network configurations obtained through a strategic arrangement of

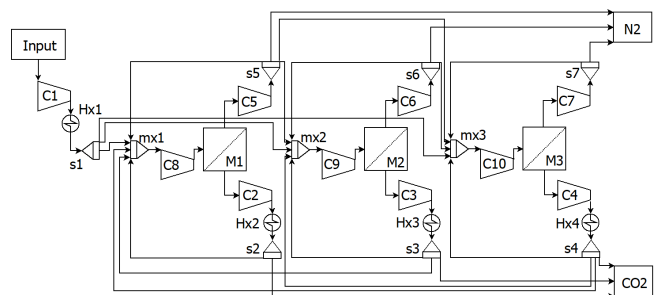

mixers, splitters, and compressors. Arias et al. [11] used mathematical programming and superstructure-based optimization to design multi-stage CO<sub>2</sub> capture membrane systems, to find the optimal configuration of membrane stages, areas, power requirements, recycle stream placement, and operational conditions.

In this work, we formulate a superstructure optimization for the optimal design of a membrane-based carbon capture process, where we use rigorous CFD simulations to build the models for the membrane modules.

## METHODOLOGY

Based on the literature [10,11], we formulate the superstructure shown in Fig. 1 for the optimal design of the multi-stage membrane process for carbon capture. In the present work, we demonstrate the potential of the technology using three separation stages. However, based on the application and the end goals, we could increase the number of stages as needed.

The input stream can be conditioned by increasing its pressure and/or a cooling operation. Then, the input stream could be sent to any of three possible membrane stages. For each membrane stage, the input stream, the retentate product, and the permeate product stream could be pressurized if this operation contributes to increasing the objective function. In addition, the permeate product could be cooled if required. It should be noted that this superstructure configuration embeds the potential process configurations, and the membrane order is not fixed beforehand. On the contrary, the order is determined based on the configuration that optimizes the objective function of the problem.

**Figure 1.** Superstructure for the optimal design of the multi-stage membrane process for carbon capture. M: membrane separation stage. C: compressor. Hx: heat exchangers. s: splitters. mx: mixers.

In order to model the superstructure of Fig. 1, we develop mathematical models for each equipment unit, and we consider the connections between them. Our modeling framework is mainly based on the literature [12,13] for the general process units, including the compressors, the heat exchangers, the mixers, and the splitters. For the calculation of the compound properties,

we fit polynomials based on the data from Aspen Plus, and we consider ideal gas thermodynamics calculations.

The objective function is the minimization of the capture cost, and it is defined as follows

$$CapCost = \frac{(\phi + \varpi) \cdot CAPEX + OPEX + M_{REP}}{F_{CO_2}} \quad (1)$$

where  $CAPEX$  and  $OPEX$  are the capital and operating costs, respectively;  $\phi$  is the capital recovery factor (0.154),  $\varpi$  is a factor to consider the annual maintenance cost (0.045),  $M_{REP}$  is the annualized replacement cost of the membrane modules, and  $F_{CO_2}$  is the flowrate of the captured  $CO_2$  in the plant. The  $CAPEX$  is calculated from the purchased equipment cost of individual equipment units, and we use the cost correlations reported in [14], while the capital costs are updated to 2023 dollars by using a Chemical Engineering Plant Cost Index (CEPCI) of 803.3.

Regarding the membrane modules, we formulate a model including mass and enthalpy balances for the membrane modules, and we consider the operation of them in parallel. To calculate the  $CO_2$  recovery and the purity product in the permeate we also develop surrogate models based on a rigorous CFD model, which is described in the next section.

### Rigorous CFD simulation

The representation of the CFD model for the membrane module is shown in Fig. 2. We consider a 3D geometry that includes two main parts: the retentate side and the permeate side. The input  $CO_2$ -rich stream enters the feed side, and carbon dioxide efficiently crosses through the selective boundary to the permeate side, where a concentrated  $CO_2$  stream is recovered. This technology utilizes thin film composite membranes consisting of rubbery polymer blends [5], without the inclusion of carriers.

We implement the CFD model in Comsol Multiphysics to describe the separation process using membranes. For this, we use the Navier-Stokes equation to calculate the velocity distribution, considering compressible laminar flow with Mach number less than 0.3, as shown in Eq. (2):

$$(\mathbf{u} \cdot \nabla) \mathbf{u} - \nu \nabla^2 \mathbf{u} + \frac{1}{\rho} \nabla p = 0 \quad (2)$$

where  $\mathbf{u}$  is the velocity,  $p$  is the pressure,  $\nu$  is the kinematic viscosity and  $\rho$  is the density.

Regarding the mass transfer phenomena, we use the physics for transport of concentrated species, by considering the following expression:

$$\rho \mathbf{u} \cdot \nabla \omega_i + \nabla \cdot (-\rho D_i \nabla \omega_i) = 0 \quad (3)$$

where  $\omega_i$  is the mass fraction of species  $i$ , and  $D_i$  is the diffusion coefficient of species  $i$ .

For both retentate and permeate sides, we consider the coupled phenomena, which include the physics of the

laminar flow and the mass transport. However, these domains have different reference pressures since the retentate side operates near atmospheric pressure and the permeate side usually operates under vacuum. The driving force for the species flow through the selective boundary is the  $CO_2$  partial pressure difference; increasing this pressure difference increases the stage cut of the membrane process.

**Figure 2.** CFD model for the membrane module. a) Main configuration and flux directions. b) Domains and selective boundary

In order to model the membrane separation process, we define the selective boundary layer as a boundary condition for both physics. This selective layer is located at a height  $z_m$  in the membrane module, as shown in Fig. 2. The species fluxes ( $J_{x,i}, J_{y,i}, J_{z,i}$ ) are given by Eq. (3) in the transport phenomena, considering experimental data for the permeance of  $CO_2$  and  $N_2$  as pure gases ( $Q_i$ ). In this way, the modeling approach considers the different mass transfer resistances due to the membrane. Therefore, we do not have to include the information associated with the porosity of the support in the model. Regarding the velocity profile calculation, we consider a leaking wall as a boundary condition, calculating the equivalent velocity to satisfy momentum balances (see Eq. (4)).

$$z = z_m \rightarrow \begin{cases} J_{x,i} = 0 \\ J_{y,i} = 0 \\ |J_{z,i}| = Q_i M_i (p^{ret} x_i^{ret} - p^{per} x_i^{per}) \end{cases} \quad (3)$$

$$z = z_m \rightarrow \begin{cases} u_x = 0 \\ u_y = 0 \\ u_z = -\frac{1}{\rho} \sum_{i \in \{CO_2, N_2\}} J_{z,i} \end{cases} \quad (4)$$

where  $Q_i$  is the permeance of species  $i$ , and  $M_i$  is the molar mass of species  $i$ .

Regarding the boundary conditions for the inlet and outlet streams, we use the conventional approach to specify them, as explained in [15]. In particular, we run the CFD model several times to generate data for the reduced model generation, as we explain below. In this matter, we consider inlet mass flowrates between 40-220 mg/s, inlet CO<sub>2</sub> concentrations between 0.1 and 0.7, retentate outlet pressures between 1.02-2 atm, and permeate outlet pressures between 0.09-0.6 atm.

### Model simplification and mesh studies

To enhance the computational tractability of the CFD model, a symmetry plane has been introduced for the membrane module. This modification involves the incorporation of a yz plane, resulting in a halved geometry, as depicted in Fig. 3. In this way, the number of cells required for the mesh is also halved.

Regarding the mesh, we have developed a mapped mesh for the geometry as shown in Fig. 3. This meshing technique has shown a superior performance for mesh generation, offering the possibility of reducing the required number of cells to achieve accurate results.

**Figure 3.** Mesh for the membrane module (637,460 degrees of freedom)

For the present case study, we perform a mesh independence study to select an appropriate number of mesh elements. This analysis is shown in Fig. 4, where we show the influence of degrees of freedom, directly proportional to the number of mesh nodes, on the CO<sub>2</sub> recovery of the membrane module for the mapped mesh and the free tetrahedral mesh. The results indicate that as the mesh becomes finer, the CO<sub>2</sub> recovery decreases for the free tetrahedral mesh and increases for the mapped mesh. In addition, it is observed that the number of degrees of freedom to obtain accurate results is lower for the mapped mesh. It is worth noting that beyond 637,460 degrees of freedom, there is no significant change in the CO<sub>2</sub> recovery. The relative difference between this point and the one with the highest number

of nodes (which is also the most accurate) is only 0.076%. This suggests that a mesh containing 637,460 degrees of freedom provides sufficient computational accuracy.

**Figure 4.** Variation of the CO<sub>2</sub> recovery with the degrees of freedom in the mesh. Input flow: 1250 SCCM;  $x_{CO_2}$ : 0.3;  $p^{ret}$ : 1.2 bar;  $p^{per}$ : 0.2 bar.

### Surrogate model for the membrane process

The CFD for the membrane module was validated using experimental data, as described in the literature [16], for a bench-scale experimental implementation. In the present work, we have scaled up the membrane module to a length of 1 m and a width of 0.375, as shown in Fig. 2. Then, from this model, we generate sampling data and build a reduced model by using kriging-based methodology available in the IDAES computational framework [17]. This modeling approach considers a correlation function between different sampling points, which is usually called kernel. In the present case, we use the Gaussian kernel ( $k(\mathbf{x}_i, \mathbf{x}_j)$ ), which is shown in Eq. (5).

$$k(\mathbf{x}^i, \mathbf{x}^j) = \exp\left(-\sum_{r=1}^d \theta_r |x_r^i - x_r^j|^2\right) \quad (5)$$

where  $\mathbf{x}^i$  and  $\mathbf{x}^j$  are sampling points,  $\boldsymbol{\theta} = \{\theta_1, \theta_2, \dots, \theta_d\}^T$  is vector associated with the length scale hyperparameters, and  $d$  is the dimension of the input variable vector. The values of output variables are calculated through the following expression:

$$y_* = \mu + \mathbf{k}_*^T (\mathbf{K} + \sigma^2 \mathbf{I}_n)^{-1} (\mathbf{y} - \mathbf{1}\mu) \quad (6)$$

where  $y_*$  is the expected value of the output variable,  $\mu$  is the mean,  $n$  is the number of sample points,  $\mathbf{I}_n$  is the identity matrix of dimension  $n$ ,  $\sigma$  is the regularization parameter associated with the noise of the data and  $\mathbf{y}$  is the vector of the sampled output variable. The vector  $\mathbf{k}_*$  and the matrix  $\mathbf{K}$  are calculated through Eqs. (7) and (8), considering the Gaussian correlation function (see Eq. (5)).

$$[\mathbf{K}]_{i,j} = k(\mathbf{x}^i, \mathbf{x}^j) \quad (7)$$

$$[\mathbf{k}_*]_i = k(\mathbf{x}^i, \mathbf{x}^*) \quad (8)$$

In particular, we build reduced models that consider the

following input variables: i) inlet flowrate; ii) pressure in the retentate; iii) pressure in the permeate; iv) inlet CO<sub>2</sub> concentration. On the other hand, we consider the CO<sub>2</sub> recovery and the CO<sub>2</sub> purity in the permeate side as output variables for the model. In this way, we can exploit the information of the rigorous CFD simulation to create a reduced model, which is implemented in the superstructure for the selection of the multistage membrane process.

**Table 1.** Main statistics metrics of the Kriging model for the CO<sub>2</sub> recovery (output variable)

CO <sub>2</sub> recovery	Training data	Validation data
R <sup>2</sup>	1.0000	0.9992
Mean squared error	2.6·10 <sup>-6</sup>	4.7·10 <sup>-5</sup>
Mean rel. error (%)	0.2819	1.5116
Max. rel. error (%)	2.1905	5.9386

The main performance metrics for our built-reduced models are shown in Table 1. It is observed that the performance of the built reduced models is appropriate for their implementation in the optimization model since the R<sup>2</sup> coefficients are close to one, for both output variables. In addition, the statistics metrics for the training and the validation data do not change significantly, indicating a low risk of overfitting.

**Table 2.** Main statistics metrics of the Kriging model for the CO<sub>2</sub> purity in the retentate (output variable)

Purity	Training data	Validation data
R <sup>2</sup>	1.0000	0.9998
Mean squared error	4.8·10 <sup>-7</sup>	8.0·10 <sup>-6</sup>
Mean rel. error (%)	0.1266	0.4301
Max. rel. error (%)	0.7907	1.9357

## RESULTS

In the present work, we consider the optimal design of a plant to treat a flue gas of 30 % CO<sub>2</sub> -70% N<sub>2</sub> and a molar flow rate of 1000 mol/s, as a case study. This CO<sub>2</sub> concentration is representative of steel plants but our model can account for any set of inlet and operating conditions. We set the lower bounds for CO<sub>2</sub> recovery and the purity at 80 % and 90 %, respectively.

The mathematical programming model is implemented in Pyomo and solved using IPOPT [18]. As commercial solvers for global optimization turn out to be inefficient in solving the present problem design, we use a multi-start approach to increase the possibility of finding the global optimal solution.

The optimization problem includes 539 variables and 50 optimization variables. We note that the use of

reduced models reduced the problem complexity significantly since the rigorous simulation of each membrane separation stage includes 637,460 variables. Therefore, solving the full optimization model for optimal design represents computational challenges, which would be the bottleneck of any decision-making. It is only through surrogate models that we can seek a practical design optimization in an acceptable timeline.

The main economic indicators are shown in Table 3. The objective function is the capture cost, for which we obtain a value of 45.4 \$/t-CO<sub>2</sub>. This value is of the expected order for a multi-stage membrane process [6]. The total annual cost for the capture plant is also shown in Table 1. The main contributor to this economic indicator is the annualized capital cost (51 %), while the operating cost represents 29 % of the total annual cost. Our results indicate that the capital cost associated with compressors accounts for 65 % of the CAPEX, while the membrane cost is 33%. It should be noted that the purity and the CO<sub>2</sub> recovery are at their lower bounds for the optimization problem.

**Table 3.** Economic indicators associated with the optimal design of the membrane-based carbon capture

	Value
Capture cost (\$/t-CO <sub>2</sub> )	45.69
Total annual cost (MM\$/y)	13.89
Capital cost (MM\$)	46.25
Operating cost (MM\$/y)	4.00
Purity (%)	90
CO <sub>2</sub> recovery (%)	80

**Figure 5.** Optimal configuration for the membrane process. M: membrane separation stage. C: compressor. Hx: heat exchangers. s: splitters. mx: mixers.

The optimal configuration for the membrane-based carbon capture process is shown in Fig. 5. It comprises a three-stage membrane separation setup. The inlet flue gas is introduced into the second membrane module, M2. The retentate product from M2 is fed to the third module, M3, where a N<sub>2</sub>-rich stream is recovered in the retentate stream, while the permeate side is recirculated back to M2. The permeate stream originating from M2 is then

sent to the first module, M1, which yields the purified CO<sub>2</sub> stream. The retentate product from M1 is also recycled to M2 for further processing.

It should be noted that the optimal network for the separation process using membranes is not trivial, and there is a trade-off between the recovery and purity in each separation stage. At process level, there are also trade-offs related to recycled streams; high recirculation rates increase the operating costs but they have the potential to reduce the required membrane area. In this context, the proposed superstructure optimization is a valuable tool for finding a solution, considering these process interactions in the design.

Regarding the operating condition and separation performance of the membrane stages, Table 4 shows the main results. It is observed that the membrane M2 includes a higher area than M1 and M3, and this result is associated with its high inlet flow (recycling streams for M1 and M3 are sent to M2 in the process network). In addition, we observe that M1 operates at high inlet CO<sub>2</sub> concentration to achieve the target purity of the CO<sub>2</sub> product (90 %), while M3 operates with a CO<sub>2</sub>-dilute stream (15 %) to recover the greenhouse gas before expelling the N<sub>2</sub>-rich stream from the retentate of this membrane stage. The permeate side for the membrane stages is at vacuum pressure, while the retentate is at atmospheric pressure. M2 and M3 operate at low pressure (0.1 atm) in the permeate side to promote CO<sub>2</sub> transport through the selective layer; while the pressure of the permeate side of M1 is 0.4 atm. For each membrane stage, we also report the dimensionless feed flow and the retentate recovery, which are associated with the capital cost and the energy requirement [19], respectively.

In order to verify the accuracy of the reduced models in the environment of the optimal solution, we have run the rigorous CFD simulation considering the input variables reported in Table 4 for each membrane stage. These input variables include the inlet flow, the inlet CO<sub>2</sub> molar fraction, and the pressure of the retentate and the permeate sides. The results associated with this analysis are shown in Table 5. In general, we obtained relative differences between the reduced model and the rigorous CFD simulations lower than 1 %. The sole exception is the prediction of the reduced model for the CO<sub>2</sub> purity for M3, which is 5 % lower than the value obtained by the CFD simulation. This means that the objective function of the optimization problem could slightly improve by updating the reduced model with this information. Future work will focus on using the trust-region filter method [20,21] to solve the problem and obtain highly accurate solutions

**Table 4.** Operating conditions and results for the membrane stages

	M1	M2	M3
Membrane area (m <sup>2</sup> )	30,849	107,800	54,887
Inlet flow (mol/s)	565	1465	901
Inlet CO <sub>2</sub> molar fraction	0.70	0.36	0.15
Retentate pressure (atm)	1.02	1.02	1.02
Permeate pressure (atm)	0.40	0.11	0.10
CO <sub>2</sub> recovery	0.61	0.74	0.55
CO <sub>2</sub> purity	0.90	0.70	0.42
Dimensionless feed flow	0.33	0.25	0.30
Retentate recovery	0.53	0.62	0.81

**Table 5.** Output variables from the rigorous CFD simulations and the NLP model (calculated from the Kriging approach), using the input variables shown in Table 4

	M1	M2	M3
CO <sub>2</sub> recovery (CFD model)	0.608	0.740	0.551
CO <sub>2</sub> recovery (NLP model)	0.614	0.745	0.552
CO <sub>2</sub> purity (CFD model)	0.906	0.701	0.445
CO <sub>2</sub> purity (NLP model)	0.900	0.700	0.423

The CO<sub>2</sub> molar fraction profile ( $x_{CO_2}$ ) of membrane stage M2 is shown in Fig. 6. Initially, the inlet  $x_{CO_2}$  is 0.36, while the retentate outlet  $x_{CO_2}$  is 0.15. The decrease in  $x_{CO_2}$  is attributed to the selective CO<sub>2</sub> flow through the membrane selective layer during the separation process. In the permeate region close to the feed,  $x_{CO_2}$  reaches high purities of up to 0.90. However, as we move closer to the permeate side near the retentate outlet, the CO<sub>2</sub> purity decreases to around 0.50. Consequently, the average CO<sub>2</sub> purity of the outlet permeate flow is estimated to be approximately 0.70.

**Figure 6.** Profile of CO<sub>2</sub> molar fraction ( $x_{CO_2}$ ) for M2. Input flow: 86.06 mg/s;  $x_{CO_2}$ :0.36;  $p^{ret}$ : 1.02 atm;  $p^{per}$ : 0.11 atm.

### Effect of the CO<sub>2</sub> concentration in the feed stream

We also explore the effects of changing the CO<sub>2</sub> molar fraction in the feed stream on key parameters, such as the objective function (capture cost), the membrane area, and the energy demand. For this purpose, we run the optimal design problem by considering different inlet CO<sub>2</sub> molar fractions in the interval of 0.2-0.3, while keeping the input molar flowrate of CO<sub>2</sub> constant.

The results associated with this analysis are shown in Table 6. In all of the cases, the purity and the CO<sub>2</sub> recovery were found at their lower bounds, 90 % and 80 %, respectively. It is observed that the capture cost decreases significantly as the inlet CO<sub>2</sub> molar fraction increases. These results are in agreement with the literature [14]. This trend can be explained by the simultaneous reduction in both membrane area and energy demand as the inlet CO<sub>2</sub> molar fraction rises, as detailed in Table 6.

**Table 6.** Effect of the inlet CO<sub>2</sub> concentration of the feed in the capture cost, membrane area, and energy demand

Inlet CO <sub>2</sub> molar fraction	Capture cost (\$/t-CO <sub>2</sub> )	Membrane area (m <sup>2</sup> )	Energy demand (kWh/t-CO <sub>2</sub> )
0.2	73.13	371,880	284.5
0.225	64.77	320,059	252
0.25	57.90	277,819	231.4
0.275	52.01	244,103	206.51
0.3	45.69	193,536	182.8

### CONCLUSIONS AND FUTURE WORK

In this work, we address the optimal design of a multi-stage membrane process for carbon capture. For this task, we develop a CFD model of a membrane module, from which we generate a Kriging reduced model to

be implemented in an optimization problem. In order to design the separation network, we formulate a superstructure to consider a three-stage membrane process. As the main case study, we consider an inlet flue gas stream with a CO<sub>2</sub> molar fraction of 30 % and a molar flowrate of 1000 mol/s. However, our computational framework is flexible and versatile and can therefore be adapted to accommodate various inlet and operating conditions to simulate any post-combustion or industrial plant and real-life gas stream compositions. Our work could also be extended to inform both new plants and to retrofit existing ones.

Our results show that the optimal design includes the three membrane stages and the capture cost of the process is 45.69 \$/t-CO<sub>2</sub>. Determining the resulting network configuration and optimal operating conditions for the membrane stages is a non-trivial task. In this context, the optimization formulation shows its value as it determines optimal trade-offs between the decision variables.

Future work will focus on including additional design variables associated with the membrane module, i.e., geometric variables. In addition, we will include the effect of temperature on the transport phenomena for the CFD model. Regarding the solution strategy, we will solve the problem by using trust region methods, to guarantee the optimality of the solution.

## ABSTRACT

In this work, we propose a Mixed Integer Nonlinear Programming (MINLP) model to determine the optimal sustainable design of a poly(hydroxyalkanoate)s (PHAs) production plant configuration and its heat exchanger network (HEN). The superstructure-based optimization model considers different carbon sources as raw material: glycerol (crude and purified), corn starch, cassava starch, sugarcane sucrose and sugarcane molasses. The PHA extraction section includes four alternatives: the use of enzymes, solvent, surfactant-NaOCl or surfactant-chelate. Model constraints include detailed capital cost for equipment, mass and energy balances, product specifications and operating bounds on process units. To assess the feasibility of the PHA plant, we considered the Sustainability Net Present Value (SNPV) as the objective function, a multi-criteria sustainability metric that considers economic, environmental and social pillars. The Net Present Value (NPV) was also calculated. SNPV metric provides useful insights on sustainable PHA production, as the optimal technological route results in the sugarcane-surfactant-chelate option, rather than the sugarcane-enzyme pathway which proves more economically profitable, but with higher environmental impacts. Moreover, inclusion of HEN design significantly improves the objective function value, mainly due to a 24% carbon footprint impact reduction.

**Keywords:** Biomass, Environment, Modelling, Optimization, Process Design

## INTRODUCTION

Poly(hydroxyalkanoate)s (PHAs) constitute a family of biodegradable and biocompatible polymers emerging as promising alternatives to substitute conventional synthetic plastics such as polypropylene and polyethylene [1]. PHAs can be intracellularly stored as a carbon and energy reservoir in the cytoplasm of different microorganisms capable of metabolizing various substrates [2].

Koller and Mukherjee (2022) [3] documented the current global companies actively engaged in the commercialization of PHAs. However, its industrial scale production is constrained by high production costs mainly attributed to the feedstock used as carbon source [4]. Consequently, competing with petroleum-based plastics market price becomes challenging. Nevertheless, embracing an integral process optimization framework [5] and a circular economy action plan emerges as a favorable strategy for biopolymers, envisioning sustainability by

addressing not only economic aspects but also environmental and social considerations.

Previous work shows that employing sugarcane as carbon source for PHAs production and enzymes for PHAs extraction, results in a biopolymer production cost round to 3 USD/kg of PHA [6]. In this context, an extension of this study focusing on sustainability design, could offer valuable insights on whether the chosen carbon source and extraction method align with optimal sustainable approaches for PHAs production, as well as simultaneously design the HEN.

In this work, a superstructure is presented for the simultaneous optimal sustainable design of a PHA production process and its heat exchanger network (HEN). The objective function is the maximization of the sustainability net present value (SNPV) proposed by Zore *et al.* (2018) [7]. The model has into account several alternative carbon sources as substrates and includes different technological pathways for the biosynthesis, extraction

and purification stages.

## PROCESS DESCRIPTION

The PHA production process has three main stages: upstream processing (raw material pretreatment), biosynthesis and downstream processing (biopolymer extraction and purification). Figure 1 presents the proposed superstructure, including different technological alternatives. For a more comprehensive description of the technological pathways, refer to Ramos *et al.* (2019) [6].

### Upstream processing

Three different raw materials and some of their derivatives are considered as carbon source, namely, glycerol, starch and sugarcane. Raw glycerol can be employed as an economical carbon source for several microbiological processes such as PHAs production [8]. Crude glycerol can be fed to the fermentation step after being sterilised, or it can be purified to improve downstream biomass growth. If glycerol purification step is selected, methanol can be sold as a co-product after recovery. It is worth mentioning that selling purified glycerol also is set as a possible alternative, instead of being used as carbon source for PHAs production.

Starch is one agro-industrial product that holds a promising outlook as substrate for biomaterial production. Three potential alternatives are considered for starch production in the superstructure presented in Fig. 1. The first one consists of including the process of starch production from corn. The second option involves the direct purchase of corn starch, while the third one contemplates the possibility of using cassava starch [9]. The superstructure also includes the possibility of producing

glucose, through starch liquefaction and saccharification, to be used as substrate for the microbial biosynthesis in the PHA production stage.

The last alternative is the use of sucrose from sugarcane as a carbon source for the production of biopolymers [10]. In this sense, sugarcane processing is embedded within the proposed superstructure for PHA production. Sugarcane bagasse constitute an important residue from the sugar industry, which can be processed for the production of thermal and electrical energy. In the proposed superstructure, a typical electrical energy production system is considered as a destination for this sub-product [11]. As alternatives to the processing of sugarcane, the possibility of directly buying processed sucrose or sugarcane molasses is included in the superstructure [12].

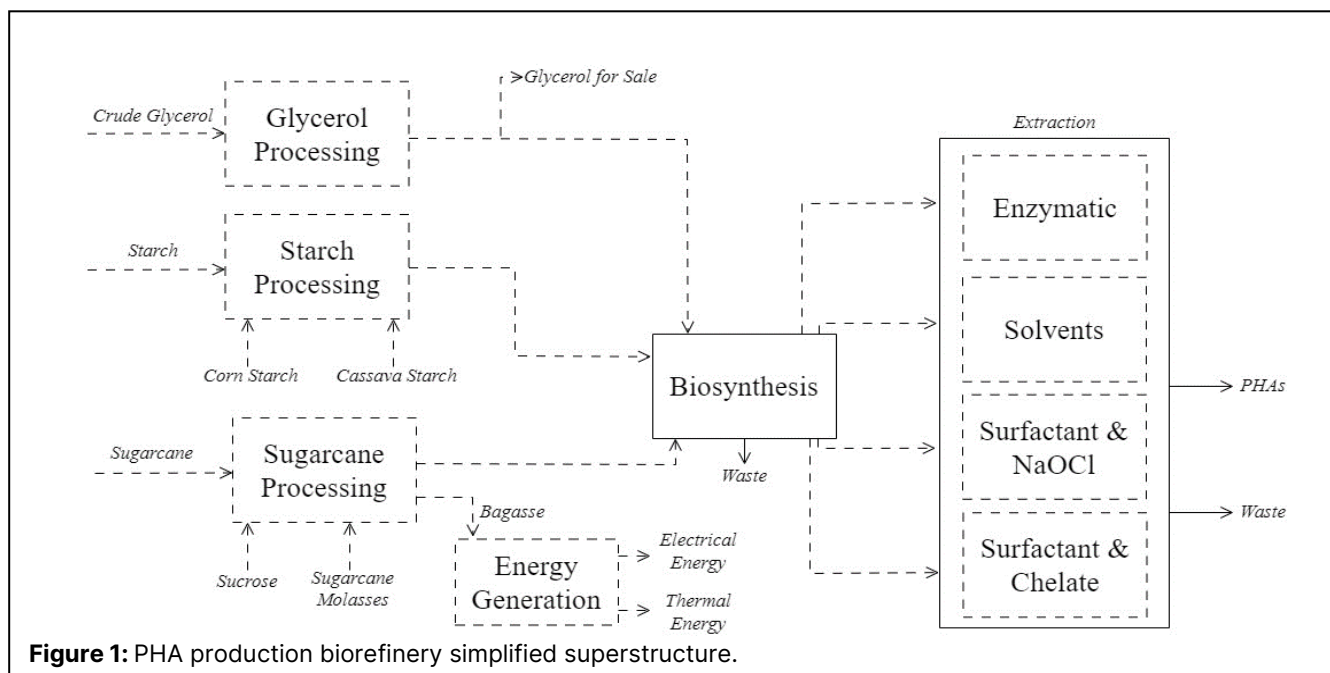

### Biosynthesis

PHA production takes place in the biosynthesis stage by the biopolymer intracellular accumulation in a microbial strain, through an excess supply of a carbon source and the limitation of another growth essential nutrient like nitrogen or phosphorus.

According to the selected carbon source, several operational alternatives are presented for the bioreactors used in this stage of the production process. Available technologies involve two fermentation stages. The first stage is included for biomass optimal growth without nutrient limitation imposed, while in the second, PHAs production takes place and its accumulation is triggered by the limitation of essential nutrient sources.

### Downstream processing

The extraction of biopolymers from the

**Figure 1:** PHA production biorefinery simplified superstructure.

microorganism's cytoplasm is a crucial step in the production process, as its quality directly impacts the final product. Therefore, an appropriate selection of the extraction technology is essential to establish a viable process in terms of sustainability. As shown in Fig. 1, four extraction alternatives are included in the PHA production process superstructure, the use of enzymes, solvent, surfactant- sodium hypochlorite (NaOCl) or surfactant-chelate.

The enzymatic extraction alternative is based in a digester, where the cell wall lysis is carried out by the use of enzyme pancreatin in a 2 wt % [13]. The process that employs solvent for PHA extraction uses diethyl succinate (DES) and includes a homogenizer, which operates at a high pressure to enable cell lysis [14]. The third option involves the use of NaOCl and a surfactant for biopolymer extraction. The last technological route embedded in the superstructure comprises surfactant and chelate as extraction agents. This method is based on the process proposed by Chen *et al.* (2001) [15], and is presented as a promising alternative because it is environmentally friendly having a higher quality of the final product and minimizing the requirement of chemicals.

## MATHEMATICAL MODEL

The proposed superstructure is formulated as a mixed-integer nonlinear programming (MINLP) problem and implemented in GAMS 35.2.0 [16] in order to determine the optimal sustainable design of a PHAs production plant and its heat exchanger network (HEN). The objective function is to maximize the monetary-based sustainability metric, Sustainability Net Present Value (SNPV) [7]. The proposed superstructure includes mass and energy balances, equipment design equations and capital cost correlations for the PHAs production plant processes, as well as its HEN design and connection equations to link process design variables with HEN variables. Binary variables are associated to potential units and to heat exchanger matches.

Nonreactive units mass balances within the superstructure are formulated as shown in Eq. (1).

$$\sum_{u1 \in UI_u} f_{u1,u,j} = \sum_{u2 \in UO_u} f_{u,u2,j} \quad j \in J, u \in U^{NR} \quad (1)$$

where  $f_{u1,u,j}$  is the flowrate from unit  $u1$  to  $u$  of component  $j$ ;  $UI_u$  and  $UO_u$  are subsets that define the connection between units. Nonreactive units splitting are represented by Eq. (2) as it is shown below.

$$f_{u,u2,j} = \alpha_{u,u2,j} \cdot \sum_{u1 \in UI_u} f_{u1,u,j} \quad j \in J, u \in U^{NR}, u2 \in UO_u \quad (2)$$

where  $\alpha_{u,u2,j}$  is a splitting parameter for component  $j$  that

leaves unit  $u$  and leads to unit  $u2$ . It is worth mentioning that Eq. (3) should be verified in order to fulfill mass conservation.

$$\sum_{u2 \in UO_u} \alpha_{u,u2,j} = 1 \quad j \in J, u \in U^{NR} \quad (3)$$

Reactive unit mass balances are described by Eq. (4).

$$\sum_{u2 \in UO_u} f_{u,u2,j} = \sum_{u1 \in UI_u} f_{u1,u,j} + \sum_{r \in R_u} \left( \xi_{u,r,j} \sum_{u1 \in UI_u} f_{u1,u,r} \right) \quad (4)$$

$j \in J, u \in U^R$

where  $\xi_{u,r,j}$  denotes the mass coefficient for component  $j$  from the main reactant  $r$  in reactive unit  $u$ . This coefficient is positive for products and negative for reactants. Reactive unit splitting is represented by Eq. (5) as follows.

$$f_{u,u2,j} = \alpha_{u,u2,j} \cdot \left[ \sum_{u1 \in UI_u} f_{u1,u,j} + \sum_{r \in R_u} \left( \xi_{u,r,j} \sum_{u1 \in UI_u} f_{u1,u,r} \right) \right] \quad (5)$$

$j \in J, u \in U^R, u2 \in UO_u$

The electrical energy consumption ( $EC_u$ ) is calculated through linear functions, as shown in Eq. (6).

$$EC_u = ECR_u \cdot \left( \sum_{u1 \in UI_u} \sum_{j \in J} f_{u1,u,j} \right) \quad u \in \{U^{NR} \cup U^R\} \quad (6)$$

where  $ECR_u$  is the energy consumption ratio per unit of mass flowrate relative to unit  $u$ . Conditional units proposed in the superstructure are associated with binary variables through Big-M formulations in order to determine the optimal technological route. The corresponding mixed integer constraints are formulated as it is shown in Eq. (7)

$$\sum_{u2 \in UO_u} \sum_{j \in J} f_{u,u2,j} - BM \cdot y_u \leq 0 \quad u \in U^C \quad (7)$$

where  $y_u$  is the binary variable related to the selection of conditional unit  $u$ ; and BM is a big M parameter [28].

Regarding equipment design equations and capital cost correlations, we include standard capital cost models from the literature [17-18].

The objective function Sustainability Net Present Value (SNPV) presented by Zore *et al.* (2018) [7], includes economic ( $NPV^{Economic}$ ), environmental ( $NPV^{Environmental}$ ) and social ( $NPV^{Social}$ ) net present values (Eq. (8)). It is worth mentioning that, in order to assess sustainability from a combined point of view of the company and government, we consider the SNPV macroeconomic

perspective [7].

$$SNPV = NPV^{Economic} + NPV^{Environmental} + NPV^{Social} \quad (8)$$

The economic pillar of the objective function is represented by  $NPV^{Economic}$  and is calculated as shown in Eq. (9). The annual cash flows are discounted from its year to the present time by the use of a corresponding factor that involves the discounted rate,  $i=10\%$ , and the project lifetime,  $n=20$  years.  $R$  accounts for annual revenues from products and by-products sales,  $E$  includes annual manufacturing and general costs.  $I$  is the total capital investment cost for a turnkey plant and involves the sum of equipment cost, considering tax contingency factor ( $\varphi_1=1.18$ ) and a grass-root factor ( $\varphi_2=1.3$ ), land cost, piping and instrumentation cost, and the working capital. In addition,  $V_{rec}$  is the recovery value, an income estimation from selling the equipment and recovering the working capital at the end of the project lifespan.

$$NPV^{Economic} = (R - E) \cdot \frac{(1+i)^n - 1}{i \cdot (1+i)^n} - I + V_{rec} \cdot (1+i)^n \quad (9)$$

Furthermore,  $NPV^{Environmental}$  stands for the environmental pillar of sustainability and is defined by Eq. (10.1). The annual environmental benefit ( $EB$ ) represents, in monetary terms, the unburdening effect of raw materials, products, technologies, transport, energy and waste on the environment (Eq. (10.2)). On the other hand, the annual environmental cost ( $EC$ ) corresponds to their burdening effect on the environment (Eq. (10.3)). Both terms are calculated by the eco-cost coefficients [7],  $c_{i,tech}$  and  $c_{j,tech}$ , for annual raw materials and products, respectively. Superindexes  $R^{UNB}$  and  $R^B$  denote the unburdening and burdening effect of the annual raw materials required by process  $tech$ , respectively. Similarly,  $P^{UNB}$  and  $P^B$  denote the unburdening and burdening effect of the annual products produced by unit  $tech$ , respectively. These environmental effects are proportional to annual raw material and product mass flowrates,  $q_{m_i}$  and  $q_{m_j}$ , respectively. Also, a substitution factor,  $f_{j,tech}^{S/P^{UNB}}$ , is taken into account to represent the ratio between the annual amount of product to be substituted and the annual amount of product obtained in the bioprocess.

$$NPV^{Environmental} = (EB - EC) \cdot \frac{(1+i)^n - 1}{i \cdot (1+i)^n} \quad (10.1)$$

$$EB = \sum_{tech \in T} \sum_{ieR^{UNB}} f_{i,tech}^{R^{UNB}} \cdot c_{i,tech}^{R^{UNB}} + \sum_{tech \in T} \sum_{jeP^{UNB}} f_{j,tech}^{P^{UNB}} \cdot S f_{j,tech}^{S/P^{UNB}} \cdot c_{j,tech}^{P^{UNB}} \quad (10.2)$$

$$EC = \sum_{tech \in T} \sum_{ieR^B} f_{i,tech}^{R^B} \cdot c_{i,tech}^{R^B} + \sum_{tech \in T} \sum_{jeP^B} f_{j,tech}^{P^B} \cdot c_{j,tech}^{P^B} \quad (10.3)$$

Referring to the environmental pillar of the objective function, it is important to note that environmental burden can be classified into a set of impact categories as midpoints or endpoints. The former are considered to be links in the cause-effect chain of an impact category at which characterization factors can be derived to reflect the relative importance of emissions or extractions [19]. Midpoints that are considered in this framework are global warming (*Globwarm*), acidification (*Acid*), eutrophication (*Eutro*), ecotoxicity (*Ecotox*), photochemical oxidants (*Sums*), human toxicity carcinogens (*Htoxc*), human toxicity non carcinogens (*Htoxcnc*), fine dust (*Fined*), metals scarcity (*Mets*), fossil products (*Foss*), uranium (*Ura*), land-use (*Lanu*) and baseline water stress (*Basew*). On the other hand, the endpoints are indicators that show the environmental impact on higher aggregation levels, being considered carbon footprint (*Globwarm*), ecosystems (*Acid*, *Eutro*, *Ecotox*), human health (*Sums*, *Htoxc*, *Htoxcnc*, *Fined*) and resource scarcity (*Mets*, *Foss*, *Ura*, *Lanu*, *Basew*).

The social term of the objective function,  $NPV^{Social}$ , is represented by Eq. (11.1) and considers social security contributions ( $SS$ ), social unburdening effect due to new jobs creation ( $SU$ ) and social cost ( $SC$ ). Social security contributions (Eq. (11.2)) are defined as the difference between gross and net annual salaries ( $S^{gross}$  and  $S^{net}$ , respectively) for the number of jobs created ( $N^{jobs}$ ). This variable is included in the model through the manufacturing cost term, which takes into account direct costs such as operating labor associated with the attention required by an operator to run the equipment [18]. Social unburdening effect is described by Eq. (11.3) and contemplates the state social transfer needed to annually support an unemployed person ( $C_s^{UNE,state}$ ) who is now employee ( $N^{jobs}$ ). Eq. (11.4) describes the annual social support of the state and the company for each employee ( $N^{jobs}$ ) considering a state social transfer ( $C_s^{EMP,state}$ ) and a company social charge ( $C_s^{EMP,company}$ ) parameter.

$$NPV^{Social} = (SS + SU - SC) \cdot \frac{(1+i)^n - 1}{i \cdot (1+i)^n} \quad (11.1)$$

$$SS = N^{jobs} \cdot (S^{gross} - S^{net}) \quad (11.2)$$

$$SU = N^{jobs} \cdot C_s^{UNE,state} \quad (11.3)$$

$$SC = N^{jobs} \cdot (C_s^{EMP,state} + C_s^{EMP,company}) \quad (11.4)$$

In this work, we address a simultaneous design of the bioprocess and its heat exchanger network (HEN),

following Pedrozo *et al.* [17]. It is worth mentioning that, since we performed a simultaneous process and HEN design, heat balance equations at each stage are nonlinear, as both process stream flowrates and stage temperatures are variables, as presented in the previous publication. The heat exchanger network capital cost ( $HENC$ ) is calculated as shown in Eq. (12), while the total utility cost ( $TUC$ ) is given by Eq. (13), as follows,

$$HENC = \sum_{k \in ST} \sum_{c \in C} \sum_{h \in H} (\alpha_0 z_{h,c,k} + HX_{h,c,k}) + \sum_{h \in H} (\alpha_0 z_h^{CU} + HX_h^{CU}) + \sum_{c \in C} (\alpha_0 z_c^{HU} + HX_c^{HU}) \quad (12)$$

$$TUC = \beta_{CU} \sum_{h \in H} q_h^{CU} + \beta_{HU} \sum_{c \in C} q_c^{HU} \quad (13)$$

where  $\alpha_0$  corresponds to fixed cost associated with heat exchanger units;  $HX_{h,c,k}$  is the heat exchanger cost corresponding to the hot stream  $h$  and cold stream  $c$  match at stage  $k$ ;  $HX_h^{CU}$  and  $HX_c^{HU}$  are the heat exchanger cost of the hot stream  $h$  and cold stream  $c$  with their respective external utilities;  $z_{h,c,k}$  is the binary variable that is equal to one when the hot stream  $h$  matches the cold stream  $c$  at stage  $k$  and equal to zero otherwise;  $z_h^{CU}$  and  $z_c^{HU}$  are binary variables that are equal to one when the hot stream  $h$  and the cold stream  $c$  require extreme external utilities, respectively, and equal to zero otherwise.  $\beta_{CU}$  and  $\beta_{HU}$  stand for the cooling utility and the heating utility costs, respectively.  $q_h^{CU}$  and  $q_c^{HU}$  are cooling and heating utilities for hot and cold streams, respectively. It is worth noting that the continuous elements of the model, involves mass flowrates, equipment cost, sustainability indices, and energy variables. Conversely, the discrete component comprises unit selection variables ( $y_u$ ) and binary variables involved in the HEN model ( $z_{h,c,k}$ ,  $z_h^{CU}$  and  $z_c^{HU}$ ). For further details regarding HEN design, please refer to Pedrozo *et al.* [17].

## NUMERICAL RESULTS AND DISCUSSION

The MINLP model formulated for sustainability optimization and simultaneous process and HEN design includes 5,412 discrete variables, 30,228 continuous variables and 41,632 constraints. It was solved to an objective function value of  $SNPV = -111.40$  M USD using DICOPT, with CONOPT and CPLEX as nonlinear and linear subsolvers, respectively [20]. The optimal technological route in terms of sustainability, includes the use of sugarcane (0.21 Mt/y) as carbon source for biopolymer production, selecting the surfactant-chelate pathway as the PHA extraction method. A PHA capacity is fixed at 10,000 t/y is achieved, which is similar to numerous currently industrial production plants [21].

A conventional techno-economic assessment was

carried out for the optimal configuration, considering an interest rate of 10 % and a project lifetime of 20 years, providing a Net Present Value (NPV) of 131.93 M USD, which is consistent with the results already presented in Ramos *et al.* (2019) [6].

With respect to the SNPV value, a deeper analysis for comparing purposes was performed, considering four different suboptimal technological routes. Table 1 shows for the different alternatives, the SNPV and NPV values. The alternatives were based on sugarcane (*sc*) or sugarcane molasses (*m/s*) as carbon source, as these resulted to be the more sustainable options. Also, the extraction methods for PHAs that prove to be the more sustainable, were enzymatic extraction (*enz*), NaOCl and surfactant extraction (*surf*) and surfactant and chelate as extraction (*surf & ch*).

Alternative 1, which is based on sugarcane as a carbon source and whose extraction method is enzymatic, yielded more economical profitability in comparison with the optimal configuration. Alternative 2, also based on sugarcane as carbon source, with surfactant and NaOCl as option for PHA extraction method, resulted in nearly the same economical profitability in comparison to the optimal scheme. Although the economical profitability is higher or nearly the same for alternatives 1 and 2, respectively, there is a significant detriment in the SNPV value. This is mainly due to the ecotoxicity environmental impact of NaOCl emissions [22], chemical that is used for dissolution improvement of the cell wall for the enzymatic extraction in alternative 1, and for chemical digestion in surfactant and NaOCl extraction in alternative 2. Considering alternatives 3 and 4, where is employed sugarcane molasses as carbon source, there is a worsening in both SNPV and NPV. Hence, processing of sugarcane leads to enhanced sustainability in PHAs production plant design.

**Table 1:** Set of potential technological routes for PHAs production.

Alternative	SNPV (MUSD)	VPN (MUSD)
Optimal	-111.40	131.93
1 ( <i>sc</i> + <i>enz</i> )	-217.86	187.88
2 ( <i>sc</i> + <i>surf</i> )	-608.76	131.69
3 ( <i>m/s</i> + <i>enz</i> )	-340.43	117.31
4 ( <i>m/s</i> + <i>surf &amp; ch</i> )	-244.06	58.40

Regarding heat integration, additional runs were carried out without heat integration and numerical results show that the optimal integrated scheme with HEN increased the number of heat exchangers required, as compared to the optimal base case without HEN (16 vs 15) and it also reduced the cost of external thermal utilities by 35.60 % (from  $123.65 \times 10^6$  kJ/h to  $79.64 \times 10^6$  kJ/h). Moreover, the reduction of utilities matches from 15 to 13 accounts for significant utility savings that improve the sustainability objective function (see Table 2), that led to

an improvement of 48.58 % in the objective function. This aligns with the results reported by Ramos *et al.* (2023) [27].

According to the results shown in Table 2, a meaningful enhancement of 15.14 % is found in the economic pillar between the two proposed cases. This is due to the energy savings, that result economically more impactful than the increase of the heat exchanger capital cost (1 extra heat exchanger for HEN case). Furthermore, there is a significant improvement of 19.42 % in the environmental pillar, while only a difference of 0.89 % can be reached in the social pillar. Regarding the economic pillar, a further analysis demonstrates that, while the utility cost reduction with heat integration represented a 34.14 % (from 8.46 M USD to 5.57 M USD), the heat exchanger capital cost increased in a 19.72 % (from 1.20 M USD to 1.43 M USD). The social pillar difference is associated with the increase in the number of heat exchangers after heat integration, representing more workers' contracts. A decrease of fossil fuels requirements (external utilities), positively benefits the environmental pillar in the objective function.

**Table 2:** Sustainability Net Present Value pillars comparison for heat and non-heat integration scenarios.

Sustainability metric (MUSD)	With HEN	Without HEN	Difference
SNPV	-111.40	-216.64	48.58 %
NPV <sub>economic</sub>	208.11	180.74	15.14 %
NPV <sub>environmental</sub>	-322.91	-400.75	19.42 %
NPV <sub>social</sub>	3.39	3.36	0.89 %

In order to provide a comprehensive insight into the environmental pillar of the objective function, Fig. 2 displays a breakdown in endpoint impact categories, for the heat and non-heat integration scenarios, both for the optimal configuration of the PHAs production plant.

The highest environmental burden is attributed to carbon footprint, as a consequence of the thermal energy required in the surfactant and chelate extraction method, which is the extraction method with the higher thermal energy demand. Significant reductions in the carbon footprint impact category can be achieved with heat integration, as it reduces this burden by 23.65 %. This reduction is mainly attributed to the lower thermal energy consumption required at the biorefinery, leading to less energy production from conventional sources.

In the case of eco systems environmental burden, impact that follows carbon footprint in intensity, the major contribution to this category resulted from the background environmental impact of the acquisition of raw sugarcane. This background accounts for all the environmental burdens related to eco systems category, primarily linked to ecotoxicity and acidification impacts, that were generated in order to bring along the carbon source

into the Biorefinery.

Human health and resource scarcity resulted in the least negatively impacted categories, where the minor contributions were the background process environmental burden from energy requirements. Overall, numerical results reinforce the need for including simultaneous HEN models within the superstructure framework [23].

**Figure 2.** SNPV environmental pillar breakdown.

In order to provide major insight into environmental impacts due to foreground and background processes emissions, Fig. 3 presents the midpoints radar chart expressed in M USD, for the optimal configuration of the biorefinery (HEN scenario).

**Figure 3.** Midpoints radar chart for heat integration case.

Also, we performed a local sensitivity analysis in order to determine most influential parameters on SNPV, that could be improved to achieve a higher sustainability profit on the biorefinery, considering a variation of  $\pm 10\%$  from base value of the parameters (Figure 4). It can be seen that PHA's selling price resulted in the parameter with the largest effect on SNPV. For instance, a 10 % increase in this parameter (from 5.46 USD/kg<sub>PHA</sub> [24] to 6.01 USD/kg<sub>PHA</sub>) represents an objective function enhancement of 41.74 % (from -111.40 M USD to -64.90 M USD). On sensitivity effects, it is followed by PHA yield, CEPCI index, sugarcane raw material price.

PHA yield [11] resulted in a meaningful effect on SNPV, mainly due to the fact that, if this yield is higher in the biosynthesis section, this leads to a minor requirement of sugarcane as carbon source in order to achieve

the PHA demand. As it was aforementioned, sugarcane background processes' environmental burden resulted in a major contribution in the ecosystems impact category. Also, reduction of sugarcane results in a decrease of capital costs.

It is worth noting that SNPV is not particularly sensitive to interest rate and utility service's cost. This last outcome, is due to the fact that the major impact on SNPV for the optimal configuration of the biorefinery, is the environmental pillar. Hence, the external utilities cost is not as relevant as diminishing the utilities requirements.

Based on these results, some of the above-mentioned parameters can be modified to potentially improve plant economics as proposed by Aui *et al.* [25] and Rizwan *et al.* [26], and subsequently enhance the proposed objective function for the biorefinery. However, some of these parameters are intrinsically connected with the market, such as product selling price, CEPCI index or interest rate. Therefore, special attention should be devoted to the technology-dependent parameters, such as the biological parameter PHA yield, since it is crucial to improve the sustainability objective function.

**Figure 4.** Sensitivity analysis for the optimal scheme.

## CONCLUSIONS

In this work, we have addressed the production of biopolymers, namely PHAs, by a mixed integer nonlinear programming (MINLP) model for the optimal sustainable design of a biorefinery and its heat exchanger network (HEN). A superstructure that considered the processing of different carbon sources and PHAs extraction methods was developed. Optimization results point out that the optimal technological route is the one that employs sugarcane as a carbon source for PHAs production and surfactant-chelate for PHAs extraction. Heat integration was proved to be valuable since it enhanced significantly the SNPV objective function. Also, various technological alternatives were explored, and although they exhibited economic parity or superiority, they were notably inferior in terms of sustainability in comparison with the optimal scheme. Moreover, a breakdown of the environmental pillar was conducted, in order to provide insights into the

environmental impacts related to the biorefinery design. It was clearly demonstrated that the reduction of external utilities through heat integration, resulted in a significant decrease in carbon footprint impact category. Furthermore, sensitivity analysis shows the potential aspects that should be taken into account to increase the process sustainability.

## ABSTRACT

Computer-aided molecular and process design (CAMPD) tries to find the best molecules together with their optimal process. If the optimization problem considers two or more components as degrees of freedom, the resulting mixture design is challenging for optimization. The quality of the solution strongly depends on the accuracy of the thermodynamic model used to predict the thermophysical properties required to determine the objective function and process constraints. Today, most molecular design methods employ thermodynamic models based on group counts, resulting in a loss of structural information of the molecule during the optimization. Here, we unlock CAMPD based on property prediction methods beyond first-order group-contribution methods by using molecule superstructures, a graph-based molecular representation of chemical families that preserves the full adjacency graph. Disjunctive programming is applied to optimize molecules from different chemical families simultaneously. The description of mixtures is enhanced with a recent parametrization of binary group/group interaction parameters. The design method is applied to determine the optimal working fluid mixture for an Organic Rankine cycle.

**Keywords:** Molecular Design, Energy Conversion, Process Design, Optimization, Exergy Efficiency

## INTRODUCTION

Computer-aided molecular and process design (CAMPD) [1] determines optimal molecules jointly with their optimal process. Evaluating molecules for their performance in a process enables a comprehensive assessment. The influence of different molecular characteristics is combined in a process-level target function that can quantify the thermodynamic, economic, or environmental performance of the process.

Molecules occur as degrees of freedom for various energy conversion processes like heat pumps [2] and organic Rankine cycles (ORC) [3-5] or separation processes like CO<sub>2</sub> capture [6]. The design space of molecules is vast but can even be extended exponentially by considering blends of multiple molecular species [7,8].

To optimize a molecule, its structure must be featurized, i.e., expressed in a machine-readable way [9]. Common features used in molecular design are group counts that indicate the number of occurrences of predefined groups in a molecule. The group counts can be used as degrees of freedom in an optimization algorithm.

Additional molecular constraints can ensure that the optimization only generates valid molecules.

The group counts are used in group-contribution methods to determine the thermophysical properties required for the process model [10]. A disadvantage of using group counts as features is that some of the structural information of the molecule is lost in the featurization. Therefore, the optimization does not necessarily allow the identification of an optimal molecule but rather a set of optimal isomers that share the same group counts.

The limitation of group counts is alleviated by maintaining structural information during the optimization. This can be achieved by optimizing the coefficients of an adjacency matrix [11]. However, the number of degrees of freedom becomes large, which is a limiting factor in the presence of expensive model evaluations that occur in an integrated molecular and process design. As an alternative, we recently introduced molecule superstructures [12]. The superstructures can encode all molecules of a particular chemical family using a significantly reduced number of binary variables.

The molecular design space superstructures offer is

smaller than first-order group-contribution methods. However, the molecular representation should not only be picked for computational convenience but also based on the expected accuracy of property prediction methods. Often, extrapolating a group contribution method to molecules significantly different from the molecules used for parameter adjustment (e.g., polyfunctional molecules) leads to low accuracies that undermine the results of a molecular design.

Evaluating a process model requires an equation of state or an equivalent model. For mixture design, the model should predict a wide range of fluids and their mixtures. Molecular equations of state like those based on statistical associating fluid theory (SAFT) [13] leverage molecular insights to describe mixtures accurately based on pure-component parameters. If a higher accuracy is required, binary interaction parameters can further enhance the description of mixtures.

In a recent study, the authors and co-workers [14] extended the group contribution method for PCP-SAFT [15,16] by Sauer et al. [17] to mixtures by accounting for hydrogen bonding between polar molecules (aldehydes, ketones, ethers, formates, and esters) and self-associating molecules (alcohols and amines), and by parametrizing a group contribution method for binary interaction parameters. The study compares a homosegmented and a heterosegmented group-contribution method. The homosegmented approach determines PCP-SAFT parameters from group counts and group-specific parameters. In the heterosegmented approach, segments replace molecules as species in the equation of state. The heterosegmented approach was determined to be more accurate for pure components [17] and for mixtures [14], but to parametrize the model, the number of bonds between different groups is required in addition to the group counts. The molecule superstructures [12] can be used to infer both group counts and bond information.

In this work, the more accurate heterosegmented group-contribution method for PCP-SAFT is unlocked for application in an integrated molecular and process design using molecule superstructures. We demonstrate the approach in a case study determining the optimal working fluid mixture for an organic Rankine cycle (ORC). Due to the combinatorial complexity of possible working fluid mixtures, a molecular design is necessary to determine the optimal working fluid systematically.

## MOLECULE SUPERSTRUCTURES

To optimize molecules in a computer-aided molecular and process design, the structure of the molecule needs to be represented in a format that is accessible to the optimization algorithm. Molecule superstructures are a graph-based representation of a molecular family [12]. Fig. 1 shows an example of a small molecule structure. It

consists of a graph with four nodes and three edges. Every node corresponds to an atom type and a binary structure variable. Structural constraints are introduced to ensure that only valid molecules are generated (in this case water, methanol, ethanol, or dimethyl ether). The structure variables are converted to group and bond counts that are required to parametrize the equation of state. The structural constraints and group/bond counts can be derived generically for arbitrarily large superstructures. We refer to the original publication [12] for the detailed expressions.

**Figure 1:** Example for an ether/alcohol superstructure including the corresponding structural constraints and resulting group and bond counts.

Previously, optimal molecules were determined for every chemical family individually [12]. For mixtures, the number of possible combinations of chemical families becomes large. Therefore, we extend the superstructure approach to optimize any number of chemical families simultaneously using methods from disjunctive programming [18].

The superstructure converts binary structure variables  $y_k$  into molecular features used in the property prediction method. Linear inequality constraints are required to ensure that only valid molecules are found. The specific constraints are elucidated in the original publication [12]. In general, the constraints can be expressed as

$$\sum_k a_{ijk} y_k \leq b_{ij} \quad (1)$$

Here,  $i$  enumerates the chemical families and their respective molecule superstructures,  $j$  indicates different constraints, and  $k$  enumerates the structure variables  $y_k$ . The number of constraints  $N_{c,i}$  and structure variables  $N_{y,i}$  depends on the considered molecule superstructures.

To combine the different chemical families in one structure, a common set of structure variables is defined by using  $N_y = \max_i N_{y,i}$  binary variables and adding additional constraints that force the unused variables to 0.

$$\sum_{k=N_{y,i}+1}^{N_y} y_k \leq 0 \quad (2)$$

The constraints associated with each molecule superstructure can then be formally expressed as disjunctions in the optimization problem.

$$v_i [\sum_k a_{ijk} y_k \leq b_{ij}] \quad (3)$$

The Big-M method and convex hulls have been established as standard methods to convert disjunctive programs into MILPs or MINLPs [18]. The convex hull has a tighter feasible region than the Big-M formulation but requires more additional variables. Therefore, the Big-M formulation is better suited for the integrated process design task with expensive target function evaluations. Applying the Big-M method introduces additional binary variables  $c_i$ , one for each disjunction and hence chemical family. Only one disjunction can be active at the same time, leading to the additional constraint:

$$\sum_i c_i = 1 \quad (4)$$

The constraints for every molecule superstructure are rewritten by introducing the parameter  $M_{ij}$ .

$$\sum_k a_{ijk} y_k + M_{ij} c_i \leq b_{ij} + M_{ij} \quad (5)$$

In general,  $M_{ij}$  must be large enough to ensure that the constraint is turned off if  $c_i = 0$ , but as small as possible to ensure tight relaxation bounds. For the binary variables  $y_k$ , the optimal value for  $M_{ij}$  can be derived generically, as

$$M_{ij} = \sum_k \max(a_{ijk}, 0) - b_{ij} \quad (6)$$

The original publication on molecule superstructures [12] describes a generic method to infer the group and bond counts from the structure variables. The same method is used for every individual superstructure. The resulting group counts  $n_{i,\alpha}$  and bond counts  $b_{i,\alpha\beta}$  are then weighted with the chemical family indicator  $c_i$  of every superstructure to give the total group and bond counts.

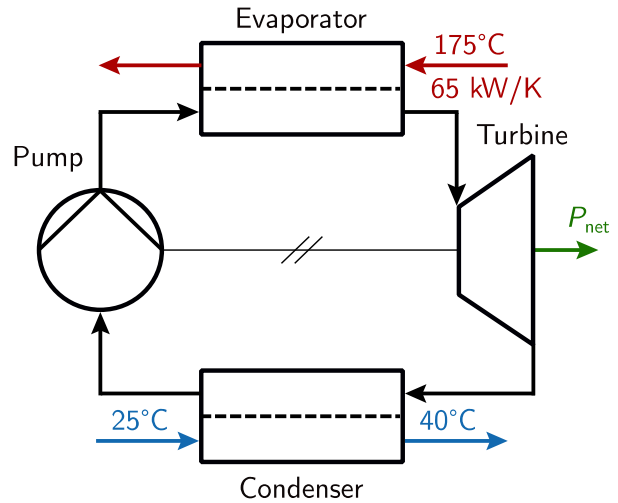

$$n_\alpha = \sum_i c_i n_{i,\alpha}, \quad b_{\alpha\beta} = \sum_i c_i b_{i,\alpha\beta} \quad (8)$$

The group and bond counts are used to parametrize the heterosegmented group-contribution method for PCP-SAFT [17], which is used to determine phase equilibria and residual properties. To calculate caloric properties, the group counts are also used in the group-contribution method for the ideal gas heat capacity by Joback and Reid [19]. The resulting MINLP is solved using the branch-and-bound implementation in Artelys Knitro [20].

## CASE STUDY: ORGANIC RANKINE CYCLE

We apply the molecular design method using molecule superstructures to the integrated design of an organic Rankine cycle (ORC) and its working fluid. ORCs can convert waste heat into power, reducing energy losses and increasing the exergetic efficiency of processes. The process flowsheet of the standard ORC used in this case study is shown in Fig. 2. Analogous to a regular Rankine cycle, the working fluid of the ORC is evaporated and potentially superheated to be then fed into a

turbine that extracts power from the working fluid. Part of the power is used to pump the working fluid that leaves the condenser back to the pressure level of the evaporator.

**Figure 2:** Flowsheet and key specifications for the ORC.

Using an organic working fluid rather than water enables the operation above atmospheric pressures, even for low-temperature heat sources. This work optimizes the working fluid mixture to maximize the power output of the ORC. The design of an actual waste heat valorization unit needs to consider additional aspects regarding safety, stability, and costs that are outside the scope of this study.

ORC processes are promising targets for mixture design since replacing pure working fluids with zeotropic mixtures leads to non-isothermal evaporation and condensation. The resulting temperature glide in the condenser and evaporator can be tuned to the respective temperature glides in the heat source and cooling mediums. A more homogeneous temperature difference across the heat exchangers reduces the exergy loss during heat transfer and, in conclusion, increases the net power output of the process.

The case study is based on the analysis of Chys et al. [21] and the design study by Schilling et al. [8]. The most important specifications are shown in Fig. 2: The heat source has an inlet temperature of 175 °C and a heat capacity rate of 65 kW/K. The cooling medium is heated from 25 °C to 40 °C. The outlet temperature of the heat source medium is only indirectly constrained via the pinch condition. The heat exchangers are modeled as isobaric. The full specification of the process is given in Tab. 1. This thermodynamic optimization aims to maximize the net power  $P_{net}$  of the cycle.

**Table 1:** ORC case study specifications from [8,21]

Component	Parameter	Value
Heat source	Inlet temperature	175 °C
	Heat capacity rate	65 kW/K
	Min. approach temp.	20 K
Turbine	Isentropic efficiency	0.65
	Min. vapor quality (outlet)	1
Pump	Isentropic efficiency	0.8
Condenser	Min. absolute pressure	1 bar
	Min. relative pressure	1e-3
Evaporator	Max. absolute pressure	50 bar
	Max. relative pressure	0.8
Cooling	Inlet temperature	25 °C
	Outlet temperature	40 °C
	Min. approach temp.	10 K

## RESULTS

As a reference, the molecule superstructures with disjunctions are first used to determine the optimal pure working fluid for the ORC. A ranking of the ten molecules that yield the highest net power output is shown in Tab. 2. The ranking consists of alkanes, alkenes, and propyne.

**Table 2:** Ranking of the best pure component working fluids based on the net power output of the ORC.

#	SMILES	Name	Net power [kW]
1	CCC	propane	472
2	C=CC	propene	435
3	C#CC	propyne	425
4	CC(C)C	isobutane	412
5	CC(C)(C)C	neopentane	409
6	CCCC	butane	399
7	C=C(C)C	isobutene	396
8	C=CCC	butene	395
9	C=CC(C)(C)C	neohexene	395
10	CCC(C)C	isopentane	394

The molecular design space also contains polar (aldehydes, ketones, ethers, formates, and esters) and self-associating molecules (alcohols and amines). However, these molecular families are unsuitable for the application due to their lower vapor pressures and higher critical temperature. The ranking is topped by the C3 hydrocarbons propane, propene, and propyne, with the highest achievable net power output being 472.25 kW using propane as the working fluid.

Higher net power outputs can be achieved by considering mixed working fluids. To obtain a ranking of working fluid candidates, we use the molecule

superstructure concept to find optimal additives for each of the ten best-performing pure components. The ranking is shown in Tab. 3. The ten best mixtures all consist of mainly propane or propene with traces of larger, mostly non-polar molecules. The mixtures containing one of the other well-performing fluids from the pure-component case consistently lead to lower power outputs than those based on propane or propene. This observation strongly implies that optimizing additives can determine the optimal mixture for this case study. However, both molecules must be optimized in a single optimization problem for a more comprehensive result. Schilling et al. [8] demonstrate how the approach can significantly reduce the number of function evaluations compared to a screening of mixtures using a CAMD method based on group counts. The design setup in our study allows the simultaneous optimization of both constituent molecules, but the prevalence of local optima impedes an efficient direct determination of optimal working fluid mixtures. Therefore, it was not possible yet to determine a ranking comparable to Tab. 3 by optimizing both fluids rather than an additive in a reasonable timeframe. A MINLP solution algorithm better suited for the specificity of integrated molecular and process design is required to improve the solution times and generate more robust candidate mixtures [22]. The non-convexity of the MINLP also suggests using global optimization [23], however, the expensive function evaluations that include multiple phase equilibrium calculations with the heterosegmented group-contribution method for PCP-SAFT are a limiting factor.

Fig. 3 compares the process for the optimal pure working fluid (propane) with the best mixed working fluid candidate. In the pure-component case, the temperature of the working fluid is constant during evaporation and condensation. Therefore, the optimization mainly determines process conditions in which the temperature glide of the heat source medium aligns well with the temperature during the preheating step in the evaporator. The mixed working fluid shows a temperature glide in the condenser. The resulting process conditions find a compromise between the exergy loss in the evaporator and the condenser. Consequently, the net power output of the ORC is increased by 11% compared to propane as the working fluid. This increase is partly driven by the temperature glide in the cooling medium, which is fixed to 15 K in this case study. For other process conditions, the benefit of using mixed working fluids can be small [24], and a reduced heat transfer during condensation and evaporation must be considered for an economic assessment of the process [25,8].

Choosing the correct composition of the mixture is essential for the performance of the ORC. Fig. 4 shows the optimized net power output of the ORC using the four best mixtures from Tab. 3 over the entire composition

**Table 3:** Ranking of the best working fluid mixtures found in the integrated design.

#	Component 1		Component 2		Molar composition	Net power [kW]
	SMILES	Name	SMILES	Name		
1	CCC	propane	C#CC(C)C	3-methyl-1-butyne	85% / 15%	525
2	CCC	propane	CC(C)(C)C	neopentane	92% / 8%	524
3	CCC	propane	C#CCC	1-butyne	65% / 35%	522
4	CCC	propane	CCC(C)C	isopentane	94% / 6%	519
5	C=CC	propene	CCCC	butane	83% / 17%	519
6	C=CC	propene	CCC(C)C	Isopentane	93% / 7%	518
7	CCC	propane	C=C(C)CC	2-methyl-1-butene	95% / 5%	518
8	CCC	propane	CCCCC	pentane	97% / 3%	515
9	CCC	propane	CCCO	1-methoxypropane	96% / 4%	514
10	CCC	propane	COC(C)C	2-methoxypropane	95% / 5%	512

**Figure 3:** Ts-diagram for the ORC using propane (left) and the best mixture (right) as working fluid. The phase change of the working fluid (green) is isothermal for pure components but exhibits a temperature glide for mixtures. In the optimization the temperature glide is adjusted to the temperature profiles in the heat source medium (red) and the cooling water (blue).

range. The solutions from the mixture design align well with the maxima in the discretized curves. In all cases, adding the longer hydrocarbon to pure propane initially increases the net power due to the establishment of the temperature glide. Further increasing the amount of additive reduces the performance, with the curves showing local minima that, in one case, are even below the net power output of the pure additive.

The net power output is strongly related to the ratio of the temperature glides in the condenser and the cooling medium [8]. Changing the composition of the mixtures affects the glide in the condenser, with the largest glide occurring in the middle of the composition range. The glide also explains the shape of the maxima in the net power: A jump of the pinch from the condenser outlet to the inlet leads to a kink in the net power (cf. Fig. 4). If the temperature profile in the condenser is shaped in a

way that the pinch is located between the inlet and the outlet, the maximum in the net power is smooth.

A strong sensitivity to variations in the composition of the working fluid can be problematic in an actual ORC process when leakage is non-negligible, and the composition can change due to the constituents' different relative volatilities. With the abundance of near-optimal mixtures in the solution space of the molecular design, the robustness with respect to composition changes can be incorporated as an additional constraint in the optimization problem.

**Figure 4:** Optimized net power output of the ORC using a propane + X mixture with the specified composition. The marks represent the optimal composition found in the molecular design.

## CONCLUSION

Molecule superstructures are used to determine the optimal working fluid mixture for an ORC. Multiple chemical families represented by their own superstructure are optimized simultaneously using disjunctive programming. Due to the full structural information available during the molecular design, the accurate heterosegmented group-contribution method for PCP-SAFT can be used as a property prediction method. The model accuracy is further enhanced by a recent parametrization of binary group/group interaction parameters [14].

The optimization determines mixtures of propane or propene with larger hydrocarbons as optimal working fluids. The top-ranked mixtures deliver comparable performances. This observation suggests that additional material properties should be considered within the optimization to reduce the molecular design space. Amongst the mixtures with the best thermodynamic properties are two that contain alkynes, components that are unsuited for long-term application as working fluids due to their low chemical stability. If predictive models are available, adding constraints for the working fluid's safety, stability, and environmental impact avoids a posteriori filtering of the results and provides a more efficient design method. Finally, economic considerations were circumvented by empirical pinch constraints instead of a direct consideration by using more detailed, rate-based process models [8]. Also, in this case, the more detailed representation by molecule superstructures could enable advanced thermodynamic models, e.g., for the required transport properties.

# Internally Heated Crackers for Decarbonization and Optimization of Ethylene Production

Edwin A. Rodriguez-Gil and Rakesh Agrawal\*

Purdue University, Davidson School of Chemical Engineering, West Lafayette, IN, USA

\* Corresponding Author: [agrawalr@purdue.edu](mailto:agrawalr@purdue.edu)

## ABSTRACT

Ethylene is a crucial precursor for a diverse spectrum of products and services. As global production exceeds 150 million tons annually and is projected to surpass 255 million tons by 2035, the imperative for sustainable and efficient ethylene production becomes increasingly clear. Despite Externally Heated Crackers (EHCs) dominating ethylene production for over a century, they face intrinsic limitations that necessitate transformative solutions, including intense radial thermal gradients, high metal demand, and substantial CO<sub>2</sub> emissions. This study employs a robust combination of Computational Fluid Dynamics (CFD) coupled with detailed chemical kinetics to rigorously assess selected configurations of Internally Heated Crackers (IHCs) against the leading EHC designs. Our findings reveal that IHCs exhibit the potential to enhance ethylene output by a factor of 1.66 when compared to EHCs of the same length, diameter, and surface temperature. These results herald a promising era for developing more efficient cracking reactor designs, poised to redefine the landscape of sustainable chemical manufacturing towards achieving Net-Zero emissions. Embracing innovative technologies like IHCs presents an opportunity for the chemical industry to make significant strides in reducing its environmental footprint while meeting the growing global demand for ethylene and its derivatives.

**Keywords:** Net-Zero, Decarbonization, Ethylene, Cracking, Reactor Design, Process Optimization, CFD

## INTRODUCTION

Ethylene (C<sub>2</sub>H<sub>4</sub>) may be one of the simplest hydrocarbons, yet it is a pillar of the global economy. Its value chain includes vital chemical products like polyethylene, ethylene oxide, and polyester. These, in turn, are used across multiple sectors, such as internet communications, medical sterilization, and textiles [1], [2]. The level of importance of ethylene is such that in 2017, the American Association of Fuel and Petrochemical Manufacturers (AAPM) referred to it as the "World's Most Important Chemical" [3].

### 1.1 Externally Heated Crackers (EHCs)

Since their industrial debut in 1921, Externally Heated Crackers (EHCs) have been the dominant technology for ethylene production [4], [5]. These specialized units operate at temperatures of ~850°C to split or "crack" hydrocarbon feedstocks into ethylene [6]. Figures 1, 2, and 3 illustrate the main EHC configurations.

**Figure 1.** Illustration of a Flame-heated Tubular Cracker (FTC). External burners heat a series of long reaction tubes, facilitating cracking. This configuration is commonly called a steam cracker when steam serves as the diluent.

**Figure 2.** Illustration of an Impedance Tubular Cracker (ITC). Electricity flows directly through the reaction tubes generating heat. This configuration is also known as direct heating cracking [7].

**Figure 3.** Illustration of an External Resistance Tubular Cracker (ERTC). Electric heating elements outside the reaction tube provide heat to facilitate cracking. This configuration is also known as indirect heating cracking [8].

## 1.2 Intrinsic Limitations of EHCs

The efficiency of cracking reactors is intrinsically tied to their heat transfer performance. In the case of EHCs, one of the primary limitations stems from internal radial thermal gradients, reaching up to 100°C from the tube walls to the center [9]. These uneven reaction conditions result in reduced ethylene yields near the center and promote undesired reactions close to the wall. To mitigate this effect, tube diameters are kept remarkably small, sometimes as narrow as 3 cm [10]. However, this approach reduces the flow area, necessitating a large number of parallel tubes to scale up production. Depending on the specific design, a single EHC may require up to 200 reaction tubes, representing ~2500 tons of raw metal and costing around half a billion dollars due to the specialized alloys involved [11], [12].

Achieving precise temperature control in EHCs is also challenging due to the large number of reaction tubes and the difficulty in continuously monitoring internal temperatures. In practice, only the mean outlet temperatures are measured, resulting in sub-optimal ethylene outputs and reduced reactor lifespan. At typical reaction conditions, an increase of just 20°C in the metal temperature can halve its lifespan [13]. This situation is highly undesirable due to the high cost of the materials involved. Furthermore, when fossil fuels are used for heating, EHCs can release vast amounts of CO<sub>2</sub>.

## 1.3 EHCs and CO<sub>2</sub> emissions

Over the past century, fossil fuel combustion has been the default alternative for heating in EHCs. This is due to the historically lower cost of fossil fuels compared to other energy sources. However, this approach also entails a substantial climate cost. For every ton of ethylene produced, between 1.0 and 1.6 tons of CO<sub>2</sub> are released [6]. In 2021 alone, with a market of ~150 Million tons (Mt), EHCs emitted ~200 Mt of CO<sub>2</sub>, accounting for ~0.6% of global CO<sub>2</sub> emissions [14], [15]. The ethylene market is projected to increase ~73% from \$132B in 2022 to \$228B by 2032 [16]. In a business-as-usual scenario, emissions could surpass 335 Mt in the next decade, directly conflicting with global decarbonization efforts to reach a Net-Zero emissions economy before 2050 [17], [18].

## 1.4 Electric & Hydrogen-powered EHCs

EHCs powered by electricity or hydrogen have recently emerged as alternatives to reduce CO<sub>2</sub> emissions [19], [20]. Notably, in September 2022, BASF, in collaboration with Linde and SABIC, began the construction of a pilot-scale Impedance Tubular Cracker (ITC) and External Resistance Tubular Cracker (ERTC) in Germany [21]. When coupled with low-carbon energy sources, these units can help reduce CO<sub>2</sub> emissions by up to 95% compared to FTCs [22]. However, since they still rely on heat transfer to the gas from the tube walls, they present the same intrinsic limitations that affect all EHC designs.

## 1.5 Internally Heated Crackers (IHCs)

The limitations of EHCs have prompted the quest for alternative reactor configurations with superior performance and lower carbon emission, leading to the emergence of Internally Heated Crackers (IHCs) [23], [24]. IHCs set themselves apart by embedding the heating elements directly within the reaction zone, where energy is needed, effectively reducing the radial thermal gradients. This innovative approach facilitates using larger diameter reaction tubes while increasing the heat transfer area, consequently reducing the required amount of metal during construction, and lessening the weight for transportation compared to EHCs [25]. Furthermore, as they are electrically heated, they retain the same benefits of decarbonization. Configurations featuring combined internal and external heating options offer added versatility [26], especially at small diameters where the tube's external surface contributes more to the total heat transfer area.

This study focuses on comparing external heating against solely internal heating designs. However, future simulations will delve into the effects of the combined approach. Figures 4 and 5 illustrate two IHC configurations introduced by Agrawal et al. [23] [26], which will be employed in this study.

**Figure 4.** Illustration of an Internally Heated Cracker (IHC) with one heating rod. An electrical element generates heat directly inside the reactor, in the reaction zone.

**Figure 5.** Illustration of an Internally Heated Cracker (IHC) with four heating rods. The additional heat transfer area enhances heat delivery, producing more ethylene.

## 1.6 IHC vs EHC: A Comparative Study

While IHCs hold promise over traditional EHCs, it is imperative to demonstrate their performance quantitatively through rigorous modeling and experimentation. This study employs a robust combination of Computational Fluid Dynamics (CFD) coupled with detailed chemical kinetics to compare selected lab-scale EHC and IHC configurations. This scale was selected to provide a basis for subsequent experimental work.

The following sections delve into the comparative analysis details and the results obtained, shedding light on the intricacies of ethylene production and the efficiency of these two distinct technologies.

## METHODS

### 2.1 The need for CFD simulations

Evaluating novel cracking reactor designs requires a modeling approach capable of handling fluid dynamics and predicting the heat transfer coefficient for arbitrary geometries. This model must seamlessly integrate with detailed chemical kinetics to rigorously account for free-radical reactions while addressing turbulence effects and heat transfer from radiation. Additionally, it should converge quickly enough and offer reasonable numerical stability to allow for timely simulations. Computational Fluid Dynamics (CFD) simulations provide a useful modeling tool to meet these requirements.

## 2.2 Types of CFD Simulations

Accurately selecting a simulation strategy for a specific project is crucial for ensuring reliable results and overall success. For example, Direct Numerical Simulation (DNS) is the most accurate CFD method, avoiding flow approximations. However, it is also characterized by high computational costs and is primarily reserved for specialized applications and benchmarking. In contrast, approaches like Large Eddy Simulation (LES) or Reynolds-Averaged Navier-Stokes (RANS) deliberately simplify physics across spatial scales, sacrificing some precision, but reducing the computational cost by orders of magnitude compared with DNS.

This research utilizes the RANS equations coupled with an Menter's Shear Stress (SST)  $k$ - $\omega$  model to account for turbulence and a Surface to Surface (S2S) model to address radiation. The SST  $k$ - $\omega$  model was chosen as it is widely accepted as an industry standard for turbulence. The S2S model although computationally expensive, was selected because it is particularly good for modeling the radiative heat transfer in closed domains.

## 2.3 Kinetic Model

The correct implementation of chemical kinetics is a critical element for the modeling of cracking reactors. While the concept of cracking can be traced back to the early 1800s [27], it was not until the 1970s that compelling kinetic models were readily available. This research implements Sundaram and Froment's (1978) kinetic model [28], recognized as some of the most comprehensive in the field, enabling the modeling of feedstocks containing ethane, ethylene, propane, propylene, n-butane, and iso-butane.

Olsvik and Billaud's model (1992) can be added to account for methane thermal decomposition [29]. However, at the reaction conditions for ethylene production, methane behaves mainly as inert, resulting in little differences compared with just Froment's model [30]. Combined, both models comprise a total of 170 chemical reactions and 41 chemical species, including free radicals.

## 2.4 Thermodynamic Properties

Given the temperature changes and chemical reactions involved, obtaining a comprehensive set of thermodynamic properties for each species is essential to model cracking reactors accurately. As the reactions occur in the gas phase, the main properties needed are heat capacity, enthalpy, entropy, and Gibbs free energy. This research employs the NASA 7-coefficient polynomial system with coefficient values sourced from the Active Thermochemical Tables (ATcT), maintained by Argonne National Laboratory [31].

## 2.5 Boundary Condition

Common boundary conditions for inlet/outlet ports in cracking reactors include mass flow rate, flow velocity, and flow pressure. Mass flow rate is often employed for closed domains like tubes, while flow velocity is typically for open environments. Pressure conditions can be used to complement both open and closed domains. This study implemented a combination of pressure boundary conditions at the reactor inlet and mass flow at the reactor outlet.

The inlet pressure was maintained at a constant value of 2 bar across all simulations, aligning with typical industrial ethylene cracker conditions. At the same time, the outlet mass flow was optimized for each configuration to maximize ethylene production. This setup ensures fair evaluation across all cases.

For the reactor walls, common boundary conditions include isothermal, constant heat, and convection cases. Isothermal conditions can be used to assess the maximum ethylene production capacity for a given configuration as it predicts the heat transfer capacity ceiling when the maximum metal temperature is used across all surfaces. Constant heat flow conditions can be used to simulate the effect of electric heating but require prior knowledge of the heat transfer profile. Convection boundary conditions can be used to model heat transfer in open environments. This study implements isothermal walls at 1100 °C for all simulations to compare the maximum ethylene production capacity across designs. The selected temperature mirrors the upper limit achievable with industry-standard nichrome alloy heating elements.

## 2.6 Feed Composition

Industrial ethylene crackers utilize diverse feedstocks, often based on local availability. In the United States, for example, gas feedstocks like ethane or shale gas are prevalent, while in Europe, liquid feedstocks like naphtha are more common [6].

Another crucial aspect is the inclusion of dilution agents, which enhance reaction conversion and reduce coke formation. The level of dilution is an economic optimization variable; higher dilution favors reaction but increases energy consumption [32]. Typical dilution ratios range between 0.3 - 0.7 kg of inert per kg of hydrocarbon [33]. Historically, steam has been the most common dilution agent, but the shale revolution has made methane an attractive alternative due to its abundance in shale gas deposits [34], [35].

Our simulation scheme can incorporate various dilution agents, including steam, methane, nitrogen, and carbon dioxide. However, for this study, no dilution agent was implemented; instead, pure ethane was used as feed in all simulations. This choice enables the isolation of geometry effects from those of dilution. Future simulations will explore the combined effects.

## 2.7 Feed Temperature

Another essential aspect is the inlet feed temperature. In Industrial EHCs, the feed is preheated using the flue gases from combustion or heat integration with the product, reaching ~650 °C inlet feed temperature [6]. In this case, all simulations use 350 °C, aligned with typical lab-scale cracking reactors.

## 2.8 Tube Material

As the material for the reactor tubes, all simulations employ SANDVIK 353 MA. This material is an austenitic chromium-nickel steel alloy with nitrogen and rare earth metals and is representative of the alloys utilized in industrial cracking reactors. Its maximum operating temperature is ~1175 °C and is characterized by a high resistance to oxidation and carburization environments. The main material properties required for simulation are density, heat capacity polynomial, and thermal conductivity polynomial, which can be found in its datasheet.

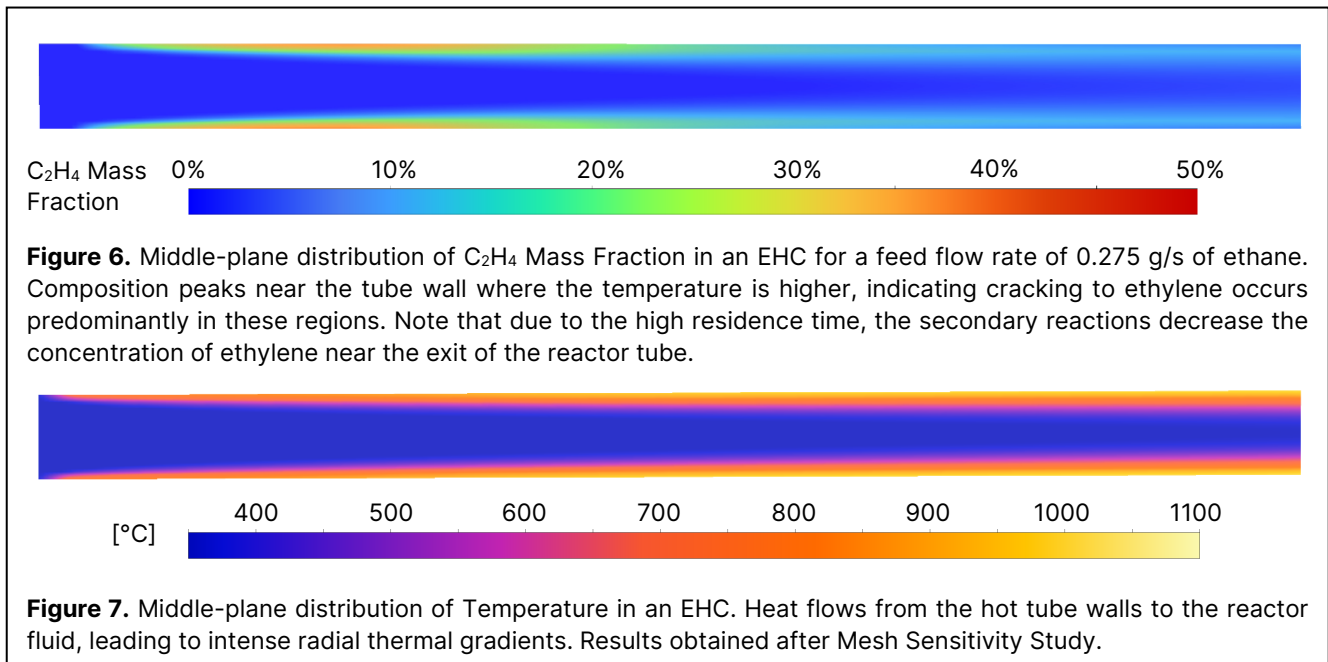

## 2.9 Convergence

In CFD simulations, the convergence criteria play a crucial role in determining the accuracy of the results. While residual functions are commonly used and provide a good indication of the simulation state, defining a set of parameters is advisable to determine when a simulation has reached a converged state.

This study employs the Mass-Weighted Average Gas Temperature and Mass-Weighted Average Ethylene Mass Fraction at the outlet as convergence criteria. When further iterations do not yield changes beyond the third decimal point, convergence is deemed achieved. Also, since this study focuses on the system's steady state, intermediate-state results are not saved, allowing the use of pseudo-transient solvers. Future simulations could explore the effects of reactor configuration on the system's dynamic response.

## 2.10 Mesh Sensitivity Study

In CFD simulation, selecting an appropriate mesh density is crucial for achieving accuracy and efficiency. Coarse meshes may introduce spatial discretization errors, while excessively fine meshes prolong simulation times unnecessarily. A Mesh Sensitivity Study (MSS) should be conducted to balance these factors. An MSS involves running the same simulation sequentially using higher mesh densities until the convergence parameters reach a stable value within a defined tolerance. This analysis should be performed for each configuration under consideration for best practices. In this research, the mesh densities were sequentially increased until a 2% change in convergence variables was no longer observed. At this point, the results were deemed independent of spatial resolution, ensuring acceptable accuracy for further analysis.

## 2.11 Simulation Workflow

This research implements the following workflow:

1. Define reactor geometry using Ansys Design Modeler.
2. Discretize the domain using the Ansys Mesh editor.
3. Load Fluent. Activate and set up the energy, viscous, species, and radiation models.
4. Load kinetic model and thermodynamic properties.
5. Establish boundary conditions, starting with an initial mass flow guess.
6. Define convergence criteria.
7. Run simulations until convergence is achieved.
8. Repeat the process from step 5 to determine a first approximation of the mass flow that maximizes ethylene production.
9. With a well-informed guess for the optimal mass flow, conduct a mesh sensitivity study, increasing mesh density by a factor in the range of 1.5–2.0 between cases.
10. Once the final mesh density has been established, optimize the mass flow again.
11. Save results.

## 2.12 Reactor Dimension

Simulations were performed considering lab-scale reactors to lay the groundwork for future experimental efforts. Typical lab-scale EHCs range from 1–2 m long by 5–13 mm diameter. However, to better showcase the potential of internal heating for more compact reactors with larger diameter tubes, a length of 0.5 m and internal diameter of 35 mm (Schedule 40 NPS 1-1/4 piping) were selected.

## 3. RESULTS

Figures 6 and 7 illustrate the outcomes obtained during step 10 of the simulation workflow, presenting a series of fields displaying the parameter distributions within the reaction domain. Analyzing these fields provides crucial insights into the system's performance. For instance, Figure 6 showcases the intense radial thermal gradients of EHCs. Also, since the peak ethylene composition is observed within the unit rather than at the outlet, it suggests the mass flow of 0.275 g/s is too low in this case. Moreover, radial temperature distribution results in higher reaction rates at the tube walls rather than evenly distributed across the cross-section. These Figures were generated using a mesh density of ~150k nodes. As shown in Figure 8, this resolution allows for mesh-independent results in this case. 50

**Figure 8.** Mesh sensitivity study for the externally heated case. Results converge after ~150,000 nodes.

Figure 9 illustrates the optimization process for the inlet feed flow in the externally heated case. Each data point represents a fully converged CFD simulation after the MSS study. The analysis reveals that the optimal feed flow for this configuration is  $\sim 1.2$  g/s, accompanied by a corresponding outlet ethylene feed flow of  $\sim 0.09$  g/s. This specific value emerges as the optimal operating point for the externally heated case.

The same iterative process is systematically repeated for the other configurations as well. For instance, Figures 10 and 11 offer comprehensive 2D and 3D views of the composition and temperature profiles of one of the simulations for the internally heated case with four rods. In contrast to the externally heated configuration, the radial gradients are less pronounced, resulting in a more even radial temperature distribution and higher ethylene production.

**Figure 9.** Feed flow rate optimization for the externally heated case. The optimal point is at 1.2 g/s.

**Figure 10.** (A) External-face and (B) Middle-plane C<sub>2</sub>H<sub>4</sub> mass fraction distribution in an Internally Heated Cracker (IHC) with four rods.

**Figure 11.** (A) External-face and (B) Middle-plane temperature distribution in an Internally Heated Cracker (IHC) with four rods. Results obtained after Mesh Sensitivity Study.

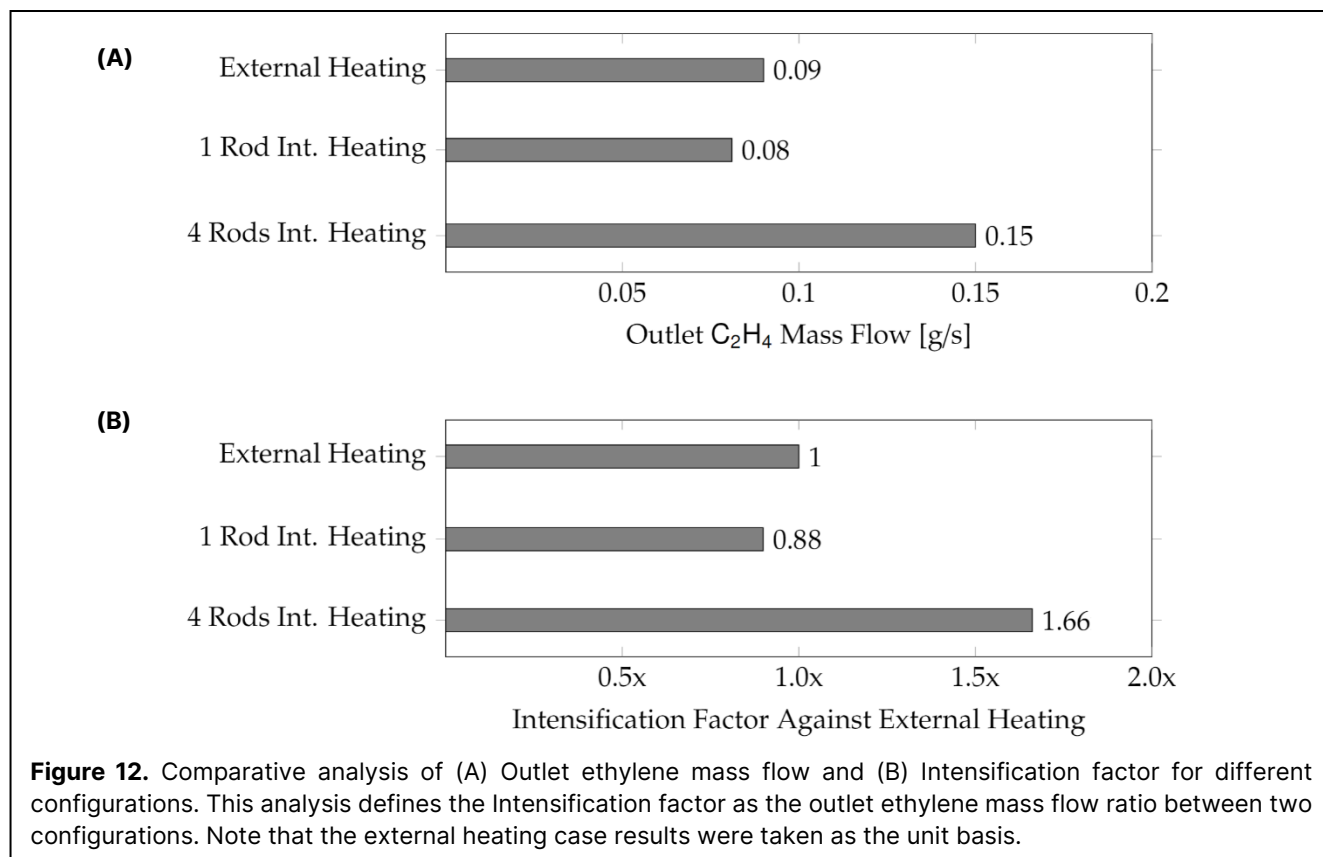

Figure 12 summarizes the results obtained for each configuration after step 11 of the workflow. The results reveal compelling insights. For example, the configuration featuring a single internally heated rod achieves a lower ethylene composition of ~0.08 g/s than the externally heated case, taken as a reference. This behavior is attributed to the limited heat transfer area offered by a single rod. In contrast, the scenario with four heated rods exhibits a remarkable outlet ethylene composition of ~0.15 g/s, surpassing the external heating case by a factor of ~1.66, showing the potential for achieving higher ethylene production than state-of-the-art externally heated designs. This behavior is attributed to more homogeneous set reaction conditions and increased transfer area. Furthermore, these findings encourage further exploration to discover new internally heated configurations capable of achieving even higher performance levels.

The analysis presented in this study sheds light on the intricacies of ethylene production and heralds a promising frontier for developing more efficient cracking reactor designs, poised to redefine the chemical manufacturing landscape toward achieving a Net-Zero future.

## ABSTRACT

Sand produced along with well-production fluids accumulates in the surface facilities over time, taking valuable space, while the sand carried with the fluids damages downstream equipment. Thus, sand is separated from the fluid in the sand traps and separators and removed during periodic clean-ups. But at high sand productions, the probability of unscheduled facilities shutdowns increases. Such extreme production conditions can be handled by strategic planning and optimal design of the separator network to enable maximum sand separation at minimal equipment cost while ensuring the accumulation extent is within tolerable limits. This paper develops a mathematical model to optimize the separator network design to maximize sand separation while the sand accumulation extent and total equipment cost are minimal. The optimization model is formulated using multi-objective mixed-integer nonlinear programming (MINLP). The capabilities of the developed model to assist sand management in the separator network are demonstrated with a case study of optimizing the network for two wells producing sand particles of different sizes. A residence time distribution-based model is used to predict sand settling behavior. The developed Pareto Front shows the trade-off between the increase in total sand accumulation rate and total equipment cost for an increase in the fraction of sand settled.

**Keywords:** Optimization, Planning, Oil and Gas, Separator, Sand

## INTRODUCTION

On the surface, sand produced with oil and gas accumulates in the separators, leading to costly unscheduled shutdowns, while the sand carried over damages the downstream equipment [1]. Sand management practices include sand separation from the fluid in the sand traps and separators and removal during periodic clean-ups. Multiple separators are generally necessary to separate the multiphase production containing oil, gas, water, and sand. The extent of sand separation and accumulation in separators depends on the production conditions, separator design, and separator network. Previous studies have developed algorithms for simultaneous optimization of the well production and separation systems for production management and enhancement [2,3]. However, these studies do not account for the sand separation in the separators.

This paper develops a mathematical programming model to optimize separator network design with three

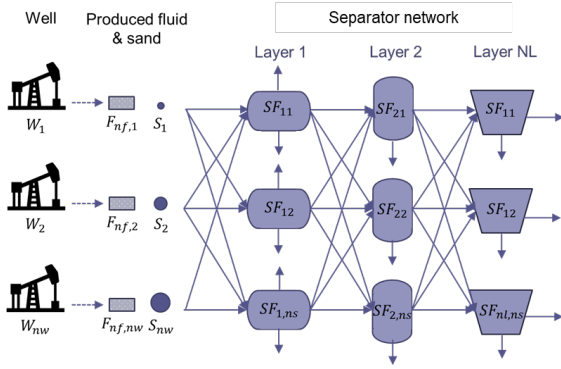

objectives: (i) to maximize the overall sand separation, (ii) to minimize sand accumulation in each separator, and (iii) to minimize the total purchased equipment cost. The model is formulated as a multi-objective mixed-integer nonlinear programming model (MINLP) and solved using epsilon-constraint method.

## PROBLEM STATEMENT

The main goal is to develop an optimization-based framework that assists the design of the separator network by (i) selecting separators from each layer of the separator network for the separation of produced fluid and sand, (ii) determining the design specifications of the selected separators, and (iii) estimating sand settling rate in the separators. The objective is to maximize sand separation from the produced fluid while minimizing sand accumulation in each separator and the total equipment cost of the separators.

The superstructure in Figure 1 illustrates the

separator network. Production fluids ( $F_{nf,nw}$ ) and sand ( $S_{nw}$ ) from wells ( $W_{nw}$ ) enter the network. The sets  $nf \in NF$  and  $nw \in NW$  represent the fluid phases and wells. The layers correspond to different stages of separation, and each layer consists of separators ( $SF_{nl,ns}$ ). The sets  $nl \in NL$  and  $ns \in NS$  represent the layers and separators in each layer. The well fluids are separated into their constituents in each layer.

**Figure 1.** The superstructure of the separator network.

## MULTI-OBJECTIVE OPTIMIZATION MODEL FORMULATION

The three objectives of the separator network design optimization model are: i) to maximize the overall sand separation, ii) to minimize the sand accumulation in each separator, and iii) to minimize the total purchased equipment cost of the separators in the network. The overall sand separation is represented as a fraction of sand produced by the wells that are separated from the produced fluid in the separators ( $FS$ ) (Eq. 1). It is computed using the total sand production rate from the wells and the total sand settling rate in the separators in each layer of the network. The sand accumulation in each separator in the network is minimized by minimizing the summation of the sand accumulation rate in each separator ( $AC$ ). The sand accumulation rate is determined as the rate at which the sand bed height increases in the vessel (Eq. 2). The total purchased equipment cost of the separators network ( $TC$ ) is computed from the equipment cost of each separator in the network (Eq. 3).

$$\begin{aligned} \text{Max } FS &= (\sum_{nl1 \in NL1} ms1'_{nl1} + ms2'_{nl2} \\ &+ \dots + \sum_{nln \in NLN} msn'_{nln}) / \sum_{nw \in NW} Mw_{nw} \quad (1) \end{aligned}$$

$$\text{Min } AC = \sum_{nl1 \in NL1} ac1_{nl1} + \dots + \sum_{nln \in NLN} acn_{nln} \quad (2)$$

$$\text{Min } TC = \sum_{nl1 \in NL1} ce1_{nl1} + \dots + \sum_{nln \in NLN} cen_{nln} \quad (3)$$

The sets  $nw \in NW$  and  $nl1 \in NL1$ ,  $nl2 \in NL2$ , ...,  $nln \in NLN$  represent the oil and gas wells and separators in the different layers of the network, respectively. The parameter  $Mw_{nw}$  represents the sand production rate from each well  $nw$ . The variables  $ms1'_{nl1}$ ,  $ms2'_{nl2}$ , and  $msn'_{nln}$

represent the sand settling rate in each separator in each network layer. The variable  $FS$  represents the fraction of produced sand separated (i.e., settled) in the separators network. The variables  $ac1_{nl1}$  and  $acn_{nln}$  represent the sand accumulation rate in each separator in each network layer and the summation of the accumulation rates is represented by the variable  $AC$ . The variables  $ce1_{nl1}$  and  $cen_{nln}$  represent the purchased equipment cost of the separators in different network layers, and  $TC$  represents the total equipment cost of all the separators in the network.

## Binary Variables

A set of binary variables,  $y1_{nl1}, \dots, yn_{nln}$ , is defined in Eqs. (4) and (5) to represent the selection of separators in each network layer ( $nl1 \in NL1, \dots, nln \in NLN$ ). Another binary variable,  $l1_{nw,nl1}$ , is defined in Eq. (6) to represent the interaction between the wells and the first-layer separators ( $nl1 \in NL1$ ). Similarly, another set of binary variables,  $l2_{nf,nl1,nl2}, \dots, ln_{nf,nln-1,nln}$ , is defined in Eqs. (7) and (8) to represent the interaction between the first- and second-layer separators and the separators in the subsequent  $NLN - 1$  and  $NLN$  layers. If fluid phase separation occurs in the first-layer separators, the individual or mixed phases (the phases that are still not separated) enter the second network along with sand. Thus, the interaction variables  $l2_{nf,nl1,nl2}, \dots, ln_{nf,nln-1,nln}$  are written in terms of the set of fluid phases  $nf \in NF$ . All fluid phases from the  $NLN$  layer separators exit the separator network.

$$y1_{nl1} = \begin{cases} 1, & \text{if separator } nl1 \text{ in } NL1 \text{ layer is selected} \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

$$yn_{nln} = \begin{cases} 1, & \text{if sep. } nln \text{ in } NLN \text{ layer is selected} \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

$$l1_{nw,nl1} = \begin{cases} 1, & \text{if fluid from well } nw \text{ enters} \\ & \text{sep. } nl1 \text{ in } NL1 \text{ layer} \\ 0, & \text{otherwise} \end{cases} \quad (6)$$

$$l2_{nf,nl1,nl2} = \begin{cases} 1, & \text{if phase } nf \text{ from sep. } nl1 \text{ in } NL1 \\ & \text{layer enters sep. } nl2 \text{ in } NL2 \text{ layer} \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

$$ln_{nf,nln-1,nln} = \begin{cases} 1, & \text{if phase } nf \text{ from sep. } nln - 1 \\ & \text{in } NLN - 1 \text{ enters} \\ & \text{sep. } nln \text{ in } NLN \text{ layer} \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

$$\forall nf \in NF, nw \in NW, nl1 \in NL1, \dots, nln \in NLN$$

## Parameters

The parameters are defined for the produced fluid, produced sand, separators design, and separators cost models. (i) Produced fluid: The volumetric flow rate of each fluid phase  $nf$  ( $Q_{nf,nw}$ ) produced from each well  $nw$  are given. Similarly, the physical properties of each fluid phase ( $\varepsilon_{nf,nw}$ ), such as density and viscosity, are given for each well  $nw$ . (ii) Produced sand: The sand density

( $\rho_s$ ), sphericity ( $\psi$ ), and the sand production rate ( $M_{w_{nw}}$ ) and mean particle diameter of sand produced ( $d_{nw}$ ) from each well  $nw$  are given. The fraction of produced sand dispersed in each fluid phase ( $Fd_{nf,nw}$ ) is given for each well  $nw$ . (iii) Separators design: Lower and upper limits are given for each design specification of the separators in the network,  $Dl$  and  $Du$ , respectively. (iv) Separators cost models: The cost model parameters,  $\alpha_{1nl1}, \alpha_{2nl2}, \dots, \alpha_{nln}$  specific to separators in each network layer are given.

## Constraints

If the separator  $nl1$  is selected in the first layer of the network, the binary variable  $y_{1nl1}$  takes a value of one, and if the separator has input from the well  $nw$ , the binary  $l_{1nw,nl1}$  takes a value of one. The fraction of the total produced fluid and sand from well  $nw$  that enters the separator  $nl1$  is represented by the variable  $fr_{1nw,nl1}$ . Thus, it can take a value of zero to one. If the separator  $nl1$  does not have input from the well  $nw$ , the variables  $l_{1nw,nl1}$  and  $fr_{1nw,nl1}$  take a value of zero. This disjunction is given in Eq. (9). Similarly, the interaction between separators in the subsequent layers  $NLN - 1$  and  $NLN$  are represented by the binary variable  $ln_{nf,nln-1,nln}$  and the fraction of each fluid phase  $nf$  entering the separator in  $NLN$  layer from  $NLN - 1$  layer is represented by the variable  $fr_{nf,nln-1,nln}$  (Eq. 10).

$$\left[ \begin{array}{l} l_{1nw,nl1} = 1 \\ 0 \leq fr_{1nw,nl1} \leq 1 \end{array} \right] \vee \left[ \begin{array}{l} l_{1nw,nl1} = 0 \\ fr_{1nw,nl1} = 0 \end{array} \right] \quad (9)$$

$\forall nw \in NW, nl1 \in NL1$

$$\left[ \begin{array}{l} ln_{nf,nln-1,nln} = 1 \\ 0 \leq fr_{nf,nln-1,nln} \leq 1 \end{array} \right] \vee \left[ \begin{array}{l} ln_{nf,nln-1,nln} = 0 \\ fr_{nf,nln-1,nln} = 0 \end{array} \right] \quad (10)$$

$\forall nf \in NF, nln - 1 \in NLN - 1, nln \in NLN$

The design specifications, fluid flow rate and properties, and sand properties in the separator  $nln$  selected in  $NLN$  network layer are given in Eq. (11). The design specifications of the separator ( $Dn_{nln}$ ) should be within the specified lower and upper bounds ( $Dl$  and  $Du$ ). The total volumetric rate of each fluid phase ( $qn_{nf,nln}$ ) entering the separator is computed from the fraction of each fluid phase entering the separator  $nln$  from each separator  $nln - 1$  in the previous layer  $NLN - 1$  ( $fr_{nf,nln-1,nln}$ ) and the volumetric rate of each fluid phase in the previous layer separators ( $qn_{nf,nln-1}$ ). Similarly, the rate at which sand of size  $nw$  dispersed in phase  $nf$  enters the separator  $nln$  ( $men_{nf,nw,nln}$ ) is computed using the amount of sand carried by the fluid phase from the previous layer separators ( $mcn_{nw,nf,nln-1}$ ) and the fraction of that fluid phase entering the separator  $nln$ ,  $fr_{nf,nln-1,nln}$ .

In the previous description, the set  $nw \in NW$  is used to denote the different particle sizes from different wells in the network. The physical properties of each fluid phase are estimated ( $\epsilon n'_{nf,nln}$ ) based on the properties of fluid from each previous layer separator ( $\epsilon n_{nf,nln-1}$ ). The design specifications, fluid flow rate and properties, and sand amount variables take a value of zero if the separator is not selected in the network, i.e., when  $y_{nln} = 0$ . The design specifications ( $Dn_{nln}$ ) depend on the total volumetric flow rate of each fluid phase in the separator ( $qn_{nf,nln}$ ) and other separator type-specific factors ( $\sigma n_{nln}$ ) (Eq. 12).

$$\left[ \begin{array}{l} y_{nln} = 1 \\ Dl \leq Dn_{nln} \leq Du \\ qn_{nf,nln} = \sum_{nln-1} fr_{nf,nln-1,nln} qn_{nf,nln-1} \\ men_{nf,nw,nln} = fr_{nf,nln-1,nln} mcn_{nw,nf,nln-1} \\ \epsilon n'_{nf,nln} = f(fr_{nf,nln-1,nln}, \epsilon n_{nf,nln-1}) \end{array} \right] \vee \left[ \begin{array}{l} y_{nln} = 0 \\ Dn_{nln} = 0 \\ qn_{nf,nln} = 0 \\ men_{nf,nw,nln} = 0 \\ \epsilon n'_{nf,nln} = 0 \end{array} \right] \quad (11)$$

$$Dn_{nln} = f(qn_{nf,nln}, \sigma n_{nln}) \quad (12)$$

$$\forall nf \in NF, nw \in NW, nln - 1 \in NLN - 1, nln \in NLN$$

Sand particles of different sizes ( $d_{nw}$ ) from different wells are settling in the separator  $nln$ . The fraction of sand particles of each size initially dispersed in phase  $nf$  that settle to the vessel bottom ( $Fsn_{nw,nf,nln}$ ) depends on the properties of the fluid ( $\epsilon n'_{nf,nln}$ ) it is dispersed in, separator design specifications ( $Dn_{nln}$ ), and particle diameter ( $d_{nw}$ ) (Eq. 13). Similarly, the fraction of each sand size carried by each phase from the separator  $nln$  ( $Fcn_{nw,nf,nln}$ ) is estimated. Some amount of sand initially dispersed in the fluid phase  $nf = 1$  can move to the phase  $nf = 2$ , and vice versa. This amount is accounted for by adding the variables  $\delta sn_{nw,nf,nl1}$  and  $\delta cn_{nw,nf,nl1}$  to the fraction settled and fraction carried, respectively. This variable can take a value in the range  $[-1, 1]$  based on the sand dispersion and settling model selected for the separator. The rate of sand settling at the bottom ( $msn_{nw,nf,nln}$ ) and sand being carried ( $mcn_{nw,nf,nln}$ ) for different sand sizes are computed from the amount of each sand size entering the separator ( $men_{nf,nw,nln}$ ). If the separator  $nln$  is not selected in the network, all these variables take a value of zero.

$$\left[ \begin{array}{l} y_{nln} = 1 \\ Fsn_{nw,nf,nln} = f(\epsilon n'_{nf,nln}, Dn_{nln}, d_{nw}) + \delta sn_{nw,nf,nln} \\ Fcn_{nw,nf,nln} = f(\epsilon n'_{nf,nln}, Dn_{nln}, d_{nw}) + \delta cn_{nw,nf,nln} \\ msn_{nw,nf,nln} = men_{nf,nw,nln} Fsn_{nw,nf,nln} \\ mcn_{nw,nf,nln} = men_{nf,nw,nln} Fcn_{nw,nf,nln} \end{array} \right]$$

$$\forall \begin{cases} \mathbf{yn}_{nl_n} = \mathbf{0} \\ FSN_{nw,nf,nl_n} = 0 \\ FCN_{nw,nf,nl_n} = 0 \\ msn_{nw,nf,nl_n} = 0 \\ mcn_{nw,nf,nl_n} = 0 \end{cases} \quad (13)$$

$$\forall nf \in NF, nw \in NW, nl_n \in NLN$$

The fluid and sand produced from each well should be treated in the separator network. Thus, the total fraction of fluid entering from each well into different separators in the first network layer ( $fr1_{nw,nl_1}$ ) is equal to one (Eq. 14). The fluid phases exiting separators in each network layer either enter the separators in the subsequent layer or exit the network based on the interaction variable  $frn_{nf,nl_n-1,nl_n}$  given in the Eq. (10).

$$\sum_{nl_1} fr1_{nw,nl_1} = 1 \quad \forall nw \in NW \quad (14)$$

The total amount of sand settled in each separator  $nl_n$  ( $msn'_{nl_n}$ ) is computed as the total amount of each sand size dispersed in each phase that has settled to the separator bottom ( $msn_{nw,nf,nl_n}$ ) (Eq. 15). The sand accumulation rate (i.e., rate of increase of sand bed height) in each separator is computed based on the amount of sand particles of each size settled in the separator and the void space between the settled particles. The void space is accounted for using void fraction, which depends on the mean particle size, particle size distribution, and the sphericity of the particles ( $\psi$ ) [7]. The mean particle size and particle size distribution are estimated based on the amount of different particle sizes settled in the separator. Thus, the void fraction of the sand particles settled in the separator ( $\phi_{nl_n}$ ) depends on the particle sizes present ( $d_{nw}$ ) and the amount of each particle size settled in the separators ( $msn_{nw,nf,nl_n}$ ) (Eq. 16). The sand accumulation rate in the separator ( $acn_{nl_n}$ ) is computed using the void fraction ( $\phi_{nl_n}$ ), the total amount of sand settled in the separator ( $msn'_{nl_n}$ ), sand density ( $\rho_s$ ), and cross-sectional area of the separator ( $CSn_{nl_n}$ ) (Eq. 17).

$$msn'_{nl_n} = \sum_{nw,nf} msn_{nw,nf,nl_n} \quad \forall nl_n \in NLN \quad (15)$$

$$\phi_{nl_n} = f(d_{nw}, msn_{nw,nf,nl_n}) \quad (16)$$

$$acn_{nl_n} = msn'_{nl_n} / (CSn_{nl_n} \rho_s (1 - \phi_{nl_n})) \quad (17)$$

$$\forall nf \in NF, nw \in NW, nl_n \in NLN$$

The purchased equipment cost of each separator depends on its design specifications. The cost of the separator  $nl_n$  ( $cen_{nl_n}$ ) is estimated based on its design specifications ( $Dn_{nl_n}$ ) using the separator-specific cost model ( $\alpha n_{nl_n}$ ) (Eq. 18).

$$cen_{nl_n} = f(Dn_{nl_n}, \alpha n_{nl_n}) \quad \forall nl_n \in NLN \quad (18)$$

## CASE STUDY

The equations (1) to (18) yield a deterministic multi-

objective mixed-integer nonlinear programming model (MINLP) that maximizes sand separation, minimizes sand accumulation, and minimizes the total purchased equipment cost of the separator network. The disjunctive constraints in the model are reformulated using Big-M Reformulation [4]. In the developed multi-objective model, a set of decision variables improving one objective's value could negatively affect another objective and vice versa. Thus, a single optimal solution is not possible; rather, a set of optimal solutions is obtained, which forms the Pareto front [5]. This work uses the epsilon-constraint method [6] to obtain the Pareto front for the developed model. The model is solved by selecting one of the objective functions as the only objective and the remaining objective functions as constraints. Then, the constraint bounds are systematically varied to obtain the Pareto front.

The capabilities of the developed model to optimize a separator network design for sand management are demonstrated with a test problem. The well production and the separation of the produced fluid and sand in the separator network are shown in Figure 2. Two wells producing oil, gas, water, and sand are considered. The amount of fluid produced, the fluid's physical properties, and the sand's size differ for the two wells. It is assumed that the production from the two wells is completely mixed before it enters the separator network. The produced fluid now contains two different sizes of sand particles, which are assumed to be evenly dispersed in the liquid phases (oil and water). The produced fluid and sand particles enter the separator network containing two layers of separators, and each layer contains two separators. The separators in the first layer separate the produced fluid into its constituents: oil, water, and gas. A fraction of the sand particles is separated from the produced fluid by settling to the bottom of the separators. The remaining sand particles are carried by oil and water. These liquid phases carrying sand enter the separators in the second layer, where more sand particles are separated from the liquid. It is assumed that liquid phases separated in the first-layer separators cannot enter the same second-layer separator, i.e., the second-layer separators can handle sand/oil or sand/water only. Thus, a two-phase vertical gravity separator is used for separation in the second layer.

The design specifications of the four-phase gravity separator are given in Eqs. (19-21). The vessel diameter ( $D_s$ ) is selected based on the volumetric flow rate of liquid (oil and water) separated in the vessel ( $Q_o$  and  $Q_w$ ) and the mean residence time of the liquid phases in the vessel ( $\tau$ ). The separator height ( $H_s$ ) is selected based on the ratio of the height to the diameter for the separator ( $r$ ). The vessel's capacity should be large enough that the liquid level is within the maximum allowable level ( $H_{s,lmax}$ ) (Eq. 19). A minimum vessel diameter ( $D_{min}$ ) is required to

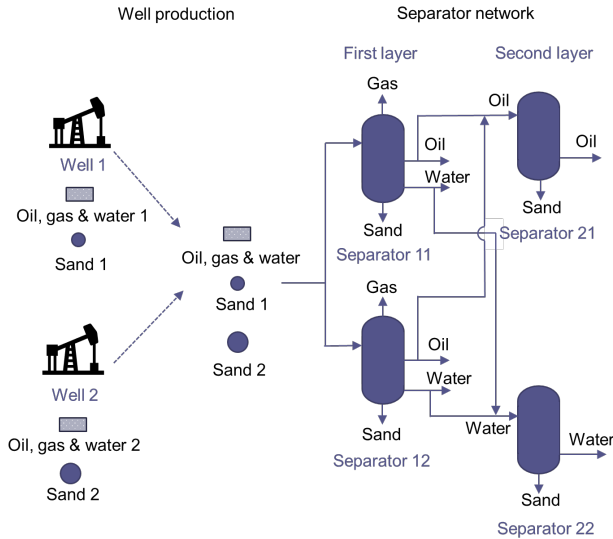

slow the gas to a velocity at which the liquid droplets settle and separate from the gas phase [8]. This minimum diameter depends on the volumetric flow rate of the gas ( $Q_g$ ) and the settling velocity of liquid droplets in the gas phase in the separator ( $v_l$ ) (Eq. 20). Thus, the vessel diameter should be greater than the minimum diameter (Eq. 21). The two-phase gravity separator has only sand/oil or sand/water phases, and it is also designed using Eqs. (19-21).

$$(Q_o + Q_w)\tau/(\pi/4D_s^2H_s) = H_{max}/H_s \quad (19)$$

$$D_{min} = [4Q_g/(\pi v_l)]^{0.5} \quad (20)$$

$$D_s \geq D_{min} \quad (21)$$

Sand settles at the bottom of the gravity separator when its settling time is less than the residence time of the fluid it is dispersed. The residence time of the fluid is expressed using Residence Time Distribution (RTD) models [9]. In our previous work [10], an RTD-based model was developed to compute the fraction of sand settled in a vertical gravity separator. This model is used to estimate the extent of sand separation in each separator in the network.

**Figure 2.** Well production (oil, gas, water, and sand) from two wells enters a separator network with two layers. The separators in the first layer separate the produced fluids. Sand is separated from the produced fluids in both layers.

The model assumptions for the sand settling behavior in a four-phase gravity separator are: (i) As oil and water separate inside the vessel, the sand particles initially dispersed in the oil move to the oil column, while the particles dispersed in the water move to the water column. (ii) Sand particles in the oil column gradually settle with a constant terminal settling velocity, during which a

fraction of the sand particles get carried away by the flowing oil. Similarly, in the water column, the sand particles settle down at a constant velocity specific to the water phase, and the water carries a fraction of these particles. (iii) The remaining sand particles in the water column eventually settle down at the bottom of the separator. The remaining particles in the oil column enter the water phase and settle at a constant velocity. The water carries away some particles, and the rest settle at the separator's bottom.

The terminal sand settling velocity in the oil and water phases is estimated using Stokes' law [11]. The settling time of a sand particle in a liquid column is estimated as the time required to settle through the entire liquid column height at terminal velocity. The distribution of residence time ( $E(t)$ ) is expressed by the RTD model for a single CSTR [9] (Eq. 22). The mean residence time is represented as  $\tau$ .

$$E(t) = \frac{e^{-t/\tau}}{\tau} \quad (22)$$

The fraction of sand particles initially dispersed in the oil phase is  $Fd_o$ , and the rest in the water phase ( $Fd_w$ ). The fraction of sand dispersed in oil fraction with residence time less than sand settling time in oil ( $ts_o$ ) is carried away by oil ( $F_{o,co}$ ), and it is estimated by Eq. (23). The remaining fraction of sand in oil ( $F_{o,ew}$ ) settles through the oil column and enters the water phase (Eq. 24). Thus, two sets of sand particles are dispersed in water, particles initially dispersed in water ( $Fd_w$ ) and particles that entered the water from oil ( $F_{o,ew}$ ). Sand dispersed in the water fraction with residence time less than sand settling time ( $ts_w$ ) is carried away by water. Thus, a fraction of sand initially dispersed in water, and another fraction that entered the water from oil gets carried by water,  $F_{w,cw}$  and  $F_{o,cw}$ , respectively (Eqs. 25 and 26). The remaining fraction of sand in the water settles to the separator bottom ( $F_s$ ) (Eq. 27).

$$F_{o,co} = Fd_o \int_0^{ts_o} E(t_o) dt_o \quad (23)$$

$$F_{o,ew} = Fd_o - F_{o,co} \quad (24)$$

$$F_{w,cw} = Fd_w \int_0^{ts_w} E(t_w) dt_w \quad (25)$$

$$F_{o,cw} = F_{o,ew} \int_0^{ts_w} E(t_w) dt_w \quad (26)$$

$$F_s = (Fd_w - F_{w,cw}) + (F_{o,ew} - F_{o,cw}) \quad (27)$$

The void fraction of the sand particles settled at the separator bottom is estimated using a semi-empirical relation [7] developed for a loosely packed bed.

The purchased equipment cost of the separators ( $C_e$ ) is approximated using the cost model for vertical pressure vessel [8] (Eq. 28). The equipment cost depends on the shell mass of the separator ( $SM$ ), which is a function of the separator diameter, height, and shell

thickness. The equipment cost is in the United States Gulf Coast basis, January 2006 (Chemical Engineering (CE) index = 478.6 and Nelson-Farrar Cost Index (NFCI) = 1961.6). The cost is converted to 2023.

$$C_e = -10000 + 600 SM^{0.6} \quad (28)$$

## RESULTS AND DISCUSSIONS

In the test problem, the total fluid production rate from the two wells is 50 m<sup>3</sup>/h of oil, 50 m<sup>3</sup>/h of water, and 900 m<sup>3</sup>/h of gas. Sand is produced along with wellbore fluid at a rate of 26.5 kg/h. The sand concentration in the liquid is 0.01 vol%. The particles are spherical and have diameters of 150 microns and 50 microns. The sand density is 2650 kg/m<sup>3</sup>. The produced oil, water, and gas densities are 700 kg/m<sup>3</sup>, 990 kg/m<sup>3</sup>, and 23.6 kg/m<sup>3</sup>, respectively. The viscosities of the oil and water are 0.77 x 10<sup>-3</sup> kg/m/s and 0.55 x 10<sup>-3</sup> kg/m/s. The lower and upper bounds for the separator diameter ( $D_s$ ) are 1 m and 3.5 m, respectively, and for the mean residence time of production fluids in the separator ( $\tau$ ), they are 10 mins and 20 mins. The height-to-diameter ratio ( $r$ ) for the separator is 3. The maximum liquid level in the separator ( $H_{s,max}$ ) is 50% of the separator height. The shell thickness is assumed to be 5 mm.

The optimization models are formulated in Python V3.8.6 using PYOMO V6.4.1. The MINLP models are solved using BARON V23.11.13 to 5% optimality gap, all on an Intel Xeon Gold 6248R 3 GHz processor with 48 cores and utilizing a maximum of 100 GB RAM.

Firstly, the separator network optimization model is solved for the three objectives ((i) maximizing sand separation, (ii) minimizing equipment cost, and (iii) minimizing accumulation rate) separately to obtain the bounds for the Pareto front. The results for separator design specifications, separation extent, accumulation rate, and solution time for solving for each objective are given in Table 1. (i) For the given production conditions, a maximum of 84% of the produced sand can be separated from the production fluid with the separator network under study. One large separator (D=2.98 m) and another small separator (D=1.18 m) are selected for the first-layer separation, and the residence time of production fluids is 20 mins in both separators. For second-layer separation, two more equally sized separators are selected to separate sand from the oil and water phases further, with a residence time of 20 mins in the separator. (ii) To minimize the total cost of the network (\$43,000), a single separator (D=2.4 m) with a residence time of 10 mins is selected to separate the production fluids to their constituents. (iii) A single large separator (D=3.04 m) is selected to ensure that the bed height increase rate is minimal (0.93 m/week). Only 56% of the sand is separated with this network design. The highest sand separation (84%) is achieved with a total network cost of \$107,000

and a weekly total sand accumulation rate of 1.77 m in the separators in the network. The solution time is the highest while solving for the equipment minimization objective (6958 CPU s).

**Table 1:** Sand separation extent, accumulation rate, network cost, network design specifications, and solution times for three cases: (i) maximum sand separation, (ii) minimum equipment cost, and (iii) minimum total accumulation rate.

Design spec. / Solution time	Results
<b>(i) Maximum sand separation</b>	
Fraction of sand settled*	0.84
Total cost (thousand \$)	107
Total accumulation rate	1.77
Layer 1

Layer 2	
	Not selected

\* denotes the model objective for each case  
O and W denote the two-phase separators  
for oil/sand and water/sand separation

A Pareto front plot has been developed by plotting

the total equipment cost and total accumulation rate in the network against the fraction of total sand settled in Figure 3. For low sand separation extent, a single separator is selected in the network. A larger separator is used to decrease the accumulation rate, while a smaller residence time is used to decrease the equipment cost. To achieve higher sand separation, a second separator is added in the second layer to separate the sand from the oil phase further while minimizing accumulation. Cost is reduced for a higher separation extent by using two smaller separators in the first layer and a second-layer separator for the water phase, in which the sand settling rate is higher than that in oil. But this arrangement significantly increases the sand accumulation rate, as seen for 71% separation extent. Maximum sand separation is achieved by using all the separators in the network. A high residence time and smaller diameter are preferred for these separators.

**Figure 3.** Pareto front for separator network design.

## CONCLUSION AND FUTURE WORK

A multi-objective separator network optimization model was developed to maximize the sand separation while minimizing the total equipment cost and total sand accumulation rate in the separators. The developed model was used to obtain a Pareto front for a separator network with two separation stages containing two separators each. The Pareto front can be used for the selection and design of the separators to achieve a desired sand separation extent with the separator network, without high accumulation in the separators and at less equipment cost.

This work will be extended to use the developed model for solving larger separator networks with more design and decision flexibility, such as optimizing the height-by-diameter ratio and determining the conditions under which the production fluids from two wells should/should not be separated in the same separator. Reformulation approaches will be investigated for reducing the solution time of the developed MINLP model.

## ABSTRACT

Most studies in process systems engineering are applying incomplete methods when incorporating sustainability. Including sustainability is a laudable goal, and practitioners are encouraged to develop systems that promote economic, environmental, and social aspects. Ten methods that are often overlooked in performing sustainable process systems engineering are listed in this effort and discussed in detail. Practitioners are encouraged to create designs that are inherently safer, to be more complete in their identification of process chemicals used and released, to be complete in their definitions of supply chains, and to apply additional environmental impact categories. Other methods point to items that are factors in process systems engineering such as disruptive recycling, robust superstructures for optimizations, and employing complete sets of objectives. Finally, users should be aware that sustainability tools are available, which might have been outside of their awareness.

---

**Keywords:** Optimization, Process Design, Supply Chain, Life Cycle Analysis, Environment, Sustainability

## INTRODUCTION AND BACKGROUND

Practitioners of process systems engineering stand at the cusp of chemical process design / analysis and life cycle assessment. For those interested in sustainability the methods available to users are growing in popularity but perhaps remain still largely unknown.

In an effort to promote sustainability, studies that developed into the modern methods of life cycle assessment (LCA) were first reported in the 1960s [1]. These studies considered cumulative energy use and comparisons of different beverage containers to quantify the use of natural resources and releases to the environment. Today, rules are being set to formally compare products within categories [2], and LCA studies can model regions [3] and the whole economy [4].

Unlike the above evaluations of supply chain (i.e., cradle-to-grave) sustainability, efforts to optimize chemical processes have smaller single-system domains. The potential addition of new chemicals or technologies into a process makes them open ended, and demonstrated methods for the conceptual design of processes are available [5]. A subset of the open-ended problems can

be optimized, and this is where various process system engineering methods realize their power.

These fields cross pollinate as described in a review of design methods for the environment by Cano-Ruiz and McRae [6]. Alternative generation for designs is combined with optimization methods. One can consider the sustainability of processes within a system by continually expanding the system boundaries to the enterprise, life cycle, economy, and ecosystem [7]. Most studies which make an attempt towards sustainability are incomplete, and so a listing of commonly overlooked methods is offered here.

## TEN UNDERVALUED METHODS OF SUSTAINABLE PROCESS SYSTEMS ENGINEERING

Awareness of methods to improve sustainable process and system design are available as listed in Table 1. Following the table, a series of descriptions will be provided to describe each item in more detail.

**Table 1:** Ten methods for sustainable process systems engineering that are undervalued.

Number	Name
1	Use Inherently Safer Designs
2	Incorporate Inputs / Outputs of Complete Supply Chains
3	Account for All Chemicals and Releases
4	Define Final Fate / Destination for Every Chemical
5	Include All Emissions, Discharges, and Solid Wastes
6	Apply Additional Impact Categories
7	Recognize the Disruptive Nature of Recycling to Design / Optimization
8	Create a Robust Superstructure of Alternatives
9	Use Complete Sets of Objectives
10	Realize Sustainability Tools are Available

### Use Inherently Safer Designs

Inherently safer designs avoid circumstances that could cause accidents as well as chemicals that are unnecessarily toxic. This is one of the original principles of green chemistry, which are listed along with engineering principles in one reference [8]. While not repeated here, the intent is to include all of these principles in this listing of methods for process systems engineers to consider. Only designs that advance these principles will be aligned with sustainability.

### Incorporate Inputs / Outputs of Complete Supply Chains

Designing chemical processes is an open-ended problem with the potential to introduce various chemicals to be part of a product formulation, reacted, or to ease processing. Each chemical introduced requires its own supply chain of processes to manufacture and transport the used chemical. This complete inventory of reactants, solvents, catalysts, processing aids, and cleaning agents is not simple to assemble [9], but the reaction products may be a much longer and less well-known list. Each of these byproducts should be considered for where it ends up and the output system of processes required to handle non-products. Some of these non-product processes may involve flaring, wastewater treatment, hazardous waste treatment, or recycling, each with its own supply chain and releases to the environment. Many of these processes are never seen in studies that show process system diagrams. Therefore, in many cases of process design and analysis, it can generally be concluded that little attention is paid to the fact that every input / output to / from a system requires an upstream / downstream supply chain.

### Account for All Chemicals and Releases

The reactions most process systems engineering studies and life cycle inventory databases consider are overly simplified. As an example, acetic acid production can be modeled according to the stoichiometry of carbon monoxide and methanol reacting to form acetic acid. The actual components found in a real process are often much higher [10]. Beyond the process inputs, chemicals might be introduced to a process for a number of reasons: absorption, boiler feedwater circulation, catalysis, cleaning, cooling tower circulation, input water treatment, wastewater treatment, etc. Some examples of these are presented in the context of early-stage process development [11]. All of these inputs might be released to the environment. In addition, boilers, cooling towers, and fugitive emissions can dramatically increase the number of chemicals released to the environment.

### Define Final Fate / Destination for Every Chemical

When considered holistically, one can envision that every chemical must eventually be reacted, recycled, released, or treated. Certainly, some chemicals go into products, but holistically they will have to realize one of these fates. The challenge for the practitioner of process systems engineering is to logically identify the chemicals present and then track their fates. First, one can apply a version of the methodology described by Douglas [12] where each reactor effluent component is given a destination code. Products and by-products exit as product streams, but impurities of these products will likely be in other streams. In addition, consider that there will be other impurities in the product streams. Unused inputs will mostly be recycled, where possible, but input impurities and unrecycled quantities will exit in various streams. Some streams may have a high enough energy content to legitimately be used as fuel. The other streams will exit as process wastes, where their phase will dictate their form and whether they are vented, process liquid wastes, or solid wastes. Where captured, each of these can be treated with absorption, flaring, land disposal, thermal oxidation, wastewater treatment, etc., and each of these processes has its own resource use and releases to the environment [13]. In addition to exiting in the paths described above, the uncaptured chemicals (some of which will be valuable products, reactants, etc.) may be released or exit as fugitive emissions.

### Include All Emissions, Discharges, and Solid Wastes

In designing and analyzing processes, the releases to the environment include air emissions, liquid discharges, and solid waste. Air emissions are the best represented and analyzed of the releases. The most common of the reported air emissions are greenhouse gases

(GHGs), which are easily determined through calculations of energy type and amount used.

One can speculate that the search for data that is relevant to environmental impact categories suffers from the “streetlight effect”. This effect is told as a story of someone looking for their keys under a streetlight, and a passerby who stopped to help look for them finally asks where the keys were dropped. The answer is two blocks away, but the light is better here, with the analogy for emission data being the easy-to-see GHG data. Other forms of bias, like availability, can play a role as well, as that bias selects easily recalled items as being important. In general, analyses would benefit from not prescribing what important emissions, discharges, and solid waste flows are in advance of evaluations.

To improve process models that have been ignoring storage, transfer, vent, and fugitive emissions as well as liquid discharges and solid wastes, a number of methods are reviewed in the literature [10]. In addition, specific methods for estimating emissions for unit operations such as boilers, loaders / forklifts, and cooling towers are available [11].

### Apply Additional Impact Categories

The number of human health and environmental impact categories included in most studies are very limited. Global warming potential is often incorporated, but many other categories are dismissed through omission. I.e., no one has made a conscious decision to give a zero weighting to other categories; they have simply been omitted. Even in examples where more categories are used, the number is still relatively small [14]. A more extensive taxonomy of environmental impacts is available consisting of many tables of detailed midpoint effects (e.g., global warming potential (GWP) is a midpoint effect determined from emissions), endpoint effects (e.g., skin cancer, reduced lung function), and damage groupings (e.g., disability adjusted life years) [15]. Seldom, if ever, will a study use all of the available impact categories, but a review of those that are available can inform a more complete analysis, i.e., one in which more categories are included, or the text better describes the intent and caveats of the system analysis.

### Recognize the Disruptive Nature of Recycling to Design / Optimization

In chemical engineering process design, an early lesson is the effect a recycle loop can have on a design. Whereas in a straight-line process, or single-pass process, the highest yield is the best use of raw materials, when a recycle loop is added the optimum conversion can move towards the highest selectivity for use of raw materials. Recycle loops can return raw materials to the reactor system to react them more efficiently at higher selectivity. The optimum is often balanced by larger

equipment and recycle streams that can increase energy use and costs.

The advantages of recycling along a supply chain are somewhat different. For post-consumer use materials, a meta-analysis using 366 datasets for 14 materials was performed, and the mean GWPs for secondary production were better than the mean GWPs for primary production (i.e., with virgin materials) [16]. However, experience has shown that the quality of recycled materials is not equivalent to virgin for many reasons (e.g., for PET plastic bales other materials are present, and for PET items other materials are part of their composition) [17]. Thus, the secondary production process is different from the primary one. This represents a radical divergence from internal recycle loops in chemical processes, where higher selectivity accomplished with more recycling leads to less impurities.

For both process systems and supply chain systems, recycling must be evaluated. A combined analysis was done for producing waste-recycled feeds using styrene “tar” from the bottoms of a styrene-refining column [18]. There is no generalization to make regarding the desirability of recycling such streams, as the system depends both on the technology and the materials recycled and produced. A practitioner of process systems engineering would do well to design and analyze each system.

### Create a Robust Superstructure of Alternatives

In process systems engineering a common problem studied is the superstructure-based reactor synthesis. An early paper on the subject used a recycle reactor with heat exchange as the basis [19]. More recently, superstructure methods were applied to complex sets of reactions modeled with uncertain inputs and limiting reagents [20]. The process synthesis problem is aimed at achieving a conceptual design that identifies the operations to do. A similar larger-scale problem is challenging at the process level when new chemicals can be introduced into a process [5]. In each case the idea is to have a robust superstructure of equipment and interconnections that is flexible enough to capture designs when applying optimization. Further, at a larger supply chain scale the analysis of designs is challenging when new chemicals are introduced, as up- and down-stream processes and their resource use and environmental releases will be affected.

### Use Complete Sets of Objectives

In the real world, decisions are not simple because there is seldom a real-world decision that only has one objective. Our models of processes and systems can diverge strongly from this generalization, as assumptions are made to only consider a single dimension. In process design, one might optimize economics, flexibility,

controllability, safety, and environmental impacts. The GREENSCOPE tool of Ruiz-Mercado et al. has approximately 140 indicators in the four E's of Environment, Economics, Energy, and mass Efficiency, thus providing many possible objectives to optimize chemical processes [21].

There are various ways of handling multiple objectives. One method is to rearrange an objective as a constraint on acceptable solutions. Solving over a range of different values for the constraint will create a series of solutions. Another method to address multiple objectives is to normalize each objective (i.e., dividing by a maximum possible value is one normalization), weighting the multiple objectives with respect to each other, and finally adding the objectives together on a single scale. A method for applying these steps using marginal rates of substitution and total utility is described by Smith and Ruiz-Mercado [22]. Others may approach the multiple objectives through the simultaneous development of many Pareto solutions, although dimensionality issues require a method for spacing solutions among the various objectives [23].

## Realize Sustainability Tools are Available

In designing or analyzing process systems it may be that people are unaware of tools that are available. Examples of tools one can use to further sustainability include GREENSCOPE [21], release estimation [11], and LCA [4] tools. In addition, solvent replacement and toxicity prediction methods are available from the U.S. EPA's Office of Research and Development (ORD). The Program for Assisting the Replacement of Industrial Solvents (PARIS) allows one to quickly find solvent replacements (either individual solvents or mixtures) that are similar in physical and chemical properties to the original. The program also provides a calculation of potential environmental impacts in eight categories, from global warming potential, ozone depletion potential, acidification potential, and smog potential, to four categories of potential toxicity [24]. Additional toxicities and many other physical properties can be estimated with the Toxicity Estimation Software Tool (TEST), also available from EPA's ORD [25].

## DISCUSSION

Practitioners of process systems engineering are encouraged to employ the above list to improve their chemical processes and associated supply chains. To summarize the above, one should first create designs that are inherently safer, including other principles of green chemistry and engineering. Sustainable research and development breakthroughs advanced through sustainable chemistry and engineering improve system performance while reducing environmental burdens and

economic and social costs. In the absence of breakthroughs, one can only optimize systems to make them more sustainable.

Practitioners should also be as complete as possible in their identification of process chemicals used and released, be more complete in their definitions of supply chain processes, resources used, and releases, and apply additional environmental impact categories as appropriate.

Users are likely already familiar with recycling, superstructure optimizations, and creating sets of objectives. This effort simply advises to employ these in a manner that positively disrupts systems, defines the widest possible variety of system structures, and includes complete sets of objectives. This setting of objectives, as choices of objectives, constraints, and boundaries of what is included and excluded, is critically important in defining the scope of studies.

Finally, users should be aware that sustainability tools are available, which might have been outside of their awareness. In the end practitioners of process systems engineering will likely still limit their studies with incomplete methods for sustainability, but perhaps the listing here can be used as a checklist to address what could be considered and help refine some future work.

## ABSTRACT

Reverse electrodialysis (RED) is a nascent renewable technology that generates clean, baseload electricity from salinity differences between two water streams, a renewable source known as salinity gradient energy (SGE). Full-scale RED progress calls for robust techno-economic and environmental assessments. Using generalized disjunctive programming (GDP) and life cycle assessment (LCA) principles, this work proposes cost-optimal and sustainable RED process designs involving different RED stack sizes and width-over-length ratios to guide the design and operation from the demonstration to full-scale phases. Results indicate that RED units will benefit from larger aspect ratios with a relative increase in net power of over 30% with 6 m<sup>2</sup> membrane size. Commercial RED unit sizes (0.25–3 m<sup>2</sup>) require larger aspect ratios to reach an equal relative increase in net power but exhibit higher power densities. The GDP model devises profitable RED process designs for all the assessed aspect ratios in a foreseeable scenario for full-scale deployment, that is, the energy recovery from desalination concentrates mixed with reclaimed wastewater effluents. A RED system with 3 m<sup>2</sup> RED units nine times wider than its length could earn a net present value of \$2M at a competitive levelized cost of electricity of \$111/MWh in the Spanish electricity market. On-site, RED-based electricity could abate roughly 7% of the greenhouse gas emissions from the desalination plant's energy supply, given the low emissions contribution of RED supply share. These findings demonstrate that optimization-based eco-technoeconomic assessments are a vital ally in making RED a full-scale reality.

## INTRODUCTION

Demonstrating and deploying clean renewable energy technologies must be a global priority in pursuing a net-zero emissions economy by mid-century [1]. Salinity gradient energy (SGE) technologies offer deep and sustained reductions in greenhouse gas (GHG) emissions to keep the 2050 goal within reach. These technologies recover the chemical energy released when high-salinity and low-salinity streams are reversibly mixed. Reverse electrodialysis (RED) is one of the most researched and advanced SGE technologies.

RED employs ion-exchange membranes (IEMs) to generate electricity from SGE directly. These IEMs allow ions of opposite charge but not water to pass through. A RED device is built by stacking a series of alternating cation (CEMs) and anion exchange membranes (AEMs) that separate salt solutions of different concentrations. Selective transport of ions through the IEMs creates an electric potential across the pairs of AEMs and CEMs that drive redox reactions at electrodes on either side of the membrane pile. The overall electric potential of the set of cell pairs and the electric current then power an external load that closes the circuit [2].

In 2014, REDstack BV hit a significant milestone when their demonstration plant was successfully put into operation on the Afsluitdijk in the Netherlands, meeting Technology Readiness Level (TRL) 7. With a total membrane area per stack of 250 m<sup>2</sup>, this plant is powered by a blend of salt water and freshwater, producing 50 kW at present [3,4]. The REAPower pilot plant in Trapani, Italy is not functioning now and is being used as a demonstration project. Using both natural saturated brine from a saltworks and brackish water from a shoreline well, a trio of RED stacks were able to generate a total power output of 330 W, with a combined membrane area of more than 400 m<sup>2</sup> [5]. The main barriers preventing RED technological readiness are the low power density of large-scale RED systems (0.38–2.7 W/m<sup>2</sup> total membrane area), fouling, and the high cost of commercial membranes (> \$100/m<sup>2</sup>) [6–8]. The development of high-performing membranes, electrode segmentation, and multi-staging are some of the approaches to enhance the power density and energy efficiency of RED.

The water sector opens new avenues to prove and advance full-scale RED. Desalination concentrates and treated wastewater effluents are abundant yet largely untapped waste streams from which RED can extract sustainable and clean electricity [9]. On-site RED electricity generation in desalination plants can also lessen the dependence on the water and energy-intensive grid mix and reduce the environmental burden and costs associated with brine treatment and disposal [10]. This, in turn, contributes to more sustainable and self-sufficient water supply systems. Besides, RED operation with desalination brines delivers higher power densities than river/seawater pairs, and the reject brine does not require further energy-intensive treatment as raw seawater.

Even so, the complex process configuration and operational decision space make it technically challenging to estimate the costs and performance of RED with conventional heuristics. In previous work, we developed a Generalized Disjunctive Programming (GDP) optimization model incorporating a RED stack predictive model to define the cost-optimal RED process design in different scenarios [11]. The solution for the GDP model provided the flowsheet design that maximizes the process net present value (NPV) for a given RED stack design.

The quantification of the RED process environmental loads is also a valuable input to devise environmentally sound design alternatives to RED technology. In this regard, we conducted a life cycle assessment (LCA) of the RED stack to define the environmental profile of RED and to estimate greenhouse gas (GHG) emissions reduction in desalination plants partly sourced with SGE [12].

Building on the LCA of the RED unit and the GDP optimization model of the RED process, this follow-up work explores how scaling up and the design of the RED units' compartments may affect the eco-technoeconomic performance of the optimal RED process flowsheets.

## METHODS

The performance metrics in the eco-techno-economic assessment (eTEA) are the net power output (NP), the net power density (NPD, i.e., net power per total membrane area), the NPV, the levelized cost of electricity (LCOE), and the global warming potential (GWP).

### Problem Statement

Given a set of identical candidate RED units  $r \in RU = \{r1, \dots, rN_r\}$ , the goal is to determine which ones are active, how they are hydraulically arranged, and their working conditions (*e.g.*, electric current, inlet flow rate, and molar concentration of the HC and LC streams) that yield the cost-optimal flowsheet design of the RED process for a given concentration, volume, and temperature of the high-salinity and low-salinity feed streams, and design parameters of the RED units.

The superstructure in Figure 1 incorporates all the alternative hydraulic topologies for the RED system with  $N_r$  conditional RED units. The superstructure and notation are fully described in previous work [11].

Table 1 summarizes the design parameters of the RED units spanning pilot to commercial scales and different compartment geometries. We set seven distinct sizes (active area in Table 1) and, for each size, nine different width-over-length ratios (aspect ratio, Table 1). Using the predictive model, we estimate the operational conditions that maximize the net power of the stand-alone RED unit for each size and aspect ratio. This sensitivity analysis provides guidelines for RED unit design and operation in all development stages.

We quantify the GWP of the RED units in Table 1 based on the previous LCA of pilot-scale RED units [12].

Later, to explore how the design of the RED stack compartments affects the techno-economic and environmental performance of the optimal RED process design, we solve the GDP model of the RED system with 3 m<sup>2</sup> size RED units varying their aspect ratio.

**Table 1:** Design parameters of the RED stack [11].

Parameter	Value
Number of cell pairs	1000
Aspect ratio, w/L	1–9
Active area	0.25, 1, 2, 3, 4, 5, 6 m <sup>2</sup>
<b>Spacers</b>	
Thickness	270 μm
Porosity	82.5%
<b>IEM: fumasep® CEM (FKS-50) / AEM (FAS-50)</b>	
Areal resistance	1.8 / 0.6 Ω/cm <sup>2</sup>
Permselectivity	0.93
Thickness	50 μm

## Optimization Model

The set of equations (1) defines the general form of the Generalized Disjunctive Programming (GDP) optimization model for the superstructure in Figure 1.

We code the GDP model using the algebraic modeling language Pyomo [13] and Pyomo.GDP [14], a dedicated Pyomo library extension for logic-based modeling and optimization.

$$\begin{aligned}
 \max NPV &= f(x) \\
 \text{s. t. } &g(x) \leq 0 \\
 &\begin{bmatrix} Y_r \\ h_r(x) \leq 0 \end{bmatrix} \vee \begin{bmatrix} \neg Y_r \\ B^r x = 0 \end{bmatrix} \quad \forall r \in RU \quad (1) \\
 &\Omega(Y_r) = True \\
 &x \in X \subseteq R^n \\
 &Y_r = \{True, False\} \quad \forall r \in RU
 \end{aligned}$$

In problem (1), the objective is to maximize the NPV of the RED process. The continuous variables  $x$  are the molar concentration and flow rate of the streams and the internal variables of the active RED units. The decision variables are the electric current, inlet concentration, and flow rate of the RED stacks.

The global constraints,  $g(x) \leq 0$ , describe specifications and physical relationships that must hold for any selection of alternatives in the superstructure, *e.g.*, mass balances of the feed, source, sink, and discharge units, and concentration and flowrate upper and lower bounds.

The  $N_r$  two-term disjunctions denote the discrete activation and deactivation of the  $N_r$  candidate RED units governed by the corresponding Boolean variables  $Y_r$  in each disjunct. When the unit exists ( $Y_r = True$ ), the active constraints  $h_r(x) \leq 0$  impose the RED unit discretized model equations (*e.g.*, mass and energy balances or other physicochemical phenomena within the RED unit), compute the capital and operating costs, and set bounds on the internal variables and the concentration and flow rate of the inlet and outlet streams; otherwise, ( $\neg Y_r$ ) the RED unit equations in the inactive disjunct are ignored, and  $B^r x = 0$  constraints set to zero a subset of the continuous variables and cost terms in the objective function.

The logical relationships ( $\Omega(Y_r) = True$ ) establish the logic conditions for selecting the candidate RED units.

To formulate the GDP problem, we assume:

1. Pure sodium chloride (NaCl) feed solutions, thus presuming ideal aqueous solution (*i.e.*, unity activity coefficients) and the absence of other species.
2. The ionic resistances of solutions and membranes are the unique internal energy loss.

3. Constant membranes' permselectivity and ionic resistance with concentration and temperature.
4. No water transport across membranes due to osmosis, so the streamwise volumetric flow rate in the RED channel is constant.
5. Salt diffusivities in the membrane phase are independent of concentration and temperature.
6. No fluid leakage or ionic shortcut currents in the RED stack's manifolds.
7. Co-current flow.
8. Isothermal and isobaric conditions.

Be aware that simplifying the RED stack model [11] leads to an increased net power output, causing the LCOE to be underestimated and the NPV to be overestimated.

The NPV of the RED process (2) accounts for discounted annual revenues from electricity sales and carbon pricing incentives and discounted operating costs (OPEX in \$/year) and capital expenses (CAPEX in \$). The OPEX and annualized CAPEX define the total annual cost (3), TAC, of the RED system. The CAPEX is annualized over the expected lifetime of the plant  $LT$  in years, using the capital recovery factor,  $CRF$ , given in (4) with a discount rate  $DR$ .

We assume the RED plant electricity is sold to the grid at the Spanish average price of electricity for non-house consumers,  $ep$  [15], and that the abated GHG emissions from the grid mix (Spanish emission factor,  $ef$ ) are subsidized at the average price,  $cp$ , in the European Union Emission Trading System (EU ETS) [16].

$$NPV = \frac{(ep + cp ef) TNP - TAC}{CRF} \quad (2)$$

$$TAC = CRF CAPEX + OPEX \quad (3)$$

$$CRF = \frac{DR}{1 - (1 + DR)^{-LT}} \quad (4)$$

$$TNP = \sum_{r \in RU} NP_r \quad (5)$$

We adapt our RED stack model [10] for a tractable yet rigorous solution. When the RED unit is active ( $Y_r = True$ ), the discretized model computes the net power output,  $NP_r$ , that is added to the RED system net power capacity, *i.e.*, total net power,  $TNP$  in kW (5). The net power output equals zero when the RED unit is absent ( $\neg Y_r$ ).

We apply a load factor,  $LF$ , to the annual full-capacity energy yield (kWh/year) of the RED plant to account for plant downtime due to membrane cleaning and system maintenance.

The capital investment involves the cost of RED stacks,  $\sum_{r \in RU} CC_{stack,r}$ , pumps,  $CC_{pump}$ , and civil and electrical infrastructure costs,  $CC_{civil}$ .

$$CAPEX = \sum_{r \in RU} CC_{stack,r} + CC_{pump} + CC_{civil} \quad (6)$$

The annual operating cost comprises the electricity cost from pumps,  $\sum_{r \in RU} OC_{pump,r}$ , the replacement cost of membranes,  $\sum_{r \in RU} OC_{IEMsrep,r}$ , and maintenance and labor costs (2% of CAPEX).

$$OPEX = \sum_{r \in RU} OC_{pump,r} + \sum_{r \in RU} OC_{IEMsrep,r} + 0.02 CAPEX \quad (7)$$

When the RED unit is active,  $CC_{stack,r}$  is added to CAPEX, and  $OC_{pump,r}$  and  $OC_{IEMsrep}$  to the OPEX; if not, these terms take zero values.

The objective function in (2) is maximized subject to constraints in the GDP detailed in [11]. The main financial parameters are reported in Table 2.

## Solution Strategy

We solve the GDP problem with the Global Logic-based Outer Approximation (GLOA) algorithm [17,18] implemented in the logic-based solver GDPopt version 20.2.28 built on Pyomo.GDP. The GLOA algorithm decomposes the solution to the GDP into a sequence of mixed-integer linear programming (MILP) problems and reduced nonlinear programming (NLP) subproblems.

We solve the MILP master problems with CPLEX and the NLP subproblems with BARON setting the time limit at 1 hour and 1% optimality gap on a machine running Windows 10 (x64) with 6 cores processor (Intel® Core™ i7-8700 CPU @3.2 GHz) and 16 GB of RAM. We use the MINLP and NLP solver versions from GAMS 34.1.0.

**Table 2:** Financial parameters of the RED process.

Parameter	Value
Plant lifetime, $LT$ [19]	30 years
Membrane lifetime [19]	10 years
Membrane price [20]	\$10/m <sup>2</sup>
Load factor, $LF$ [19]	90%
Discount rate, $DR$ [19]	5%
Spanish GWP, $ef$	0.374 kg CO <sub>2</sub> -eq/kWh
Carbon price, $cp$	\$27.8/t CO <sub>2</sub> -eq
Electricity price, $ep$	\$197/MWh

Spanish 2019-average price of electricity for non-house consumers. Band IB: annual consumption between 20 MWh and 500 MWh, excluding taxes and levies.

## RESULTS AND DISCUSSION

In all the assessments the RED units retrieve energy from the concentrate effluent of the Maspalomas II sea-water reverse osmosis desalination plant in Gran Canaria (Canary Islands, Spain) [21–23]. Maspalomas II plant rejects 17,602 m<sup>3</sup>/day (733 m<sup>3</sup>/h) of brine (1.67 M NaCl, 20°C) and consumes 3.77 kWh per cubic meter of desalted water. The low-salinity feedwater (20mM NaCl) is obtained from nearby wastewater treatment plants (*e.g.*, el Tablero, las Burras) [24], so the same LC and HC feed volume is available for SGE conversion.

### Stand-alone RED unit

The discretized RED unit NLP model involves 107–1187 variables and 107–1232 constraints is solved in 237 s up to an hour CPU time with BARON depending on the number of finite elements (from 3 up to 48 finite elements) that is set to keep the same axial discretization accuracy between the different sizes and aspect ratios.

Pilot-scale research often employs stack designs based on their counterparts in desalination, *i.e.*, electro-dialysis [6,25]. These modules feature greater length and smaller width, as the objective is to dilute the feed to comply with a given quality standard [26]. Alternatively, square geometries are usually adopted [5,6].

The premise of this study is that using modules that are wider than longer (*i.e.*, aspect ratio greater than one) while housing the same membrane area would allow more powerful systems and the treatment of larger feed volumes with fewer units. This would result in more compact and cost-effective systems.

The RED unit power generation sensitivity to aspect ratio increases with size (Figure 2). The smaller units require larger aspect ratios to reach an equal relative increase in NP. For instance, 1 m<sup>2</sup> units reach a 13% relative increase in NP when the aspect ratio moves from 1:1 to 9:1, while a RED unit twice its size requires a 4:1 ratio to reach the same increase. Increasing the width of the largest 6 m<sup>2</sup> stack nine times would lead to a 31% boost in net power generation, from 24.6 kW to 32.2 kW. In comparison, the smaller unit with an area of 0.25 m<sup>2</sup> and the same shape only generates 6% more net power than the square one.

Findings also indicate that while the largest RED unit delivers more net power than its pilot counterparts (Figure 2), it exhibits a lower power density (Figure 3). This may raise the cost per kWh of the RED unit despite the improvement in net power output.

Depending on the stack's geometry and size, and ultimately its ability to sustain the salinity gradient along the flow path, the optimal solution tunes the linear flow velocity in the HC and LC channels, the inlet concentration of the LC feedstream, and the electric current of the RED unit to maximize the net power output.

Shorter flow paths—realized by reducing the size for a given aspect ratio or increasing the aspect ratio for a given size—keep the inlet concentration gradient, *i.e.*, the highest driving force, along the channels. If the length is enlarged, there is enough time for ions to flow from the HC to the LC side, fading the concentration gradient.

**Figure 2:** Optimal net power output of the stand-alone RED unit with different sizes (active area) and width-over-length ratios.

Recovering energy from high salinity gradients gives rise to two opposing effects on power generation. On one hand, the electric potential of the cell pairs increases, resulting in a higher gross power generation. On the other hand, the low conductivity of the LC channel increases the internal losses, leading to a decrease in gross power.

Given that the electric current drives the migration of ions across membranes from high-salinity to low-salinity compartments, the optimal electric current should decrease with longer RED units to extend the concentration gradient along the flow path. The opposite is true for shorter RED units, where the optimal solution sets a higher electric current, balancing the increase in the electric potential and internal resistance loss that arises from a higher concentration gradient, as shown in Table 3.

**Figure 3:** Net power density of the stand-alone RED unit with different sizes (active area) and width-over-length ratios under optimal net power conditions.

**Table 3:** Optimal operation variables of the 3 m<sup>2</sup> stand-alone RED unit.

		Aspect Ratio, w/L			
		1:1	3:1	6:1	9:1
Current density		7.64 mA/cm <sup>2</sup>	8.08 mA/cm <sup>2</sup>	8.26 mA/cm <sup>2</sup>	8.35 mA/cm <sup>2</sup>
Potential per cp		68.76 mV	69.94 mV	70.43 mV	70.65 mV
Linear velocity	HC	2.9 cm/s	2.5 cm/s	2.2 cm/s	2.1 cm/s
	LC	4.8 cm/s	3.9 cm/s	3.4 cm/s	3.1 cm/s
Flow rate	HC	40.66 m <sup>3</sup> /h	59.88 m <sup>3</sup> /h	76.08 m <sup>3</sup> /h	87.40 m <sup>3</sup> /h

As the optimization model predicts, shifting to a wider-than-long stack design allows preserving the salinity gradient along the flow path with a lower linear velocity in the compartments. This, in turn, reduces hydraulic losses and pumping power to overcome head losses. Table 3 highlights the impact of this effect on the module with a membrane area of 3 m<sup>2</sup>. As the module length decreases, a downward trend in the optimal linear velocity is observed in both the HC and the LC. The flow rate rises despite the lower linear velocity due to the larger cross-sectional area. Concurrently, the concentration of the LC feed increases to offset the rise in the internal resistance.

### Optimal RED process design

We assume the superstructure has 25 identical candidate RED units with an active membrane area of 3 m<sup>2</sup>. For each aspect ratio (*i.e.*, 1, 3, 6, and 9) and the given financial parameters, the optimal solution provides the topology and decision variables that balance electricity production and capital and operating expenses. Discrete decisions involve the working RED units and the active water streams. Continuous variables are the inlet streams flow rate and concentration and active RED stacks electric current.

The GDP model finds profitable RED process designs for all the assessed RED units' aspect ratios (Table 4). But wider-than-long RED units earn more profits than the square peers with almost the same number of active RED units. As anticipated in the former section, the shorter RED stacks exhibit a higher power density. If the total membrane area and HC and LC feed volumes are the same, the RED process using shorter units can produce more power. In the NPV-optimal solution, to accommodate more wider-than-long RED units, the optimal solution makes them operate with flow rates below the optimal ones in Table 3. Such reduced inlet flowrate declines the RED units' net power density. Nevertheless, the increase in electricity production revenues considerably outstrips the increase in capital and operating cost of the wider-than-long RED units with lower power density.

By incorporating RED-based electricity, the grid mix share of the desalination plant supply could be decreased by as much as 7%, thereby reducing GHG emissions. This results from RED's relative emissions contribution to the energy supply being perceptibly slighter, at 2.6–2.9 kg CO<sub>2</sub>-eq/MWh compared to the Spanish grid mix, which emits 374 kg CO<sub>2</sub>-eq/MWh.

Overall, the GDP model defines cost-effective and sustainable RED process designs that improve the environmental profile and resource circularity of energy-intensive desalination and wastewater treatment plants; however, the nonconvexities leads to GDP problems that takes hours to solve with conventional global solvers (Table 4). This may be particularly true in full-scale RED systems with large-scale RED units.

## CONCLUSIONS

This work provides environmentally sustainable and cost-effective RED process designs exploring the RED units' different sizes and aspect ratios based on mathematical programming and the LCA framework. As a case study, we define energy recovery from mixing a real desalination plant's brine with reclaimed wastewater treatment plant effluents, a promising scenario for full-scale RED implementation.

The technical assessment of the size and different width-over-length ratios gives design and operation guidelines to derive compact systems that treat larger feed volumes with fewer yet powerful RED units. The assessment can assist in identifying the best aspect ratio for each module size.

Regarding the NPV-optimal RED process design with 3 m<sup>2</sup> RED units, the 9:1 width-over-length ratio yields the highest profit, \$2M, with an LCOE of \$111/MWh below the Spanish electricity market price (\$197/MWh) and a net power capacity of 282 kW from 22 RED units and virtually no added emissions to desalination plant's energy supply. As a result, RED-based electricity can abate around 7% of desalination plant's GHG from the grid mix supply at a competitive cost.

Overall, these results indicate that fine-tuning the aspect ratio is an effective way to advance in the development and commercial deployment of RED technology and prove that optimization-based eTEA is a robust tool to assist all development stages of emerging technologies such as RED electricity production.

Nonconvexities in the mixers and the RED unit model led to multiple optimal local solutions, therefore requiring computationally demanding global optimization techniques to solve to global optimality. This is particularly true, in large-scale RED systems where the model size significantly grows. A natural progression of this work is to reformulate the nonlinear equations into quadratic or linear approximations to exploit the bilinear nature of the GDP problem that solvers like Gurobi may effectively solve.

## ABSTRACT

This paper presents optimal design for an energy-integrated biogas-fuel cell system for renewable electricity generation. The integrated process consists of two steps. The first step generates hydrogen from biogas via methane steam reforming (SMR), whereas the second step electrochemically converts this hydrogen into electricity using a solid oxide fuel cell (SOFC). These two steps are coupled via material and energy integration. Specifically, various design alternatives like anode and/or cathode gas recycling, biogas upgradation by CO<sub>2</sub> removal, external versus direct internal reforming, and auxiliary power production through steam and/or micro gas turbine are explored to improve the overall efficiency and total annualized cost of the system. Specifically, a flowsheet superstructure is developed by incorporating all the available design alternatives. An optimal flowsheet with minimum total annualized cost is extracted from this superstructure using formal optimization techniques to meet the desired power target. Heat exchanger network superstructure is used to incorporate energy integration effectively. The proposed flowsheet and the corresponding optimal operating conditions are explained by analyzing the trade-offs associated with the corresponding design variables in terms of power production, capital expenditure, and utility consumption. For a power target of 300 kW, the proposed optimal energy-integrated process has a total annualized cost of \$608,955/y with a net electrical efficiency of 67.1% and corresponds to electricity cost of \$0.23/kWh.

**Keywords:** Process design, Optimization, Heat integration, Renewable electricity

## INTRODUCTION

Growing push towards sustainable practices has led to an increase in research activity in the area of power production from clean and renewable energy sources. Biogas, generated from the anaerobic digestion of organic matter, holds significant potential as a promising source for renewable power generation. Traditionally, biogas has been utilized to generate power through the use of reciprocating engines, microturbines, gas turbines, and steam turbines, resulting in low electrical efficiency. An efficient way to enhance the overall electrical efficiency of biogas is to integrate it with hydrogen fuel cells [1].

Integration of biogas with a fuel cell is, in principle, a two-step process. The first step generates hydrogen from biogas via a reforming reaction, like steam methane reforming (SMR), autothermal reforming, partial oxidation or dry reforming [2]. The second step electrochemically

converts this hydrogen into electricity using a fuel cell like solid oxide fuel cell (SOFC), proton exchange membrane fuel cell or molten carbonate fuel cell. These two steps can be coupled via material and energy integration. Specifically, various processing options like anode and/or cathode gas recycling, biogas upgradation by CO<sub>2</sub> removal, external versus direct internal reforming, use of steam turbine and/or micro gas turbine can be incorporated to improve the overall efficiency of the system.

Several studies have reported flowsheets for such integrated process. Piroonlerkgul et al. [3] proposed four designs differing on the basis of reforming agent (steam, air, or both) for external reformer and auxiliary power generation via steam turbine. Farhad et al. [4] proposed three designs involving external reformers with steam methane reforming or partial oxidation and explored the possibility of anode gas recycling. Trendewiz and Braun [5] presented designs for small, medium, and large-scale

integrated biogas-SOFC systems with anode gas recycling, external pre-reforming and direct internal reforming. They subsequently performed techno-economic analysis to estimate minimum electricity cost. Siefert and Lister [6] proposed a pressurized system with anode gas recycling and a micro gas turbine to generate auxiliary power from combustion of unspent fuel. Lastly, Baldineili et al. [7] proposed a design with biogas upgradation using membrane separator and proposed the use of direct internal reforming. It can be noted that most of these studies focus on only few select options for performance comparison, use parametric analysis to obtain final design instead of formal optimization and incorporate energy integration in an ad hoc manner. Thus, there is a need for a systematic approach for design and optimization of such highly integrated systems.

Motivated by this, the objective of this work is to develop an optimal flowsheet for power production via integrated SMR-SOFC system with biogas feed. A flowsheet superstructure is proposed based on the available design alternatives. Using formal optimization techniques, the optimal flowsheet is extracted from this superstructure by selecting the best combination of the processing alternatives to meet the set power target. The proposed flowsheet as well as the corresponding optimal operating conditions are explained by analyzing the trade-offs associated with the corresponding design variables in terms of power production, capital expenditure and utility consumption.

The rest of the paper is organized as follows. The next section describes the proposed flowsheet superstructure. The following section presents the optimal design framework with special emphasis on the trade-offs associated with key decision variables. The solution of the optimization problem and the corresponding results are discussed in the subsequent section.

## PROCESS SUPERSTRUCTURE

Superstructure optimization is a systematic technique to evaluate the different process alternatives. The first step involves generating a process flowsheet superstructure incorporating all the potential design alternatives. In the second step, this superstructure is converted into an optimization problem by incorporating material and energy balance equations along with operating and capital cost correlations. In the final step, this optimization problem is solved to obtain the optimal flowsheet along with the corresponding performance indices.

In this work, the various design alternatives proposed in literature (such as anode gas recycle, biogas upgradation, pre-reformer and direct internal reforming, steam and gas turbine) are combined together to generate the flowsheet superstructure. Previously unexplored options like cathode gas recycle or micro gas turbine on

membrane separator retentate are also incorporated. Lastly, a superstructure of heat exchanger networks is included to ensure efficient energy integration. The resulting superstructure is depicted in Figure 1.

The feed biogas at ambient conditions is supplied to the process via a blower or a compressor (C1) based on the system's operating pressure. Biogas production/cleanup is not explicitly considered in this work. Instead, cost of cleaned biogas is considered as feed cost as shown in Eq. (3). There are two potential routes for this biogas. In the anode gas recycle route, the feed biogas is mixed with a part of the spent anode gas which is rich in steam and  $H_2$  and proposes advantages in operating cost due to reduced consumption of fresh feed and steam. However, there is a penalty in terms of capital cost of reformer and fuel cell due to large flow rates and dilute conditions. The biogas upgradation route considers removal of  $CO_2$  via membrane separation. In this route, the biogas is pressurized using compressors C2 and C3.  $CO_2$  is removed as a low pressure permeate. The high-pressure retentate is expanded over a micro gas turbine to produce auxiliary power. The output of both these routes is heated using internal or external heating sources and subsequently fed to the external reformer. The  $H_2$ -rich exhaust of this reformer is fed to the anode section of the SOFC. If required, heating is provided by internal sources or hot utility. The SOFC anode is also capable of performing internal reforming to generate  $H_2$ . The relative extent of external and internal reforming can be manipulated by adjusting reformer operating conditions and the bypass provided over the reformer. The air required by the SOFC is sent through a blower/compressor (C4). Similar to the anode gas, it can be heated to the required temperature through internal or external sources. A part of the hot cathode effluent gas, which is rich in oxygen, is recycled back to reduce air demand as well as utility consumption. Similarly, in the case of anode gas recycle route, a part of the hot anode effluent gas is recycled back to the reformer. The rest of the anode and cathode spent gas (after taking out the anode and cathode recycle) is sent to the combustor. The combustor converts the chemical energy available with the spent fuel (unconverted hydrogen) into thermal energy which can be used for heating or auxiliary power generation. A part of the hot exhaust gas from the combustor is used to generate high-pressure steam via PPX10. This steam subsequently drives a steam turbine (T1) to generate auxiliary power. The rest of the hot gas is used for internal energy integration. It can be used to supply heat to the external reformer (PPX2) or meet high-temperature heating demand of the anode (PPX1) and cathode (PPX3) or reformer (PPX4 and PPX5) feed. The steam turbine exhaust can also be used to meet low temperature demands of reformer feed (PPX7), cathode (PPX6), reformer steam (PPX8) and membrane separator retentate

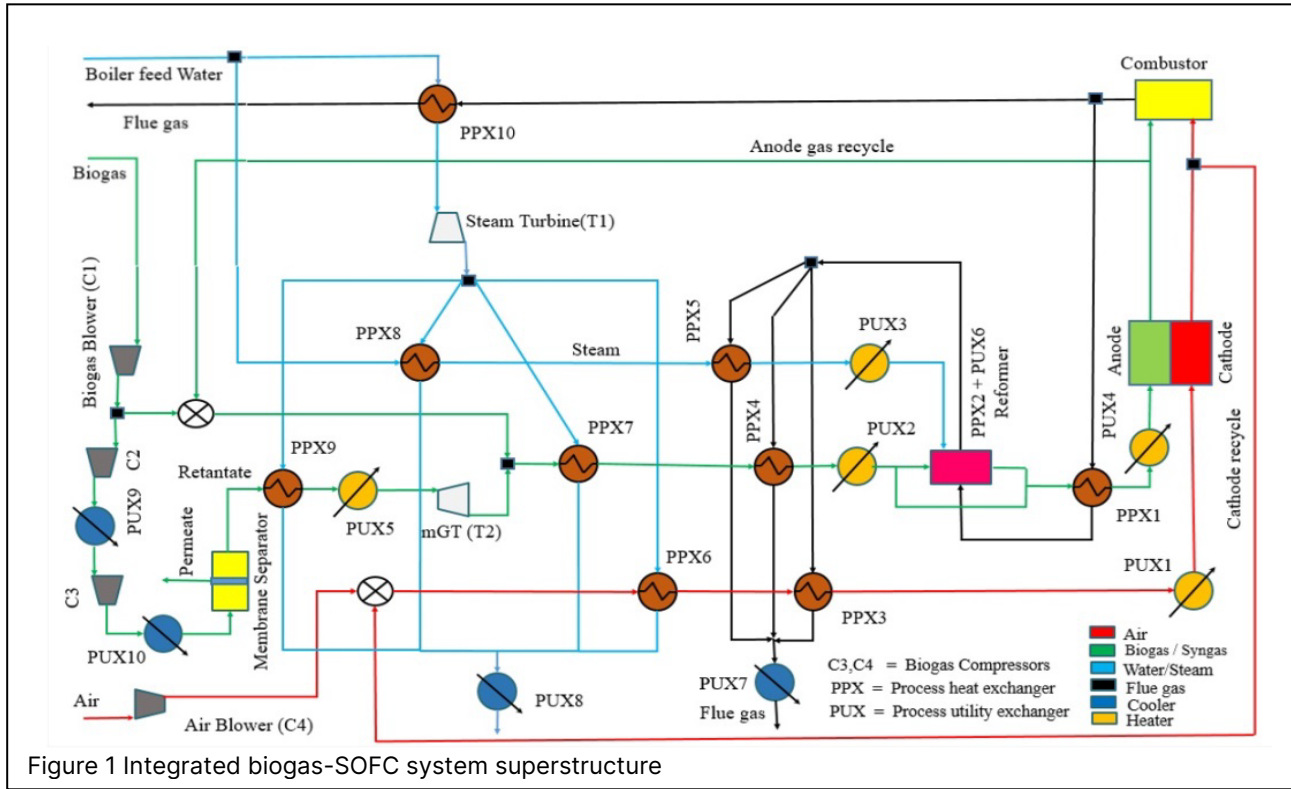

Figure 1 Integrated biogas-SOFC system superstructure

(PPX9). Process utility heat exchangers (PUX1 through PUX10) are placed to meet the rest of the heating and cooling demands.

It can be noted that the SOFC, along with steam (T1) and micro gas (T2) turbine produce electrical power. A part of this power is consumed internally to drive compressors C1, C2 and C3. The performance of the optimal integrated process is quantified by net electrical efficiency ( $\eta_{net-elect}$ ). It represents the conversion efficiency of the process and is defined as the ratio of the net power output to the total energy fed to the system. It can be computed using Eq. (1).

$$\eta_{net} = \frac{P_{SOFC} + \sum_j W_{turb,j} - \sum_j W_{comp,j}}{LHV_{BG} + \sum_j Q_{H,j}} \quad (1)$$

where  $P_{SOFC}$  represents power generated by the SOFC,  $W_{turb,j}$  and  $W_{comp,j}$  represent power generation and consumption by turbine and compressor, respectively.  $LHV_{BG}$  represents the heating value of the biogas feed and  $Q_{H,j}$  represents the hot utility consumption. Along similar lines, the performance of the SOFC is quantified by its conversion efficiency and is defined as the ratio of its power output to thermal energy input. The corresponding SOFC efficiency ( $\eta_{SOFC}$ ) is computed using Eq. (2).

$$\eta_{SOFC} = \frac{P_{SOFC}}{LHV_{BG}} \quad (2)$$

## OPTIMIZATION PROBLEM FORMULATION

The superstructure optimization problem consists of three components; the objective function, the decision variables and the process constraints. This section provides details about each of these components.

### Objective function

In order to obtain an economically efficient design, it is important to consider capital as well as operating cost. To this end, minimization of total annualized cost (TAC) is considered as an objective function. The capital cost for each equipment is computed using cost correlations given in Table 1. In the case of SOFC, the capital cost consists of cost of electrode active surface area ( $A_{SOFC}$ ), enclosure cost, converter cost and stack replacement cost. The cost of membrane separator is estimated based on required membrane area ( $A_{membrane}$ ). This area is computed through material balance and considering membrane permeance of 100 GPU.

The installed capital cost is computed by multiplying the above capital cost by the corresponding installation factors. It is subsequently scaled to 2023 cost using cost index (CECPI). Finally, the annualized capital cost is obtained by dividing this cost by equipment life. For this study, expected life of 10y is considered for all equipment, except membrane separator whose expected life is taken as 5y.

Operating cost consists of biogas feed cost along

with hot and cold utility as all the electrical power requirements are met internally. Thus the total annualized cost is computed using Eq. (3).

$$TAC = C_{BG}n_{BG} + C_{HU/CU} \sum_k Q_{H,k/C,k} + \sum_k \frac{E_k}{L_k} \quad (3)$$

where  $C_{BG}$  is the cost of feed biogas,  $C_{HU/CU}$  is the cost of hot or cold utility,  $E_k$  is the installed equipment cost and  $L_k$  is the expected life of that equipment.

**Table 1.** Cost correlations and parameters

Equipment/Feed/Utility	Cost correlation/value
SOFC Active surface area	\$ 1700 × $A_{SOFC}$ (m <sup>2</sup> ) [6]
SOFC Enclosure	\$ 80 × ( $P_{rSOFC}$ (atm)) <sup>0.33</sup> [6]
SOFC stack replacement	\$ 350 × $P_{SOFC}$ (kW) [6]
DC/AC convertor	\$ 70 × $P_{SOFC}$ (kW) [6]
Air/Biogas Blower	\$ 16,216 × ( $Q$ (m <sup>3</sup> )) <sup>0.56</sup> [8]
Steam turbine	\$ 29,410 × ( $P$ (kW)) <sup>0.49</sup> [8]
Micro gas turbine	\$ 200 × ( $P$ (kW)) [6]
Combustor	\$ 266.58 × ( $Q$ (kW)) <sup>0.871</sup> [8]
Utility heater	\$ 173.6 × ( $Q$ (kW)) <sup>0.765</sup> [8]
Process heat exchanger	\$ 147.5 × $A$ (m <sup>2</sup> ) [6]
Membrane Separator	\$ 150 × $A_{membrane}$ (m <sup>2</sup> ) [6]
Reformer	\$204,000 ( $m_{H_2}/1125$ ) <sup>0.7</sup> [5]
Biogas feed ( $C_{BG}$ )	\$18/kmol [9]
Hot utility ( $C_{HU}$ )	\$ 3.45 × 10 <sup>-5</sup> /kJ [9]
Cold utility ( $C_{CU}$ )	\$ 2.00 × 10 <sup>-6</sup> /kJ [9]

## Decision variables

The key decision variables and the corresponding trade-offs are given below.

1. SOFC operating pressure ( $P_{rSOFC}$ ): High SOFC pressure favors high open circuit voltage and SOFC efficiency. However, it increases capital cost, air compressor power consumption and lowers power production via micro gas turbine.
2. SOFC operating temperature ( $T_{SOFC}$ ): High SOFC temperature reduces voltage losses in SOFC, requires less airflow to carry exothermic heat and exit gases have high energy integration potential. However, it reduces open circuit voltage and increases hot utility consumption.
3. SOFC Fuel utilization factor ( $U_f$ ): It represents the fractional conversion of hydrogen in the SOFC. A high value of  $U_f$  increases power generation from the SOFC. However, it leads to increased current density and voltage losses as well as an increase in airflow to maintain SOFC temperature. To accommodate voltage losses, a higher SOFC area is required, which leads to increased capital cost. Furthermore, it reduces opportunity for anode gas recycle, auxiliary power production via steam turbine and internal energy integration.
4. SOFC Air utilization factor ( $U_a$ ): It represents the fractional conversion of oxygen in the SOFC. A low value of  $U_a$  allows for better heat management in SOFC, but results in increased air compression power and dilution at the cathode reduce SOFC efficiency.
5. Reformer temperature ( $T_{ref}$ ): High reformer temperature results in increased CH<sub>4</sub> conversion and H<sub>2</sub> yield, subsequently leading to high cell voltage and SOFC power generation. However, it also increases the heat load of the reformer and reduces net electrical efficiency. Moreover, with more CH<sub>4</sub> conversion, reformer capital cost and hot utility cost increases at the expense of improved SOFC efficiency.
6. Reformer S/C ratio ( $SCR$ ): A high value of SCR increases H<sub>2</sub> yield and potential of high SOFC efficiency. However, it also dilutes the anode gas, leading to lower open circuit voltage and increased hot utility for steam generation. Furthermore, it increases reformer and steam generator capital cost.
7. Reformer bypass fraction ( $f_{byp}$ ): This fraction controls the extent of external and internal reforming. External reforming results in high hydrogen partial pressure in the SOFC; hence, higher SOFC efficiency, thus lowering the feed demand and operating cost. However, it also suffers from increased hot utility and reformer capital cost. On the other hand, direct internal reforming provides better synergy between endothermic reforming and exothermic electrochemical reactions, thereby reducing the utility cost but results in lower partial pressure of hydrogen, cell voltage and thus increases SOFC capital cost.
8. Anode gas recycle fraction ( $f_{AGR}$ ): A high value of anode gas recycle fraction represents better material and energy integration and thus reduces feed and hot utility cost. However, it reduces auxiliary power production through steam turbine and thus increases SOFC capital cost.
9. Cathode gas recycle fraction ( $f_{CGR}$ ): A high value of cathode gas recycle fraction reduces the fresh air flow and the corresponding heating and compression loads, reducing hot utility cost and compression cost. However, it causes dilution of cathode gas and reduces cell voltage.

10. Flue gas split fraction ( $f_{split}$ ): This fraction controls the extent of internal energy integration and auxiliary power production via steam turbine. A high fraction of flue gas going to steam generator increases turbine power contribution and unloads the SOFC, resulting in lower SOFC capital cost. However, it limits internal energy integration and increases hot utility consumption. Consequently, the hot utility cost increases.
11. SOFC active surface area ( $A_{SOFC}$ ): A high value of active surface area reduces the current density, resulting in lower voltage loss and high operating voltage, and high SOFC efficiency, leading to a reduction in feed demand and corresponding operating cost. However, increased SOFC area results in increased capital cost of the SOFC.
12. Hot effluent split fractions ( $f_s$ ): There are total 5 such split fractions, two on exhaust gas and three on steam turbine exhaust. These split fractions control the relative extents of the heat transfer among various process heat exchangers.
13. Route selector ( $y$ ): This binary variable provides selection between anode gas recycle and biogas upgradation route. While anode gas recycle reduces feed cost through material integration, it also results in increased utility cost as well as increased SOFC capital cost. On the other hand, biogas upgradation route reduces SOFC capital cost but increases capital cost contribution from membrane separator and compressors.

### Process constraints

The key equality constraints are the material and energy balance equations for each process unit. These equations relate the various process inputs like pressure, temperature, flow rate, area, etc. to the key outputs like power generation, reaction conversion, etc. The details of these equations can be found in our earlier publication [9]. The key inequality constraint corresponds meeting power production target and is represented by Eq. (4).

$$P_{target} \leq P_{SOFC} + \sum_j W_{turb,j} - \sum_j W_{comp,j} \quad (4)$$

For each heat exchanger, there is a need to ensure positive thermal driving force. Correspondingly, the following constraints are incorporated for each of the process heat exchangers (PPX1 through PPX10).

$$T_{H,in,j} - T_{C,out,j} \geq \Delta T_{min}, \quad T_{H,out,j} - T_{C,in,j} \geq \Delta T_{min} \quad (5)$$

Lastly, upper and lower bounds for each decision variable are included.

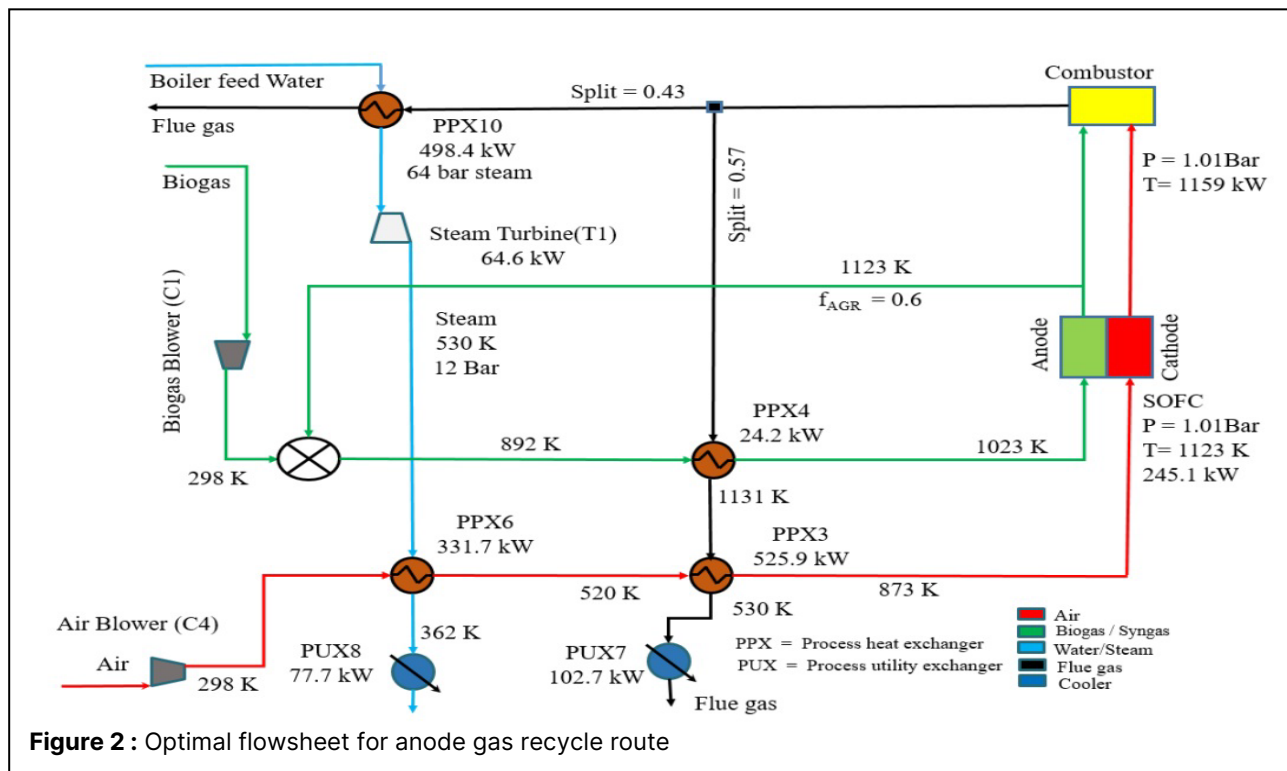

## RESULTS AND DISCUSSION

For this study, biogas composition of 65% CH<sub>4</sub> and 35% CO<sub>2</sub> is considered. Optimal flowsheet is designed for a power target of 300 kW. This capacity represents power potential of a small-scale wastewater treatment facility [5]. The optimization problem presented in the previous section is a mixed integer nonlinear programming (MINLP) problem. However, there is only one binary variable. It can therefore be easily split into two nonlinear programming problems (NLP), one for each processing route. As a NLP problem is easier to solve, we have obtained separate optimal flowsheets for each processing route. These NLP problems are solved using GAMS with Baron as a solver and the corresponding solutions are presented through Figure 2, 3 and Table 2.

**Table 2:** Optimal solution for each processing route (LB: lower bound, UB: Upper bound)

Variables	Anode gas recycle	Biogas upgradation
TAC (\$/y)	608,955	687,475
$\eta_{net}$ (%)	67.14	65.1
$\eta_{SOFC}$ (%)	54.86	55.48
$P_{SOFC}$ (kW)	245.119	255.712
$W_{turb,steam}$ (kW)	64.685	67.63
$W_{turb,gas}$ (kW)	-	0
$W_{comp,C1}$ (kW)	0	0
$W_{comp,C2}$ (kW)	-	6.702
$W_{comp,C3}$ (kW)	-	6.416
$W_{comp,C4}$ (kW)	-	0
$n_{BG}$ (mol/s)	0.857	0.884
$n_{Air}$ (mol/s)	46.143	46.094
$n_{BFW}$ (mol/s)	8.134	8.505
$Pr_{SOFC}$ (bar)	1.01 (LB)	1.01 (LB)
$T_{SOFC}$ (K)	1123 (UB)	1123 (UB)
$U_f$	0.78	0.85 (UB)
$U_a$	0.10 (LB)	0.10 (LB)
$T_{ref}$ (K)	-	-
SCR	-	-
$f_{byp}$	1.0 (UB)	1.0 (UB)
$f_{AGR}$	0.604	-
$f_{CGR}$	0.0 (LB)	0.0 (LB)
$f_{split}$	0.433	0.445
$A_{SOFC}$ (m <sup>2</sup> )	128.76	159.7

It can be seen that the anode gas recycle route results in lower TAC as compared to the biogas upgradation route. The optimal process recommends operating

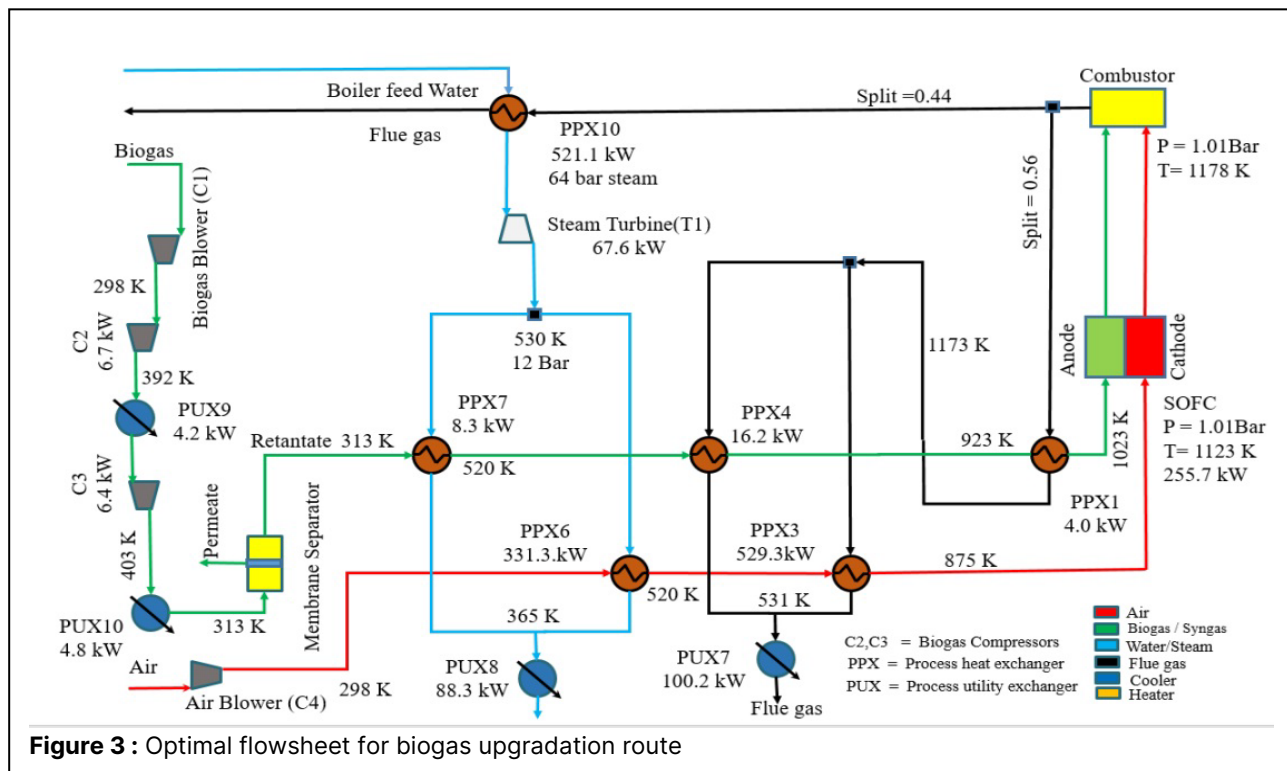

the SOFC at atmospheric conditions and high temperature (1123K). Total internal reforming is chosen over external reforming to save the capital cost of reformer and hot utility consumption for reforming reaction. Cathode gas recycling is not selected as dilution effects outweigh material and energy integration benefits. It can be noted that considerable fraction (60%) of anode gas is recycled back to utilize the unconverted hydrogen and generate power with higher efficiency (SOFC versus combustor + steam turbine). 43% of the high temperature flue gas is sent to the high-pressure steam generator for the auxiliary power generation and the rest of the fraction is sent to the process for heat integration to meet the internal heat demands of the process. By using heat from this flue gas as well as turbine exhaust, all of the heat demands are met. The SOFC generates 78% of the total power, and the steam turbine contributes the rest. Removal of the external reformer, efficient energy integration and synergy between the SOFC and steam turbine resulted in high net electrical efficiency of 67.1%. The total annualized cost of the plant is \$608955/y which corresponds to electricity production cost of \$0.23/kWh. This is slightly higher than typical electricity cost from conventional resources. The feed cost dominates the overall economics and contributes to 72% of the total annualized cost. This is due to capital intensive biogas production and cleanup process. (%). The cost of electricity can be further reduced by optimizing biogas production and cleanup process leading to reduced feed cost. The second most significant cost contribution comes from the SOFC (13%). Another way to reduce the cost of electricity

is to improve SOFC electrode design to reduce its cost per unit active surface area. This will allow for increasing the SOFC active surface area to further improve net electrical efficiency and lower the contribution of feed cost.

A similar trend is observed for the biogas upgradation route as well. Specifically, SOFC temperature and fuel utilization are set at upper bound, while pressure and air utilization are constrained at lower bound. Internal reforming is chosen over external reforming and cathode gas recycling is excluded. Even though more power is generated through the steam turbine, SOFC generates 82% of the total power, which is slightly higher than the previous case. This is due to increased power consumption via biogas compressors C2 and C3. It should be noted that the option of gas turbine is not selected as the power generated through it is sufficient enough to justify capital expenditure in turbine and the entry heat exchanger. 44.5% of the flue gas goes for auxiliary power generation, and the rest is utilized for heat integration. Similar to the previous case, this process also does not require any hot utility, resulting in net electrical efficiency of 65.1%. The total annualized cost for this process is \$687475/y and the corresponding cost of electricity is \$0.26/kWh. Similar to the previous process, the feed cost contributes significantly (66%) towards the total cost.

Let us now compare the two routes. The process with anode gas recycle has lower feed demand for the same power target and thus results in higher SOFC efficiency. Overall, the net electrical efficiency of anode gas recycle route is slightly better than biogas upgradation route. The other operating conditions of the two routes

**Figure 3 :** Optimal flowsheet for biogas upgradation route

are similar.

Let us now assess the impact of capital cost on the optimal design of the integrated process. Previously, optimal flowsheet was designed to minimize total operating cost [9]. Anode gas recycle was the most optimal option in that case as well. Most of the optimization variables had similar values. The total annualized cost of that process was \$609688/y, marginally higher than the proposed solution. This corroborates well considering that the feed cost dominates the overall economics.

The optimization problem for anode gas recycle involved 753 equations, 692 variables, and took 2583 s (CPU time) to solve. Similarly, the optimization problem for biogas upgradation involved 863 equations, 765 variables and took 4489 s to solve. The problems were solved on an Intel i7-7700 CPU @ 3.60 GHz processor.

## CONCLUSION

This paper presents optimal design for a biogas-based fuel cell system for electricity generation. A biogas superstructure consisting of various design alternatives is constructed. An optimal flowsheet is synthesized by minimizing the total annualized cost. The optimal flowsheet results in electrical cost of \$0.23/kWh. The following key conclusions can be drawn from this study.

1. Anode gas recycling route is more optimal as compared to biogas upgradation. A high value of recycle fraction is recommended to balance the trade-offs between material and energy integration and

auxiliary power generation.

2. Internal reforming provides better heat management, high net electrical efficiency, low capital investment, and low utility costs as compared to external reforming.
3. Feed biogas cost is the major contributor towards the total annualized cost.
4. Cathode gas recycle option does not provide net benefits towards efficiency improvement.

## ABSTRACT

The study of sustainable design has gained prominence in response to the growing emphasis on environmental and social impacts of critical infrastructure. Addressing the different dimensions inherent in sustainability issues necessitates the application of many-objective optimization techniques. In this work, an illustrative four-objective design system is formulated, wherein uncertainties lie within two different socially-oriented objectives. A stochastic community detection approach is proposed to identify robust groupings of objectives. The findings reveal that the modularity of the optimal solution surpasses that of the average graph, thus demonstrating the efficacy of the proposed approach. Furthermore, a comprehensive exploration of the Pareto frontiers for both the robust and single-scenario best groupings is undertaken, demonstrating that using the robust grouping results in little to no information loss about tradeoffs.

## INTRODUCTION

Various global events over the past several years have made clear the importance of designing new infrastructure not only at low cost but also that does not negatively impact global climate, that is resilient against disruptive events such as pandemics and wars, and that provides positive social outcomes for all relevant stakeholders [1]. For many large industries, shareholders are increasingly concerned about the significance of environmental, social, and governance (ESG) considerations within the framework of sustainability. The chemical industry is no exception to this trend. Consequently, there exists a compelling impetus to investigate sustainable process designs which perform well both in traditional economic metrics, such as net present value, annualized cost, or payback period, while also achieving positive social and environmental outcomes [2]. Moreover, when such environmental and social outcomes are considered, it is important to consider tradeoffs between different aspects of these main pillars. For instance, a socially positive outcome will consist of outcomes such as added jobs, safe operation, equitable outcomes among relevant stakeholders, and community acceptance, some of which may be in conflict with one another when considering

design alternatives. To evaluate the potential tradeoffs between these various goals, we employ many-objective optimization, an approach with widespread applicability in chemical process systems research. [3] The result of many-objective optimization is not a singular solution but a Pareto frontier, illustrating the tradeoffs between different objectives. All points along the Pareto frontier indicate the best one objective can do without hurting another one.

Unfortunately, for problems with large number of objectives, the time that is required to solve the sustainable design problem escalates significantly when the number of objectives increases, with problems of more than three objectives impractical to solve and interpret using rigorous solution methods such as the weighted sum or epsilon constraint approaches. Additionally, when Pareto frontiers can be obtained in these high dimensional spaces, they are challenging if not impossible for relevant stakeholders to interpret. To address these issues, our previous work developed a method for systematically reducing the dimensionality of a many-objective optimization problem on the basis of their competing or correlating nature using a network theoretic approach [4]. We then extended this framework to process operations problems where the underlying economic or

environmental parameters inherently varied in time (due to, for example, varying costs and emissions associated with grid-purchased electricity), demonstrating that the time-varying natures of these signals can alter the appropriate grouping of objectives when repeatedly solving the operation problem over time [5]. This work builds upon our previous efforts in the many-objective optimization space by analyzing how to group objectives which inherently contain a large degree of uncertainty. This phenomenon is most commonly seen when considering social objectives, which are typically ill-defined and difficult to quantify, and thus can be subject to large ranges of uncertainty.

In this work, we focus on an illustrative four objective design problem formulated as a linear program (LP). The objectives to minimize include net present costs, carbon emissions, safety risk and social inequity. We assume the presence of uncertain parameters in the two social objectives, risk and equity. The design problem is straightforward and illustrative in nature, with all four objectives being linear combinations of design variables.

The dimensionality reduction approach is systematically applied in all different scenarios generated from uncertain parameters. We want to find out the most robust grouping of objectives among the scenarios identifying the grouping of objectives with the highest expected modularity over all scenarios. To achieve this, a novel approach is developed which treats the community detection of an uncertain graph as a stochastic optimization problem and employs a column generation approach to decompose the problem into several interconnected deterministic community detection problems with modified modularity objectives. The remainder of this paper is structured as follows: in the next section, we describe the many-objective optimal design problem considered in this work. Then, a novel approach for stochastic community detection of uncertain graphs is described. Next, we present results of solving applying our dimensionality reduction approach and solving the many-objective optimization design problem. Finally, concluding remarks and avenues for future work are presented.

## PROBLEM FORMULATION

**Figure 1.** Two reactor, two separator superstructure considered in this work.

## System description

In this study, we demonstrate a straightforward design problem with two reaction and two separators as shown in Fig. 1, which depicts the superstructure of the reactor/separator system. The chemical reaction design model considered has two reactants and one product, necessitating separation in the designated separators as part of the design problem. Flow with both reactants allows for reactions in either Reactor A, Reactor B or both. Additionally, there are two choices for separators, and all flow resulting from the chemical reaction is directed towards these separators. Each reactor and separator is characterized by a unique conversion for both the reaction and separation processes.

Moreover, specific carbon emission and operating cost parameters are assigned to each unit in the system. There are uncertain parameters in the system that are associated with safety risk and social equity objectives; in this problem, we assume that there are two possible realizations of this objective parameter for each unit considered.

## Objective functions

The first objective that we consider is to minimize the annualized net present cost  $N$  that combines the capital cost and operating cost of the design system:

$$N = \sum_{i=1}^4 cap_i * \frac{1}{\theta} + op_i \quad (1)$$

$$cap_i = c_i^{ref} \left( \frac{F_i}{F_i^{ref}} \right)^\gamma \quad (2)$$

$$op_i = \alpha_i F_i \quad (3)$$

where  $\theta$  is the NPC-scaled lifetime used to annualize the capital cost and  $F$  is the flow through the reactors or separators, which acts as a proxy for unit size. The capital cost as we can see in equation (2) is a nonlinear function, where  $c_i^{ref}$  and  $F_i^{ref}$  are the sizes and capital costs, respectively, of the reference for unit  $i$ , and  $\gamma$  is the scaling exponent. Unit subscripts  $i$  correspond to the four units shown in Fig. 1. In order to formulate the problem as an LP such that our objective reduction framework can be applied, we choose  $\gamma$  as 1; extension of our dimensionality reduction framework to nonlinear problems will be the scope of future work. The operating cost is given in equation (3) and it is proportional to the flow through each unit, where  $\alpha_i$  are cost parameters and  $F_i$  are flow in each units.

Besides the traditional economic factors, we consider minimization of carbon emissions  $H$ , related to the usage of all the facilities in the system, where  $\beta_i$  represent emission parameter of different units:

$$H = \sum_{i=1}^4 \beta_i F_i \quad (4)$$

The emission objective has similar structure with operating cost: it is linear combination of the flow through

the different units. Moreover, two social objectives, risk and inequity, are analyzed in the optimization:

$$R = \sum_i \delta_{ri} F_i \quad (5)$$

$$E = \sum_i \delta_{ei} F_i \quad (6)$$

In this work, the coefficients for the two social objectives,  $\delta_{ri}$  and  $\delta_{ei}$ , are uncertain parameters. Note that for this illustrative example, the emissions, risk, and inequity objectives are a linear combination of all design variables, which for this problem are simply the flows. Thus, while it's uncommon to find that social objectives are determined by the same variables as cost and emission objectives in practical applications, the approach shown here is generalizable for linear objectives as variables which do not impact a given objective can have the corresponding coefficient set to zero. The extension of this approach to more realistic nonlinear problems is still ongoing work which is beyond the scope of this paper.

### Model Constraints

The chemical design system should follow physical and practical limitations. First, we set a total amount of initial feed in the system ( $F_t$ ) that equals to the sum of the flow in the reactors ( $F_1, F_2$ ):

$$F_1 + F_2 = F_t \quad (7)$$

$$F_t \geq F_i \geq 0$$

Since an  $A+B \rightarrow C$  reaction is assumed, total amount of flow (on a molar basis) will reduce after the reaction based on different conversions ( $E_1, E_2$ ) of the reactors:

$$\left(1 - \frac{E_1}{2}\right) F_1 + \left(1 - \frac{E_2}{2}\right) F_2 = F_3 + F_4 \quad (8)$$

We assume that the separators can distinguish the specific product that we want but can't totally remove the product from the flow. Thus, here we use the flow from the reactors to the respective separators ( $F_3, F_4$ ) and parameters for efficiency of the separators ( $E_3, E_4$ ), which are all based on the mixture of reactants and products.

$$E_3 F_3 + E_4 F_4 \geq F_{min} \quad (9)$$

Equation (9) indicates that a minimum requirement of the product ( $F_{min}$ ) needs to be satisfied in the reaction system.

### Case study data

As this problem acts to serve as an illustrative example, problem parameters are chosen by the researchers and not necessarily meant to be representative of a real process. We aim to apply our method to analyze objective tradeoffs for different practical process designs from the literature as future work.

The conversions of the two reactors are 80% and 95% which means that 80% or 95% of the reactants are transformed into product. The two separators can obtain 25%

and 40% of the product from the flow relatively. The total feed flow into the reactors is constrained as 100mol/h and the total flow goes into the separators is calculated from the conversions of the reactors.

For annualized net present cost, cost references of 2000, 5000, 700, 1200 dollars are set for the capital cost of the facilities. Operating cost and carbon emission parameters of all the facilities are set as 2, 0.9, 0.2, 0.15 dollar per mol/h and 80, 50, 80, 35 kg CO<sub>2</sub> per mol/h relatively.

**Table 1:** uncertain parameters in Risk and Equity objectives.

Facility	Risk parameter	Equity parameter
1	100 or 80	800 or 40
2	50 or 30	500 or 30
3	20 or 15	50 or 70
4	10 or 5	300 or 20

Risk and equity objectives are linear combination of the flow in each facility with uncertain parameters. Possible values of the parameters are shown in the Table 1. As social objectives such as equity can be difficult to quantify, we consider that these values can differ by a large amount. Each facility has two possible values of both risk and equity parameters, all 256 scenarios from their combinations are considered in the optimization. Despite having only two uncertain parameters, we note that the wide range of uncertainty and large number potential scenarios resulting from their combination showcases the ability of our proposed approach to deal with highly uncertain objectives. We also note that our proposed approach also allows for the quantification of uncertain parameters with a larger number of values.

### STOCHASTIC OBJECTIVE REDUCTION ALGORITHM

In this section, a process for systematically reducing the dimensionality of a MILP with many uncertain objectives into a problem with three or fewer objective functions is presented. The core of the algorithm, which considers deterministic objectives, was originally developed in our group's previous work and is summarized as follows [4]. First, cost vectors (the gradient vector of the objective function) are projected onto the constraint surfaces. Strength of interaction is defined as the inner product of the projected vectors and a weighted sum of the constraint interaction strengths is used to determine the total objective correlation strength. Objective correlation strength is scaled to be between 0 and 1. This information is embedded into an objective correlation graph, which consists of nodes corresponding to the

different objectives and edges weighted by the objective correlation strength. Community detection is applied to identify groups of objectives that are strongly correlated within the group and competing with objectives in other groups. For more details about the objective reduction algorithm, please reference our previous works [4,5].

For problems with uncertain objective functions, this uncertainty will manifest itself as uncertainty in the edge weights of the objective correlation graph. For each realization of uncertainty, a different objective correlation graph can be obtained. Since the true realization of uncertainty is not known *a priori*, it is essential to identify a grouping of objectives that performs robustly well for all realizations of uncertainty to be able to obtain a full understanding of the tradeoffs between the many objectives.

### Stochastic community detection

The community structure within a network manifests as a statistically significant configuration of edges which can be evaluated through the value of the modularity. [6] The modularity is described by the number of edges falling within groups minus the expected number in an equivalent network with edges placed at random, as depicted in formulation (10):

$$\max_z \sum_{i \in I, i' \in I} \left( \frac{A_{ii'}}{m} - \frac{a_i a_{i'}}{m^2} \right) z_{ii'} \quad (10a)$$

$$\text{s.t. } z_{ii} = 1 \quad \forall i \in I \quad (10b)$$

$$z_{ii'} + z_{ii''} - z_{i'i''} \leq 1 \quad \forall i \in I, i' \in I \setminus \{i\}, i'' \in I \setminus \{i, i'\} \quad (10c)$$

$$z_{ii'} \in \{0, 1\} \quad \forall i \in I, i' \in I \quad (10d)$$

where  $I$  is the set of nodes in the graph,  $A$  is the graph adjacency matrix,  $a_i = \sum_{i' \in I} A_{ii'}$  is the degree of node  $i$ ,  $m = \sum_{i \in I} a_i$  is twice of the total number of edges in the network, and  $z_{ii'}$  is a binary partitioning variable that is one if nodes  $i$  and  $i'$  are assigned to the same community, and zero otherwise. The community detection is accomplished by maximizing modularity.

To apply this approach to uncertain graphs, such as those obtained from our objective reduction approach with uncertain objectives, the traditional community detection problem must be recast as a stochastic optimization problem. In this case, a reasonable goal is to pursue the most robust partition that has consistently high modularity across all realizations of uncertainty. Here, we use expected value of modularity to evaluate partitions:

$$\max_z E_{\Sigma} \left[ \sum_{i \in I, i' \in I} \left( \frac{A_{ii'}}{m} - \frac{a_i a_{i'}}{m^2} \right) z_{ii'} \right] \quad (11)$$

$$\text{s.t. } (10b - d)$$

Note that other stochastic metrics, such as conditional value at risk, may also be used in place of expected value; we will assess how this proposed approach

extends to other metrics in future work. To simplify the equation, we assume all scenarios are equally likely and replace the expectation operator with an average over all scenarios:

$$\max_z \frac{1}{|K|} \sum_{k \in K} \sum_{i \in I, i' \in I} \left( \frac{A_{ii'k}}{m_k} - \frac{a_{ik} a_{i'k}}{m_k^2} \right) z_{ii'k} \quad (12)$$

$$\text{s.t. } (10b - d)$$

Set  $K$  indicates all the scenarios from the uncertain parameters. Unfortunately, fast algorithms for community detection such as spectral partitioning [7], fast unfolding [8], or the Leiden algorithm [9] are not directly applicable to the problem. However, this problem can be decomposed into a set of single-scenario community detection problems with a slightly modified objective. First, copy variables corresponding to each scenario are introduced to generate exploitable structure:

$$\max_z \frac{1}{|K|} \sum_{k \in K} \sum_{i \in I, i' \in I} \left( \frac{A_{ii'k}}{m_k} - \frac{a_{ik} a_{i'k}}{m_k^2} \right) z_{ii'k} \quad (13)$$

$$\text{s.t. } z_{iik} = 1 \quad \forall i \in I, k \in K$$

$$z_{ii'k} + z_{ii''k} - z_{i'i''k} \leq 1 \quad \forall i \in I, i' \in I \setminus \{i\},$$

$$i'' \in I \setminus \{i, i'\}, k \in K$$

$$z_{ii'k} \in \{0, 1\} \quad \forall i \in I, i' \in I, k \in K$$

$$z_{ii'k} = z_{ii'k'} \quad \forall i \in I, i' \in I, k \in K, k' \in K$$

In this problem, the non-anticipativity constraints  $z_{ii'k} = z_{ii'k'}$  are complicating, such that if they were removed, the stochastic problem could be treated as  $|K|$  independent community detection problems. Using column generation [10] can help to solve formulation (13). It can be transformed into the following master problem:

$$\max_{z, \lambda} \frac{1}{|K|} \sum_{k \in K} \sum_{c \in C} \lambda_{ck} f_{ck}^* \quad (14)$$

$$\text{s.t. } \sum_{c \in C} \lambda_{ck} z_{ii'ck}^* = z_{ii'} \quad \forall i \in I, i' \in I, k \in K \quad (\pi)$$

$$\sum_{c \in C} \lambda_{ck} = 1 \quad \forall k \in K \quad (\mu)$$

$$\lambda_{ck} \in \{0, 1\} \quad \forall k \in K, c \in C$$

where  $C$  is the set of columns generated which correspond to a specific partitioning of the graph into communities,  $f_{ck}^*$  is the modularity of column  $c$  in scenario  $k$ ,  $z_{ii'ck}^*$  is the partitioning variable in the corresponding modularity.  $\pi$  and  $\mu$  are the dual variables corresponding to the constraints in the same line, which are used to generate new columns (potential partitions) via the following set of  $|K|$  subproblems, one per scenario  $k$ :

$$\max_z \sum_{i \in I, i' \in I} \left( \frac{A_{ii'k}}{m_k} - \frac{a_{ik} a_{i'k}}{m_k^2} - \pi_{ii'k} \right) z_{ii'k} + \mu_k \quad (15)$$

$$z_{iik} = 1 \quad \forall i \in I, k \in K$$

$$z_{ii'k} + z_{ii''k} - z_{i'i''k} \leq 1 \quad \forall i \in I, i' \in I \setminus \{i\},$$

$$i'' \in I \setminus \{i, i'\}, k \in K$$

$$z_{i'k} \in \{0, 1\} \quad \forall i \in I, i' \in I, k \in K$$

Formulation (15) is the modularity in scenario  $k$  with two Lagrangian terms resulting from the column generation decomposition. Since both are constants obtained from the dual solution of the master problem, only the  $\pi z$  term needs to be considered when implementing the objective change into a community detection algorithm. Doing so is straightforward: using Newman's spectral partitioning algorithm [7], which makes use of the eigenvalues and eigenvectors of the modularity matrix  $M$ , we modify the modularity matrix by subtracting the symmetric part of the  $\pi$  matrix:

$$\widehat{M}_{ii'} = \frac{A_{ii'k}}{m_k} - \frac{a_{ik}a_{i'k}}{m_k^2} - \frac{\pi_{iik} + \pi_{i'ik}}{2} \quad (16)$$

The eigenvalues and eigenvectors of the new matrix  $\widehat{M}$  are then used to partition the graph in the same way as before. Alternatively, when using the fast unfolding (Louvain) [8] and Leiden [9] algorithms, we take grouping steps which give the largest increase in the modularity augmented with the Lagrangian  $\pi z$  terms, rather than just the modularity. As in any column generation approach, the algorithm proceeds by iteratively solving the master problem and subproblems until no subproblem returns a partition with positive objective value, indicating that no partition not already in the set of columns has the potential to improve the objective value.

## RESULTS AND DISCUSSION

To study the stochastic design problem, objective correlation graphs are generated for all 256 possible scenarios of the social objective parameters. We then compare the results of community detection applied to each individual graph and show the resulting grouping frequencies are in Table 2. Notably,  $[[N, H], [R, E]]$  and  $[[N, E], [H, R]]$  emerge as the most common partitions, where the symbols N, E, H, and R refer to the four different objectives as introduced in the problem formulation section and defined again in Table 2. However, we observe that four different "best" objective groupings occur depending on which scenario is actually realized, and it is unclear which performs best, on average, over all possible scenarios with this approach. It's essential to highlight that there aren't any uncertain values in the annualized net present cost and emission objectives in our system, signifying a constant correlation strength between them. The established correlation strength, determined through our previous algorithm, is 0.813, a relatively but not overwhelmingly high value which explains the prevalence of 111 instances where annualized net present cost and emission fall within the same group.

In contrast, the introduction of uncertain parameters in risk and equity objectives brings variability to the correlation strengths between different objectives. For instance, with risk parameters set at [100, 50, 20, 10] and

equity parameters at [800, 500, 70, 20], the correlation strength between risk and equity is notably high at 0.991, resulting in the grouping  $[[N, H], [R, E]]$ . Conversely, when using [80, 30, 20, 10] and [40, 500, 50, 20] as risk and equity parameters, the correlation strength significantly decreases to 0.094, leading to the grouping  $[[N, E], [H, R]]$ . Thus, the frequencies that risk and equity are in the same group or not depends on the realization of uncertain parameter set of the two objectives. In this case, these two objectives are in the same group over half of the scenarios.

**Table 2:** Community detection results of the uncertain system. N: annualized net present cost, H: carbon emissions, R: risk, E: Equity.

Grouping	Frequency
$[[N, H], [R, E]]$	94
$[[N, E], [H, R]]$	95
$[[N], [H, R, E]]$	50
$[[R], [N, H, E]]$	17

**Figure 2.** Grouping and expectation results of the average graph (left) and the most robust grouping (right)

Despite this variability, to address the tradeoffs within the uncertain design problem effectively, it is rational to identify the most robust partition across all scenarios as defined by the expected modularity over all scenarios. The results, as depicted in Fig. 2 through the application of the stochastic algorithm, reveal that the optimal grouping is,  $[[N, E], [H, R]]$ . It is important to note that this grouping differs from what one would find by just averaging the edge weights from the objective correlation graphs generated from all 256 scenarios,  $[[N], [H, R, E]]$ . The expectation of the modularity in the optimal solution is 0.0649, and the expectation of the second-best partition,  $[[N, H], [R, E]]$  is 0.0615. Both are higher than the partition of the average graph, which gives an expected modularity of 0.0475, suggesting that a

**Figure 3:** Illustration of different design configurations

**Figure 4:** Weighted sum Pareto frontier between (left) risk and cost + equity + emission as well as (right) risk+emission and cost + equity in the scenario of  $[[R], [H, N, E]]$  grouping.

deterministic approach of averaging edge weights is not an effective mechanism for identifying objective groupings that preserve tradeoff information in as many scenarios as possible.

For further study of the system, we compare the weighted sum Pareto frontiers for one scenario using both robust grouping found by community detection and the grouping that is “best” for the specific scenario considered,  $[R], [H, N, E]$ . Fig. 3 illustrates all optimal design configurations occurring along the Pareto frontier. Pareto frontiers are depicted on the left side of Fig. 4 for the scenario which uses risk and equity parameters set at  $[100, 30, 15, 5]$  and  $[40, 30, 70, 300]$ . Points sharing the same color on the Pareto frontier represent the same optimal design configuration within the Pareto frontier. In configuration 1, the emphasis is on risk reduction, leading to the utilization of Reactor B and Separator B, both possessing the lowest risk parameters. Conversely, Configuration 3 aims to minimize the sum of costs, equity, and emissions. Only Reactor A is constructed due to its lower cost, emissions, and equity parameters. Separator A and B are both utilized with specific flow values to optimize the three objectives.

In the middle of the Pareto frontier, the tradeoff point results from balancing the sum of costs, equity, and emissions against risk. In this case, only Reactor B is employed compared to Configuration 3, and the flow values in the separators are also different. The Pareto frontier for the optimal result's grouping,  $[[N, E], [H, R]]$ , is displayed on the right side of Fig. 4. The trade-off point using the  $[[R], [H, N, E]]$  grouping also appears in the Pareto frontier of  $[[N, E], [H, R]]$ , suggesting that employing the most robust grouping can provide valuable insights in a certain extent, and demonstrating that tradeoff

information can be preserved in the robust grouping even when it is not the same as the “best” grouping for a particular scenario.

However, in numerous other scenarios, the Pareto frontier of  $[[N, E], [H, R]]$  does lose a bit of information about design tradeoffs in comparison to the individual scenario's best grouping. This is not unexpected, as choosing a grouping of objectives with suboptimal modularity for a particular scenario inherently means that objectives with some degree of competition are being grouped together, which will result in loss of information regarding tradeoffs between the grouped objectives. The  $[[N, E], [H, R]]$  grouping with 95 times and other scenarios with no information loss in  $[[N, E], [H, R]]$  reveal that opting for the most robust grouping is a practical choice when attempting to understand tradeoffs in many-objective optimization problems with uncertain parameters.

## CONCLUSIONS AND FUTURE WORK

Environmental and social considerations for sustainability are essential aspects of optimal design problems for modern chemical production infrastructure. However, they can be subject to a great deal of uncertainty making critical evaluation of tradeoffs between objectives challenging. In this work, we developed a method for systematically identifying groups of objectives that, on average, tend to be more correlating than competing, forming the basis of a dimensionality reduction in many-objective optimization problems that is robust to uncertainty. Through the use of an illustrative case study with a two reactors, two separators superstructure, the efficacy of our approach towards identifying an objective grouping with low loss of tradeoff information was demonstrated.

As future work, we aim to apply this framework to a set of more practically relevant design problems from the literature such as a hydrogen production process and green ammonia production system, in order to better understand the tradeoffs inherent in designing future chemical production infrastructure. This analysis will entail further development of our objective reduction algorithm, such that it can be applied to nonlinear, as well as linear, many-objective optimization problems.

## ABSTRACT

This work explores the economic and environmental opportunities for sustainable aviation fuel (SAF) in the Brazilian sugarcane industry. Brazil was one of the first countries to use biomass fuels for transportation and is currently the 2<sup>nd</sup> largest producer of the world's bioethanol. Bioethanol produced from sugarcane can be upgraded to SAF via the American Society for Testing and Materials (ASTM)-certified pathway alcohol-to-jet (ATJ); however, at least two challenges exist for commercial implementation. First, technologies to produce bio-jet fuels cost more than their conventional fossil-based counterparts. Second, there is considerable uncertainty regarding returns on investment as the sugar and ethanol markets have been historically volatile. As such, we propose a new optimization model to inform risk-conscious investment decisions on SAF production capacity in sugarcane mills. Specifically, we propose a linear program (LP) to model an integrated sugarcane mill that can produce sugar, ethanol, or SAF. Then, using historical price data as scenarios, we determine optimal operation at different market scenarios. Based on the relationship between ethanol, sugar, and SAF prices, we show that the integrated sugarcane mill operates in four production regions. Furthermore, through sensitivity studies, we quantify the impact of SAF prices showing a premium SAF price of 2 \$ L<sup>-1</sup> results in 100% of scenarios favoring SAF production. These results allow us to guide SAF buyers or policymakers by showing the price point for SAF to become attractive for sugarcane mill integration.

## INTRODUCTION

The aviation industry accounted for 2.8% of global GHG emissions in 2019. These emissions are expected to increase due to more global air traffic and high dependence on traditional fossil jet fuel [1]. In response to global sustainability efforts following the 2016 Paris Agreement, the aviation industry pledged to reduce emissions by 50% by 2050 [2]; however, decarbonization options are limited in this industry as electrification and advanced fuels (e.g., hydrogen) require two or three decades of development [3]. Sustainable Aviation Fuels (SAFs) are one of the most promising options for reducing greenhouse gas (GHG) emissions in aviation due to their technology readiness and drop-in compatibility with existing aircraft

and fuel systems; however, high costs compared to fossil-based fuels have led to slow capacity development [4].

SAF demand is expected to increase significantly by the year 2050 to combat high GHG emissions in the aviation industry. To reach the SAF demand track for net-zero emissions by 2050, the current global SAF capacity would need to increase by ~46 billion L by 2030 [4,5]. Thus, there is an urgent need to increase global SAF capacity efficiently and economically to meet 2050 sustainability goals.

Brazil was one of the first countries to use biofuels for transportation in the 1970s. In 2023, 25.3 million m<sup>3</sup> of bioethanol was consumed (mostly to fuel private vehicles in the country, 10.1 million m<sup>3</sup> used as a gasoline

blend, and 15.2 million m<sup>3</sup> used as direct fuel) [6]. Brazil is currently the second-largest producer of the world's bioethanol and the first-largest bioethanol producer from sugarcane [7]. A conventional sugarcane mill starts with juice extraction from crushed sugarcane stalks. The extracted juice is treated to remove impurities, and the clarified juice is then shared between the ethanol distillery and the sugar factory. The juice split fractions for ethanol and sugar production are decided at the beginning of a harvesting season and are important operational decisions for the mill [8]. Typical juice split fractions vary between 40% and 60%, with many sugarcane mills only containing installed capacity for sugar production between 50–75% of the total juice extracted during one season [8].

Several existing sugarcane mills have already expanded their product range beyond sugar and ethanol to produce fertilizer, industrial salts, animal feed, etc. These diversified products boost the overall financial security of the sugarcane mill and provide an opportunity to jump into previously unexplored markets [9–10]. Following their footsteps, bioethanol can be upgraded to jet fuel via the ASTM-certified pathway alcohol-to-jet (ATJ) [11]. ATJ converts biomass to an alcohol intermediate (typically ethanol) to jet fuel via the following three conversion steps: alcohol dehydration, oligomerization, and hydrogenation. Partnerships targeting SAF production exist between companies producing alcohols and converting alcohols to fuels, notably BioChemtex/Gevo and LanzaTech/Swedish Biofuels [12].

Bioethanol from sugarcane is considered a first-generation biofuel since it is derived from a food-based feedstock. Although first-generation biofuels are questioned due to food security, they are currently economically feasible and commercially supplied [13]. Sustainable biofuel production generally considers second-generation (non-edible crops) to fourth-generation (waste) feedstocks [14]. From an environmental perspective, Foteinis et al. [15] illustrate the non-linear nature of the relationship between feedstock generation and environmental impact. Foteinis et al. [15] compare life cycle analysis (LCA) results for biodiesel production from sunflower seed oil (first-generation), used cooking oil (second-generation), and micro-algae (third-generation). Biodiesel from used cooking oil (second-generation) had the lowest environmental impact and third-generation biodiesel had the highest environmental impact [15].

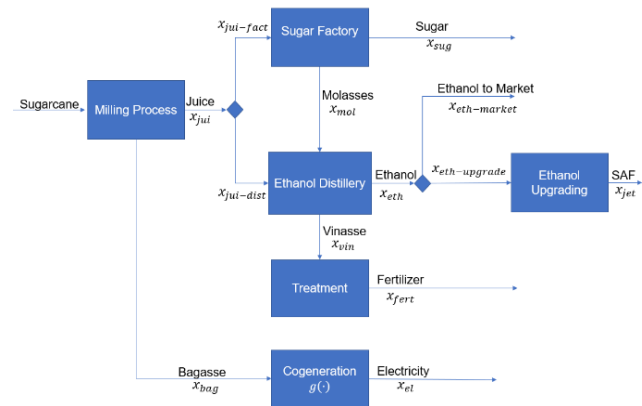

Integration of SAF in the Brazilian sugarcane industry presents complex and interdependent optimization problems. Several factors complicate the decision to invest in new technologies in the sugarcane industry. First, the mill's final product mixes must be decided at the beginning of a harvesting season, with little operational flexibility throughout the remaining season [16]. Second, weather conditions, international sugar prices, and

instability of governmental fuel policies and subsidies create substantial uncertainties in sugar and ethanol market prices [8]. The interdependence of these two factors leads to large uncertainty on the return on investment, which hinders risk-conscious mill owners from investing in new technologies. Furthermore, it is well known that SAF technologies are not cost-competitive with their fossil-based counterparts [4], leading to additional financial risk with SAF integration.

Mutran et al. [8] developed a multi-objective, two-stage stochastic program to de-risk bioenergy investment decisions in the sugarcane industry to address some of these complexities. In this work, we extend the optimization analysis of Mutran et al. [8] to inform risk-conscious investment decisions on SAF capacity in sugarcane mills by considering the uncertainty in sugar, ethanol, and jet fuel markets and the interrelation between production decisions in terms of the final product mix. Furthermore, we quantify the impact of government incentives or environmentally conscious industry contracts on SAF economics.

## METHODS

We propose a linear program (LP), adapted from [8], to study the economic risk of integrated SAF production in a sugarcane mill in Brazil. Specifically, we study the optimal operation of an integrated sugarcane mill that can produce sugar, ethanol, and SAF.

**Figure 1.** Process flow diagram (PFD) of integrated SAF production in a single sugarcane mill.

Fig. 1 presents a process flow diagram of the integrated sugarcane mill process. The units in this process include sugarcane milling (mill), sugar factory (fact), ethanol distillery (dist), treatment of vinasse residues (treat), a cogeneration system using a traditional Rankine cycle with back-pressure turbine (rank), and an ethanol upgrading to SAF (upgrade). Saleable products from the sugarcane plant comprise sugar (sug), ethanol directed to the market (eth-market), SAF (jet), fertilizer from

vinasse residue (fert), as well as electrical power for the regulated market (el). In contrast, intermediates are considered to be juice (jui), juice directed to the sugar factory (jui-fact), juice directed to the ethanol distillery (jui-dist), ethanol directed to the upgrading (eth-upgrade), bagasse (bag), molasses (mol), and vinasse (vin).

**Table 1:** Nominal parameter values from [8] except  $\lambda_{jet}$  and  $\omega_{eth,upgrade,jet}$  which originate from [17].

Symbol	Description	Nominal Value
$\omega_{cane,mill,jui}$	Conversion	0.734 tonne/tonne
$\omega_{cane,mill,bag}$	Conversion	0.266 tonne/tonne
$\omega_{jui,fact,sug}$	Conversion	0.123 tonne/tonne
$\omega_{jui,dist,eth}$	Conversion	0.123 tonne/m <sup>3</sup>
$\omega_{mol,dist,eth}$	Conversion	0.373 tonne/m <sup>3</sup>
$\omega_{eth,upgrade,jet}$	Conversion	0.4284 m <sup>3</sup> /m <sup>3</sup>
$\omega_{vin,treat,fert}$	Conversion	1 m <sup>3</sup> /m <sup>3</sup>
$\rho_{mol,fact}$	Generation	1.05 tonne
$\rho_{vin,dist}$	Generation	10 m <sup>3</sup>
$\Gamma_{mill}$	Maximum Capacity	3,000,000 tonne/year
$\Gamma_{fact}$	Maximum Capacity	2,202,000 tonne
$\Gamma_{upgrade}$	Maximum Capacity	270,000 m <sup>3</sup>
$\Gamma_{dist}$	Maximum Capacity	2,202,000 tonne
$\gamma_{sug}$	Minimum Production	0.4
$\gamma_{eth}$	Minimum Production	0.4
$\gamma_{eth-market}$	Minimum Production	0.2
$\gamma_{jet}$	Minimum Production	0.4
$\lambda_{sug}$	Production Cost	1,150 \$/tonne
$\lambda_{eth}$	Production Cost	1,800 \$/m <sup>3</sup>
$\lambda_{jet}$	Production Cost	4,600 \$/m <sup>3</sup>
$\lambda_{el}$	Production Cost	7 \$/MWh
$\lambda_{fert}$	Production Cost	0.002 \$/m <sup>3</sup>

In the mathematical model formulation that follows, the continuous variables  $x_i \geq 0$  refer to the yearly production of product  $i$ , the parameters  $\omega_{i,u,j}$  refer to the conversion of product  $i$  to product  $j$  in unit  $u$ , the parameters  $\rho_{j,u}$  refers to the yield of intermediate product  $j$  in unit  $u$ , the parameters  $\lambda_i$  refers to the production cost to produce product  $i$ , the parameters  $\pi_i$  refers to the market price for product  $i$ , the parameters  $\Gamma_u$  refers to the maximal annual processing capacity of unit  $u$ , and the parameters  $\gamma_i$  refers to the minimum production fraction of

product  $i$ . Table 1 reports the nominal parameter values.

The LP is formulated below in Eq. (1). The objective is to maximize the sugarcane mill's expected revenue (i.e., profit) Eq. (2) constrained by mass balances Eq. (3)-(13), unit capacity restrictions Eq. (14)-(16), and minimum production constraints Eq. (17)-(20). Minimum production constraints are enforced to maintain typical juice shares for sugar and ethanol production (40 – 60%), limit food supply (sugar) competition, sufficiently utilize installed SAF capacity, and require a contribution to the bioethanol available for private vehicle use.

This optimization formulation is an adaption of the model proposed by Mutran et al. [8] with the addition of the SAF upgrading unit Eq. (9)-(10) and the minimum production constraints Eq. (16)-(19). Electricity generation is determined using a piece-wise linear surrogate model to determine the amount of surplus bagasse based on the shares of ethanol and sugar. We denote this relationship as  $g(\cdot)$ , represented by Eq. (18)-(20) in Mutran et al. [8].

$$\max R(x|\pi, \lambda, \omega, \rho)$$

$$s. t. \text{ Eq. (3) – (20)} \quad (1)$$

$$g(\cdot) \geq 0$$

$$x_i \geq 0$$

$$R(x) = (\pi_{sug} - \lambda_{sug})x_{sug} + \pi_{eth}x_{eth-market} - \lambda_{eth}x_{eth} + (\pi_{jet} + \pi_{premium} - \lambda_{jet})x_{jet} + (\pi_{el} - \lambda_{el})x_{el} + (\pi_{fert} - \lambda_{fert})x_{fert} \quad (2)$$

$$x_{jui} = \Gamma_{mill}\omega_{cane,mill,jui} \quad (3)$$

$$x_{bag} = \Gamma_{mill}\omega_{cane,mill,bag} \quad (4)$$

$$x_{jui} = x_{jui-fact} + x_{jui-dist} \quad (5)$$

$$x_{sug} = x_{jui-fact}\omega_{jui,fact,sug} \quad (6)$$

$$x_{mol} = x_{sug}\rho_{mol,fact} \quad (7)$$

$$x_{eth} = x_{jui-dist}\omega_{jui,dist,eth} + x_{mol}\omega_{mol,dist,eth} \quad (8)$$

$$x_{eth} = x_{eth-market} + x_{eth-upgrade} \quad (9)$$

$$x_{jet} = x_{eth-upgrade}\omega_{eth,upgrade,jet} \quad (10)$$

$$x_{vin} = x_{eth}\rho_{vin,dist} \quad (11)$$

$$x_{fert} = x_{vin}\omega_{vin,treat,fert} \quad (12)$$

$$x_{el} = g(\cdot) \quad (13)$$

$$x_{jui-fact} \leq \Gamma_{fact} \quad (14)$$

$$x_{jui-dist} \leq \Gamma_{dist} \quad (15)$$

$$x_{eth-upgrade} \leq \Gamma_{upgrade} \quad (16)$$

$$x_{jui-fact} \geq \gamma_{sug}x_{jui} \quad (17)$$

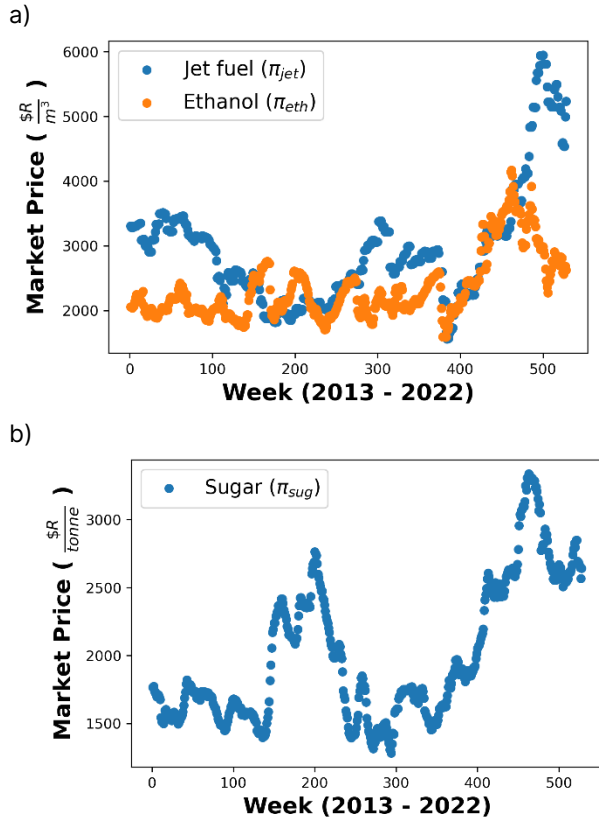

$$x_{eth} \geq \gamma_{eth}x_{jui}\omega_{jui,dist,eth} \quad (18)$$

$$x_{eth-market} \geq \gamma_{eth-market}x_{eth} \quad (19)$$

$$x_{jet} \geq \gamma_{jet}x_{eth} \quad (20)$$

Product prices for sugar, ethanol, and jet fuel are taken from weekly price records in Brazil over the period of 2013–2022 [18-20] a total of 526 observations. Fig. 2 shows the weekly price signals ( $\pi_{jet}$ ,  $\pi_{eth}$ , and  $\pi_{sug}$ ) for the three main products expressed in the 2023 \$R. We

assume that SAF prices are equivalent to market prices of jet fuel plus some premium ( $\pi_{premium}$ ) paid by airline companies or policy incentives.

**Figure 2.** Weekly historical market data for ethanol and jet fuel (a) and sugar (b) in Brazil from 2013 to 2022 expressed in the 2023 \$R [18-20].

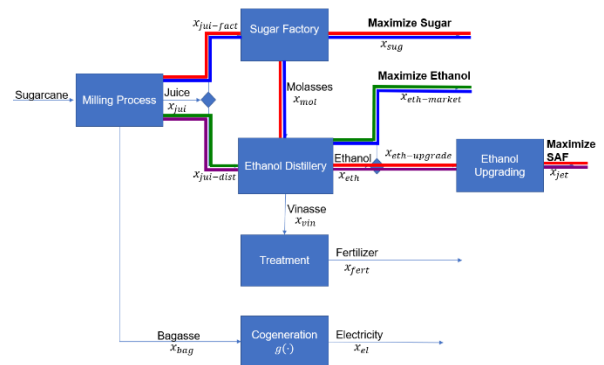

## RESULTS

We start by solving optimization problem Eq (1) – (20) independently for each week from 2013 to 2022, considering historical price data for sugar, ethanol, and jet fuel (Fig. 2). We then map the optimization results for each scenario (week) into four categories based on the core products:

1. Maximize sugar and send the maximum amount of residual ethanol to the market (blue in Fig. 3 and Fig. 4).
2. Maximize sugar and upgrade the maximum amount of residual ethanol to SAF (red in Fig. 3 and Fig. 4).
3. Maximize ethanol and send the maximum amount of residual ethanol to the market (green in Fig. 3 and Fig. 4).
4. Maximize ethanol and upgrade the maximum amount to SAF (purple in Fig. 3 and Fig. 4)

Fig. 3 shows the optimal operation pathways

colored on the process flow diagram. Fig. 4 shows the percentage of market scenarios (weekly) for each of the four operation pathways while varying the SAF premium parameter  $\pi_{premium}$ . At a SAF premium price of 1 \$ L<sup>-1</sup>, the sugarcane mill prefers to operate under standard practice, maximizing sugar production and sending any ethanol produced to the market. On the contrary, at a SAF premium of 3 \$ L<sup>-1</sup>, the sugarcane mill prefers to send all its resources towards maximizing SAF production. Both of these scenarios represent cases where there is one predominant operating mode regardless of market prices. In between these cases ( $\pi_{premium} = 1.5$  to 2.5 \$ L<sup>-1</sup>) we observe variation between optimal operating modes. Furthermore, after applying a SAF premium of 2 \$ L<sup>-1</sup>, 100% of all market scenarios favor SAF production (red and purple) over selling ethanol to the market (green and blue).

**Figure 3.** Optimal operation pathways colored on the process flow diagram (PFD) of integrated SAF production in a single sugarcane mill.

The multiple optimal operating modes in SAF premium cases 1.5 \$ L<sup>-1</sup> to 2.5 \$ L<sup>-1</sup> (Fig. 4) motivate investigating the operational flexibility in the sugarcane mill, i.e., changing the product flow rates in response to weekly market conditions. Standard practice in the sugarcane industry is to choose ethanol and sugar shares at the beginning of the harvesting season with little flexibility throughout the year. Our analysis shows there may be some financial benefit to change operation in response to market prices (different optimal operating modes). Profit savings from flexibility may be significant for SAF integration in the sugarcane industry, especially with uncertainty in monetary incentive timelines for SAF.

**Figure 4.** Percentage of scenarios under each operating region at different levels of SAF premiums

Furthermore, the competition that may arise between ethanol use for ground and air transportation should be carefully considered. If the majority of sugarcane mills favor SAF production over selling ethanol to the market (e.g., SAF premium of 2 \$ L<sup>-1</sup>), private vehicles in the country may be forced to use gasoline (electric vehicles in Brazil are currently underdeveloped). Future work should include LCA to better understand the environmental impact of producing SAF from sugarcane bioethanol and bioethanol produced from other sugarcane mill waste residues (i.e., bagasse).

## CONCLUSION

In summary, we proposed a LP to model SAF production integrated in the Brazilian sugarcane industry. Then, using historical prices, we compute the optimal operation over a variety of market scenarios for ethanol, sugar, and SAF prices. We show that the integrated sugarcane mill operates in four production regions based on the relationship between ethanol, sugar, and SAF prices. Furthermore, through sensitivity studies, we quantify the impact of SAF prices (e.g., price premiums airlines may pay for SAF compared to conventional jet fuel to meet industry/government decarbonization goals) and discuss the potential for operational flexibility in a sugarcane mill.

This research motivates the following open research questions:

1. How to economically distribute ethanol upgrading technologies throughout Brazil to allow for ethanol-use flexibility (integrated vs. stand-alone)?
2. How to develop detailed process designs for integrated SAF-producing systems under uncertainty?
3. How to integrate techno-economic analysis and

policy design for biofuel technologies?

4. What is the difference in carbon intensity in the ground and air transportation sectors?

## ABSTRACT

Triacetic acid lactone (TAL) is a bio-privileged molecule with potential as a chemical precursor, traditionally synthesized from petroleum. Current trends are shifting towards the use of renewable biomass or CO<sub>2</sub>-derived feedstocks to enhance sustainability. However, comprehensive studies on the techno-economic viability and carbon life cycle of such methods are limited. This study assesses TAL production from conventional glucose and a novel approach co-feeding *Yarrowia lipolytica* (YL) with glucose and formic acid (FA), aiming for a more cost-effective and eco-friendly process. We confront the inherent challenges in this process by exploring different technology scenarios using kinetic bioprocess modeling underpinned by techno-economic analysis (TEA) and life cycle assessment (LCA) to identify the most cost-effective and sustainable routes to TAL production. A noteworthy component of our investigation centers around the prospect of recycling and utilizing the CO<sub>2</sub> emitted from the YL bioreactor to eliminate greenhouse gas emissions inherent in aerobic fermentation processes. The study combines TEA and LCA to dissect the proposed TAL bio-production routes, evaluating the sustainability of the process and the implications of net-zero greenhouse gas emission manufacturing. We employed SuperPro Designer and Aspen software for process simulation and energy balance computations. The results underscore the benefits of CO<sub>2</sub> recycling in TAL production, with an estimated minimum selling price (MSP) slightly increasing by 6.21-7.80% compared to traditional methods, but significantly undercutting the market price of \$51000/mt-TAL and achieving net-negative CO<sub>2</sub> emissions. This research illustrates a viable route to bio-production with net-zero emissions, providing a model for future bioprocessing and industrial practices.

**Keywords:** Technoeconomic Analysis, Life Cycle Assessment

## INTRODUCTION

Energy systems across the globe are moving towards more integrated, cleaner, and sustainable processes [1]. However, attaining a carbon-free economy presents a formidable challenge, as it requires a significant reduction in emissions from hard-to-decarbonize sectors such as industrial and chemical processes. This study explores the production of triacetic acid lactone (TAL) through carbon dioxide utilization in aerobic

fermentation cycles. The goal is to achieve Net-Zero emissions by identifying economically viable and environmentally friendly processes to produce chemicals. The study aims to guide the development of sustainable industrial methodologies using TAL as a case-study.

TAL is a promising molecule for sustainable chemical production, obtained through bio-production from renewable resources [2]. It has the potential to serve as a key precursor for the production of valuable chemical intermediates, as well as end products like sorbic acid [3],

which have significant global demand (market size was USD 500 million in 2022, reported by Reports and Data, a market research and consulting company). Traditional synthesis methods rely on petrochemical processes that are not sustainable [4]. With the engineering *Yarrowia lipolytica* (YL), a yeast and model organism and naturally proficient lipid producer, to produce TAL, we can shift towards using biomass as a renewable feedstock [5-6]. This addresses the growing need for carbon-neutral production pathways. However, bioproduction involves metabolic processes that produce significant amounts of CO<sub>2</sub>, which is typically considered waste [7]. In this study, the bioprocess emits CO<sub>2</sub> at concentrations greater than 99 wt.% by assuming high-purity O<sub>2</sub> used in providing aerobic fermentation. [8]. Rather than releasing it into the atmosphere, there is an opportunity to repurpose this emission [8]. The current trend is to convert CO<sub>2</sub> into value-added chemicals, which aligns with the industrial symbiosis paradigm of repurposing waste streams to reduce environmental impact [9].

One innovative approach is the electrocatalytic conversion of CO<sub>2</sub> into formic acid [10-11]. This process recycles carbon and transforms it into a chemical with significant utility in various industrial applications. Formic acid is an auxiliary energy source for numerous microbial species that use formate dehydrogenase enzymes (FDH) to transfer electrons to NAD<sup>+</sup>, generate NADH and release CO<sub>2</sub> [10-11]. This metabolic pathway is central to the co-feeding strategy used in the TAL production process with YL [10-11]. By co-feeding formic acid with glucose, YL can utilize additional reducing power for biosynthesis, contributing to the efficient production of TAL. The integration of CO<sub>2</sub>-to-formic acid utilization in the production process has a dual benefit. It provides a supplementary energy source that enhances microbial growth and product yield and represents a strategic move toward decarbonization. The application of this technology on an industrial scale promises to reduce the carbon footprint of biochemical production and to mitigate the impact of climate change associated with industrial activities that are otherwise difficult to decarbonize.

When developing a bioprocess to supplement or replace an existing chemical product, it is crucial to conduct a techno-economic analysis. Despite the significant economic and environmental implications of developing biorefinery processes for TAL manufacture, only a few studies have examined it through techno-economic analysis (TEA) [12-13]. Based on the current retail price of \$550/kg, sourced from Biosynth (bio-synth.com), and a bulk chemical price of \$51,000/mt from vendors, all the scenarios are economically feasible in the proposed TAL production routes. By integrating carbon dioxide recycling into the current systems, biogenic carbon capture could be achieved, leading to a substantial reduction in greenhouse gas (GHG) emissions.

This study explores a novel route for TAL production by focusing on CO<sub>2</sub>-to-formic acid electrocatalysis and co-feeding formic acid with glucose in the YL process. This approach highlights the transformative potential of recycling CO<sub>2</sub>, which is traditionally viewed as a drawback in economics (options such as storage only add costs) [14], into a value-added input. This enhances the sustainability profile of TAL production, epitomizing the principles of a circular economy. Furthermore, the proposed model has the potential to shift toward more sustainable industrial practices, meet economic and environmental benchmarks, and contribute to the goal of achieving net-zero greenhouse gas emissions.

## PROCESS OVERVIEW

The focus of the present study is to conduct a thorough comparison between two YL production systems, each scaled to produce 100 metric tons of TAL annually, examining their techno-economic and life cycle aspects. The first system utilizes *Yarrowia lipolytica* fed solely with glucose, while the second system involves a simultaneous feed of YL with glucose and formic acid [10-11]. This latter system utilizes electrochemical production of formic acid from carbon dioxide [15-16].

In the present study, process simulations were executed using SuperPro Designer [17], while energy balances and heat integration analyses were computed via Aspen Plus, employing the Non-Random Two-Liquid (NRTL) thermodynamic model to ensure accurate calculations of properties [18]. The scope of the investigation extends to a LCA and TEA across two distinct system configurations as exhibited in Figure 1A and 1B, further delineated into four specific scenarios. Within these scenarios, glucose serves as the primary substrate within the YL bioreactor, facilitating the biosynthesis of bio-TAL. Further explorations, as demonstrated in Figure 1B, illustrate the particular scenario in which a co-feeding strategy of formic acid and glucose is employed, showcasing an integrated method for enhancing the bio-production efficiency of TAL. It considers the sourcing of glucose and the subsequent recycling of off-gas into the three-compartment cell (TCC) reactor [15,19]. This innovative approach integrates the reactor for the electrochemical synthesis of formic acid from carbon dioxide emissions considering three carbon recycle percentage cases: 25%, 50%, and 75%.

## Substrate for the TAL Biosynthesis Process

### (A) Production of TAL Using *Yarrowia lipolytica* with Glucose as Substrate

The production of TAL through biotechnological routes is a promising alternative to traditional chemical synthesis. The process starts with the metabolic assimilation of glucose by YL, which undergoes glycolysis and

enters the tricarboxylic acid (TCA) cycle and the associated biosynthetic pathways [10]. Genetic engineering has optimized *YL* to overproduce acetyl-CoA and malonyl-CoA, the precursors necessary for TAL formation [20]. By upregulating the genes involved in these pathways and downregulating those leading to competing pathways, *YL* can produce TAL.

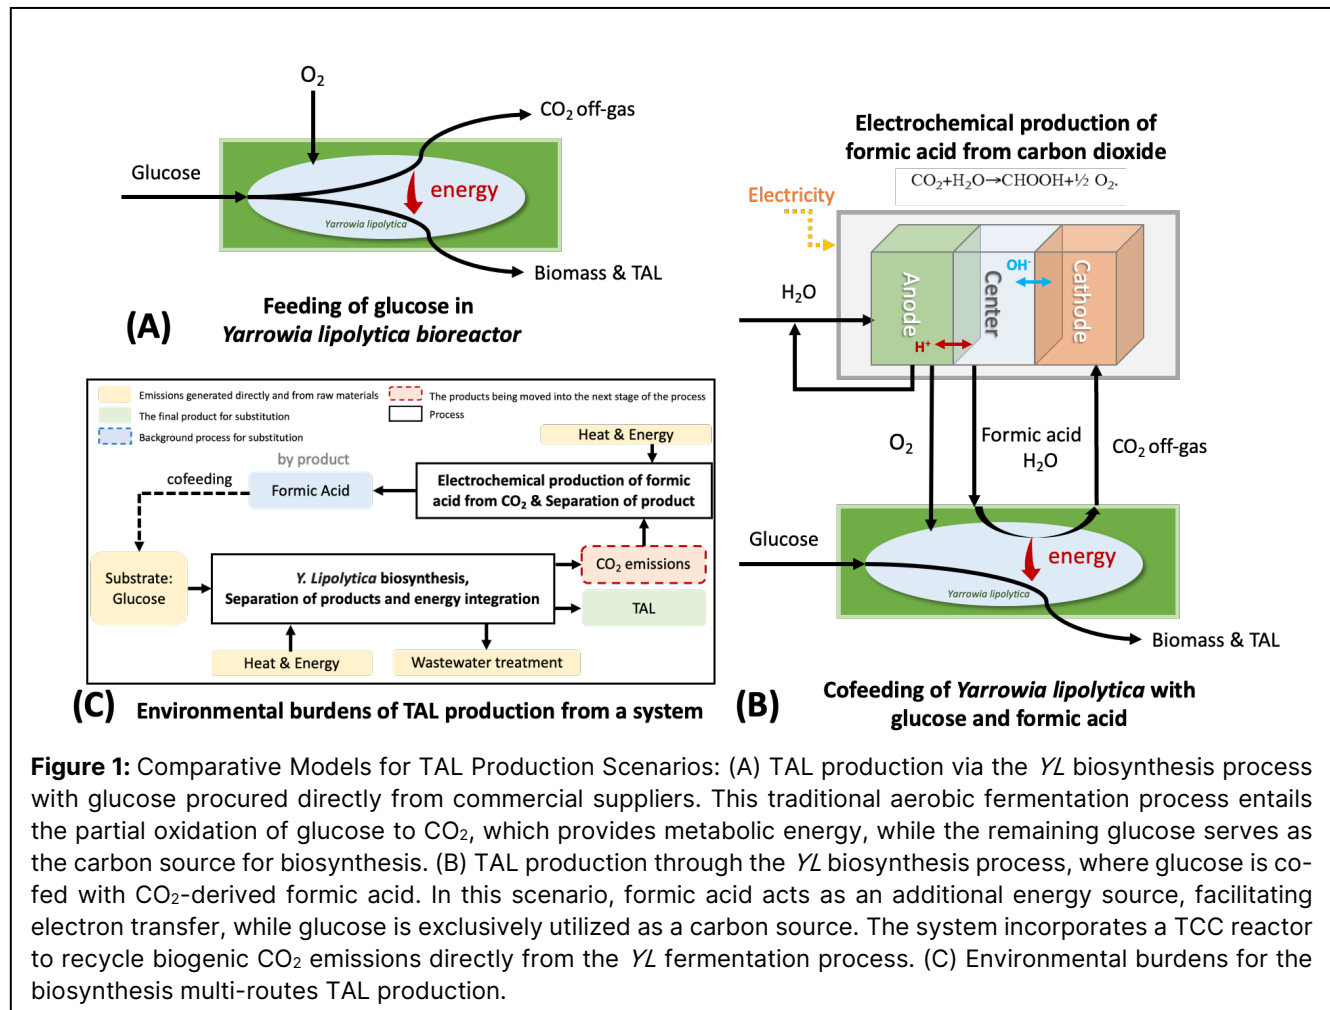

### (B) Cofeeding of *Yarrowia lipolytica* with glucose and formic acid

In the pursuit of sustainable bioproduction, a significant step forward involves capturing and utilizing CO<sub>2</sub> emissions, which is crucial for reducing the carbon footprint of biotechnological applications. According to Noorman (2020) [10-11], an innovative approach involves the electrochemical reduction of biogenic CO<sub>2</sub> using renewable electricity to form valuable organic molecules that can be fed to the fermentation process. This study uses a Three Compartment Cell (TCC) reactor to electrochemically reduce CO<sub>2</sub>, effectively converting it into formic acid with the net reaction [15,21]:

This method creates a closed carbon cycle, capturing emitted CO<sub>2</sub>, reducing it to formic acid, and reintroducing it into the fermentation stage. Theoretically, this cycle could sustain cellular energy requirements (ATP) through respiration alone. Moreover, by utilizing the primary carbon source, such as glucose, predominantly for biomass and product assimilation rather than energy production, this process substantially increases biomass and product yields, thereby enhancing the overall efficiency of the primary carbon source.

The TCC reactor's innovative configuration employs a gas diffusion electrode (GDE) cathode, GDE anode, and central flow compartments [15,19]. The central compartment is flanked by a cation exchange membrane adjacent to the anode, which is coated with an IrO<sub>2</sub> catalyst on Toray paper [15,19], and an anion exchange membrane on the cathode side, loaded with a tin (Sn) catalyst and polytetrafluoroethylene at 5% [15,19]. The key electrochemical reactions are delineated within their respective compartments. Notably, the TCC reactor design does not require the separation of by-products, given their minor concentrations within the effluent stream [21]. The efflux from the anode compartment predominantly comprises

unconverted H<sub>2</sub>O and the by-product O<sub>2</sub>, where O<sub>2</sub> will be sent to the aerobic fermentation reactor and excess water will be recycled back to the TCC reactor [15]. The formic acid flow from the center part of the TCC is sent to a pressurized 4 bar distillation tower to remove the excess water to achieve a 70 wt. % of FA and then co-fed with glucose to the *YL* bioreactor [15].

To produce 1 kg of formic acid, the process requires an input of 0.96 kg CO<sub>2</sub> and 0.57 kg H<sub>2</sub>O within the TCC reactor. The electrochemical reduction itself is powered by 4.79 kWh of electricity [15]. This co-feeding approach, where *Yarrowia lipolytica* is supplemented with both glucose and electrochemically produced formic acid, represents a shift toward more sustainable and partially decarbonized biotechnological processes.

### TAL Purification Process

Purification stands as a critical component in biorefining, with significant implications for costs. The process necessitates the removal of excess biomass, alongside organic and inorganic contaminants from the fermentation broth. Various techniques, including hexanol extraction [22], have been employed to recover TAL. However, an enhanced method utilizing charcoal adsorption has been delineated by Singh R. et al. [13], where TAL is absorbed by activated charcoal and subsequently desorbed using ethanol, which is then recovered for reuse. The selection of charcoal adsorption is predicated on its extractant reusability, providing a method that facilitates continuous operation while aligning with economic and environmental objectives, particularly leveraging the volatility of ethanol and ready availability.

### Bioprocess modeling

A bioprocess model used for this study was trained using fermentation profiles from Markham et al. [33]. A fed-batch process configuration was considered for all conditions explored. Briefly, within the system of ordinary differential equations (ODEs), the amount ATP generated from intracellular carbon catabolism at each timestep was calculated. It was then assumed that 25, 50, or 75% of the CO<sub>2</sub> emitted from the bioreactor could be captured and recycled as formic acid. An equal amount of formic acid was fed as was consumed by the organism (keeping the concentration in the bioreactor at zero). The molecular stoichiometry and energy generation from formic acid consumption defined by van Winden et al. [34] was used in the study. Energy generated from formic acid recycling was considered as a replacement for the same amount of energy generated via intracellular carbon catabolism, and the intracellular carbon that would have been used for catabolism to generate that energy was re-directed towards biomass and TAL in a ratio consistent with the carbon molar ratio of biomass and TAL produced under the glucose only feeding condition at each timepoint in the

ODE integration.

## RESULTS

### TEA results

The TEA conducted for TAL production adhered to the 2019 Chemical Engineering Equipment Cost Index and applied the discounted cash flow methodology for the determination of the Minimum Selling Price (MSP). The derived MSP was subsequently benchmarked against market prices (\$50/kg) to assess economic viability. The Internal Rate of Return (IRR) served as the economic indicator for comparison among different technologies.

Capital and operational expenditures were extrapolated from existing literature and SuperPro Designer [17], with equipment costs being estimated according to size by employing a power scaling factor, of 0.6 [23]. This calculation was based on an equipment price benchmark of a 500 m<sup>3</sup> bioreactor [35], providing a reference for cost estimations. Annual operating costs were assessed, including material, labor, utilities, and laboratory operations, along with facility expenses such as maintenance, depreciation, insurance, taxes, and overheads, with labor costs aligned with project demands. The detailed economic parameters are listed in Table 1. The TEA results, detailed in Table 2 [15,24-26], encompass capital expenditure (CapEx), operating expenditure (OpEx), the MSP of TAL, and the Internal Rate of Return (IRR) across various scenarios. Moreover, there is an additional by-product sale in the recycling scenarios examined in the TEA for TAL production. A key aspect was the conversion of all emitted CO<sub>2</sub> into FA. This process not only contributes to the sustainability of the operation but also adds a revenue stream, as the portion of FA not used for feeding back into the reactor is sold externally.

TEA analysis indicates that the scenario using glucose as the sole substrate for TAL production outperforms the co-feeding scenario with glucose and CO<sub>2</sub>-derived formic acid (FA). Notably, the co-feeding approach, with a 75% carbon recycle rate, demonstrates more than double the conversion efficiency compared to the glucose-only scenario. This enhanced efficiency is attributed to the additional NADH generated by the dissimilation of formic acid, which contributes to ATP production, thus supporting growth [11]. However, the production cost for CO<sub>2</sub>-derived FA, ranging from \$0.78 to \$2.63 per kg, exceeds that of glucose [21], priced at \$0.33 per kg on average [27].

In the co-feeding scenarios, the 25% carbon recycling case achieves the most favorable MSP at \$30.91/kg. The lower MSP in scenarios with less formic acid co-feeding correlates with the profits from by-product sales after accounting for the amounts needed for co-feeding, the surplus FA is sold as a by-product,

**Table 1:** Summary of economic assumptions for capital and operating cost.

TCC process		Capital investment cost		Fixed operating cost	
Cathode	Graphite block with Sn nanoparticles	General & Administrative Overheads	3% DFC <sup>a</sup>	Operating Labor Cost	average annual pre-taxed salary of \$80,000 per employee
Anode	Titanium anode with IrO <sub>2</sub> -based catalyst coating	Contract Fee	19% DFC	Maintenance Cost	2% of installed equipment cost
Membrane	Amberlite® IR120 strong acid ion exchange resin, 620.0 – 830.0 μm and Nafion 212/115/324	General & Administrative Overheads	3% DFC	Operating Charges	25% Operating Labor Cost
Electrolyzer cost	450 \$/kW	Working capital	20% annual operating cost	Operating General & Administrative Cost	20% direct production cost
Pressure, temperature	Ambient pressure, 25 C	Contingencies	37% DFC	<b>Time parameters</b>	
Residence time	4.0 min	Contract Fee	19% DFC	Project life	20 yr
Membrane lifetime	5000 hr	Other Capital Cost	71% DFC	Depreciation period	10 yr
				Annual operating time	8000 hr

offsetting TAL production costs). Based on the SuperPro database, with an FA market price of \$0.91 per kg, approximately 240, 448, and 648 mt/yr of FA can be sold in the 75%, 50%, and 25% carbon recycling scenarios, respectively. In these scenarios MSP is inversely correlated to TAL yield on glucose (0.30, 0.21, and 0.18 g TAL per gram of glucose for 75%, 50%, and 25% carbon recycle cases, respectively). Also worth noting, the opposite trend in TAL MSP is observed if we only produce the required amount of formic acid and release the remainder of the CO<sub>2</sub> to atmosphere (at \$33.6, \$31.74, and \$31.51 per kilogram, for 25, 50, and 75% recycle scenarios, respectively).

Figure 2 illustrates the detailed cost components contributing to the MSP for each production scenario. The primary utilities impacting the process economics are identified as electricity, steam, process water, and cooling water. The energy-efficient TAL separation process, notably the adsorption and desorption steps, is highlighted for its role in reducing utility costs. However, for the electrochemical production of FA, the requirement of 4.79 kWh of electricity per kilogram of FA [15] results in a higher proportion of utility costs compared to glucose-based TAL production.

**Table 2:** Summary of TEA for various raw materials for a benchmark plant capacity of 100 mt TAL/y.

Stream	CapEx (MM\$)	OpEx (MM\$)	MSP (\$/kg) <sup>a</sup>	IRR (%) <sup>b</sup>
Glucose	4.88	2.11	29.10	51.14
Glucose + Formic acid 75% carbon recycle	5.10	2.47	31.37	45.86
Glucose + Formic acid 50% carbon recycle	5.44	2.58	31.16	45.26
Glucose + Formic acid 25% carbon recycle	5.67	2.69	30.91	44.71

<sup>a</sup> MSP is computed when the sum of the discounted cash flow over 10 years equals zero (minimum selling price without any benefit).

<sup>b</sup> The internal rate of return after twenty years is based on the glucose-based MSP at a scale 0.1 kt/y, 50.00 \$/kg.

**Figure 2.** Cost breakdown of applying different TAL production routes.

The larger FA requirement to feed in the 75%, 50%, and 25% carbon recycle cases, with amounts of 95.95, 58.42, and 28.03 kg/hr, respectively causes an increase in electricity demands for the TCC reactor. However, TAL production using 75% carbon recycling of FA incurs less utility costs in the YL sections, as the cooling water demands of the YL bioreactor decrease, assuming that the reaction expends 115 kcal of heat for each mole of O<sub>2</sub> consumed [32]. To produce an equivalent quantity of TAL, the oxygen mole ratio required for the 75%, 50%, and 25% FA scenarios are 13.67, 15.13, and 16.59, respectively. The trade-off in utility costs between the two sections indicates that the CO<sub>2</sub>-to-FA process is more energy-intensive. When using only glucose as a substrate in the YL bioreactor, a higher capital expenditure is required due to the lower yield and productivity of TAL (larger reactor size and more fermentation broth); they are 0.40, 0.66, 0.52, and 0.45 g-O<sub>2</sub>/kg broth/h for the glucose-based scenario and FA co-feeding with glucose with 75, 50, and 25 % carbon recycle scenarios respectively. However, when FA and glucose are co-fed, yield and productivity increase. For the 75%, 50%, and 25% carbon recycle cases, they are 0.30, 0.21, and 0.18 g TAL/g glucose, that is 0.19, 0.13, and 0.10 g-TAL/kg broth/h in productivity, respectively. In these scenarios, the increase in biomass yield not only enhances product titer but also allows the system to burn less glucose for ATP generation. This efficiency results in smaller reactor sizes, with the 75% carbon recycle case being 44% smaller than the 25% case, and less fermentation broth, further improving the overall productivity (0.19 and 0.10 g-TAL/kg broth/h respectively). Moreover, in the 25% carbon recycling scenario, capital costs for the CO<sub>2</sub>-derived FA segment are lower due to the reduced CO<sub>2</sub> output from the YL section.

## LCA results

The life cycle assessment (LCA) aimed to evaluate the environmental advantages of electrochemically converting CO<sub>2</sub> to FA and the subsequent co-feeding of

glucose and FA for TAL production. The assessment, considering cradle-to-gate scope, tracked the CO<sub>2</sub> from its origin in the YL bioprocess through its transformation into FA and its return to the YL bioprocess in combination with glucose. The functional unit for this analysis was set at 1 kg of TAL.

Conforming to the ISO 14040 standard [28], the environmental evaluation of the CO<sub>2</sub>-to-FA reduction was conducted using the Brightway2 framework [29] and the Ecoinvent® v3.9.1 database [30], prioritizing US data but using global data when US data was unavailable. To determine carbon footprint and LCA, emissions factors were created and used for various activities, such as grid electricity usage, measured in g CO<sub>2</sub>/kWh consumed. These factors represent an estimate of emissions from a broad system of power generators, rather than a single point source of emissions. The ReCiPe Midpoint method (version 1.13) was employed to gauge the Global Warming Potential (GWP) of greenhouse gases over a century [31], thus ensuring a comprehensive perspective of both immediate and enduring environmental effects.

Furthermore, the LCA utilized system expansion for product allocation within multi-output processes, a method advantageous for co-products with distinct, quantifiable market values. This approach allows for the apportionment of environmental burdens proportionately to the economic value or utility of each product. In this case, the co-produced FA, derived from recycled CO<sub>2</sub>, is considered an environmental credit, acknowledging its displacement of fossil-derived equivalents, as depicted by the blue squares in Figure 1(C). Oxygen, another by-product of electrolysis, was excluded from further utility considerations in this assessment.

The LCA results demonstrate that co-feeding *Yarrowia lipolytica* with glucose and formic acid significantly improves the greenhouse gas performance of TAL production. Notably, the scenarios with 75%, 50%, and 25% carbon recycling exhibit negative net emissions, thereby enhancing the environmental profile of the process. The 25% carbon recycling case is the most effective, with a net emission reduction to -10.25 kg CO<sub>2</sub>-equivalents per kg of TAL (4.03 CO<sub>2</sub>-eq per kg of TAL, if not considering the CO<sub>2</sub>-to-FA credit), indicating an exemplary case of carbon-negative output. While if not considering the carbon credit from the by-product, FA, the 75% carbon recycling case performs the best in GWP impact. The inclusion of recycled CO<sub>2</sub> as a feedstock for formic acid production contributes to this improvement, showcasing a viable pathway for reducing GHG emissions in chemical manufacturing. On the other hand, the production of TAL using glucose-based methods, without recycling the CO<sub>2</sub> generated during fermentation, results in a higher carbon footprint. In this scenario, the carbon emissions from the fermentation process account for more than 50% of the total net emissions. This assessment solidifies the co-

feeding of glucose with formic acid, particularly with high rates of carbon recycling, as a technologically and environmentally advantageous route for TAL production, aligning with global sustainability goals.

**Figure 3.** Lifecycle greenhouse gas emissions for glucose-based TAL and cofeeding of *Yarrowia lipolytica* with glucose and formic acid-based TAL.

## DISCUSSION

The transition to sustainable energy systems is a critical endeavor in mitigating the environmental impact of hard-to-decarbonize sectors, including industrial and chemical processes. This study's LCA and TEA have shed light on a novel bioprocessing route for TAL production that integrates carbon recycling—a pivotal step towards achieving net-zero emissions.

The LCA results affirm that the co-feeding of *Yarrowia lipolytica* with glucose and formic acid significantly advances the GHG performance of TAL production. The standout 75% carbon recycling scenario not only meets but exceeds net-zero emission goals, venturing into the carbon-negative territory. This demonstrates the profound environmental benefits of incorporating CO<sub>2</sub>-to-formic acid conversion within the TAL production cycle.

From a techno-economic perspective, the TEA findings reveal that the co-feeding approach, particularly with a high rate of carbon recycling, is economically viable. Despite the higher utility costs associated with the electrochemical generation of formic acid, this is counterbalanced by the revenue generated from the sale of excess formic acid, thereby enhancing the process's cost-competitiveness.

The capital cost analyses for the bioreactor configurations further corroborate the economic viability of the co-feeding approach. Although the initial outlay is more substantial for the glucose-only scenario due to the larger reactor requirements (4.88 MM\$ CapEx of YL process), co-feeding with formic acid benefit the reactor sizing and utility consumption, leading to a reduction in both capital and operating expenses (3.21–4.66 MM\$ CapEx of YL process).

Incorporating these findings, future directions will

involve refining the bioprocesses and scaling the production while aligning with policy developments that support economic and environmental sustainability. This research sets a foundation for policy-backed industry practices that promote a circular economy and contribute to the global goal of a net-zero carbon future.

## ABSTRACT

Managing oil and gas produced water, characterized by hypersalinity and large volumes, presents significant challenges. This paper introduces an advanced optimization framework, PARETO, which offers a novel approach to strategic water management, emphasizing produced water (PW) treatment, quality tracking, quantification of emissions, and environmental justice. This work presents a case study showcasing different produced water management challenges. The PARETO framework demonstrated its effectiveness in optimizing water management strategies in line with environmental sustainability and regulatory compliance.

**Keywords:** produced water management, MINLP, process design, network optimization, MILP

## INTRODUCTION

Produced water (PW) management presents significant challenges to oil and gas industry stakeholders due to variable production volumes (unpredictable handling requirements) and water quality, especially due to its high concentrations of total dissolved solids (TDS) and other constituents (necessitating treatment). Given the variability in water produced across different basins along with the difficulty of treating hypersaline brine, oil and gas companies need to identify fit-for-purpose produced water management, treatment, and reuse approaches. Projected increases in PW volumes in coming decades [1], recent injection capacity curtailments [2 - 3], and intensive capital investments (e.g., PW infrastructure) all motivate novel, cost-effective strategies for PW management. Therefore, decision-support tools to assess techno-economic feasibility are critical. However, few such software tools currently exist.

In 2021, the US Department of Energy (DOE) launched a three-year, \$5 million PW optimization initiative to develop, demonstrate and deploy PARETO, a novel optimization framework for PW management and beneficial reuse. PARETO is developed by the National Energy Technology Laboratory (NETL), in cooperation with Lawrence Berkeley National Laboratory (LBNL),

Carnegie Mellon University, Georgia Tech, New Mexico State University, and the Ground Water Protection Council, and is designed to identify cost-effective and environmentally sustainable PW management, treatment and reuse solutions [4]. Specifically, PARETO supports decision-makers with 1) PW management, including infrastructure buildout recommendations and the coordination of PW deliveries; 2) PW treatment, including treatment facility placement recommendations and the selection of effective treatment technologies; and 3) PW beneficial reuse, including the identification of beneficial reuse options and the distribution of treated PW and/or concentrated brine.

In previous versions of PARETO, the tool's core capabilities for optimizing water distribution across the network were demonstrated using the Mixed Integer Linear Programming (MILP) method [4]. These capabilities included user-defined treatment site specifications and post-process water quality tracking. The optimization aimed at various objectives, such as minimizing costs or maximizing water recycling within the network. Building upon this work, the current version of PARETO introduces significant enhancements, including new methods for integrating produced water (PW) treatment and quality tracking. This is achieved through surrogate modeling of rigorous desalination models, which capture the impact

of water quality and flow rate on treatment costs, utilizing both MILP and Mixed Integer Nonlinear Programming (MINLP) methods. Furthermore, this update includes advanced techniques for quantifying emissions and promoting environmental justice, enabling a detailed analysis of the trade-offs between economic factors and environmental objectives. 1) the PARETO treatment module includes a library of PW desalination technologies that can be used to obtain treated water for use outside oil and gas operations; 2) the PARETO environmental module allows a user to track pollutants generated during produced water operations and provides a tool to bring environmental justice to communities located near oil and gas operations.

The results show PARETO’s advanced mathematical modeling capabilities are able to solve large scale water network problems, with an emphasis on complex nonlinearities arising from studying effective formulations for solving water networks with water quality predictions.

## CASE STUDY AND PROBLEM STATEMENT

This work presents an industrial-size produced water network based on the Permian Basin (New Mexico and Texas).

The main characteristics of PW networks in this region are the availability of pipelines and limited use of trucking for transport (the opposite is true in some other basins such as the Appalachian). Figure 1 shows a representative PW network, which consists of 14 production pads, 3 completion pads, 5 disposal wells, 4 treatment sites (one of which is for desalination – R03), and 3 treatment technologies (i.e., membrane vapor compression, membrane distillation, and osmotic assisted reverse osmosis). Figures 2-4 show the time-varying nature of the water production forecast and completions demand. The PW forecasts follow an exponential decay pattern, whereas the completions pads demand large amounts of water during specific time windows. Table 1 summarizes the water volumes, as can be seen, the PW forecast exceeds the completions demand, which is typical in PW networks.

The main challenges associated with PW network management are:

- Handling large volumes of produced water during specific time windows. (see Figure 3 and 4)
- High salinity (TDS > 120,000 mg/L) and other constituents (i.e., oil, grease, barium, lithium, etc.).
- Pipeline hydraulics (i.e., pressure drop, pumping stations, etc.).
- Active development in the area requiring infrastructure buildout (i.e., new pipelines, new

disposal wells, new treatment plants).

- Selecting appropriate treatment and beneficial reuse alternatives for produced water (if available/applicable).

Figure 1: PW network schematic.

Figure 2: PW forecasts from production pads.

Figure 3: Completions demand volumes.

**Figure 4:** Flowback forecast from completions pads.

**Table 1:** Total PW volume and completion demand.

Item	Volume (bbl/day)
Completions Demand	1,481,429
Produced Water Forecast	2,825,953
Disposal Capacity	2,525,714
Starting Treatment Capacity	0

## PARETO PRODUCED WATER QUALITY MODELING APPROACH

In produced water network management, a key element involves the estimation of flowrates and water qualities. This process involves tracking various components within the network to efficiently manage and reuse water, tailored to the quality requirements of specific end uses. A notable consideration in modeling these networks is the non-convex and bilinear term in the mass balances emerging from the product of flow rates and concentrations of various components. Within its comprehensive management framework, PARETO adopts two distinct methods to estimate water quality. The main goals are to allow users to: 1) identify component/quality peaks within the produced water network; 2) simulate operating constraints based on water quality limitations; 3) enable the selection and sizing of treatment technologies to enable beneficial reuse.

**Quality Post-Processing:** In this case, PARETO solves an MILP model focusing on binary decisions and flow rates, without considering water quality. Once these flow rates are estimated, quality constraints are activated and flows and binary variables serve as parameters for subsequent quality assessment, simplifying these calculations to linear constraints. This approach is particularly valuable for pinpointing specific areas in the network that require targeted treatment and for identifying the most suitable technologies for the reuse of produced water (see Figure 5).

**Predictive Quality Management:** This more

advanced method begins with optimizing flow rates using an MILP, followed by the explicit integration of quality constraints. Subsequently, the system is initialized for a comprehensive MINLP model. While this method adeptly sets the stage for detailed analysis, the primary challenge emerges from the intricacies of the bilinear terms, particularly their nonconvex nature. This complexity hampers the achievement of a global optimum, highlighting the advanced analytical challenges inherent in accurately modeling and optimizing such systems. This approach is valuable for adding performance constraints, and/or to identify the best treatment technology for a given network. Figure 5 presents a case study demonstrating the application of an MILP model without quality level restrictions, resulting in elevated quality levels at specific locations. However, by integrating an MINLP model with explicit quality level constraints, it becomes feasible to precisely regulate and monitor the water flow and quality in these areas, ensuring that the quality does not exceed a specified threshold.

**Figure 5.** The TDS (g/L) level at a specific location in the PW network.

With both these methodologies in play, a pivotal aspect is the role of water treatment centers. The efficiency of these centers in component removal and water recovery is integral to determining the final quality and quantity of treated and residual streams. The PARETO framework provides flexibility by allowing users to define specific water recovery and removal efficiency targets for each treatment site and technology.

## PARETO Treatment and Desalination

Treatment systems are critical in achieving the required water quality for diverse applications such as beneficial reuse and critical minerals recovery. The costs linked to these treatment systems, varying with the purpose and intensity of treatment, play a substantial role in determining the overall investment in PW management strategies. It is, therefore, imperative to give due consideration to the cost and functionality of treatment models within the broader context of produced water management strategies.

**PARETO advanced water treatment analysis:** PARETO provides three methodologies (high-level cost analysis, semi-rigorous, and rigorous cost analysis):

- 1) discrete numerical inputs to enable flexible sizing of treatment plants (PARETO documentation includes a detailed literature review and vendor survey of treatment CAPEX and OPEX: [https://pareto.readthedocs.io/en/latest/model\\_library/water\\_treatment/index.html](https://pareto.readthedocs.io/en/latest/model_library/water_treatment/index.html)).
- 2) the deployment of detailed rigorous models for comprehensive process design and network optimization.
- 3) the application of surrogate models for streamlined computational analysis.

Notably, while discrete numerical inputs facilitate the estimation of treatment costs, they fall short in capturing the intricate interplay between water quality and cost implications. To bridge this gap, this work presents a PARETO surrogate modeling approach. These surrogate models adeptly establish correlations between water quality, plant capacity (measured as flow rate), and cost, thereby furnishing a more rigorous cost analysis framework.

PARETO effectively leverages the WaterTAP [5] library's rigorous models, which include a selection of advanced desalination technologies. Among these, Osmotically Assisted Reverse Osmosis (OARO), Mechanical Vapor Compression (MVC), and Membrane Distillation (MD) are prominent for their applicability in treating hypersaline produced water. The presented case study includes these technologies alongside primary treatment processes to produce both purified water and clean brine for beneficial reuse and network recycling, respectively.

The methodologies utilized in PARETO, as previously detailed, provide a platform for diverse approaches in water treatment analysis. To showcase and compare these capabilities, we evaluate three distinct cases, each reflecting a different strategy within the PARETO framework:

**Case 1: Discrete Input Values:** In this approach, the PARETO framework is applied to analyze a system with discrete input values, where cost data for discrete expansion sizes of the plants are provided. The model uses this data to evaluate and identify the most cost-efficient desalination method among Mechanical Vapor Compression (MVC), Membrane Distillation (MD), and Osmotic Assisted Reverse Osmosis (OARO).

**Case 2: MILP-NN Surrogate:** This approach involves the use of the MILP integrated with a surrogate neural network (NN). Operating under fixed feed quality assumptions typical of Permian produced water with 128,000 mg/L Total Dissolved Solids (TDS), the model allows for variability in feed flow rate, demonstrating the effectiveness of MILP-NN in systems with fixed quality and variable flow rates.

**Case 3: MINLP-NN Surrogate:** This case employs an MINLP model, incorporating a surrogate for the MVC

process. It enables analysis under varying inlet feed quality and flow rate, providing a comprehensive view of the system's performance under different conditions.

## Surrogate Models

Surrogate models are essential for simplifying complex processes in situations where computational limitations (i.e., large scale network problems such as produced water networks), lack of algebraic representation, or external functions/constraints are present.

In our study, we address the complexities of Mechanical Vapor Compression (MVC) produced water treatment technology, which features a non-linear, non-convex nature, making it unsuitable for direct representation in the large-scale Mixed-Integer Linear Programming (MILP) framework. To manage the substantial increase in problem size from the MVC model's 54 constraints/variables (per time period), we employ surrogate models based on simulations and empirical data, focusing on regression techniques.

Machine learning surrogate models, particularly Neural Networks with Rectified Linear Unit (ReLU) activation functions, are integrated into PARETO strategic model optimization frameworks. These models are applied to MVC plant scenarios, focusing on inputs like water quality and recovery, and outputs including CAPEX, OPEX, and energy consumption.

This work leverages the IDAES-PSE [6] machine learning toolset to train surrogate models for the treatment technologies and integrate the surrogate model within the PW network problem to determine the optimal selection of treatment technologies (case 2 and 3 mentioned above).

## PW Quality and Treatment Results

The results presented in Table 2 provide a comprehensive overview of the model's performance across the various cases.

The overarching goal here is not to compare these cases on absolute numbers but rather to demonstrate the PARETO framework's flexibility and adaptability. The basis of calculations and underlying assumptions varies for each method, reflecting the diverse scenarios and user requirements each case study aims to address. This framework is designed to cater to a range of user needs, offering tailored solutions for different operational conditions and types of analysis.

An important observation across all cases is the model's effectiveness in optimizing water management, particularly in its emphasis on recycling water for completions purposes. The data shows that a significant portion of produced water, approximately 45%, is recycled, which substantially reduces reliance on freshwater sources (only about 4%).

**Table 2:** PW quality and treatment results. <sup>a</sup> kbbl

	Case 1	Case 2	Case 3
Total Cost, k\$	18,603	18,470	18,306
Sourced Water <sup>a</sup>	515	515	515
Disposal Volume <sup>a</sup>	7,218	7,000	7,100
Reuse Volume <sup>a</sup>	8,805	8,805	8,805
Piping OPEX, k\$	15	14	13
Disposal CAPEX, k\$	142	140	140
Pipeline CAPEX, k\$	111	113	127
R03 treatment tech.	MVC	-	-
R03 inlet salinity, g/l	134	128	130
Run time, seconds	272	400	1600
Gap, %	0	0	13

As shown in Table 2, the model suggests investing in pipeline, treatment, and disposal infrastructure as an optimal long-term solution. This recommendation is based on a detailed cost-benefit analysis, indicating that such investments, despite their initial capital requirements, are beneficial in the long run for sustainable and efficient water management.

**Case 1: Basic Approach with Discrete Input Values:** Case Study 1 represents a fundamental yet effective approach, utilizing discrete input values for treatment costs and plant sizes. This method simplifies the analysis by not tracking water quality within the network, focusing instead on optimizing cost and size parameters. One of the significant advantages of this approach is its reduced computational intensity. As indicated in the results, this method can solve the network in just 272 seconds, demonstrating its efficiency and suitability for quick assessments or preliminary planning phases.

Another notable aspect of Case 1 is its suitability for scenarios where vendor or industrial data is available in a discrete format. This approach aligns well with situations where the costs and technologies for water treatment are not heavily dependent on the inlet water quality. It is particularly beneficial in cases where the variation in water quality across the network is minimal, allowing for a more straightforward optimization process without the need for intricate quality tracking mechanisms.

**Case 2 Advanced Approach with Surrogate Model Integration:** Case 2 incorporates a neural network based surrogate model that is responsive to both inlet flowrate and inlet water quality. To maintain the MILP structure while capturing the effects of varying costs associated with plant capacity and treatment, the water quality in this model is assumed to be a fixed value, representative of the conditions in the Permian Basin. A key attribute of Case Study 2 is its ability to strike a balance between computational efficiency and the adaptability of the model (reaching zero gap after 400s).

One of the most notable features of Case 2 is its capacity to effectively capture the nuances of centralized

versus decentralized treatment systems. By providing a finer-scale comparison that takes into account varying treatment cost and plant sizes in various location, this model delivers insights crucial for the consideration of transportation costs associated with water movement to the treatment centers.

Further enhancing the model's capabilities, Case 2 can incorporate an iterative procedure yielding to a dynamic and adaptable analysis by leveraging the post-processing approach (i.e., estimate cost/performance, update quality levels, and re-estimate cost/performance, until convergence is reached).

**Case 3 - Advanced Modeling with MINLP and Quality Tracking:** Case Study 3 employs an advanced MINLP model that intricately incorporates aspects of water quality, flowrate, and recovery. The scope of Case 3 extends beyond mere operational optimization. It is specifically designed to not only address environmental and regulatory considerations, but also efficiently predict treated water, recovery, and concentrated water. Which is critical to enable beneficial reuse (i.e., recovery of critical minerals from produced waters).

While Case Study 3 offers the most detailed and sophisticated analysis among the three models, it is also the most computationally demanding. As evidenced by the results, this model requires a significant amount of time to reach an acceptable optimality gap. This computational intensity reflects the model's complexity and the depth of analysis it provides. Users of Case Study 3 need to be cognizant of the trade-off between its comprehensive analytical capabilities and the time and computational resources required.

## QUANTIFYING EMISSIONS AND ENVIRONMENTAL JUSTICE IN PRODUCED WATER NETWORKS

Accurate estimation of emissions is not only critical for maintaining regulatory compliance but also for the economic considerations of PW systems, especially with the introduction of new emissions regulations. The Inflation Reduction Act, for example, established the Methane Emissions Reduction Program which introduces a charge for reported waste emissions beginning in 2024 [7]. While emissions measurements are generally acknowledged, there is also a growing interest in environmental justice impact. In 2021, the Justice40 initiatives in response to Executive Order 14008 outlined new guidance for environmental justice, including specific recommendation for the decrease of environmental exposure and burdens for Disadvantaged Communities. [8].

The PARETO framework includes three categories of environmental impact and environmental justice measures: (1) air pollutant metrics, (2) environmental exposure in disadvantaged communities, and (3) trucking

activity. Air emissions are tracked at different sources throughout the system: trucking, pipeline operations, pipeline installation, disposal, storage, and treatment. Five measures of air pollutants were identified for this case study: Greenhouse gas emissions (CO<sub>2</sub> equivalents), NH<sub>3</sub>, NO<sub>x</sub>, SO<sub>2</sub>, and PM<sub>2.5</sub>. Table 2 presents the respective coefficients. PARETO reports on air emissions at each source and across the full PW network for each air pollutant type. Total emissions are also calculated as the sum across all pollutant types. To incorporate emissions metrics into PARETO decision-making, users can select to optimize the PW network with an objective to minimize total emissions.

**Table 3:** Air emission coefficients.

Source	Unit	Type	Coefficient
Trucking	g/hour	CO <sub>2</sub>	2,035,000
		NH <sub>3</sub>	35
		NO <sub>x</sub>	12650
		SO <sub>2</sub>	770
		PM <sub>2.5</sub>	121
Pipeline Operations	g/bbl-mile	CO <sub>2</sub>	22
		NH <sub>3</sub>	0.0002
		NO <sub>x</sub>	0.014
		SO <sub>2</sub>	0.0071
		PM <sub>2.5</sub>	0.00086
Pipeline Installation	g/mile	CO <sub>2</sub>	310,000,000
		NH <sub>3</sub>	2,800
		NO <sub>x</sub>	190,000
		SO <sub>2</sub>	100,000
		PM <sub>2.5</sub>	12,000
Disposal	g/bbl	CO <sub>2</sub>	970
		NH <sub>3</sub>	0.13
		NO <sub>x</sub>	9.5
		SO <sub>2</sub>	2.8
		PM <sub>2.5</sub>	0.87
Storage	g/bbl-week	CO <sub>2</sub>	1,000
		NH <sub>3</sub>	0.012
		NO <sub>x</sub>	2
		SO <sub>2</sub>	0.65
		PM <sub>2.5</sub>	0.076

Table 3 and Table 4 present coefficients used to estimate air emissions output for unit of time, volume, distance, or combination, depending on the source. Air emissions coefficients and mathematical constraints are based on environmental impact modeling in Bartholomew & Mauter [7]. Ongoing work for emissions measurement includes establishing coefficients for technologies

beyond Mechanical Vapor Compression.

**Table 4:** Treatment technology air emission coefficients.

Treatment Technology	Type	Coefficient (g/week)
Mechanical Vapor Compression	CO <sub>2</sub>	9600
	NH <sub>3</sub>	1.45
	NO <sub>x</sub>	12.8
	SO <sub>2</sub>	13.5
	PM <sub>2.5</sub>	1.5

The second category included in the PARETO framework addresses environmental justice and focuses on Disadvantaged Communities (DAC) as defined by the Climate and Economic Justice Screening Tool [9]. This metric is a function of air emission measures and reports the air pollutants contributed from sources in the produced water system that fall within a DAC. Ongoing work for environmental justice measures includes incorporating penalties for building new PW infrastructure into an environmental objective function.

The third category reports trucking activity for the total volume of water trucked and total hours of trucking time with non-zero water load.

### Environmental Impact Assessment

The above-mentioned metrics have been added to the PARETO framework. Figures 6 to 8 present detailed emissions for the given produced water network. The results presented correspond to Case 1 from the previous section (base case – minimize total cost). It is worth noting that, in the context of this case study and based on the specific data analyzed, the emissions originating from disposal, storage, and pipeline operations are minimal compared to those from treatment and pipeline installation. For this reason, they are not depicted in the figures but are instead included in the analysis.

**Figure 6:** CO<sub>2</sub> emissions in PW networks [kton].

**Figure 7.** NO<sub>x</sub> emissions in PW networks [kton].

**Figure 8.** PM<sub>2.5</sub> emissions in PW Networks [kton].

### Emissions Trade-offs in Produced Water Management

The emissions calculations presented in Table 5 of our study provide insightful findings on the environmental tradeoffs of various produced water management strategies. These results reveal the trade-off between minimizing costs and reducing total system emissions. The data indicates that while some strategies effectively reduce overall costs, they may result in higher total emissions. Conversely, approaches focused on minimizing emissions demonstrate a substantial decrease in environmental impact but at an increased cost. These findings underscore the complexities involved in balancing economic and environmental objectives in produced water management, highlighting the need for multi-faceted approaches that consider both financial and ecological sustainability.

For the given case study, PARETO framework reduced PW treatment in favor of increasing produced water disposal to reduce the overall emissions. This result can be seen as contradicting from the water sustainability perspective, presenting a potential opportunity to explore different environmental objectives.

**Table 5:** Results environmental KPIs.

Objective (minimize)	Cost	Emissions w/ limits
Total Cost (k\$)	18,603	20,410
Total Emissions (kton)	126,486	126,482
Sourced Water (kbbbl)	515	515
Disposal Volume (kbbbl)	7,218	9,312
Reuse Volume (kbbbl)	8,805	8,805
Piping operational costs (k\$)	15	12
Disposal CAPEX (k\$)	142	286
Pipeline CAPEX (k\$)	111	127

It is crucial to acknowledge the intrinsic limitations of the network studied, particularly in the context of the Permian case study which primarily relies on piping for water transportation. Piping, as demonstrated by prior research [10], offers emission savings compared to trucking, which is absent in our base case scenario, inherently limiting the scope for further emission reductions. Furthermore, the scope of the presented case study is constrained to a 52-week period, covering only 16 production and completion pads. This limited geographical and temporal scale suggests that the observed emission savings, while seemingly modest, may represent a larger potential for emission reduction across broader basins and over the operational lifetime of wells.

Lastly, it is pertinent to consider that the direct emission savings, while valuable, may not fully capture the broader environmental and health benefits. These benefits are more significantly recognized when emissions are translated into cost dollars in terms of Human Health Effects (HHE). Although the conversion to an HHE-focused objective is beyond the scope of this iteration of the PARETO framework, it represents a critical area for future exploration to comprehensively assess the value of emission reductions.

### CONCLUSIONS

This work presents an update on project PARETO's capabilities for advanced treatment modeling and quality tracking, and the quantification of environmental justice and emissions in produced water networks. We demonstrated the use of PARETO framework to determine optimal infrastructure buildout, PW management, and the selection of treatment technologies that will enable potential beneficial reuse options in oil and gas produced water networks.

Further work will focus on demonstrating multi-objective optimization tools for optimizing produced water networks under different objectives (i.e., water quality, cost, emissions and environmental justice, PW reuse,

etc.). Additionally, PW quality can be seen as a source of uncertainty in the decision-making process; process design under uncertainty is a promising topic in the area of PW desalination.

## ABSTRACT

Equation-oriented (EO) modeling has the potential to enable the effective design and optimization of the operation of advanced energy systems. However, advanced modeling of energy systems results in a large number of variables and non-linear equations, and it can be difficult to search through these to identify the culprit(s) responsible for convergence issues. The Institute for the Design of Advanced Energy Systems Integrated Platform (IDAES-IP) contains a tool to identify poorly scaled constraints and variables by searching for rows and columns of the Jacobian matrix with small  $L^2$ -norms so they can be rescaled. A further singular value decomposition can be performed to identify degenerate sets of equations and remaining scaling issues. This work presents an EO model of a flowsheet developed for post-combustion carbon capture using a monoethanolamine (MEA) solvent system as a case study. The IDAES diagnostics tools were successfully applied to this flowsheet to identify problems to improve model robustness and enable the optimization of process design and operating conditions of a carbon capture system.

**Keywords:** Pyomo, Optimization, Carbon Dioxide Capture, Jacobian, Modelling

## INTRODUCTION

In order to achieve carbon neutrality by 2050, as is the US Department of Energy's present goal [1], a wide variety of energy systems must be deployed. Process optimization can help allocate resources in the most efficient manner to effect the changes necessary in the US and world economies to achieve this goal. The Institute for the Design of Advanced Energy Systems (IDAES) was founded in 2015 to study such advanced energy systems and to develop the IDAES Integrated Platform (IDAES-IP) to facilitate their development and optimization. [2] IDAES-IP is based on the Pyomo modeling language [3-4] in Python and has been used to simulate a wide variety of chemical and energy process systems.

Because IDAES-IP is equation-oriented (EO), it can provide improved convergence when closing recycle loops over the sequential-modular (SM) approach that is used in popular commercial process modeling and simulation tools like Aspen Plus®. [5] However, it also requires more user skill to ensure that the model is well-

formulated to benefit from these theoretical convergence improvements. IDAES has developed and implemented a diagnostics toolbox leveraging several years of experience of many experts in EO modeling, debugging, and optimization, making it available to the public. [6] In this work, we detail some of the techniques that have been incorporated in that toolbox as applied to a flowsheet being developed for analysis of post-combustion carbon capture (PCC) systems.

## METHODS

When prototyping a model, it is typically best to solve a "square problem," i.e., one in which there are an equal number of free variables and equality constraints. The number of degrees of freedom can be checked by the function `idaes.core.util.model_statistics.degress_of_freedom`. There are zero degrees of freedom in a square problem. Variable bounds can be present, as they are often helpful to keep the nonlinear solver from exploring areas with non-physical solutions

or areas in which equations become undefined. For example, if a logarithm of a variable is taken, its lower bound should be set to zero.

However, variable bounds *should not* be active at a solution, because the inclusion of such a bound is effectively a constraint, reducing the number of degrees of freedom by 1. The system of equations then either becomes infeasible, which precludes a solution, or degenerate, which means that some of the equations are redundant. Different nonlinear solvers handle degeneracy differently, but it either prevents or dramatically slows convergence to a solution. For this reason, inequality constraints more complex than variable bounds should be avoided when formulating a square problem.

The principal diagnostic methods used in this work utilize the Jacobian. When solving a root-finding problem

$$\begin{bmatrix} f_1(x_1, \dots, x_n) \\ \vdots \\ f_n(x_1, \dots, x_n) \end{bmatrix} := \mathbf{f}(\mathbf{x}) = \mathbf{0} \quad (1)$$

the Jacobian matrix of  $\mathbf{f}(\mathbf{x})$  is given by

$$J(\mathbf{x}) := \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \dots & \frac{\partial f_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \dots & \frac{\partial f_n}{\partial x_n} \end{bmatrix} \quad (2)$$

For a square problem, the Jacobian matrix is square. Each row of  $J(\mathbf{x})$  corresponds to an equality constraint and each column corresponds to a free variable. Therefore, we can examine  $J(\mathbf{x})$  to find clues about problems in equations and constraints. In the past, calculation of the Jacobian was difficult because derivatives had to either be calculated by hand or by finite differences. However, advances in algorithmic differentiation (AD) allow for automatic, precise calculation of derivatives. Pyomo offers access to the AD capacities of the AMPL solver library (ASL) [7] through the PyNumero interface [8].

The most common methods of solving multivariate root-finding problems of the form of (1), like the one utilized in IPOPT [9], which is freely available and was used as a nonlinear solver in this paper, are variations on Newton's Method. The method approximates  $\mathbf{f}(\cdot)$  as linear and then repeatedly solves the linearized equation

$$\mathbf{f}(\mathbf{x}_k) + J(\mathbf{x}_k)\Delta\mathbf{x}_k = \mathbf{0} \quad (3)$$

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \Delta\mathbf{x}_k \quad (4)$$

until the condition

$$\|\mathbf{f}(\mathbf{x}_{k+1})\|_2 \leq \varepsilon \quad (5)$$

in which  $\|\cdot\|_2$  is the vector two (Euclidean) norm, is satisfied for some chosen tolerance  $\varepsilon$ . In a practical implementation, the Newton step (4) may be truncated, either to account for variable bounds or because  $\|\mathbf{f}(\mathbf{x}_{k+1})\|_2 > \|\mathbf{f}(\mathbf{x}_k)\|_2$ , but it is desirable to take the full step when possible. It is a sign of a well-formulated method working

on a well-formulated problem when the full step (4) is frequently taken until a solution is reached.

A condition number of a matrix is a measure of the sensitivity of changes in the solution to a system of linear equations. For example, for the Newton step-finding problem

$$J(\mathbf{x}_k)\Delta\mathbf{x}_k = -\mathbf{f}(\mathbf{x}_k) \quad (6)$$

suppose we perturb the function output by  $\delta\mathbf{f}_k$  and want to estimate the perturbation in the resulting step  $\delta\mathbf{x}_k$

$$J(\mathbf{x}_k)(\Delta\mathbf{x}_k + \delta\mathbf{x}_k) = -(\mathbf{f}(\mathbf{x}_k) + \delta\mathbf{f}_k) \quad (7)$$

Use of the condition number for the 2-norm  $\kappa_2(J(\mathbf{x}_k))$  gives us the bound

$$\|\delta\mathbf{x}_k\|_2 \leq \kappa_2(J(\mathbf{x}_k))\|\delta\mathbf{f}_k\|_2 \quad (8)$$

In practice, such perturbations in the function output always exist from the roundoff errors in floating point arithmetic. The relative error inherent in double precision floating point arithmetic is on the order of  $10^{-16}$ . Additionally, a large condition number  $\kappa_2(J(\mathbf{x}_k))$  (greater than about  $10^8$ ) makes it difficult to solve the problem (6) numerically, increasing the time that Newton iterations take to solve.

The condition number of  $J(\mathbf{x})$  is given by

$$\kappa_2(J(\mathbf{x})) = \|J(\mathbf{x})\|_2 / \|J(\mathbf{x})^{-1}\|_2 \quad (9)$$

in which  $\|\cdot\|_2$  is the operator norm induced by the vector 2-norm, provided  $J(\mathbf{x})$  is full rank. A more useful formula comes from the singular value decomposition (SVD). We factorize

$$J(\mathbf{x}) = U\Sigma V^T \quad (10)$$

in which  $U$  and  $V$  are orthogonal matrices and

$$\Sigma = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \sigma_n \end{bmatrix} \quad (11)$$

in which  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n \geq 0$ . If  $J(\mathbf{x})$  is full rank, then  $\sigma_n > 0$  and

$$\kappa_2(J(\mathbf{x})) = \sigma_1/\sigma_n \quad (12)$$

Therefore, we can improve the problem formulation by reducing the condition number by bringing the values of  $\sigma_1$  and  $\sigma_n$  closer together. This can be done by appropriate scaling of variables and constraints.

## Scaling

When working in SI units, it is common to have variables and equations that vary over many orders of magnitude, from mole fractions of trace components with magnitudes  $10^{-6}$  to enthalpy flow values that can be up to  $10^6$ . IDAES-IP offers a variety of tools to assist in scaling both variables and constraints. Scaling serves two purposes: first, to ensure that the convergence criterion

(5) guarantees that all equations are satisfied without being unduly difficult to satisfy, and second, to reduce the condition number of the Jacobian. A method exists [10] for calculating scaling factors for variables and constraints that minimize the condition number of the Jacobian by solution of a convex program. While this method achieves the second goal, it has no guarantee of achieving the first goal.

Let there be two example equations that may occur in, for example, a heater:

$$y_{trace,in} - y_{trace,out} = f_1(\mathbf{x}) \quad (13)$$

$$H_{in} + Q - H_{out} = f_2(\mathbf{x}) \quad (14)$$

in which  $y_{trace}$  is the mole fraction of a trace component,  $H$  represents stream enthalpies, and  $Q$  is a heat duty. If the initial values were off by a relative error of 100%, the error in (13) would be of the order  $10^{-6}$  and the error in (14) of the order  $10^6$ . If equations of these magnitudes are loaded into the same  $f(\cdot)$ , significant error can exist in the values of mole fractions with the equation ostensibly satisfied while the solver would strain to keep reducing the error in the enthalpy equation far beyond what is significant. IDAES and Pyomo allow us to give the first equation a scaling factor of  $10^6$  and the second one of  $10^{-6}$  to bring them to the same basis.

Let us note the effect of such scaling on the function and the Jacobian. We would replace (13) and (14) with

$$10^6(y_{trace,in} - y_{trace,out}) = \tilde{f}_1(\mathbf{x}) \quad (15)$$

$$10^{-6}(H_{in} + Q - H_{out}) = \tilde{f}_2(\mathbf{x}) \quad (16)$$

and the corresponding rows in the Jacobian would be replaced by

$$J(\mathbf{x}) := \begin{bmatrix} 10^6 \frac{\partial f_1}{\partial x_1} & \dots & 10^6 \frac{\partial f_1}{\partial x_n} \\ 10^{-6} \frac{\partial f_2}{\partial x_1} & \dots & 10^{-6} \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \vdots \end{bmatrix} \quad (17)$$

Now we have coefficients in the Jacobian of extremely different values. Row 1 has norm  $10^6\sqrt{2}$  and row 2 has norm of  $10^{-6}\sqrt{3}$ . We can derive a lower bound for the condition number in terms of rows with largest and smallest 2-norm. Rearrange Jacobian rows so that they are sorted in descending order of 2-norm magnitude

$$J(\mathbf{x}) = \begin{bmatrix} r_{max} \\ \vdots \\ r_{min} \end{bmatrix} \quad (18)$$

Then we have that

$$\|r_{max}\|_2 = \left\| \begin{bmatrix} 1 & 0 & \dots \\ \vdots \\ r_{min} \end{bmatrix} \right\|_2 \leq \sigma_1 \quad (19)$$

and

$$\|r_{min}\|_2 = \left\| \begin{bmatrix} \dots & 0 & 1 \\ \vdots \\ r_{min} \end{bmatrix} \right\|_2 \geq \sigma_n \quad (20)$$

so, we have that

$$\kappa_2(J(\mathbf{x})) = \sigma_1/\sigma_n \geq \|r_{max}\|_2/\|r_{min}\|_2 \quad (21)$$

Presently, the Jacobian matrix has condition number greater than  $\frac{\sqrt{6}}{3} \cdot 10^{12}$ . To reduce it, we need to also set scaling factors for variables. We define

$$\tilde{y}_{trace,in} := 10^6 y_{trace,in}$$

$$\tilde{H}_{out} := 10^{-6} H_{out}$$

Suppose we had  $y_{trace,in} = x_1$  and  $H_{out} = x_n$ . The Jacobian now looks like

$$J(\mathbf{x}) := \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \dots & 10^{12} \frac{\partial f_1}{\partial x_n} \\ 10^{-12} \frac{\partial f_2}{\partial x_1} & \dots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \vdots \end{bmatrix} \quad (22)$$

The entry involving  $10^{12}$  would be potentially problematic, but because  $\frac{\partial f_1}{\partial x_n} = 0$ , it is irrelevant. In short, scaling a constraint *multiplies* the corresponding Jacobian *row* by that scaling factor, and scaling a variable *divides* the corresponding Jacobian *column* by that scaling factor.

It is not necessary to manually create transformed variables and constraints because Pyomo allows the user to store scaling factors associated with variables and constraints as part of the model. The unscaled model can then be transformed into the scaled model before being passed to the nonlinear solver.<sup>1</sup> A scaled version of the model can also be retrieved for debugging purposes through a scaling transformation.

In a model with thousands of variables and constraints, however, it is difficult to keep track of which variables and constraints have been scaled, and whether the scaling factors assigned are appropriate. The IDAES diagnostics toolbox, described in [6], has the methods `display_constraints_with_extreme_jacobians` and `display_variables_with_extreme_jacobians` that iterate over Jacobian rows and columns, respectively, to display the ones with 2-norms larger and smaller than some user-specified tolerances (by default  $10^4$  and  $10^{-4}$ ). These methods highlight areas of the model that require work, but the user still needs to determine appropriate values for scaling factors, as well as which variables and constraints need to be scaled. For example, rows 1 and 2 would be highlighted in the Jacobian of (17),

<sup>1</sup> Scaling at the time of passing the model to the solver can be done by use of the `ipopt_v2` solver in Pyomo through the `SolverFactory` function.

when it is the variables, not the constraints, that require scaling.

Scaling is often an iterative process. Once appropriate scaling factors are assigned to variables, bringing the Jacobian into the form (22), large or small entries can appear in additional rows, corresponding to other constraints, that would then need to be scaled. Finally, a large entry can correspond to a model that is *intrinsically* ill-conditioned. For example, when modeling a process with a large recycle ratio, large terms can appear in the corresponding Jacobian. Small impurities in the feed stream can become concentrated by factors of 100 or 1000 as a feature of the process. Scaling might be able to hide this feature, but it can cause a loss in accuracy and will be revealed by performing SVD of the Jacobian.

## Singular Value Decomposition

Even once rows and columns with inappropriately large or small norms have been removed by scaling, the Jacobian's condition number, which can be revealed through the SVD of the Jacobian, can still be extremely large. Both  $\sigma_1$  and  $\sigma_n$  appear directly in the expression for the condition number, so reducing  $\sigma_1$  and increasing  $\sigma_n$  should help reduce it. In practice,  $\sigma_1$  is usually reduced to a reasonable level by scaling rows and columns, so we will focus on increasing  $\sigma_n$  instead.

Consider the solution to a Newton step problem

$$\mathbf{f}(\mathbf{x}_k) = -J(\mathbf{x}_k)\Delta\mathbf{x}_k \quad (23)$$

By decomposing  $J(\mathbf{x})$  using the SVD and using that to solve (23), we obtain

$$\mathbf{f}(\mathbf{x}_k) = -U\Sigma V^T \Delta\mathbf{x}_k \quad (24)$$

$$-\Sigma^{-1}U^T \mathbf{f}(\mathbf{x}_k) = \Sigma^{-1}U^T U \Sigma V^T \Delta\mathbf{x}_k = \Delta\mathbf{x}_k \quad (25)$$

So, in solving the perturbed problem, the constraint residual is projected by  $U^T$  into orthogonal components in the space of the singular values, scaled by the inverse singular values, and those scaled values are projected by  $V$  into the space of variables.

Looking at (25) another way

$$-U^T \mathbf{f}(\mathbf{x}_k) = \Sigma V^T \Delta\mathbf{x}_k \quad (26)$$

Each column of  $U$  (row of  $U^T$ ) is an orthogonal vector, associating elements of  $\mathbf{f}(\mathbf{x}_k)$ , i.e., particular constraints, with a singular value. Likewise, each column of  $V$  (row of  $V^T$ ) is a vector associating elements of  $\Delta\mathbf{x}_k$ , i.e., particular variables, with a singular value. The SVD shows which constraints are being satisfied using which variables in a neighborhood of  $\mathbf{x}_k$ , and the sensitivity of the variables with respect to constraints.

If the smallest singular value  $\sigma_n \ll 1$ , a small change in certain function values requires a large change in variable values. By looking at the constraints involved in the  $n$ th left-singular vector  $u_n$  and the variables involved in  $n$ th right singular vector  $v_n$  we can attempt to determine

what is causing this dysfunctional relationship. Because of the dense linear algebra involved, we expect most entries of  $u_n$  and  $v_n$  to be populated by nonzero numbers. A simple but crude method is to filter for indices that have values greater than some tolerance. We have found absolute values of 0.1 to 0.3 work well for this. If too many variables and constraints appear, raise the tolerance. If too few appear, decrease it.

Ideally, we would want the condition number of  $J(\mathbf{x}_k)$  to be relatively small. In practice, however, we typically accomplish a condition number on the order of  $10^6$ - $10^8$ . That means filtering for singular values smaller than  $10^{-8}$ - $10^{-6}$  and attempting to remedy them. In general, there are four causes of small singular values:

1. Incorrect scaling of variables or constraints
2. Redundant equations, hinting a problem that over-specifies some variables and under-specifies others, i.e., global degeneracy
3. A local singularity, caused by evaluating  $J(\mathbf{x})$  at a point where it locally loses rank, i.e., local degeneracy
4. Attempting to solve a problem that is inherently ill-conditioned.

Incorrect scaling is probably the most common cause of small singular values of values  $10^{-12}$ - $10^{-6}$ , followed by inherent ill-conditioning. For singular values smaller than  $10^{-12}$ , the cause is typically local or global degeneracy. The next section presents a carbon capture application in which these concepts can be demonstrated.

A similar technique for identifying sets of degenerate equations is given by the Degeneracy Hunter algorithm proposed in [11]. This algorithm is also incorporated into the IDAES diagnostics toolbox. It differs from this technique by performing a QR factorization instead of an SVD, then solving a mixed integer linear program (MILP) to find an irreducible degenerate set of equations. Which algorithm is appropriate for a given problem depends on the algorithms available for a sparse QR factorization, a sparse SVD, and MILP solution. An advantage the SVD provides, however, is that it shows which combinations of variables are being used to satisfy combinations of constraints. If a degenerate constraint is removed, then another constraint must be added to constrain that combination of free variables.

## CASE STUDY: POST COMBUSTION CARBON CAPTURE FLOWSHEET

A flowsheet in which  $\text{CO}_2$  is captured from flue gas (from a ~690 MWe Natural Gas Combined Cycle power plant) by absorption into monoethanolamine (MEA) provides several examples in which these diagnostic tests were of great assistance in model refinement and increasing robustness. This flowsheet was first presented in [12], but despite the techniques used to provide robust

solutions, such as a four-stage initialization routine for the absorption and stripping columns, it remained fragile and prone to failure. It was desirable to improve convergence and numerical robustness so the flowsheet could be used for robust design optimization. The flowsheet consists of an absorption column, stripper column, lean-rich heat exchanger, and balance-of-plant equipment. It is divided into two sub-flowsheets, an absorber section and a stripper section, that are solved independently before being linked and solved together.

**Figure 1.** MEA carbon capture flowsheet, divided into stripper and absorber sections.

We begin with a flowsheet that has some partial scaling applied to the column model, but does not have scaling for any other models. The column model has already been reformulated to remove division in constraints where possible, which helps avoid bad numeric behavior when the denominator of an expression is nearly zero at an intermediate iteration. For an unscaled or partially-scaled model, the output can be hundreds of lines long. The output length is mostly the result of scaling issues in indexed variables or constraints resulting in those variables or constraints being printed for each value of their indices. Since the column model is discretized into 40 finite elements along its length, 10 badly-scaled equations results in 400 entries. Therefore, the output cannot be fully displayed here, but some representative entries can be shown.

## Jacobian Analysis

Here, we run the diagnostics tools after a successful solution of the flowsheet. They can be used after failures to solve a flowsheet, but care should be taken as variables may not have realistic values, which is reflected in the model Jacobian. The following is one line (out of hundreds) produced by the `display_variables_with_extreme_jacobians` command from the `DiagnosticsToolbox`:

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].temperature: 1.997E+08
```

This entry indicates a column norm of  $2 \cdot 10^8$ . We can inspect the associated column of the Jacobian to find which rows are associated with this large value. In IDAES-

IP, we can do this using the `display_constraints_including_variable` function in the `SVDToolbox`.

```
fs.strip_section.reflux_mixer.enthalpy_mixing_equations[0.0]: 1.997e+08
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_k_eq_constraint[bicarbonate]: 5.364e+00
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_k_eq_constraint[carbamate]: 6.551e+00
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_conc_mol_phase_comp_true_eq[Liq,MEACO_0-]: 1.514e+00
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_conc_mol_phase_comp_true_eq[Liq,HCO3-]: 2.333e-01
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_conc_mol_phase_comp_true_eq[Liq,MEA+]: 1.748e+00
```

```

```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_conc_mol_phase_comp_true_eq[Liq,MEA]: 1.129e+00
```

```
fs.strip_section.reflux_mixer.rich_solvent_state[0.0].log_conc_mol_phase_comp_true_eq[Liq,CO2]: 5.685e-03
```

```
fs.rich_temperature: 1.000e+02
```

From inspection, the problematic Jacobian entry is associated with a mixer enthalpy mixing equation that is not yet scaled.

To fix the problem, we need to determine an appropriate scaling factor. We can calculate such a value from scaling factors for both the molar flow and the specific molar enthalpy. Finding the molar flow scaling factor is easy; it is generally observed that the molar flow rates are on the order of  $10^3$ - $10^4$  throughout the flowsheet, so we choose  $3 \cdot 10^{-4}$  as a scaling factor for the molar flow rate. Determining a scaling factor for the specific molar enthalpy is harder. Enthalpy can be either positive or negative in different areas of the flowsheet, so its order of magnitude does not make a good scaling factor. By evaluating the liquid-phase enthalpy in the reflux mixer, the water makeup mixer, and the reboiler, we get values of  $-42200$ ,  $-43600$ , and  $-38800$ . With an apparent range of 4800, a scaling factor of  $3 \cdot 10^{-4}$  is also a good choice for this variable. Values for scaling factors do not have to be exact: almost counts in horseshoes, hand grenades, and model scaling.

The process of removing this scaling issue took us through at least three Pyomo sub-models (and associated Python files) to determine a process through which the scaling factor for one equation was calculated. However, had reasonable default scaling factors for the property sub-model been set by the user ahead of time, this issue would never have arisen.

Next, we consider scaling the equations describing

heat transfer in the column

$$h_V a_e Ack = -(\underline{C}_{pCO_2,V} N_{CO_2,V} + \underline{C}_{pH_2O,V} N_{H_2O,V}) \quad (28)$$

$$h'_V a_e (1 - \exp(Ack)) = \underline{C}_{pCO_2,V} N_{CO_2,V} + \underline{C}_{pH_2O,V} N_{H_2O,V} \quad (29)$$

in which  $h_V$  is the heat transfer coefficient from liquid to vapor,  $a_e$  is the effective area of heat transfer per unit column volume,  $\underline{C}_{p,i,V}$  is the heat capacity of species  $i$ ,  $N_{i,V}$  is the molar flux of species  $i$  from vapor to liquid, and  $Ack$  is the Ackerman factor, which is a measure of how much diffusive heat fluxes are distorted by convective heat transfer. It was discovered that  $|Ack| \leq 10^{-2}$  for operating conditions of interest and was frequently on the order of  $10^{-5}$ . This causes ill-conditioning in both equations because the factors  $Ack$  and  $1 - \exp(Ack)$  became close to zero. Because  $Ack$  could vary over several orders of magnitude depending on location and operating conditions, assigning a consistent scaling factor is difficult.

If we first rearrange (28) and (29) to make the relationship between  $h_V$  and  $h'_V$  more clear

$$h'_V = h_V \frac{Ack}{(\exp(Ack)-1)} \quad (30)$$

several solutions are possible. The function

$$\theta(x) = \frac{x}{\exp(x)-1} \quad (31)$$

has an indeterminate form at  $x = 0$ , but a well-defined Taylor expansion

$$\theta(x) \approx 1 - \frac{x}{2} + \frac{x^2}{12} + O(x^4) \quad (32)$$

A Taylor approximation could be substituted for  $\theta(Ack)$  in (30), but  $\theta(x)$  could also be implemented as an external grey-box function in IDAES, switching between the full form (31) and Taylor form (32) based on  $|x|$ . Both options were eventually implemented. An external function for  $\theta(x)$  is implemented in IDAES with a sixth-order Taylor approximation, but the trivial Taylor approximation  $\theta(x) \approx 1$  is presently used in the MEA flowsheet because not every solver in Pyomo supports external functions.

## SVD Analysis

The SVD also tells us valuable information about the state of the flowsheet. Its condition number is  $9.2 \cdot 10^{17}$ , so the matrix is singular to machine precision. The smallest singular value is  $\sigma_n = 3.1 \cdot 10^{-10}$ . Using a tolerance for the singular vectors of 0.1, we find the following variables involved:

```
fs.stripper_section.reflux_mixer.re-
flux_state[0.0].log_conc_mol_phase_comp_true[Liq,H
CO3_-]
```

```
fs.stripper_section.reflux_mixer.re-

All these variables and constraints occur in the condenser, which makes interpretation of the problem easier. However, if multiple degeneracies are present, they can mix between different tiny singular values, so sometimes additional analysis is necessary to separate different degeneracies.

Because the property model in this flowsheet does not account for amine volatility, the mole fraction of MEA in the condenser is effectively zero. All the variables implicated here are dissociation species of MEA, which similarly have concentrations of effectively zero. The constraints are likewise the disassociation equations for MEA. Thus, the absence of MEA causes degeneracy in the system of equations governing the dissociation reactions. Different strategies can be employed to overcome this degeneracy. The easiest is to increase the mole fraction of MEA to around  $10^{-4}$ . However, this merely mitigates the ill-conditioning—it does not remove it—and the addition of extra MEA in the system could cause problems with material balances converging.

IDAES-IP allows the user to define property packages that bundle together thermodynamic calculations into a single sub-model that can then be employed in different unit models. The solution we employed was to create a duplicate property package without the dissociation reactions and use that for the condenser and reflux mixer. That solution works only because the liquid phase property sub-model does not rely on ion concentrations for the calculation of enthalpy. For one that requires ion concentrations to calculate the enthalpy of mixing, like

eNRTL, another solution would have to be devised.

## Limits of Scaling and Reformulation

Not every problem that can be discovered by these diagnostic tools has a nice solution. Such is the case with the system of equations for the enhancement factor for mass transfer in reactive systems. Taken from [13] for the MEA-CO<sub>2</sub> system, the full enhancement factor model has ten tightly coupled numerical expressions in it. However, the core numerical issues derive from two equations:

$$E = 1 + (E_{\infty}^* - 1) \frac{1 - Y_{MEA}^i}{1 - Y_{CO_2}^b} \quad (33)$$

$$E = Ha \sqrt{Y_{MEA}^i \frac{1 - Y_{CO_2}^*}{1 - Y_{CO_2}^b}} \quad (34)$$

in which  $E$  is the enhancement factor,  $E_{\infty}^*$  is the “instantaneous enhancement factor,” a theoretical maximum value for the enhancement factor,  $Y_{MEA}^i$  is a dimensionless concentration of MEA at the vapor/liquid interface,  $Y_{CO_2}^*$  is the dimensionless concentration of CO<sub>2</sub> at the interface,  $Y_{CO_2}^b$  is the dimensionless concentration of CO<sub>2</sub> in the bulk liquid, and  $Ha$  is the Hatta number, the ratio of reaction film to the rate of diffusion in the film. Absorption happens when  $Y_{CO_2}^b < 1$ , desorption happens when  $Y_{CO_2}^b > 1$ , and equilibrium occurs when  $Y_{CO_2}^b = 1$ .

The problem occurs near equilibrium, because the expression  $1 - Y_{CO_2}^b$  is nearly equal to zero, and the quotients in (33) and (34) are nearly singular. At actual solutions to the system of equations, numerical tests show that  $1 - Y_{CO_2}^*$  and  $1 - Y_{MEA}^i$  also approach zero, so the quotient remains defined. However, since we now must deal with a multivariate function, we have been unsuccessful at removing the singularity by use of a Taylor series, like we did with the Ackerman factor. The expressions  $1 - Y_{CO_2}^b$  and  $1 - Y_{CO_2}^*$  will have the same sign at any solution to the activity factor system. However, contrary to what is stated in [13], there exist at least one scenario in which  $1 - Y_{CO_2}^b$  has the opposite sign as  $1 - Y_{MEA}^i$ . When CO<sub>2</sub> is desorbing at low temperatures, the rate of reaction can become slow enough that the rate of desorption is lower with reaction than it would be without reaction, and the enhancement factor drops below one. That fact limits possible reformulations of these two equations.

The equations were ultimately reformulated in several steps. First, a log variable  $S_{CO_2}$  was introduced for one of the singular ratios:

$$(1 - Y_{CO_2}^b) \exp(S_{CO_2}) = 1 - Y_{CO_2}^* \quad (35)$$

so that (34) could be rewritten as the linear equation

$$\log E = \log Ha + \frac{1}{2} \log Y_{MEA}^i + S_{CO_2} \quad (36)$$

in which  $\log E$ ,  $\log Ha$ , and  $\log Y_{MEA}^i$  are all additional log variables defined using equations of the form

$$\exp(\log x) = x \quad (37)$$

To be completely clear,  $\log x$  is a single variable, not an expression denoting the logarithm of the variable  $x$ , which we denote  $\log(x)$ . We have that  $\log x = \log(x)$  at solutions of the model, i.e., when  $f(x) = 0$ , but equality does not necessarily hold at intermediate Newton iterates. The benefit of implicitly taking the logarithm in equations like (35) and (37) instead of using a log function in (36) is that the variable  $\log x$  can maintain numerical accuracy even when the values of  $x$  are extremely small or extremely large.

**Figure 1.** Convergence of the pilot-scale stand-alone column model depending on inlet parameters (a) before and (b) after the scaling and reformulations detailed here. A filled square indicates it converged, an unfilled square indicates it did not converge. In the reformulated model, divergence typically is a result of  $Y_{CO_2}^*$  incorrectly converging to 1, resulting in (35) and (38) becoming degenerate.

**Figure 2.** Convergence of the plant-scale full flowsheet model depending on inlet parameters (a) before and (b) after the scaling and reformulations detailed here. A filled square indicates it converged, an unfilled square indicates it did not converge.

Unfortunately, both (35) and (39) become degenerate when  $Y_{CO_2}^b = 1$ . Because the enhancement factor system can be largely decoupled from the remaining equations, a surrogate model was created to

give the log enhancement factor as a function of liquid phase CO<sub>2</sub> and H<sub>2</sub>O loading, vapor phase CO<sub>2</sub> partial pressure, temperature, and liquid and vapor mass transfer coefficients. However, too much accuracy was lost in the first attempt at a surrogate model, and the reformulated enhancement factor model is reliable enough to keep. Figures 1a and 1b show the convergence of the original and reformulated stand-alone column models, while Figures 2a and 2b show the convergence of the original and reformulated full flowsheet models (with all changes, not just to the enhancement factor calculations), respectively. The numerical robustness of the reformulated and scaled models is significantly improved over that of the original model.

It is possible to use the same technique as (35) for the ratio of MEA to CO<sub>2</sub> in (33). However, that implicitly assumes that  $1 - Y_{CO_2}^*$  and  $1 - Y_{MEA}^i$  have the same sign, which is true for most operating conditions of interest, but is not true for desorption at low temperatures. The resulting reformulation of (33) is then

$$\exp(\log E)(1 - Y_{CO_2}^b) = \exp(\eta)(1 - Y_{MEA}^i) \quad (38)$$

$$\exp(\eta) = E^* - 1 \quad (39)$$

in which the log variable  $\eta$  has been introduced for the instantaneous enhancement factor minus one because there is a simple expression for  $\eta$  (not given here) in terms of logarithms of other variables.

## CONCLUSIONS

We have outlined model diagnostic methods using tools available in Pyomo and IDAES-IP. As illustrated through the example of the MEA flowsheet, these tools can be of great assistance to the user by serving to point out likely problems. However, they do not solve them for the user. Finding problems in a model with tens of thousands of constraints and variables is a major service, but the user's insight and modelling expertise is still necessary to solve them. Nevertheless, these tools and techniques can help make EO modeling frameworks more accessible and facilitate the use of advanced optimization techniques in process design.

## ABSTRACT

We present the implementation of combined junior course projects encompassing three core courses: reaction engineering, separations, and process simulation and design. The combined project aims to enhance the vertical integration of process design learning through all levels of the curriculum. We design the projects to utilize novel modular process technologies (e.g., membrane separation) and to emphasize new process design goals (e.g., sustainability, decarbonization). Two example projects, respectively on green methanol synthesis and ethylene oxide production, are showcased for project implementation. Feedback from junior and senior students is also presented to motivate the development of such joint project in CHE curriculum. We will also discuss the challenges we hope to address to maximize student learning from this unique project.

**Keywords:** Education, Modelling and Simulations, Process Design, Process Intensification, Carbon Capture.

## INTRODUCTION

Chemical Engineering curriculum is well-recognized for its broad scope covering many core concepts with a wide range of engineering applications. Students typically acquire the fundamentals distributed over courses in the first three years while applying the entire body of knowledge to a capstone design project during the senior year. Given this, vertical integration of process design experiences through the curriculum<sup>1-2</sup> offers promise to help students develop a connected ChE knowledge map and foster critical thinking before starting senior design.

In this paper, we present our efforts on advancing junior-level design education, in particular, leveraging combined projects joint across three courses that students are taking in the Spring semester, namely Reaction Engineering, Separations, and Process Simulation and Design. The major goals of the combined project include:

1. Students work in teams to solve open ended chemical engineering problems.
2. Integrate topics and knowledge from multiple courses towards plant design and optimization.
3. Learn emerging new modular units (e.g., membrane) and integrate to existing process options.
4. Learn new process design goals including decarbonization, sustainability, etc.

## EXAMPLES OF COMBINED PROJECT

### Project 1: Methanol Synthesis using Captured CO<sub>2</sub> and Green Hydrogen

The Spring 2022 combined project is shown in Fig. 1, which involved the modeling, simulation, and optimization of an industrial-scale methanol synthesis process using captured CO<sub>2</sub> and green hydrogen. The CO<sub>2</sub> capture unit, which was the focus of Separations course, involved designing and optimizing a membrane-based process for CO<sub>2</sub> capture from natural gas combined cycle plant<sup>3</sup>. This enabled the students to be familiar with a relatively new separation technology as opposed to traditional sorbent-based processes. For the CO<sub>2</sub> hydrogenation reactor, the focus of Reaction Engineering course, students analyzed various reactor designs and operating conditions with an emphasis on the impact of recycle stream. This enabled the students to model a more complex reactor while investigating how the reactor design was influenced by the up/down process streams. Students also simulated and analyzed the entire flowsheet<sup>4</sup> as part of Process Simulation and Design course. Process design optimization strategies were proposed and investigated by students, assessed against multiple economics and sustainability metrics.

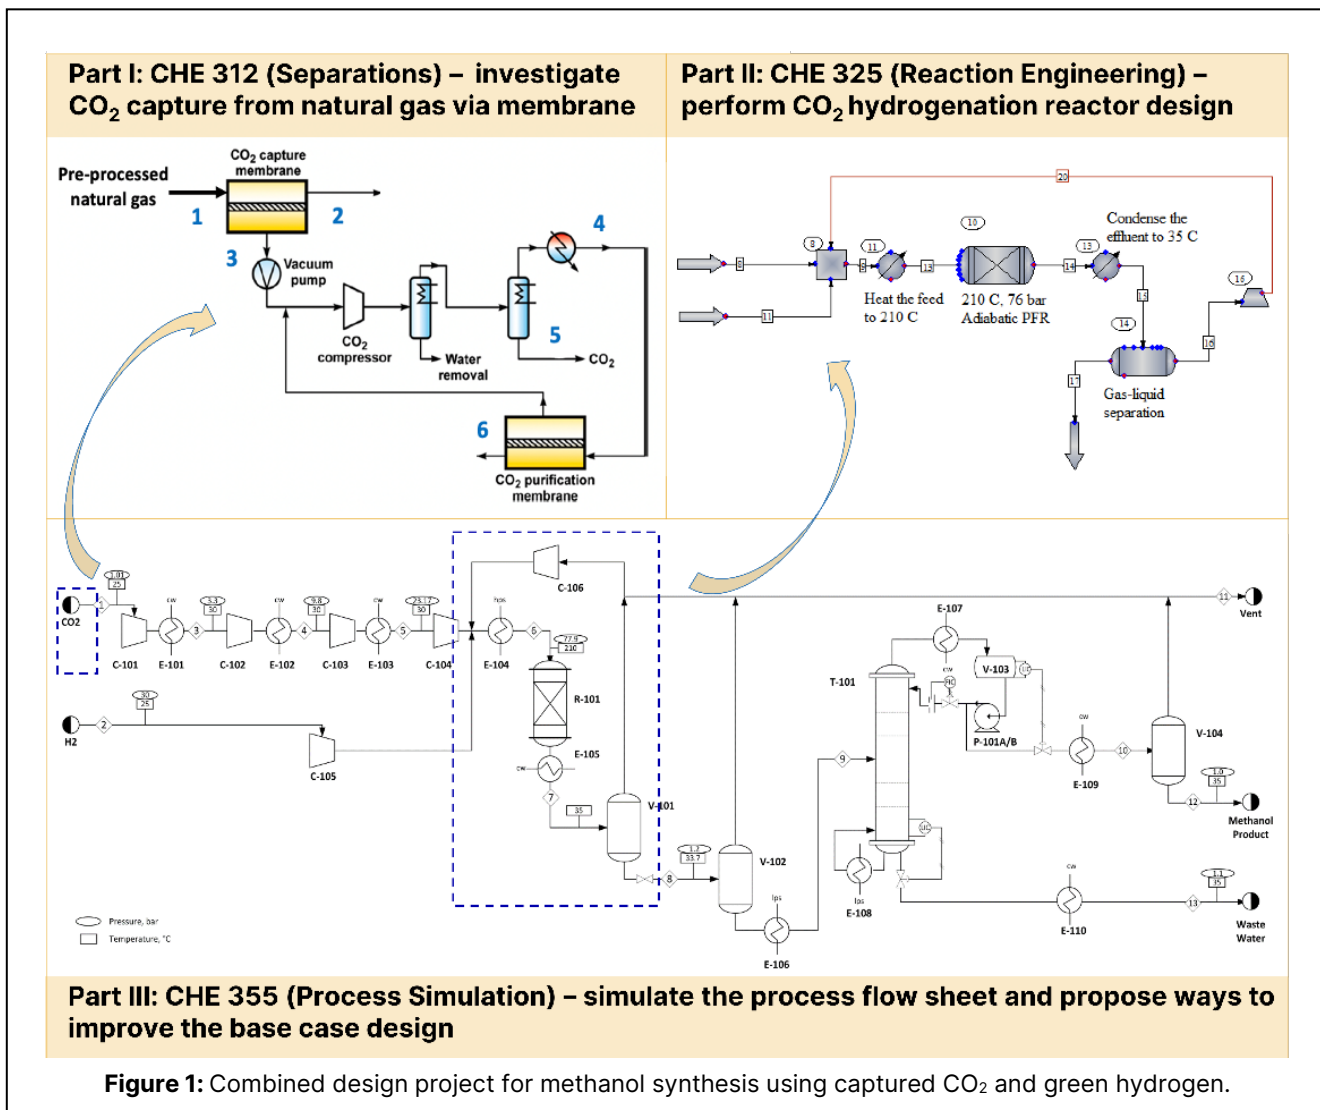

Figure 1: Combined design project for methanol synthesis using captured CO<sub>2</sub> and green hydrogen.

## Project 2: Ethylene Oxide Production

Fig. 2 illustrates the Spring 2023 combined project to design an ethylene oxide production plant via the direct oxidation of ethylene. The base case process design starts with compressing a mass amount of dry air which includes both nitrogen and oxygen. The multi-stage compressors are the major energy consumer in this process. The Separations course focuses on analyzing an alternative route in which oxygen is first separated from air via membranes before being sent to compressors. This enabled the students to quantitatively compare two process options, including a well-established process with high energy intensity and an emerging modular process where the large-scale commercialization is at an early stage. For the ethylene oxidation reactor, the focus of Reaction Engineering course, students compared the simulation using equilibrium-based reactor and kinetic reactor to understand the characteristics of this reaction. Students also searched for alternative catalysts from open

literature, such as the use of promoters on the Ag catalyst to improve selectivity to the ethylene oxide product. This enabled the students to learn the impact of reaction kinetics on the design and optimization of this reactor unit as well as the integrated process systems. Students simulated and optimized the entire flowsheet as the focus of Process Simulation and Design course. They also analyzed the bottleneck of base case process design based on cost breakdown and investigated systems-level integration of the upstream membrane units.

## IMPLEMENTATIONS AND OUTCOMES

This section presents several examples to showcase student implementations for the green methanol synthesis project (Fig. 1).

### Separations

The Separations design project was focused on simulating a hollow fiber membrane-based carbon capture

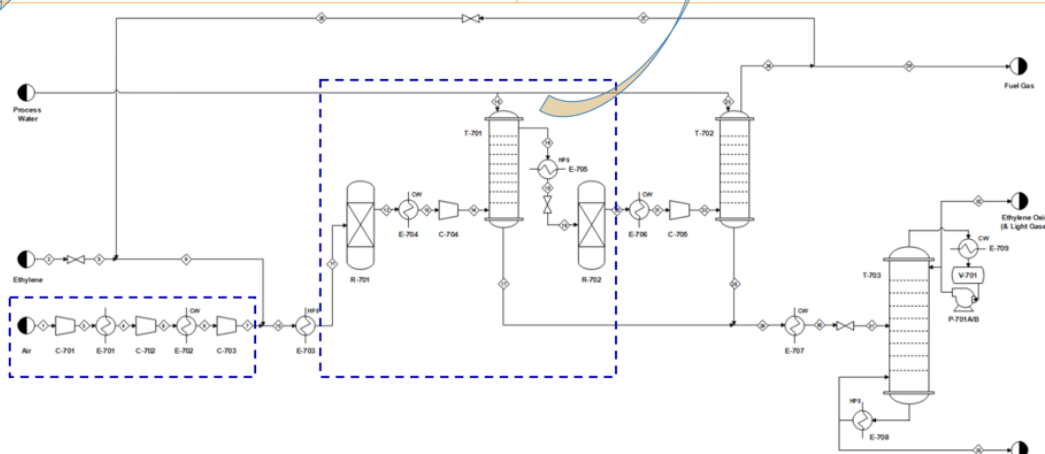

**Part I: CHE 312 (Separations) – investigate O<sub>2</sub> separation from air via membrane**

**Part II: CHE 325 (Reaction Engineering) – study the impact of catalyst and optimize reactor**

**Part III: CHE 355 (Process Simulation) – simulate the process flow sheet and propose ways to improve the base case design**

**Figure 2:** Combined design project for ethylene oxide production.

process, in conjunction with natural gas combined cycle (NGCC), i.e., primarily aimed at CO<sub>2</sub>/N<sub>2</sub> separation. The project involved analysis of the effects of intrinsic membrane parameters (CO<sub>2</sub> permeability and CO<sub>2</sub>/N<sub>2</sub> selectivity) on the overall system performance such as product quality, recovery, and membrane area. The membrane properties were chosen from prior experimental studies. Some preliminary calculations were expected to be done by students using the membrane separation principles covered during regular lectures. The students were also required to identify the input parameters (e.g., membrane performance, upstream/downstream pressure) which significantly affect the final product purity. Finally, the student groups were asked to identify improvement and possible modifications to the proposed system. Results from one representative group are shown in Fig. 3.

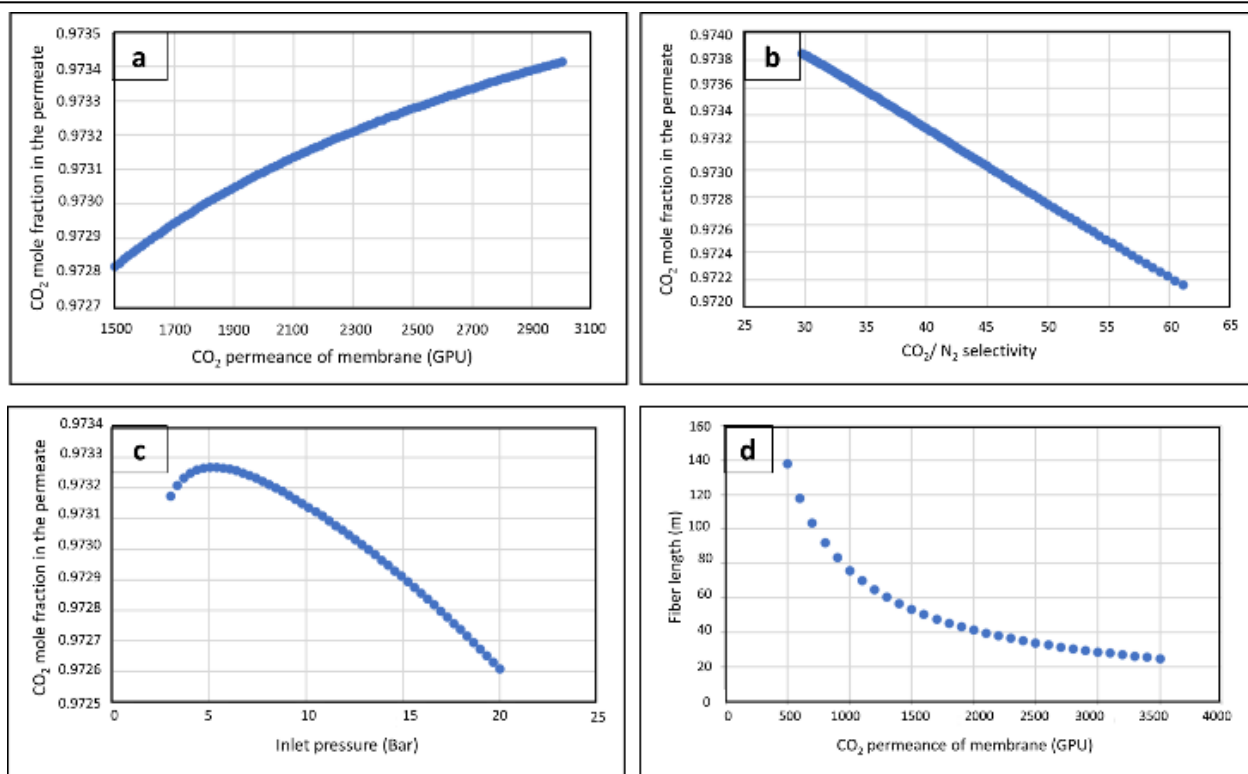

### Reaction Engineering

The Reaction Engineering design project section was focused on simulating the CO<sub>2</sub> hydrogenation reactor and investigating the impact of the recycle stream on reactor performance. The rate expressions for both methanol

synthesis and the reverse water gas shift reactions were provided along with the corresponding kinetic parameters. These kinetic expressions were implemented into CHEMCAD by the students and compared the reaction section - including reactor, heat exchanger, flash vessel, and recycle - modeled with these kinetics vs a reactor at equilibrium. Students were asked to report selectivity and yield, as well as fractional conversion as a function of the reactor volume to optimize the reactor sizing. Additionally, they were asked to propose a reactor improvement based on either economic or performance metrics. As an example of the results, one project group results are shown in Fig. 4. This specific group used profit as the metric by which to conduct their optimization and determined the reactor volume based on maximum profit.

### Process Design and Simulation

The Process Simulation and Design project section was focused on simulating the entire flowsheet using CHEMCAD, which included (multi-stage) compression of the CO<sub>2</sub> and H<sub>2</sub> feed streams, CO<sub>2</sub> hydrogenation reactor, and a series of separation units (flash and distillation

**Figure 3:** Effects of (a) CO<sub>2</sub> permeance, (b) CO<sub>2</sub>/N<sub>2</sub> selectivity and (c) Inlet pressure on permeate quality and (d) effect of CO<sub>2</sub> permeance on the fiber length.

columns). Students were also required to perform equipment sizing and calculate the equivalent annual operating cost (EAOC) to identify the process design bottlenecks. On this basis, students would propose and implement two major areas for process improvements. Fig. 5 presents an example of the improvements by one of the design groups, where they applied heat integration utilizing the high temperature reactor effluent to heat the inlet streams respectively to reactor and distillation column. Additionally, they added a membrane module to recover hydrogen from the vent stream. As this project assumed the use of green hydrogen, the raw material cost took up more than 80% of base case EAOC. The recovery of remaining H<sub>2</sub> would effectively reduce the cost. The students proposal of using a membrane for downstream gas separation also well justified the efficacy of this combined project to bring emerging modular intensified process technologies to the toolbox of next-generation chemical engineers. To address the trade-off between sustainability and economic competitiveness as illustrated by this green methanol process, one design group explored the impact of carbon tax.

## STUDENT FEEDBACK

After the second year of project implementation, surveys were conducted for both project cohorts of

students. The survey administered to the junior students who had just completed the project (2023 project on ethylene oxide production) focused on how the project helped them develop skills and apply technical content from the courses. The survey administered to the senior students, who had completed the joint project approximately one year prior (2022 project on methanol synthesis), focused on how the project prepared them for senior design.

### Junior Survey on Combined Project

The primary survey question investigated whether students felt the joint project helped them to practice material from each of the three courses, shown in Fig. 6.

Most students felt that the joint project helped them practice material from the Process Design course, with a strong majority answering “very much”. For the Separations and Reaction Engineering courses, however, responses were more distributed with approximately equal numbers of students responding 3 (neutral), 4, or 5 (very much).

Additionally, students were asked to compare their skills before and after working on the junior design project across a range of areas, including technical skills such as process design and optimization as well as skills

Figure 2: Base Case Methanol Yield vs. Reactor Volume

Figure 3: Base Case Carbon Dioxide Conversion vs. Reactor Volume

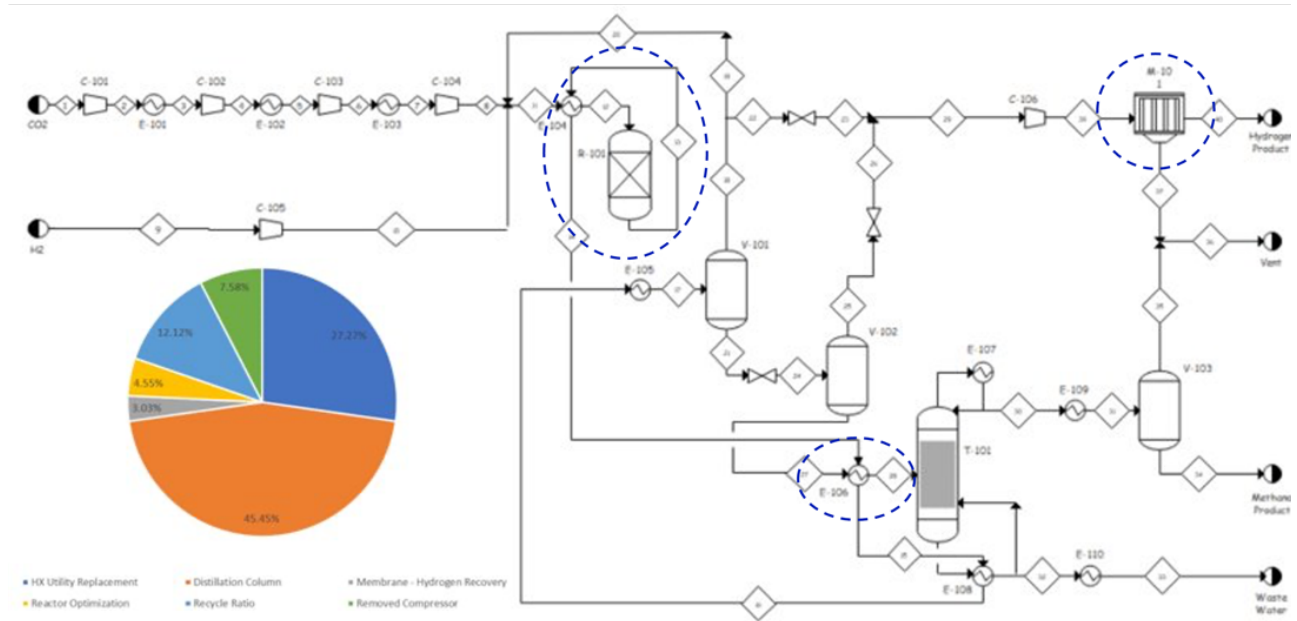

Figure 8: Closer Examination of "Profit" Plot to Find Ideal Reactor Volume

**Figure 4:** (Top) Methanol yield as a function of reactor volume, (bottom left) conversion and equilibrium conversion as a function of reactor volume, and (bottom right) process profit as a function of reactor volume to determine the optimum reactor size.

**Figure 5:** Process design improvements via heat integration and membrane-based hydrogen recovery.

such as teamwork, communication, and creativity. The results are shown in Fig. 7, with the left of each bar indicating before the project and the right of each bar indicating after the project.

While all skills showed an improvement after participating in the design project (indicated by more green and blue and less red/orange/yellow), the most significant improvements were observed for the technical skills. In reflecting on the beginning of the class, at least half the

class rated themselves as having poor, fair, or good skills in process/single unit design and optimization. After participating in the project, the vast majority of the students reported their skills in these areas as very good or excellent. Improvements to group work, communication, and other similar skills were less drastic.

**Figure 6:** Responses from junior students to “Did the course project help you put into practice material from Separations (blue), Reaction Engineering (red), and Process Design (yellow)?” Responses were given on a scale of 1 (not at all) to 5 (very much).

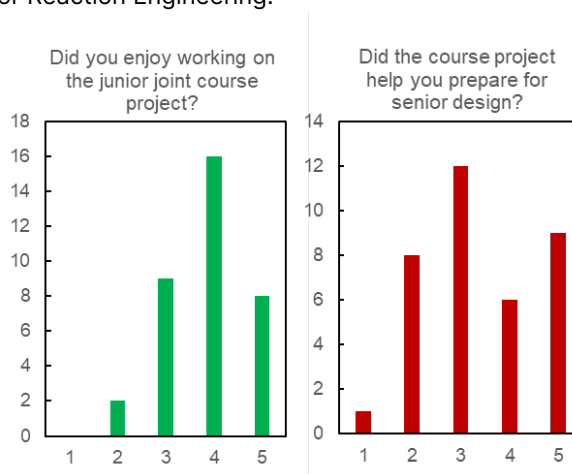

**Figure 7:** Responses from junior students on their skills in a variety of topic areas before (left, faded) and after (right, darker) working on the junior design project. Responses were given on a scale of poor, fair, good, very good, and excellent.

### Senior Survey on Preparation for Capstone Design

The senior students who participated in the first implementation of the joint project in Spring 2022 were surveyed about their experience in Spring 2023. This survey served to assess their perception of preparation for their senior design course, as well as their retrospective perception of how well the project helped them practice material from each of the junior level courses. Most students reported a neutral or positive experience of working on the project, however the perception of preparation for

senior design was mixed. Students reported an average of 3.4 (out of 5) indicating they felt that the junior course project somewhat prepared them for senior design.

Additionally, when asked if the joint course project helped students practice material from each of the three courses, a range of responses were given. Notably, the students reported that the project helped them practice course material to a lesser extent than the junior responses, indicating that the project modifications between implementation in 2022 and 2023 better connected the course content and project. Similar to the responses from the junior class above, the students found that the project helped them put into practice material from Process Design to a greater extent than Separations or Reaction Engineering.

**Figure 8:** Survey results for seniors, responses collected approximately one year after completing the joint junior course project. Scale of 1 (not at all) to 5 (very much).

**Figure 9:** Survey results for seniors, responses collected approximately one year after completing the joint junior course project. Scale of 1 (not at all) to 5 (very much).

## Select Student Comments

### Comments from seniors who took CHE 355 in Spring 2022 (surveyed a year later)

**Q → What was the most interesting/enjoyable part of the junior course project?**

**Response:** The integration of a single topic between all of our core classes (since it reflected more of a real-world process design project)

**Q → What was the most challenging part of the junior course project?**

**Response:** Finding a true optimum case because so many factors + process units depend on each other

### Comments from juniors who took CHE 355 in Spring 2023 (surveyed at the end of semester)

**Q → What was the most interesting and/or enjoyable part of the project?**

**Response 1:** The most interesting part of the project was finally integrating all of the information we've learned into one project instead of a bunch of little bits and pieces.

**Response 2:** Seeing how much money that can be saved with implementation of simple optimizations was very interesting.

## CONCLUDING REMARKS

In this paper, we have introduced our development of combined junior process design project across reaction engineering, separations, and process simulation and design. Two project examples are presented which strive to integrate the knowledge from different courses and highlight the increasingly important process design goals such as sustainability and decarbonization. It is worth highlighting that the implementation of such combined course projects can be greatly benefited by, while not restricted to the availability of, a specialized process design course at junior level. Based on student feedback, we aim to address the following key points to continuously improve the combined project in future semesters:

- Emphasize systems-level optimization and its interactions (or trade-offs) with single unit optimization.
- Emphasize process design and optimization with simultaneous considerations of multiple objectives (e.g., economics, carbon footprints, water usage).
- Arrange training workshops on Aspen and custom modeling to prepare students for senior design with an enriched set of simulation tools and skills.
- Integrate graduate student teaching practice to train next-generation process design educators.

## ABSTRACT

Equation-Oriented (EO) modeling techniques have been gaining popularity as an alternative for simulating and optimizing process systems due to their flexibility and ability to leverage state-of-the-art solvers inaccessible to many procedural modeling approaches. Despite these advantages, adopting EO modeling tools remains challenging due to the significant learning curve and effort required to build and solve models. Many techniques are available to help diagnose problems with EO process models and reduce the effort required to create and use them. However, these techniques still need to be integrated into EO modeling environments, and many modelers are unaware of sophisticated EO diagnostic tools. To survey the availability of model diagnostic tools and common workflows, the U.S. Department of Energy's Institute for the Design of Advanced Energy Systems (IDAES) has conducted user experience interviews of users of the IDAES Integrated Platform (IDAES-IP) for process modeling. The interviews reveal a gap between the availability and utilization of model diagnostic tools driven primarily by a lack of awareness of and lack of standard interfaces among different tools. To address this gap, the IDAES team has developed a recommended workflow for integrating diagnostics into the model development process and an IDAES Model Diagnostics Toolbox that provides a standard interface for many of these best practices. This paper identifies barriers to the widespread adoption of diagnostic tools for EO models and reduces these barriers by providing a standard, user-friendly interface for many different tools.

## INTRODUCTION

Equation-Oriented (EO) modeling techniques are powerful tools for solving complex process engineering models, providing modelers with access to powerful gradient-based solvers and greater flexibility than more traditional sequential-modular tools [1]. Several EO-based modeling tools are now available for use, including ABA-CUS [2], AIMMS [3], AMPL [4], Aspen Custom Modeler [5], DAEPACK [6], GAMS [7], gPROMS [8], JuMP [9,10], and Pyomo [11].

However, EO-based tools come with several challenges, especially when applied to large models, as

model tractability significantly depends on the formulation and the provision of good initial guesses to the solver. The number of potential issues in EO models is extensive, and understanding how to identify and remedy them during model development requires significant expertise from the user. Some possible problems include:

- inconsistencies in units of measurement,
- numerical evaluation errors and singularities,
- structural singularities in the problem matrix [12,13],
- degenerate equations and rank deficiency in the

Jacobian of the model [14],

- poorly scaled variables and constraints, and
- bound violations and infeasible constraints.

These issues are easily overlooked when manually inspecting large, complicated models such as those required for sophisticated process systems.

In 2015, the U.S. Department of Energy established the Institute for the Design of Advanced Energy Systems (IDAES) to develop a next-generation platform for process modeling: the IDAES Integrated Platform (IDAES-IP) [15,16]. IDAES aims to make state-of-the-art EO modeling techniques accessible to the process modeling community. A significant advantage of the IDAES-IP is that it is built on Pyomo [11] and Python, allowing the development of algorithms that directly interrogate a model's structural and numerical properties.

## UNDERSTANDING CURRENT APPROACHES

To understand the challenges faced by modelers, the IDAES team started by performing a user experience study, interviewing a range of users of both IDAES-IP and Pyomo with varying backgrounds and levels of modeling experience. These interviews sought to discover each modeler's most common issues and the workflows and tools they used to help diagnose them. Additionally, the interviews sought to understand how modelers developed these workflows and learned about the different tools they applied to better inform the education of new modelers.

The interviews were structured as free-form conversations to capture the range and nuance of users' experiences. With encouragement, interviewees often expanded on their responses to an initial set of questions and provided relevant anecdotes. While much of each interview was open-ended, **Table 1** summarizes the responses to three interview questions. Note that the categorization of issues in responses to **Q1** is imperfect due to imprecise definitions of various modeling issues. For example, what one user may refer to as a "degeneracy" due to a flow rate approaching zero, another may refer to as a "scaling issue." In responses to **Q2** and **Q3**, "Basic 'model statistics'" refers to simple utility functions for identifying variables and constraints with useful properties, *e.g.*, variables close to (or exceeding) their bounds or constraints with large residuals, that are provided by the `idaes.core.util.model_statistics` module.

The most frequently identified issue was poor model scaling. This is partly because the IDAES-IP (and Pyomo) tools are designed to be as general as possible to cover a wide range of operating conditions. For best performance, modelers should specify scaling factors to tailor

the problem to the specific operating range of interest.

Another common issue IDAES-IP users encounter is infeasibility, usually due to bound violations, partly due to the modular nature of the IDAES model libraries. Modelers frequently rely on pre-built sub-models, *e.g.*, for thermodynamics, but often do not check that the ranges of applicability, and thus bounds, for those sub-models match the needs of their application.

A third common issue was numerical evaluation errors, such as divisions by zero or logarithms of negative numbers. Nearly a quarter of the interviewees reported numerical evaluation errors related to zero-flow conditions in their models. These frequently arise in process systems involving reactions where not all components are present in every process stream. Suppose care is not taken to eliminate these components in streams where they do not exist or to ensure a minimum positive lower bound on flow/concentration. In that case, these values can cause numerical errors in complicated thermodynamic expressions involving logarithms or divisions.

Perhaps surprisingly, degenerate equations were not a common issue identified by users. However, this might indicate a need for more awareness of degeneracies rather than their infrequent occurrence. Most process flowsheets include at least one recycle stream, and these can easily introduce degeneracies into a model unless care is taken to identify an appropriate tear stream. Degeneracies are often tricky to identify unless the modeler knows what to look for. Degenerate models have a family of feasible solutions; thus, the solver frequently reports "optimal solution" termination messages. Hence, if the modeler does not intentionally inspect the solver logs, they may miss that their model is degenerate.

Qualitatively, the interviews revealed that most users had no formal training in diagnosing modeling issues and that most learning had come through experience. As a result, there was little uniformity in the workflows and tools used, and the interviewees tended to only think about issues they had previously encountered. Additionally, while most modelers interviewed used a bottom-up approach, starting with small models and gradually adding complexity and resolving issues as they appeared, some of those interviewed used a top-down approach, building the full complex model first and then trying to work backward to find the resulting issues.

A second finding was that there were two types of modelers within the IDAES user base: those who focused on developing models for unit operations and those who generally constructed flowsheets from pre-existing unit models in model libraries. Modelers in the first category were generally more aware of the different modeling issues they might encounter and how to fix them. At the same time, those who used existing models tended to struggle with diagnosing modeling issues. One key aspect of this is awareness of the model equations; unit

**Table 1:** Questions asked and responses received during 13 user experience interviews.

**Q1.** What are the issues you most commonly encounter with equation-oriented modeling and optimization in IDAES?

Response	Number of users
Scaling issues	8
Infeasibility	4
Incorrect degrees of freedom	4
Evaluation errors	4
Initialization issues	3
Zero-flow issues	3
Not understanding library models	3
Degeneracy	1
Incompatible assumptions	1

**Q2.** How do you recognize when these problems occur in your model or workflow?

Response	Number of users
Solver log	8
Basic “model statistics”	4
Inspect Jacobian	2
Incidence graph analysis	1
Test failure	1
Physical sanity check	1

**Q3.** What tools do you use to diagnose the cause of the issue or propose a fix?

Response	Number of users
Basic “model statistics”	8
Degeneracy Hunter	8
Inspect Jacobian	4
Change solver options	4
Solver log	3
Incidence graph analysis	2
Ask for help	2
Parameter sweep	2
Pyomo model viewer	2
Solver callback	1
Singular value decomposition	1
Serialize model state	1

model developers were generally fully aware of the equations in their models as they had written most equations themselves, while model users typically treated the library models as black boxes and were thus unable to resolve modeling issues that arose from them.

Finally, while solver logs were the most common method of identifying that a problem had occurred, many interviewees were not familiar with the full content of these. They focused mainly on apparent signs such as the final solver status, number of iterations, and obvious warning messages. This practice reveals a need to educate modelers about the data provided by solvers and how it can be used to identify potential modeling issues. Indeed, many modelers interviewed assumed that once a solver reports an “optimal solution,” that their model is

well-behaved; it is crucial to educate modelers that just as one should always check that the solution of their model makes sense, they should also check the solver logs to ensure that no warnings were encountered.

In terms of tools used to help diagnose modeling issues, the modelers identified existing tools within the IDAES-IP toolset, Pyomo, or other Python packages (*e.g.*, the SciPy packages for linear algebra [17]) to diagnose most of the modeling issues encountered. These tools fell into three categories:

1. *Structural analysis* tools that analyze constraints, variables, and bounds without depending on specific variable values. These tend to be computationally cheap and do not require the model to be initialized.

2. *Numerical analysis* tools that analyze constraints, bounds, and their Jacobian at specific variable values. These tend to be slightly more computationally expensive and require that all variables have values from a previous solution or initialization.
3. *Advanced techniques*, such as singular value decomposition or meta-modeling techniques, to identify irreducible degenerate sets. These tend to be more computationally expensive.

However, as these tools were scattered across different packages with different interfaces and output formats, no single modeler who was interviewed was aware of all the tools and how to use them. When asked about other tools, the most common response was that modelers were unaware of them, followed by comments about the lack of user-friendliness of some tools.

The interviews reveal that the main barrier to effective debugging of EO models was awareness of different issues modelers might encounter, the tools available to diagnose them, and methods to remedy them when they occur. To address this, the IDAES team developed and documented a comprehensive workflow and set of best practices for diagnosing modeling issues, accompanied by an integrated toolbox interfacing with most of the existing tools mentioned by the interviewees.

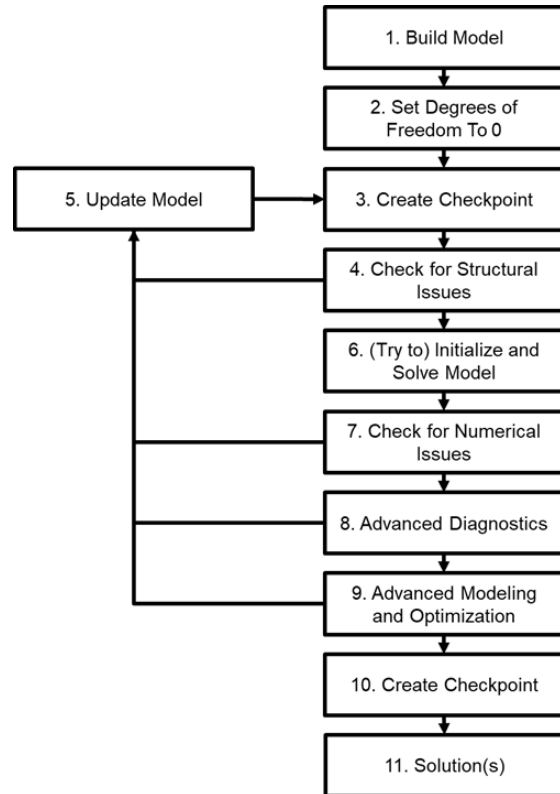

## PROPOSED DIAGNOSTICS WORKFLOW

The interviews revealed that issues can arise at many points during the modeling process. Therefore, modelers must continuously iterate between model development and diagnostic testing. Almost all the modelers interviewed agreed that the best approach to model development was to start from the bottom up, starting from simpler sub-models and gradually adding complexity, checking for and resolving issues at each step. In this way, the source of the problems can be easily traced to the most recent changes made to the model, and the smaller these changes, the easier it is to identify the root cause. As such, model development and diagnosis should always be viewed as an incremental process of gradual development and refinement, not a “one-shot” fix-all operation.

Additionally, the consensus across the modelers interviewed was that diagnosis should start with a “square” simulation model with no degrees of freedom; all optimization models derive from an underlying deterministic model by releasing some degrees of freedom. Adding degrees of freedom to the problem can often make it easier to solve, but this can obscure issues in the model. If the simulation model is ill-posed or poorly formulated, then these issues remain in the optimization model even if they are not apparent.

Based on this incremental, iterative approach and

the “hierarchy” of diagnostic tools, a sequence of common steps for model development was proposed, which is shown in **Figure 1** and explained below.

**Figure 1.** Proposed Model Diagnostics Workflow.

1. The workflow begins with an existing model, which should be the simplest possible model to start with (or an existing model that has been thoroughly tested for issues).
2. Next, the degrees of freedom necessary to form a square simulation model should be fixed. If the modeler is uncertain of which degrees of freedom to choose, they should take their best guess and allow the subsequent checks to identify any potential singularities.
3. As the model development and diagnosis process is iterative and often involves trial and error, modelers should always take the time to create a checkpoint so that they can easily revert changes to earlier states in case the current thrust of development becomes a dead-end. This is especially important results are being generated and recorded in parallel with the model development; there is nothing more frustrating than to discover that you can no longer reproduce a previous set of results with no idea of how or why this occurred. (Tip: version control systems such as git make it much easier to systematically track incremental model changes during

iterative diagnostics and refinement.)

4. When checking for potential modeling issues, the modeler should first apply structural analysis tools. As these only rely on model structure, they do not require an initial guess for the model solution. Fixing these structural issues before calling a solver decreases the chance of a critical solver failure.
5. Modelers should resolve issues as they are identified and should generally only make changes to address one issue at a time. Issues can often be interwoven, and fixing one issue may create or reveal other issues (or resolve other known issues). As each change is made to the model, modelers should return to the top of the workflow and follow all the steps again to make sure they are not accidentally introducing new issues.
6. Only once all (known) structural issues are resolved should modelers attempt to solve their model (initializing as necessary). Modelers should always review the solver output logs, as these can contain helpful information for diagnosing modeling issues. Hopefully, the solver will return a solution, even if it is infeasible, which can be used to continue the model diagnostics workflow. (Tip: If a solution is not returned, then the modeler can re-run the solver with a lower iteration limit or use a block triangular decomposition solve (see Section 3.6 of [12]) to obtain a partial solution.)
7. Once an initial solution is obtained, even if it is infeasible, the modeler can check for potential numerical issues at the current state. Again, problems should be resolved as they are identified, and modelers should return to the top of the workflow after each change. Numerical issues inherently depend on the current state of the model. As optimization involves exploring the behavior of the model over an entire design space, it is essential to perform numerical checks across this design space.
8. If issues remain (*e.g.*, failure to converge or signs of poor behavior in the solver logs), modelers should then apply the advanced diagnostics tools to try to find the root cause of the issues. As these techniques are computationally intensive, they are reserved for the final step to address challenging issues.
9. Once a reliable model has been identified, modelers can then move on to optimization studies and other more complex modeling tasks. Modelers should continue monitoring the solver logs for signs of potential issues and should apply the model diagnostics workflow if these signs appear.
10. Finally, as solutions and results are generated,

modelers should always maintain a checkpoint and log of the model state (*e.g.*, git commits) to ensure that they can reproduce these results in the future and to provide a point of comparison in case future changes to the model change these results.

Finally, modelers should keep in mind that their model may be used by others in the future who may not have the same level of familiarity with the model equations and formulation; this is especially important for developers of model libraries such as those in IDAES-IP. As the original modeler has the most experience with the formulation of the model, they are best suited for ensuring the model is as robust as possible to minimize the challenges faced by future users.

## IDAES DIAGNOSTICS TOOLBOX

Whilst the workflow described above provides modelers with a series of steps to take when developing their models and diagnosing any issues that arise, they also need access to a suite of tools to perform these checks. To limit the number of methods and interfaces modelers need to know, a new Diagnostics Toolbox has been added to the IDAES-IP (v2.2.0, released September 2023) [16], which incorporates tools to check for a wide range of common modeling issues.

To assist users with the model diagnostics workflow, the Diagnostics Toolbox guides them through the diagnostics process through a series of “reporting methods.” These reporting methods call a series of tools to check for different types of issues and then provide the modeler with a summary of the issues found and a set of next steps for further investigation. Each of these “next steps” corresponds to a “display” method to call one of the underlying methods and provides a detailed description of the issue and, if possible, its source.

Currently, the Diagnostics Toolbox contains three reporting methods—one for structural issues, one for numerical issues, and one for irreducible degenerate sets—and approximately 22 associated display methods. To assist modelers with identifying the most likely causes of model failures, problems are further divided into “warnings” representing issues that will most likely result in solver issues or incorrect results (*e.g.*, singularities and degeneracies), and “cautions” that warrant checking but may be expected model behavior (*e.g.*, variables which do not appear in any constraint). The Diagnostics Toolbox may be imported from IDAES as:

```
from idaes.core.util import DiagnosticsToolbox
```

The remainder of this section gives a brief overview of the structural and numerical issues that can be diagnosed by the Diagnostics Toolbox.

### Structural Issues

The Diagnostics Toolbox contains three methods that check a model for unexpected variable status:

- variables which do not appear in any constraints,
- variables which are not declared as part of the model being diagnosed,
- and variables with a value fixed to exactly 0.

If any such variables are encountered, the modeler is cautioned. Additionally, the Diagnostics Toolbox contains methods to check constraints and objectives for consistent units, verify that the over and under-constrained subsystems of the model's Dulmage-Mendelsohn decomposition [12,13] are empty, and check for potential evaluation errors. If any of these checks fail, a warning is displayed.

### Numerical Issues

The Diagnostics Toolbox contains several checks performed with simple variable and expression evaluations. These check for:

- variables with values at or outside their declared bounds,
- variables with no values,
- variables with values near zero,
- variables with extremely large or small values,
- variables with values approaching their bounds,
- and constraints with large residuals.

These checks display a warning or a caution depending on the magnitude of *e.g.*, variable value or bound proximity/violation. A variable with no value always yields a caution. The Diagnostics Toolbox also contains methods that analyze the model's Jacobian matrix to detect the following indicators of ill-conditioning:

- values in the Jacobian matrix with extremely large or small values,
- rows and columns in the Jacobian matrix with extreme 2-norm values,
- and condition number of the Jacobian.

Whether a warning or a caution is displayed again depends on the magnitude of the value detected.

### Advanced Diagnostics Tools

For cases where the above tools are not sufficient to fully diagnose the issues in a model, the Diagnostics Toolbox also contains an implementation of Degeneracy Hunter [14] and an interface for performing Singular Value Decomposition (SVD) analysis on the model (by default using the SciPy linear algebra libraries [17], but with support for modeler-provided SVD routines).

## CASE STUDY

To better demonstrate the application and utility of the Diagnostics Toolbox, consider the following toy problem with variables  $v_1$ [units:  $m$ ],  $v_2$ [ $m$ ],  $v_3 \in [0,5]$ ,  $v_4$ ,  $v_5 \in [0,1]$ ,  $v_6, v_7 \in [0m, 1m]$ , and  $v_8$ , and constraints:

$$v_1 + v_2 = 10 \quad 1)$$

$$v_3 = v_4 + v_5 \quad 2)$$

$$2v_3 = 3v_4 + 4v_5 + v_6 \quad 3)$$

$$v_7 = 1 \times 10^{-8}v_1 \quad 4)$$

One common issue facing modelers relying on pre-built EO models is identifying suitable degrees of freedom to fix for their application. Poor choices can often result in infeasible models or structural singularities. To demonstrate this, consider setting the following conditions for fixed variables:  $v_4 = 2$ ,  $v_5 = 2$ , and  $v_6 = 0$ .

While the above problem may appear relatively simple and involve only linear constraints, the model will yield an infeasible result after fixing the specified degrees of freedom and attempting to solve it. This is because there are several issues in the model as posed. As this model is small, an experienced modeler can likely identify most or all these issues by manually inspecting the variables and constraints; however, it will likely take a few minutes. The Diagnostics Toolbox, however, can automatically detect all these issues in under a second and direct the modeler to the root causes.

Following the diagnostics workflow, the first step is to check the model for structural issues. This is done by calling the `report_structural_issues` method from the Diagnostics Toolbox. This executes the series of checks described in the previous section, which reveals two warnings (critical issues) and two cautions.

*Structural warning 1:* Checking unit consistency reveals an issue in constraint 1):  $v_1$  and  $v_2$  were assigned units of meters; however, the constant in the constraint was not assigned units. If this constant was in units other than meters, then the solution to the model would be incorrect. This should be corrected by rewriting constraint 1) to include the units for the constant and applying any necessary unit conversion.

*Structural warning 2:* Performing a Dulmage-Mendelsohn partition of the incidence matrix reveals a structural singularity. After fixing  $v_4$ ,  $v_5$ , and  $v_6$ , constraints 2) and 3) include only a single free variable. Similarly, constraints 1) and 4) include three free variables, and thus this sub-system is under-constrained. Addressing this issue requires the modeler to rethink the degrees of freedom they have chosen or the constraints they have chosen to write. The Dulmage-Mendelsohn partition helps the modeler choose degrees of freedom, as variables that are candidates for degrees of freedom must be in the under-constrained subsystem.

*Structural caution 1:* A simple inspection routine reveals that  $v_8$  does not appear in any constraint. This could be considered a modeling error. Either it was meant to be included in a constraint, but a mistake was made, or this variable is extraneous and should be removed from the model definition.

*Structural caution 2:*  $v_6$  has been assigned a value of exactly 0. While this will not cause an issue in the current model, modelers should be careful when assigning values of zero to ensure this will not cause numerical issues (e.g., appearing in a denominator or logarithm).

For this example, assume that the units of the constant in constraint 1) were meters and that the modeler decides to use  $v_2 = 5$  instead of  $v_4 = 2$ . After reviewing the two cautions,  $v_8$  should be removed from the model, while  $v_6$  can remain fixed to 0 for now. After making these changes and confirming that the structural issues have been resolved, the next step is to try to solve the model. The solver reports that the model is infeasible, so the next step is to check the model for numerical issues by calling the `report_numerical_issues` method from the Diagnostics Toolbox. This will execute the second set of checks described above, which will reveal two additional warnings and four cautions.

*Numerical warning 1:* At least one of the constraints has a large residual. The specific constraint may depend on the solver used but will be constraints 2) or 3). This should not be unexpected due to the infeasible solution returned by the solver.

*Numerical warning 2:* Iterating over all the variables in the model and comparing their values to any bounds specified will reveal that  $v_3$  and  $v_5$  have values at or outside their bounds. In the case of  $v_3$ , this is because the value required to satisfy both constraints 2) and 3) lies below the lower bound of 0, while for  $v_5$  the issue is that it was fixed to a value outside of its bounds (it was assigned a value of 5 but had bounds of [0,1]). Addressing these issues requires the modeler to consider why these bounds were placed on the model in the first place (e.g., to indicate a range over which an empirical correlation is reliable or to protect against a numerical singularity) and to decide whether the bounds can be relaxed or if changes to the model constraints are required.

*Numerical cautions 1-4:* All four cautions arise because  $v_7 = 5 \times 10^{-8}$ , which is likely close to the solver tolerance. Additionally, while it does not violate the bounds, this value is very close to the lower bound. Analysis of the Jacobian will reveal a large value for  $v_1$  in constraint 4). This points to poor scaling of  $v_7$  and constraint 4) and addressing this will likely improve solver performance.

As mentioned previously, an experienced modeler would likely discover most of these issues by manual inspection. However, this becomes more challenging for more complex (and especially nonlinear) models or modelers with less experience. The Diagnostics Toolbox runs

these checks automatically and quickly, providing the modeler with immediate guidance on which constraints and variables to investigate to resolve any issues observed with solver behavior or solutions.

A full demonstration of applying the Diagnostics Toolbox to this example can be found here:

[https://idaes-examples.readthedocs.io/en/latest/docs/diagnostics/diagnostics\\_toolbox\\_doc.html](https://idaes-examples.readthedocs.io/en/latest/docs/diagnostics/diagnostics_toolbox_doc.html)

## ONGOING WORK

Since the release of the IDAES Diagnostics Toolbox, the team has been working to advertise these capabilities to users and solicit feedback on how they can be improved. The IDAES team have begun using these tools to debug modeling issues, and future work will involve a second round of user interviews to determine whether the tools have been successful. The team is also continuing to identify additional modeling issues and tools to diagnose them, as well as visualization tools to improve user-friendliness and aid in interpreting results.

Anecdotally, initial responses have been uniformly positive, and including a handful of users who have successfully applied the tools in practice during the past few months. Users have reported that the Diagnostics Toolbox has greatly reduced the time required to get their models to solve. One user reported that the toolbox helped them resolve a structural singularity due to mis-specified initial and boundary conditions in a discretized PDE model that they described as “like searching for a needle in a haystack.”

However, diagnosing issues with nonlinear optimization problems remains challenging with many open questions. To quote an experienced researcher in process systems engineering consulted for this study:

*Automatically diagnosing arbitrary issues with nonlinear optimization problems is a Holy Grail of Operations Research.*

While identifying the presence of an issue in a model can be automated, tracing this back to the true root cause and identifying a fix often requires a degree of engineering knowledge that can only be gained by experience. Documentation to help users in this process is still required, and a long-term goal for IDAES is to create a library of examples for resolving different issues.

## CONCLUSIONS

The IDAES Diagnostics Toolbox and workflow have been developed to assist modelers with addressing issues encountered when developing, debugging, and solving equation-oriented models. A standard workflow for systematically identifying issues has been created.

This workflow is supported by a toolbox that includes methods for automatically detecting common modeling issues and identifying the associated variables and constraints for the modeler. This workflow and toolbox will significantly reduce the time, effort, and expertise that modelers require for diagnosing issues when working with large, complicated models.

---

## ABSTRACT

Chemical engineering is a highly complex interconnected major. Just as chemical engineers have broken complex processes into unit operations, the chemical engineering curriculum has been broken up into courses. The organization of these courses vary among institutions and are based on years of prior teachings and research. Despite this, there have been calls to reevaluate the curriculum from both industry and academia. We propose a graph-based representation of curricula in which topics are represented by nodes and topic dependencies are represented by directed edges forming a directed acyclic graph. This enables using graph theory measures and tools to provide formal ways of evaluating a curriculum. Additionally, the abstraction is readily understandable meaning conversations between instructors regarding the curriculum can occur within a department and even across institutions. This abstraction is explained with a simplified curriculum and applied to the undergraduate chemical engineering curriculum at University of Wisconsin-Madison. Highly and lowly connected topics are identified and approaches for grouping the topics into modules are discussed.

---

**Keywords:** Education, Curriculum, Graph Theory

## INTRODUCTION

The early days of chemical engineering focused on tools such as unit operations, material and energy balances, process control, transport phenomena, and more to develop petrochemicals. Since then, these tools have been increasingly applied to more applications, and chemical engineers can be found in diverse industries and roles. Climate change has also placed pressure on industries to decrease the environmental impact of their products and processes. However, there are proven difficulties in embedding sustainability in engineering curricula, and industry has identified ability shortages in graduating chemical engineers [1]. For these reasons and more, there have been calls to evaluate the chemical engineering curriculum, and some departments have elected to no longer seek accreditation to allow students more personalized paths towards different careers [2].

Process design is often treated as the culmination of the undergraduate chemical engineering curriculum. This course draws on knowledge from previous chemical engineering courses including transport, balances,

controls, and more. Students are often reminded of what they learned in previous courses and are for the first required to pull knowledge from multiple previous courses. This means students are likely seeing the interconnectivity of the curricula for the first time at the very end of their education. Additionally, process design tends to focus on the design of a single process typically within the chemicals or petrochemical sector. This means that students interested in other fields of such as biological systems or semiconductors may be less motivated in this course. For these reasons, there is discourse on implementing systems thinking and design throughout the curriculum to instead tying the curriculum together at the very end of a student's learning experience.

The ability shortages and the changing field of chemical engineers means the curriculum needs to evaluate to improve outcomes. There are some tools to analyze curricula, such as curriculum prerequisite maps to identify bridge and source-hub courses, tree-structured topic modeling, and concept maps [3,4]. Concept maps have been applied to chemical engineering courses and curriculum to enhance student learning and explore the

ontology of topics covered [5]. Other work has applied statistical tools to study how chemical engineering curricula has changed focus and analyzed different sequencing of transport courses at institutions [6].

We propose a graph-based representation in which topics are represented by nodes and dependencies between topics are represented by directed edges. Unlike in concept maps, the directed edges do not have words attached to them. This enables the use of graph tools guide curriculum analysis with numerical measures to formalize discussion in improving a curriculum.

## GRAPH ABSTRACTION

To explain graph theory applied to a curriculum, a simplified Curriculum A will be used. Curriculum A is composed of six courses which are named ABC 101-106. These courses depend on one other through prerequisites. For example, ABC 101 is a prerequisite to complete ABC 103. The full list prerequisites and the credits for each course can be found in **Table 1**.

**Table 1:** Courses making simplified Curriculum A.

Course	Credits	Prerequisite(s)
ABC 101	3	None
ABC 102	4	None
ABC 103	4	ABC 101
ABC 104	2	ABC 102
ABC 105	2	ABC 102, ABC 103
ABC 106	3	ABC 105

This table looks like one a student would find in their handbook or when registering for the courses for the term. This table can be represented with a graph abstraction in which courses are represented by nodes and directional edges connecting nodes represent dependencies as seen in **Figure 1**. The edges are directional to represent the sequence of the courses and follows the thinking of "I have to take this course before I take that course." With the nature of course progression there are no cycles. For example, ABC 103 would not and cannot be a prerequisite for ABC 101 because then there would be no way take either of them. This makes the graph abstraction both directional and acyclic. Within this representation, the number of credits for each course is reflected by the node size.

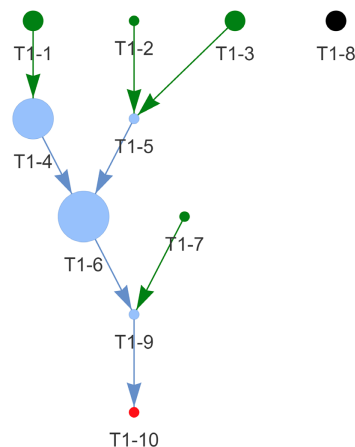

The course level graphical abstraction can allow for the scheduling one's term and visualizing how courses interact with one another. However, these dependencies rely on the accuracy of the prerequisites which could have been established years prior and the courses and, more broadly, the curriculum could have changed since. For example, students may be encouraged by their adviser to take ABC 103 and ABC 104 in the same term. From the graph abstraction, this need is not clear perhaps because ABC 103 has topics that are required for

ABC 106 despite not showing up in the prerequisites. This means looking more closely into the courses and their interconnectivity is required to fully understand the curriculum.

To look more closely at the curriculum, we can develop topic level graphs for each course within Curriculum A. This could be generated from the schedule of topics in a syllabus, recommended textbook readings, and more. The selection of topics and their connectivity takes some expertise and refinement, but the generation of the abstraction can provide invaluable insights. The graph abstraction for ABC 101 is presented in **Figure 2**.

**Figure 1.** Course level graph abstraction of Curriculum A in which courses are represented as nodes and directed edges represent course dependencies. Node size represents the credit hours for the course. Courses without prerequisites are green, ternary courses are red, and courses with both prerequisites and subsequent dependencies are blue.

**Figure 2.** Graph abstraction of course ABC 101 in which nodes represent topics and topic dependencies are represented as directed edges. Node size represents the relative resources use in terms of credit hours.

In this topic level graph abstraction of ABC 101, topics are represented by nodes and the size of the nodes

represent the relative time spent covering the topic in terms of the credit hours for the course. This means the sum of all the node sizes is the number of credit hours for the course. Topic connectivity is represented by the directional edges. A topic without any preceding topics, such as T1-1, means it can be taught without any other prior knowledge. These can be thought of as introductory topics like how one would think about an introductory course. A topic with preceding topics, such as T1-6, means it requires the preceding connected topics (T1-4 and T1-5) to be taught. This follows the logic of "I need to know numbers and counting to learn addition." These dependencies can also be used to help plan the course by noticing topic T1-10 requires all other topics besides T1-8. Topics not connected to any others, such as T1-8, means it can be taught at any time during the course because it does not build on previous topics, nor is it required to understand other topics.

While the graph abstraction of ABC 101 provides a lot of valuable insights, it is not the complete picture. ABC 101 is a prerequisite for ABC 103, but this is not yet indicated. Expanding the topic level abstraction to include all courses will provide the complete picture of the

curriculum and enable understanding of the inter-connectivity of the topics and courses. This is accomplished by constructing a graph abstraction of each course and then connecting them where appropriate. This results in the topic level graph abstraction of Curriculum A in **Figure 3**.

Topics can be introduced in one course and later reviewed in another. Reviewing a topic and then building off it (connecting to another topic) is different than just building off one topic to another because of the time spent on the review. To reflect this, if a topic is introduced and later reviewed, then the size of the topic is the sum of both times. To distinguish between, a border will be added to node. For example, T3-24 is introduced in ABC 103, but is later reviewed in ABC 105. As such the inner circle represents the resources first spent learning T3-34 and the outside circle represents the resources spent reviewing.

Reviewing topics in later courses could seem to lead to a cycle being created. The simplest case of a reviewing a topic is to remind students of what they were taught due to the time between the topic was first presented and when it needs to be built off from. For this case, no

**Figure 3.** Topic level graph abstraction Curriculum A in which topics are represented by nodes and topic dependencies are represented by directed edges forming a directed acyclic graph. Node size reflects the relative resources required for the topic in terms of the credit hours for the course.

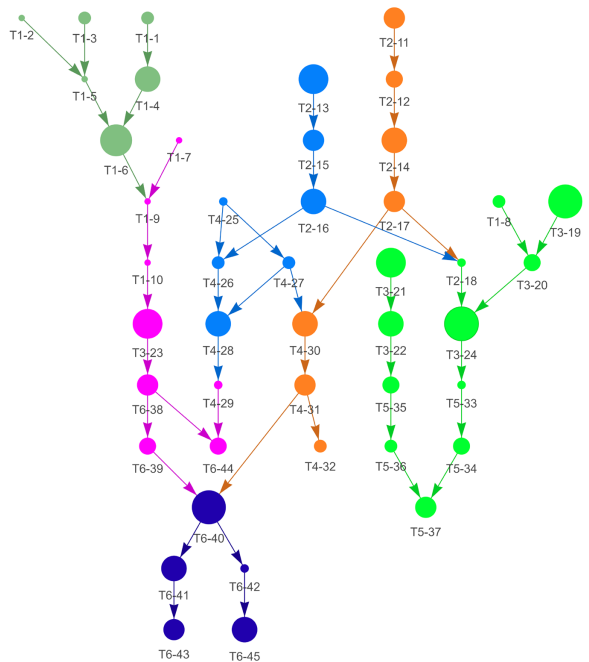

cycle is formed because it is just a reminder of what was taught with no other context or methods. A topic may also be reviewed to provide more detail in a new framework or using a new skill that has since been taught. For example, phase equilibrium may be introduced in the context of pure components in a first course on thermodynamics. Then phase equilibrium may be introduced in a multicomponent context in a second course on thermodynamics. This scenario would then be composed of three nodes: “Phase Equilibrium of Pure Components”, “Mixtures”, and “Phase Equilibrium of Mixtures”. In this scenario to teach “Phase Equilibrium of Mixtures” one would review “Phase Equilibrium of Pure Components” and combine that with “Mixtures”. This example demonstrates that revisiting a concept in a new context can be treated as a review of the original topic plus a dependency on the context.

The topic level graph of Curriculum A can be very useful on its own to understand the scope of the curriculum and discuss properties amongst instructors. However, the analysis can be improved by using tools from graph theory to provide formalized measures to discuss ways of changing the curriculum. Measures like the degree of node (the number of edges connected to a node), determining paths (getting from one node to another without any repeat nodes), the number of components (subsets of nodes that do not have edges to other nodes), connected vs. strongly connected graphs, and more can be considered. For this analysis, grouping of nodes through community detection and modularity and the degree of a node will be critical for analysis.

For grouping of nodes, a common approach is known as community detection which seeks to maximize “modularity” using optimization. The “modularity” is function of the interconnectivity of communities that make up the graph. These algorithms can be useful to identify which topics form areas of dense interconnectivity, but it does not consider the size of the nodes. This means it may result in communities of varying sizes. For example, applying the community detection algorithm known as greedy modularity maximization to Curriculum A results in the communities in **Figure 4**. Here the number of communities was restricted to be equal to the number of original courses (six). It is important to note that the topics forming a community are not always from the same course. The community sizes are 5.8, 3.4, 3.2, 2.7, 2.65, and 2.25 credit hours which when turned into courses could lead to an unbalanced course load.

To improve upon the community detection, a different approach to modularity will be considered. This approach described in [7] can restrict the sizes of the module in addition to the number of modules. This approach maximizes a different measure of modularity with constraints to set the number of modules and the size of modules are within a given size. This is cast a binary

quadratic optimization program. Additionally, we can use the framework to provide a definition of a modular curriculum. A curriculum will be considered modular if: (a) the topics in a module form a cluster of dense dependency, (b) connectivity between modules is sparse, and (c) the modules are within a set resource use (credit hours). These two approaches enable evaluating the modularity of the curriculum using modules to guide course organization and overall curriculum planning.

**Figure 4.** Topic level graph abstraction Curriculum A grouped into six communities (equal to the number of original courses) using greedy community detection.

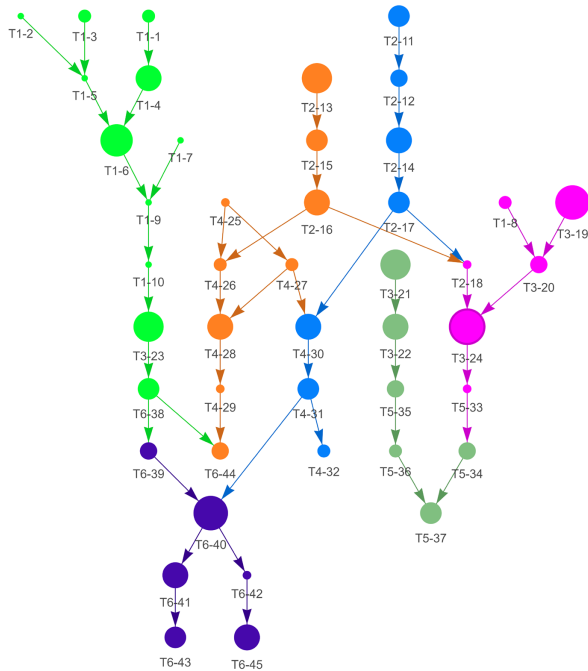

Restricting the module size between 2.9 and 4.1 credit hours, the new topic grouping is presented in **Figure 5**. This results in community sizes of 3.9, 3.8, 3.4, 3.1, 2.9, and 2.9 credit hours. This approach leads to more balanced course load implementable sizes.

## CASE STUDY

To demonstrate some the capabilities and insights that can be gained from this graph abstraction, this analysis will be applied the undergraduate chemical engineering curriculum at University of Wisconsin-Madison. This curriculum is composed of 19 credit hours of math, 10 of physics, 20 of chemistry, 6 of life sciences, 6 of communication skills, 16 of liberal studies, 6 of professional depth, 40 of core chemical engineering courses, and 9 chemical engineering electives for a total of 132 semester credit hours. The focus of this analysis will be on the core chemical engineering courses listed in **Table 2** along with their already defined prerequisites. Most of

these courses are similar to courses required by other undergraduate chemical engineering programs.

**Figure 5.** Topic level graph abstraction Curriculum A grouped into six communities (equal to the number of original courses) when restricting modules size.

A graph abstraction of the core chemical engineering courses is presented in **Figure 6**. One interesting note of the curriculum is CBE 250 can be taken concurrent with CBE 255 and CBE 255 can be taken concurrent with CBE 310, but CBE 250 is a prerequisite for CBE 310. Since this graph abstraction is made to model the flow of topics, CBE 250 will be treated as a prerequisite CBE 255 and CBE 255 will be treated as a prerequisite for CBE 310.

A similar scenario exists for CBE 320 and CBE 324 and CBE 430 and CBE 470. From this course level abstraction, one can easily see just how many courses depend on CBE 320 based on the connectivity.

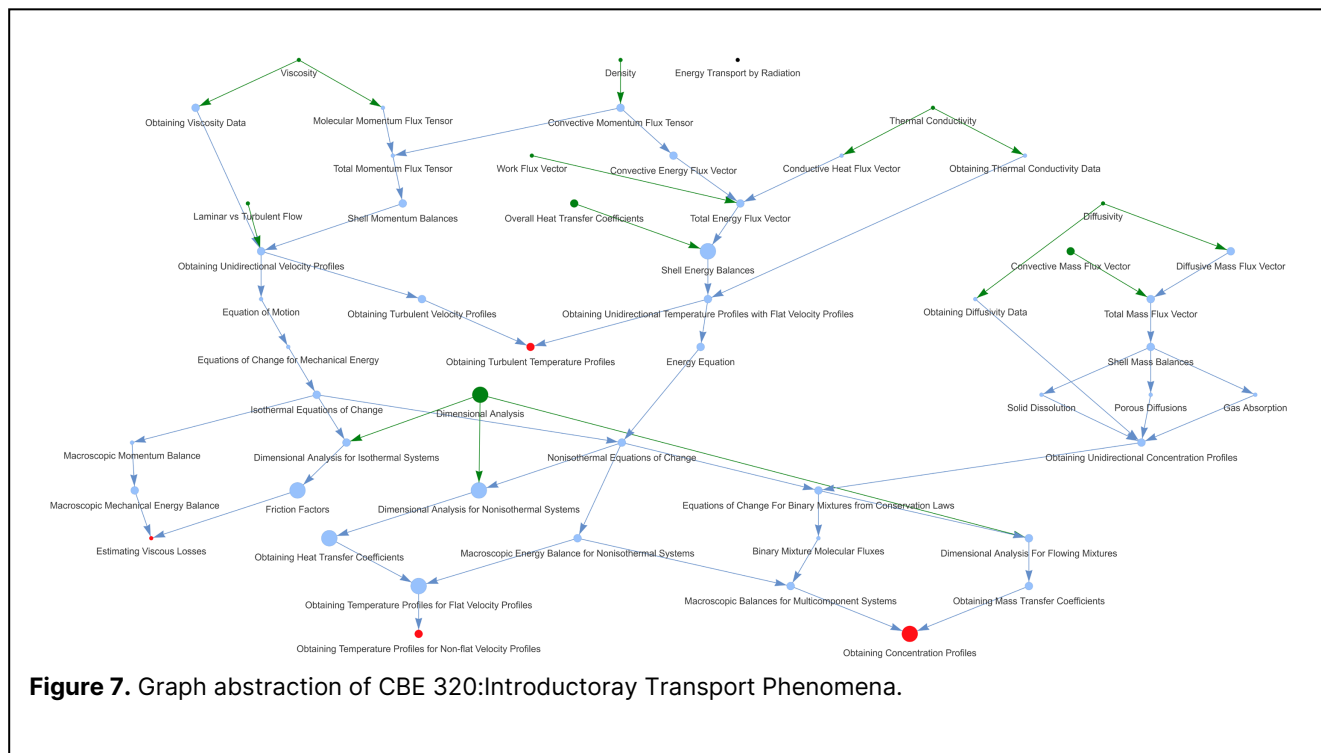

**Figure 6.** Course level graph abstraction of the core chemical engineering courses.

To construct the topic level graph abstraction of the curriculum, the syllabuses, course schedules, course readings, and lab documents were collected from recent occurrences of the courses. Then, a graph abstraction was developed for each course. For example, the graph CBE 320: Introductory Transport Phenomena is shown in **Figure 7**. This course covers momentum, heat, and mass transport at a theoretical level. The selection of topics and the “resolution” (how detailed the topics are e.g., Energy Flux Vector vs Convective, Conductive and Work Flux Vector) of the topics had to be decided for each course. This was an iterative process to ensure the graphs for each course were similar in terms of the level of resolution. While the graphs made and presented with this approach could look different depending on who

**Table 2:** Core chemical engineering courses at University of Wisconsin-Madison. Term taken is the term a student would normally take the course where 1F means fall of year one and 4S means spring of year four.

Course	Name	Term	Credits	Prerequisite(s)
CBE 150	Intro to Chemical Engineering	1F	1	None
CBE 250	Process Synthesis	2F	3	None
CBE 255	Intro to Chemical Process Modeling	2S	3	CBE 250 (co)
CBE 310	Chemical Process Thermo	2S	3	CBE 250 (co)
CBE 311	Thermodynamics of Mixtures	3F	3	CBE 310, CBE 255
CBE 320	Intro Transport Phenomena	3F	4	None
CBE 324	Transport Phenomena Lab	3S	3	CBE 310, CBE 320
CBE 326	Momentum and Heat Transfer	3S	3	CBE 320 (co)
CBE 426	Mass Transfer Operations	4F	3	CBE 311, CBE 320
CBE 430	Chem Kinetics and Reactor Design	4F	3	CBE 311, CBE 320
CBE 450	Process Design	4S	3	CBE 326, CBE 430, CBE 426
CBE 470	Process Dynamics and Control	4S	3	CBE 326, CBE 430 (co)
CBE 424	Operations Process Lab	4Su	5	CBE 324, CBE 326, CBE 426, CBE 430

makes them, it opens a more formal discussion of what is being taught to students in a course. This could be used alongside learning goals to get the full picture of a course.

With a graph abstraction of each course, the topic level graph abstraction of the core chemical engineering courses can be constructed. To do this, the dependencies between courses and review of topics in subsequent courses were identified. For example, there is review of some material from CBE 310: Chemical Process Thermodynamics in CBE 311: Thermodynamics of Mixtures and there are topics introduced in CBE 320: Introductory Transport Phenomena that are required to understand topics in CBE 426: Mass Transfer Operations. This was also an iterative process to ensure topics of the same name had the same scope and to ensure the interconnectivity of courses was fully captured. Again, the interconnectivity of the topics between courses could be up for debate. However, this abstraction encourages conversation beyond “Make sure you introduce the Peng-Robinson Equation of State in Thermodynamics I because I need it for Thermodynamics II” that may occur between instructors teaching a series.

The topic level graph abstraction is presented in **Figure 8**. Due to the size of the graph, interactive versions of the graph are available in the supplementary material. Across the 13 courses and 40 credit hours, there are 286 topics and 398 edges. 43 topics are introduced in one course and reviewed later in another totalling 4.96 credit hours. Introductory topics often involve a physical property like density and entropy while topics without successors are often lab experimentation or extensions

into more complex application such as multiphase reactions.

The grouping of topics into modules was conducted restricting the module size to three to four credit hours across 13 modules resulting in modules in **Figure 9** (unfortunately, due to the size of the problem, the optimization was solved to 4.4% optimality gap in one hour and

future work will need to be done to optimize an entire curriculum with reasonable solver times). The modules here would reflect if the department wanted to keep the same number of courses but rearrange the topics to create more even courses rather than being between one and five credits. Some of the modules are close to what they were prior. For example, topics covered within CBE 470 and CBE 450 are largely still with the same topics. This demonstrates these courses are distinct from other parts of the curriculum. For CBE 450, this means that implementing systems thinking and design throughout the curriculum would require a different approach than just rearranging the topics from process design. As such, to teach systems design throughout a curriculum we would have to revisit the entire curriculum and identify gaps and areas where concepts from systems design could be introduced using this framework.

**Figure 9.** Graph abstraction the core chemical engineering courses with topics grouped into modules.

An additional note is on the transport related courses of CBE 320, CBE 324, CBE 326, CBE 426, and CBE 424. Previous work has discussed how different institutions sequence transport topics. The curriculum is currently designed to introduce the theoretical aspects of transport in one course and equipment and experimentation in subsequent courses. The modules determined by the optimization, on the other hand, tend to have the theoretical, equipment, and experimentation of each transport type (momentum, heat, mass) together due to the higher connectivity of topics within the same transport type compared to between the transport types.

## CONCLUSION

This work presented a graph abstraction in which courses are represented by nodes and connections between courses are represented by directed edges. Additionally, a graph abstraction in which topics are represented by nodes and topic dependencies are represented by directed edges was presented. This graph abstraction was applied to the core chemical engineering courses required for undergraduate chemical engineering students at University of Wisconsin-Madison. This abstraction identified lowly and highly connected topics and discussed ways of grouping topics. This abstraction encourages instructors to discuss how topics and curricula are presented. This work improves upon past efforts by formalizing the node attributes (topic size, review size) and the direction of edges between nodes. This formalization allows the exploration of topic dependencies and grouping with measurable features from graph theory.

## FUTURE WORK

While the core chemical engineering courses for the undergraduate chemical engineering program at University of Wisconsin-Madison was presented here, this analysis can easily and will be expanded to include the entire undergraduate chemical engineering curriculum. This will enable further study into the interconnectivity between chemical engineering courses and background courses from chemistry, math, and physics. With this ability, the determination of which courses should be taught by the chemical engineering department and which courses are appropriate to be taken from other departments.

For example, the chemical engineering undergrads at University of Wisconsin-Madison are required to take the three-credit STAT 324: Introductory Applied Statistics for Engineers course while there also exists CBE 562: Statistics for Chemical Engineers and can be used towards the chemical engineering elective requirement. This graph abstraction could be used with connectivity measures to make a case for CBE 562 to replace STAT 324 entirely to improve the connectivity of the topics with more relevant chemical engineering examples and improve reinforcement of topics.

In the current framework, some additional constraints could be added to account for additional attributes of topics. For example, a topic could be categorized as being a lab or lecture topic and a constraint could be implemented to ensure modules are made such that they are either lab or lecture modules. This would make the modules more accurately reflect more traditional course organization.

While the module sizes were set to the sizes of typical courses in this analysis, the module size can be smaller. Setting the module size smaller would reflect smaller units within a course. This would enable writing

specific learning objectives for each module and package the curriculum into more easily presented sizes. This would further encourage discourse surrounding the curriculum and what exactly is and should be taught within it. The creating of smaller modules could have the added benefit of increased flexibility to move modules around and replace modules with different concepts such as adding and electrochemistry module to the curriculum.

Another use for this graph abstraction is to embed important concepts or ideas throughout it such as safety, sustainability, and systems thinking and design. For example, implanting systems thinking and design throughout the curriculum can be accomplished by creating case studies. These case studies would involve systems thinking and design that depend on topics from different stages in the curriculum. In doing so, the case studies would have to be designed in a way such that all topics are used to understand and solve the case studies. A similar approach could be used for implementing safety and sustainability.

## ABSTRACT

Some educators place an emphasis on the commonalities between engineering mathematics with process control, among others and this helps students see the bigger picture of what is being taught. Traditionally, some of the concepts such as diffusion and heat transfer are taught with a mathematical point of view. Now-a-days, Machine Learning (ML) has emerged as topic of greater interest to both educators and learners and new and disparate modules are sometimes introduced to teach the same. With the emergence of these new topics, some students (falsely) believe that ML is a new field that is somehow different and not linked to engineering mathematics. In this work, we show the link between the different topics from engineering mathematics, that are traditionally taught in UG education, with ML. We hope that educators and learners will appreciate the treatise and think differently, and we further hope that this will further increase the interest to improve ML models.

---

**Keywords:** Education, Machine Learning, Optimization, Numerical Methods, Modelling, Process Control

## INTRODUCTION

It is important that students understand the similarities and differences between the various modules in UG education so that they become well rounded engineers. To this end, mathematics, kinetics, thermodynamics, and process control allow us to explain the link between the different modules. While each module is designed to be disparate for the convenience of teaching, without placing due emphasis on the commonalities, it is easy to forget that all the topics are linked. Some educators place an emphasis on the commonalities between a.) engineering mathematics (ordinary differential equations, eigen values and eigen vectors) with process control (Laplace Transforms, poles, and state space modelling), b.) engineering mathematics and diffusion/heat transfer via partial differential equations, among others and this helps students see the bigger picture of what is being taught. Further, the concept of empirical equations and models is introduced much earlier to students through topics in fluid mechanics and heat and mass transfer.

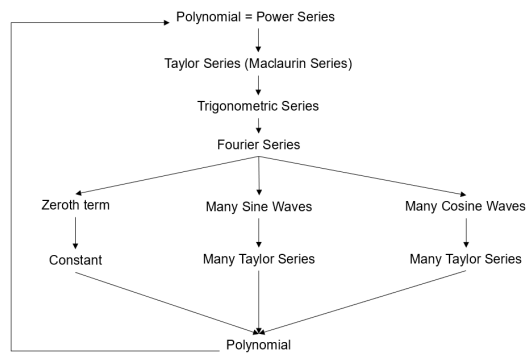

Considering UG Chemical Engineering education at the Newcastle University in Singapore, the different modules that teach applied mathematics are Engineering Mathematics – I & II, Computing & Simulation, Process Measurement Dynamics and Control, Process Control 2, and Chemical Process Optimization. In these modules, the following topics are taught. Linear algebra, ordinary differential equations (ODEs), numerical methods – solution to linear and nonlinear systems, series (Taylor, Fourier, Trigonometric), partial differential equations (PDEs), introduction to artificial neural networks (ANN), and Laplace Transforms. In addition, students are also taught to program some of the topics using Matlab and Python.

A focused student and an experienced educator can readily see that the solution to some common ODEs is either in terms of an exponential or in terms of a sine or cosine function. Further, some common PDEs can be written as a combination of exponential, sine, and cosine functions using the Fourier Law. Through the study of Taylor series, we know that any function (exponential, sine, cosine, or others) can be written as a polynomial and

hence we can hypothesize that the solution to any ODE or PDE is a polynomial. We know that the trigonometric functions such as sine and cosine can be written as a polynomial using Maclaurin series. Thus, a system represented as a trigonometric series can be shown to be a polynomial. Fourier series is a special case of trigonometric series in which the coefficients can be calculated through the given formulae. Thus, Fourier series is also a polynomial (Fig. 1).

Further, transfer functions in ANN have its foundations in exponential functions. Albeit the exponential is in the denominator, we will be able to convert this into a polynomial using Taylor series. Exploring such commonalities, we aim to bring forth a common thread between engineering mathematics and machine learning so that readers will better appreciate what they are learning in the new and emerging topics.

**Figure 1.** System (One Dependent and One Independent Variable) – Polynomial

Through some examples, this paper will lay the foundations of the inter-links between the different topics and show that “any (simple) system can be modelled as a polynomial”. It is believed that the motivational examples will lay the foundations for understanding machine learning better. To this end, we start with univariate problems, as simple polynomials (and straight lines which are first degree polynomials) are taught to students at the beginning are most courses as they are easy to comprehend.

## SINGLE-INPUT SINGLE OUTPUT MODELS

Single-input, single-output (SISO) models are the earliest and easiest to understand, especially so in UG education. We begin first by introducing the power series whose parameters must be estimated. A simple example is that of a solution to a 1<sup>st</sup> order ordinary differential equation (ODE) shown in Eqn. 2. This can be re-arranged and shown that the solution is an exponential function i.e.,  $e^{x+c}$ , where ‘c’ is a constant. If  $e^c = a_0$  the solution is  $a_0e^x$ . While it is known that  $e^x$  can be written as a

polynomial using Maclaurin series (derivation not shown), the solution to Eqn. 2 becomes a polynomial. Separately, we can also calculate the coefficients of the power series by substituting it (Eqn. 1) in Eqn. 2 and prove that the power series is the same as the polynomial obtained through direct integration.

$$f(x) = a_0 + a_1x + a_2x^2 + a_3x^3 \dots \quad (1)$$

$$\frac{dy}{dx} = y \quad (2)$$

Substituting Eqn. 1 in Eqn. 2 gives,

$$(a_1 - a_0) + (2a_2 - a_1)x + (3a_3 - a_2)x^2 + \dots = 0 \quad (3)$$

Thus,  $(a_1 - a_0) = 0$ ;  $(2a_2 - a_1) = 0$ ;  $(3a_3 - a_2) = 0$ . This shows that  $a_1 = a_0$  and  $a_n = \frac{a_0}{n!}$  and hence,  $y = a_0e^x$

## Modelling differential equations as polynomials

The solution to a simple 1<sup>st</sup> order ODE has been presented from Eqn. 1 onwards. Here, let us look at some other examples where the solution to an ODE can be presented as a polynomial. Consider a 2<sup>nd</sup> order ODEs which can be written in homogeneous form as,

$$a \frac{d^2y}{dx^2} + b \frac{dy}{dx} + cy = 0 \quad (4)$$

The solution to this can be obtained by solving for the roots of the characteristic equation. If the roots are real, the solution only has exponentials, however, if the roots are complex, the solution has trigonometric functions which causes the system to oscillate (relevant to stable and unstable systems in process control). And since trigonometric functions can always be written polynomials, the solution to the above ODE is a polynomial. Here, we should note (details not shown) that we can show that the roots of the characteristic equation are the same as the poles of second order equation solved using Laplace Transforms (in process control) and that the roots are also same as the eigenvalues if we were to solve the second order equation by reducing it into a system of two first order equations written in homogeneous form. As a side note, we need to remember that eigenvalues and eigenvectors are also useful in state-space modelling in process control. While it is possible to obtain the solution for homogeneous form of ODEs, the concept of system as a polynomial can also be extended to non-homogeneous forms by obtaining the complementary function (solution to homogeneous form which is a polynomial) and the particular-integral (where solution is assumed as either being a polynomial or a trigonometric function which in turn is a polynomial).

If we consider higher order ODEs, which is still a SISO system, it can be reduced to a system of first order

linear ODEs that can be represented in a homogeneous form ( $\frac{dx}{dt} = A$ ) and can be solved using Eigenvalues and Eigenvectors of the matrix A. The solution would be of the form,  $x = \sum_{i=1}^n c_i v_i e^{\lambda_i t}$  where,  $\lambda_i$  are the eigenvalues,  $v_i$  are the eigenvectors, and  $c_i$  are the constant of integration which can be obtained using the initial conditions. Since an exponential can be written as a polynomial, we can conclude that the solution to a system of first order linear ODEs is a polynomial as well. Whether this structure can be represented as a graph, or a neural network would be of interest.

Consider the third order ODE,  $\frac{d^3y}{dt^3} - 6\frac{d^2y}{dt^2} + 11\frac{dy}{dt} - 6y = 0$ . Fig. 2 shows the ODE represented as a graph. Readers who are familiar with Simulink would readily see that this graph has similarities with it. Simulink would have an inverse representation and solve the system using integration while the representation in Fig. 2a, shown as a graph, uses differentiation. The same is further elaborated in Fig. 2b as activity on node so that it is easier to see the similarities with a neural network. Hence, it is not entirely surprising that ODEs have been incorporated into neural networks. In our syllabus, we cover the famous Lotka-Volterra model to explain solution to system of ODEs.

**Figure 2a.** Representation of an ODE as a graph.

**Figure 2b.** Representation of an ODE as a network with activity on node, which is akin to a neural network.

More in-depth studies incorporating solution of ODEs had been addressed by the development of neural differential networks where researchers have commented that “neural differential equations (NDEs) demonstrate that neural networks and differential equation are two sides of the same coin” [1]. While the details of NDEs are beyond the scope of this work, we believe that Fig. 2 aptly captures this statement. A simplistic view

is that the neural network in NDEs is a series of first order ODEs resulting in a higher order system.

### Use of SISO models in neural networks

When we move to artificial neural networks (ANN), the logistic regression, a special case of the sigmoid function, is used as the activation function (Eqn. 5). The sigmoid function, given below, can also be represented as a polynomial. There are three ways of deriving the polynomial. One, we could use the Maclaurin series to derive the same. Two, one can assume a higher order polynomial and estimate the parameters using matrix operations. Three, estimate the parameters using optimization (error minimization).

$$y = \frac{1}{1 + e^{-(x-\mu)/s}} \quad (5)$$

where,  $\mu$  is a location parameter used to recenter ‘x’ around ‘0’ and ‘s’ is scaling parameter used to normalise the value of ‘x’. For simplicity, we can assume that  $\mu = 0$  and  $s = 1$ .

A comparison of the 10<sup>th</sup>-degree and 13<sup>th</sup>-degree polynomials generated by using matrix operations for parameter estimation with a sigmoid function is shown in Fig. 3 (method of estimation and parameters not shown). We observe that it is rather easier to represent the data/system as a sigmoid than a polynomial and that the polynomials generated do not completely represent the sigmoid. Whether a higher order polynomial is required remains to be seen. Thus, for use in ANN, it is prudent to use sigmoid instead of an equivalent polynomial. For more on the equivalent polynomials used in ANN and other advanced versions of neural networks, the reader is referred to [2]. Another point to note here is that We can clearly see here that we have plotted only [-7, +7] range for the polynomials which already resulted in poor accuracy whereas we can plot for any range  $[-\infty, +\infty]$  when sigmoid is considered. While it is known that Polynomial Neural Networks are difficult to implement because polynomials have ‘exploding gradients’ i.e., steep inclines in the plot, this simple single input, single output system clearly demonstrates the pitfalls of using a polynomial as an activation function. Will a trigonometric series give a better fit? Probably (see next section on sawtooth wave alludes to it), however, we refrain from doing it for the SISO system.

Although our attempt to represent sigmoid function has failed (miserably), one can readily see why. Sigmoid function is in fact a ratio of two polynomials, and we can see this if we try to bring the exponential to the numerator. It may be worthwhile try to model sigmoid as the ratio of two different polynomials, but we refrain from doing it here.

To conclude this section, while any SISO system can be modelled as a polynomial, the question remains as to

whether it is necessary to do so in neural networks especially since many hidden layers with the activation function in each will result in a nonlinear system and may sufficiently capture the system dynamics.

**Figure 3.** Comparison of sigmoid function with a 10<sup>th</sup> and 13<sup>th</sup> degree polynomial.

### A side note

Using the Maclaurin series, the formula for the binomial series, which is  $(1 + x)^n$ , can be derived, and by using the binomial series, the expanded equation for  $(a + b)^n$  can be found by assuming that  $\frac{b}{a} = x$ . As an example, we can expand  $(a + b)^3$  as,

$$a^3(1 + x)^3 =$$

$$a^3(1 + 3(1 + x_{x=0})^2x + \frac{3 \times 2(1 + x_{x=0})x^2}{2!} + \frac{3 \times 2 \times 1 \times x^3}{3!})$$

which becomes,

$$a^3(1 + 3x + 3x^2 + x^3) = (a^3 + 3a^2b + 3ab^2 + b^3).$$

We must note here that this derivation is normally not taught using series and it is hence interesting that algebraic formulae can also be derived using series and represented as a polynomial.

## DOUBLE-INPUT SINGLE OUTPUT MODELS

Double input, single output systems can also be called Two/Twin input, single output models (TISO). Let us consider two problem types for this analysis. The first is that of geometric shapes and the second is solution of 2<sup>nd</sup> order partial differential equations used in heat and mass transfer.

### Modelling topology using neural networks

We first consider the case of a cone and a paraboloid. They can be represented by Eqn. 5a & 5b

respectively.

$$z^2 = x^2 + y^2 \tag{5a}$$

$$z = x^2 + y^2 \tag{5b}$$

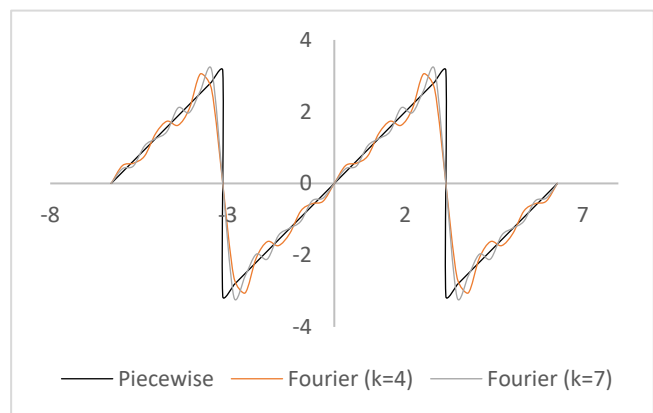

In theory, these two surfaces can be modelled as an ANN with two inputs ( $x$  and  $y$ ) and one output ( $z$ ). Once the ANN model is generated (using data generated by Eqn. 5), we should be able to calculate  $z$  by giving different values of  $x$  and  $y$  and regenerate the surfaces using the ANN model. The question then is that if surfaces can be modelled simply as in Eqn. 5, should we resort to using neural networks to do the same? Or, a more philosophical question is, how can topology be modelled as a neural network? The answer does not seem to be simple or straight forward, and it appears that when the physics is well understood, there is no need to use a neural network, or is that so? Let us understand this visually by taking a step back by looking at a SISO problem.

Consider the sawtooth wave which can be represented by simple piecewise linear mathematical representation as given in Eqn. 7. While this is simple, engineers however are interested in a continuous function that can be differentiated and is easy to implement (especially in electronics and signal processing). Fourier transforms allow us to generate an equivalent continuous function which allows us to do the same. The equation for the Fourier series is given in Eqn. 8.

$$f(x) = x \quad \forall 0 \leq x < \pi \tag{7a}$$

$$f(x) = x - 2\pi \quad \forall \pi \leq x < 2\pi \tag{7a}$$

$$f(x) = 2 \sum_{k=1}^{\infty} ((-1)^{k+1} \frac{\sin(kx)}{k}) \tag{8}$$

**Figure 4.** Sawtooth wave. A comparison of piecewise linear representation vs. Fourier series ( $k = 7$ ).

It can be seen from Fig. 4 that although the Fourier series will have increasing accuracy with increasing 'k', the 'edge-effects' will continue to be present. While the

application of this simple example is easy to understand, and we are willing to compromise accurate (accuracy beyond a point is not perceived to the end-user) for easy of use, we do not fully understand the implications of compromising accuracy over easy of use in multidimensional problems where neural networks are typically used. Note: It is possible to represent the sigmoid function, presented in the earlier section, as a trigonometric series or Fourier series, but we will refrain from doing it here.

Another way to look at the issue of accuracy is by considering a cone or a paraboloid. While Eqns. 5a & 5b give a perfectly smooth representation, objects in the real world are not nearly as perfect at the microscopic level. We can only achieve certain level of smoothness using machining processes and objects are always non-smooth when we see them under magnification. Thus, we can probably say that neither of Eqn. 5a & 5b are perfect representations of the reality. We do not however know what the implications are if we can represent this 'imperfect reality' through imperfect neural networks! Fig. 3 shows both the smoothness and the gaps between the data points in a cone ('imperfections' arising from discrete datasets).

**Figure 5.** A cone, with both smoothness and gaps (imperfections) is shown.

Having said that, developing neural networks that understand or replicate topology may open new doors for the field of artificial intelligence in its quest for developing cognitive capabilities. Here, we should emphasize that we must not confuse 'topology of neural networks' with 'modelling topology using neural networks' – we are alluding to the later and not the former. Readers who are

more interested in 'topology of neural networks' with applications to 'modeling topology using neural networks' are referred to what is known as 'Geometric Deep learning', more specifically 'Geodesic Convolutional Neural Networks' [3], which are beyond the scope of a typical undergraduate programme in chemical engineering.

## Modelling partial differential equations using neural networks

Solution to partial differential equations with two independent variables and one dependent variable can also be derived by using Fourier series and the same is taught in our undergraduate courses. Consider the case of a hotplate shown in Fig. 6. The solution, temperature vs. location, of this problem which can be derived from first principles is given in Eqn. 9. We can see from Eqn. 9 that the solution is an infinite series that involves trigonometric function sine as well as exponentials. The data for change in temperature with location can be obtained by direct integration of the constant,  $c_n$ , and substituting different values of  $x$  and  $y$ . We must note here that, just as in SISO Fourier series, the accuracy increases as 'n' becomes large.

**Figure 6.** Hotplate that is heated at  $y = b$ .

$$T(x, y) = \sum_{i=1}^{\infty} c_n \sin\left(\frac{n\pi x}{a}\right) \left(e^{\frac{n\pi}{a}y} - e^{-\frac{n\pi}{a}y}\right) \quad (9)$$

$$\text{where, } c_n = \frac{2}{a\left(e^{\frac{n\pi b}{a}} - e^{-\frac{n\pi b}{a}}\right)} \int_0^a f(x) \sin\left(\frac{n\pi x}{a}\right) dx$$

This equation can be visualised as being equivalent to a graph or a network through Fig. 7. Here, the node represents a product (multiplication) and the arc represents the transformation of the input node to the output. This is not exactly like the traditional neural network, but it is important to understand that the equation can be represented as a graph. When  $n=1$ , only the equations in big rectangle are used. As 'n' increases, the number of such rectangles can be increased as the structure within the rectangle remains the same.

Separately, the graphical representation of solution of Eqn. 9 is shown in Fig. 8a as a 3D image. On the other hand, obtaining the neural network model of the solution using data either from experiments or data generated

using Eqn. 9 is also possible. While it may not be clear from Fig. 8a that we can model this as a neural network, Fig. 8b makes it clearer. It being a 2D image with different colours, we can clearly see that generating multiple such images with different values of  $f(x)$  and calculating 'T' with respect to 'x' and 'y' will clearly help us generate an equivalent neural network model. We can say this with reasonable confidence since making sense of 2D images is one of the earliest applications of neural networks. While four sub-models are required if we are to obtain the solution to a hotplate that is heated on all four sides, Fig. 8c (equations not shown), it may be possible to generate an equivalent neural network model that can model a hot plate heated on all sides within one model.

**Figure 7.** Graph representation of Eqn. 9 with hotplate heated on one side.

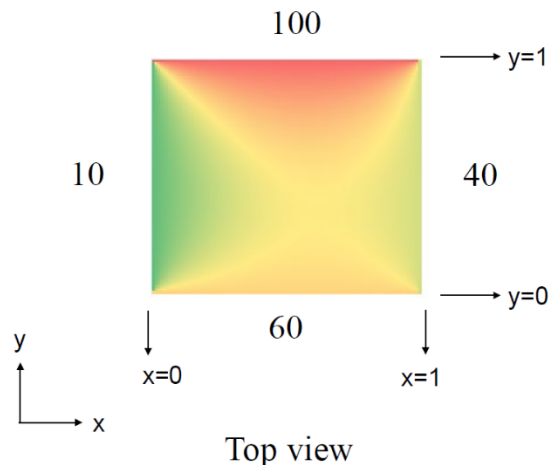

**Figure 8a.** Solution to PDE (in 3D) of a hotplate that is heated on one side. *Note: Fig. 6a-c are from lecture notes, CHE1021 Engineering Mathematics II by Liu Wen Paul, former faculty at Newcastle University.*

To elaborate, in a simple image analysis problem,

the value in each pixel is vectorized and several such pictures are used to train (parameter estimation) the model to determine if the image is that of a cat or a dog i.e., the training data consists of  $1024 \times 1024$  inputs (assuming that image dimension is  $1024 \times 1024$ ) vs. one output (cat or dog). On the contrary, if a hot plate is to be modelled as a neural network, there will be six inputs (location  $(x, y)$  and temperature,  $T$ , on the four sides) and one output (temperature at the given pixel/location). Even though the image dimensions are large ( $1024 \times 1024$ ), the problem can be modelled with fewer number of input nodes in the neural network.

**Figure 8b.** Solution to PDE (in 2D) of a hotplate that is heated on one side.

**Figure 8c.** Solution to PDE (in 2D) of a hotplate that is heated on all four sides.

We should note here that, just as accuracy increases with increasing 'n' in Eqn. 9, the accuracy of the neural networks also increases with increasing hidden layers and nodes. We should note here that parameters and hence model size increases with 'n' in Eqn. 9 and with the number of hidden layers and nodes in neural networks.

Hence, we may allude that similarities exist between first principles models and neural networks that more the parameters, the more accurate representation of the reality.

We should also note that parameter estimation becomes more tedious in this TISO model if we were to formulate is as a pure mathematical model with no understanding of Fourier series. We can envision that higher dimensional problems can also be modelled as a trigonometric series and exponentials. We must however remember that the issue with using trigonometric functions in mathematical modelling and then performing parameter estimation is that trigonometric functions create 'ripples' which have multiple (bad) local minima and hence parameter estimation may become difficult, if not impossible. On the contrary, neural networks have been extensively used to model higher dimensional problems. So, unless there is an easier way to estimate the parameters when using trigonometric series, such as in Fourier series, it is probably better to use neural networks in the near term. Having said that, it may be worthwhile to explore use of trigonometric series and exponentials in neural networks. One rather interesting use of trigonometric functions in neural networks is the use of wavelets and the treatise of the same is beyond the scope of this work.

## CONCLUSIONS

In this work, we have demonstrated through simple examples how engineering mathematics course in undergraduate education can be used to lay the foundations of neural networks. The author is of the view that other topics such as numerical methods, optimization, parameter estimation can also be taught with a machine learning flavour.

To conclude, although any SISO system may be a polynomial or may be reduced to be a polynomial, it is rather difficult to model (and perform parameter estimation on) all systems by assuming that they are multi-input, multi-output polynomials or as combination of trigonometric functions. Hence, modellers should be conscious to incorporate the physics of the system into the modelling framework where possible. Alternatively, an appropriate existing model must be used, typically with an understanding of the problem under consideration which incorporated known knowledge into the model. This must be emphasized early on in mathematics education so that future research and education can be directed at bridging the gap between traditional mathematics and machine learning, possibly leading to explainable AI.

# Accelerating Discovery in Consumer Product Design

**Brian T. Gettelfinger**

Procter & Gamble, Mason, OH, USA  
[gettelfinger.bt@pg.com](mailto:gettelfinger.bt@pg.com)

**Keywords:** Consumer Products, Modeling, Design

## DESIGNING IRRESISTIBLE SUPERIORITY

At Procter and Gamble, innovation is based on a framework of Irresistible Superiority [1] that utilizes five complementary components – Products, Packages, Communication, Retail Execution, and Value. Increasingly, the computational techniques heavily leveraged within the Process Systems Engineering community are playing a leading role in delivering these five vectors, and they become increasingly valuable as we aim to deliver products in more exploratory consumer spaces – where combining high-volume data, advanced modeling, and quantified uncertainty will allow us to discover and deliver better products faster than ever before.

### Superior Product & Package Design

In the product design space, we have a long history of utilizing traditional modeling & simulation to deliver superior products [2]. In today's technology landscape, we see potential in both product and ingredient discovery through the complementary use of traditional modeling with machine learning techniques for high-throughput screening applications. This approach allows us leverage digital twins to explore a wide variety of environments in which our products must perform, but it also allows for a simultaneous exploration of numerous – and often competing – constraints on ingredient safety, sourcing, and performance.

Packaging presents different opportunities for computer aided design. We continue to use modeling & simulation to design our physical packages to be resilient in the supply chain and to give novel and superior consumer experiences. These same models – and specifically the material constitutive equations therein – can help us identify more sustainable materials and can improve our internal processing of our packages. In more recent developments, we are also using package models combined with formulation understanding to improve product/package interactions, enabling the delivery of sustainability without sacrificing product performance in our consumers' daily use.

### Superior Communications & Retail Execution

While the above two areas seem somewhat conventional domains for computational design, perhaps some of our biggest opportunities lie in consumer communication. We are constantly challenged to translate our products' technical superiority to consumer-noticeable superiority, and measuring that superiority is very well-suited to Bayesian inference from small testing and larger consumer behaviors data. For example, we have long utilized Bayesian methods for estimating latent effects in sensory tests, and we leverage learnings from these small experiments in well-established methods for claims and communication testing (i.e. A/B tests). These techniques help us ensure that the best aspects of our technical performance are meaningfully visible to our consumers.

Retail execution presents still more opportunities for computer-aided design – especially as an increasing amount of retail activity is conducted via digital platforms. We learn through online channels and ML models which aspects of brand propositions work well with consumers, and we are then able to leverage those best-performing elements into successful retail executions. Conversely, we often supplement our retail displays with digital information that is relevant to consumers based on environmental & behavioral trends – enabling models to present the most meaningful content to a consumer who is searching for more about our brands [3].

### Superior Value to Customers & Consumers

Finally, it is essential that we continue to deliver the above superiority at an exceptional value – to both the consumer and the customer. This value delivery is readily enabled by productivity-enhancing AI in data-rich areas like ingredient screening, but in other areas of design, we rely heavily on Process Systems Engineering experts across the whole of our supply chain. Increasingly, we are using process systems & machine learning together to prioritize & screen new ingredients not based solely on their performance properties, but also on their possible

supply chains & their actual and perceived safety & regulatory risks. This allows us to deliver new products quicker and more affordably than could have been imagined even 10 years ago.

## COMPUTATIONAL DESIGN SKILLS OF THE FUTURE

What then does this multi-faceted approach to design demand of the computational design community? First and foremost, it demands partnership. We need a diverse set of skills in computational disciplines that span data engineering, machine learning, multi-objective optimization, and Bayesian inference – all of which must complement well-established modeling disciplines! We cannot possibly expect researchers and students to master each of these disciplines, so they must instead demonstrate their ability to master a few areas and partner very effectively with the others as quickly as possible.

Second and just as importantly, we require practitioners of computational design to become obsessed with the decisions they are driving and the problems they are solving rather than the computational capabilities themselves. Practically, this means being keenly aware of the decisions being influenced by any prediction or optimization algorithm. And in an innovation environment, we need computational leaders to recognize that accelerated *learning* is an objective in itself – learning in new spaces, as efficiently as possible, with the possibility of generating new data in areas where we have never explored. This combination of factors paints an exciting picture of the future of computational design of consumer products, and as consumers ourselves, we should all be eager to enjoy the fruits of these superior design capabilities in our daily lives.

# Process Design for the Energy Transition: An Industrial Perspective

Jaffer H. Ghouse\*

Systems Integration and Operations, New Energy Solutions, Woodside Energy, Houston, TX, USA

\* Corresponding Author: [jaffer.ghouse@woodside.com](mailto:jaffer.ghouse@woodside.com).

**Keywords:** Energy Systems, Optimization, Process Design, Hydrogen, Ammonia

## EXTENDED ABSTRACT

The United States' Inflation Reduction Act (IRA) of 2022 has established incentives to facilitate the energy transition. While these policies provide economic incentives that encourage investment and may reduce financial risk for the private sector on the supply side, transitioning to a lower carbon or net-zero economy by 2050 presents several challenges. These include designing flexible production systems that can interact with intermittent renewable energy resources, ensure process safety, redesigning existing energy infrastructure to support new energy carriers like hydrogen or ammonia, and making long-term investment decisions in an uncertain and evolving market. Addressing these challenges presents significant opportunities for the computer-aided design community to leverage techniques at the intersection of process design, AI/ML, data science, and optimization, which will play a key role in designing robust systems that can thrive during the energy transition.

This presentation aims to provide an overview of different technologies that are being considered and associated challenges faced by the industry at the ground level, particularly around hydrogen and ammonia production routes, as shown in Figure 1, in a post-IRA era. Specifically, the presentation will highlight the policy details in sections 45V and 45Q of the IRA and how these influence problem formulations and economic calculations. It will also demonstrate the importance of considering process design for hydrogen and ammonia production from a systems-level perspective that incorporates the interaction of tightly coupled, time-varying systems, and how conventional techno-economic designs need to consider emissions at the design stage given the incentive structures in the IRA are related to carbon intensity. In addition, this presentation will discuss how optimization-based end-to-end pipelines are deployed in production within a business environment while addressing

challenges around comparison to pre-existing methods, data uncertainty, problem infeasibilities, and sustaining engagement with end users.

**Keywords:** Process Design, Energy, Energy Efficiency, Carbon Capture, Process Synthesis, Decarbonization, Energy Transition

## INTRODUCTION

The overarching goal of process design (Figure 1) is to find technologically feasible, operable, economically attractive, safe and sustainable processing pathways and process configurations with specifications for the connectivity and design of unit operations that perform a set of tasks using selected functional materials (e.g., catalysts, solvents, sorbents, etc.) to convert a set of feedstocks or raw materials into a set of products with desired quality at a scale that satisfies the demand. Process synthesis and integration can further screen, optimize and improve these pathways for given techno-econo-environmental targets or objectives. These objectives may include, but are not limited to, minimizing the overall investment and processing costs, minimizing the energy consumption, minimizing the emissions or wastes, maximizing the profit, and enhancing the safety, operability, controllability, flexibility, circularity, and sustainability, among others.

**Figure 1.** Overarching goal of optimal process design.

For a long time, fossil fuels (petroleum, natural gas, and coal) have been predominantly used as primary feedstocks as well as primary energy providers for the chemical process industry (CPI). The chemicals and refining is by far the largest contributor of industrial direct

and indirect carbon emissions [1]. In recent times, decarbonization and transition to renewable energy have emerged as the major pathways for reducing anthropogenic greenhouse gas emissions that contribute to global warming and climate change. Like many other sectors, CPI is considering them to reduce its overall carbon footprint.

Industrial decarbonization primarily refers to reduction or elimination of CO<sub>2</sub> emissions from a manufacturing process. For CPI, it would include the following, among others [1]: (i) improving energy efficiency through novel process design, optimization and integration, (ii) incorporating bridging reduced/net-zero/negative emission technologies such as carbon capture, utilization and storage (CCUS) [2], direct air capture (DAC), hydrogen and/or biomass based energy & fuels, (iii) electrification of process heating and cooling, and (iv) substitution of fuels, feedstocks, and energy sources.

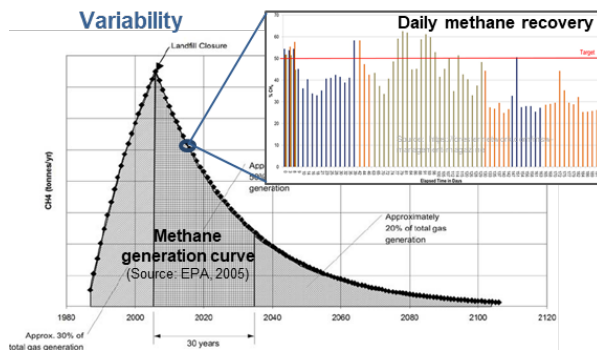

Energy transition is another broad concept that encapsulates a significant shift in the way we produce, distribute, and use our primary energy sources. Typically, it refers to move from conventional fossil fuels to more sustainable and environmentally friendly alternatives, such as renewables (solar, wind, hydro, geothermal), energy storage technologies, and increased energy efficiency measures.

This work explores the pivotal role of process design and optimization as the CPI navigates through different challenges and opportunities towards mitigating carbon emissions and facilitating the shift towards renewable energy.

## CHALLENGES AND OPPORTUNITIES

While these measures show great promise for reducing carbon emissions, an effective integration and deployment of these measures pose are significant and,

in some cases, unique challenges for the CPI. Chemical and refining processes are historically developed considering a steady supply of conventional feedstocks and energy. High efficiency and low capital intensity, both of which contributed to high economic gain, were achieved through economies-of-scale of large, centralized processing facilities. However, as we consider shifting towards utilizing unconventional feedstocks and renewable energy sources, we lose the economies-of-scale. Many unconventional feedstocks and most renewable energy sources are distributed, only intermittently available, and uncertain. One such example is shown in Figure 2, where we observe significant variability in the long-term, seasonal, and daily availability of methane from landfill gas, which is an unconventional feedstock.

**Figure 2.** Long-term, seasonal and daily variability in landfill-based methane feedstock availability.

Similar to the unconventional feedstocks, renewable energy sources such as solar and wind are distributed and intermittent. The future price of renewable electricity could decrease substantially to compete with traditional fossil fuels [3]. However, intermittency, spatio-temporal variability and non-dispatchability of renewables pose considerable challenges for systems integration. Figure 3 shows an example of variability of solar and wind energy availability.

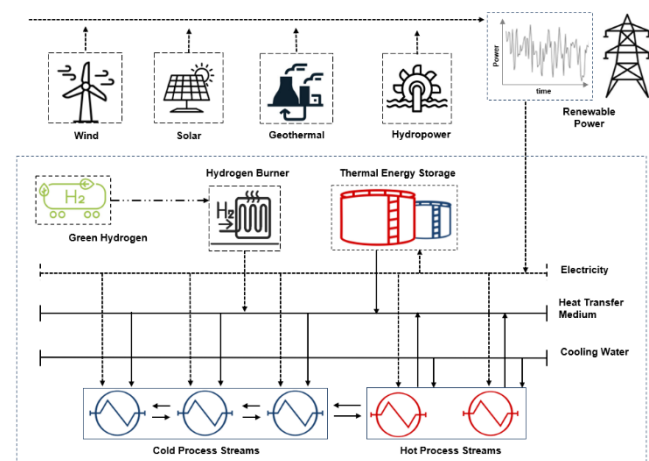

**Figure 3.** Temporal variability in solar and wind energy.

The intermittency of these variable renewable sources and the high energy requirement of carbon capture restrict their widespread deployment in the CPI. This often leads to simultaneous design and scheduling prob-

lems [4]. These challenges are traditionally addressed independently at the grid-level, leading to conservative costs and limited operational flexibility for both systems. However, opportunities exist to examine the synergistic integration of renewables and flexible carbon capture with individual chemical plants. Renewables can provide clean energy for carbon capture, while energy storage can be incorporated to counter renewable intermittency. To assess whether the benefits obtained from integration outweigh the capital cost under spatiotemporal variability of electricity markets and renewable energy, we can develop and use mathematical programming-based optimization frameworks for process design and optimization. We can decouple the design and operational decisions in a two-stage optimization strategy to efficiently solve the large-scale problem.

Electrification of the chemical industry reduces the reliance on fossil fuels across the economy and enables plants to integrate cleaner energy sources such as renewables. However, the variation and intermittency in renewable energy supply is a key challenge in electrifying industrial processes. Plant-wide energy storage will most likely play an important role in electrification by leveling off the change in energy supply [5]. Thermal energy storage (TES) is particularly suitable for chemical process plants due to the use of low-cost storage mediums. With the support from TES, renewable powered electric heaters can be introduced. However, there is a need for systematic methods that simultaneously consider the time-varying utility supply from renewables, the design and integration of single/multistage TES process configurations with heat exchanger networks, the scheduling of optimal charging/discharging operations, and the selection of energy storage mediums. One such concept of renewable-powered electrification is illustrated in Figure 4.

**Figure 4.** Renewable powered chemical process heat integration with TES and backup green hydrogen.

By integrating advanced modeling techniques, simulation tools, and artificial intelligence, engineers can further optimize the performance of existing processes and develop novel, sustainable solutions under uncertainty.

<sup>c</sup> The Dow Chemical Company, Lake Jackson, TX 77566, USA

\* Corresponding Author: [qizh@umn.edu](mailto:qizh@umn.edu).

**Keywords:** Design Under Uncertainty, Optimization

Flexibility is a critical feature of any industrial system as it tells us about the range of conditions under which the system can effectively and safely operate. It is becoming increasingly important as we face greater volatilities in market conditions, diverse customer needs, more stringent safety and environmental regulations, the growing use of resources with varying availability such as renewable energy, and an increased likelihood of disruptions caused by, for example, extreme weather.

In process systems engineering, there is a long history of applying *flexibility analysis* [1] to evaluate and design flexible process systems. In particular, Swaney and Grossmann [2] introduced the concept of flexibility index to quantify the level of operational flexibility in a given design. Here, one assumes that the system's input parameters can take values within certain ranges defined by a so-called uncertainty set, which typically takes the form of a hyperrectangle. The size of the uncertainty set is given by a scalar parameter, and for a given design, the flexibility index is the largest possible value of that size parameter for which the operation of the system is guaranteed to be feasible with proper adjustment of the control variables. In addition, we often want to optimize the design of a system while satisfying given flexibility requirements. In that case, the uncertainty set is fixed, and the design problem can be formulated as a two-stage robust optimization problem [3].

In this work, we propose a new design approach that can directly determine the design that maximizes the flexibility of the system. It also provides a rigorous way of investigating the trade-off between cost and flexibility, and it can be especially useful when the uncertainty set has a more complex structure with multiple parameters defining its shape and size. We find that the problem can be formulated as a two-stage robust optimization problem with endogenous uncertainty [4]. Its trilevel nature and the decision-dependent uncertainty set give rise to a computationally highly complex optimization problem. For its solution, we apply variants of the column-and-

constraint generation algorithm proposed by Zeng and Wang [5]. We demonstrate the key features and efficacy of this new design approach using several examples, including a computational case study considering the design of a supply chain involving mobile modular plants under uncertainty.

## EXTENDED ABSTRACT

Process design is a core component of chemical engineering education and either involves or is followed by an extensive design project in most schools. The design project is often considered a core activity in the education of future chemical engineers because it develops their skills in creative and critical thinking beyond the boundaries of their acquired knowledge, as well as training them in teamwork. Such skills are likely to be crucial to empower students to develop process technologies that respond to the relevant future challenges in process design. These future challenges include accommodating alternative raw materials and energy resources, addressing sustainability concerns, and arranging production schedules that are more flexible. Some schools already integrate certain of these challenges in process design courses and design projects, e.g., water and energy conservation as well as CO<sub>2</sub> capture, storage and utilization, and biochemical manufacturing. At the same time, process design tools are also evolving, including, for example, increased emphasis on combination with data-based methods, digital twin concepts, or integration with virtual and augmented reality tools.

On the other hand, only a small fraction of chemical engineering departments teach product design. With industrial diversification, it is of growing importance to teach techniques for selecting products that satisfy consumer needs while incorporating the latest new R&D technologies. Our presentation will describe methods for helping undergraduate students learn the technologies sufficiently well to incorporate them in designing new products. Here expert faculty and industrial persons, along with doctoral researchers, can formulate timely product design problems, while helping students obtain solutions. Clearly, new products should be accompanied by process designs, but product-design strategies are emphasized. Also, initially, methods for selecting new

products using well-known technologies are emphasized. Furthermore, product-designs that involve AI and account for the environment and sustainability can be considered. Finally, reasons many departments teach only process design are covered. For FOCAPD 2024, an extensive report, prepared by faculty and industrial persons, describing the latest approaches, will be summarized. The report, Teaching Chemical Product Design, will have been circulated worldwide with a survey concerning product design – the results of which will be described at the conference.

To summarize our combined position, we propose to present the state of the art in teaching process and product design, and to begin a discussion on how to achieve these objectives within the timeframe that is allocated to chemical process/product design instruction.

# Forces Shaping the Future of Design and Design Education

Jeffrey J Sirola

Davidson School of Chemical Engineering, Purdue University, West Lafayette, Indiana, USA

**Keywords:** Process Design, Process Synthesis, Parameter Optimization, Structural Optimization, Carbon Dioxide Capture, Process Electrification, Hydrogen

## CHEMICAL PROCESS DESIGN

All ABET-accredited engineering programs mandate a culminating major design experience based on knowledge and skills acquired in earlier course work and incorporating realistic appropriate engineering standards and multiple realistic constraints. Some chemical companies organize their Manufacturing Innovation Process into a sequence of stages which typically include Need Identification, Product Design, Basic and Detailed Chemistry, Process Design, Equipment Design, Plant Design, Detailed Engineering and Vendor Specifications, Component Acquisition, Plant Construction Planning and Execution, Operating Procedure Development, Plant Commissioning and Start-up, and Production Planning, Scheduling, and Operation. Each of these stages involve the solution of many "design" problems that could be the subject of the culminating undergraduate chemical engineering design experience.

Most chemical engineering programs historically have chosen Process Design and Equipment Design for the capstone design experience as these aspects incorporate more of the science and engineering principles (mass and energy conservation, classical, solution, and reaction thermodynamics, transport phenomena, kinetics, separations, unit operations, control, safety, etc.) and computational tools (equation solvers, physical property prediction, process and fluid dynamics simulators, etc.) taught within undergraduate chemical engineering curricula. However, some programs have chosen instead a Product Design experience, especially if the product is itself a process (like an analytical instrument, oxygen concentrator, etc.) or if product fitness-for-use depends on its performance in a process (a solvent, mass separating agent, refrigerant, membrane, catalyst, etc.) or user experience (microstructured consumer products, etc.). Other aspects of the innovation process (e.g., Needs Identification, Basic and Detailed Chemistry, Plant De-

sign, Vendor Specification, Construction Planning, Operating Procedure Development, Production Planning and Scheduling, etc.), while certainly interesting, typically have not been used as the capstone design experience either because they require more specialized mathematics, chemistry, biology, materials science, etc. knowledge than most undergraduates are exposed to, or because they require prerequisite Process and Equipment Design.

## Process Design at Purdue

At Purdue our chemical engineering senior design experience has focused on Conceptual Process Design and Economic Evaluation with some aspects of Plant Design, Plant Wide Control, and Process Safety. This includes Equipment Design at different levels of detail appropriate for conceptual economic evaluation and sometimes for vendor specification. Our subject processes may be of any scale, usually continuous but can be batch, and of a complexity that can be reasonably solved by teams of four or five students within one semester. We expect this course scope to continue into the future.

We teach a design paradigm (using terminology appropriate for Process Design, but applicable in general to many design problems within the innovation process) involving Formulation, Synthesis, Analysis, Evaluation, and Optimization.

As might be expected, we have a somewhat greater emphasis on Process Synthesis (generation of process flowsheet alternatives by identifying tasks required to achieve objectives, phenomena to be exploited to accomplish these tasks, equipment and utilities required to implement these tasks, and interconnections among those equipment) than most process design courses or textbooks. We describe three basic approaches to Process Synthesis: Evolutionary Modification (alteration of existing flowsheets), Superstructure Optimization (simultaneous selection of equipment, equipment interconnections, and operating conditions with a purported optimizing simulator), and Systematic Generation

(hierarchical specification of property difference resolving tasks between raw materials and desired products). We make a specific distinction between the Tasks that must be completed in a process and the Equipment in which these tasks will be accomplished. We teach both goal-oriented and constraint-oriented (largely the result of nonideal solution thermodynamics) strategies for identifying process tasks as well as patterns of interconnected tasks that have previously found applicability in specific situations, for example for breaking homogeneous and heterogeneous azeotropes. Our process design approach is specifically task-oriented rather than equipment-oriented. We further take the position that process designs have Primary Objectives (make the right stuff, in the right amount, fit for use - not too difficult; even a computer can do it) while at the same time optimizing as best as possible Secondary Objectives (economics, environmental impact, safety, controllability, sustainability, societal impact, etc. - the real challenge). We note that the relative importance of some of these secondary objectives are currently changing, and new emphasis especially on the environment is the principal challenge impacting the future of chemical process design.

Our approach to Process Analysis and Evaluation is fairly conventional, involving computer-simulation-assisted heat and material balancing about each proposed task in the synthesized flowsheet, choosing operating parameters and finding annual utility requirements and costs for each task, and flows and other properties of the interconnecting streams among the tasks to meet the Primary Design Objectives. Then an initial assumption is made that each task can be implemented in a single piece of equipment after which that equipment is designed at an appropriate conceptual level of detail using (sometimes computer-assisted) methods learned throughout the curriculum just sufficient to estimate a preliminary acquisition and installation cost. Then these equipment capital costs are combined with utility and other annual operating costs in an appropriate way to produce an economic Figure of Merit, initially simple Total Annual Cost (or Levelized Cost) and later Net Present Cost better accounting for variable cash flow timing and financing, depreciation, and income tax implications,

At this point we turn our attention to Optimization of the Secondary Design Objectives. Students first start with Design Heuristics (published results of previous equipment selection and parameter optimization experience) for example, best equipment type selection in particular situations, optimum approach temperatures, operating number of stages and reflux ratios, multistage compression pressure ratios, economic pipe velocities, etc. These will be starting points for more detailed model-based parameter optimizations with realistic objective functions typically economic considering both capital and annual operating costs, but other objectives including

improved safety or environmental impact minimization may also be appropriate. Preliminary safety studies such as Failure Modes and Effects Analysis are also performed early, especially since proposed response to identified critical issues may involve changes to the process structure or operating conditions.

In addition to Design Parameter Optimizations, we also consider what we call Structural Parameter Optimizations. These are based on consideration of some sixty thought-provoking ideas we have accumulated related to reaction path, input-output-recycle structure, heat and power management and thermodynamic efficiency (including heat and power integration algorithms and process condition adjustment to increase the opportunities for such integration), alteration of phase, solution, or reaction equilibria or rate- (and size-) determining mechanisms (classical process intensification), changing the order of tasks and the relationship between tasks and the equipment used to execute them (another form of process intensification), advantaged scale-up or scale-down, cost reduction, and improved safety, operability, controllability, and maintainability. This broader consideration of structural parameter optimization all involves synthesizing local alternatives (for example, a proposed heat integration, or compressor staging with intercoolers, or enhanced heat transfer device, or alternative solvent, or combined reaction and separation, etc.) with selection then based on capital and operating cost economic evaluation or other appropriate criteria. Finally, development of equipment layout, plot plans, and a plant-wide control strategy complete our process design approach. Although not required for conceptual capital cost estimation and more appropriate for vendor specification, sometimes more detailed design of selected equipment such as shell-and-tube heat exchangers or distillation columns using more of the methods described in textbooks and handbooks is performed for the learning experience.

## WHAT IS CHANGING

Not too long ago, after not discovering any new large oil or gas fields for a few decades, there was prediction of "peak oil" and a time when we would run out of finite fossil reserves not only for fuels but also as organic chemical industry feedstocks exacerbated by higher prices as worldwide demand approached known productive capacity. While some suggested a return to coal (whose reserves appeared to be an order of magnitude greater than those of oil and gas), others advocated a switch to "renewable" (recently alive biological) feedstocks ultimately derived from continuing photosynthesis. As these renewable materials, for example cellulose, starch, lignin, triglycerides, etc., are compositionally different from traditional coal, petroleum, or natural gas, it was thought that entirely new processes would need to

be developed, or entirely new products more appropriate to renewable raw materials would need to be developed to meet society's needs (especially for fuels, but other products as well). As these renewable raw materials were created by biological reactions, it was assumed that biological reactions may also be important in their transformation to products. As a result, biochemistry was added to the scientific foundation in many chemical engineering curricula and fermentation was added to the list of unit operations studied. While the process design paradigm remained applicable essentially unchanged, the chemistries and products to which it could be applied in practice and in the classroom were significantly expanded.

Then, with the successful development of directional drilling, logging-while-drilling, slickwater hydraulic fracturing, and microseismic monitoring technologies to extract fossil hydrocarbons from impermeable shale formations, shale resources became included within exploitable reserves expanding them to more than a century of projected demand. Peak oil never happened, and prices fell (and in the case of natural gas, to half its historical ratio compared to oil). Access to hydrocarbon feedstocks for both fuels and chemicals no longer appears to be an immediate problem.

## Carbon Dioxide Emissions

However, continued emission of carbon dioxide to the atmosphere is. These emissions principally come from burning carbonaceous fuels for heating, power (electricity production), transportation, and from certain chemistries (notably the smelting of ores, limestone decomposition, and the production of hydrogen). These emissions are measurably increasing the concentration of CO<sub>2</sub> in the atmosphere which in turn is causing deleterious climate change. Carbon dioxide emissions, and not feedstock availability, is the real sustainability issue facing society in general and the processing industries in particular.

If the carbon source resulting in CO<sub>2</sub> emissions were biological ("renewable"), then some would consider such a process to be "carbon neutral" just recycling CO<sub>2</sub> back to where it came, although others would argue that such a process should not be considered carbon neutral until the biological feedstock is actually regrown.

If CO<sub>2</sub> emissions are from a stationary source like an electricity-producing power plant boiler, utility steam boiler, furnace, fired heater, lime kiln, etc., in principle they could be captured, separated from other things with which they may be admixed, and permanently sequestered from the atmosphere, for example by injection into a suitable capped porous geological formation, dissolution in a deep saline aquifer, or reaction with an appropriate alkaline geologic material such as basalt. This is not widely done at present, but to do so does not involve any new process design paradigm.

If CO<sub>2</sub> emissions are from a mobile source, carbon capture may not be practical. Either some other non-CO<sub>2</sub>-emitting process must be used, or the emitted amount of CO<sub>2</sub> must be captured from the atmosphere (true for any CO<sub>2</sub>-emitting process). CO<sub>2</sub> must also be captured from the atmosphere if it is desired to reduce atmospheric concentrations from existing levels.

## Process Electrification

Since most CO<sub>2</sub> emissions are currently from the combustion of carbonaceous fuels for heat and power (space heating, industrial heating, electricity generation, and transportation), there is interest in substituting carbon-emissions-free electric power in as many of these applications as possible. Carbon-emissions-free electricity does exist from nuclear, hydroelectric, wind, photovoltaic, and geothermal sources (and stationary fossil-fired power plants might also be included if the resulting CO<sub>2</sub> were captured and sequestered). Electricity is already widely used for space heating and also increasingly for short distance transportation. Until now because of cost, electricity is not much used for heating in the process industries, with the exception of electric arc furnaces in steel production. That is about to change, and that will be one of the biggest factors affecting the future of the process industries.

## Hydrogen

Hydrogen is a major chemical mostly used for desulfurization in petroleum refineries and for ammonia and methanol production. It is now also being considered as a carbon-emissions-free fuel for all sorts of heating applications in furnaces, for power production, and for transportation. Currently, hydrogen is usually made from high temperature endothermic steam reforming of a carbonaceous feedstock (methane, light naphtha, coal, etc.) resulting in significant CO<sub>2</sub> coproduction. Although not yet much practiced, this CO<sub>2</sub> could be captured and sequestered ("blue hydrogen"), or hydrogen could be made by water electrolysis with carbon-emissions-free electricity using a number of different electrolyzer technologies ("green hydrogen").

## Direct Air Capture

If to offset CO<sub>2</sub> emissions to the atmosphere an equal amount of CO<sub>2</sub> is removed from the atmosphere (Direct Air Capture), then how should this CO<sub>2</sub> be captured, and what should be done with this captured atmospheric CO<sub>2</sub>? Both biological (agricultural, silvicultural, aquicultural, etc.) and technical (absorption, adsorption, etc.) carbon capture processes are possible. Then after capture, this CO<sub>2</sub> could be sequestered or it could be converted into the very products that resulted in CO<sub>2</sub> emissions to the atmosphere, although this latter choice would generally involve chemical reduction, likely with carbon-emissions-free hydrogen (a new demand for

hydrogen).

## THE FUTURE OF PROCESS DESIGN

What does all this likely mean for the future of process design?

First, many new processes, using new chemistries, and involving new raw materials (possibly biological where that may make sense) will be developed. But not necessarily any new theory of process design.

Second, energy will become more expensive (because of carbon capture and sequestration or CO<sub>2</sub> emissions avoidance). That may lead to even more consideration of energy-saving structural optimizations involving heat integration and process intensification. Even so, it is not necessarily certain that there will be a fundamental shift in the ratio of operating costs to capital costs, since historically as process energy costs have risen (for whatever reasons), so too soon thereafter have process capital costs (because energy is the major economic input in producing the material for process equipment).

Third, carbon-free electricity will replace fossil fuel combustion for space heating and short distance transportation throughout society. This will approximately double total electricity demand requiring a corresponding increase in total electrical generation and distribution capacity (with any fossil-fired capacity either retired or retrofitted with carbon capture and sequestration).

Fourth, the process industries will become electrified for heat as they already have increasingly become for work. Electric heating will be implemented in numerous ways including resistive heating, inductive heating, dielectric (microwave) heating, plasma heating, arc heating, etc. Much of this detail will be new to chemical process and equipment designers. Electricity may be used to boil steam (so that chemical processes heated by steam condensation remain unchanged), or to directly heat equipment (perhaps more precisely) including replacement of fired heaters and furnaces for temperatures greater than steam.

Fifth, chemical processes are unique in that many kinds of operations like distillation and absorption both require heat at higher temperature and reject nearly the same quantity of heat at lower temperature. These situations may be appropriate for electricity-powered heat pumps moving heat from the lower temperature source to the higher temperature requirement (generally more efficient than straight electrical heat itself) which heretofore have been practically limited to the distillation of close-boiling mixtures but whose applicability may be much expanded given CO<sub>2</sub> emission elimination considerations.

Sixth, hydrogen will be more in demand both as a chemical reducing agent and as a carbon-emissions-free fuel for both mobile and stationary applications. It remains to be seen whether that hydrogen is best

produced by carbon-free electrolysis or carbon-free electrically-powered carbon-captured fossil reforming.

Seventh, powerful oxidants oxygen and chlorine are already produced by electrically powered air separation and chloride electrooxidation. Reductant hydrogen will either be made by water electrolysis or electrically powered fossil reformation (with carbon capture). Given these reagents, it is not yet clear if chemical electrosynthesis will find other major advantaged applications.

While process design theory may not change, the future overarching emphasis on carbon dioxide emissions elimination, atmospheric CO<sub>2</sub> concentration reduction, and process electrification will have a significant impact on Structural Optimization objectives in addition to traditional economics, safety, waste minimization, and controllability. This inevitably will result in new and different process flowsheets, product costs different from current experience, and many new problems and case studies for undergraduate design courses. However, our students will be prepared and will be up to the challenge.

# Decarbonization of Oil Refineries through Electrification and Low-Carbon Feedstocks

Ana I. Torres<sup>a\*</sup>

<sup>a</sup> Carnegie Mellon University, Department of Chemical Engineering, Pittsburgh, PA, USA

\* Corresponding Author: [aitorres@cmu.edu](mailto:aitorres@cmu.edu)

**Keywords:** Decarbonization, Green Fuels, Process Design, Oil refineries, Sustainability

Chemical Process Industries must navigate a series of changes in their operations to comply with increasing sustainability targets. These changes may involve the use of electricity-based operations, the implementation of carbon capture strategies, and the use of biomass or end-of-life carbon-containing waste as feedstocks. Decarbonizing oil refineries is particularly challenging as they possess highly valuable infrastructure. Discarding this infrastructure before the end of its life to build entirely new electric and biomass-based operations does not seem to be an economical or even a sustainable solution. This presentation will cover recent work in my group related to the decarbonization of oil refineries, focusing on proposing solutions that could be integrated with existing plants.

In the first part of the talk, we will present a decision-making tool to assist chemical industries in their transition to decarbonization. The proposed tool considers a given process flowsheet, representing current operations in the refinery, a list of decarbonization initiatives based on the electrification of steam and hydrogen production, and carbon capture initiatives, along with costs, expenditure limits, and carbon emission reduction goals. Based on the available decarbonization options and existing plant needs, we propose a superstructure and model it as a multiperiod MILP. The tool returns an optimal technology switch strategy and the timeline for its implementation, where optimal means the one with the lowest net present cost. We will present the results of an oil refinery in the United States that intends to reduce its carbon emissions by half by 2030 and become carbon-free by 2050. We then explore the trends across various scenarios of electricity costs and carbon tax levels, among others, to find those that will result in a more extensive adoption of electrified technologies.

The second part of the talk discusses several works on the use of biomass in oil refineries. We start with a short overview of a project whose objective was to

design a sustainable aviation fuel (SAF) process based on the hydrotreatment of oil seeds that could be adapted to an existing refinery infrastructure. Hydrotreatment of oil seeds results in hydrocarbons that produce green naphtha and green diesel that can be seamlessly blended with oil-based fuels (i.e. drop-in fuels).

Next, we discuss a second project where we expand these ideas to consider other possible biomass and technologies. In this case, we assume six well-established biomass to fuel technologies and identify the oil refinery operations that can be repurposed for biomass processing. A retrofitting problem is formulated to find the optimal facility repurpose strategy that meets a given fuel demand.

Finally, we explore possible synergies between the forest supply chain and existing fossil-based facilities to produce fuels from biomass residues from the first one. We propose a decision-making problem to define the location and possible integration of new facilities to produce intermediates, assuming that traditional pulp-producing and sawmill facilities, as well as refineries and biorefineries, are already operating.

# Challenges in Design for Sustainability

Gavin Towler\*

Honeywell, Sustainable Technologies

\* Corresponding Author: [gavin.towler@honeywell.com](mailto:gavin.towler@honeywell.com)

**Keywords:** Process Design, Renewable and Sustainable Energy

## EXTENDED ABSTRACT

There is a global consensus that steps must be taken to mitigate the impact of anthropogenic climate change. The Paris Agreement on climate change has been ratified by 192 countries and the signatories have pledged to make changes to their patterns of energy and land use that achieve “carbon neutrality” or net-zero emissions of greenhouse gases (GHG) by approximately mid-century. In these countries, energy ministries, energy companies and utilities are evaluating alternative fuels and power sources that can deliver the heat and power required for a modern economy with reduced GHG emissions. While technically proven low-emissions alternatives exist for almost every application, most of these alternatives cost substantially more than the fuels or energy sources they replace. Consequently, most countries will use a combination of regulations, taxes and subsidies to distort the energy market in favor of the lower-emissions alternatives.

Achieving a net-zero GHG economy while meeting the energy demand and economic growth needs of the world’s population requires a substantial transformation of every industry. No human activity is strictly carbon neutral unless it removes sufficient carbon dioxide from the atmosphere to offset the emissions from all the manufacturing, operation and decommissioning steps associated with the activity. Electric power can be produced with relatively low GHG footprint by wind turbines, solar cells, hydroelectric plants, geothermal plants and nuclear power, enabling electrification as a decarbonization strategy in many applications.

While electrification will pay a large role in reducing GHG emissions, there are several industrial and transportation applications that are difficult to electrify. These applications either require high temperature heat that is best delivered by burning a fuel, or else require rapid refueling to maximize capital efficiency of vehicle utilization. In the future, these applications will be served by a mixture of hydrogen, renewable fuels derived from

biological sources, and fossil fuels whose GHG impact has been offset by activities such as land use changes that sequester an amount of carbon dioxide equivalent to the GHG emissions.

The pace of the energy transition will be constrained by the speed at which new vehicle, power generation and fuel production technologies can be deployed. The transition to lower GHG emission transportation modes (battery electric vehicles and hydrogen- or electric-powered trucks) is constrained by both the rate of global fleet turnover and the rate at which the global vehicle manufacturing industry transitions fully to low emissions vehicles. Similarly, the transition to lower GHG forms of industrial heat will be constrained both by the supply of renewable electric power and the availability of low-GHG fuels such as hydrogen.

There are multiple implications for design practitioners, particularly those who are developing large capital projects that must remain economically viable throughout the energy transition period. Some recent case studies from industrial practice will be presented to illustrate how companies are responding to these challenges.

## INTRODUCTION

### Achieving Sustainability

Achieving sustainability in the energy sector requires an economically viable path with a balanced transition that does not aggravate environmental and sociological problems associated with current fossil-based power production. Increasing the grid penetration of intermittent renewables to realize a sustainable energy future without consideration of the balanced transition may result in devastating economic and societal impacts [1]. As we press for the minimization of renewable power curtailment, current fossil-based technology struggles to meet demand under extreme transient and part-load conditions. This results in dramatic reduction of efficiency and a corresponding increase in emissions of not only carbon, but far more devastating pollutants.

Without a doubt, the needs of a sustainable future require new technologies, not only for renewable power like wind and solar, but also for dispatchable power [2]. Ideally, technology to serve the transition would provide a significant increase in the efficiency of fossil fuels conversion under transient and part-load conditions as well as an opportunity to use renewable fuels and integrate with existing wind and solar. To meet the aggressive timelines for decarbonization and transition to a renewable energy sector posed by many world governments, these new technologies would need to be developed with an unprecedented haste not supported by our current technology development paradigm [3].

### Integrated Energy Systems

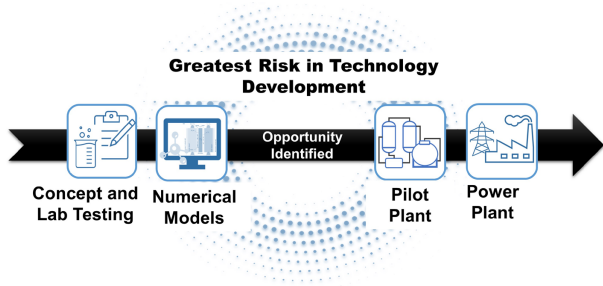

Integrated energy systems provide hope for high efficiency conversion of fuels to electricity, low emissions, load following flexibility, and low-cost carbon management. By integrating a variety of power generation assets, developing technologies can be matched with

mature technologies, mitigating risk and facilitating early adoption of novel component concepts.

As an example, the synergies of a solid oxide fuel cell (SOFC) – gas turbine system through thermal integration result in efficiencies that exceed the sum of the individual parts. Through optimizing the integration of fuel reforming in the cycle, theoretical efficiencies over 70% low heating value (LHV) natural gas can be realized at SOFC fuel utilizations below 45% where the fuel cell represents less than half the power of the cycle [4]. Merging developing (SOFC) and mature (gas turbine) technologies mitigates SOFC early adoption risk by lowering the fraction of power generation and associated costs. Even if the SOFC does not function to its fullest potential, higher efficiencies and turndown capabilities can be realized through the thermal energy storage capacity of the SOFC materials, facilitating the transition to a sustainable future. Similarly, concentrated solar power and thermal energy storage can be coupled to the mature gas turbine technology.

### Co-Design

Although many benefits of integrated energy systems have been extolled in the literature and even in distributed scale demonstrations, system integration and dynamic control issues inhibit commercial adoption of these technologies. In the current technology development paradigm, integration and control issues are not often identified until the completion of a pilot scale system [3,5], as shown in the abbreviated technology development timeline in Figure 1. Failure at the pilot scale stems further investment and shatters all hope for commercialization efforts. As such, the bridge between numeric models and the hardware of a pilot plant represents the greatest risk in technology development and the opportunity for the greatest gain in accelerating the path to commercialization of new concepts.

**Figure 1.** Current paradigm of technology development

The simultaneous co-design of system components, system integration, and dynamic control would be required to minimize development risks. If a pilot plant could be built with some confidence of the operability and potential for automation, the chances for success would be greatly improved. This could be best accomplished if component design could be changed based on identified needs for system integration and controls. To realize effective co-design, the use of new tool would be required [3,6,7].

### Cyber-Physical Systems

When considering the design tools needed in the transition from numeric models to pilot-scale hardware, cyber-physical systems (CPS) come to the forefront as a method to model complex integrated energy systems. As shown in Figure 2, CPS interact with a physical environment through a seamless combination of numeric models and hardware through a series of sensors and actuators.

**Figure 2.** Interaction between physical environment and real-time numerical models in cyber-physical systems

Simulations using cyber-physical models are distinguished from hardware-in-the-loop simulations (HILS) that couple a physical component to a virtual environment for testing. Although commercial digital twin (Twin) products also couple numeric models to hardware, CPS requires the models to converge within the sampling frequency of the dynamic controller. In power systems, Twins generally require convergence within the optimization time of a supervisory controller, or about 5 to 15 minutes. The CPS facility at NETL requires convergence in 5 milliseconds. Concepts of HILS, Twin and CPS are compared in Figure 3.

**Figure 3.** Illustration of the concepts of hardware-in-the-loop, digital twins, and cyber-physical system

### Changing the Paradigm

To minimize the highest risk or “valley of death” in the technology development, the current paradigm must be modified to accommodate co-design by including a feedback loop in the highest risk part of the design process [3,5]. As shown in Figure 4, if CPS techniques could be employed before investment in a full pilot scale power system, opportunities to modify materials and bench scale systems would be available to maximize success at the pilot scale.

**Figure 4.** De-risk technology development through cyber-physical systems

The new design paradigm for integrated energy systems of the future must include pathways that make use of dynamic models, hardware-in-the-loop simulation, digital twins, cyber-physical models, and ultimately, cyber-physical systems to support intelligent power generation. As shown in Figure 4, filling the “valley of death” with a continuum of simulation methods between numeric models and hardware models can provide an opportunity to achieve commercialization of new energy system technologies within the time scale needed to realize economically viable energy transitions on an international scale.

### ACKNOWLEDGEMENTS

This work was done with support and funding from the Advanced Sensors, Controls, and Novel Concept Program and the Solid Oxide Fuel Cell Research Program, Office of Fossil Energy and Carbon Management, U.S. Department of Energy.

## EXTENDED ABSTRACT

The future of computer-aided process design hinges on continued recruitment, training, and retention of the next generations of engineers. Many elementary and secondary school programs focused on engineering have made substantial impacts in informing children about careers in science, technology, engineering, and mathematics (STEM). A report by the National Academies established three general principles for pre-college engineering education, the first of which is that elementary and secondary engineering education should emphasize engineering design<sup>1</sup>. Curricula focused on teaching the engineering design process have been developed for K-12 students and educators<sup>2,3</sup>. These materials often emphasize engineering design as an engaging process with iterative prototype testing and a supportive process where learning from failure is encouraged in a positive way. However, these engineering design process concepts have not necessarily been communicated to university-level engineering faculty (in contrast to the scientific method). This is a problem when college students only see design as a high-stakes, time-intensive senior capstone project or as highly specialized content siloed in upper-division courses with design explicitly in the name such as Plant Design, Process Design, or Product Design.

Despite upward trends for exposure to engineering design in pre-college settings and for students majoring in engineering more broadly, particularly computer science, a concerning trend is the decline in chemical engineering enrollments<sup>4</sup>. Computer-aided process design presents the opportunity to integrate design into engineering education at the pre-college and undergraduate levels while also leveraging strong interests in computational sciences and data-oriented careers. This presentation will focus on surveying several design project activities from the author and others<sup>5-9</sup> aimed at high

school and early college students to teach chemical engineering principles and attract them to and retain them in chemical engineering. Recommendations for integrating design across the curriculum through hands-on and computational activities will be also discussed to support the future of computer-aided process design.
